Message from the OSDI '22 Program Co-Chairs

Dear colleagues,

Welcome to the 16th USENIX Symposium on Operating Systems Design and Implementation (OSDI '22).

This year OSDI '22 is co-located with the 2022 USENIX Annual Technical Conference (ATC '22). We are holding the joint conference in a hybrid format, with the option of virtual or physical participation. We are excited to return to a physical event, in Carlsbad, California, after a two-year hiatus. Due to Covid, the previous two instances of OSDI (2020 and 2021) were held only virtually, and we have made the best of it. That has made OSDI more accessible but less interactive. This year, with the hybrid format, we hope to get the best of both worlds. We have encouraged presenters to attend in person if they can, while attendants have the option of joining in person or virtually.

OSDI '22 received 253 submissions and accepted 49 of them for a 19.4% acceptance rate. As in the last OSDI, we did not allow the program chairs to submit papers. Due to the historically high number of submissions, we recruited a large PC of 76 members in addition to the two chairs. PC members included academics, industrial researchers, and industrial practitioners. We also recruited a few additional people to serve as an external review committee to provide additional coverage of expertise if necessary. We are grateful to all the committee members for their hard work that was essential to the success of OSDI '22.

The program committee reviewed the submissions in two rounds. In the first round, papers received three reviews. About 29% of papers were then rejected based on these reviews, while the others advanced to the second round. In the second round, papers received at least two additional reviews and, in some cases, we solicited additional input from expert external reviewers. We discussed these papers online and reached a decision for another 52% of the submitted papers. The remaining papers were discussed and decided over a three-day online PC meeting. Each of the accepted papers was shepherded by a PC member to help the authors address the reviewers' comments in the camera-ready version. In total, we produced over 1130 reviews and 2900 online comments, representing an enormous amount of work. We estimate the human cost of evaluating the papers to be above $1M based on an average of 4.5 hours per review (to read the paper, write the report, and discuss it in the group) and a cost of $200/hour per reviewer. This is a significant price to the community and as such we must optimize it going forward while maintaining the high quality that OSDI is known for. Toward that goal, OSDI '22 experimented with some approaches that make better use of the collective effort.

In particular, OSDI '22 introduced a change to the reviewing process: the option to revise and resubmit. This option was given to a small number of papers that were rejected but that reviewers felt would have been accepted if authors could address a list of objective issues. This list was provided to authors so they can work on a revision of the paper. The revision will then be re-evaluated by the same reviewers if possible, for publication in OSDI next year, OSDI '23, based on how well the authors address the issues on the list. This year, only six papers were given the option to revise-and-resubmit but this number should increase in future years if OSDI continues with this practice. All six papers have decided to resubmit. These revise-and-resubmit papers are now under evaluation.

After finalizing the program, we proceeded to decide the Jay Lepreau Best Paper Awards. We asked all PC members to nominate papers. We next created a short list based on the nominations, the reviews, and the paper themselves. We then selected a small set of PC members that were not conflicting with any of the papers in the short list, and we asked them to score each paper. Based on the nominations, reviews, and scores, the best papers were selected.

OSDI '22 had an artifact-evaluation process organized by three co-chairs: Anuj Kalia, Neeraja J. Yadwadkar, and Chengyu Zhang. Of the 49 papers accepted to OSDI '22, 35 had artifacts submitted by their authors. Of those 33 earned the "Available" badge, 31 artifacts earned the "Functional" badge and 27 earned the most challenging "Results Reproduced" badge. For more details, see the Message from the OSDI '22 Artifact Evaluation Committee Co-Chairs.

OSDI '22 had a poster submission process organized by Natacha Crooks and Adriana Szekeres. Submissions were open to all, and authors of papers accepted to OSDI '22 were encouraged to submit a poster. We accepted 52 posters. For more details, see the Message from the OSDI '22 Poster Co-Chairs.

As PC co-chairs, we rely on many people to make OSDI '22 a success, to whom we are grateful. We thank the authors for choosing to submit their work to OSDI. We thank the program committee and external reviewers for their arduous work in reviewing and discussing the submissions. We thank the co-chairs and all members of the Artifact Evaluation Committee, who conducted thorough evaluations. We also thank the co-chairs of the poster committee, who identified high-quality posters for the conference. We thank Jiri Schindler and Noa Zilberman, the program co-chairs of ATC '22, for coordinating with us efficiently, productively, and enjoyably. We thank the USENIX staff, who have been fundamental in organizing OSDI '22 as we transition to a hybrid format. The logistics of the online PC meeting were facilitated by PhD student Daniel Amir, whose assistance we greatly appreciate. Finally, OSDI wouldn't be what it is without our attendees. Thank you for listening to our speakers, asking challenging and insightful questions, and sharing your ideas with others.

We hope you will find OSDI '22 interesting, educational, and inspiring!

OSDI '22 Program Co-Chairs

Message from the OSDI '22 Artifact Evaluation Committee Co-Chairs

We are happy to report about the OSDI '22 artifact evaluation process. This is the third time that OSDI conducted such a process and we hope to keep improving it so that artifact evaluation will become more common in our community's conferences. This year, the OSDI '22 artifact evaluation process is combined with USENIX ATC '22. The combined artifact evaluation committee consists of 118 artifact reviewers from academia and industry.

Process
We continued to use the three-badge approach (vs. the single-badge approach) from OSDI '21 evaluation and these three badges include:

- **Artifacts Available:** To earn this badge, the AEC must judge that the artifacts associated with the paper have been made available for retrieval, permanently and publicly.
- **Artifacts Functional:** To earn this badge, the AEC must judge that the artifacts conform to the expectations set by the paper in terms of functionality, usability, and relevance.
- **Results Reproduced:** To earn this badge, the AEC must judge that they can use the submitted artifacts to obtain the main results presented in the paper.

Evaluation
In the evaluation process, each artifact was evaluated by 3 reviewers. The evaluation process had two key phases: the kick-the-tires phase and the in-depth evaluation phase. During the kick-the-tires phase, reviewers made a quick first pass over all assignments to identify and report obvious problems and communicated them with the authors. After the kick-the-tires phase, reviewers evaluated each assignment thoroughly and wrote detailed reviews. Finally, reviewers coordinated and communicated with fellow AEC members and decided which badges should be awarded to each artifact.

Results
OSDI '22 accepted 49 papers and 35 papers participated in the AE. Of the 35 submitted artifacts:

- 33 artifacts received the Artifacts Available badge (94%).
- 31 artifacts received the Artifacts Functional badge (88%).
- 27 artifacts received the Results Reproduced badge (77%).

Key Takeaways
Our experience shows that after the kick-the-tires response period, reviewers can still encounter technical problems that obstruct their evaluation. We suggest future AEC chairs extend the kick-the-tires response period and encourage more interaction between reviewers and authors during the period.

Finally, we deeply thank the authors and the AEC committee for all their efforts in making the OSDI '22 artifact evaluation possible.

OSDI '22 Artifact Evaluation Committee Co-chairs

Message from the OSDI '22 Poster-Session Co-Chairs

We are happy to report about the OSDI '22 poster session. We accepted a total of 52 posters. 28 of these posters correspond to accepted OSDI papers. The remaining 24 were independent submissions. We reviewed these posters for conference fit and clarity of problem exposition and motivation. We intentionally encouraged posters describing early work, as well as more mature projects.

We look forward to lively and interesting discussions at the OSDI '22 poster session.

Owl: Scale and Flexibility in Distribution of Hot Content

Jason Flinn, Xianzheng Dou, Arushi Aggarwal, Alex Boyko,
Francois Richard, Eric Sun, Wendy Tobagus, Nick Wolchko, Fang Zhou
Meta

Abstract

Owl provides high-fanout distribution of large data objects to hosts in Meta's private cloud. Owl combines a decentralized data plane based on ephemeral peer-to-peer distribution trees with a centralized control plane in which tracker services maintain detailed metadata about peers, their cache state, and ongoing downloads. In Owl, peer nodes are simple state machines and centralized trackers decide from where each peer should fetch data, how they should retry on failure, and which data they should cache and evict. Owl trackers provide a highly-flexible and configurable policy interface that customizes and optimizes behavior for widely-varying distribution use cases. In contrast to prior assumptions about peer-to-peer distribution, Owl shows that centralizing the control plan is not a barrier to scalability: Owl distributes over 800 petabytes of data per day to millions of client processes. Owl improves download speeds by a factor of 2–3 over both BitTorrent and a prior decentralized static distribution tree used at Meta, while supporting 106 use cases that collectively employ 55 different distribution policies.

1 Introduction

Within Meta's private cloud, efficient distribution of large, hot content to end hosts is an increasingly important requirement. Three dimensions express the scope of the task: (1) scale: the same content may be read by anywhere from a handful of clients to millions of processes running in data centers around the globe, (2) size: objects to be distributed range from 1 MB to a few terabytes, and (3) hotness: all clients may read an object within a few seconds of each other, or their reads may be spread over hours. At Meta, executables, code artifacts, AI models, and search indexes are content types commonly distributed within this scope.

Distribution requirements are exacting. First, content distribution must be *fast*: the predictive value of AI models decreases over time, and slow executable delivery increases downtime and delays deploying fixes. We expect to provide data at a rate bounded by either the available network bandwidth of the reading host or by the available write bandwidth of its storage media.

Second, content distribution must be *efficient*. One dimension of efficiency is scalability, i.e., the number of clients that can have their distribution needs met by a given number of servers. Another dimension is network usage, which we measure both in terms of bytes transmitted and communication locality (e.g., an in-rack data transfer is less costly than a cross-region transfer) . A final dimension of efficiency is resource usage on client machines; e.g., CPU cycles, memory, and disk I/O. Not only should we use as few resources as possible, but we should also adjust for their relative importance on different clients; e.g., some services are memory-constrained, while others are CPU-constrained or cannot afford to write to disk.

Finally, content distribution must be *reliable*. Reliability is measured as the percentage of download requests that the distribution system satisfies within a latency SLA. Operational ease-of-management is an oft-overlooked prerequisite for high reliability. In a production environment, workloads change, dependent service and infrastructure may have partial outages, and performance faults in which a dependency doesn't meet its own SLA are not uncommon. In order to maintain a high SLA for distribution, engineers need to be alerted quickly about such events, and they need a clear picture of operational health for each client type. Finally, they need simple knobs that adjust behavior when reliability, speed, or efficiency starts to degrade in order to restore operational health quickly.

Prior to our work, Meta used at least three different systems for large content distribution. No prior solution met all of the above requirements. We identified two root causes: (1) no prior system struck the correct balance between decentralization and centralization, and (2) no prior system was sufficiently flexible to meet all of the requirements of the many different types of services at Meta that require content distribution.

Meta previously implemented highly-centralized distribution via hierarchical caching, in which clients download content from first-level caches on remote hosts. These caches, in turn, handle cache misses by reading from other caches, with the final layer of the hierarchy being a distributed storage system. Hierarchical caching is inefficient for hot content distribution, and it is difficult to scale. Meta needed dedicated hosts in great quantity to implement the cache hierarchy. The number of hosts increased to keep pace with growth in workloads from services consuming the data and with growth in the number of reading clients. Load spikes caused by hot con-

tent were a continual problem: strict quotas were necessary to protect the centralized caches. However, readers of hot content were frequently throttled because they exceeded their quotas. In general, provisioning for transient spikes caused by hot content and setting quotas appropriately was quite challenging.

Meta also used two highly-decentralized systems: a location-aware BitTorrent [7] implementation and a static peer-to-peer distribution tree based on consistent hashing, which we will refer to as StaticTree. In both cases, a peer is any process that wishes to download data, and there are millions of such processes at Meta. The decentralized systems scaled much better than hierarchical caching, but they brought their own problems. First, because each peer made distribution decisions based on local information, resource efficiency and speed could be poor; e.g., with each peer making independent caching decisions, the collection of peers could retain either more or less copies of a data object than necessary. Perhaps more importantly, these decentralized solutions were difficult to operate. Engineers could not get a clear picture of health and status without aggregating data from large numbers of peers. Each peer had a different and limited view of the state of distribution, so it was often hard to tell whether or not a collection of peers was making good decisions. In general, it was very hard to reason about system-wide correctness or efficiency.

In summary, decentralized systems were inefficient and difficult to operate, while centralized systems scaled poorly. As a result, we chose to create a new, split design with a decentralized data plane and a centralized control plane. The decentralized data plane streams data from sources to clients via a distribution tree. However, its trees are *ephemeral*, i.e., each tree tracks a single data chunk, and each edge in a tree persists only while the chunk is being transferred from a source to a peer.

The design realizes a mechanism-policy split. Peers are simple and provide the mechanism for caching and transferring data chunks. The centralized control plane makes all detailed policy decisions about distribution, e.g., from where peers should get each chunk of content, when and how they should cache content, and how they should retry failed downloads. The control plane is implemented by a small set of *trackers* [1]. Trackers have a complete picture of the distribution state; e.g., which data each peer is downloading, where these peers are located, and which chunks are in each peer's cache. Detailed state enables trackers to make highly-optimized decisions about data placement and distribution that minimize the use of expensive network links and maximize cache hit rate. Centralizing the control plane has also made distribution easy to operate and debug: engineers can understand which decisions led to low availability, high latency, or poor hit rate because these decisions are made by a tracker with a consistent view of distribution state.

When workloads scale beyond the capacity of a single tracker, the detailed state is sharded across several cooperating trackers, each managing a distinct set of peers. Trackers exchange lower-fidelity views of their individual state with other trackers. Thus, each tracker has a fine-grained view of the state it manages and a coarse-grained view of the entire state. Trackers use the coarse-grained view to delegate decisions to other trackers when using peers that those trackers manage.

The second major problem faced by prior distribution systems was a lack of flexibility. At Meta, clients have vastly different resources to spare for distribution; e.g., some clients can dedicate gigabytes of memory or disk for peer-to-peer caching, while others have no resources to spare. Client have very different access patterns and scale. Finally, the objectives for distribution can differ: some clients need low latency, while others wish to reduce the load on external storage to avoid throttling or excess quota requests. The variety in client needs was one reason Meta needed many different distribution solutions; each solution was customized for a small set of use cases. To unify the disparate distribution solutions, we could not simply provide a one-size fits all solution because that would regress many clients on their key metrics.

We therefore chose to make customization a first-class design priority. Trackers implement modular interfaces for specifying different *policies* for caching and fetching data. Further, each policy is itself configurable to allow for different tradeoffs across client types and responses to changing workloads. We use trace-driven emulation to search through the space of possible customizations and find the best policies and configurations for each observed workload.

This paper describes our solution, Owl, a highly-customizable data distribution system with a centralized control plane and a decentralized data plane. Owl has been in production use at Meta for almost 2 years. Owl has scaled out rapidly (production traffic increased by almost 200x in 2021). Currently, Owl has over 10 million unique clients (binaries concurrently using the Owl library), and it downloads over 800 petabytes of data per day. Owl supports 106 unique types of clients and has customized policies for 55 of these. In production, Owl improved download latency over prior systems by a factor of 2–3 for our most important use cases, while requiring only a fraction of the resources needed by prior centralized solutions.

In summary, this paper makes the following contributions:

1. It shows that a centralized control plane need not be a barrier to scalability in peer-to-peer distribution.

2. It shows that tracker sharding and delegation retain the benefit of fine-grained management even when load grows beyond the capacity of a single tracker.

3. It shows that first-class support for flexible distribution

[1] borrowing terminology from BitTorrent

Client API function and arguments	Description
`read_blob (object, offset, length, deadline, integrityChecker, decryptor)`	Fetches all or part of an object to memory.
`read_blob_to_file (object, fd, offset, length, deadline, integrityChecker, decryptor)`	Fetches all or part of an object to a file.
`provide_file (object, fd, length)`	Allows a file to be distributed ephemerally.
`evict_file (fd)`	Evicts a file from the peer cache.

Table 1: **Owl client API**

and caching policies can provide substantial gains in efficiency and latency, especially when combined with tools that automatically search the space of possible policies for optimizations.

2 Design and Implementation

Owl has two basic components: *peers*, libraries linked into every binary that uses Owl to download data, and *trackers*, dedicated Owl services that manage the control plane for a group of peers. A physical host often has several Owl peers due to container stacking and use of Owl by the Twine container infrastructure [16]. Each tracker manages many peers: over 10 million Owl peers are currently managed by 112 trackers. Additionally, Owl has approximately 800 *superpeers*, dedicated services running the Owl library that provide extra caching or perform specialized tasks.

2.1 Peers

Owl peers provide a simple API for downloading data, shown in Table 1. Client processes call `read_blob` to fetch content from a source object, specifying a range of data to read. The object name encodes an external storage source and a unique identifier for the object within the external storage namespace. Owl currently supports 3 types of external storage. The caller can optionally specify a deadline and classes that check data integrity or decrypt provided data (discussed in Section 2.9). `read_blob` returns a reference-counted memory buffer, while `read_blob_to_file` writes the content to a file. The `provide_file` function allows peers to provide ephemeral content, as discussed in Section 2.11, and `evict_file` lets clients manage disk caches shared with Owl, as discussed in Section 2.7.

Owl peers cache data in memory and on disk. These caches may be shared with the client binary if the client does not modify downloaded data. Owl uses the caches to serve content requests from other peers. Owl policies usually prefer to fetch data from a peer rather than from an external data source, so most requests are satisfied by peer-to-peer distribution.

In the design of Owl, a key principle is that peers should be as simple as possible. This is achieved via a mechanism-policy split, where peers provide the mechanism to perform simple actions such as downloading a chunk of content from a single source, caching or evicting a chunk in memory or on disk, or providing cache data in response to a request from another peer. When downloading content, peers ask trackers to decide from where they should fetch content, how they should retry failed downloads, and even which chunks they should cache locally.

This design principle has been invaluable for operational simplicity. At Meta, the Owl team can control the deployment of its own service (i.e., trackers and superpeers); however, Owl peers are linked with client binaries and so deploy according to different schedules controlled by many other teams. The Owl team deploys code changes to trackers daily, and the team can change configuration values on trackers within seconds if necessary. In contrast, peer code changes can take months to fully deploy. By keeping peers as simple as possible, the team minimizes the need to change a widely-deployed and hard to modify part of the system.

Each peer is associated with a *bucket*, which uniquely identifies the type of the client binary with which the library is linked. The bucket provides a way to customize Owl behavior for each type of client and it lets us monitor usage, performance, and reliability for each Owl customer individually. Currently, Owl supports production traffic for 106 buckets.

2.2 Trackers

A tracker manages download state for a set of peers. Typically, peers and trackers are grouped by region (a region is several co-located data centers), with 3–4 trackers per region providing scale and redundancy. Trackers are homogeneous and multi-tenant. In general, each tracker supports all Owl buckets, and the association between peers and trackers in a region is random. However, Owl uses a separate set of trackers in each region for binary distribution to provide strict performance isolation for this sensitive workload.

Trackers associate data and peers. Downloaded objects are divided into chunks; chunk size varies by bucket with 50 MB being the most common size. For each chunk, tracker metadata specifies which peers are caching the chunk and which are downloading it. Tracker metadata also specifies the source of each peer's download (e.g., an external source or another peer). For each peer, the tracker metadata specifies the

peer's location (host, rack, region, etc.) and its cache state (the chunks in the cache, last access time, and so on). In contrast to highly-decentralized systems, Owl trackers can maintain such detailed state because trackers make all major decisions about caching and downloading chunks on behalf of peers.

As our evaluation shows, a single Owl tracker can scale to handle 1.5–2.4 TB/s of distribution traffic, depending on assumptions about cache hit rate for download requests. To achieve this scalability, we have used careful, but mostly standard, engineering practices. Trackers are implemented in C++ and use common abstractions (coroutines, reader-writer locks, and standard library containers). Trackers maintain geographically-sorted indexes to order peers and the chunks they cache by location; these indexes allow trackers to efficiently find the nearest peers caching a particular chunk of data. Geographically-sorted indexes are used frequently by location-aware selection polices. Trackers store all metadata in memory, and they rebuild their state quickly when restarted.

Peers associate with one tracker. Each peer picks a random instance from the set of available trackers and registers by sending an RPC. Peers register with a new random tracker if their association with the current tracker fails. Section 2.8 describes how peers are sharded across multiple trackers.

2.3 Superpeers

Superpeers are tasks running the Owl peer library as a standalone process (without any client). Superpeers sometimes provide specialized functionality. For example, some external storage systems use mountpoints that are not available on most hosts, so we access this storage only via superpeers that have been configured with the necessary mountpoint. To read external storage, the tracker directs such a superpeer to fetch and cache a data chunk, and it directs a reading peer to get the data from the superpeer.

Some Owl buckets need more peer resources than their clients can provide. For example, some clients are extremely memory and disk constrained and yet also require a high cache hit rate to reduce load on external storage. Superpeers can use all the resources of their hosts for caching, and so Owl uses superpeer caches to supplement peer caches for such buckets.

When used in this manner, a collection of superpeers can be viewed as a hierarchical caching layer. It is possible to craft Owl selection policies that direct all requests to superpeers and bypass fetching from other peers. Early in the project, we created one such policy to support an AI bucket that could spare no memory or disk for peer caching. However, we soon found that shared caching, discussed in Section 2.7, allowed Owl to temporarily access data buffers in use by the application to provide a decent peer-to-peer cache hit rate. Superpeers are still valuable because their additional caching resources improve the total Owl cache hit rate from the base peer-to-peer rate up to the target needed by the AI team. Currently, the Owl team discourages superpeer-only policies because there are several existing systems at Meta that provide excellent standalone caching solutions.

At the other end of the spectrum, it is also possible to craft Owl selection policies that do not use superpeers at all. For buckets with very large working sets and large numbers of clients, the additional cache resources of superpeers make little difference in overall cache hit rate. In practice, though, Owl selection policies for these types of buckets still use superpeers as a last level of retry if a direct fetch from storage by the peer fails. We have found this to be useful in handling rare corner cases such as particular peers being in a bad state where they cannot fetch from external storage. Because peers run on heterogeneous hosts not owned by the Owl team, they can be less stable than superpeers. The superpeer layer thus still plays a role in improving overall data availability.

Superpeers have occasionally been quite useful in mitigating production issues that lead to a poor cache hit rate. In such scenarios, we have quickly stood up a large number of superpeers in a region to provide temporary caching that restores the desired hit rate until we are able to deploy a fix for the underlying problem.

We originally implemented superpeers as a sharded service built on a standard caching library [3]. This approach proved to be insufficiently flexible; it was difficult to customize superpeer cache behavior for each bucket. Later, we rewrote superpeers to use the Owl peer library, which let us customize superpeers via tracker policies and which also provided the simplicity of code reuse for peers and superpeers. From the point of view of a peer, there is no distinction between fetching a data chunk from a superpeer or another peer.

2.4 Tracker-Peer Communication

Peers register with a tracker by sending an RPC with their bucket and location. Trackers customize behavior by bucket; e.g., tracker configuration parameters assign specific download and caching policies to each bucket. When registering, peers select trackers randomly within a geographic scope, and the association between a tracker and peer persists until a peer terminates or cannot communicate with the tracker. On failure to communicate with a tracker, peers re-register with a randomly-chosen tracker.

To download data, an Owl peer first makes an RPC to the tracker specifying the object to be downloaded and the range of data to read. The tracker returns the chunk size (determined by the bucket configuration). It initializes a state machine to track the download of each chunk that has data in the specified range. If the download later fails or times out, the tracker cancels all per-chunk state machines for the download. Otherwise, each chunk is handled independently.

Peers download chunks in parallel. Download concurrency is limited by the per-bucket configuration, which specifies both the maximum number of chunks each peer can download in parallel and a maximum number of chunks that can be read

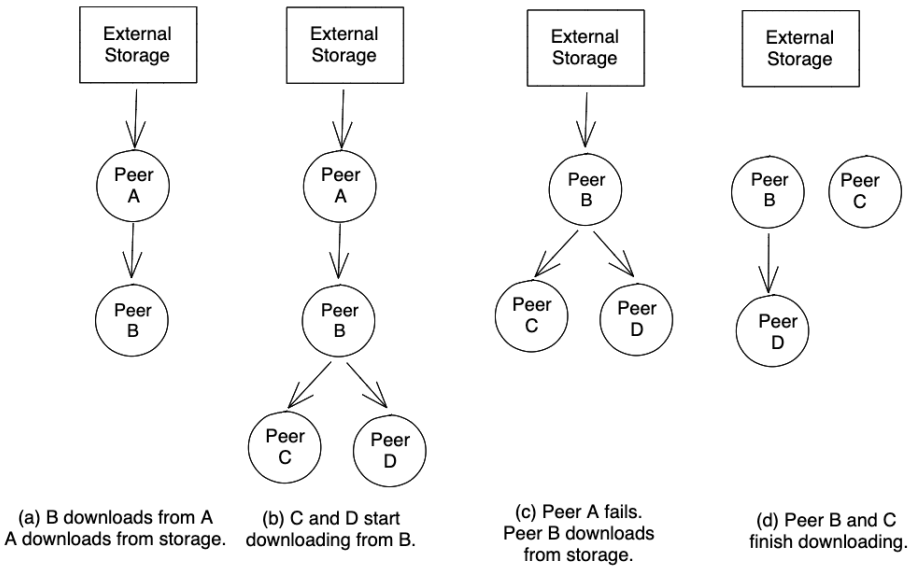

Figure 1: **Ephemeral distribution tree.** This figure shows how a tracker uses a per-chunk ephemeral distribution tree to track which peers cache a chunk and which are downloading the chunk.

in parallel for each individual `read_blob` request.

For each chunk, the peer first checks if the chunk is in its cache already. If so, it sends an RPC to the tracker, which terminates the per-chunk download state machine and updates the access time in the peer metadata for LRU and similar eviction policies. Otherwise, the peer sends a `getSource` RPC to the tracker that asks how it should get the data. The tracker can respond with a peer from which data can be obtained. Alternatively, the tracker may specify an external data source from which the peer should fetch content directly. The `getSource` response specifies whether the peer should cache the downloaded chunks and lists chunks that should be evicted from the peer cache to make room. The tracker updates its peer and chunk metadata, along with the per-chunk download state machine to reflect its decision.

The peer next attempts to obtain the data in the manner specified by the tracker, and it informs the tracker of the result. On success, the tracker terminates the state machine. On failure, the tracker makes a new decision based on its current metadata. Based on per-bucket policies and the failure type, the tracker may specify a new source (or possibly retry the same source in rare cases), or it may tell the peer to give up (e.g., because a maximum number of retries has been exceeded or it believes the chunk is not available from any source).

Prior systems such as BitTorrent [7] provide a list of candidate sources to a peer and let peers handle retries transparently. Owl's approach of involving trackers in retry decisions has several advantages. First, trackers can pick a new source based on the latest state about which peers cache the chunk and current peer load. In contrast, the peers included in BitTorrent's initial list can be stale when retries are needed. Second, Owl trackers maintain very detailed state about which peers are fetching from others. This allows trackers to enforce precise caps on the maximum number of inflows and outflows per peer, and it allows trackers to make more informed selection decisions. Finally, this detailed state gives operators a complete picture of Owl download state, making it easier to determine why downloads may be slow or failing.

The peer simply follows the tracker's instructions at each step. On retry, if a prior step returned partial content before failing, the peer resumes fetching from a new source after the last byte it received (so failures do not lead to excess data being transmitted).

If a chunk download fails (because the tracker tells the peer to give up) or the download time exceeds a deadline specified by the client, the peer cancels all remaining chunk downloads and fails the `read_blob` request. Otherwise, the peer returns the requested data either via a memory buffer or by writing to a specified disk file. The tracker also sets a timeout for each chunk download; it terminates a download and cleans up download state if the peer does not respond within this time.

2.5 Ephemeral Distribution Trees

The *ephemeral distribution tree* is the core abstraction used by the tracker to manage per-chunk download state. The root of a tree is an external data source or a peer that caches the chunk. Directed edges indicate which peers are actively downloading the chunk from others; e.g., in Figure 1(a), peer A

is downloading the chunk from external storage, and peer B is downloading the chunk from peer A. While prior distribution systems have commonly used trees to efficiently distribute data, Owl's trees are particularly ephemeral in that each chunk of data has its own forest of trees, and nodes remain in a tree only while they are downloading a particular chunk or providing a chunk to another peer.

In the data plane, chunks are streamed from the root to leaves; i.e., bytes along each edge are sent in order, followed by a per-chunk checksum used to verify integrity. Each peer forwards data to its children as soon as it receives new bytes. With large chunks, this design means that tree depth does not strongly affect latency. Leaf-nodes see only the first-byte latency of additional communication hops, which is often quite small within a data center or region. In Figure 1(b), when peers C and D request the chunk; the tracker tells them to get it from B, which is still receiving data. Peer B first sends its cached bytes and then forwards additional chunk bytes as it receives them.

When a peer reports a failure fetching data, the tracker removes the edge connecting the peer to its parent. If the tracker chooses a new source, it creates an edge from the peer to that source. Thus, the entire subtree rooted at the peer reporting the failure is moved to a have a new parent in the tree. When choosing a new peer, the tracker avoids creating download cycles; i.e., it will not designate a descendent of a peer as a new source for that peer. Tree repair minimally impacts downstream nodes because Owl resumes a new download after the last byte fetched from the previous attempt. In Figure 1(c), peer A fails, and the tracker tells peer B to fetch the remaining bytes from external storage. Peers C and D are oblivious to this change since they continue to download from B.

When a peer reports a successful download, the edge connecting it to its parent is removed. The tracker adds the peer to the list of nodes that have the chunk fully cached if the tracker asked the peer to retain the chunk. Since chunks may be cached at multiple peers, the download state for a chunk is a forest of ephemeral distribution trees rooted at multiple such peers and/or the external data source. In Figure 1(d), peers B and C have downloaded and cached the chunk, while peer D is still downloading bytes from B. Thus, we have two ephemeral distribution trees in the forest; a new peer that requests the chunk may be directed to any of these peers or to external storage, depending on the selection policy for the bucket.

At first glance, it might seem surprising that Owl often prefers to download chunks from peers that have partially downloaded a chunk in preference to peers that have the chunk fully cached. However, selecting a peer that has partially downloaded a chunk has little latency cost. The peer immediately starts streaming out the bytes it has already downloaded and sends remaining bytes out as soon as they arrive. Network locality and quick scale-out of hot contents are bigger concerns in practice. For instance, many peers in a rack often request a chunk at the same time. Most Owl policies are location-aware and build a tree so that a single peer downloads data from outside the rack and other peers in the same rack get the chunk from that peer or one of its children. Similarly, if many peers in a data center request a chunk at the same time, typically only one peer fetches the chunk from outside the data center. Allowing peers to fetch from other peers that are still downloading the chunk is essential to achieving network locality for hot content.

2.6 Selection Policies

Each bucket has a selection policy that the tracker executes on each `getSource` request. The selection policy considers the result of all prior attempts by a peer to fetch a chunk, as well as per-chunk state that includes the set of caching peers and ephemeral distribution trees. The result of the selection policy often directs a peer to fetch the chunk from another peer or an external data source; these decisions add a new edge to an ephemeral distribution tree. The policy is implemented as a class inheriting from an abstract interface; each policy class has a considerable number of parameters that can be further customized via configuration [15].

A selection policy may use a superpeer to assist in the download. The tracker directs the superpeer to fetch the chunk from an external source, and it directs the requesting peer to get the chunk from the superpeer. This creates a 2-edge distribution tree. Usually, the tracker will have the superpeer cache the chunk so other peers can fetch the same chunk without reading from external storage; this is especially useful when many chunk requests arrive within a short time window.

The *location-aware* policy is the default selection policy. This policy selects the nearest peer that caches or is downloading the chunk, subject to per-peer constraints on maximum fanout and bandwidth usage. Distance is determined by network topology; peers on the same host are preferred over peers in the same rack, which are, in turn, preferred over peers in the same network cluster, etc. To make location-aware selections quickly, the tracker maintains a topological sort over all peers caching or downloading a chunk. A selection policy also specifies the number and type of retries. By default, the location-aware policy tries up to 5 peers, then tries to fetch the chunk via a superpeer, then tries to fetch the chunk directly from a source before giving up. The policy also has unique handling for specific errors, such as external source throttling.

Another common policy is the *hot-cold* policy, which refines the location-aware policy by using superpeers for hot data. If no peer can provide a chunk from its cache, this policy reads data from an external source via superpeers if the chunk is hot or directly from the source if the chunk is cold. Hotness is determined by examining the number of chunk reads within a recent time window. The policy improves hit rate in superpeer caches for buckets that have a mix of hot and cold content.

Other policies implement load balancing; e.g., spreading

```
1  Decision selectSourceForData(
2      const ChunkMetadata& MD,
3      std::shared_ptr<PeerMetadata> requester,
4      const ChunkStatus& stat,
5      const ShardedChunksMap& shardedChunks,
6      const DownloadContext& context) override {
7
8    if (hasDirectFetchFailed(stat)) {
9      return Decision{GIVE_UP, nullptr};
10   }
11
12   if (cannotFindSuperpeer() ||
13       noMoreSuperpeerAttempts(stat) ||
14       noMoreAttempts(stat)) {
15     return Decision{DIRECT_FETCH, nullptr};
16   }
17
18   if (noMorePeerAttempts(stat)) {
19     return Decision{SUPERPEER_FETCH, nullptr};
20   }
21
22   peer = selectPeer(MD, requester, stat, context);
23   if (peer) {
24     return Decision{PEER_FETCH, peer};
25   }
26
27   delegation = findDelegation(shardedChunks);
28   if (delegation) {
29     return Decision{DELEGATED_FETCH, delegation)};
30   }
31
32   return Decision{SUPERPEER_FETCH, nullptr};
33 }
```

Figure 2: Pseudocode: Location-Aware Selection Policy

downloads from sources evenly. Still others always fetch via superpeers, select random peers, and direct whether and how chunks should be fetched from out-of-region peers.

To illustrate how policies are written, Figure 2 shows pseudocode for Owl's location-aware selection policy. Each policy is implemented by overriding a C++ base class; in this case we show the `selectSourceForData` method, which is used to determine how and from where a peer should fetch data on each chunk download attempt. The method's inputs are: chunk metadata that includes a topologically sorted index of all peers and superpeers caching the chunk, metadata describing the peer requesting the data that incudes its location info, a status object containing all prior attempts to fetch the chunk for this download and their results, a list of other trackers that have the chunk available for delegation, and bucket-specific context about the chunk.

Policy implementations are usually a series of simple rules. The location-aware policy first calls a helper function (line 22) to select the nearest peer or superpeer caching or downloading the chunk, as long as such a peer is healthy (no recent failures reported) and would not exceed limits on number of downloads, network bandwidth, etc. The helper function considers past attempts and only tries each source once.

If the tracker has no more locally-managed peers or superpeers caching the chunk, it tries to find a delegation for the chunk from a peer tracker (line 27). If this fails, the policy asks a superpeer to fetch the chunk from an external source, cache it, and provide it to the requester (line 32).

The policy has configurable limits on the number of peer and superpeer attempts. If there are no more peer attempts allowed, the next retry asks a superpeer to fetch the chunk from an external source (lines 18–19). If there are no more superpeer attempts left or the policy has attempted to find a free superpeer and failed, the peer is asked to fetch the data from the external source directly (lines 12–15). If this direct fetch fails, the policy gives up (lines 8–9).

2.7 Caching policies

Per-bucket caching polices determine how peers cache data. Peers may cache data in memory or on disk, with some buckets using both types of cache. Cache size is configurable; the default memory cache size is 1 GB but size varies widely across buckets, depending on memory constraints and desired cache hit rates.

Some buckets use a *shared* peer cache, in which a single copy of data is shared read-only between the client application and Owl distribution. For in-memory caching, Owl returns a reference-counted buffer from `read_blob`. The buffer remains in the cache until the client releases the reference. For example, one memory-constrained client type reads AI models using a shared cache. While the client has no memory to spare, it retains data read for several seconds while it transforms the model chunk into a different format. By sharing the buffer with the client, Owl can satisfy many peer-to-peer download requests during this time. This sharing is essentially free because the data would reside in memory for the transformation anyway. This particular bucket needed a good hit rate to avoid overloading its external storage. Shared caching got us most of the way there, and we used superpeer cache capacity to further improve the hit rate to meet the bucket's requirement.

Buckets with disk caching often use shared caching. Downloaded objects are written to files with Owl retaining an open file handle so that it can serve cached file content to peers. The client controls when files are garbage collected by calling `evict_file` in Table 1. Owl also provides an interface that watches downloaded files and calls `evict_file` on the client's behalf if the file is deleted. In lieu of controlling eviction explicitly, some clients provide a *TTL* (time-to-live) that specifies how long downloaded data should be cached before eviction.

For private (non-shared) caching, Owl trackers manage peer caches. On each `getSource` request, the caching policy determines whether the peer should cache the requested chunk and which chunks to evict to make room in the cache. Peers specify their current cache state when registering with a new tracker so management persists across tracker failures.

The default caching policy is LRU (least recently used). Another popular policy, used for shared caching, never evicts chunks because the eviction is done explicitly by each peer.

Many clients that need good peer-to-peer cache hit rates use a *least rare* policy that prefers to evict chunks cached on more peers over chunks cached on fewer peers. A hybrid policy uses least-rare eviction for hot chunks and LRU eviction for cold chunks. Owl also supports random chunk eviction, which often has good properties for hot data [18].

2.8 Tracker sharding

For the first year of operation, Owl used a single tracker per region, with hot spares providing primary-backup fault tolerance. The simplicity of a single tracker allowed us to start serving production traffic 3 months after the start of the project. However, we knew that our workload would eventually exceed the capacity of a single tracker. Thus, we added the capability to shard peers across multiple trackers.

With sharding, trackers have equivalent responsibilities. A sharded tracker maintains the complete peer state for a given set of peers, but per-chunk and per-download state is split across the shards. Peers and superpeers register with random trackers.

Sharded trackers periodically exchange the set of chunks cached by at least one peer or superpeer that they manage. Trackers normally send incremental updates once a second with additions to and removals from this set. However, a receiving tracker may request a full snapshot when needed; e.g., because it just restarted or it missed an incremental update. Thus, each tracker has a coarse-grained and slightly stale view of the global distribution state that maps chunks to trackers rather than to specific peers.

Selection policies can decide to fetch a chunk from another sharded tracker; typically, this happens when the chunk is not cached on any peer managed by the local tracker and another tracker has reported that it has the chunk. The tracker running the selection policy sends a *delegation* request to the other tracker. In turn, that tracker selects and returns a peer caching or downloading the chunk. The delegation request fails if no such peer exists.

On successful delegation, each tracker updates state for the peer it manages. The `getSource` response simply specifies the endpoint of the delegated peer, so peers are oblivious to delegation. When the downloading peer reports success or failure, its tracker forwards the report to the delegating tracker and both trackers update their individual state accordingly.

On receiving a successful delegation response, a tracker starts a new ephemeral distribution tree. The root of a tree is a *delegated peer*, which indicates that the peer is managed by another tracker. The tracker grows the tree as other peers request the chunk, since selection policies commonly prefer to fetch from a locally-managed peer over a delegated one.

The ephemeral distribution tree for a chunk is now partitioned across multiple trackers with a node in the tree of one tracker serving as the root of a subtree in another tracker. In order to prevent cycles in this partitioned tree, a tracker will not provide any peer in a tree rooted at a delegated peer in response to a delegation request.

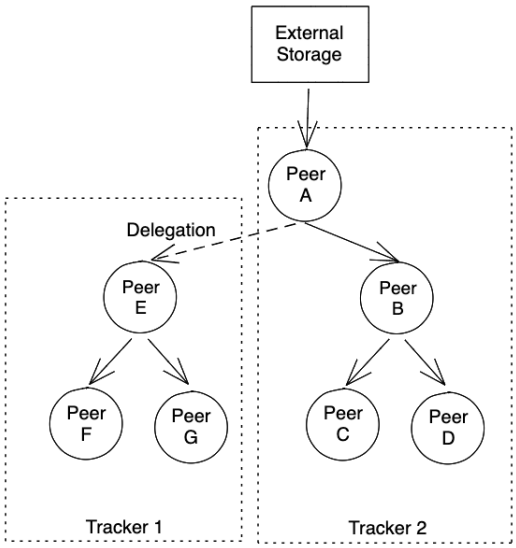

Figure 3: **Delegation with 2 sharded trackers.** Peer E fetches a chunk from a peer managed by another tracker to reduce load on external storage.

Figure 3 shows an ephemeral distribution tree sharded between 2 trackers. Tracker 2 initially receives a `getSource` request from peer A and instructs peer A to read the chunk from external storage. At this point, tracker 2 starts advertising that it has the chunk to other sharded trackers. Next, tracker 1 receives a `getSource` request from peer E. It does not have the chunk on any of its peers, but it knows that tracker 2 has advertised the chunk. Tracker 1 sends a delegation request to tracker 2, which selects and returns peer A. Tracker 1 tells peer E to fetch the chunk from peer A. When tracker 1 receives subsequent `getSource` requests from peers F and G, the bucket's selection policy prefers locally-managed peers, and so these peers are directed to fetch from peer E. As this example shows, delegation improves cache hit rate for sharded trackers. Without delegation, both peers A and E would fetch from external storage. With delegation, there is only a single fetch by peer A, which achieves the same overall cache hit rate that would have been achieved without sharding.

Some data sources accessed by Owl are regional. In these cases, when an out-of-region peer requests a chunk that is not cached by another peer, selection policies use delegation to ask an in-region tracker to have one of its superpeers read the chunk. The requesting peer is directed to that superpeer for the data. Selection policies consider cross-region latency to find the closest location from which to read data.

2.9 Security and integrity

All communication between Owl components in encrypted, and all RPCs are checked against access control lists. Many data sources read by Owl encrypt data at rest, so chunks in Owl caches are often encrypted. Owl clients can provide decryption functions to read decrypted data. For shared caching, Owl must cache and share unencrypted data with clients (because that is how they consume the data). In this case, Owl decrypts each chunk when writing it to the cache and reencrypts it to share it with another peer.

Owl generates an internal checksum when reading chunks from external sources, passes the checksum with the chunk data, and validates chunks with the checksum before returning them to clients. Many Owl clients generate end-to-end hashes when writing to external storage. These clients can optionally provide Owl an integrity checker class containing these hashes and the hash calculation function to validate that the data being read is the same as what they originally wrote. Owl calls the integrity checker as data is being written to a disk or a memory buffer. It fails the download if the integrity checker reports that the calculated hash does not match the write hash.

2.10 Virtual superpeers

One of our original design principles for Owl was that peers should not fetch content that their clients do not read. This led to high network efficiency and made it easier to convince users to adopt Owl since their clients would not be doing work for other services.

However, one recent bucket demonstrated a drawback with this approach. For this bucket, reducing load on external storage is crucial; if data is read too fast, the external storage system throttles readers and performance degrades rapidly. Periodically, a new search index is generated and distributed, which each client then reads at a random time over the next few hours. The first client reads the index directly from external storage, but its memory cache fits only a few chunks. The next client reads those chunks from the first client, and it reads the remainder of the index from external storage. As more clients download the index, their collective caches are eventually sufficient to hold all the data (especially since we use the least-rare caching policy to maximize hit rate for the bucket). However the clients together read many extra chunks from external storage until the index is fully cached, and this causes the external storage system to throttle readers.

To solve this problem, we added a new Owl abstraction called a *virtual superpeer*. If a bucket is configured with a virtual superpeer, the tracker divides each peer's cache into a normal portion and a portion reserved for the virtual superpeer. The tracker aggregates the virtual superpeer portions and manages the collection in the same way that it would manage a superpeer dedicated solely to the bucket. When the first client reads the index, the bucket selection policy routes the ephemeral distribution tree for each chunk through the virtual superpeer. The tracker uses the per-bucket policy to select one peer to fetch the chunk from external storage and cache it; the tracker also selects chunks to evict from the virtual superpeer portion of that peer's cache, if necessary. The requesting peer streams each chunk from the peer that fetched it from the external source. After the index is loaded by one peer, the next peer to fetch the index finds all chunks in the virtual superpeer cache. Thus, Owl makes no additional reads to external storage, and it achieves a high cache hit rate.

The benefit of virtual superpeers over non-virtual (physical) superpeers is that virtual superpeers use spare memory capacity on peers rather than dedicated machines. The bucket described in this section would require approximately 640 physical superpeers to achieve the same cache hit rate as Owl achieves with virtual superpeers. Another bucket that we are currently onboarding would require approximately 10,000 physical superpeers; we are avoiding this cost by leveraging spare peer memory via virtual superpeers.

Virtual superpeers are a tracker-only concept; peers are unaware of the abstraction because they simply follow tracker instructions for where to fetch data and which chunks to cache. Further, the abstraction is implemented almost entirely via Owl selection and caching policies (we added a few hundred lines of tracker code to implement cache partitioning and eliminate double-buffering). Overall, virtual superpeers demonstrate the flexibility of Owl policies: we were able to implement a substantial change not envisioned in the original Owl design primarily by writing new policies.

2.11 Ephemeral data sources

Owl was originally designed to download content from external storage. However, several clients wanted to use Owl to distribute content produced by instances of their service directly to other instances, bypassing storage entirely. For AI models and search indexes that have diminishing value over time, durable storage provides little benefit. Yet, the resources used to read and write large data objects to distributed storage can be significant. We modified Owl to support these use cases by adding *ephemeral data sources*.

An ephemeral data source is simply a peer that promises to supply specific content when requested. The client calls `provide_file` in Table 1 to specify a file containing content for a given unique identifier. In turn, the peer tells the tracker that this content is now in its cache. When other peers requests chunks from this content, the tracker builds ephemeral distribution trees rooted at the providing peer to distribute the chunks. The tracker also advertises and provided content to other sharded trackers, which makes the content available via delegation.

Owl guarantees that the data will be provided only as long as an ephemeral data source provides the data. It caches ephemeral content on peers and superpeers as normal, and

it falls back to the peer(s) providing the data as a last resort. Ephemeral data sources must re-register with a new tracker if their connection with the current tracker fails; they send heartbeats every second to their trackers to proactively detect failures and re-register quickly. A client may stop providing content by calling `evict_file`.

2.12 Fault tolerance

Tracker sharding allows Owl to tolerate tracker faults. When a peer detects that its tracker has failed, it re-registers to use a new tracker. Trackers have only soft state, and a new tracker learns a peer's existing cache state as part of registration. We regularly test failover by continuously deploying tracker code each workday, during which trackers are sequentially killed and restarted. We occasionally experiment by killing and restarting all sharded trackers simultaneously to ensure that performance does not drop below SLA bounds when all trackers restart. This has proved enlightening; e.g., we added peer re-registration when we noticed that SLA bounds had been violated during one such trial.

The RPC routing layer at Meta (not part of Owl) load balances requests among sharded trackers at the granularity of each new chunk download. However, peer associations with trackers are typically long-lived, as rebalancing does not need to be done often in steady state. In contrast, Owl load balances superpeers among trackers itself because the number of superpeers per tracker is small and we want to maintain a tighter balance than the RPC router layer provides.

Trackers detect peer failures when a peer reports that it cannot reach a peer from which it is trying to get data. Peers are marked down (and not used to serve further requests) after a configurable number of consecutive failures. Peers are marked up again when they re-register with a tracker. The Owl library explicitly deregisters on shutdown, but many peers don't shut down cleanly, in which case there is no deregistration.

Generally, we do not allow peers to fail over and use trackers outside their region. Experiences with other systems left us concerned about cascading failures in which a failure in one region causes out-of-region requests to overload services in other regions. We use a separate set of global trackers for buckets that require peers to contact out-of-region trackers.

2.13 Emulation and customization

Over time, Owl has become more customizable as we have added new policies and enabled different behavior via configuration within each policy. This flexibility often makes it difficult to determine the best set of policies for each bucket.

The Owl team writes all policies and helps Owl users pick the best policy for their needs. If the team identifies a specific need not covered by an existing policy, we write a new policy; the development of the virtual superpeer policy, described in Section 2.10, is a good example of this process.

Choosing the best policy is difficult. Many engineers who wish to use Owl do not understand their service traffic patterns well. In some cases, it is not clear whether their workload would benefit from peer-to-peer distribution. In other cases, it is difficult to choose the best set of policies or explain specific configuration tradeoffs; e.g., how much additional cache hit rate can the bucket expect for each additional gigabyte of peer memory used? For existing users of Owl, traffic patterns and distribution goals change over time (e.g., a service can spare less memory or require better cache hit rate to reduce external storage load). Thus, initial policy choices often need to be tuned to keep pace with client changes. As the number of buckets using Owl grew, it became infeasible for the Owl team to manually choose and tune policies for each unique workload.

Owl uses offline, trace-driven emulation to guide policy choices. On a per-bucket basis, Owl can be configured to log basic information about each client request to a database; e.g., the timestamp of the request, the object, and data range read. When we onboard a new bucket that reads data from an external source, we first use an *evaluation mode* policy that always instructs the peer to fetch from the external source and not cache data. The peer thus performs the same actions it would perform without Owl except that each request is routed through a tracker for logging. For existing buckets, logging is always enabled.

An Owl emulator runs our actual tracker service with mock peers and superpeers that generate traffic and service requests. The emulator is event-driven and uses a virtual clock to determine when events occur. Mock peers register, deregister, and generate requests at the times recorded in the production traces. The emulator adds configurable network and storage delays, and can simulate different error profiles. Because we run the actual tracker code, we can emulate any Owl policy or configuration. The emulator reports key statistics such as overall cache hit rate, load on external storage, and tracker CPU usage.

To find the best policy, we compare statistics from multiple emulation runs with the same trace and different policy/configuration settings. As the setting space is quite large, we use random-restart hill climbing [10] to search for the best choice for each bucket. Currently, we run the emulator weekly on existing Owl buckets, and we use the emulator to evaluate all new buckets during onboarding.

3 Evaluation

Our evaluation answers the following questions:

1. How well does Owl provide hot content distribution in production?

2. How does Owl compare to other centralized and decentralized distribution solutions?

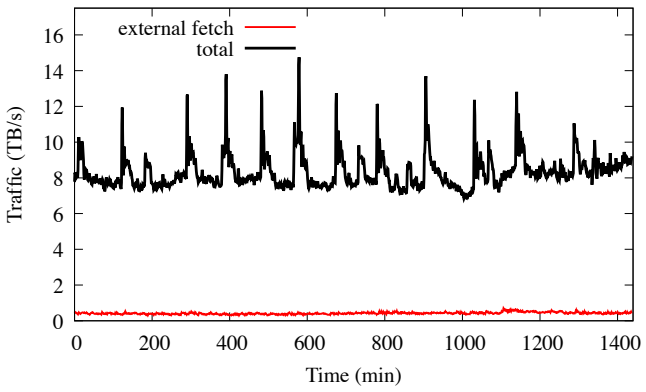

Figure 4: **Owl traffic over a 24 hour period.** The top line shows total bytes downloaded by all clients averaged every minute. The bottom line shows the total bytes read from external storage. The difference between the two lines is the reduction in external storage load due to Owl peer-to-peer caching and distribution.

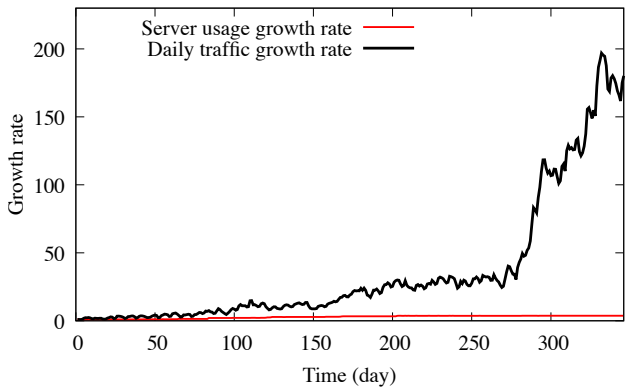

Figure 5: **2021 growth in traffic and server usage.** The top line shows Owl's daily 2021 traffic load relative to the load at the beginning of the year, and the bottom line shows the number of servers (trackers and superpeers) used in production relative to the number used at the beginning of the year.

3. How much benefit does Owl realize from delegation?
4. What are the benefits of flexible distribution policies?
5. How well does Owl scale and how many peer resources does it require?

3.1 Reducing load on external storage

Figure 4 shows a recent (and typical) 24 hours of Owl production traffic, aggregated by minute. The top line is the amount of data read by clients; this is the load they would impose on external storage without Owl. The bottom line shows the load on external storage with Owl. During the 24 hours, Owl clients read 717 PB of data, yet only 36.5 PB was read from external storage, for a cache hit rate of 94.9%.

The cumulative read rate across all Owl clients varies from a minimum of 6.84 TB/s to a maximum of 14.75 TB/s. Figure 4 shows that peer-to-peer distribution and caching hides the client load spikes almost entirely from external storage; in fact, the load on external storage never exceeds 0.72 TB/s.

A CDN or hierarchical caching could also reduce the load on external storage, as in a recently reported study of CacheLib [3]. In that study, each caching node could sustain a maximum data rate of approximately 640 MB/s. Thus, even assuming perfect load distribution, it would require over 23,000 caching nodes to handle Owl's peak client request rate for the reported period, which is more that 200 times the number of current Owl trackers (112).

Figure 5 shows the scalability benefit of Owl's decentralized data plane by comparing the relative growth in production traffic and servers (trackers and superpeers) in 2021. While Owl's peak traffic is almost 200 times greater than traffic at the beginning of the year, server usage has grown by less than a factor of 4.

When Owl replaced hierarchical caching solutions at Meta, we also saw latency speedups from 50% to 100% for several large buckets due to better network locality and elimination of throttling errors.

3.2 Benefits of delegation

Figure 6 shows the number of successful and failed delegation requests for all Owl trackers over the same 24 hour period. 97.5% of delegation requests are successful; they return a peer that provides the requested content. The primary reason why delegation requests fail is because a sharded tracker's list of cached objects is stale. The low rate of delegation failure indicates that a 1 second update interval is sufficient for the majority of our workloads. We verified this by reducing the delegation interval to 250 ms in one region for 24 hours. Owl's largest bucket saw only a 1% improvement in cache miss rate, and overall cache miss rate did not improve within experimental error.

Delegation provides 10.1% of the total data read by Owl in the 24 hour period. In other words, without delegation, the Owl cache hit rate would decrease from 94.9% to 85.4% (increasing the miss rate by nearly a factor of 3). Delegation is thus an essential factor in providing good download efficiency with sharded trackers.

3.3 Comparison with prior systems

We next compare Owl with the two peer-to-peer distribution systems it replaced at Meta. The first such system was a location-aware implementation of BitTorrent. We configured roughly half the hosts in one region to download binaries

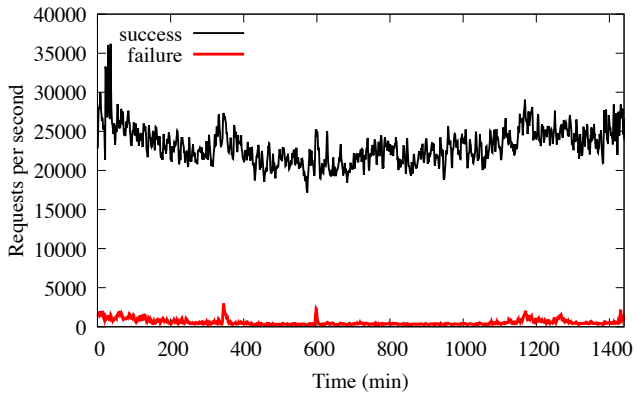

Figure 6: **Delegation success rate over a 24 hour period.** The top line shows the number of successful delegation requests, and the bottom line shows the number of unsuccessful delegation requests.

for provisioning via Owl; the remaining half used BitTorrent. Both systems had identically-sized disk caches. During a 24 hour experiment, these hosts downloaded 17.6 million binaries with a median size of approximately 300 MB. Table 2 compares results for the two systems. Owl is significantly faster than BitTorrent, almost doubling the median per-client download throughput and more than quintupling the p95 throughput. Because the client writes downloaded binaries to local storage, the maximum throughput of Owl was often capped by the available write bandwidth of local media on each host; in contrast, BitTorrent rarely reached the storage bandwidth limit. Additionally, Owl reduces the load on external storage by 42% due to its higher cache hit rate (99.21% for Owl and 98.64% for BitTorrent). Both Owl and BitTorrent provided 4 9's of availability. BitTorrent had slightly higher availability due to allowing more retries with additional backoffs; we later adjusted Owl's retry policies for this bucket to more closely match BitTorrent's policy.

The second prior download system at Meta, StaticTree, used a relatively-static distribution tree constructed via consistent hashing. Each chunk has one primary cacher that fetches the chunk from storage and caches it. The primary cacher is determined by hashing the unique chunk id and selecting a host from a membership list stored in Zookeeper [9]. Each tree level corresponds to a location type (e.g., region, data center, rack, etc.) with the node at each level and location responsible for a chunk again selected via consistent hashing. Secondary nodes at each level provide fault tolerance.

Table 3 compares important download metrics for Owl and StaticTree. Experiments ran for 1–7 days and consisted of millions of production requests to both systems. Both systems use identically-sized memory caches. Owl provides 4 9's of availability in 3 of the 5 experiments and 3 9's in the remaining experiment. StaticTree provides substantially lower availability because of the time needed to detect and route around failed nodes in the tree, as well as the need to remove failed nodes from the membership list in Zookeeper. In contrast, with Owl, ephemeral distribution trees let trackers avoid using a peer immediately for new chunk downloads as soon as that peer is suspected of being unhealthy or slow.

Compared to StaticTree, Owl improves p50 download latency by an average of 55% and p99 latency by 32% across the five experiments. While Owl's latency improvement comes partially from better failure handling, the improved latency also results from the tracker dynamically picking the best data source for a chunk on each *getSource* request. Trackers improve latency by considering load on peers and network locality based on detailed peer and chunk state.

Improving per-chunk download latency often translates into even greater improvements for application-level metrics. Table 4 compares the average time to load six different types of AI models in production via Owl and StaticTree. Owl speeds up model loading time from 1.44x to 3.48x, for an average speedup of 2.92.

Cache hit rates are roughly equivalent for the two systems (StaticTree provides better cache hit rate in 3 out of 5 experiments, but Owl's cache hit rate improvement in Bucket D is by far the most substantial). We also examined network locality for peer-to-peer data transfers between the two systems; we found locality to be roughly the same as both systems optimize for this metric.

3.4 Optimization results

Owl currently has 106 buckets that use 55 distinct policies and configurations. We use the Owl emulator to regularly search for potential policy improvements. Table 5 shows the optimizations that we found in the previous month. We report savings in either peak or total storage usage over 24 hours that we achieved by modifying bucket policies in production. All of these buckets were seeing throttling from external storage at the time, so reducing storage usage was an important goal.

For the first two buckets, emulation lets us inform bucket owners how much improvement in cache hit rate they could expect from allocating more peer memory to Owl caching. Because these clients had memory to spare, we were able to achieve a substantial reduction in peak load. For the remaining three buckets, we achieved better cache hit rate without the need for any additional peer resources simply by changing the policies used by the tracker to manage each bucket.

3.5 Overheads

We measured Owl overhead on peers by profiling one thousand hosts during production usage. Owl's CPU overhead is only 0.05% on 26-core Intel Cooper Lake processors. Owl allocates memory for data caches and for network buffers; both uses of memory are configurable and controlled by the per-bucket policy depending on the client's tradeoff between

	Availability	Cache hit rate	Per-host throughput (MB/s)		Latency (s)	
			p50	p95	p50	p99
Owl	99.994%	99.21%	130.1	20.17	2	132
BitTorrent	99.996%	98.64%	66.9	3.89	4	255

Table 2: **Comparing download metrics for Owl and BitTorrent.** Both systems are used side-by-side to download binaries in one region for 24 hours. We compare the percentage of successful downloads (availability), the reduction in load on external storage (cache hit rate), the median and 95th percentile throughput (download rate), and the median and 99th percentile download latency for five different buckets.

Bucket	Experiment duration	Downloaded bytes	System	Availability	Cache hit rate	Latency (s)	
						Average	p99
A	7 days	14 PB	Owl	99.99%	85%	46.7	47.9
			StaticTree	99.60%	86%	72.2	78.2
B	1 day	30 PB	Owl	99.99%	99.34%	48.8	107.5
			StaticTree	99.91%	99.50%	51.48	122.8
C	1 day	1 PB	Owl	99.99%	69.47%	114.7	507.9
			StaticTree	99.99%	72.52%	180.5	630.8
D	7 days	22 PB	Owl	99.91%	92.70%	44.8	119.0
			StaticTree	99.83%	81.87%	99.8	128.4
E	7 days	50 PB	Owl	99.96%	99.63%	8.5	69.1
			StaticTree	99.95%	99.47%	13.3	112.1

Table 3: **Comparing download metrics for Owl and StaticTree.** Both systems are used side-by-side in production. We compare the percentage of successful downloads (availability), the reduction in load on external storage (cache hit rate), and the median and 99th percentile download latency for four different buckets.

Model	Loading Latency (sec.)		Speedup
	Owl	StaticTree	
A	31	97	3.13
B	138	199	1.44
C	78	264	3.38
D	75	261	3.48
E	82	282	3.44
F	137	465	3.39

Table 4: **Latency improvement in AI model loading** Each row compares the average loading time using StaticTree with the average loading time using Owl for a different bucket.

performance and resource usage. Outside of these two uses, Owl uses less than 0.01% of RSS (resident set size) memory on hosts with 64 GB memory. For comparison, StaticTree uses 0.15% CPU and 0.03% memory for roughly the same workload, which is 3x the resources used by Owl.

To verify scalability, we ran a load test with Owl trackers running on hosts with 64 GB memory, a 26-core Intel Cooper Lake processor, and a 25 Gb/s NIC. Our load tests showed that each such Owl tracker can support 2.4 TB/s client traffic when the Owl cache hit rate is 99%, or 1.5 TB/s client traffic when the Owl cache hit rate is 70%. The trackers are CPU-bound at these traffic levels. As an additional confirmation of being CPU-bound, over 30 days of operation, tracker memory (RSS) stayed at 11% or less on 64 GB hosts, while CPU usage spiked up to a maximum of 37%. In practice, Owl uses many more trackers than these numbers would indicate to provide redundancy for failures, regional failure isolation, and performance isolation among critical buckets.

4 Related work

BitTorrent is the most widely-recognized solution for peer-to-peer data distribution. Classic BitTorrent [7] is highly-decentralized; the trackers simply help peers find each other. Trackers originally returned a random list of peers containing desired data, but later BitTorrent implementations introduced refinements. For instance, the BitTorrent version at Meta sorts peers by location before returning the list. Many recent BitTorrent versions replace trackers with a decentralized distributed hash table [14] for so-called trackerless torrent.

Recently, peer-to-peer distribution has been used to provision containers and virtual machines in public and private clouds. Some implementations have used BitTorrent directly [5]. Uber's Kraken [1] uses a BitTorrent-like architecture to provision containers. Kraken uses trackers that returned an ordered list of candidate peers for downloading data, and it uses dedicated seeders to read from external storage. Alibaba's Dragonfly [2] also provides peer-to-peer container provisioning. Dragonfly's SuperNodes combine tracker and

Bucket	Metric	Before	After	Optimization
A	Peak storage usage	124 GB/s	54 GB/s	Increase peer cache size from 0.2 GB to 4 GB
B	Peak storage usage	63 GB/s	27 GB/s	Increase peer cache size from 0.2 GB to 4 GB
C	Peak storage usage	95 GB/s	18 GB/s	Change selection policy from location-aware to hot-cold
D	Daily storage usage	1.7 PB	1.3 PB	Change eviction policy from LRU to least-rare
E	Daily storage usage	11.7 PB	10.7 PB	Change eviction policy from LRU to least-rare

seeder functionality.

FaaSNet [17], also from Alibaba, takes an even more decentralized approach for distributing serverless containers, foregoing the use of all centralized nodes and instead utilizing a tree-based network overlay. Dadi [13] and VMThunder [19] also use a tree overlay to distribute container/VM images among peers, with cache misses serviced by nodes higher in the tree. These approaches are similar to Meta's StaticTree, except that StaticTree constructs locality-aware trees that minimize the network distance between sibling nodes.

Classically, many tree- and mesh-based networks have been proposed for high-bandwidth data distribution to many hosts [4,6,11,12]. While Owl uses a forest of distribution trees, these trees are per-data-chunk and ephemeral, with edges persisting only for the time needed for a peer to download a single chunk of data. The trees in prior works are longer-lasting and used for more than just a single data chunk.

In contrast to all of these prior distribution systems, Owl's control plane is significantly more centralized. Owl trackers make explicit decisions on behalf of peers about what data to cache and evict, where to download each chunk from, and how to retry failed downloads. Owl trackers consequently have a much more complete view of download and peer state, which allows for making more optimal, global decisions. Centralization also improves ease-of-management. The classic argument against centralizing the distribution control plane has been a projected scalability bottleneck; Owl refutes this argument by demonstrating that careful design can scale even a highly-centralized control plane to support millions of clients and hundreds of petabytes of data distributed per day. Additionally, Owl demonstrates more flexibility than prior systems through its customized policies; container provisioning is currently just a small portion of Owl's total workload.

The control plane and data plane taxonomy used in this paper comes from software defined networking (SDN). Recently, Google's Orion [8] demonstrated the benefits of centralizing the SDN control plane. Distribution and SDNs both provide routing and store-and-forward-style caching. Yet, Owl tracks each individual chunk of data at a level of detail that is infeasible for network packets. This is possible because Owl operates on much larger units of data.

5 Conclusion

Owl distributes over 800 PB of hot content per day to millions of peers at Meta. Owl combines a decentralized peer-to-peer data plane with a highly-centralized control plane in which trackers make detailed decisions for peers such as for where to fetch each chunk of data, how to retry failed fetches, and which chunks to cache in peer memory and storage. Owl is highly-customizable through tracker policies that allow a unique configuration for each type of client.

BlockFlex: Enabling Storage Harvesting with Software-Defined Flash in Modern Cloud Platforms

University of Illinois at Urbana-Champaign †*Microsoft Research*

Abstract

Cloud platforms today make efficient use of storage resources by slicing them among multi-tenant applications on demand. However, our study discloses that cloud storage is still seriously underutilized for both allocated and unallocated storage. Although cloud providers have developed harvesting techniques to allow evictable virtual machines (VMs) to use unallocated resources, these techniques cannot be directly applied to storage resources, due to the lack of systematic support for the isolation of space, bandwidth, and data security in storage devices.

In this paper, we present BlockFlex, a learning-based storage harvesting framework, which can harvest available flash-based storage resources at a fine-grained granularity in modern cloud platforms. We rethink the abstractions of storage virtualization and enable transparent harvesting of both allocated and unallocated storage for evictable VMs. BlockFlex explores both heuristics and learning-based approaches to maximize the storage utilization, while ensuring the performance and security isolation between regular and evictable VMs at the storage device level. We develop BlockFlex with programmable solid-state drives (SSDs) and demonstrate its efficiency with various datacenter workloads.

1 Introduction

In modern cloud platforms, storage devices such as flash-based solid-state drives (SSDs) have been virtualized as system-wide shared resources to provide storage services across multiple application instances [5, 9, 14, 29, 38, 65]. This enables cloud platforms to make efficient use of storage capacity and bandwidth by slicing them among multiple multi-tenant virtual machines (VMs) [43, 60, 75]. However, our study of the event traces collected from popular cloud platforms [3, 9, 22] reveals that storage I/O is still significantly underutilized for both unallocated (unsold) and allocated storage. For instance, we find that 40% of the cloud storage servers have 25% of their storage unallocated, and the I/O utilization of allocated storage is under 33% on average (see Figure 1 and §2.1).

To improve the resource efficiency in the cloud, providers offer evictable VMs (i.e., Spot VMs or Harvest VMs) [4, 23, 62]. These evictable VMs allow users to use unallocated resources with low priority, i.e., the resources of evictable VMs can be reclaimed by regular VMs at any time. Recent studies [5, 48, 69, 76] advanced this technique by improving the resource allocation and scheduling for evictable VMs with heuristic-based harvesting approaches.

However, prior work on resource harvesting mainly focused on CPU and memory resources, which cannot be directly be applied to cloud storage for three reasons. First, current cloud storage virtualization approaches do not support storage harvesting, and dynamic reallocation of resources is not feasible. Second, cloud storage usually stores sensitive application data, which requires careful management for storage allocation and deallocation. Third, cloud storage can suffer from significant harvesting overhead due to the block erasure and metadata updates, which requires specific optimizations for enabling efficient storage harvesting.

In this paper, we present BlockFlex, the first learning-based storage harvesting framework, which enables transparent storage harvesting for both allocated and unallocated storage at a fine-grained granularity, while ensuring data privacy for cloud users with low harvesting overhead.

To develop BlockFlex, we first conduct a characterization study of storage resources that could be harvested in a cloud platform. According to our study (see §2), we find that for unallocated VMs configured with 512GB SSD, 78%, 43%, and 25% of them can be harvested and used for 1 hour, 6 hours, and 12 hours, respectively. This provides us the heuristic information about how these unallocated storage resources can be utilized. As for the allocated storage for VMs, an average of 70% can be harvested, however, the time available for harvesting varies depending on the workloads running in the VMs. Our study discloses the dynamics of available storage resources, which drives us to develop a learning-based approach for assisting the storage harvesting.

*Co-primary authors.

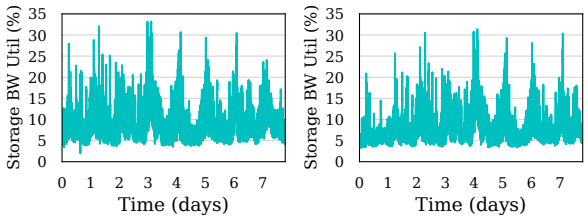
To enable transparent and fine-grained storage harvesting, we rethink the abstractions of storage virtualization for flash-based SSDs. The recent development of software-defined flash (SDF) in datacenters [29, 51] allows VMs to map their storage to dedicated flash channels. We build on top of the SDF abstraction and propose a new class of virtualized SSDs, named *ghost vSSD*. A ghost vSSD is created by harvesting free flash blocks from either unallocated or allocated but unused storage. The ghost vSSD provides the flexibility for fine-grained storage allocation and deallocation as well as block-level state tracking. It enables storage harvesting at the device level, which is transparent to the upper-level applications running on the VMs. Each ghost vSSD aims to meet the storage capacity and bandwidth requests from an evictable VM, however if needed, they can be reclaimed by regular VMs at any time.

However, frequent preemption and harvesting will inevitably introduce performance overheads to both regular VMs and evictable VMs, and even cause VM recreations. Therefore, it is desirable to provision the best-fit storage resource for an evictable VM. To achieve this, we develop learning-based techniques to predict the storage demands as well as the storage resources available for harvesting, in terms of storage capacity, bandwidth, and the duration available for harvesting. With these predictions, for each ghost vSSD, BlockFlex ensures the harvested storage resource will maximally meet the requirements of evictable VMs, while minimizing the opportunity of being preempted unexpectedly by regular VMs.

BlockFlex uses the Long Short-Term Memory (LSTM) network for online predictions at runtime, because of its low overhead and ability to make time-series predictions. We improve the prediction accuracy by developing different LSTM models for different dimensions of storage properties. For the predictions of storage capacity, bandwidth, and the time available for harvesting, BlockFlex can reach at 94.1%, 95.3%, and 93.1% accuracy, respectively, with slight over-provisioning. Upon mispredictions, BlockFlex implements different exception handlers for different cases (see the details in Table 1). As mispredictions do not happen frequently, the performance impact of misprediction handling is negligible in BlockFlex.

To minimize the performance interference between the regular VM and evictable VM caused by the storage harvesting, we assign higher priority to I/O requests from regular VMs when sharing the same SSDs with evictable VMs. When the harvested storage needs to be reclaimed, its flash blocks will be erased first to ensure data security, and then returned back to the corresponding regular VMs. Overall, we make the following contributions in this paper.

- We conduct a characterization study of the storage efficiency in different cloud platforms, our observations motivate the desirable need for storage harvesting.
- We rethink the abstractions of storage virtualization in modern cloud platforms for enabling fine-grained storage harvesting with software-defined flash.



(a) Storage utilization per VM. (b) Storage utilization per server.

Figure 1: The bandwidth utilization of allocated cloud storage.

- We build a learning-based storage harvesting framework named BlockFlex that can harvest both unallocated and allocated storage resources.
- We develop lightweight predictors that can make efficient predictions for both storage demand and availability in terms of storage capacity, bandwidth, and the time available for harvesting.
- We implement BlockFlex with real programmable SSDs and show its efficiency with various datacenter workloads.

Our experiments show that BlockFlex can improve the overall storage utilization by up to 1.75× in cloud platforms. BlockFlex is lightweight, it incurs trivial additional overheads to cloud platforms. BlockFlex can improve the performance of evictable VMs running with batch-processing workloads by 1.68× on average, while having negligible negative impact on the performance of regular VMs. The codebase of BlockFlex is available at https://github.com/platformxlab/blockflex.

2 Characterization for Storage Harvesting

Although storage virtualization has been widely deployed in cloud platforms, we observe that storage devices are still significantly underutilized, in terms of both storage bandwidth and capacity. In this section, we first quantify the cloud storage utilization, and then we conduct a hypothetical analysis of the opportunities for storage harvesting.

2.1 Cloud Storage Utilization

The storage underutilization in cloud platforms is due to both the poor utilization of allocated storage resources and the large portion of unallocated resources, as we discuss below.

Allocated storage resources. We conduct the storage utilization study based on the open-source cloud traces from Alibaba [3] and Google [22]. These traces track the usage of allocated storage resources across both VMs and physical servers. Alibaba cloud traces contain the VM utilization logs of 4K servers over 8 days, and Google cloud traces were collected from 12.5K servers over 29 days. As different cloud traces emphasize different aspects of the cloud storage usage (e.g., storage capacity, I/O bandwidth, server utilization, and

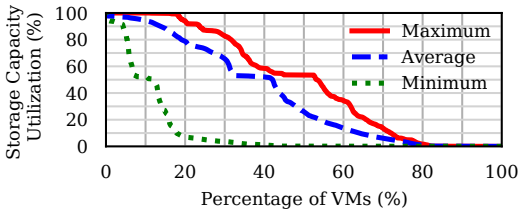


Figure 2: The capacity utilization of allocated cloud storage.

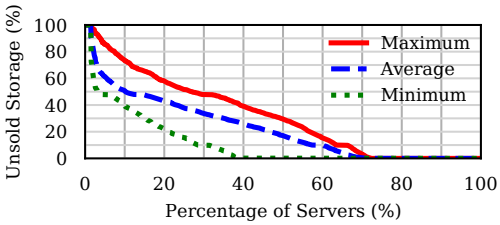

Figure 3: Unallocated storage in cloud servers.

VM utilization), we analyze both traces. We summarize our study results as follows:

- *Storage bandwidth:* We show the bandwidth utilization of Alibaba cloud [3] in Figure 1. The bandwidth utilization of allocated storage across all VMs is below 33%, and the average bandwidth utilization across all VMs over their entire lifetime is 9.2%. For physical servers that usually host multiple VMs, we obtain a similar trend: the bandwidth utilization of the physical storage devices is below 31%, and the average bandwidth utilization is 8.6%.
- *Storage capacity:* We present the cumulative distribution of storage capacity across the VMs of Google cloud [22] in Figure 2. We find that 20% of the VMs almost did not use their allocated storage capacity, 50% of the VMs used only 26.4% of the allocated storage capacity on average, and only 20% of the VMs used up to 90% of their allocated storage. Although different VMs may allocate different storage capacities, our study shows that their capacity utilization is surprisingly low.

The low utilization of allocated cloud storage resources is mainly due to two major reasons. First, cloud platforms usually allocate storage resource associated with each VM at a coarse-grained granularity for simplified storage management. For instance, the storage capacity of a VM in the Azure Cloud is linearly proportional to the number of allocated processor cores [5, 76], no matter whether the VM is I/O-intensive or CPU-intensive. Second, storage allocation is usually conducted in a static manner, while the storage usage of the workloads running in each VM changes dynamically over time. Therefore, the user of a VM has to over-provision sufficient storage for the peak demand upon VM creation.

Unallocated (unsold) storage resource. Beyond the allocated storage, the unallocated (unsold) storage in cloud platforms is another source for storage underutilization. This is because cloud providers usually over-provision VMs in their resource pool to satisfy the elasticity requirement from customers [5]. As each unsold VM consumes a fixed amount of resources

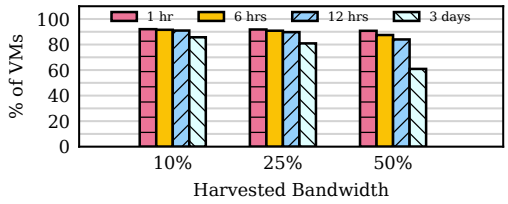

Figure 4: The availability of allocated storage for harvesting.

(e.g., processor cores, memory, and storage), it will result in storage resources unallocated.

To further understand the unallocated storage, we analyze the cloud traces of unsold storage resources from Azure Cloud [5]. The traces include the VM allocation/deallocation logs for about 1,400 servers over 24 hours. As shown in Figure 3, nearly 70% of cloud servers have unsold storage resources, 50% of the servers have an average of 17.3% of their storage unallocated, and 20% of the servers have at least 20.1% of their storage unallocated. Given that a datacenter has thousands of servers, the unallocated storage is another critical source for the storage underutilization.

2.2 Opportunities for Storage Harvesting

As discussed in §2.1, we identify two sources for storage harvesting: unallocated storage and allocated storage. In this part, we conduct a hypothetical analysis of these storage resources to understand their potential for storage harvesting.

Analysis methodology. We study the cloud traces as discussed in §2.1, with a focus on the storage resource allocation and deallocation. We analyze the available storage in allocated and unallocated VMs over time, and check (1) whether we can harvest storage from them for a hypothetical harvest VM requesting a certain amount of storage capacity; (2) how long the harvested storage can last; (3) how many storage resources we can potentially harvest for the hypothetical harvest VMs. Note that Google and Alibaba cloud traces only report normalized numbers, so we use percentages rather than absolute numbers in our analysis.

Allocated storage resource. We first apply the hypothetical analysis on the allocated storage resource. Given a hypothetical harvest VM requesting different percentages (10%, 25%, and 50%) of storage bandwidth from a regular VM, we investigate how many servers have such available bandwidth, and how long these resources are available for harvesting. We report the average percentage across the entire trace. The results are summarized in Figure 4. We observe that more than 91% of the servers have harvestable bandwidth for 12 hours, and about 76% of the servers have harvestable bandwidth for 3 days. As we harvest storage for a shorter time (i.e., less than 12 hours), the portion of the available servers is consistently high. This is due to the constant low storage utilization of allocated VMs, as shown in Figure 1.

Unallocated storage resource. We now explore the unallocated storage resource. Given a hypothetical harvest VM that

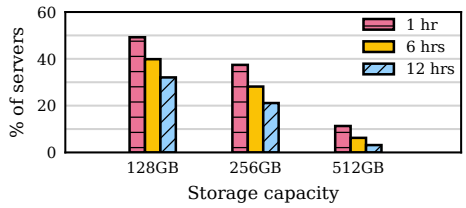

Figure 5: The availability of unallocated storage for harvesting.

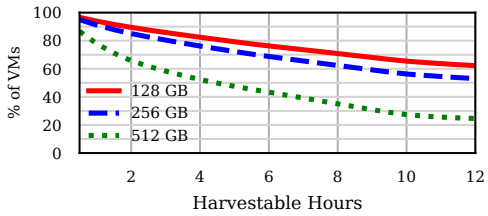

Figure 6: The availability of unsold regular VMs for storage harvesting with different capacities.

requests different storage capacities (128GB, 256GB, and 512GB), we analyze how many servers can satisfy the request from this harvest VM, and how long the available storage can last. We present the study results in Figure 5. Our study finds that 32% of the servers can satisfy the requirement of 128GB storage capacity for 12 hours. If the harvest VM requests storage for a shorter time, such as 1 hour, 50% of the servers can meet the request. As harvest VM increases the requested storage capacity, the number of harvestable servers decreases.

We also study unsold regular VMs. We vary the storage capacity request from 128GB to 512GB for the hypothetical harvest VM, and demonstrate our study results in Figure 6. For a hypothetical harvest VM of 128GB storage capacity, 94%, 76%, and 62% of the unsold regular VMs can be harvested for 1 hours, 6 hours, and 12 hours, respectively. As we increase the requested storage capacity for the harvest VM, the percentage of available unsold regular VMs drops. However, we still find a decent amount of unsold regular VMs can be harvested. For instance, for the harvest VM that requests 512GB storage capacity, 43% and 24% of the unsold VMs are available for 6 hours and 12 hours, respectively.

It is worth noting that the storage bandwidth is usually allocated proportionally with storage capacity in cloud platforms [19, 29]. This is also reflected in the cloud traces we studied in this paper. For instance, as for the VM with 128GB, 256GB, and 512GB, the storage bandwidth is 192 MB/s, 384 MB/s, and 768 MB/s, respectively. Thus, our study on the unsold storage capacity also applies to the storage bandwidth.

Takeaways. Our characterization study shows that:

- Both unallocated and allocated storage have sufficient storage capacity and bandwidth for harvesting, and they are available long enough to facilitate harvesting.
- The harvestable storage resource varies depending on the storage capacity and time available for harvesting. Harvesting a large storage capacity for a longer time has a lower chance of identifying the available storage resource.
- The harvestable storage resource from unallocated VMs and allocated VMs shows different availability patterns and trade-offs. We have a larger chance to harvest storage in allocated VMs, but this may have interference with the regular VM. The harvestable storage from unallocated VMs is limited, but it has no impact on the performance of regular VMs.

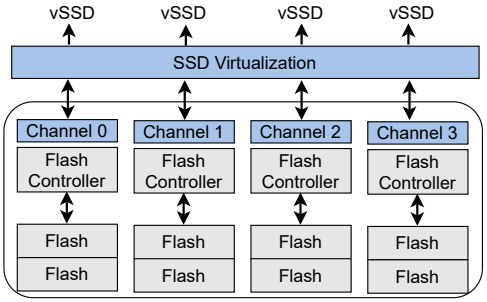

Figure 7: Storage virtualization with software-defined flash.

With BlockFlex, we aim to improve the cloud storage utilization by harvesting the available storage resources from both allocated and unallocated storage.

3 Technical Background

To facilitate our discussion, we first present the essential technical background of storage virtualization in cloud platforms, and then discuss the harvest VMs that will benefit from storage harvesting.

3.1 Storage Virtualization and SDF

In modern cloud platforms, storage virtualization has become the backbone of the storage infrastructures, in which storage devices such as flash-based solid-state drives (SSDs) are virtualized and shared by multiple VMs in order to improve storage utilization [29, 38, 60, 65]. The storage virtualization layer provides the system abstraction of virtualized storage devices (e.g., virtual disks) and hides the underlying hardware complexities from upper-level VMs. Each VM can have one or more virtual storage devices, and each virtual storage device can be mapped to one or more physical storage devices.

At the same time, SSDs are increasingly being adopted by cloud providers for their low latency and high throughput [1, 29, 30, 46]. Internally, an SSD consists of multiple flash channels, each channel has multiple flash chips, and each chip has thousands of flash blocks (see Figure 7). Each channel can issue I/O requests independently, thus, offering high parallelism and performance isolation. SSDs can only write data to free blocks, and once a free block is written, it is no longer available for future writes until it is erased. However, the erase operation is time-consuming. Thus, writes are issued to

flash blocks that have been erased in advance (i.e., out-of-place update). Because of this, SSDs employ a flash translation layer (FTL) to maintain the logical-to-physical address mapping, and manage the garbage collection (GC) operations.

To ultimately exploit the performance benefits of SSDs in the cloud, software-defined flash (SDF) was developed [39, 51]. In the context of SSD virtualization, SDF allows the upper-level VM to map its virtual SSD (vSSD) to a set of flash channels, as shown in Figure 7. Therefore, cloud providers can allocate storage capacity and bandwidth to each vSSD per its request by allocating fewer/more flash channels, following the pay-as-you-go model, while enabling the device-level performance isolation between vSSDs. The vSSD performs like a conventional storage disk, it provides the block interface to upper-level software, and uses a mapping table to index the logical-to-physical block address mappings [29, 51]. As SDF enables various cloud services such as Database-as-a-Service (DaaS) and Infrastructure-as-a-Service (IaaS) to achieve predictable storage performance and satisfy their service level objectives (SLOs), it has become an essential component in modern cloud platforms [16, 31, 55, 56, 64]. In this work, we develop BlockFlex based on the software-defined flash infrastructure.

3.2 Harvest Virtual Machine

To improve the resource utilization in cloud platforms, a few VM techniques have been developed recently [4, 5, 12, 20, 58, 62, 69]. Cloud providers offer *evictable VMs* or *Spot VMs* that run with lower priority than regular VMs, they can be evicted if resources are needed by a regular VM [4, 62]. With evictable VMs, cloud providers can sell unsold resources at a lower price while providing resource guarantees for regular VMs. Therefore, cloud customers usually rent evictable VMs to run batch-processing workloads or similar applications that have lower requirements on resource guarantees. Based on the evictable VMs, researchers developed *harvest VM* [5], *elastic VM* [69], and *memory-harvesting VM* [20], which further improve the cloud resource utilization by enabling flexible and dynamic harvesting of unallocated resources. To simplify the discussion, we will use harvest VM to represent these aforementioned VMs for resource harvesting in the remainder of the paper.

A majority of these harvest VMs were developed to harvest CPU and memory resources, and none of them can be directly applied to the storage resources. Additionally, prior work proposed various VM scheduling techniques by co-locating multi-tenant applications on the shared bare-metal servers to improve the resource efficiency [41, 43, 66, 71]. However, our study of various cloud traces discloses that the storage utilization is still a severe issue within modern cloud platforms. Since storage virtualization today assumes exclusive ownership of storage resources for each VM, it inevitably causes storage underutilization. In this work, we enable the storage harvesting for harvest VMs to improve the cloud storage utilization.

4 Design and Implementation

In this section, we first discuss the design goals and challenges of BlockFlex. After that, we will present the overview of the system as well as the design and implementation details of each component.

4.1 Design Goals and Challenges

As we develop BlockFlex to enable efficient storage harvesting, we aim to achieve the following goals:

- The storage harvesting should satisfy the storage requirements from harvest VMs while minimizing unexpected preemptions by regular VMs.
- The storage harvesting should be transparent to the upper-level VM to minimize changes to the VM and applications, as well as facilitate its production deployment.
- The storage harvesting should have minimal negative impact on the regular VMs to guarantee the quality of cloud services as we improve the global storage utilization.
- The storage harvesting should ensure the data safety, when it temporarily allocates unused data blocks from both allocated and unallocated storage to the harvest VMs.

Since cloud platforms today do not provide system support for storage harvesting, it is not easy to achieve the above goals. Additionally, existing resource harvesting techniques cannot be directly applied to storage resources. Specifically, we have to overcome the following challenges. First, cloud customers usually rely on the storage to permanently store their data, the data durability and availability are critical for storage services. This makes the storage harvesting fundamentally more challenging than the harvesting of CPU and memory resources. For example, shrinking available storage (upon reclamation) may result in data loss, while reclaiming memory and CPU resources mainly causes reduced performance. Second, the storage virtualization and management are different from that of CPU and memory resources, especially for SSDs that have intrinsic properties (see §3.1). Therefore, sharing storage resources while maintaining isolation among tenants needs new techniques. Third, storage allocation and deallocation usually incur more performance overhead than the context switch overhead caused by harvesting CPU and memory resources, which requires special development efforts for enabling the deployment of storage harvesting in cloud platforms.

4.2 System Overview

To the best of our knowledge, BlockFlex is the first storage harvesting framework built based on modern software-defined storage infrastructure. We present the system architecture of BlockFlex in Figure 8. To manage the harvested storage, we propose a new abstraction, named ghost vSSD (gSSD), on top of software-defined flash (§4.3). The ghost vSSDs

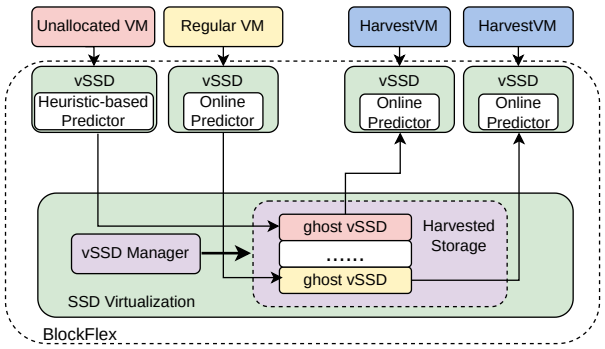

Figure 8: System overview of BlockFlex.

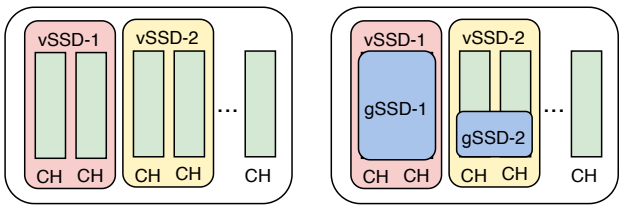

(a) Allocated and Unallocated vSSDs (b) Harvest available storage

Figure 9: Examples of harvesting storage. CH: flash channel; vSSD-1: unsold storage; vSSD-2: allocated storage; gSSD-1: harvest unsold storage; gSSD-2: harvest allocated storage.

can be attached to created vSSDs , therefore, no changes are required to VMs. BlockFlex will deploy a predictor in each vSSD (§4.4). For harvest VMs, BlockFlex will predict their demanded storage capacity and bandwidth, as well as how long the demand will last. For regular VMs, BlockFlex will predict their available storage capacity and bandwidth, as well as their available time. For unused storage resources, BlockFlex will use both heuristic-based approaches to predict the duration time available for harvesting. Based on the prediction, BlockFlex will make a best-fit match and allocate unused storage to the harvest VM. In case resource preemption happens to the harvest VM (caused by misprediction), BlockFlex will release the harvested storage to the regular VM and handle the exceptions for different scenarios (§4.5).

Since BlockFlex enables storage harvesting at the system virtualization level, it does not change the upper-level durability model (e.g., data replication) offered by current cloud storage infrastructures. For harvest VMs, cloud platforms assume their end users are aware of the relaxed durability guarantees and their applications may suffer from early reclamations. BlockFlex makes the best effort to allocate new gSSDs to ensure the data durability for harvest VMs. However, similar to Spot VMs [63], the owners of harvest VMs should be aware of the risk and take responsibility for their data as the cost of harvest VMs is much lower than regular VMs. As BlockFlex is deployed on top of existing software-defined storage infrastructure, it runs in a distributed environment where the global control plane manages the gSSDs and their allocations/deallocations. In the following section, we will discuss each technique proposed in BlockFlex, respectively.

4.3 New Abstraction for Storage Harvesting

As discussed in §3.1, with software-defined flash, the storage virtualization can map each virtual SSD to a number of flash channels depending on the storage capacity and bandwidth requested by the associated VM. We show two typical examples in Figure 9. Suppose we have a 1TB SSD that contains 16 channels. Each channel has 64GB and delivers a bandwidth of 70MB/s. As shown in Figure 9 (a), the cloud platform allocates two flash channels to vSSD-2 (128GB), leaving other flash channels temporarily unused (e.g., vSSD-1). Both vSSD-1 and vSSD-2 could provide opportunities for storage harvesting. For example, as shown in Figure 9(b), the entire unsold vSSD-1 (gSSD-1) and part of the allocated vSSD-2 (gSSD-2) could be harvested depending on their availability. The SDF offers the flexibility to allocate fewer/more resources to each gSSD.

However, the harvested storage still belongs to the original vSSDs, which could be preempted by existing or newly allocated regular VMs. Since the availability of harvested storage varies depending on the workloads in the cloud platform, it increases the complexity of storage harvesting.

4.3.1 Definition of Ghost vSSD

To simplify the management of harvested storage, we develop the gSSD abstraction. Its block interface is the same as that of the regular vSSD. Therefore, no code modifications are required for the VMs. Similar to vSSDs, each gSSD has a block-level mapping table to index the mappings of logical block addresses to physical block addresses , and a free block list to manage the free flash blocks. However, since each gSSD is created/borrowed from regular vSSDs and has a different lifetime (the time available for harvesting), we maintain a metadata structure for each gSSD, as shown in Figure 10.

The metadata of a gSSD includes its maximum bandwidth and capacity. We use the number of flash channels to represent the storage bandwidth, and the number of flash blocks to represent the storage capacity. As the actual storage bandwidth and capacity offered by a gSSD could vary at runtime, we use their maximum values because they are provided on a best-effort basis. We use the *expire* to indicate when the gSSD will no longer be available for use. This value is predicted with our duration predictor (see the detailed discussion in §4.4). The metadata structure also has a bit *in_use* to indicate whether the gSSD has been assigned to a harvest VM or not. If yes, the *vm_id* stores the ID of the corresponding harvest VM. The *home* pointer points to the regular vSSD from which the blocks in the gSSD are harvested. The *ghost* points to the created ghost vSSD after storage harvesting. The metadata is stored in the gSSD. It is initialized when the gSSD is created and updated when the gSSD is harvested/reclaimed.

```
typedef struct vmeta {
    int bandwidth          ; maximum bandwidth of gSSD
    int capacity           ; maximum capacity of gSSD
    int expire             ; how long the gSSD lasts
    boolean in_use         ; used by harvest VM or not
    string vm_id           ; harvest VM ID
    struct vssd* home      ; vSSD that owns these blocks
    struct vssd* ghost     ; points to the attached gSSD
} vmeta_t;
```

Figure 10: Metadata of a ghost vSSD in BlockFlex.

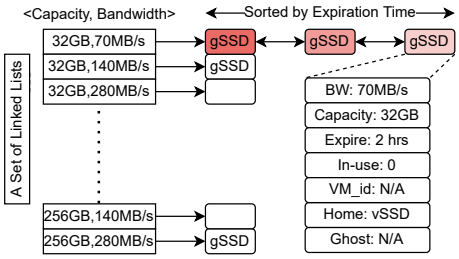

Figure 11: The organization of the gSSD pool in BlockFlex.

4.3.2 Management of Ghost vSSDs

We now discuss the gSSD creation and management.

Creating gSSDs. Instead of harvesting storage upon requests, BlockFlex allows regular vSSDs to proactively create gSSDs and add them into the gSSD pool managed by the vSSD manager (see Figure 8). This removes the harvesting procedure from the critical path. A vSSD creates a gSSD when its predictor predicts that it will have available storage resources for harvesting. These predictions occur at regular intervals (every three minutes by default). In order to create a new gSSD, BlockFlex will harvest free blocks from the vSSD and create a mapping table for them. Following our prior study on SDF [29], we use block-level address mapping tables for indexing flash blocks in the gSSDs/vSSDs. We align the address mapping granularity and flash erase granularity to simplify the storage management with improved efficiency. And each gSSD/vSSD has its own mapping table. Although the flash blocks of a gSSD could be harvested from a vSSD, the corresponding gSSD and vSSD will not share these harvested flash blocks. Therefore, we do not need to synchronize the mapping table entries between the gSSD and vSSD at runtime.

The metadata of a gSSD (Figure 10) is initialized with the number of flash channels harvested (*bandwidth*), the number of free blocks (*capacity*), and the predicted time the resources will be available for use (*expire*). The *home* of the gSSD will point to the regular vSSD, and the *ghost* will point to the newly created gSSD. At the same time, the gSSD will be added to the gSSD pool for serving future harvesting requests.

To simplify the management of gSSDs, we only create a gSSD when harvesting a chunk of resources. BlockFlex enables the storage harvesting at the granularity of a flash channel, 16GB size, and 30-minute for storage bandwidth, capacity, and duration time, respectively. To ensure reasonable performance isolation between regular VMs and harvest VMs, we restrict each vSSD to provide only one gSSD.

Managing gSSDs. To facilitate fast gSSD lookup, we organize gSSDs in a set of lists in the vSSD manager with considering the sorting in three dimensions: storage bandwidth, capacity, and time available for harvesting. We optimize the lists based on our observations that (1) the storage bandwidth and capacity are correlated with the number of channels available in a vSSD; (2) the time available for harvesting for each gSSD needs to be updated at regular intervals; and (3) we will not update the maximum storage capacity and bandwidth over the lifetime of a gSSD. Therefore, as shown in Figure 11, BlockFlex maintains a set of gSSD lists sorted by <capacity, bandwidth>. In each list, the gSSDs are sorted by their expiration time from the farthest one to the nearest one. There is a timer running periodically (per 15 minutes by default) to update the expire time in the gSSD pool. For the expired gSSDs but have not been allocated to any harvest VM, BlockFlex will remove them from the list.

Harvesting gSSDs. Upon receiving a request for storage harvesting, BlockFlex will check the gSSD pool to identify a best-fit match for the requested storage capacity, bandwidth, and time available for harvesting. BlockFlex uses the best-fit matching policy to minimize the waste of storage resources. These requested parameters are obtained from the predictors deployed in the vSSD of the corresponding harvest VM (see §4.4). Since the gSSD pool is sorted, we use the binary search to first locate the corresponding list that matches with the requested storage capacity and bandwidth. After that, we walk through the list until identifying an available gSSD whose expire time matches with the requested harvestable time.

Once a gSSD is identified in the pool, we set its *in_use* to 1 to indicate this gSSD has been assigned to a harvest VM and the corresponding harvest VM ID is recorded. BlockFlex supports concurrent gSSD allocations by managing the gSSD lists using non-blocking linked-lists implementation with the compare-and-swap operations [27]. Compared to the lifetime of a gSSD (hours or even days), the gSSD allocation overhead (a few microseconds) is trivial.

With a harvested gSSD, BlockFlex will assign its flash blocks to the vSSD of the corresponding harvest VM. This harvesting procedure is transparent to the harvest VM, as we track these blocks in the mapping table of the vSSD of the harvest VM, as shown in Figure 12. The address mapping table in the vSSD is extended to include the ID of the harvested gSSD. Therefore, upon data accesses from the harvest VM, its vSSD will conduct the address translation to translate the logical block address (LBA) to [gSSD-ID, gLBA]. With the obtained gSSD-ID, the corresponding gSSD will translate the gLBA to the physical block address (PBA). This enables BlockFlex to harvest multiple gSSDs for a harvest VM. With the expanded vSSD, the harvest VM can resize the vSSD and its file system with existing virtual disk and file system tools [13, 18, 67]. Note that the address mapping of a vSSD will also index the

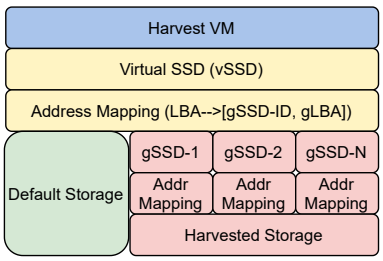

Figure 12: Harvesting multiple ghost vSSDs for a harvest VM.

default storage allocated when a harvest VM is created.

We assume each harvest VM will not request more than 256 gSSDs, so 1 byte is used to index the gSSDs. In total, each address mapping entry takes 9 bytes (4 bytes for LBA and 4 bytes for PBA). Given a harvest VM that requests 128GB storage, and each flash block is 4MB, the block-level address mapping of a vSSD will take only 288KB.

Reclaiming gSSDs. When a harvest VM finishes its jobs, the harvested gSSDs will be reclaimed to the pool in the vSSD manager. Upon the gSSD reclamation, the corresponding entries in the address mapping table of the vSSD will be removed. BlockFlex will check whether a gSSD will expire soon or not (i.e., in 30 minutes by default). If yes, BlockFlex will erase the flash blocks for data safety, and remove the gSSD instance. Otherwise, BlockFlex will add the gSSD into the gSSD pool for future harvesting. Since the erase operation is expensive, BlockFlex leverages the channel parallelism of an SSD to execute them in parallel.

The additional erase operations caused by gSSD reclamation has minimal impact on the lifetime of SSDs. This is for two major reasons. First, BlockFlex ensures wear leveling of SSDs by following a relaxed wear-leveling scheme proposed in our prior study [29]. It showed that SDF can achieve near-ideal SSD lifetime by swapping channels every 19 days on average for data center workloads, and 12 days on average for the worst case of erasing channels at full bandwidth. The wear leveling plays a fundamental role of ensuring the device lifetime, no matter whether flash blocks are used by regular VMs or harvest VMs. Second, the harvesting procedure itself only introduces erases when harvested storage is reclaimed, and it happens infrequently. Based on our study, for a given vSSD, it is harvested about every 2.1 days and consumes an average of 25% of the SSD (see §5.2), meaning the entire vSSD is erased once per 8.4 days. For modern SSDs that usually have 10K P/E cycles and can last 5-year lifetime, the storage harvesting operations will consume about 2% of the device lifetime, which is acceptable in practice.

In addition, with the assistance of predictors (see §4.4), BlockFlex minimizes the chances of early reclamation, and takes the erase operations from the critical path. However, a reclamation would still happen, even though a gSSD is in use by a harvest VM. This could be caused by the resource preemption issued by a regular VM. We will discuss how BlockFlex handles this in details in §4.5.

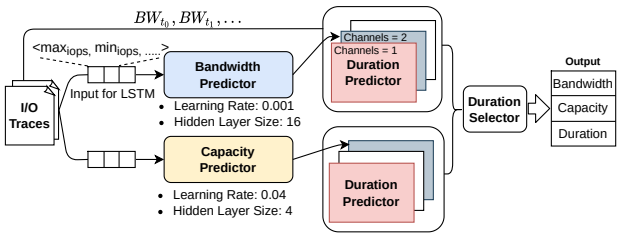

Figure 13: The workflow of the predictors used in BlockFlex.

4.4 Predictions for Storage Harvesting

Instead of relying on the cloud customers or VM users to specify their demanded or unused storage resource, we use a lightweight online learning approach to predict them. As discussed in §4.2, each vSSD has an online predictor, except those for the unallocated (unsold) VMs.

4.4.1 Heuristic-based Prediction for Unsold VMs

For the unallocated (unsold) VMs, we use a heuristic-based approach, based on our study characterizing the unallocated storage in cloud platforms (see §2). Recall that cloud providers usually over-provision VMs to provide the elasticity for their services. They reserve different regular VMs with various storage capacities. The common sizes include 128GB, 256GB, and 512GB for simplified VM management and deployment. According to our study in Figure 6, their availability for harvesting varies by their capacities.

Previous harvesting studies have identified that past values are a useful indicator for the available time of unsold storage [5]. In our study of unsold storage resource, we confirm that the available time of unsold storage for harvesting is stable. For this reason, we tag each unsold VM with a predicted duration time using the histogram of previous available times for the unsold VM with the same storage capacity. For instance, for the unsold VMs with 512GB storage capacity, we can use 20% of them as gSSDs that would be available for 12 hours, 20% for 6 hours, and the remaining for 1 hour. This distribution could change depending on the heuristic study of the corresponding cloud platform. The distribution of these gSSD sizes depends on the configured storage capacities for the unsold VMs.

4.4.2 Online Learning for Allocated and Harvest VMs

We predict the harvestable storage resource for allocated VMs, and demanded storage resource for harvest VMs. Since the predictions for allocated VMs and harvest VMs are both determined by their workloads, they use the same learning-based approach but different learning parameters.

We show the entire prediction workflow of BlockFlex in Figure 13. In each vSSD, we collect the read, write, and erase operations at the block layer for online predictions, therefore, we do not rely on the systems software running on top of

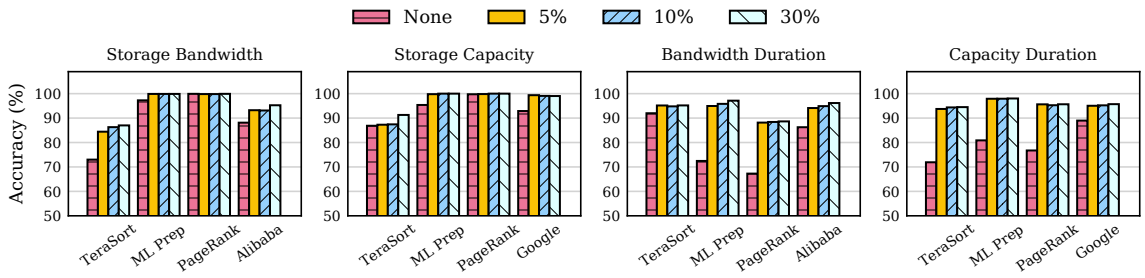

Figure 14: Prediction accuracy of storage bandwidth, capacity, and duration time available for harvesting, with various over-provisioning ratios. A slight over-provisioning for storage harvesting can significantly improve the prediction accuracy.

the vSSD. Based on these I/O traces, we infer the bandwidth, throughput (IOPS), and current storage utilization.

We use Long-Short Term Memory (LSTM) models [28] to develop our predictors, because of their strength in time-series predictions and relatively low overhead. The inputs for LSTMs are statistical measures gathered from the bandwidth, IOPS (e.g., max_{iops}, min_{iops}), and storage utilization. By default, BlockFlex trains the models every three minutes using the collected statistics from the preceding 15 minutes. This introduces minimal performance and memory overhead. Both bandwidth predictor and capacity predictor use the same LSTM model, but we tune their learning rate and hidden layer size slightly differently for improved accuracy (see Figure 13). These predictors will generate the predicted bandwidth (in channels) and predicted capacity (in GB), respectively.

The predictions of storage bandwidth and capacity are passed to their respective duration predictors. Each duration predictor consists of a collection of individual sub-predictors. Each sub-predictor is responsible for a possible output from the bandwidth/capacity predictors. For instance, if the output of the bandwidth predictor ranges from 1 to 16 channels, we will have 16 duration sub-predictors, each sub-predictor will predict its corresponding duration time by using the history of previous durations at that demand.

To ensure a gSSD can satisfy both the storage and bandwidth requirements from a harvest VM, the duration selector takes the maximum duration for demanded storage resources. To ensure a regular VM will not reclaim resources early, the selector takes the minimum duration for the harvestable storage resources. The final output delivered by the predictors in BlockFlex is presented in a tuple of <bandwidth, capacity, duration>. We describe the details of each predictor as follows.

Storage bandwidth: For the prediction of storage bandwidth, we use six inputs for the LSTM model: the *maximum, minimum, and average* for both bandwidth and IOPS. We do not use other statistical measures as inputs because they do not improve the prediction accuracy and slow down the convergence of the model. As the number of flash channels is proportional to the storage bandwidth, we use the number of channels as the bandwidth metric to simplify the bandwidth prediction.

Storage capacity: The prediction model for the storage capacity is similar to the model used for the storage bandwidth. We use the *maximum, minimum, and average* of past storage utilizations, and the *current changes in storage utilization* as the inputs. We find that using the changes in storage utilization helps differentiate long periods of sequential writes against shorter changes. We use the number of flash blocks as the output of the capacity predictor.

Duration: For the duration, we make the predictions for storage bandwidth and capacity separately. For allocated VMs, we predict how long their available storage capacity and bandwidth can be used by harvest VMs; for harvest VMs, we predict how long a demand of storage capacity and bandwidth will last before more resources are needed. As discussed, a set of sub-predictors are used for each demanded bandwidth/capacity. BlockFlex updates and maintains the history of durations for model training and inference.

4.4.3 Resource Provisioning for Improved Accuracy

We examine the accuracy of the LSTM models we develop for the aforementioned predictors using various cloud workloads (see their descriptions in Table 2). A prediction for storage bandwidth and capacity is considered accurate if the predictor predicts at least as much as the actually demanded/available storage. A prediction of duration time is considered accurate if the predicted storage bandwidth and capacity lasts as long as the actual demand/availability. We track the actual storage demand/availability and predicted storage demand/availability to calculate the prediction accuracies.

As shown in Figure 14, the average accuracies of predicting storage bandwidth, capacity, and their durations are 89%, 93%, 79%, and 79% on average. Their accuracy varies for different workloads. To further improve the prediction accuracy and avoid resource preemptions (see §4.5), we use a simple yet effective approach – over-provisioning more storage resources based on the predictions of demanded storage resources, and under-provisioning storage resources based on the predictions of harvestable storage resources. We vary the provisioning ratio from 5% to 30%, and show the updated accuracies in Figure 14. We find the accuracies of all the predictions can reach 93–96% with a provisioning ratio of 5%. As we increase the provisioning ratio, we do not see much accuracy improvement. Therefore, we use the 5% provisioning ratio in BlockFlex by default.

Table 1: Exception handling for different scenarios.

ID	Harvestable Storage	Demanded Storage	Possible Exceptions
❶	Over-predict	Over-predict	Waste or Early Reclamation or N/A
❷	Over-predict	Under-predict	Under-Harvest or Early Reclamation
❸	Under-predict	Over-predict	Waste
❹	Under-predict	Under-predict	Under-Harvest or Waste or N/A

4.5 Exception Handling in Storage Harvesting

Although the predictors in BlockFlex deliver high accuracy as discussed in §4.4, mispredictions can still happen, causing exceptions during storage harvesting. Typical exceptions include the resource preemption in which a regular VM prematurely reclaims the harvested storage from a harvest VM, and under-harvesting in which a harvest VM must request additional storage resources to satisfy the request of more storage resource than the predicted demand. VM terminations and data loss could happen if these exceptions are not handled properly.

Misprediction types. Mispredictions can be categorized into two types: over-prediction and under-prediction. As we make predictions for both harvestable storage (in the regular VMs) and demanded storage (in the harvest VMs), the two misprediction categories apply to both sides, as shown in Table 1.

An over-prediction of demanded storage means that a harvest VM harvests more storage resources than it really needs; an under-prediction of demanded storage means that a harvest VM harvests less storage resources than it really needs. In contrast, an over-prediction of harvestable storage means that a regular VM has less harvestable storage resources than predicted; an under-prediction of harvestable storage means that a regular VM has more harvestable storage resources than predicted. During storage harvesting, any misprediction or combinations of mispredictions could cause an exception. BlockFlex employs different exception handling for each scenario.

Exception handling. As shown in Table 1[1], mispredictions could mainly cause three exceptions: *waste of storage resources*, *early resource reclamation*, and *under-harvesting*.

Waste of storage resources. BlockFlex could waste storage resources when mispredictions leave them unused. In the case ❶ of Table 1, a regular VM provides the storage resource requested from the harvest VM, although the harvest VM may over-predict its demanded storage resource. In case ❸, the waste of storage resources becomes worse, because the regular VM actually has more harvestable storage resources than the requested resources from the harvest VM. As we trade the over-provisioning of demanded storage in the harvest VMs for increased prediction accuracy, it is inevitable to cause some waste of storage resources. However, since BlockFlex uses a 5% over-provisioning ratio (see §4.4) in its predictors, the waste is minimal. Compared to the cloud platforms without storage harvesting, BlockFlex still improves the storage utilization. Therefore, BlockFlex does perform special exception handling for this exception.

Early resource reclamation. This could happen when a regular VM has less harvestable storage resources than the demanded storage resources from a harvest VM. Typical examples include the case ❶ and ❷ in Table 1, in which we over-predict the harvestable storage resource in a regular VM, but in reality, the regular VM has less harvestable storage than the demanded storage from a harvest VM. In both cases, the regular VM has to reclaim its storage from the harvest VM. To handle this exception, BlockFlex will identify a new gSSD that meets the requirements for storage capacity, bandwidth, and duration. After that, BlockFlex will copy all the data from the old gSSD to the new gSSD and update the address mapping table in the vSSD of the corresponding harvest VM. BlockFlex will migrate data between gSSDs at block granularity to minimize the impact on the running applications. BlockFlex will reclaim the old gSSD while ensuring its flash blocks are erased before being used by the regular vSSD (see §4.3.2). However, if there is no satisfactory gSSD available, an exception will be reported to the end users of the harvest VM (like what is done today for spot VMs [63]).

Under-harvesting. The exception of under-harvesting could happen when a harvest VM under-predicts its demanded storage resources (i.e., it requests less storage resources than it really needs). Typical examples include the cases ❷ and ❹. For the case ❷, under-harvesting could happen when the harvest VM under-predicts its demanded storage resources. For the case ❹, although the regular VM under-predicts its harvestable storage resources, the demanded storage in reality could still be more than the available storage resources in the regular VM. To handle this exception, BlockFlex will harvest new gSSDs for the harvest VM until meeting the demand. As discussed in Figure 12, BlockFlex enables the use of multiple gSSDs in a single vSSD. However, if there is no gSSD available, BlockFlex will report an exception to the users of the harvest VM, resulting in a termination of the harvest VM or a delay of job executions in the harvest VM.

Note that mispredictions could happen along all three dimensions (i.e., storage capacity, bandwidth, and time available for harvesting) of the storage resource. The described exception handling is used in BlockFlex for mispredictions along any of the three dimensions.

4.6 Implementation Details

We implement the gSSD abstraction of BlockFlex using a programmable SSD with 1TB capacity. The SSD has 16 channels, each channel has 4 dies, each die has 4 planes, each plane has 1024 blocks. Each block consists 256 pages, each 16KB. Its controller allows read/write/erase operations against the raw flash resources and enables the host to develop their own FTL for address translation, GC, and wear leveling.

The gSSD implementation takes 4.1K lines of code (LoC) using C programming language. The vSSD used in this paper

[1] If the demanded storage resource from a harvest VM exactly matches with the harvestable storage resource in a regular VM, there is no exception (N/A).

Table 2: Workloads used in our evaluation.

Workload	Description
TeraSort [25]	Sort data generated by TeraGen.
ML Prep [2]	Preprocess images for machine learning tasks.
PageRank [24]	Compute the pagerank of a graph.
YCSB [73]	Transaction processing on a database.

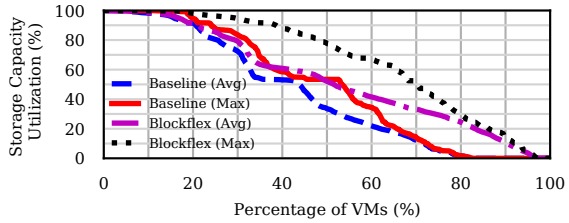

Figure 15: Improved utilization for underutilized storage.

is similar to the virtualized SSDs in our prior work [29]. BlockFlex creates different vSSDs for harvest VMs and regular VMs. It allocates physical flash channels for each vSSD to ensure performance isolation. Upon workload execution, BlockFlex handles the logical block I/O requests received by the vSSDs with actual read and write operations to the allocated physical flash blocks. We run BlockFlex on a real server with 8 Intel(R) Xeon(R) CPU E3-1240 v5 cores running at 3.5 GHz.

BlockFlex's predictors are implemented using PyTorch v1.9.0 [52] in 2.8K LoC using Python. Each model is implemented with one hidden LSTM layer fully connected with the input and output layers. The bandwidth and space predictors have an additional softmax layer applied to the output. All models use *adam* [36] as an optimizer and mean squared error as a loss function. We vary the learning rate and sizes of the hidden layer. Bandwidth prediction uses a learning rate of 0.005 and 16 hidden nodes. Capacity prediction uses a learning rate of 0.04 and 4 hidden nodes. Bandwidth duration uses a learning rate of 0.006 and 50 hidden nodes. Capacity duration uses a learning rate of 0.001 and 50 hidden nodes.

5 Evaluation

Our evaluation demonstrates that: (1) BlockFlex improves the storage utilization in cloud platforms by leveraging both underutilized and unallocated storage resources (§5.2); (2) BlockFlex improves the performance of harvest VMs while minimizing the impact on regular VMs (§5.3 and §5.4); (3) BlockFlex introduces negligible overhead to storage management (§5.5);

5.1 Experimental Setup

We evaluate BlockFlex with a set of synthetic workloads and real-world applications as shown in Table 2. We use Hadoop's TeraSort [25], ML Prep [2], and the PageRank implementation in GraphChi [24] to represent common applications in harvest VMs, while YCSB [73] represents common regular VM workloads. For TeraSort, we generate and sort 75GB datasets with

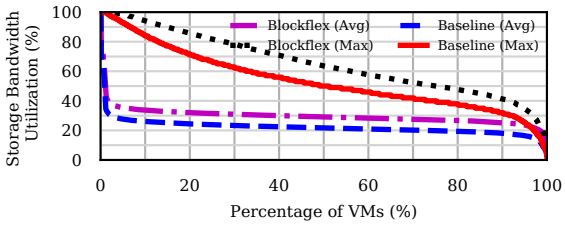

Figure 16: Improved utilization for underutilized bandwidth.

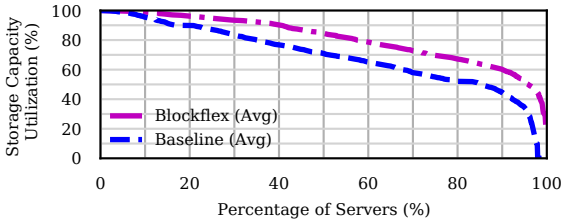

Figure 17: Improved utilization for unallocated resources.

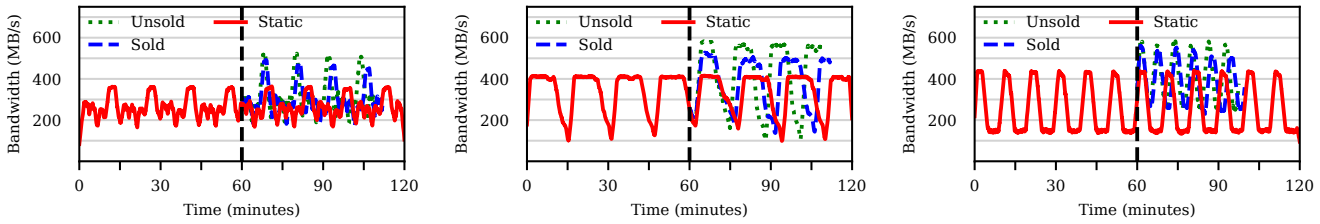
the TeraGen in Hadoop [25]. For PageRank, we use the Friendster graph (61GB) [72]. For ML Prep, we process images from the ImageNet data set (220 GB) [17]. For YCSB, we populate a key-value store RocksDB [54] with 180GB of data and run workloads A-E. In the evaluation, we report the numbers for YCSB-A since the workloads B-E deliver similar results.

5.2 Improved Storage Utilization

To evaluate the improved utilization of BlockFlex, we gather requests from 60,000 low priority VMs from Google traces to characterize the demand of harvest VMs. Their storage requests vary between 32GB and 512GB, and last between 30 minutes and 8.5 days (2.1 days on average). The demanded bandwidth is proportional to the demanded storage. We match these storage demands with harvestable storage capacity from 4,000 regular VMs. When evaluating the benefits of utilizing unallocated storage, we match them with unallocated VMs of 1,400 servers. Since VMs with low storage utilization present a greater opportunity for harvesting, we highlight the capability of utilizing the heavily underutilized storage with BlockFlex.

Underutilized Capacity. We first analyze the impact on the underutilized storage capacity, summarized in Figure 15. We compare the average and maximum utilization when using BlockFlex against the baseline utilization for VMs without harvesting (originally shown in Figure 2). We see an average improvement of 1.25× (43% vs. 54% utilization) across all VMs and an improvement of 1.75× (20% vs. 35%) for those that had less than 60% storage utilization. This shows the benefits BlockFlex can obtain, especially when harvesting flash blocks from VMs with low storage utilization.

Next, we see that the maximum utilization across all of the VMs is increased by 1.37× (49% vs. 67%). We also observe that the over-provisioning we add to the predictions ensures that we do not fully utilize any regular VM. This reinforces



(a) TeraSort (b) ML Prep (c) PageRank

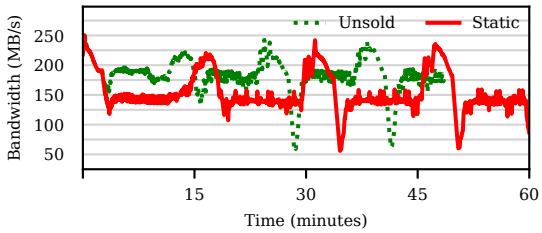
Figure 18: Performance benefits of storage harvesting for harvest VMs.

that BlockFlex has a low probability of reclamation.

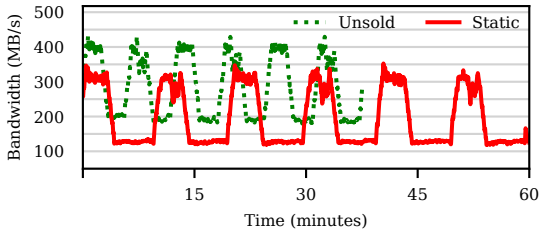
Underutilized Bandwidth. We now analyze the underutilized storage resource from a bandwidth perspective, summarized in Figure 16. Our results show a stable improvement of 1.34× (22% vs. 30%) for all VMs. BlockFlex also increases the maximum utilization by 1.27× (53% vs. 66%). As with underutilized storage, we avoid reclamations by not fully utilizing the bandwidth of regular VMs. This demonstrates that BlockFlex can improve both the bandwidth and capacity utilization of cloud storage from underutilized resources.

Unallocated Storage. We analyze the utilization improvement by harvesting unallocated VMs, presented in Figure 17. We observe that BlockFlex improves the overall utilization by 1.17× (69% vs. 81%). Servers with utilization below 60% are improved by 1.42× (45% vs. 64%).

For underutilized and unallocated storage resources, we observe 1.25× improvement on average, showing that BlockFlex can significantly use both underutilized and unsold storage resources to improve utilization. For extremely underutilized cases (under 60%), we observe 1.48× improvement on average. This shows that BlockFlex can successfully match the harvestable storage resources to the demands from harvest VMs.



(a) ML Prep Bandwidth



(b) PageRank Bandwidth

Figure 19: Read bandwidth of ML Prep and PageRank workloads after storage harvesting.

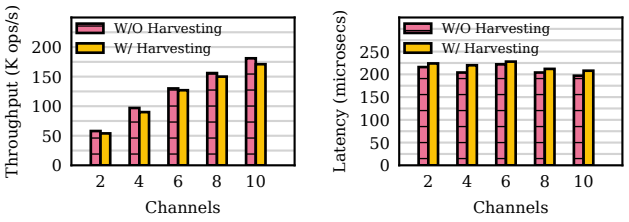
5.3 Improved Performance for Harvest VM

We examine how BlockFlex improves the performance of harvest VMs. The results are shown in Figure 18. We evaluate three different configurations: **Static:** the harvest VM is statically configured with 8 channels and does not harvest. This represents the current (baseline) storage virtualization. **Sold:** a 4-channel gSSD is allocated from channels occupied by a regular VM that uses 50% of its maximum bandwidth. **Unsold:** a 4-channel gSSD is allocated from unallocated channels. For both unsold and static, the gSSD is harvested after one hour. Before each experiment, we warm up the SSD to ensure GC will occur. We run all workloads for two hours.

By harvesting additional channels, the harvest VM has significantly improved bandwidth. As we compare the Sold scheme with the Static scheme, the workload performance is improved by 16–51% on average. For the Unsold scheme, the lack of interference with the regular VM improves the storage bandwidth by 22–60%. We observe the best improvement for PageRank, as its workload spends more time on I/O than TeraSort or ML Prep workloads. The Unsold scheme provides an additional 6% bandwidth improvement over the Sold scheme on average. As we translate this into the end-to-end execution time, we see an average performance improvement of 20% using Sold storage, and 25% improved performance using Unsold storage. This demonstrates the significant performance benefits BlockFlex can obtain for IO-intensive applications, when utilizing either sold or unsold storage.

Clearly, additional flash channels can benefit write-heavy workloads, as we increase the I/O parallelism. It is less clear whether additional channels can benefit read heavy workloads, as the harvested channels cannot immediately satisfy reads. To investigate this, we focus on the read bandwidth improvements in Figure 19. For both ML Prep and PageRank workloads, we see an increase of 10−21% after 5 minutes of harvesting. After the full 60 minutes, the average increase of the read bandwidth stabilizes and reaches an overall improvement of 22−60%.

Specifically, for ML Prep, we see a slight increase (10%) as



(a) Bandwidth (b) 95th Percentile Latency

Figure 20: Performance of a regular SSD with storage harvesting enabled.

we redirect writes to the additional channels immediately upon harvesting (0-5 minutes). Afterwards, as we start issuing writes and reads to the new channels, we see the read bandwidth benefit stabilizes at an improved level (24%). As for the PageRank workload, it shows relatively consistent benefit in the read bandwidth (60%). This is because PageRank workload is write intensive, during the first two minutes of harvesting. Thus, the PageRank data is aggressively written to the new harvested channels, which benefits the read bandwidth in return.

5.4 Performance Impact on Regular VM

To investigate the impact of storage harvesting on regular VMs, we examine the interference generated by the harvest VM. We run the YCSB workload-A with 10 threads in the regular VM, and vary the number of flash channels in its vSSD from 2 to 10. The database tables are striped across all the available channels in the vSSD. We first measure the throughput and tail latency (95th percentile latency) of the YCSB workload without enabling storage harvesting. After that, we create a harvest VM to run the ML Prep workload. The harvest VM will harvest all the channels of the regular VM, and we measure the performance of the regular VM after the harvesting.

As shown in Figure 20, the throughput of YCSB Workload-A decreases slightly, while the latency is almost constant as we increase the number of channels. The storage harvesting does not introduce much overhead (5.1% on average), since the regular VM always has the higher priority for its I/O requests and available storage bandwidth. We observe a similar overhead for the tail latency, demonstrating that the storage harvesting has negligible negative impact on the performance of regular VMs.

We also examine the interference caused by additional GC and storage reclamations. As indicated in §5.3, GC is enabled in our experiments. We believe the GC overhead can be further reduced with erase suspension available in modern SSDs [35, 70]. We wish to explore this feature in our future work. As for the overhead caused by storage reclamations, we observe that reclaiming an entire flash channel results in 1.5% slowdown in the average bandwidth of regular VMs. Such an overhead is acceptable in reality, as storage reclamations do not happen frequently over the entire lifetime of VMs.

Table 3: Learning overheads for each iteration in our predictors

Predictor	Training Time (millisecs)	Inference Time (millisecs)	Model Size (KB)
Bandwidth	10.3	2.5	22
Space	13.0	0.4	12
Bandwidth Duration	410.0	4.1	1153
Space Duration	42.0	0.3	510
Total	**475**	**7.3**	**1697**

5.5 Overhead Sources in BlockFlex

We now profile the overheads introduced by BlockFlex. We begin by analyzing the overheads introduced by the predictors. We present the summary of these overheads in Table 3. First, we measure the time consumed by training each predictor for one iteration of online training. As discussed in §4.4, each model is trained one iteration every three minutes. Since each duration predictor has multiple models, their training is more expensive than storage bandwidth and capacity predictors. In total, training all of the predictors consumes 0.48 seconds on our multi-core server. In this case, cloud platform operators do not need powerful hardware accelerators like GPUs to deploy BlockFlex. Since input sizes and training frequency do not change by workload, the training overhead is the same across all the workloads evaluated in this paper.

For each inference, the total execution time is 7.3 milliseconds. This overhead is also incurred once every three minutes, but can be further optimized. For example, we can decrease the inference frequency when a vSSD has generated a gSSD.

To store the predictors for each vSSD, BlockFlex allocates about 1.7MB memory space. It also allocates 4KB memory to store the history of bandwidth/capacity information used for training each iteration. This demonstrates the minimal performance and storage overheads of the predictors in BlockFlex.

We also profile the overheads of gSSD creation and lookup. They include the overheads of creating a new gSSD and harvesting free blocks from a regular vSSD. Since they only involve metadata operations, the overhead is 61 μs for creating a gSSD with 64GB. As gSSDs are created in the background, their creation overhead is not on the critical path. We organize the gSSD pool in sorted lists, the gSSD lookup takes 1.2 μs on average.

As we reclaim a gSSD from a harvest VM, its primary cost is on the erase of all the written blocks. Since we can parallelize the erase operations across channels, the limiting factor is the channel with the most allocated blocks. The total overhead is 17.1, 34.2, and 68.4 seconds for a channel (64GB) with 25%, 50%, 100% harvested, respectively. According to our study of various cloud traces, we observe that storage harvesting is infrequent (once every few hours). Additionally, compared to the lifetime of VMs in the cloud, the overhead of storage reclamation is relatively small, which has negligible impact on the performance of regular VMs.

6 Discussion and Future Work

Security implications of storage harvesting. A few potential security concerns may arise when sharing physical flash blocks in a cloud environment. First, we consider whether data could be leaked via harvested blocks. Since BlockFlex erases the flash blocks before creating/reclaiming the gSSD, it guarantees that user data will not be leaked through the storage harvesting. Second, we consider whether information could be leaked through the cached data, such as LBA-PBA mappings. As existing cloud infrastructure prevents access to the SSD virtualization, device driver, and controller layers without permission checking, therefore, even though a flash channel is shared across VMs, their accesses are protected. Third, we consider whether multiple VMs sharing a physical flash channel could suffer from side-channel attacks. It is actually hard for attackers to obtain meaningful information, since the variations could be caused by many factors, such as the number of co-located VMs or the CPU/memory contention.

Compatible with compute and memory harvesting. Upon the creation of harvest VMs, cloud platforms will allocate essential compute, memory, and storage resources. BlockFlex mainly targets storage harvesting to improve the overall cloud storage utilization, and improve the performance of applications bottlenecked by storage resources. It is compatible with prior studies on compute and memory harvesting [20, 69] for improving the whole-system resource utilization.

Semantic-aware storage harvesting. BlockFlex utilizes the vSSD interface in its implementation, making it transparent to applications in VMs. However, due to the lack of semantic information from upper-level applications, BlockFlex has to rely on the predictors to decide the harvestable and demanded storage resources. Additionally, preventing data loss is one of the key challenges when developing BlockFlex, allowing systems software to manage their data in harvested storage would be an alternative solution to address this challenge. Therefore, new APIs can be developed and exposed to popular software systems such as key-value stores and Hadoop Distributed File System (HDFS), which offers more flexibility for applications to manage their data in harvested storage.

7 Related Work

Storage virtualization and efficiency. Storage devices such as SSDs have been virtualized as system-wide shared resources for improved utilization in cloud platforms [29, 34, 43, 60, 61, 75]. Based on this, most recent studies focused on improving the performance isolation between collocated applications [6, 32, 33, 42, 49, 65]. However, our study (see §2) reveals that the cloud storage is still significantly underutilized. Ouyang et al. [51] identified the resource underutilization in the SSDs and developed the software-defined flash for cloud platforms. Similar to software-defined networking, software-defined flash is becoming a backbone technique in datacenters today [16, 56, 65]. However, most of them still use a static-allocation approach, which inevitably causes the waste of both storage capacity and bandwidth [11, 51]. Disaggregated storage architectures are proposed [40, 47, 50, 57, 68]. However, they still suffer from storage underutilization when we allocate disaggregated storage to VMs, due to the dynamic workload changes in VMs. BlockFlex addresses the storage underutilization problem by enabling storage harvesting in software-defined datacenters.

Resource harvesting in cloud platforms. Harvesting resources for VMs to improve the resource utilization is not a new concept in cloud platforms. Similar to the harvest VM, many studies have been developed recently, such as Spot VMs and burstable VMs [5, 7, 8, 20, 21, 59, 69]. However, they typically harvest compute and memory resources at a VM granularity. BlockFlex is the first work that focuses on storage harvesting, and addresses the unique challenges in storage harvesting and exception handling. Beyond harvesting unsold resources [5], we can also harvest underutilized allocated storage resources, while providing the performance and security isolation between regular VMs and harvest VMs.

Learning approaches for resource efficiency. Most recently, researchers started to leverage learning techniques to improve the task scheduling [53, 69, 77], cluster resource management [5, 10, 15, 45, 74], and performance optimizations [26, 37, 44, 78]. They showed that the learning-based approach is a promising method to address system optimization problems. However, it is still unclear how they can benefit the cloud storage. In this work, we apply the learning-based approach to improve the storage utilization within our storage harvesting framework. We customize the classical LSTM models for the predictions of harvestable and demanded storage resources, and show their efficiency in our evaluation.

8 Conclusion

In this paper, we first conduct a characterization study of the cloud storage utilization, and discloses that the low storage utilization exists pervasively in modern cloud platforms. To this end, we develop a learning-based storage harvesting framework BlockFlex, which can harvest both allocated and unallocated storage for evictable VMs. Our experiments show that BlockFlex can significantly improve the cloud storage utilization, while accelerating the storage performance of harvest VMs with minimal impact on the regular VMs.

Acknowledgments

We thank the anonymous reviewers and our shepherd Swami Sundararaman for their helpful comments and feedback. We thank Íñigo Goiri for providing part of the cloud traces for our study as well as insightful discussions. Abstract

Far-memory techniques that enable applications to use remote memory are increasingly appealing in modern data centers, supporting applications' large memory footprint and improving machines' resource utilization. Unfortunately, most far-memory techniques focus on OS-level optimizations and are agnostic to managed runtimes and garbage collections (GC) underneath applications written in high-level languages. With different object-access patterns from applications, GC can severely interfere with existing far-memory techniques, breaking remote memory prefetching algorithms and causing severe local-memory misses.

We developed MemLiner, a runtime technique that improves the performance of far-memory systems by "lining up" memory accesses from the application and the GC so that they follow similar memory access paths, thereby (1) reducing the local-memory working set and (2) improving remote-memory prefetching through simplified memory access patterns. We implemented MemLiner in two widely-used GCs in OpenJDK: G1 and Shenandoah. Our evaluation with a range of widely-deployed cloud systems shows MemLiner improves applications' end-to-end performance by up to **2.5**×.

1 Introduction

Datacenters are becoming increasingly *memory constrained* [65, 45, 40] with the ubiquitous deployment of in-memory data analytics and ML systems like Neo4j [52], Cassandra [12], Spark [74] and TensorFlow [5], which hold large amounts of intermediate data in memory for quick processing. To tackle this constraint, far-memory techniques [30, 10, 63, 58, 26] that enable applications to use remote memory are increasingly appealing, backed by advances in hardware and networking techniques [13, 62, 66, 23, 19, 28, 35, 49, 55, 59, 32, 8, 16, 38, 41, 33, 63, 43, 57, 37, 42, 60, 7] that allow remote memory to offer much lower latency and higher bandwidth than local block devices.

♣ Contributed equally.

Most of these far-memory systems [30, 10, 63, 48, 68] build on a cache-and-swap mechanism: the application's host server uses local memory as a *data cache*. Once a page that does not reside in the local memory is accessed, a page fault is triggered and the page is fetched from a remote server into the local memory. Good locality and effective remote-memory prefetching [50, 48] are crucial to the performance of applications running in such far-memory systems.

Unfortunately, the interference from garbage collection (GC) severely degrades the memory-access locality and remote-memory prefetching for applications written in high-level languages (e.g., Java, Go, and Python), which are dominant in datacenter workloads. At run time, application threads access heap objects following their program-execution paths, while GC threads *concurrently* scan the heap, performing graph traversal from a set of "roots" (*i.e.*, objects referenced by stack and global variables) to mark live objects. Object accesses by these two sets of threads are uncoordinated, creating two disjoint working sets, as illustrated by Figure 1(a), and causing severe performance problems.

Problem 1: Resource Competition. Pages swapped in for GC's heap traversal are often not used (in near future) and hence evicted by the application; conversely, pages swapped in for the application are often not needed (in near future) and evicted by GC. Evicting each other's pages, the application and GC both suffer from severe local-memory misses and further compete for RDMA bandwidth for page swapping. The more concurrent activities a GC runs , the more the resource competition between GC and the application—our results show that running Spark with the Shenandoah concurrent GC [25] on the 25% memory configuration incurs a 12× slowdown to the end-to-end performance, which is 5× larger than the default G1 GC that reclaims memory in stop-the-world pauses.

Problem 2: Ineffective Prefetching. Monitoring the execution of a managed program, an OS-level prefetcher such as [48] cannot recognize clear memory-access patterns and has to give up prefetching. The reason is that, even if the appli-

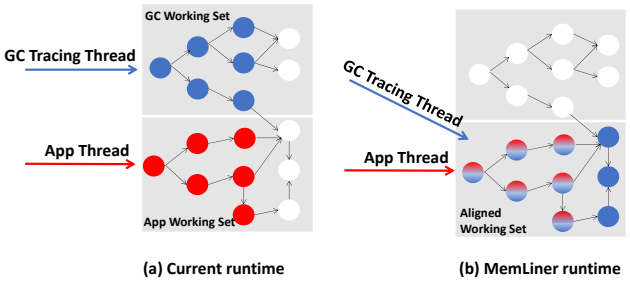

Figure 1: Our main idea: the working sets of GC threads, in blue, and application threads, in red, during a time window (a) without or (b) with the access alignment from MemLiner.

cation's memory accesses follow a simple sequential pattern, the combined accesses from both the application and the GC often appear random from the OS' perspective.

State of the Art. In the past, supporting applications that have large memory footprints (*e.g.*, larger than the main memory size) is not the priority of traditional GC. Although there exists a body of work (such as Platinum [70]) on concurrent GC, such work focuses primarily on improving throughput and reducing latency on memory-abundant servers. However, remote memory is designed to enable applications to use more memory than what their hosts can offer; as a result, developing new GC techniques to support these applications becomes a crucial task.

Recent work Semeru [68] supports running Java programs on disaggregated hardware by disaggregating the traditional JVM into two new ones, with the CPU-JVM executing the program on the CPU server and the memory-JVM performing GC on the memory server. The idea of offloading GC completely to a remote server works for Semeru where *all* the application's memory data is located in a remote server, but does not suit today's datacenters where resources are not entirely disaggregated and applications use remote memory only if their local memory runs out. Furthermore, this offloading approach imposes extra communication overhead for CPU-JVM and memory-JVM to coordinate, and extra computation cost on the remote memory server to run the memory-JVM, which may impose deployment challenges.

Another recent work AIFM [58] proposes a novel runtime to improve the prefetching and swap performance of applications running in remote-memory systems. AIFM targets applications written in native languages (C/C++), and hence cannot easily be applied to solve the GC interference problem in the managed language runtime.

MemLiner. This paper presents a fully-automated runtime technique, MemLiner, for programs written in high-level languages (HLLs) to efficiently use remote memory.

The design of MemLiner is based on two key observations.

First, the objects accessed by the application and the GC are not completely unrelated—they are just not temporally aligned. The live objects traced by the GC are mostly accessed by the application at some point during the execution; the objects accessed by the application must be live objects at the moment of the access and hence the target of GC.

Second, although changing object-access order in application threads would break the application semantics, changing that order in GC would not. Specifically, GC threads aim to trace and mark all reachable objects in the heap, while the *order* of that tracing and marking (*e.g.*, which objects are traced first) does not matter.

Guided by these observations, the key idea behind MemLiner is *working set alignment*. MemLiner carefully reorders the objects traced by the GC threads, so that they follow a similar, although not identical, memory-access path of the concurrent application threads (illustrated by Figure 1(b)). Consequently, their working sets can better overlap with each other; the resource competition can be much alleviated, with much reduced page faults and on-demand swaps; the application's access patterns can be more easily recognized by the underlying prefetcher such as Leap [48]. All of these are achieved in a way that is compatible with existing GC algorithms, without offloading the GC to another machine or re-desgining the prefetcher.

MemLiner must overcome several challenges.

First, *how to align GC threads with application threads*. In a conventional setting, GC traces objects using a graph traversal starting at the root objects. To align GC's accesses with application threads', MemLiner uses a *priority-based* algorithm—MemLiner makes application threads inform the GC of the objects they are accessing; these objects, which must be live and reachable in the object graph at that moment, are then immediately traced and marked by the GC, without any risk of triggering page faults and expensive remote swaps. To enable such communication, MemLiner leverages the *read-write barrier*—a piece of code executed by the runtime at each heap read/write in the application—to inform GC of the objects on the application's access path. Details of the coordination are discussed in §4.1.

Second, *when to break the alignment* so that GC can finish its work without unnecessary delays. Completely aligning GC threads with application threads could severely delay GC from reclaiming dead heap space, as application threads may take a long time, sometimes even the whole execution, to access every live object. In fact, a complete alignment is unnecessary, as application threads may repeatedly access the same object in a short time window due to application semantics, like during a loop, while GC only needs to mark that object live once. Consequently, MemLiner allows GC to break from the alignment to work on another part of the heap traversal from time to time. To minimize the interference, MemLiner prioritizes two types of objects in GC's unaligned accesses: (1) objects that will likely be accessed by the application soon; (2) objects that were accessed by the application not long ago and hence are likely still inside the local memory. The former is predicted based on what objects

the application just accessed; the latter is predicted based on object-access history that MemLiner efficiently encodes inside the per-object pointer. Details can be found in §4.2.

Results. We have integrated MemLiner into two widely used GCs (G1 and Shenandoah) in OpenJDK 12. A thorough evaluation with Spark, Cassandra, Neo4J, QuickCached and DayTrade demonstrates that MemLiner improves the end-to-end execution time by an overall of **1.48**× and **1.51**× under the 25% and 13% local memory configurations for the G1 GC, and **2.16**× and **1.80**× for the Shenandoah GC (which runs concurrent GC threads more frequently than G1). Furthermore, MemLiner improves Leap's prefetching coverage and accuracy by **1.5**× and **1.7**×, respectively. Compared to Semeru [68], MemLiner achieves a comparable performance without offloading any computation on remote servers.

Key Takeway. Although there are several directions of work on remote memory (*e.g.*, clean-slate approaches such as AIFM [58] and Kona [17], swap optimizations such as InfiniSwap [30] and FastSwap [10], as well as distributed runtimes such as Semeru [68]), MemLiner takes an *easy-to-adopt, non-intrusive* approach that enables performance improvements for a wide variety of new and legacy applications. MemLiner is orthogonal to (and complements) these existing techniques—aligning the memory accesses between application and GC threads reduces thread-level interference and the application's local-memory working set regardless of the underlying remote-access mechanisms and optimizations.

2 Background

GC. A major benefit of high-level languages over native languages is their support for automated memory management—developers are released from the burden of deallocating objects, leading to improved reliability and security. Automated memory management is enabled by garbage collection (GC), which runs when the heap has little free space. The key idea of GC is simple [36]: perform a reachability analysis to identify a transitive closure of live objects and reclaim objects outside the closure. Consequently, a modern GC algorithm has two main components: (1) *tracing* the heap graph to compute that closure and identify live objects, and (2) *reclamation* of dead objects, while evacuating live objects to contiguous space and updating pointers.

Concurrent Tracing. To ensure the correctness of pointer updating, a conservative way of running GC is to pause all application threads (*i.e.*, a stop-the-world phase) for full-heap tracing and reclamation, which incurs significant delays [53, 47]. To address this performance limitation, starting from the G1 GC [22], which is the default GC in Oracle's JVM, all modern garbage collectors, including Shenandoah [25] from Red Hat and ZGC [2] from Oracle, run the tracing phase concurrently with application threads to (1) leverage the many available cores and (2) minimize GC pauses. For example, in G1, the number of tracing threads is configured, by default, to be 1/4 of the number of cores. Concurrent tracing often uses a snapshot-at-the-beginning (SATB) algorithm [73]—tracing traverses the heap graph from a logical snapshot of the heap; it will not miss any live object as long as object allocation and pointer updates made by the application since the snapshot are recorded and considered conservatively. G1 runs stop-the-world phases to reclaim memory by evacuating live objects into new regions while Shenandoah and ZGC run evacuation also concurrently to minimize the pause time.

Tracing Algorithm. Logically, tracing divides objects into three colors: *white*, *black*, and *gray*. The white set is the set of objects that are candidates for reclamation. The black set is the set of objects that can be shown to have no references going to objects in the white set, and to be reachable from the roots. Objects in the black set are not candidates for reclamation. The gray set contains all objects reachable from the roots but yet to be scanned.

Initially, all objects are white. Tracing implements a graph traversal algorithm that gradually changes the color of objects reachable from the roots from white to black. For each reachable object *o*, tracing marks it black, retrieves all objects referenced directly by *o*, and adds them into the gray set. Each iteration retrieves an object from the gray set, marks it black, and adds more objects into the gray set. The algorithm repeats until the gray set becomes empty; objects that remain white can be safely reclaimed. In practice, a modern runtime uses a bitmap to mark live objects efficiently.

3 Motivation

In this section, we use an experiment to quantitatively demonstrate (1) how tracing and application threads interfere with each other, and (2) why simply disabling concurrent tracing cannot solve the problem.

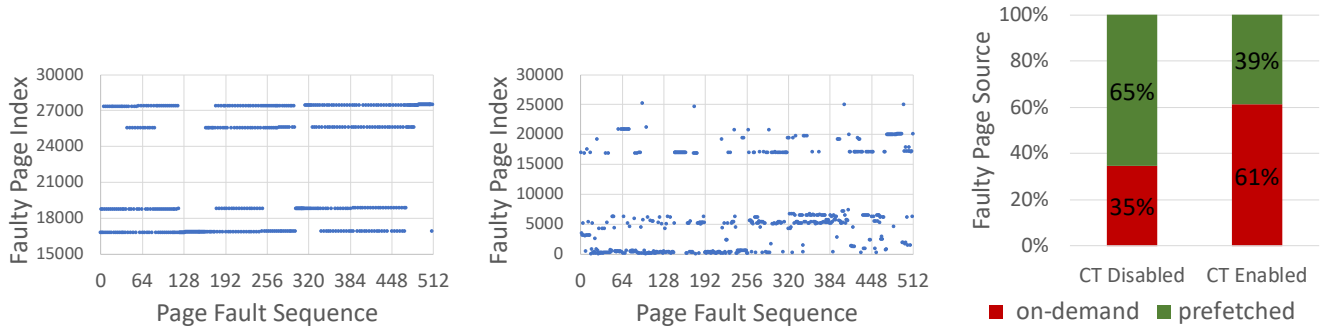
Setup. We ran Spark Logistic Regression (LR) with the Wikipedia dataset on OpenJDK 12 and its default G1 GC. We used two machines, each with 2 Xeon(R) CPU E5-2640 v3 processors, 128GB memory, 1024GB SSD, and CentOS 7.5, connected by RDMA over a 40Gbps InfiniBand network. One machine runs Spark, using local memory and remote memory on the other machine. We configured the first machine to have just enough memory to host 25% of Spark's working set. We name the first server providing compute resource as *host server* and the second server providing remote memory as *remote server*.

We compare the execution of Spark LR in two modes:

(1) The G1 GC's concurrent tracing is *disabled*;

(2) The G1 GC's concurrent tracing is *enabled*—the default option in G1 GC. The number of tracing threads is set to be a quarter of the number of available cores, as suggested by G1.

In both cases, the heap size of Spark LR is set to 32GB and the host server can hold up to 8GB of its heap. The execution goes through application-execution phases and stop-the-world GC phases alternatively.



(a) Page fault trace of Spark LR. (b) Page fault trace of Spark LR with CT. (c) Prefetching effectiveness.

Figure 2: Prefetching effectiveness for Spark LR executed atop OpenJDK 12 (with its default G1 GC): (a) trace of faulty page index for application threads only; (b) trace of faulty page index when concurrent tracing (CT) is enabled; (c) disabling CT significantly improves the effectiveness of Linux' default swap prefetcher.

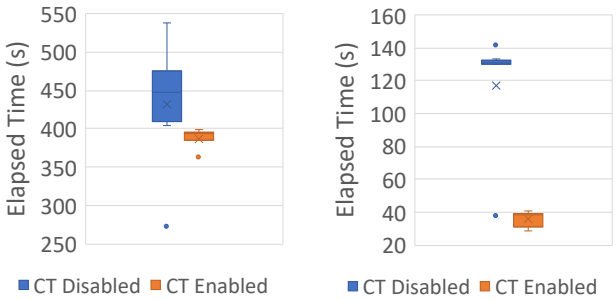
How much interference from concurrent tracing? To have an intuitive look at how well prefetching may or may not work, we randomly sampled 512 *consecutive* page faults in the middle of Spark LR's execution under both execution modes. Note that, since we collected page-fault information from inside the kernel and the execution under the two GC modes proceeds at vastly different paces, we cannot guarantee that the two samples come from the same window of application instructions, but we do make sure that the stop-the-world GCs did not occur during our samples.

Figure 2 (a) and (b) illustrate the virtual page index of the faulty addresses (Y-axis) ordered by when each fault occurs, with the sequence number shown in the X-axis. Without concurrent tracing, each of the application threads has a clear streaming access pattern, as shown in Figure 2(a), which should be detected by an advanced prefetcher. This clear pattern is messed up by concurrent tracing, as shown in Figure 2(b), making prefetching much harder.

To quantitatively measure the impact of concurrent tracing on prefetching, we checked 500 application-execution phases (*i.e.*, the period between two stop-the-world GCs) to understand, among all the page faults, how many were resolved through on-demand swaps from remote memory and how many were resolved using data already brought in through prefetching. Clearly, this ratio of on-demand swapping versus prefetching directly affects the application performance.

As shown in Figure 2(c), without concurrent tracing, prefetching is effective, addressing 65% of the page faults. Unfortunately, with concurrent tracing, this ratio greatly dropped to only 39%, with the remaining 61% of page faults leading to costly remote-memory accesses. Note that our experiments use Linux's default swap prefetcher. If an advanced prefetcher such as Leap [48] is used, the prefetch-ratio would be even higher without concurrent tracing and hence suffer even more from the interference (see §7).

Finally, to understand how much the interference has affected the working set of the execution, we also measured the average number of page faults encountered by application threads. The page-fault rate jumps from **3.5K** per second per thread to **9.6K** per second per thread, when concurrent tracing is enabled, indicating a huge interference.



(a) End-to-end execution time. (b) GC pause time.

Figure 3: Concurrent tracing improves overall performance. (Data is from 10 runs of each program; dots are outliers.)

Why not just disable concurrent tracing? Having seen significant interference from concurrent tracing, a strawman solution is to simply disable concurrent tracing for applications running in far-memory systems.

Unfortunately, this strawman solution does not work. First, modern concurrent GCs such as Shenandoah [25] and ZGC [2], which are designed for low-pause and used widely by latency-sensitive cloud applications, rely on concurrent tracing to reclaim memory (also concurrently). Disabling concurrent tracing would destroy the functionality of such collectors. Second, even for GCs such as G1 that could perform tracing in a stop-the-world phase, the end-to-end execution time suffers significantly without concurrent tracing. As shown in Figure 3(a), the execution time increases by **18%** on average in 10 runs. The main reason is that the aggregated stop-the-world GC periods now take **2.7**× longer without concurrent tracing, as shown in Figure 3(b). Without concurrent tracing, each (fast young-generation) GC cannot

reclaim as many dead objects in the same amount of time and has to resort to *slow, full-heap GC* that scans and compacts the whole heap space in a stop-the-world period, which is extremely time consuming. For example, the longest full-heap GC (*i.e.*, a single pause) in Spark LR takes 76.9 seconds, clearly an intolerable delay.

Key Takeway. Memory accesses from application and GC threads exhibit diverse patterns, significantly increasing the application's working set and making prefetching harder. Simply disabling concurrent tracing in GC would not work, as it reduces the number of local-memory misses at a cost of significantly increased GC pause and end-to-end execution time. MemLiner offers a solution that can greatly reduce the number of local-memory misses and increase the effectiveness of existing prefetchers without introducing extra GC-pause time, and hence effectively reduce the end-to-end execution time.

4 MemLiner Design and Implementation

This section presents the design and implementation of MemLiner, particularly how we realize the two key ideas: (1) making GC concurrently trace objects immediately after their access by application threads (§4.1) and (2) making GC trace other live objects through a novel priority-based algorithm (§4.2) to reduce interference.

MemLiner modifies the garbage collector inside the runtime and the swapping system inside the kernel, while requiring *no* changes to applications. In terms of runtime changes, MemLiner is a general mechanism that can be integrated into any modern runtime that performs concurrent tracing. This paper focuses on a design for Oracle's OpenJDK, a commercial JVM that supports a variety of high-level languages such as Java, Scala, Python, Ruby, *etc.* In terms of kernel changes, we build MemLiner atop paging/swap mechanisms that already exist in the OS kernel, with minimal invasion. Any swap optimizations such as InfiniSwap [30] and FastSwap [10] can be readily used to improve the swap performance for a MemLiner-equipped runtime. MemLiner's runtime design is independent of how remote memory is accessed; for example, MemLiner could also run on a clean-slate platform such as Kona [17] that access remote memory based on cache coherence, not page faults, if coherence is provided by hardware.

When a MemLiner-equipped JVM is launched, the maximum heap size M is specified by the user via a command-line option. A small amount of physical memory on the local machine is initially used to back up the heap (which is much smaller than M). The heap stays entirely in local memory until its usage exceeds the size of local memory, in which case, the OS kernel allocates remote memory by registering it as an RDMA buffer. The kernel uses an approximate LRU algorithm to evict pages. MemLiner does not require any software/hardware support on remote servers, providing a practical solution that can be readily used in today's cloud.

4.1 Application and GC Coordination

To align memory accesses, application threads inform GC's tracing threads of the objects they are accessing so that tracing threads can trace these objects immediately.

To facilitate such communication, we need to instrument every heap read/write instruction so that the application can send an object pointer to GC when it dereferences the pointer: *(1)* At a statement that reads an object field or an array element of the form $a = b.f$ or $a = b[i]$, our instrumentation pushes the corresponding address in b into a thread-local producer-consumer queue (PQ), which will be read by GC during tracing. *(2)* At a statement that writes an object field or an array element of the form $b.f = a$ or $b[i] = a$, we similarly push the object reference in b into the PQ.

MemLiner implements this instrumentation through existing read/write barriers—a piece of code that is executed by modern runtimes at each heap read/write operation to record heap information for GC purposes. MemLiner piggybacks on the existing implementation of read/write barrier in OpenJDK 12 that intercepts both interpreted and compiled code. A PQ is created for each application (producer) thread so that no synchronization is needed for enqueuing pointers. A GC tracing (consumer) thread constantly checks PQs to retrieve pointers for tracing. Consumer threads use atomic instructions when dequeuing object pointers. In practice, the number of application threads is often larger than the number of tracing threads; hence, there is little contention when PQs are accessed by multiple threads.

To minimize the maintenance overhead, we represent each PQ as a non-blocking *ring buffer*. Producers and consumers do not synchronize at all—an application thread keeps writing into the queue even if it is full. As such, the application thread may overwrite entries that have not yet been picked up by GC. Note that this would not cause any correctness issues because those entries only indicate *tracing priority*: overwriting an entry will delay the corresponding object's tracing, but the tracing of these objects will eventually happen in GC's regular graph traversal, which will be discussed in the next sub-section.

Note that our instrumentation code at different program points is unlikely to enqueue the same object reference multiple times (*e.g.*, neighboring reads to the same data structure). This is because marking an object live sets a bit in a global live bitmap. Before pushing each object reference into the queue, an application thread checks its bit from the bitmap and filters it out if the bit is already set.

4.2 MemLiner Tracing Algorithm

4.2.1 Design Overview

A major challenge in aligning tracing and application threads is that GC has to compute a *full* closure of live objects to reclaim memory. Hence, it is unproductive to trace a live object only right after it is accessed by the application, which

will delay the closure computing, leading to inefficiencies in memory reclamation.

The key question here is: *how can GC make quick progress in closure computation without producing a working set that significantly departs from that of the application?* On the one hand, after processing all objects in the PQ, we want GC to trace as many other live objects as possible, even if not in the PQ, to complete the closure. On the other hand, GC should better *not* trace many objects that do not reside in local memory because tracing those objects triggers page faults and swaps. How to reconcile these seemingly conflicting goals is a problem MemLiner must solve.

Reachable Object Classification. To better explain our tracing algorithm, we first classify all live objects at any moment of the execution into three categories based on their location and when they are accessed by the application, as illustrated in Figure 4[1]:

*(1) Objects in local memory (*i.e.*, data cache):* These objects have recently been accessed by the application and have not been evicted yet. Clearly, tracing them at this moment (or in the near future) would not generate any page faults or interfere with the application. Many of these object (*i.e.*, the red ones in the figure) are made known to the GC through the PQ discussed in §4.1. However, since the PQ is designed to be a ring buffer, some of these objects (*i.e.*, the striped ones in the figure) may be missed by GC due to being overwritten in the ring buffer. How to trace them sooner rather than later requires extra handling that we will discuss later.

(2) Objects in remote memory and to be used soon: Since these objects (*i.e.*, the wavy nodes in Figure 4) will soon be accessed by the application, they are typically just a few references away from the objects being accessed by the application. Tracing them is also desirable—although they are currently not local, they will soon be needed by the application. If GC triggers page faults when accessing them, the costs of handling these faults and swapping would be *necessary* as they are "prepaid" by GC for the application.

(3) Objects in remote memory and not used soon: These are illustrated as clear-circle objects in the figure. They were used by the application a while ago and got evicted to remote memory. Tracing them is needed *eventually* but is undesirable now or in the near future, as tracing them pays the high cost of fault handling and swapping (which is entirely wasted if they are not used by the application before their next eviction).

Handling Different Categories in GC. MemLiner's central design goal is to let GC trace objects in Category (1) and (2) right away *to maximize progress* and delay tracing objects in Category (3) *to avoid unnecessary page faults and interference*. Among the different categories of objects, our starting point is the set of red objects, which are captured by the read/write barrier, sent to GC via the PQ, and traced by GC immediately.

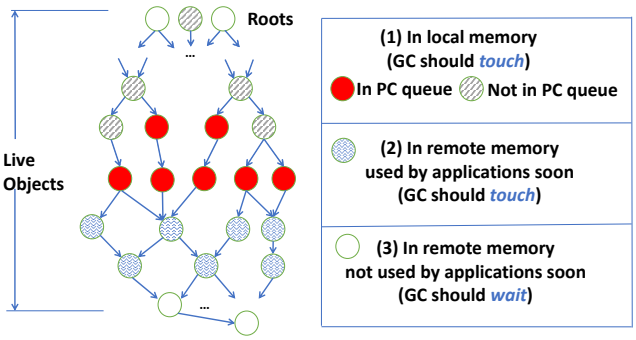


Figure 4: Classification of reachable objects in the heap: red objects are being accessed by the application and shaded objects are what MemLiner intends to trace.

With the red objects in hand, the wavy objects in Category (2) are just a few references away. To mark these objects, we let GC trace *a small number of references forward* from the red objects, which were retrieved from the PQs. As discussed above, tracing such an object will likely trigger swapping, prepaying the cost for the application to access the object soon later. Note that tracing too many references forward will not be useful, as that may bring in objects not used by the application in the near future. In our implementation, we limit the number of hops to 3, which is often large enough to cover objects in the same logical data structure [72].

After red objects and wavy objects, the remaining live objects to trace are those in Category (3) and the striped objects in Category (1). There are two challenges here. First, there are no easy ways to reach them from the red objects. Second, to reduce memory interference, it is better to trace the striped Category (1) objects before the Category (3) objects, as discussed above.

To tackle these challenges, MemLiner makes every concurrent tracing thread alternate between two modes:

(1) When the PQ is not empty, trace objects in the PQ (*i.e.*, red) and objects a few references forward (*i.e.*, wavy);

(2) When the PQ is empty, perform normal object-graph traversal that starts from root objects like traditional GC.

Different from a traditional GC, MemLiner modifies the traversal algorithm to consider whether an object o to be traced is likely in local memory (*i.e.*, whether o is a striped Category (1) object or a Category (3) object)—if o is *estimated* to reside in local memory (*i.e.*, a striped Category (1) object), it is traced right away in GC; if not (*i.e.*, Category (3)), MemLiner postpones processing o in its graph traversal until a later time, optimistically hoping that o will be used by the application before it is encountered again in GC. After postponing a number of times (referred to as MAX_DL below) , GC processes o even if it is still estimated to be remote, so that the closure computation will not be significantly delayed. MemLiner dynamically adjusts the value of

[1]For ease of discussion, here we do not consider cold objects staying in cache due to hot objects on the same page. We will discuss it in Section 4.3.

Figure 5: A 64-bit object pointer in MemLiner.

MAX_DL, in response to the size of available heap space. For example, when the available heap size is in the *red zone* (*i.e.*, <15% available space), MAX_DL will be set to 0, letting GC quickly finish tracing and collect memory. Details of this adaptive algorithm can be found in this section.

4.2.2 Object Location Estimation

Now, the only missing piece of MemLiner's tracing algorithm is a way to *estimate* whether an object is local or not. A naïve solution is to create a system call that allows GC to query the page table. However, this can be prohibitively expensive as it requires a system call per object visited during tracing.

To solve this problem, we conceptually divide the execution into *epochs* and encode the current epoch ID into each *object pointer* whenever an object is accessed. Later on, during concurrent tracing, this epoch ID will allow the GC to estimate how recently an object was accessed and hence how likely it is still in local memory.

Epoch. Given our goal of estimating whether an object is in local memory, we define an *epoch* to be an execution period in which the set of pages in local memory that belongs to the JVM process are *relatively stable* (*i.e.*, they do not change much). This set changes as new pages of this JVM process are swapped in and old pages are swapped out. When the change becomes significant (*e.g.*, larger than $N\%$ of the total number of JVM pages), a new *epoch* starts. We modify the kernel swap system to keep track of the pages in the cache and determine the start of a new epoch. A global epoch counter is maintained in the JVM and its address is passed into the swap system. This epoch counter starts from zero and is increased by one whenever a new epoch starts.

Timestamp. In the JVM, virtual addresses of objects are represented as *references*, which are essentially pointers with a strong type. In a 64-bit JVM, the format of an object reference is shown in Figure 5. Recall that our need is to estimate whether an object is in local memory from a reference/pointer of the object (*e.g.*, recorded in a field of another object) during GC's graph traversal. Our idea here is to modify the pointer format by reserving 4 unused bits as a *timestamp* (ts in Figure 5) that indicates *the epoch in which the pointer was last dereferenced*—once the epoch ID reaches 15, the next epoch ID goes back to 0. Dereferencing the pointer accesses the target object (*i.e.*, bringing the object to local memory if it is remote). As such, if the timestamp is close to the current epoch, the object is likely in local memory (*i.e.*, Category (1)) and GC should follow the pointer to trace the object; otherwise, the object may not be local (*i.e.*, Category (3)), and GC should postpone tracing it.

Algorithm 1: Allocation semantics.

Input: Allocation site $o = new\ C$.
Output: Object reference o.

```
1 addr ←ALLOCATE(SIZEOF(C))
2 o ←UPDATEPOINTER(addr, CURRENTEPOCH())
3 return o
```

Algorithm 2: Object read and write semantics in application threads.

Input: Object read/write access $a = b.f$ or $b.f = a$.

```
1 ENQUEUE(PQ, b)
2 b ← UPDATEPOINTER(b, CURRENTEPOCH())
3 if ISREFERENCE(a) then
4     b.f ← a ← UPDATEPOINTER(a, CURRENTEPOCH())
```

Upon the allocation of a new object o, MemLiner sets the timestamp bits in o's pointer to be the current epoch number (with function UPDATEPOINTER in Algorithm 1).

Whenever an object is read/written in an application thread like $b.f = a$ or $a = b.f$ (Algorithm 2), MemLiner updates the timestamp ts in the dereferenced pointer b to be the current epoch ID. Furthermore, if a and $b.f$ are also object references, we write an updated pointer of a into $b.f$, indicating that soon the object referenced by $b.f$ will be accessed through a. Again, this instrumentation is implemented through read-/write barriers.

Note that we use Algorithm 1 and Algorithm 2 to illustrate the high-level logic. Our implementation actually inserts assembly code for efficiency. Changing object pointers in the JVM would not cause problems for actual memory accesses—although each pointer represents a virtual address, the barriers we use mask pointers so that only the last 42 bits are used to access memory.

4.2.3 MemLiner Tracing Algorithm

Algorithm 3 shows GC's tracing logic, which was summarized in §4.2.1. The algorithm takes two queue data structures as input: TQ is a standard tracing queue (already used by the JVM) that contains references yet to be explored in object graph traversal; it is initialized with a set of object references in the stack and global variables (*i.e.*, roots). PQ, as discussed earlier, is the producer-consumer queue that contains references of red objects sent to GC by application threads.

As discussed in §4.2.1, every tracing thread of MemLiner alternates between two modes. In the default mode, tracing loops over the tracing queue TQ, shown in Line 2-13 in Algorithm 3, to perform normal graph traversal. Whenever PQ is not empty (Line 3), the tracing thread interrupts the normal traversal and switches to the other mode to handle the (red) objects in PQ (Line 4); this logic is listed in Algorithm 4 and will be discussed shortly.

Algorithm 3: Main tracing logic in MemLiner's GC.

Input: (1) Producer-consumer queue PQ; (2) tracing queue TQ.
Output: Fully marked live bitmap for all live objects.

```
1  Function TRACING(TQ, PQ):
2      while TQ ≠ ∅ do
3          if PQ ≠ ∅ then
4              TRACEREDANDCATEGORY2(TQ, PQ)
5          Tuple ⟨o, dl⟩ ← DEQUEUE(TQ)
6          if DIFF(TS(o), CURRENTEPOCH()) > δ ∧ dl <
            MAX_DL then
7              ENQUEUE(TQ, ⟨o, dl + 1⟩)
8              Continue
9          if CHECKLIVEBITMAP(o) = 0 then
10             MARKLIVEBITMAP(o)
11             foreach Non-null reference-type field f ∈ o do
12                 Object reference p ← o.f
13                 ENQUEUE(TQ, ⟨p, 0⟩)
```

Algorithm 4: Tracing logic for red and Category-(2) objects.

Input: (1) Producer-consumer queue PQ; (2) regular tracing queue TQ.

```
1  Function TRACEREDANDCATEGORY2(TQ, PQ):
2      while PQ ≠ ∅ do
3          o ← DEQUEUE(PQ)
4          EXPLORE(o, TQ, 0)
```

Input: (1) Object reference o; (2) tracing queue TQ; (3) current exploration depth $depth$.

```
5  Function EXPLORE(o, TQ, depth):
6      MARKLIVEBITMAP(o)
7      foreach Non-null reference-type field f ∈ o do
8          Object reference p ← o.f
9          if depth < MAX_Depth then
10             EXPLORE(p, TQ, depth + 1)
11         else
12             ENQUEUE(TQ, ⟨p, 0⟩)
```

In the default mode, each iteration of the tracing loop retrieves a 2-tuple $\langle o, dl \rangle$ from TQ, representing an object reference o and a *delay limit* dl. MemLiner compares TS(o) with the current epoch ID (Line 6). If these two IDs are close to each other (DIFF(TS(o), CURRENTEPOCH()) $\leq \delta$), MemLiner goes ahead to mark this object in the global live bitmap (Line 10) and pushes all the non-null object references stored in this object into the tracing queue TQ (Line 13). Otherwise, MemLiner estimates that the object is not in the cache and hence pushes this tuple back into TQ (Line 7), hoping that the application will use this object and bring it to the cache before the next time it is dequeued in tracing. To avoid pushing back an object too many times, which would delay the completion of closure computation, MemLiner uses a *delay limit* dl, which is initialized to 0. Every time a tuple is pushed back, its dl is incremented (Line 7). Once it becomes *MAX_DL* (*i.e.*, the additional check at Line 6), GC is forced to mark the object. *MAX_DL* is auto-tuned based on the amount of available heap space (discussed shortly).

The other mode of tracing red objects is triggered when PQ is not empty, as illustrated in Algorithm 4. Similar to the default tracing loop, each iteration of the loop (Line 2) in Algorithm 4 retrieves an object reference from PQ, calling a recursive function EXPLORE to not only mark red objects themselves, but also trace a few references forward to mark objects in Category (2), which may be soon used by the application. We use a recursive function here to control the number of references (*i.e.*, data structure depth) to be explored—once $depth$ exceeds a constant *MAX_Depth* (Line 9, 3 by default), the function does not further explore the object graph, but instead, pushes these unexplored references into the regular tracing queue TQ (Line 12) so that they can be traced later in a normal graph traversal without priority. This is because, as discussed in §4.2.1, following long reference chains can swap in objects that may not be needed by the application in the near future, leading to wasted efforts.

Marking an object live flips its corresponding bit in a global live bitmap (Line 6); as a result, the regular graph traversal (Algorithm 3) would not mark it again if it is encountered there. Once the tracing of the red and Category-(2) objects is done, GC resumes the normal graph traversal in Algorithm 3.

In modern GC with concurrent tracing, each tracing thread works on its own tracing queue TQ. MemLiner modifies each tracing thread to run Algorithm 3 so that the work on TQ is interrupted if there are outstanding red objects in a PQ. Each application thread independently pushes red objects into its thread-local PQ while each tracing thread can consume objects from all PQs. This design makes it possible to enable *work stealing* between threads to balance the number of red and Category-(2) objects processed by these threads. The read/write barrier is already used in existing GC algorithms, such as G1, Shenandoah and ZGC, as well as other far-memory techniques such as AIFM [58]. To further reduce MemLiner's overhead at each read/write barrier, we only need to push the object reference o (64 bit) onto the queue with a very small number of instructions.

Autotuning of MAX_DL. How much delay should be introduced to tracing depends on how urgently GC must be completed. As a result, we develop an autotuner that dynamically adjusts the value of *MAX_DL* in response to the available heap size. The rationale is straightforward: if the heap is almost full, there is an urgent need to complete GC and hence we should use a small value for *MAX_DL*; on the contrary, if the heap is mostly available, delaying GC will not have a large impact on memory and hence we use a large value for *MAX_DL* to minimize interference.

MemLiner uses two thresholds for heap availability: 15% and 50%. When the percentage of available memory is lower than 15%, the JVM is in a *red zone*. If the percentage is between 15% and 50%, it is in a *yellow zone*. The JVM is in a *green zone* if the amount of available memory is higher than 50% of the heap size. MemLiner monitors heap usage upon allocations and uses three values for *MAX_DL*: 0, 2, and 4 respectively if the heap falls in the red, yellow, and green zone. These thresholds were empirically chosen and worked well for all our applications.

4.3 Discussion

MemLiner performs adaptation in two dimensions: (1) adapting timestamps based on the swap behavior and (2) adapting *MAX_DL* based on heap availability. The swap behavior correlates with interference and heap availability correlates with GC urgency. We elaborate on how (1) and (2) work in harmony to make MemLiner achieve superior performance.

For (1), MemLiner uses the timestamp mechanism to reduce the interference between GC and application threads. For example, if the cached pages rarely change (*i.e.*, the application has excellent locality or the local memory size is large enough), the interference is minimal and hence it would not create performance issues if MemLiner does not deviate much from an existing GC. Indeed, our algorithm makes the global epoch change slowly and timestamps in most pointers are the same as the current epoch ID. Algorithm 3 would trace most objects in *TQ* without delays. This is a desired property—when resources are *not* constrained, MemLiner would not incur overhead because GC can trace objects and reclaim memory in a timely fashion.

Conversely, if the set of cached pages frequently changes (*i.e.*, the application has poor locality or the cache size is small), the interference is significant and MemLiner should perform differently from an existing GC. Indeed, the global epoch moves at a fast speed. As such, the timestamps in most pointers are different from the current epoch ID. In other words, most objects in the heap are Category-(3) objects that are not in local memory. Consequently, Algorithm 3 would delay the marking of most objects and thus make slow progress. This is also a desired property—tracing should "yield" to the application when local memory resource is tight and application threads are constantly accessing remote memory. In this case, MemLiner imposes a delay to GC, and the delay is bounded by *MAX_DL*.

For (2), we use heap availability to dynamically adjust *MAX_DL*, enabling MemLiner to "override" the policy made under (1) in urgent situations. For example, if the application is experiencing frequent changes in cached pages (indicating interference) while the heap is almost full, the policy under (1) would delay tracing, which can, in turn, delay the completion of GC and subsequently trigger an undesired full-heap collection. In this case, our adaptation under (2) would determine that the heap is in the red zone and thus change *MAX_DL* to 0—even if tracing is delayed, the delay length is set to 0, effectively allowing GC to move in a normal pace.

5 GC-Specific Optimizations

We have implemented MemLiner in both the JVM's default G1 GC [22] and Red Hat's Shenandoah GC [25], which are two representative GCs widely used in cloud settings. G1 is a generational GC that optimizes for throughput with stop-the-world pauses while Shenandoah is a concurrent GC that minimizes the time of each pause by concurrently tracing and compacting objects. Shenandoah optimizes for latency at the cost of reduced throughput. Our goal is to demonstrate that MemLiner can be easily integrated into both GC algorithms, providing performance benefits for different kinds of (*e.g.*, latency-sensitive or batching) workloads.

One challenge in MemLiner is its reliance on read and write barriers, which, if used naïvely, can incur a significant runtime overhead. This section discusses our optimizations to mitigate the overhead. With these optimizations, MemLiner's barrier introduces an average of 2% and 5% overheads, respectively, to Shenandoah and G1, when the application runs entirely with local memory. Such low overheads are due to the following reasons:

First, Shenandoah already utilizes both read and write barriers for concurrent tracing and concurrent evacuation. MemLiner only inserts few instructions into the existing barriers, incurring negligible overheads.

Second, the original G1 only uses the write barrier. Naïvely adding the read barrier into G1 can cause a much higher overhead. We develop the following three optimizations that successfully filter out a significant fraction of object accesses:

Optimization #1: The enqueue operation of MemLiner's barriers is enabled only when concurrent tracing is in progress. When concurrent tracing is not running, it is unnecessary to add any objects into the PQ.

Optimization #2: G1 is a generational GC that splits the heap into a young and an old generation. Concurrent tracing scans only *old-to-old references* (to compute garbage ratio for each region in the old-gen), meaning that references in the young generation are not traced in concurrent tracing at all. Based on this insight, our read barrier filters out all references in the young generation—there is no need to update their timestamps or add them in PQ because these references are not traced in G1's concurrent tracing anyways.

Optimization #3: Our read barrier does not need to update timestamps for objects whose pointer timestamp is the same as the epoch ID. Essentially, we use a check that first compares the pointer timestamp with the epoch ID and updates the timestamp only if they do not have the same value. The larger the local memory percentage is, the less frequently the epoch changes and hence more objects can benefit from this optimization. This explains why when the percentage of local memory increases, MemLiner's overhead does not increase proportionally (as shown in Figure 7).

6 Limitations

MemLiner is designed for managed applications running on a managed runtime and thus not applicable to native applications such as those written in C/C++. Furthermore, MemLiner is designed to optimize throughput (by reducing interference and improving prefetching), *not* latency. However, it does not increase the application latency (*i.e.*, making remote access longer) or the GC pause time. For the Shenandoah GC, its pauses are already very short because operations requiring a pause do not involve many remote accesses and their time is not changed much by MemLiner. For G1, by lining up the tracing and application's memory accesses, MemLiner makes concurrent tracing more efficient, thereby significantly reducing the frequency of triggering full-heap collections. However, it does not reduce the per-collection pause time.

As shown in our evaluation, the more remote memory an application uses, the more effective MemLiner's optimization. However, when a large percentage of the working set fits into local memory, MemLiner's effectiveness reduces. In fact, if this percentage exceeds 50%, MemLiner's performance is on par with that of the original JVM.

The other limitation is that MemLiner focuses on reducing interference between the application and concurrent tracing threads. Application threads may also interfere with memory reclamation threads if the GC performs concurrent reclamation (such as Shenandoah and ZGC). MemLiner cannot reduce this type of interference.

7 Evaluation

7.1 Experiment Setup

We implemented MemLiner on top of OpenJDK 12 (v 12.0.2) and Linux (v 5.4.0). Our swap system is based upon our re-implementation of FastSwap [10][2], which provides good swap performance. We implemented it on top of G1 and Shenandoah. Implementing MemLiner in other GCs would be straightforward in the future.

Environment. We ran our experiments with two machines, each with two Xeon(R) CPU E5-2640 v3 processors, 128GB memory, one 1TB SSD, and one 40 Gbps Mellanox ConnectX-3 InfiniBand network adapter. They are connected by one Mellanox 100 Gbps InfiniBand switch. One machine runs the JVM process while the other provides remote memory via RDMA. All our experiments used a 32GB heap and 4K pages.

Although our application heap size is relatively small (compared to the size of main memory on our machines), the performance of a remote-memory application depends on how much of its working set can fit into local memory and how many (application and GC) threads are used, *not* on how large local memory is. In particular, MemLiner's key data structure is a per-thread PQ (*i.e.*, TQ is not key to MemLiner as it is GC's original data structure). PQ's size depends on the ratio between the number of applications and the number of tracing threads. For instance, for G1, we follow Oracle's recommendation [56] by setting the number of parallel GC threads to be $5 \times$ (core number)/8, and the number of concurrent tracing threads to be 1/4 of the parallel GC threads. With this ratio and a per-thread PQ of 1024 entries, we rarely saw overwrites in our experiments (with our filtering optimizations stated above). However large the heap is, as long as this ratio remains the same, the size of PQ does not need to change; so does the work done by MemLiner.

[2]Its original implementation was incompatible with OpenJDK12.

Table 1: Applications and datesets used for G1.

Applications. To evaluate MemLiner, we used a range of cloud applications including Apache Spark [74] (3.0.0), the de-facto data analytics system, Apache Cassandra [12] (3.11), a widely used distributed database, Neo4j [52] (4.3.2), a graph database, QuickCached [3], a Java implementation of Memcached, as well as DayTrader [34], IBM's open-source application emulating an online stock trading system. These applications cover a wide spectrum of text and graph analytics, web services, machine learning tasks, and database query tasks. For each application, their workloads and datasets are reported in Table 1.

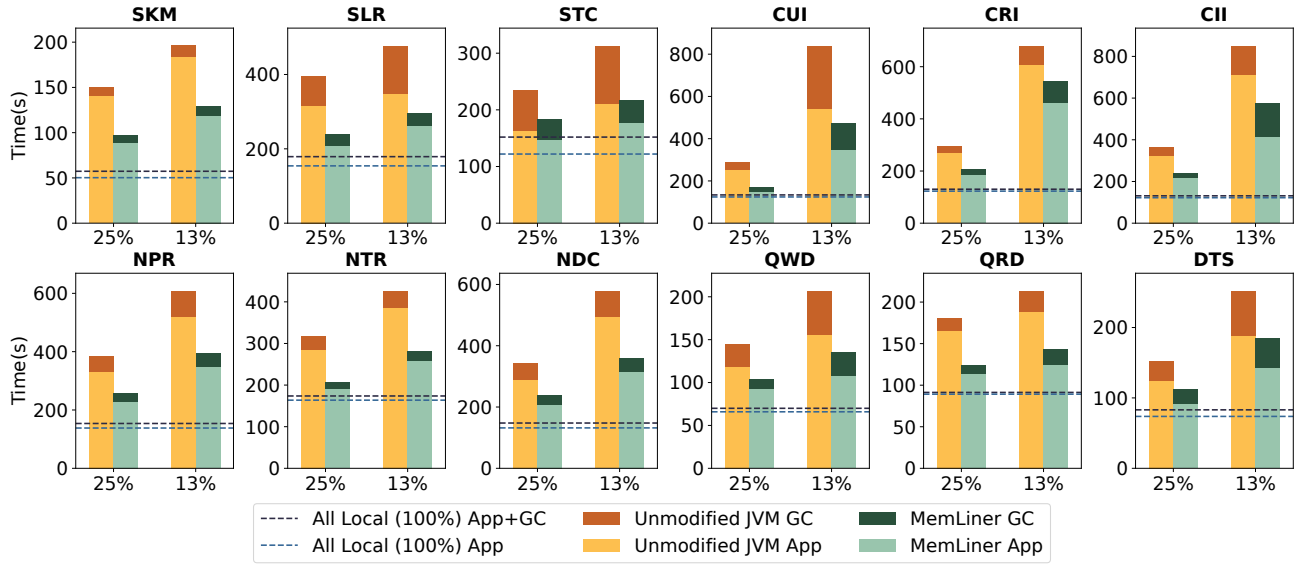

Figure 6: Performance comparisons between G1 GC (yellow bars) and MemLiner (green bars) under two local memory ratios: 25% and 13%; each bar is split into application (bottom with light colors) and GC (top with dark colors) time in seconds. The two dashed lines show application time and total time with unmodified JVM and 100% local memory (no swaps).

The memory access patterns of our applications can be categorized into three types:

- *Mostly sequential access patterns*: Spark applications operate over RDDs. An RDD is an object array or serialized primitive array. Each application thread exhibits clear memory access patterns, *e.g.*, streaming or stride.
- *Random access patterns*: QuickCached (a key-value store) and DayTrader (stock trading simulation) exhibit quite random memory access patterns.
- *Mixed access patterns*: Take Cassandra as an example. Each read/update operation goes through several micro-operations. Different micro-operations have different memory access patterns, *i.e.*, the MemTable loading exhibits a good streaming memory access pattern and some other calculations access memory randomly. Both Cassandra and Neo4j belong to this category.

Our experiments considered two local memory ratios: 25%, and 13% of the total Java heap size (32GB), which are consistent with local memory ratios used in prior work [58, 68]. We enforced these ratios with `cgroup`.

7.2 Performance with G1 GC

Overall. Figure 6 compares the performance of the baseline (the default G1 GC) and MemLiner under two different local memory ratios: 25%, and 13%. As shown, MemLiner offers better performance over the baseline JVM for all workloads, **1.48**× speedup on average under 25% local memory and **1.51**× speedup on average under 13% local memory. A summary of these performance improvements (for the application, GC, and end-to-end performance) is reported in Table 2.

Local Memory	G1 GC			Shenandoah GC		
Configuration	**App**	**GC**	**All**	**App**	**GC**	**All**
25% Local	**1.45**×	**1.65**×	**1.48**×	**1.88**×	**15.33**×	**2.16**×
13% Local	**1.46**×	**1.79**×	**1.51**×	**1.60**×	**6.20**×	**1.80**×

Table 2: Speedups provided by MemLiner for G1 and Shenandoah. (speedup: the average time under each configuration using the unmodified JVM divided by that using MemLiner)

We also compared the number of swap-in pages between MemLiner and the unmodified JVM: MemLiner reduces an average of **81%** of on-demand swap-ins and **56%** of total swap-ins (including both on-demand and prefetching swaps).

Compared with running the whole application in local memory with no swapping (illustrated by dashed lines in Figure 6), the unmodified JVM incurs 2.17× and 3.73× slowdowns under the 25% and 13% local memory configurations, respectively. MemLiner brings them down to 1.47× and 2.48×.

Details. For several workloads (e.g., **SLR**, **STC**, **CUI**, **NDC**, **QWD** and **DTS**), the default JVM's GC time increases dramatically when the local memory ratio drops from 25% to 13%. This is because when memory resources are tight, concurrent tracing becomes slow with many local-memory cache misses. It sometimes cannot finish a complete closure before the heap is full, causing the JVM to pause all application threads and run a time-consuming full-heap GC. Fortunately, MemLiner brings down that GC cost, enabling concurrent

tracing to quickly compute the closure by following the applications' accesses and reducing full-heap GCs.

Cassandra's performance degrades drastically under 13% local memory. In addition to more frequent full-heap GCs, this also stems from data spilling. When the memory usage exceeds a certain ratio (*e.g.*, 2/3) of the heap size, Cassandra automatically spills data from memory to disk. Since concurrent tracing under a tighter local-memory budget becomes much slower, the memory consumption frequently exceeds that ratio, triggering spilling and slowing down the application. In these large-scale systems, GC can actually impact the performance of applications in many unexpected ways.

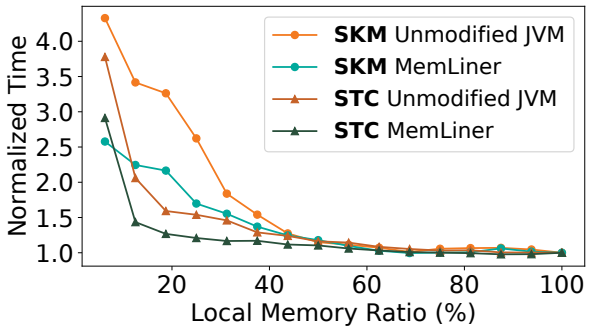

Figure 7: Performance comparisons for **SKM** and **STC** between the unmodified JVM and MemLiner under different local memory configurations.

Different Local Memory Configurations. We ran **SKM** and **STC** with various local-memory ratio configurations and report the performance in Figure 7. As shown, the lower the ratio, the higher the benefit MemLiner provides. For both applications, the turning point is around 50%—MemLiner and the baseline have about the same performance when the local memory ratio reaches 50% or above.

7.3 Performance with Shenandoah GC

To demonstrate the generality of MemLiner, we implemented MemLiner in a second garbage collector: Shenandoah[25], a widely-used highly-concurrent low-pause GC developed by Red Hat. It performs not only concurrent tracing but also concurrent object evaluation to minimize pauses.

Shenandoah provides great latency benefits under sufficient local memory. However, it has extremely poor performance with remote memory involved. For example, the slowdowns under 25% memory for our Spark and Neo4j applications are constantly above 10× and 4×, respectively. Compared to Neo4j, Spark applications usually have much larger working sets, leading to more remote accesses. Such a large overhead highlights the problem of running many concurrent GC threads that do not align with the application's memory access. In particular, Shenandoah is *not* a generational GC (while G1 is). In G1, when the young generation, which contains short-lived objects, is full, the JVM suspends application threads

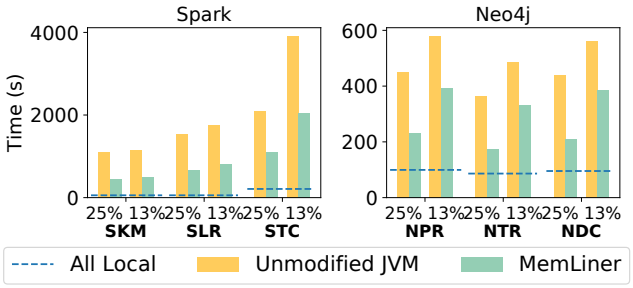

Figure 8: Performance comparison with Shenandoah GC [25].

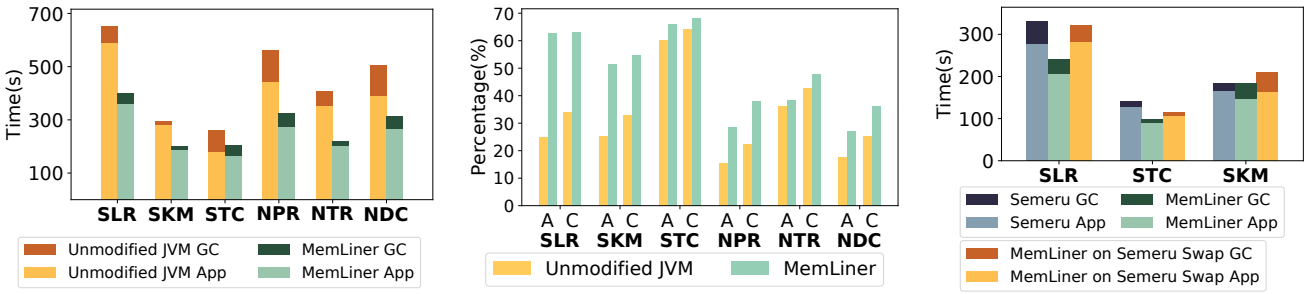
Table 3: Benchmarks and datasets for Shenandoah.

and evacuates objects in the young generation. This leads to excellent data locality after evacuation. However, under Shenandoah GC, the JVM runs concurrent tracing much more frequently to scan the full heap to identify and collect garbage. Those tracing threads exhibit particularly poor locality. To evaluate Shenandoah, we had to use smaller datasets (Table 3) for a tolerable running time.

As illustrated in Figure 8 and summarized in Table 2, MemLiner achieves an overall **2.16**× and **1.80**× speedup compared to the unmodified JVM under 25% and 13% local memory, respectively. MemLiner reduces an average of 82% on-demand swap-ins and 56% of total swap-ins under 25% local memory, while it reduces 79% of on-demand swap-ins and 22% of total swap-ins under 13% local memory. As shown in Table 2, MemLiner provides tremendous improvements for Shenandoah's GC performance, because the unmodified JVM frequently triggers *full-heap stop-the-world GC*.

7.4 Comparisons with Other Systems

Leap [48] is an advanced OS-level prefetcher. It uses a majority-vote algorithm to determine how to do prefetches. In cases where no clear access patterns are seen, Leap aggressively prefetches consecutive pages. Although this strategy may improve performance for native applications whose memory accesses often fall into large arrays, it often hurts managed applications such as Spark, as GC's pointer-chasing behavior often makes prefetched consecutive pages useless.



(a) Leap: Running time (b) Leap: Accuracy(A) and Coverage(C) (c) Semeru: Running time

Figure 9: Performance comparisons with Leap and Semeru; Semeru crashed on **NPR**, **NTR**, and **NDC** (*i.e.*, Neo4j applications).

Our hypothesis is that even aggressive prefetchers like Leap cannot handle the interference of GC, and that by aligning the memory accesses of GC with application threads, MemLiner can improve application performance under Leap just like under less aggressive prefetchers. To test our hypothesis, we compared MemLiner with the unmodified JVM (default G1 GC) both using Leap as the prefetcher. This experiment was conducted on three Spark applications: **SLR**, **SKM**, **STC**, and three Neo4j applications: **NPR**, **NTR**, **NDC**, under 25% local memory.

As shown in Figure 9(a), compared with the unmodified JVM on Leap, MemLiner improves the overall performance by an average of 1.6× and reduces 58% of on-demand swap-ins, as well as 53% of total swap-ins on average. To understand whether MemLiner improves Leap's prefetching effectiveness, we additionally measured Leap's prefetching *accuracy* (i.e., the percentage of page faults hitting on the swap cache among prefetched pages) and *coverage* (i.e., the percentage of swap cache hits among all page faults) with and without MemLiner. As shown in Figure 9(b), MemLiner helps Leap deliver higher accuracy and coverage. We still observed that MemLiner is not as useful for **STC** and **NTR** as it is for the two applications. This is because the number of live objects in **STC** during concurrent tracing is relatively small, leading to shorter tracing time and better access patterns. For **NTR**, its application threads exhibit random memory accesses themselves. Hence, Leap cannot detect clear patterns even if MemLiner has already eliminated much of the interference.

Semeru [68] is a memory-disaggregated runtime, where the entire Java heap is backed by physical memory on memory servers and the CPU server's local memory is used as an inclusive cache. Semeru completely redesigned the JVM so that all the garbage collection is offloaded from the CPU server to the memory servers, through special lightweight JVMs running there. Applications execute on the CPU server with absolutely no GC interference, at the cost of extra computation on memory servers (i.e., two extra cores for each memory server to run the offloaded lightweight JVM).

Here, to evaluate whether MemLiner can achieve similar performance as Semeru, without Semeru's intrusive changes to JVM and Semeru's extra computation load on memory servers, we ran the same three Spark applications under 25% local memory on top of (1) Semeru, (2) MemLiner on Semeru's swap system (*i.e.*, a modified version of NVMe-over-fabrics [1]), and (3) MemLiner on FastSwap [10], which is the default swap system MemLiner builds on. We ran Semeru with one CPU server and two memory servers—the Java heap is partitioned between the memory servers.

As shown in Figure 9(c) , MemLiner's performance is comparable with Semeru when using Semeru's swap system, and is much better than Semeru when using MemLiner's default swap system. The reason is that, even though Semeru completely eliminates GC tracing threads from the local machine, it has to perform a great deal of coordination between servers to handle cross-server references, incurring communication overheads. We would have also liked to run Semeru directly over FastSwap, but this was not feasible due to Semeru's runtime-kernel co-design that prevents Semeru from easily adapting to different swap systems.

We could not directly compare Memliner with AIFM [58] as AIFM targets native languages (C/C++) applications and requires rewriting programs. However, the major idea behind AIFM—swapping at the object granularity—is orthogonal to MemLiner. MemLiner can also benefit from a redesigned swap system that performs object-level swapping.

7.5 More Detailed Results

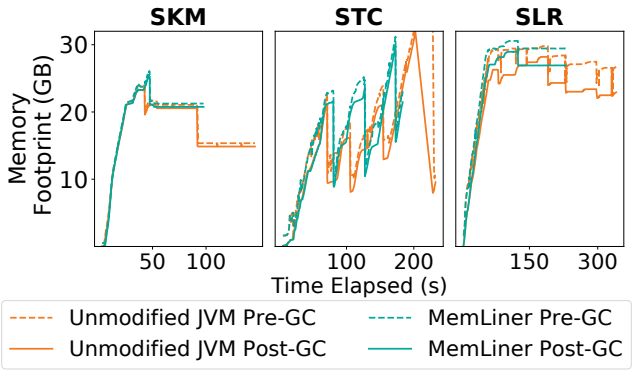


Figure 10: Memory footprints for **SKM**, **STC**, and **SLR**, between unmodified JVM and MemLiner under 25% rate.

Memory Reclamation Impact. Since MemLiner postpones tracing objects estimated to be remote, it may delay memory reclamation. To understand the impact of such a delay, we collected post-GC memory footprints for **STC**, **SKM**, and **SLR** executed atop the unmodified JVM and MemLiner under 25% local memory configuration. Figure 10 reports, for each program, both its pre-GC and post-GC memory footprints. As shown, for all three workloads, MemLiner incurs insignificant delays in memory reclamation and only a slight increase in the peak memory consumption. This is because tracing of each remote object can only be postponed a few times (*i.e.*, *MAX_DL*); when the available heap runs low, *MAX_DL* becomes 0 and we do not postpone GC at all.

Epoch Estimation Effectiveness. We collected the number of objects that are scanned from PQ and TQ for three Spark applications under 25% local memory. The ratio of objects scanned from PQ over total objects scanned during the concurrent tracing phase is 45%, 42%, and 11% respectively for **SLR**, **SKM** and **STC**. We also evaluated MemLiner after disabling epoch estimation: we saw an overall performance degradation of 8.6%, 8.8% and 11.3% respectively, for **SLR**, **SKM** and **STC** under 25% local memory.

8 Related Work

Far Memory. Due to rapid technological advances in network controllers, it has become practical to reorganize resources into disaggregated clusters [32, 18, 27, 15]. A disaggregated cluster can increase the hardware resource utilization and has the potential to overcome fundamental hardware limits, such as the critical "memory capacity wall" [14, 44, 43, 67, 20, 38, 7, 11]. A body of techniques [10, 30, 6, 58, 68, 61, 63, 68, 31, 69] have been developed to enable applications to use remote memory and efficiently access remote data.

Among these techniques, a mainstream approach [10, 30, 6] is to provide *transparent* remote memory access with *swap mechanisms* where the running application is not aware of remote memory, which is mapped into the application host server as a *swap partition*. The host server reserves a certain amount of local memory as a software-managed data cache. Once the program accesses a page that does not reside in the data cache, it triggers a page fault, and the swap system fetches the page from a remote memory server via RDMA.

A traditional swap system was designed for *slow and rare* accesses to disks, *not for fast and frequent* accesses to remote memory via RDMA. Having realized this speed discrepancy, existing techniques have performed a variety of optimizations, *e.g.*, removing redundant block layers [30], leveraging multi-queues [10], or performing per-application prefetching [48], all to maximize the paging/swap efficiency. Despite these commendable efforts, these techniques need to pay a "transparency tax"—since all remote accesses go through the OS kernel, which incurs a non-trivial overhead. To mitigate such a software-introduced overhead, work such as AIFM [58] provides primitives for developers to perform efficient remote access in the user space. AIFM outperforms swap-based techniques by bypassing the kernel data plane. However, to use AIFM, applications have to be rewritten (with new primitives), which can significantly hinder its practical use.

Modern Garbage Collectors. Modern GCs, including Oracle's Garbage-First (G1) GC [22], Red Hat's Shenandoah GC [25], Azul's pauseless GC [21], and C4 [64], all use concurrent tracing. Some also perform concurrent memory compaction [39, 2]. As big data systems gain popularity, there is a line of work that develops systems for applications running on the cloud [24, 53, 54, 51, 67], on NUMA machines [29], as well as using non-volatile memory [67, 71, 9]. Yak [53] is a region-based big-data-friendly GC. Taurus [47] coordinates GC efforts among workers in a distributed system. Facade [54] uses region-based memory management to reduce GC costs for Big Data applications. Gerenuk [51] develops a compiler analysis and runtime system that enable native representation of data for managed analytics systems such as Spark and Hadoop. Espresso [71] and Panthera [67] are designed for systems with non-volatile memory. Platinum [70] aims to reduce tail latency for interactive applications. NUMAGiC [29] is a GC that provides efficiency by considering NUMA features.

Semeru [68] and Mako [46] are both GCs developed for memory disaggregation. While they both achieve superior performance via compute offloading (*e.g.*, running concurrent tracing and evacuation on memory servers), offloading introduces numerous challenges in resource utilization and cluster scheduling. AIFM [58] performs GC-like memory compaction to eliminate dead objects to reduce read/write amplification. This approach is orthogonal to MemLiner, which leverages tracing for prefetching.

9 Conclusion

This paper presents MemLiner, a runtime technique that reduces the GC-application interference by aligning the memory accesses of application and tracing threads. We classify reachable objects into three categories and treat objects in each category in a different way to achieve the two seemingly conflicting goals. Our promising results with two production GCs demonstrate that MemLiner can be readily used in today's datacenters.

A Artifact Appendix

A.1 Artifact Summary

MemLiner is a managed runtime built for a memory-disaggregated cluster where each managed application runs on one server and uses both local memory and remote memory located on another server. When launched on MemLiner, the process fetches data from the remote server via the paging system. MemLiner reduces the local-memory working set and improves the remote-memory prefetching by lining up the memory accesses from application and GC threads. MemLiner is transparent to applications and can be integrated in any existing GC algorithms, such as G1 and Shenandoah.

A.2 Artifact Check-list

- **Hardware: Intel servers with InfiniBand**
- **Run-time environment: OpenJDK 12.02, Linux-5.4, Ubuntu 18.04 with MLNX-OFED 4.9-2.2.4.0**
- **Public link: https://github.com/uclasystem/MemLiner**
- **Code licenses: The GNU General Public License (GPL)**

A.3 Description

A.3.1 MemLiner's Codebase

MemLiner contains the following three components:

- the Linux kernel, which includes a modified swap system,
- the Java Virtual Machine (JVM) with MemLiner,
- necessary shell scripts and configuration files.

A.3.2 Deploying MemLiner

To build MemLiner, the first step is to download its source code:

```
git clone
git@github.com:uclasystem/MemLiner.git
```

When deploying MemLiner, install the components in the following order: (1) install the kernel and the RDMA module on all participating servers; (2) install the JVM with MemLiner on the server that runs the process; (3) connect the participating servers before running applications.

Kernel Installation. We first discuss how to build and install the kernel.

- Modify `grub` and set `transparent_hugepage` to `madvise`:

```
sudo vim /etc/default/grub
+ transparent_hugepage=madvise
```

- Install the kernel and restart the machine:

```
cd MemLiner/Kernel
sudo ./build_kernel.sh build
sudo ./build_kernel.sh install
```

- Install the MLNX OFED driver:

  MemLiner has only been tested on Ubuntu 18.04 with MLNX-OFED-4.9-2.2.4.0. The driver should be installed all participating servers.

```
# @all participating servers
# Remove the incompatible libraries
sudo apt remove ibverbs-providers:amd64
librdmacm1:amd64 librdmacm-dev:amd64
libibverbs-dev:amd64 libopensm5a
libosmvendor4 libosmcomp3 -y

# Download and install the MLNX OFED driver
curl https://content.mellanox.com/ofed/
MLNX_OFED-4.9-2.2.4.0/MLNX_OFED_LINUX
-4.9-2.2.4.0-ubuntu18.04-x86_64.tgz
--output MLNX_OFED.tgz
tar -xzf MLNX_OFED.tgz
sudo MLNX_OFED/mlnxofedinstall
--add-kernel-support

# Enable the openidb and opensmd services
sudo systemctl enable openibd
sudo systemctl start openibd
sudo systemctl enable opensmd
sudo systemctl start opensmd
```

- Configure and install the MemLiner RDMA module:

```
# Assign the IP of a memory server into:
# @CPU server
# MemLiner/rswap/client/rswap_rdma.c
char ip[] = "10.0.0.4"; # IP of memory server
# @memory server
# MemLiner/rswap/server/rswap_server.cpp
const char *ip_str = "10.0.0.4";

# Build the MemLiner RDMA module
# @CPU server
cd MemLiner/rswap/client
make clean && make
# @memory server
cd MemLiner/rswap/server
make clean && make
```

Install the MemLiner (JVM). We next discuss the steps to build and install the MemLiner JVM on the CPU server.

- Download Oracle JDK 12 to build the MemLiner JVM:

```
# @CPU server
# Assume jdk 12.02 is under path:
# ${HOME}/jdk-12.0.2
cd MemLiner/JDK
./configure -with-boot-jdk=${HOME}/jdk-
12.0.2 --with-debug-level=release
make JOBS=32

# Run the applications with the built JVM.
# The built JVM (MemLiner) is under:
MemLiner/JDK/build/
linux-x86_64-server-release/jdk
```

A.3.3 Running Applications

To run applications, we first need to connect the CPU and memory servers. Next, we mount the remote memory pool as a swap partition on the CPU server. When the application uses more memory than the limit set by `cgroup`, its data will be swapped out to remote memory via RDMA.

- Launch memory servers:

```
# @memory server
cd MemLiner/rswap/server
./rswap-server
```

- Connect the CPU server with memory servers:

```
# @CPU server
cd MemLiner/rswap/client
./manage_rswap_client.sh install
```

- Set a cache size limit for an application:

```
# For example, create a cgroup with a 9GB
memory limit.
# @CPU server
# Create the cgroup with the name memctl
# $USER is the username of the account
sudo cgcreate -t $USER -a $USER -g
memory:/memctl

# Set the memory limit to 9GB
echo 9g > /sys/fs/cgroup/memory/
memctl/memory.limit_in_bytes
```

- Add a Spark executor into `cgroup`:

```
# Add a Spark worker into cgroup, memctl.
# Its sub-process, executor, falls into the same
cgroup.
# @CPU server
# Modify the function start_instance under:
# Spark/sbin/start-slave.sh
cgexec -sticky -g memory:memctl
"${SPARK_HOME}/sbin" /sparkdaemon.sh
start $CLASS $WORKER_NUM -webui-port
"$WEBUI_PORT" $PORT_FLAG $PORT_NUM
$MASTER "$@"
```

- Launch the Spark cluster:

  Certain JVM options need to be added to run the MemLiner. We use the Spark as an example here. Please refer to the MemLiner's code repository for more details about how to run other applications.

```
# @CPU server
# Replace the Spark default configuration
cd ${spark-home-dir}/conf
cp MemLiner/config-files/spark-confs/
spark-defaults-memliner.conf
spark-defaults.conf

# Launch the Spark master and worker services
${spark-home-dir}/sbin/start-all.sh
```

- Run Spark applications:

  Specify the Spark application name and local memory ratio, *e.g.*, 25% or 13%, and then execute the applications:

```
# @CPU server
# Para#1 application: lr, km, tc
# Para#2 mem_local_ratio: 25, 13
MemLiner/app-scripts/memliner.sh
${application} ${mem_local_ratio}
```

  More details of MemLiner's installation and deployment can be found in MemLiner's code repository.

Abstract

Far memory systems allow an application to transparently access local memory as well as memory belonging to remote machines. Fault tolerance is a critical property of any practical approach for far memory, since machine failures (both planned and unplanned) are endemic in datacenters. However, designing a fault tolerance scheme that is efficient with respect to both computation and storage is difficult. In this paper, we introduce Carbink, a far memory system that uses erasure-coding, remote memory compaction, one-sided RMAs, and offloadable parity calculations to achieve fast, storage-efficient fault tolerance. Compared to Hydra, a state-of-the-art fault-tolerant system for far memory, Carbink has 29% lower tail latency and 48% higher application performance, with at most 35% higher memory usage.

1 Introduction

In a datacenter, matching a particular application to just enough memory and CPUs is hard. A commodity server tightly couples memory and compute, hosting a fixed number of CPUs and RAM modules that are unlikely to exactly match the computational requirements of any particular application. Even if a datacenter contains a heterogeneous mix of server configurations, the load on each server (and thus the amount of available resources for a new application) changes dynamically as old applications exit and new applications arrive. Thus, even state-of-the-art cluster schedulers [51, 52] struggle to efficiently bin-pack a datacenter's aggregate collection of CPUs and RAM. For example, Google [52] and Alibaba [34] report that the average server has only ~60% memory utilization, with substantial variance across machines.

Memory is a particularly vexing resource for two reasons. First, for several important types of applications [19, 20, 33, 54], the data set is too big to fit into the RAM of a single machine, even if the entire machine is assigned to a single application instance. Second, for these kinds of applications, alleviating memory pressure by swapping data between RAM and storage [14] would lead to significant application slowdowns, because even SSD accesses are orders of magnitude slower than RAM accesses. For example, Google runs a graph analysis engine [28] whose data set is dozens of GBs in size. This workload runs 46% faster when it shuffles data purely through RAM instead of between RAM and SSDs.

Disaggregated datacenter memory [2, 5, 15, 16, 22, 44, 46] is a promising solution. In this approach, a CPU can be paired with an arbitrary set of possibly-remote RAM modules, with a fast network interconnect keeping access latencies to far memory small. From a developer's perspective, far memory can be exposed to applications in several ways. For example, an OS can treat far RAM as a swap device, transparently exchanging pages between local RAM and far RAM [5, 22, 46]. Alternatively, an application-level runtime like AIFM [44] can expose remotable pointer abstractions to developers, such that pointer dereferences (or the runtime's detection of high memory pressure) trigger swaps into and out of far memory.

Much of the prior work on disaggregated memory [2, 44, 55] has a common limitation: a lack of fault tolerance. Unfortunately, in a datacenter containing hundreds of thousands of machines, faults are pervasive. Many of these faults are planned, like the distribution of kernel upgrades that require server reboots, or the intentional termination of a low-priority task when a higher-priority task arrives. However, many server faults are unpredictable, like those caused by hardware failures or kernel panics. Thus, any *practical* system for far memory has to provide a scalable, fast mechanism to recover from unexpected server failures. Otherwise, the failure rate of an application using far memory will be much higher than the failure rate of an application that only uses local memory; the reason is that the use of far memory increases the set of machines whose failure can impact an application [8].

Some prior far-memory systems do provide fault tolerance via replication [5, 22, 46]. However, replication-based approaches suffer from high storage overheads. Hydra [29] uses erasure coding, which has smaller storage penalties than replication. However, Hydra's coding scheme stripes a single memory page across multiple remote nodes. This means that a compute node requires multiple network fetches to reconstruct a page; furthermore, computation over that page cannot be outsourced to remote memory nodes, since each node contains only a subset of the page's bytes.

[*]Contributed to this work during internships at Google.

In this paper, we present Carbink,[1] a new framework for far memory that provides efficient, high-performance fault recovery. Like (non-fault-tolerant) AIFM, Carbink exposes far memory to developers via application-level remoteable pointers. When Carbink's runtime must evict data from local RAM, Carbink writes erasure-coded versions of that data to remote memory nodes. The advantage of erasure coding is that it provides equivalent redundancy to pure replication, while avoiding the double or triple storage overheads that replication incurs. However, straightforward erasure coding is a poor fit for the memory data created by applications written in standard programming languages like C++ and Go; those applications allocate variable-sized memory objects, but erasure coding requires equal-sized blocks. To solve this problem, Carbink eschews the object-granularity swapping strategy of AIFM, and instead swaps at the granularity of *spans*. A single span consists of multiple memory pages that contain objects with similar sizes. Carbink's runtime asynchronously and transparently moves local objects within the spans in local memory, grouping cold objects together and hot objects together. When necessary, Carbink batch-evicts cold spans, calculating parity bits for those spans at eviction time, and writing the associated fragments to remote memory nodes. Carbink utilizes one-sided remote memory accesses (RMAs) to efficiently perform swapping activity, minimizing network utilization. Unlike Hydra, Carbink's erasure coding scheme allows a compute node to fetch a far memory region using a single network request.

In Carbink, each span lives in exactly one place: the local RAM of a compute node, or the far RAM of a memory node. Thus, swapping a span from far RAM to local RAM creates dead space (and thus fragmentation) in far RAM. Carbink runs pauseless defragmentation threads in the background, asynchronously reclaiming space to use for later swap-outs.

We have implemented Carbink atop our datacenter infrastructure. Compared to Hydra, Carbink has up to 29% lower tail latency and 48% higher application performance, with at most 35% more remote memory usage. Unlike Hydra, Carbink also allows computation to be offloaded to remote memory nodes.

In summary, this paper has four contributions:

- a span-based approach for solving the size mismatch between the granularity of erasure coding and the size of the objects allocated by compute nodes;
- new algorithms for defragmenting the RAM belonging to remote memory nodes that store erasure-encoded spans;
- an application runtime that hides spans, object migration within spans, and erasure coding from application-level developers; and
- a thorough evaluation of the performance trade-offs made by different approaches for adding fault tolerance to far memory systems.

[1] Carbink is a Pokémon that has a high defense score.

2 Background

Recent work on far memory has used one of two approaches. The first approach modifies the OS that runs applications, exploiting the fact that preexisting OS abstractions already decouple application-visible in-memory data from the backing storage hierarchy. For example, INFINISWAP [22], Fastswap [5], and LegoOS [46] leverage virtual memory support to swap application memory to far RAM instead of a local SSD or hard disk. Applications use standard language-level pointers to interact with memory objects; behind the scenes, the OS swaps pages between local RAM and far RAM, e.g., in response to page faults for non-locally-resident pages. In contrast, the remote region approach [2] exposes far memory via file system abstractions. Applications name remote memory regions using standard filenames, and interact with regions using standard file operations like `open()` and `read()`.

Exposing far memory via OS abstractions is attractive because it requires minimal changes to application-level code. However, invasive kernel changes are needed; such changes require substantial implementation effort, and are difficult to maintain as other parts of the kernel evolve.

The second far-memory approach requires more help from application-level code. For example, AIFM [44] uses a modified C++ runtime to hide the details of managing far memory. The runtime provides special pointer types whose dereferencing may trigger the swapping of a remote C++-level object into local RAM. AIFM's runtime tracks object hotness using GC-style read/write barriers, and uses background threads to swap out cold local objects when local memory pressure is high. To synchronize the local memory accesses generated by application threads and runtime threads, AIFM embeds a variety of metadata bits (e.g., `present`, `isBeingEvicted`) in each smart pointer, leveraging an RCU-like scheme [36] to protect concurrent accesses to a pointer's referenced object.

Listing 1 provides an example of how applications use AIFM's smart pointers. Like AIFM, Carbink exposes far memory via smart pointers, but unlike AIFM, Carbink provides fault tolerance.

3 Carbink Design

Figure 1 depicts the high-level architecture of Carbink. **Compute nodes** execute single-process (but potentially multi-threaded) applications that want to use far memory. **Memory nodes** provide far memory that compute nodes use to store application data that cannot fit in local RAM. A logically-centralized **memory manager** tracks the liveness of compute nodes and memory nodes. The manager also coordinates the assignment of far memory **regions** to compute nodes. When a memory node wants to make a local memory region available to compute nodes, the memory node *registers* the region with the memory manager. Later, when a compute node requires far memory, the compute node sends an *allocation* request to the memory manager, who then assigns a registered, unallo-

```
RemUniquePtr<Node> rem_ptr = AIFM::MakeUnique<Node>();
{
  DerefScope scope;
  Node* normal_ptr = rem_ptr.Deref(scope);
  computeOverNodeObject(normal_ptr);
} // Scope is destroyed; Node object can be evicted.
```

Listing 1: Example of how AIFM applications interact with far memory. In the code above, the application first allocates a `Node` object that is managed by a particular `RemUniquePtr`. Such a remote unique pointer represents a pointer to an object that (1) can be swapped between local and far memory, and (2) can only be pointed to by a single application-level pointer. The code then creates a new scope via an open brace, declares a `DerefScope` variable, and invokes the `RemUniquePtr`'s `Deref()` method, passing the `DerefScope` variable as an argument. `Deref()` essentially grabs an RCU lock on the remotable memory object, and returns a normal C++ pointer to the application. After the application has finished using the normal pointer, the scope terminates and the destructor of the `DerefScope` runs, releasing the RCU lock and allowing the object to be evicted from local memory.

cated region. Upon receiving a *deallocation* message from a compute node, the memory manager marks the associated region as available for use by other compute nodes. A memory node can ask the memory manager to *deregister* a previously registered (but currently unallocated) region, withdrawing the region from the global pool of far memory.

Carbink does not require participating machines to use custom hardware. For example, any machine in a datacenter can be a memory node if that machine runs the Carbink memory host daemon. Similarly, any machine can be a compute node if that node's applications use the Carbink runtime.

From the perspective of an application developer, the Carbink runtime allows a program to dynamically allocate and deallocate memory objects of arbitrary size. As described in Section 3.2, programs access those objects through AIFM-like remotable pointers [44]. When applications dereference pointers that refer to non-local (i.e., swapped-out) objects, Carbink pulls the desired objects from far memory. Under the hood, Carbink's runtime manages objects using **spans** (§3.3) and **spansets** (§3.4). A span is a contiguous run of memory pages; a single region allocated by a compute node contains one or more spans. Similar to slab allocators like Facebook's jemalloc [17] and Google's TCMalloc [21, 24], Carbink rounds up each object allocation to the bin size of the relevant span, and aligns each span to the page size used by compute nodes and memory nodes. Carbink swaps far memory into local memory at the granularity of a span; however, when local memory pressure is high, Carbink swaps local memory out to far memory at the granularity of a spanset (i.e., a collection of spans of the same size). In preparation for

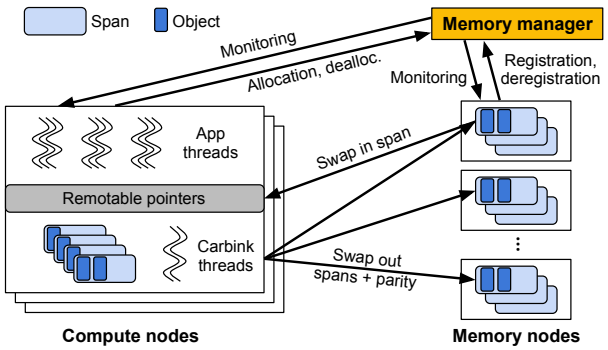

Figure 1: Carbink's high-level architecture.

swap-outs, background threads on compute nodes group cold objects into cold spans, and bundle a group of cold spans into a spanset; at eviction time, the threads generate erasure-coding parity data for the spanset, and then evict the spanset and the parity data to remote nodes. As we discuss in Sections 3.4 and 3.5, this approach simplifies memory management and fault tolerance.

Carbink disallows cross-application memory sharing. This approach is a natural fit for our target applications, and has the advantage of simplifying failure recovery and avoiding the need for expensive coherence traffic [46].

3.1 Failure Model

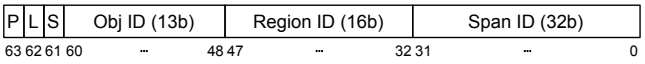
Carbink implements the logically-centralized memory manager as a replicated state machine [1, 45]. Thus, Carbink assumes that the memory manager will not fail. Carbink assumes that memory nodes and compute nodes may experience fail-stop faults. Carbink does not handle Byzantine failures or partial network failures.

The memory manager tracks the liveness of compute nodes and memory nodes via heartbeats. When a compute node fails, the memory manager instructs the memory nodes to deallocate the relevant spans; if applications desire, they can use an application-level fault tolerance scheme like checkpointing to ensure that application-level data is recoverable. When a memory node fails, the memory manager deregisters the node's regions from the global pool of far memory. However, erasure-coding recovery of the node's regions is initiated by a compute node when the compute node unsuccessfully tries to read or write a span belonging to the failed memory node. If an application thread on a compute node tries to read a span that is currently being recovered, the read will use Carbink's degraded read protocol (§3.5), reconstructing the span using data from other spans and parity blocks.

3.2 Remotable Pointers

Like AIFM, Carbink exposes far memory through C++-level smart pointers. However, as shown in Figure 2, Carbink uses a different pointer encoding to represent span information.

(a) Local object.



(b) Far object.

Field	Meaning
Present	Is the object in local RAM or far RAM?
Lock	Is the object (spin)locked by a thread?
Shared	Is the pointer a unique pointer or a shared pointer?
Moving	Is the object being moved by a background thread?
Evicting	Is the object being evicted by a background thread?
Hotness	Is the object frequently accessed?

(c) Field semantics.

Figure 2: Carbink's `RemUniquePtr` representation. In contrast to AIFM [44], Carbink does not embed information about a data structure ID or an object size. Instead, Carbink embeds span metadata (namely, a Region ID and a Span ID) to associate a pointed-to object with its backing span.

A Carbink `RemUniquePtr` has the same size as a traditional `std::unique_ptr` (i.e., 8 bytes). The **P**resent bit indicates whether the pointed-to object resides in local RAM. The **S**hared bit indicates whether a pointer implements unique-pointer semantics or shared-pointer semantics; the former only allows a single reference to the pointed-to object. The **L**ock, **M**oving, and **E**victing bits are used to synchronize object accesses between application threads and Carbink's background threads (§3.6). The **H**otness byte is consulted by the background threads when deciding whether an object is cold (and thus a priority for eviction).

If an object is local, the local virtual address of the object is directly embedded in the pointer. If an object has been evicted, the pointer describes how to locate the object. In particular, the Obj ID indicates the location of an object within a particular span; the Span ID identifies that span; and the Region ID denotes the far memory region that contains the span.

Carbink supports two smart pointer types: `RemUniquePtr`, which only allows one reference to the underlying object, and `RemSharedPtr`, which allows multiple references. When moving or evicting an object, Carbink's background threads need a way to locate and update the smart pointer(s) which reference the object. To do so, Carbink uses AIFM's approach of embedding a "reverse pointer" in each object; the reverse pointer points to the object's single `RemUniquePtr`, or to the first `RemSharedPtr` that references the object. An individual `RemSharedPtr` is 16 bytes large, with the last 8 bytes storing a pointer that references the next `RemSharedPtr` in the list. Thus, Carbink's runtime can find all of an object's `RemSharedPtrs` by discovering the first one via the object's reverse pointer, and then iterating across the linked list.

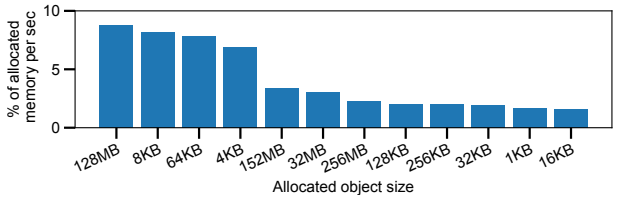


Figure 3: Allocation sizes in our production workloads.

3.3 Span-Based Memory Management

Local memory management: A span is a contiguous set of pages that contain objects of the same size class. Carbink supports 86 different size classes, and aligns each span on an 8KB boundary; Carbink borrows these configuration parameters from TCMalloc [21, 24], which observed these parameters to reduce internal fragmentation. When an application allocates a new object, Carbink tries to round the object size up to the nearest size class and assign a free object slot from an appropriate span. If the object is bigger than the largest size class, Carbink rounds the object size up to the nearest 8KB-aligned size, and allocates a dedicated span to hold it.

To allocate spans locally, Carbink uses a *local page heap*. The page heap is an array of free lists, with each list tracking 8KB-aligned free spans of a particular size (e.g., 2MB, 4MB, etc.). If Carbink cannot find a free span big enough to satisfy an allocation request, Carbink allocates a new span, using `mmap()` to request 2MB huge pages from the OS.

Allocating and deallocating via the page heap is mutex-protected because application threads may issue concurrent allocations or deallocations. To reduce contention on the page heap, each thread reserves a private (i.e., thread-local) cache of free spans for each size class. Carbink also maintains a global cache of free lists, with each list having its own spinlock. When a thread wants to allocate a span whose size can be handled by one of Carbink's predefined size classes, the thread first tries to allocate from the thread-local cache, then the global cache, and finally the page heap. For larger allocation requests, threads allocate spans directly from the page heap.

Carbink associates each span with several pieces of metadata, including an integer that describes the span's size class, and a bitvector that indicates which object slots are free. To map a locally-resident object to its associated span metadata, Carbink uses a two-level radix tree called the *local page map*. The lookup procedure is similar to a page table walk: the first 20 bits of an object's virtual address index into the first-level radix tree table, and the next 15 bits index into a second-level table. The same mapping approach allows Carbink to map the virtual address of a locally-resident span to its metadata.

Far memory management: On a compute node, local spans contain a subset of an application's memory state. The rest of that state is stored in far spans that live in far memory regions. Recall from Figure 2b that a Carbink pointer to a non-local object embeds the object's Region ID and Span ID.

To allocate or deallocate a region, a compute node sends a request to the memory manager. A single Carbink region is 1GB or larger, since Carbink targets applications whose total memory requirements are hundreds or thousands of GBs. Upon successfully allocating a region, the compute node updates a *region table* which maps the Region ID of the allocated region to the associated far memory node.

A compute node manages far spans and far regions using additional data structures that are analogous to the ones that manage local spans. A *far page heap* handles the allocation and deallocation of far spans belonging to allocated regions. A *far page map* associates a far Span ID with metadata that (1) names the enclosing region (as a Region ID) and (2) describes the offset of the far span within that region.

Each application thread has a private far cache; Carbink also maintains a global far cache that is visible to all application threads. To swap out a local span of size *s*, a compute node must first use the far page heap (or a far cache if possible) to allocate a free far span of size *s*. Similarly, after a compute node swaps in a far span, the node deallocates the far span, returning the far span to its source (either the far page heap or a far cache).

Span filtering and swapping: The Carbink runtime executes *filtering threads* that iterate through the objects in locally-resident spans and move those objects to different local spans. Carbink's object shuffling has two goals.

- First, Carbink wants to create *hot spans* (containing only hot objects) and *cold spans* (containing only cold ones); when local memory pressure is high, Carbink's *eviction threads* prefer to swap out spansets containing cold spans. Carbink tracks object hotness using GC-style read/write barriers [4, 23]. Thus, by the time that a filtering thread examines an object, the Hotness byte in the object's pointer (see Figure 2) has already been set. Upon examining the Hotness byte, a filtering thread updates the byte using the CLOCK algorithm [12].
- Second, object shuffling allows Carbink to garbage-collect dead objects by moving live objects to new spans and then deallocating the old spans. During eviction, Carbink utilizes efficient one-sided RMA writes to swap spansets out to far memory nodes; this approach allows Carbink to avoid software-level overheads (e.g., associated with thread scheduling) on the far node.

From the application's perspective, object movement and spanset eviction are transparent. This transparency is possible because each object embeds a reverse pointer (§3.2) that allows filtering threads and evicting threads to determine which smart pointers require updating.

Carbink swaps far memory into local memory at the granularity of a span. As with swap-outs, Carbink uses one-sided RMAs for swap-ins. Swapping at the granularity of a span simplifies far memory management, since compute nodes only have to remember how spans map to memory nodes (as opposed to how the much larger number of *objects* map to memory nodes). However, swapping in at span granularity instead of object granularity has a potential disadvantage: if a compute node swaps in a span containing multiple objects, but only uses a small number of those objects, then the compute node will have wasted network bandwidth (to fetch the unneeded objects) and CPU time (to update the remotable pointers for those unneeded objects). We collectively refer to these penalties as *swap-in amplification*.

To reduce the likelihood of swap-in amplification, Carbink's filtering and eviction threads prioritize the scanning and eviction of spansets containing large objects. The associated spans contain fewer objects per span; thus, swapping in these spans will reduce the expected number of unneeded objects. Figure 3 shows that, for our production workloads, large objects occupy the majority of memory. Moreover, most hot objects are small; for example, in our company's geo-distributed database [13], roughly 95% of accesses involve objects smaller than 1.8KB. As a result, an eviction scheme which prioritizes large-object spansets is well-suited for our target applications.

In Carbink, a local span has a three-state lifecycle. A span is first *created* due to a swap-in or local allocation. The span transitions to the *filtering* state upon being examined by filtering threads. Once filtering completes, those spans transition to the *evicting* state when evicting threads begin to swap out spansets. The transition from created to filtering to evicting is fixed, and determines which Carbink runtime threads race with application threads at any given moment (§3.6).

3.4 Fault Tolerance via Erasure Coding

Erasure coding provides data redundancy with lower storage overhead than traditional replication. However, the design space for erasure coding schemes is more complex. Carbink seeks to minimize both average and long-tail access penalties for far objects; per our fault model (§3.1), Carbink also wants to efficiently recover from the failure of memory nodes. Achieving these goals forced us to make careful decisions involving coding granularity, parity recalculation, and cross-node transport protocols.

Coding granularity: To motivate Carbink's decision to erasure-code at the spanset granularity, first consider an approach that erasure-codes individual spans. In this approach, to swap out a span, a compute node breaks the span into data fragments, generates the associated parity fragments, and then writes the entire set of fragments (data+parity) to remote nodes. During the swap-in of a span, a compute node must fetch multiple fragments to reconstruct the target span.

This scheme, which we call EC-Split, is used by Hydra [29]. With EC-Split, handling the failure of memory nodes during swap-out or swap-in is straightforward: the compute node who is orchestrating the swap-out or swap-in will detect the memory node failure, select a replacement memory node, trigger span reconstruction, and then restart the swap-in or

Schemes	EC data fragment size	Network transport	Parity computation	Defragmentation
EC-Split (Hydra [29])	Span chunk	RMA in & out	Local	N/A
EC-2PC	Full span	RMA in, RPC out (+updating parity via 2PC)	Remote	N/A
EC-Batch Local (**Carbink**)	Full span	RMA in & out	Local	Remote compaction
EC-Batch Remote (**Carbink**)	Full span	RMA in & out (+parallel 2PC for compaction)	Local (swap-out)+ Remote (compaction)	Remote compaction

Table 1: The erasure-coding approaches that we study.

swap-out. The disadvantage of EC-Split is that, to reconstruct a single span, a compute node must contact multiple memory nodes to pull in all of the needed fragments. This requirement to contact multiple memory nodes makes the swap-in operation vulnerable to stragglers (and thus high tail latency[2]). This requirement also frequently prevents a compute node from offloading computation to memory nodes; unless a particular object is small, the object will span multiple fragments, meaning that no single memory node will have a complete local copy of the object.

An alternate approach is to erasure-code across a group of equal-sized spans. We call such a group a *spanset*. In this approach, each span in the spanset is treated as a fragment, with parity data computed across all of the spans in the set. To reconstruct a span, a compute node merely has to contact the single memory node which stores the span. Carbink uses this approach to minimize tail latencies.

Parity updating: Erasure-coding at the spanset granularity but swapping in at the span granularity does introduce complications involving parity updates. The reason is that swapping in a span s leaves an invalid, span-sized hole in the backing spanset; the hole must be marked as invalid because, when s is later swapped out, s will be swapped out as part of a new spanset. The hole created by swapping in s causes fragmentation in the backing spanset. Determining how to garbage-collect the hole and update the relevant parity information is non-trivial. Ideally, a scheme for garbage collection and parity updating would not incur overhead on the critical path of swap-ins or swap-outs. An ideal scheme would also allow parity recalculations to occur at either compute nodes or memory nodes, to enable opportunistic exploitation of free CPU resources on both types of nodes.

Cross-node transport protocols: In systems like RAMCloud [39], machines use RPCs to communicate. RPCs involve software-level overheads on both sides of a communication. Carbink avoids these overheads by using one-sided RMA, avoiding unnecessary thread wakeups on the receiver. However, in and of itself, RMA does not automatically solve the consistency issues that arise when offloading parity calculations to remote nodes (§3.4.2).

Throughout the paper, we compare Carbink's erasure-coding approach to various alternatives.

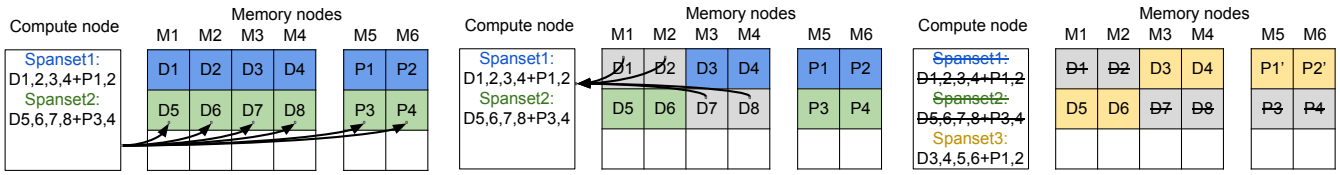
[2]Hydra [29] and EC-Cache [42] try to minimize straggler-induced latencies by contacting $k+\Delta$ memory nodes instead of the minimum k, using the first k responses to reconstruct an object. This approach increases network traffic and compute-node CPU overheads.

- **EC-Split** is Hydra's approach, which erasure-codes at the span granularity, swaps data using RMA, and synchronously recalculates parity at compute nodes when swap-outs occur. Fragmentation within an erasure-coding group never occurs, as a span is swapped in and out as a full unit.
- **EC-2PC** erasure-codes using spansets, and uses RMA to swap in at the span granularity. During a swap-out (which happens at the granularity of a span), EC-2PC writes the updated span to the backing memory node; the memory node then calculates the updates to the parity fragments, and sends the updates to the relevant memory nodes which store the parity fragments. To provide crash consistency for the update to the span and the parity fragments, EC-2PC implements a two-phase commit protocol using RPCs. There is no fragmentation within an erasure-coding group because swap-ins and swap-outs both occur at the span granularity.
- **EC-Batch Local** and **EC-Batch Remote** are the approaches used by Carbink. Both schemes erasure-code at spanset granularity, using RMA for swap-in as well as swap-out. Swap-ins occur at the granularity of a span, but swap-outs occur at the granularity of spansets (§3.4.1); thus, both EC-Batch approaches deallocate a span's backing area in far memory upon swapping that span into a compute node's local RAM. The result is that swap-ins create dead space on a remote memory node. Both EC-Batch schemes reclaim dead space and recalculate parity data using asynchronous garbage collection. EC-Batch Local always recalculates parity on compute nodes, whereas EC-Batch Remote can recalculate parity on compute nodes or memory nodes. When EC-Batch Remote offloads parity computations to remote nodes, it employs a parallel commit scheme that avoids the latencies of traditional two-phase commit (§3.4.2).

Table 1 summarizes the various schemes. We now discuss EC-Batch Local and Remote in more detail.

3.4.1 EC-Batch: Swapping

Swapping out: In both varieties of EC-Batch, a spanset contains multiple spans of the same size. At swap-out time, a compute node writes a *batch* (i.e., a spanset and its parity fragments) to a memory node. Figure 4a shows an example. In that example, the compute node has two spansets: spanset1 (consisting of data spans $< D1, D2, D3, D4 >$ and parity fragments $< P1, P2 >$), and spanset2 (containing data spans $< D5, D6, D7, D8 >$ and parity fragments $< P3, P4 >$). Carbink uses Reed-Solomon codes [43] to create parity data, and prioritizes the eviction of spansets that contain cold spans



(a) Swapping out spans and parity in a batch. **(b)** Swapping in individual spans. **(c)** Compacting spansets to reclaim space.

Figure 4: EC-Batch swapping-out, swapping-in, and far compaction.

(§3.3). Neither variant of EC-Batch updates spansets in place, so eviction may require a compute node to request additional far memory regions from the memory manager.

Swapping in: When an application tries to access an object that is currently far, the Carbink runtime inspects the application pointer and extracts the Span ID (see Figure 2b). The runtime consults the far page map (§3.3) to discover which remote node holds the span. Finally, the runtime initiates the appropriate RMA operation to swap in the span.

However, swapping in at the span granularity creates *remote fragmentation*. In Figure 4b, the compute node in the running example has pulled four spans ($D1$, $D2$, $D7$, and $D8$) into local memory. Any particular span lives exclusively in local memory or far memory; thus, the swap-ins of the four spans creates dead space on the associated remote memory nodes. If Carbink wants to fill (say) $D1$'s dead space with a new span $D9$, Carbink must update parity fragments $P1$ and $P2$. For a Reed-Solomon code, those parity fragments will depend on both $D1$ and $D9$.

There are two strawman approaches to update $P1$ and $P2$:

- The compute node can read $D1$ into local memory, generate the parity information, and then issue writes to $P1$ and $P2$.
- Alternatively, the compute node can send $D9$ to memory node $M1$, and request that $M1$ compute the new parity data and update $P1$ and $P2$.

The second approach requires a protocol like 2PC to guarantee the consistency of data fragments and parity fragments; without such a protocol, if $M1$ fails after updating $P1$, but before updating $P2$, the parity information will be out-of-sync with the data fragments.

The first approach, in which the compute node orchestrates the parity update, avoids the inconsistency challenges of the second approach. If a memory node dies in the midst of a parity update, the compute node will detect the failure, pick a new memory node to back the parity fragment, and retry the parity update. If the compute node dies in the midst of the parity update, then the memory manager will simply deallocate all regions belonging to the compute node (§3.1).

Unfortunately, both approaches require a lot of network bandwidth to fill holes in far memory. To reclaim one vacant span, the first approach requires three span-sized transfers—the compute node must read $D1$ and then write $P1$ and $P2$. The second approach requires two span-sized transfers to update $P1$ and $P2$. To reduce these network overheads, Carbink performs *remote compaction*, as described in the next section.

3.4.2 EC-Batch: Remote Compaction

Carbink employs *remote compaction* to defragment far memory using fewer network resources than the two strawmen above. On a compute node, Carbink executes several *compaction threads*. These threads look for "matched" spanset pairs; in each pair, the span positions containing dead space in one set are occupied in the other set, and vice versa. For example, the two spansets in Figure 4b are a matched pair. Once the compaction threads find a matched pair, they create a new spanset whose data consists of the live spans in the matched pair (e.g., $< D3, D4, D5, D6 >$ in Figure 4b). The compaction threads recompute and update the parity fragments $P1'$ and $P2'$ using techniques that we discuss in the next paragraph. Finally, the compaction threads deallocate the dead spaces in the matched pair (e.g., $< D1, D2, D7, D9, P3, P4 >$ in Figure 4b), resulting in a situation like the one shown in Figure 4c. Carbink's compaction can occur in the background, unlike the synchronous parity updates of EC-2PC which place consensus activity on the critical path of swap-outs.

So, how should compaction threads update parity information? Carbink uses Reed-Solomon codes over the Galois field $GF(2^8)$. The new parity data to compute in Figure 4c is therefore represented by the following equations on $GF(2^8)$:

$$P1' - P1 = A_{1,1}(D5 - D1) + A_{2,1}(D6 - D2)$$
$$P2' - P2 = A_{1,2}(D5 - D1) + A_{2,2}(D6 - D2)$$

where $A_{i,j}$ $(i \in \{0,1,2,3\}, j \in \{0,1\})$ are fixed coefficient vectors in the Reed-Solomon code. Carbink provides two approaches for updating the parity information.

- In EC-Batch Local, the compute node that triggered the swap-out orchestrates the updating of parity data. In the running example, the compute node asks $M1$ to calculate the span delta $D5 - D1$, and asks $M2$ to calculate the span delta $D6 - D2$. After retrieving those updates, the compute node determines the parity deltas (i.e., $P1' - P1$ and $P2' - P2$) and pushes those deltas to the parity nodes $M5$ and $M6$.
- In EC-Batch Remote, the compute node offloads parity recalculation and updating to memory nodes. In the running example, the compute node asks $M1$ to calculate the span delta $D5 - D1$, and $M2$ to calculate the span delta $D6 - D2$. The compute node also asks $M1$ and $M2$ to calculate partial parity updates (e.g., $A_{1,1}(D5 - D1)$ and $A_{1,2}(D5 - D1)$ on $M1$). $M1$ and $M2$ are then responsible for sending the partial parity updates to the parity nodes. For example, $M1$ sends $A_{1,1}(D5 - D1)$ to $M5$, and $A_{1,2}(D5 - D1)$ to $M6$.

In EC-Batch Local, recovery from memory node failure is orchestrated by the compute node in a straightforward way, as in EC-Split (§3.4). In EC-Batch Remote, a compute node performs remote compaction by offloading parity updates to memory nodes. The compute node ensures fault tolerance for an individual compaction via 2PC. However, the compute node aggressively issues compaction requests in parallel. Two compactions (i.e., two instance of the 2PC protocol) are safe to concurrently execute if the compactions involve different spansets; the prepare and commit phases of the two compactions can partially or fully overlap.

On a compute node, Carbink's runtime can monitor the CPU load and network utilization of remote memory nodes. The runtime can default to remote compaction via EC-Batch Local, but opportunistically switch to EC-Batch Remote if spare resources emerge on memory nodes. During a switch to a different compaction mode, Carbink allows all in-flight compactions to complete before issuing new compactions that use the new compaction mode.

The strawmen defragmentation schemes in Section 3.4.1 require two or three span-sized network transfers to recover one dead span. In the context of Figure 4, EC-Batch Local recovers four dead spans using four span-sized network transfers. EC-Batch Remote requires four span-sized network transfers (plus some small messages generated by the consistency protocol) to recover four dead spans.

3.5 Failure Recovery

Carbink handles two kinds of memory node failures: planned and unplanned. Planned failures are scheduled by the cluster manager [51, 52] to allow for software updates, disk reformatting, and so on. Unplanned failures happen unexpectedly, and are caused by phenomena like kernel panics, defective hardware, and power disruptions.

Planned failures: When the cluster manager decides to schedule a planned failure, the manager sends a warning notification to the affected memory nodes. When a memory node receives such a warning, the memory node informs the memory manager. In turn, the memory manager notifies any compute nodes that have allocated regions belonging to the soon-to-be-offline memory node. Those compute nodes stop swapping-out to the memory node, but may continue to swap-in from the node as long as the node is still alive. Meanwhile, the memory manager orchestrates the migration of regions from the soon-to-be-offline memory node to other memory nodes. When a particular region's migration has completed, the memory manager informs the relevant compute node, who then updates the local mapping from Region ID to backing memory node. At some point during this process, the memory manager may also request non-failing memory nodes to contribute additional regions to the global pool of far memory.

Unplanned Failures: On a compute node, the Carbink runtime is responsible for detecting the unplanned failure of a memory node. The runtime does so via connection timeouts or more sophisticated leasing protocols [15, 16]. Upon detecting an unplanned failure, the runtime spawns background threads to reconstruct the affected spans using erasure coding. The runtime is also responsible for allowing application threads to read spans whose recovery is in-flight.

Span reconstruction: To reconstruct the spans belonging to a failed memory node M_{fail}, a compute node first requests a new region from the memory manager. Suppose that the new region is provided by memory node M_{new}. The compute node iterates through each lost spanset associated with M_{fail}; for each spanset, the compute node tells M_{new} which external spans and parity fragments to read in order to erasure-code-restore M_{fail}'s data. As the relevant spans are restored, a compute node can still swap in and remotely compact those spans. However, the swap-in and remote compaction activity will have to synchronize with recovery activity (§3.6).

In EC-Batch Local, when a compute node detects a memory node failure, the compute node cancels all in-flight compactions involving that node. A compute node using EC-Batch Remote does the same; however, for each canceled compaction, the compute node must also instruct the surviving memory nodes in the 2PC group to cancel the transaction.

The data and parity for a swapped-out spanset reside on multiple memory nodes. As a compute node recovers from the failure of one of the nodes in that group, another node in the group may fail. As long as the number of failed nodes does not exceed the number of parity nodes, Carbink can recover the spanset. The reason is that all of the information needed to recover is stored on a compute node, e.g., in the far page heap (§3.3). Due to space limitations, we omit a detailed explanation of how Carbink deals with concurrent failures.

Degraded reads: During the reconstruction of an affected span, application threads may try to swap in the span. The runtime handles such a fetch using a *degraded read* protocol. For example, consider Figure 4a. Suppose that $M1$ fails unexpectedly, and while the Carbink runtime is recovering $M1$'s spans ($D1$ and $D5$), an application thread tries to read an object residing in $D1$. The runtime will swap in data spans $D2$, $D3$, and $D4$, as well as parity fragment $P1$, and then reconstruct $D1$ via erasure coding. Degraded reads ensure that the failure of a memory node merely slows down an application instead of blocking it. In Section 5.3, we show that application performance only drops for 0.6 seconds, and only suffers a throughput degradation of 36% during that time.

Network bandwidth consumption: During failure recovery, Carbink consumes the same amount of network bandwidth as Hydra. For example, suppose that both Hydra and Carbink use RS4.2 encoding and have 4 spans, with a span stored on each of 4 memory nodes. In Hydra, a single node failure will lose four 1/4th spans. Reconstructing each 1/4th span will require the reading of four 1/4th span/parity regions from the surviving nodes, resulting in an aggregate network bandwidth requirement of 1 full span. So, reconstructing four 1/4th spans

will require an aggregate network bandwidth of 4 full spans. In Carbink, the failure of a single memory node results in the loss of 1 full span. To recover that span, Carbink (like Hydra) must read 4 span/parity regions.

3.6 Thread Synchronization

On a compute node, the main kinds of Carbink threads are applications threads (which read objects, write objects, and swap in spans), filtering threads (which move objects within local spans), and eviction threads (which reclaim space by swapping local spansets to far memory). At any given time, a span may be in one of two concurrency regimes (§3.3): the span is either accessible to application threads and filtering threads, or to application threads and eviction threads. In both regimes, Carbink has to synchronize how the relevant threads update Carbink's smart pointers (§3.2).

At a high level, Carbink uses an RCU locking scheme that is somewhat reminiscent of AIFM's approach [44]. Due to space restrictions, we merely sketch the design. Carbink optimizes for the common case in which a span is only being accessed by an application thread. In this common case, an application thread grabs an RCU read lock on the pointer via the pointer's `Deref()` method, as shown in Listing 1. The thread sees that either (1) the **P**resent bit is not set, in which case the Carbink runtime issues an RMA read to swap in the appropriate span; (2) alternatively, the thread sees that the **P**resent bit is set, but the **M** and **E** bits are unset. In the second case, `Deref()` can just return a normal pointer back to the application. The application can be confident that concurrent filtering or evicting threads will not move or evict the object, because those threads cannot touch the object until application-level threads have released their RCU read locks via the `DerefScope` destructor (Listing 1).

The more complicated scenarios arise when the **P**resent bit is set and either the **M** or **E** bit are set as well. In this case, the (say) **M** bit has been set because the filtering thread set the bit and then called `SyncRCU()` (i.e., the RCU write waiting lock). The concurrent application thread and filtering thread essentially race to acquire the pointer's spinlock; if the application thread (i.e., `Deref()`) wins, it makes a copy of the object, clears **M**, releases the spinlock, and returns the address of the object copy to the application. Otherwise, if the filtering thread wins, it moves the object, clears **M**, and releases the spinlock. The losing thread has to retry the desired action. An analogous situation occurs if the **E** bit is set.

Carbink's eviction and remote compaction threads directly poll the network stack to learn about RMA completions and RPC completions. An application thread which has issued an RMA swap-in operation will yield, but a dedicated RMA poller thread detects when application RMAs have completed and awakens the relevant application threads. Polling avoids the overheads of context switching to new threads and notifying old threads that network events have occurred.

During recovery (§3.5), Carbink spawns additional threads to orchestrate the reconstruction of spans. Those threads acquire per-spanset mutexes which are also acquired by threads performing swap-ins, swap-outs, and remote compactions.

4 Implementation

Our Carbink prototype contains 14.3K lines of C++. It runs atop unmodified OSes, using standard POSIX abstractions for kernel-visible threads and synchronization. The runtime leverages the PonyExpress user-space network stack [35]. On a compute node, all threads in a particular application (both application-defined threads and Carbink-defined threads) execute in the same process. On a memory node, a Carbink daemon exposes far memory via RMAs or RPCs. We use Intel ISA-L v2.30.0 [25] for Reed-Solomon erasure coding.

Our current prototype has a simplified memory manager that is unreplicated, does not handle planned failures, and statically assigns memory nodes to compute nodes. Implementing the full version of the memory manager will be conceptually straightforward, since we can use off-the-shelf libraries for replicated state machines [1, 45] and cluster management [51, 52]. We also note that the experiments in §5 are insensitive to the performance of the memory manager, regardless of whether the manager is replicated or not. The reason is that memory allocations and deallocations (which must be routed through the memory manager) are rare and are not on the critical path of steady-state compute node operations like swap-in and swap-out.

To better understand the performance overheads of Carbink's erasure-coding approach, we built an AIFM-like [44] far memory system. That system uses remotable pointers like Carbink, but swaps in and out at the granularity of objects, and provides no fault tolerance. Like Carbink, it leverages the PonyExpress [35] user-space network stack. Our AIFM clone is 5.8K lines of C++.

5 Evaluation

In this section, we answer the following questions:

1. What is the latency, throughput, and remote memory usage of EC-Batch compared with the other fault tolerance schemes (§5.1 and §5.2)?
2. How does an unplanned memory node failure impact the performance of Carbink applications (§5.3)?
3. How does the performance of Carbink's span-based memory organization compare to the performance of an AIFM-like object-level approach (§5.4)?

Testbed setup: We deployed eight machines in the same rack, including one compute node and seven memory nodes; one of the memory nodes was used for failover. Each machine was equipped with dual-socket 2.2 GHz Intel Broadwell processors and a 50 Gbps NIC.

Fault tolerance schemes: Using the Carbink runtime, we compared our proposed EC-Batch schemes to four ap-

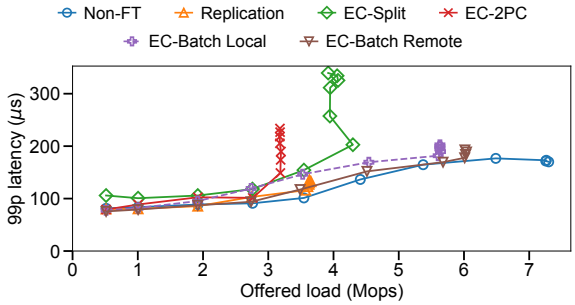


Figure 5: Microbenchmark load-latency curves.

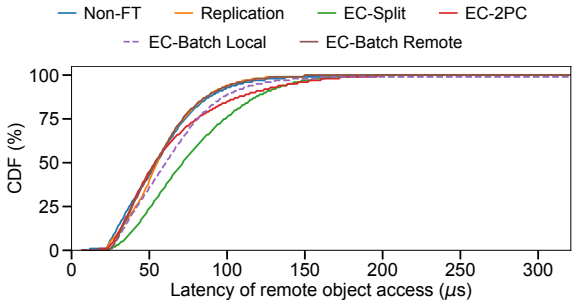

Figure 6: Latency distribution of remote object accesses in the microbenchmark under an offered load of 2 Mops.

proaches: Non-FT (a non-fault-tolerant scheme that used RMA to swap spans), Replication (which replicated spans on multiple nodes), EC-Split (the approach used by Hydra [29]), and EC-2PC (Table 1). We configured all fault tolerance schemes to tolerate up to two memory node failures. So, the Replication scheme replicated each swapped-out span on three memory nodes, whereas the EC schemes used six memory nodes—four held data, and two held RS4.2 parity bits [43]. EC-Batch spawned two compaction threads by default.

As mentioned in Section 4, we also built an AIFM-like far memory system. This system did not provide fault tolerance, but it provided a useful comparison with our Non-FT Carbink version.

Carbink borrows the span sizes that are used by TCMalloc (§3.3). These parameters have been empirically observed to reduce internal fragmentation. In our evaluation, EC-Batch (both Local and Remote) grouped four equal-size spans into a spanset, swapping out at the granularity of a spanset. Increasing spanset sizes would allow Carbink to issue larger batched RMAs, improving network efficiency. However, spansets whose evictions are in progress must be locked in local memory while RMAs complete; thus, larger spanset sizes would delay the reclamation of larger portions of local memory.

5.1 Microbenchmarks

To get a preliminary idea of Carbink's performance, we created a synthetic benchmark that wrote 15 million 1 KB objects (totalling 15 GB) to a remotable array. The compute node's local memory had space to store 7.5 GB of objects (i.e., half of the total set). By default, the compute node spawned 128

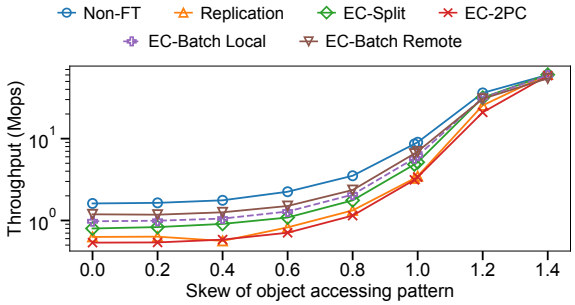

Figure 7: Impact of skew on throughput.

threads on 32 logical cores to access objects; the access pattern had a Zipfian-distributed [41] skew of 0.99. Such skews are common in real workloads for key/value stores [7].

Object access throughput and tail latency: Figure 5 shows the 99th-percentile latency with various object access loads. All of the fault-tolerant schemes eventually hit a "hockey stick" in tail latency growth when the schemes could no longer catch up with the offered load. EC-Batch Remote had the highest sustained throughput (6.0 Mops), which was 40% higher than the throughput of the state-of-the-art EC-Split (4.3 Mops). EC-Batch Local achieved 5.6 Mops, which was 30% higher than EC-Split. EC-Split had worse performance because it had to issue four RMA requests to swap in one span; thus, EC-Split quickly became bottlenecked by network IO. In contrast, EC-Batch only issued one RMA request per swap-in.

EC-Batch Remote had 18%-29% lower tail latency than EC-Split under the same load (before reaching the "hockey-stick"). The reason was that EC-Split's larger number of RMAs per swap-in left EC-Split more vulnerable to stragglers [29]. Also recall that EC-Batch can support computation offloading [3, 27, 44, 57], which is hard with EC-Split (§3.4).

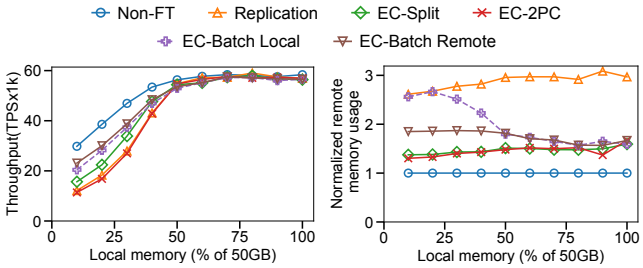
EC-2PC had the worst throughput because it relied on costly RPCs and 2PC protocols to swap out spans. Thus, EC-2PC could not reclaim local memory as fast as other schemes. The Replication scheme was bottlenecked by network bandwidth, since every swap-out incurred a 3× network write penalty; in contrast, EC-based schemes used RS4.2 erasure coding to reduce the write penalty to 1.5×.

Latency distribution of remote object accesses: Figure 6 shows the latency of accessing remote objects under 2 Mops of offered load. With this low offered load, Replication and EC-Batch Remote achieved similar access latencies as Non-FT because none of the schemes were bottlenecked by network bandwidth. EC-Batch Local had slightly higher remote access latencies. However, EC-Split had significantly higher access latencies (e.g., at the median and tail) than EC-Batch Local and Remote; the reason was that EC-Split issued four times as many network IOs and thus was more sensitive to stragglers. EC-2PC's tail latency was slightly higher than that of EC-Batch Local and Remote due to the overhead of costly RPCs and 2PC traffic.

Impact of skewness: Figure 7 shows how the skewness of object accesses impacted throughput. EC-Batch Remote and

	# Compaction threads	Norm. remote mem usage	Avg. # remote logical cores	Avg. BW (Gbps)
EC-Batch Local	1	2.54	0.23	1.27
	2	2.35	0.53	1.64
	3	2.28	0.56	1.76
EC-Batch Remote	1	1.89	1.97	2.98
	2	1.83	2.10	3.15
	3	1.74	2.27	3.40
W/o compaction	0	3.03	–	–

Table 2: Remote resource usage in the microbenchmark. The remote memory usage is normalized with respect to the usage of Non-FT. The number of remote logical cores and the network bandwidth are averaged across all six memory nodes.



(a) Transaction throughput. **(b)** Remote memory usage.

Figure 8: Transactional KV-store evaluation.

Local performed best due to their more efficient swapping approaches. However, the throughput of all schemes increased with higher skewness. The reason is that high skewness led to a smaller working set and thus a higher likelihood that hot objects were locally resident. In these scenarios, schemes with faster swapping were not rewarded as much.

Remote resource usage with compaction: Table 2 shows the impact of compaction on the average memory, CPU, and bandwidth usage per memory node. Without compaction, EC-Batch used 3.03× remote memory (normalized with respect to Non-FT memory consumption). With two local compaction threads, EC-Batch Remote's memory overhead reduced to 1.83×. The memory reduction was at the expense of 2.1 cores and 3.15 Gbps bandwidth on each memory node. With more compaction threads, Carbink could further reduce memory usage at the cost of higher CPU and bandwidth utilization. That being said, we note that the synthetic microbenchmark application represented an extreme case of remote CPU and network usage, since the workload accessed objects without actually computing on them.

EC-Batch Remote vs. Local: EC-Batch Remote had higher throughput and lower tail latency than EC-Batch Local (Figure 5). This was because EC-Batch Local's compaction required (1) local CPUs for parity computation and (2) network bandwidth for transferring span deltas and parity updates, leaving fewer local resources for application threads and RMA reads. Because of EC-Batch Remote's faster compaction, EC-Batch Remote also used 28%-34% less remote memory than EC-Batch Local (Table 2). However, EC-Batch Remote consumed more remote CPUs (2.10 vs. 0.53 cores) and more network bandwidth (3.15 vs. 1.64 Gbps) than Local. In practice, the Carbink runtime could transparently switch between EC-Batch Remote and Local based on an application developer's policy about resource/performance trade-offs.

5.2 Macrobenchmarks

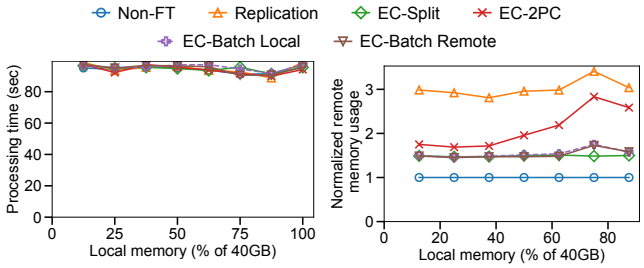
We evaluated Carbink using two memory-intensive applications that would benefit from remote memory: an in-memory transactional key-value store, and a graph processing algorithm. The two applications exhibited different patterns of object accesses, and had different working set behaviors.

Transactional KV-store: This application implemented a transactional in-memory B-tree, exposing it via a key/value interface similar to that of MongoDB [37]. Each remotable object was a 4 KB value stored in a B-tree leaf. The application spawned 128 threads, and each thread processed 20 K transactions. The compute node provisioned 32 logical cores, with the application overlapping execution of the threads for higher throughput [26, 38, 44, 56]. Each transaction contained three reads and three writes, similar to the TPC-A benchmark [53]. Each update created a new version of a particular key's value; asynchronously, the application trimmed old versions. The maximum working set size during the experiment was roughly 50 GB.

Throughput: Figure 8a shows the KV-store throughput when varying the size of local memory (normalized as a fraction of the maximum working set size). In scenarios with less than 50% local memory, EC-Batch Remote achieved higher transactions per second (TPS) than all other fault tolerance schemes. For example, TPS for EC-Batch Remote was 1.5%-48% higher than that of EC-Split; this was because EC-Batch only needed one RMA request to swap in a span. EC-Batch Remote was at most 29% slower than Non-FT, mainly due to the additional parity update required for fault tolerance. EC-Batch Local was at most 13% slower than EC-Batch Remote. EC-2PC performed the worst among EC schemes.

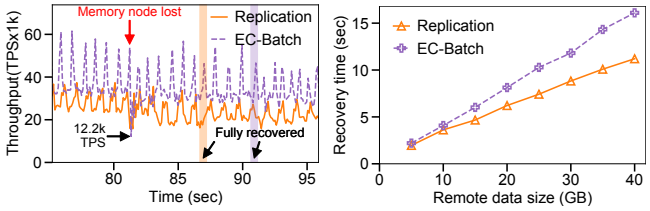
All schemes achieved similar throughput when the local memory size was above 50%. The reason was that the *average* working set size of the workload was only half the size of the *maximum* memory usage. The maximum memory usage only occurred when the B-Tree had fallen very behind in culling old versions of objects.

Remote memory usage: Figure 8b plots remote memory usage as a function of local memory sizes; remote memory usage is normalized with respect to that of Non-FT. Compared to EC-Split, EC-Batch Remote and Local used up to 35% and 93% more remote memory, respectively. EC-Batch schemes defragmented remote memory using compaction, but when local memory space was less than 50%, remote compaction could not immediately defragment the spanset holes created by frequent span swap-ins. As local memory grew larger, span fetching became less frequent, making it



(a) Processing time. **(b)** Remote memory usage.

Figure 9: Graph processing evaluation.



(a) KV-store TPS over time. **(b)** Microbenchmark recovery.

Figure 10: Failure recovery evaluation.

easier for remote compaction to reclaim space. In this less hectic environment, EC-Batch's remote memory usage was similar to that of the other erasure-coding schemes.[3]

Graph processing: We implemented a connected-components algorithm [50] that found all sets of linked vertices in a graph. This kind of algorithm is critical to various Google services. We evaluated the algorithm using the Friendster graph [30] which contained 65 million vertexes and 1.8 billion edges. In the graph analysis code, each vertex's adjacency list was referenced via remotable pointers. The total size of the objects stored in Carbink was roughly 40 GB. The application used 80 application threads that ran atop 80 logical cores. In our experimental results, the reported processing times exclude graph loading, since graph loading is dominated by disk latencies.

Figure 9a shows that all schemes had similar processing times as Non-FT, regardless of the local memory size. The reason was that the graph application had a high compute-to-network ratio—the application fetched all neighbors associated with each vertex and then spent non-trivial time enumerating each neighbor and computing on them. As a result of this good spatial locality and high "think time," the graph application did not incur frequent data swapping, and thus avoided fault tolerance overhead that the KV-store could not.

Figure 9b shows that EC-Batch Local and Remote had similar remote memory usage as EC-Split: 15%-39% lower than EC-2PC and roughly 50% lower than Replication. All EC-based schemes had lower remote memory overheads than Replication because the erasure coding only incurred a 1.5× space overhead for the extra parity data.

EC-2PC used more memory than EC-Batch because the graph workload randomly fetched diverse-sized spans. The random fetch sizes reflected the fact that different vertices had different sizes for their adjacency lists. This lack of span size locality hindered dead space reclamation, since EC-2PC had to wait longer for all of the spans in an erasure-coding group to be swapped in. EC-Batch avoided this problem by bundling equal-sized spans into the same spanset and using remote compaction.

[3]The remote memory usage of triple-replication was slightly less than 3× the usage of Non-FT because Non-FT could swap out memory faster during periods of high local memory pressure.

5.3 Failure Recovery

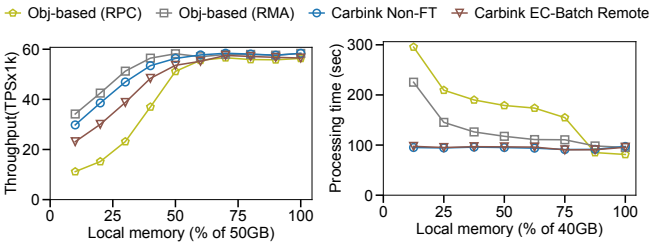
We measured the recovery time for an unplanned memory node failure in the KV-store, the graph processor, and the microbenchmark application. For the graph application, all schemes achieved similar processing time during unplanned failures; thus, in the text below, we focus on the KV-store and the microbenchmark.

Transactional KV-store: Figure 10a shows the KV-store throughput of Replication and EC-Batch Local, with a data point collected every 100 ms before and after an unplanned memory node failure. Upon detecting the failure, EC-Batch Local immediately reconstructed the lost data on a pre-configured failover memory node. We gave the KV-store 15 GB of local memory, equivalent to 30% of the 50 GB maximum working set size.

The throughput of both schemes fluctuated sinusoidally because the KV-store frequently tried to swap in remote objects, but the swap-ins sometimes had to synchronously block until eviction threads could reclaim enough local memory. After a memory node failed, EC-Batch needed 0.6 seconds to restore normal throughput, while replication needed 0.3 seconds. This is because, during failure recovery, an EC-Batch read that targeted an affected span used the degraded read protocol which uses more bandwidth than a normal read (§3.5); in contrast, a Replication read that targeted an affected span consumed the same amount of bandwidth as a read during non-failure-recovery. During recovery, the throughput of Replication and EC-Batch dropped an average of 35% and 36% respectively.

EC-Batch required 9.7 seconds to fully regenerate the lost data on the failover node, taking 1.7× longer than Replication. This difference arose because, in EC-Batch, the new memory node read 4× span/parity information involving the lost data and computed erasure codes to reconstruct the lost data. In contrast, Replication lost more data per memory node, but only read one copy of the lost data. Note that with EC-Batch, degraded reads mostly happened during the first second of failure recovery; the skewed workload meant that a small number of objects were the targets of most reads, and once a hot object was pulled into local memory (perhaps by a degraded read), the object would not generate additional degraded reads.

Microbenchmark: Figure 10b shows recovery times as a function of the remote data size. The recovery time of EC-Batch increased almost linearly with the remote data size,



(a) KV-store application. **(b)** Graph application.

Figure 11: Application performance: AIFM-like object-based systems and Carbink.

with 0.6 GB/s recovery speed. This speed was 12%-44% slower than Replication due to the larger amount of recovery information that EC-Batch had to transfer around the network, and the computational overhead of generating erasure codes.

Prior work [10, 29, 58] also found that, during recovery, erasure-coding schemes had longer recovery times and worse performance degradation than replication schemes. However, this drawback only happens for unplanned failures which, in our production environment, are rare compared to planned failures; in an erasure-coding scheme, handling a *planned* failure just requires simple copying of the information on a departing memory node, and does not incur additional work to find parity information or recompute erasure coding. Thus, in our deployment setting where unplanned failures are rare, erasure-coding schemes (which have lower memory utilization than replication schemes) are very attractive.

5.4 Comparison with AIFM-like Systems

We compared span-based swapping in Carbink with the object-based approach used in AIFM [44]. We implemented two AIFM-like systems using our threading and network stack (§4). The first system used RPCs to swap individual objects, with the remote memory nodes tracking the object-to-remote-location mapping (as done in AIFM). Our second object-granularity swapping system used more-efficient RMAs to swap objects, and had compute nodes track the mapping between objects and their remote locations; recall that RMA is one-sided, so compute nodes could not rely on memory nodes to synchronously update mappings during swaps. Like the original AIFM, neither system provided fault tolerance.

Transactional KV-store: Figure 11a shows that, if local memory was too small to hold the average working set, Non-FT Carbink had 45%-167% higher throughput than the AIFM-like system with RPC. The reason is that, when local memory pressure was high, more swapping occurred, and the better efficiency of RMAs over RPCs became important. However, Non-FT Carbink achieved 5.6%-15% lower throughput than the object-based system with RMA. This was due to swap-in amplification. For example, Non-FT Carbink might swap in an 8KB span but only use one 4KB object in the span; this never happens in a system that swaps at an object granularity.

Graph processing: Figure 11b shows the graph application's processing time. When the local memory size was below 87.5%, Carbink performed 18%-58% faster than the object-based system with RMA. This is because, in the graph workload, 4% of large objects occupied 50% of the overall data set. Carbink prioritized swapping out large cold objects (§3.3), keeping most small objects in local memory and reducing the miss rate for those objects. In contrast, the object-based systems did not consider object sizes when swapping, leading to an increased miss rate for small objects. Note that, with larger local memories, all schemes had similar performance; indeed, when all objects fit into local memory, the object-based system with RPC slightly outperformed the rest because it did not require a dedicated core to poll for RMA completions.

6 Discussion

EC-Batch for paging-based systems: Carbink uses EC-Batch to transparently expose far memory via remotable pointers. However, EC-Batch can also be used to expose far memory via OS paging mechanisms [5, 22, 46]. In a traditional paging-based approach for far memory, a compute node swaps in and out at the granularity of a page. However, a compute node can use EC-Batch to treat each page as a span, such that pages are swapped out at the "pageset" granularity, and pages are swapped in at the page granularity.

Custom one-sided operations: EC-Batch requires memory nodes to calculate span deltas and parity updates (§3.4.2). In our Carbink prototype, memory nodes use separate threads to execute these calculations. However, memory nodes could instead implement them as custom one-sided operations in the network stack, such that the network stack itself performs the calculations, avoiding the need to context-switch to external threads. This approach has been used in prior work [6, 9, 35, 47, 48] to avoid thread scheduling overheads.

Designing the memory manager: We used a centralized manager because such a manager (1) simplified our overall design, and (2) made it easier to drive memory utilization high (because a centralized manager will have a global, accurate view of memory allocation metadata). A similarly-centralized memory manager is used by the distributed transaction system FaRM [16]. If the centralized manager became unavailable, Carbink could fall back to a decentralized memory allocation scheme like the one used by Hydra [29] or INFINISWAP [22].

The state maintained by the memory manager is not large. With 1 GB regions, we expect up to 500 regions in a typical memory node (similar to FaRM [16]). With thousands of memory nodes, the memory manager just needs to store a few MBs of state for region assignments.

Fault tolerance for compute nodes: In Carbink, a compute node does not share memory with other compute nodes. Thus, a Carbink application can checkpoint its own state without fear of racing with other compute nodes that modify the state being checkpointed. Checkpoint data could be placed in a

	Fast s/o	Low mem	Fast s/i	Interface	Coding granularity
On-disk rpl.	✗	✓	✓	Various	–
In-memory rpl.	✓	✗	✓	Various	–
Hydra [29]	✓	✓	✗	Paging	Split 4KB pages
Cocytus [10]	✓	✓	✗	KV-store	Across 4KB pages
BCStore [31]	✓	✓	✗	KV-store	Across objs
Hybrid [32]	✗	✗	✓	KV-store	Split 4KB pages
Carbink	✓	✓	✓	Remotable pointers	Across spans

Table 3: Comparison of existing fault-tolerant approaches for far memory. "Fast s/o" indicates whether a system can swap out at network/memory speeds. "Low mem" means that a system has relatively low memory pressure. "Fast s/i" refers to whether a system can swap in at network/memory speeds.

non-Carbink store, obviating the need to track how checkpointed spans move across Carbink memory nodes during compaction and invalidation. Alternatively, Carbink itself could store checkpoints, e.g., in the fault-tolerant address space of a well-known Carbink application whose sole purpose is to store checkpoints.

7 Related Work

Fault tolerance for far memory: Many far memory systems do not provide fault tolerance [2, 44, 55]. Of the systems that do, most replicate swapped-out data to local disks or remote ones [5, 22, 46]. Unfortunately, this approach forces application performance to bottleneck on disk bandwidth or disk IOPs during bursty workloads or failure recovery [29]. This behavior is unattractive, since a primary goal of a far memory system is to have applications run at *memory* speeds as much as possible.

Like Carbink, Hydra [29] is a far memory system that provides fault tolerance by writing erasure-coded local memory data to far RAM. Hydra uses the EC-Split coding approach that we describe in Section 3.4. As we demonstrate in Section 5, Carbink's erasure-coding scheme provides better application performance in exchange for somewhat higher memory consumption. Carbink's coding scheme also enables the offloading of computations to far memory nodes. Such offloading can significantly improve the performance of various applications [3, 27, 44, 57].

Fault tolerance for in-memory transactions and KV-stores: In-memory transaction systems typically provide fault tolerance by replicating data across the memory of multiple nodes [15, 16, 26]. These approaches suffer from the classic disadvantages of replication: double or triple storage overhead, and the associated increase in network traffic.

Recent in-memory KV-stores use erasure coding to provide fault tolerance. For example, Cocytus [10] and BCStore [31] only rely on in-memory replication to store small instances of metadata; object data is erasure-coded using a default page size of 4KB. Cocytus erasure-codes using a scheme that resembles EC-2PC (§3.4). To reduce the network utilization of a Cocytus-style approach, a BCStore compute node buffers outgoing writes; this approach allows the node to batch the computation of parity fragments (and thus issue fewer updates to remote data and parity regions). Batching reduces network overhead at the cost of increasing write latency.

Both Cocytus and BCStore rely on two-sided RPCs to manipulate far memory. RPCs incur software-level overheads involving thread scheduling and context switching on remote nodes. To avoid these costs, Carbink eschews RPCs for one-side RMA operations. Carbink also issues fewer parity updates than Cocytus; whereas Cocytus uses expensive 2PC to update parity information during every write, Carbink defers parity updates until compaction occurs on remote nodes (§3.4.2). Carbink's compaction approach is also more efficient than that of BCStore. BCStore's compaction algorithm performs actual copying of data objects on memory nodes, whereas Carbink compaction just manipulates span pointers inside of spanset metadata.

A far memory system could use both replication and erasure coding [32]. For example, during a Hydra-style swap-out, a span would be erasure-coded and the fragments written to memory nodes; however, a full replica of the span would also be written out. Relative to Carbink, this hybrid approach would have lower reconstruction costs (assuming that the full replica did not live on the failed node). However, Carbink would have lower memory overheads because no full replica of a span would be stored. Carbink would also have faster swap-outs, because swap-outs in the hybrid scheme would require an EC-2PC-like mechanism to ensure consistency.

Table 3 summarizes the strengths and weaknesses of the various systems discussed above.

Memory compaction: In Carbink, the far memory regions used by a program become fragmented as spans are swapped in. Memory compaction is a well-studied topic in the literature about "moving" garbage collectors for managed languages (e.g., [11, 18, 49]). Moving garbage collection is also possible for C/C++ programs; Mesh [40] represents the state-of-the-art. With respect to this prior work, Carbink's unique challenge is that the compaction algorithm (§3.4.2) must compose well with an erasure coding scheme that governs how objects move between local memory and far memory.

8 Conclusion

Carbink is a far memory system that provides low-latency, low-overhead fault tolerance. Carbink erasure-codes data using a span-centric approach that does not expose swap-in operations to stragglers. Whenever possible, Carbink uses efficient one-sided RMAs to exchange data between compute nodes and memory nodes. Carbink also uses novel compaction techniques to asynchronously defragment far memory. Compared to Hydra, a state-of-the-art fault-tolerant system for far memory, Carbink has 29% lower tail latency and 48% higher application performance, with at most 35% higher memory usage.

Abstract

Recently, Bronson et al. [7] introduced a framework for understanding a class of failures in distributed systems called *metastable failures*. The examples of metastable failures presented in that work are simplified versions of failures observed at Facebook. In this work, we study the prevalence of such failures in the wild by scouring over publicly available incident reports from many organizations, ranging from hyperscalers to small companies.

Our main findings are threefold. First, metastable failures are universally observed—we present an in-depth study of 22 metastable failures from 11 different organizations. Second, metastable failures are a recurring pattern in many severe outages—e.g., at least 4 out of 15 major outages in the last decade at Amazon Web Services were caused by metastable failures. Third, we extend the model by Bronson et al. to better reflect the metastable failures seen in the wild by categorizing two types of triggers and two types of amplification mechanisms, which we confirm through developing multiple example applications that reproduce different types of metastable failures in a controlled environment. We believe our work will aid in a deeper understanding of metastable failures and in coming up with solutions to them.

1 Introduction

Building reliable distributed systems has been the holy grail of distributed computing research. Historically, academic researchers studied the reliability of distributed systems under the assumptions of fail-stop [31, 42, 46] and Byzantine [8, 32] failure modes. The proliferation of cloud services led to previously unseen scales and the discovery of new failure modes, such as stragglers [9, 12, 62], fail-slow hardware failures [3, 27, 29], and scalability failures [34, 53]. Most recently, Bronson et al. [7] introduced a new class of failures called *metastable failures*.

Bronson et al. define the *metastable failure state* as the state of a **permanent overload with an ultra-low goodput** (throughput of useful work). In their framework, they also define the *stable state* as the state when a system experiences a low enough load than it can successfully recover from temporary overloads, and the *vulnerable state* as the state when a system experiences a high load, but it can successfully handle that load in the absence of temporary overloads. A system experiences a metastable failure when it is in a vulnerable state and a *trigger* causes a temporary overload that sets off a *sustaining effect*—a work amplification due to a common-case optimization—that tips the system into a metastable failure state. The distinguishing characteristic of a metastable failure is that the sustaining effect keeps the system in the metastable failure state **even after the trigger is removed**.

This phenomenon of metastable failure is not new. However, instances of such failures look so dissimilar that it is hard to spot the commonality. As a result, distributed systems practitioners have given different names to different instances of metastable failures, such as persistent congestion [51], overload [60], cascading failures [5], retry storms [2, 56], death spirals [37], among others. Bronson et al. [7] is the first work that generalizes all of these different-looking failures under the same framework.

A key property of metastable failures is that their root cause is not a specific hardware failure or a software bug. It is an emergent behavior of a system, and it naturally arises from the optimizations for the common case that lead to sustained work amplification. As such, metastable failures are hard to predict, may potentially have catastrophic effects, and incur significant ongoing human engineering costs because automated recovery is difficult (since these failures are not understood well). For example, in Section 6.3, we discuss how code and configuration changes without truly understanding the metastable failure can exacerbate the problem and lead to future incidents. Incidentally, at the time of writing this paper, a metastable failure at Amazon Web Services (AWS) disrupted the operation of airlines [38], home appliances [30], smart homes, payment systems [52], and other critical services for several hours.

As Bronson et al. point out, operators choose to run their systems in the vulnerable state all the time because it is much more efficient than running them in the stable state. As a simple example, an operator of a system with a database that can handle 300 requests per second (RPS) can install a cache with a 90% hit-rate and start serving up to 3,000 RPS. While more efficient, the system is now operating in a vulnerable state because a cache failure can overwhelm the database with more requests that it can handle. The problem is that in a complex, large-scale distributed system, we lack the ability to analyze the consequences of this decision to run in a vulnerable state under different conditions; e.g., what happens if load increases, or if the downstream latency increases, or if messages increase in size and serialization/deserialization starts to cost more CPU? So picking "how vulnerable" of a state to operate in, under normal conditions, is a best guess and not always the right choice, which is why we continue to experience metastable failures.

[*] Equal contribution.

In this paper, we make four contributions that extend the work of Bronson et al. and increase our understanding of metastable failures:

- A study of metastable failures in the wild that confirms metastable failures are universally observed and comprise a substantial fraction of the most severe outages (Section 2).
- An improved model that categorizes two types of triggers and two types of amplification mechanisms, which better explains how metastable failures happen (Section 3).
- An insider view at Twitter of a new type of metastable failure where garbage collection acts as an amplification mechanism (Section 4).
- Three example applications on which metastable failures are experimentally reproduced, which helps researchers propose and test solutions to metastable failures (Section 5). We have open-sourced these examples at https://github.com/lexiangh/Metastability.

We hope our work will encourage more research into this devastating kind of failure and help in building more robust distributed systems, as our daily lives start to increasingly depend on them [20, 30, 38, 52].

2 Metastability in the Wild

Bronson et al. [7] used simplified examples to illustrate the mechanism of metastability and only asserted that the pattern was common, but did not present any data about real-world occurrences. Thus, we perform a large-scale study of actual metastable failures in the wild by sifting through hundreds of publicly available incident reports. It is an arduous task that requires an in-depth analysis of each incident report to understand if the failure is metastable, and the lack of details in the reports makes it even more challenging. We identify 21 metastable failures (Table 1) that are severe enough to warrant public incident reports in a range of organizations, including four at AWS, four at Google Cloud, and four at Microsoft Azure. Though this number may appear low compared to other failure types in distributed systems [26, 27, 33, 53], metastable failures usually have devastating results that last many hours, which makes them an important class of failures to study.

2.1 Methodology

To find examples of metastability, we searched through troves of publicly available post-mortem incident reports from large cloud infrastructure providers and significantly smaller companies or services. Large infrastructure providers, such as Amazon Web Services (AWS), Azure, and Google, are held accountable by many paying customers, forcing greater transparency into their reliability and operation practices. Smaller businesses often operate with higher self-imposed transparency goals until they grow large enough to become a significant target for malicious attacks.

Infrastructure providers often maintain incident and outage reporting tools [4, 11, 50], which became our primary source for metastable failures. We analyzed hundreds of incidents to find a handful that depicts systems in the metastable state. We also found several smaller failures from other public sources such as postmortem communities [13, 44, 45, 54], weekly outage incident digests [14, 17, 55], etc.

The reports from different sources do not follow the same format nor provide the same level of information, making our job of finding examples of metastability more difficult. While going through these reports, we focus on tell-tale signs of metastability—temporary triggers, work amplification or sustaining effects, and certain specific mitigation practices. More specifically, we look for patterns when a trigger initiates some processes that amplify the initial trigger-induced problem and sustain the degraded performance state even after the trigger is removed. The sustaining effect can take multiple forms, such as exacerbated queue growth or retries that create more load. We also pay attention to mitigation efforts, as metastable failures often require significant load shedding [57, 60] for recovery.

We perform a comprehensive analysis of these incidents, focusing on impact, trigger, work amplification mechanisms, and mitigation practices. To study the impact, we focus on the duration and number of impacted services. This information is usually readily available in the reports. For the triggers, we identify the triggers and classify them into several distinct categories. We use a similar identification and classification process to distill work-amplification mechanisms and mitigation patterns. We present our summarized findings in Table 1.

2.2 Summary of Metastable Failures in the Wild

In Table 1, we provide a breakdown of metastable failure incidents we have found. The examples include instances from both major cloud providers (e.g., Microsoft, Amazon, Google, IBM) and smaller companies and projects (e.g., Spotify, Elasticsearch, Apache Cassandra). Our summary table describes high-level aspects of these failures: duration of the incident, impacted services, triggers leading to the outage, the sustaining effect mechanism, and corrective actions taken by the engineers.

Due to the often limited scope of provided information, we use our best judgment in identifying metastable failures. The most important criteria we use is the sustaining effect mechanism. We highlight several instances in gray color when the incident description is not clear on the presence of such a sustaining effect, but metastable failure is plausible depending on the interpretation and given the rest of the information provided. Additionally, we assign each incident a unique identifier to refer to each incident later.

Triggers are the starting events in the chain leading to metastable failures. Around 45% of observed triggers in Table 1 are due to engineer errors, such as buggy configuration or code deployments, and latent bugs (i.e., undetected pre-existing bugs). These can be observed in incidents GGL1, GGL2, GGL3, GGL4, AWS1, AWS3, AZR3, ELC1, SPF1. Load spikes are another prominent trigger category, with around 35% of incidents reporting it. A significant number of cases (45%) have more than one trigger.

	ID	Date	Duration (hours)	Services Impacted	Triggers	Sustaining Effect	Mitigation
Google	GGL1 [22]	03/12/19	4.17	Gmail, Photos, Drive, Cloud Storage, various other GCP services	• load spike • config change	• cascading overload	• load shedding • stop config deploy
	GGL2 [23]	10/31/19	21.5	multiple components of GCE	• software bug	• retry	• load shedding • reboot • capacity increase
	GGL3 [24]	04/08/20	3.2	Google BigQuery, Cloud IAM 3% of Cloud SQL HA	• config change • software bug	• retry	• config rollback • policy change
	GGL4 [21]	04/30/13	1.5	Google API infrastructure	• config change • latent software bug	• traffic queue growth • reboots	• config rollabck • server reboot
AWS	AWS1 [47]	04/21/11	66.7	Amazon EC2, Amazon RDS	• network config change	• retry	• config rollback • policy change • load shedding • capacity increase
	AWS2 [48]	06/13/14	4.23	Amazon SimpleDB	• power loss	• retry	• load shedding • server restart
	AWS3 [49]	09/20/15	4.55	AWS SQS, EC2 Autoscaling, CloudWatch, AWS Console	• load spike • network disruption	• retry • cascading server demotion	• load shedding – pause metadata ops • capacity increase
	AWS4 [51]	12/07/21	9.3	AWS DynamoDB, EC2, Fargate, RDS, EMR, Workspaces, AWS Console, Authorization services, internal DNS	• latent software bug triggered by scale-up led to load spike	• retry	• load rebalancing • load shedding
Azure	AZR1 [4]	07/01/20	2.65	Azure SQL DB & SQL Data Warehouse, Azure Database for MySQL/PostgreSQL/MariaDB	• unspecified load imbalance trigger • latent config bug	• cascading overload	• service restart
	AZR2 [4]	04/01/21	1.15	Azure DNS	• software bug leading to cache degradation	• retry	• unknown automation • capacity increase
	AZR3 [4]	06/14/21	13.25	Management operations of many Azure Services	• latent software bug • load spike	• unspecified queue growth due to overload and timeouts	• load shedding • remove buggy software • capacity increase
	AZR4 [4]	07/12/21	7.92	Windows Virtual Desktop, Azure Front Door, Azure CDN Standard	• deployment of software bug • load spike	• retry • other unspecified	• load rebalancing • trigger hot fix • policy change
Other	IBM1 [11]	06/11/21	73.53	Private DNS, HS Crypto Service, Cloudant DNS Services, Osaka, Cloudshell services	• software bug	• retry	• load shedding • policy change • trigger hot fix
	SPF1 [19]	04/13	NA	core app/service UI	• load spike • policy failure	• retry	• load shedding
	SPF2 [19]	06/04/13	8.33	core app/service UI	• load spike due to unexpected service dependency	• retry • excessive logging in failure case	• trigger hot fix • load shedding
	ELC1 [39]	04/02/19	6.67	Elasticsearch Service	• unspecified maintenance • unspecified error	• load caused ZK churn causing more load	• restart • load shedding
	WIK1 [58]	03/30/21	2.25	media upload, misc queued jobs	• load spike	• unspecified causing queue growth	• load shedding • policy change
	CCI1 [10]	07/07/15	18.33	Core product	• load spike	• load increase due to contention	• load shedding
	CAS1 [1]	07/27/17	NA	Partial database outage	• rolling restart	• self-sustaining and increasing overload	• policy change
	CAS2 [43]	2020	0.16	ably services	• load spike of certain costly operations	• retry	• trigger removal – operated in stable state
	FB1 [18]	NA	NA	Facebook core services	• load spike	• software bug	• hot fix

Table 1: Metastable failures from public sources. Azure and IBM do not provide a direct incident link. Gray highlight indicates a plausible metastable failure, although the incident description lacked some necessary details.

Handling and recovering from metastable failures is not easy, with our data suggesting that incidents cause significant outages. For instance, the IBM1 incident lasted over three days. More generally, we have observed outages in a range of 1.5 to 73.53 hours, with 4 to 10 hours of outages being the most common (35% of incidents reporting the outage period).

While triggers initiate the failure, the sustaining effect mechanisms prevent the system from recovering. We observed a variety of different sustaining effects, such as load increase due to retries, expensive error handling, lock contention, or performance degradation due to leader election churn. By far, the most common sustaining effect is due to the retry policy, affecting more than 50% of the studied incidents—GGL2, GGL3, AWS1, AWS2, AWS3, AZR2, AZR4, IBM1, SPF1, SPF2, and CAS2 incidents are all sustained by retries.

Recovery from a metastable failure is challenging and often requires reducing load. Direct load shedding, such as throttling, dropping requests, or changing workload parameters,

Symbols	Names
L_{norm}, C_{norm}	Normal load and capacity without issues (i.e., triggers)
$L_{org}(t), C_{org}(t)$	Organic load and capacity at time t including effects from triggers
$L_{sys}(t), C_{sys}(t)$	System load and capacity at time t including metastable amplification over the organic load and capacity
C_{stable}	Stable capacity below which the system recovers from metastability
m_{trigL}, m_{trigC}	Maximum load-spike and capacity-decreasing trigger magnitudes
$\alpha_L(t)$, $\alpha_C(t)$	Workload and capacity degradation amplification factors
Δt_{trig}	Trigger overloading duration
$w_L(\Delta t_{trig})$, $w_C(\Delta t_{trig})$	Workload and capacity degradation amplification upper bound functions
w_L^*, w_C^*	Maximum workload and capacity degradation amplifications

Table 2: Symbols of Metastability Framework.

was used in over 55% of the cases. Some indirect mechanisms were also popular, such as reboots to clean the queues or operation backlogs, or policy changes. An example of such a policy change is the CAS1 incident where a feature was turned off to allow the servers to join the cluster.

3 Metastability Framework

Based on our observations of real-world metastable failures, we extend the model of Bronson et al. [7] in three ways. First, while the previous framework presumes that a system entering a metastable failure state is usually due to a load increase, we observe in multiple incidents that a software bug or a configuration change may decrease the capacity of the system and trigger a metastable failure even without a load increase. Second, although the previous framework describes a system sustaining in a metastable failure state due to workload amplification, we show examples of another type of metastable failure sustaining effect where background activities such as garbage collection cause the system's capacity to degrade or remain degraded even after the trigger is removed. Third, based on our experiments on the reproductions of metastable failures, we find that a vulnerable state is not a binary condition; whether a system transitions from a vulnerable state into a metastable failure state is determined by the current degree of vulnerability, the trigger magnitude, and its duration.

3.1 System Model

We devise our model based on the load and capacity of a system, and a summary of the symbols are shown in Table 2. The capacity of the system, $C_{sys}(t)$, is represented in terms of abstract resource units (RUs) that the system can handle per second (i.e., work per second). Each request consumes some RUs from the system's budget. For example, consider a system with a constant $C_{sys}(t) = 100$ RUs/sec; every second such a system can process up to 100 requests, each costing 1 RU, or up to 50 requests, each costing 2 RUs. The load, $L_{sys}(t)$, represents the work per second arriving to the system in terms of RUs/sec. So for a system to not be overloaded, $L_{sys}(t) < C_{sys}(t)$.

Under normal idealized conditions, we assume the processing capacity $C_{sys}(t)$ is constant, $C_{sys}(t) = C_{norm}$. However, depending on circumstances it may diminish due to failures, transient outages, or amplification effects of metastability. Similar to $C_{sys}(t)$, we set $L_{sys}(t) = L_{norm}$ as the normal load excluding transient effects and workload amplification.

Since metastability is fundamentally due to sustaining effects that amplify the load and degrade the system capacity, we also define $L_{org}(t)$ and $C_{org}(t)$ as the load and system capacity without amplification effects. That is, the organic load, $L_{org}(t)$, is the load originating from the system's clients. This includes transient effects such as load spikes, but does not include workload amplification effects such as retries. Similarly, the organic capacity, $C_{org}(t)$, represents the system capacity including transient capacity decreases, but without sustaining degradation. For example, background interference may drop the organic capacity in half temporarily until the interference ends. But sustaining amplification effects such as garbage collection would cause the system capacity to degrade further or remain degraded even after the trigger is removed. We illustrate these effects on capacity and load in Figure 1.

3.2 Triggers

Metastable failures begin with trigger events. In our survey (Section 2), we have identified two broad types of triggers. The first trigger type results from a sudden burst in organic load, $L_{org}(t)$ (e.g., a celebrity posting their baby's picture). The left two scenarios in Figure 1 illustrate how such a trigger could lead to a metastable failure, and incidents GGL1, AWS3, AZR3, AZR4, SPF1, SPF2, WIKI1, CCI1, and CAS2 are examples of such failures. The second trigger type degrades the system's organic capacity, $C_{org}(t)$ (e.g., a rack failure or deployment of inefficient code). The right two scenarios in Figure 1 illustrate how such a trigger could lead to a metastable failure, and incidents GGL2, GGL3, GGL3, AWS1, AWS2, AZR4, and IBM1 are examples of such failures. While the two types of triggers behave differently, they impact the system's operation similarly by changing the balance between the load and capacity.

Definition 1 (Trigger). A **trigger** $\mathcal{T}(m_{trigL}, m_{trigC})$ represents the total effect from one or more of the following events:

- A **load-spike trigger** is an event that increases the load on the system by some maximum magnitude m_{trigL} such that $L_{org}(t) - L_{norm} \leq m_{trigL}$ for all t.
- A **capacity-decreasing trigger** is an event that decreases the system capacity by some maximum magnitude m_{trigC} such that $C_{norm} - C_{org}(t) \leq m_{trigC}$ for all t.

We assume m_{trigL} and m_{trigC} represent upper bounds on the total trigger effect across all the triggers in a trigger event. In our survey, over half of the observed incidents had one

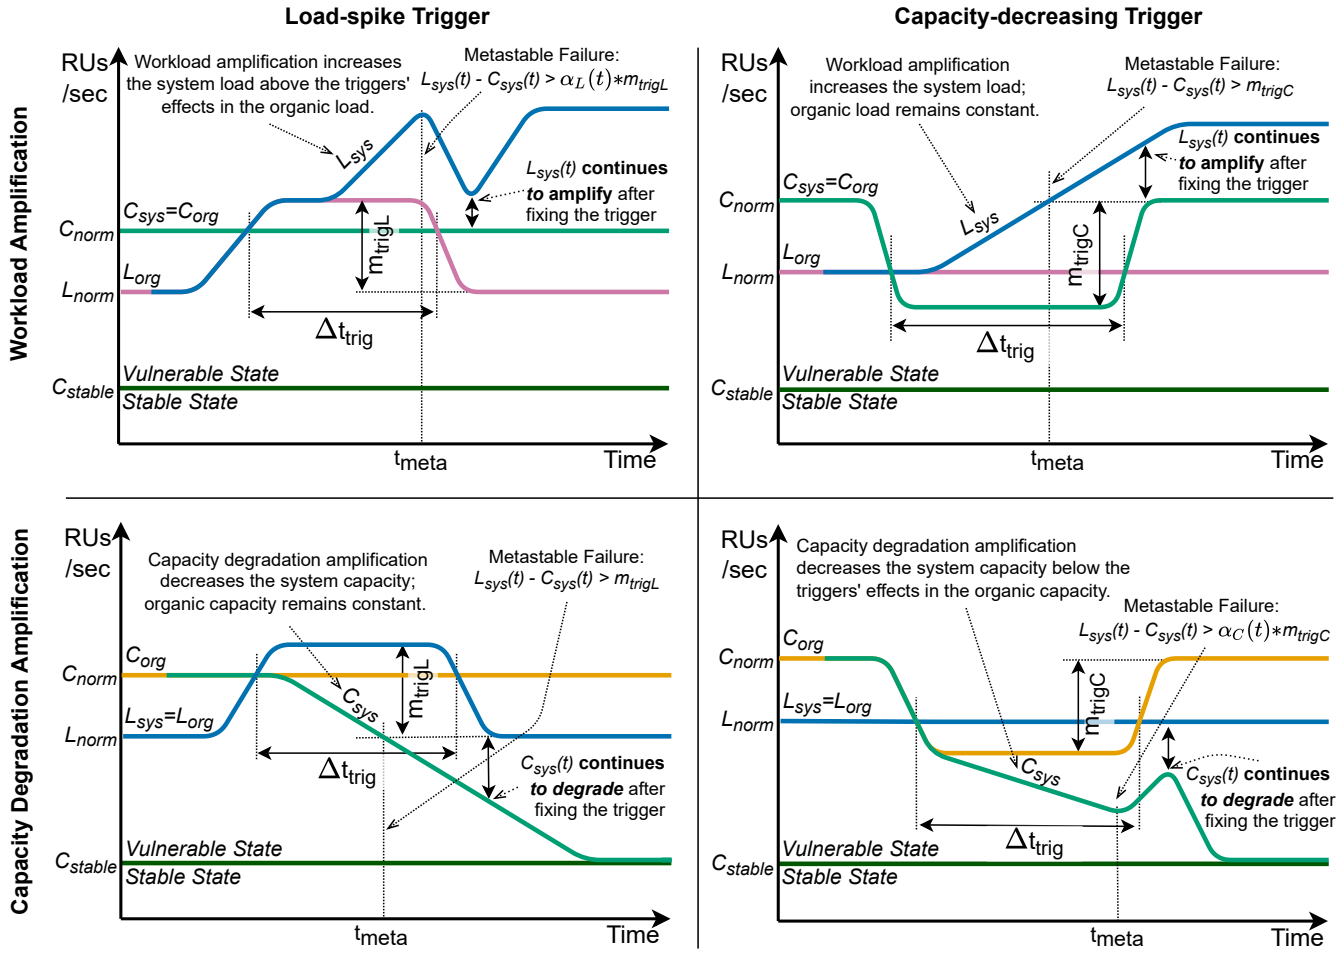

Figure 1: Four metastability scenarios (Section 3.4). Two types of triggers (i.e., load-spike and capacity-decreasing) and two types of amplification mechanisms (i.e., workload amplification and capacity degradation amplification) form the different scenarios.

overloading trigger, but to our surprise, incidents with multiple triggers were also common (GGL1, GGL3, GGL4, AWS3, AZR1, AZR3, AZR4, SPF1, and ELC1).

Not all triggers are dangerous; small variations of capacity or load are normal and unavoidable. The triggers become dangerous when they overload the system (i.e., $L_{sys}(t) \geq C_{sys}(t)$).

Definition 2 (Overloading trigger condition). If $m_{trigL} + m_{trigC} \geq C_{norm} - L_{norm}$, then the trigger(s) can overload the system.

Theorem 1 (Overloading trigger). If the system does not have an overloading trigger condition, then it will never have a metastable failure. (Proof in Section A.1.)

An overloading trigger is a necessary precursor of a metastable failure. Once the system is in an overloaded state, its performance starts to degrade, which sets off alarms and starts mitigation efforts. For instance, GGL2, GGL3, AZR2, and AZR4, among others, relied on an automated monitoring and notification system to initiate the mitigation efforts once a drop in availability is detected. Although not always explicitly mentioned, we believe that most, if not all, systems surveyed have monitoring and notification capabilities. As the system overloads, the latency of client operations will start to rise, while the goodput will stay at or below the $C_{sys}(t)$.

The overloaded state, however, is not a metastable failure state just yet. Getting out of overload is relatively straightforward — fix the trigger and restore the balance in the system, such that $L_{sys}(t) < C_{sys}(t)$ again. If the load on the system returns to a level below the system's capacity when the trigger is removed, then the system should eventually recover.

The duration of the trigger's impact on the system is another important aspect to consider. While the trigger persists, the system is working in a reduced capacity or increased load setting, depending on the trigger type. Some triggers are easy to fix and end their impact on the systems. For instance, most of the misconfiguration triggers (GGL1, GGL4, AWS1) and buggy software deployment (AZR4) can be fixed by a rollback action. Some triggers are more difficult to address since the ability to fix the trigger, ironically, may depend on the system's performance, which is degraded by the trigger. For instance, CAS1 incident had a rolling server restart for maintenance. The restart lowers the overall capacity of the system by the capacity of a server currently rebooting, placing more

load on other machines. A rebooted server needs to repair itself by catching up, which requires both the rebooted server to be fast enough to catch up with the missed and ongoing load, and the rest of the system needs to be fast enough to provide this repair service.

3.3 Sustaining Effect Loop

A metastable failure arises when the overloaded system does not eventually return to a healthy state ($L_{sys}(t) < C_{sys}(t)$). Many reasons can keep the system in a failed state, such as the inability to recover from the trigger or an uncontrolled increase in load, among others. However, all of the reasons share a common pattern of keeping systems inoperative. We refer to this pattern as a *sustaining effect*.

Definition 3 (Sustaining effect). A **sustaining effect** is a feedback loop that keeps the system in an overloaded state such that $L_{sys}(t) \geq C_{sys}(t)$ even after the trigger is removed.

The feedback mechanism itself may have existed prior to the trigger, however, the overload made the feedback mechanism self-sustaining, and we name this feedback mechanism as *metastable amplification*. For instance, the AWS4 incident occurred with networking overload due to a planned scale-up operation. The overload resulted in connection timeouts and retries, creating even more load and causing more timeouts and retries.

Definition 4 (Metastable amplification). A **metastable amplification** $\mathcal{W}(\alpha_L(t), \alpha_C(t), w_L(\Delta t_{trig}), w_C(\Delta t_{trig}), w_L^*, w_C^*)$ exacerbates the system's overload until it reaches a maximum overload limit. The amplification can manifest itself by increasing the load on the system $L_{sys}(t)$ and/or decreasing the system's capacity $C_{sys}(t)$:

- **Workload amplification** is a feedback loop that increases the system load $L_{sys}(t)$ beyond the organic load $L_{org}(t)$ (i.e., $L_{sys}(t) \geq L_{org}(t)$). The workload amplification factor, $\alpha_L(t) = L_{sys}(t)/L_{org}(t)$, can be upper bounded by some workload amplification upper bound function $w_L(\Delta t_{trig})$ and max load amplification w_L^* such that $1 \leq \alpha_L(t) \leq w_L(\Delta t_{trig}) \leq w_L^*$ for all $t, \Delta t_{trig}$, where w_L is a monotonically increasing function of the trigger overloading duration Δt_{trig} from $w_L(0) = 1$ to $w_L(\infty) = w_L^*$.
- **Capacity degradation amplification** is a feedback loop that decreases the system's capacity $C_{sys}(t)$ below the organic capacity $C_{org}(t)$ (i.e., $C_{sys}(t) \leq C_{org}(t)$. The capacity degradation amplification factor, $\alpha_C(t) = C_{sys}(t)/C_{org}(t)$, can be upper bounded by some capacity degradation amplification upper bound function $w_C(\Delta t_{trig})$ and max capacity degradation amplification w_C^* such that $1 \geq \alpha_C(t) \geq 1/w_C(\Delta t_{trig}) \geq 1/w_C^*$ for all $t, \Delta t_{trig}$, where w_C is a monotonically increasing function of the trigger overloading duration Δt_{trig} from $w_C(0) = 1$ to $w_C(\infty) = w_C^*$.

Intuitively, the upper bounds allow us to reason about vulnerability and when a system enters a metastable failure state. We do not assume the upper bounds are tight, and the intent is to explain (i) there are two different types of amplification (that may both be active simultaneously), and (ii) how the amplification factors impact metastability.

Workload amplification can manifest in multiple ways. Recall that each request in our model has some RU cost. The workload amplification, therefore, can use one of the two broad mechanisms—increasing the number of requests in the system or increasing the average cost of a request. We observe the former amplification method in incidents GGL2, SPF1, AZR2, while the latter shows up in AWS3, WIKI1, and SPF2. For example, the SPF1 incident was caused by retrying the requests, while the SPF2 issue was exaggerated by extra debug logging added for timed-out requests. In our model, this corresponds to the top left scenario in Figure 1 where a load-spike trigger (i.e., L_{org} increases) starts a workload amplification (i.e., L_{sys} increases) due to retries or an increase in the average per-request cost.

Workload amplification does not necessarily start immediately with the trigger. A common type of workload amplification is retry-driven amplification, observed in incidents GGL2, AWS1, AWS2, AZR2, SPF1, and SPF2. It occurs when the requests start to timeout after waiting for some timeout period, and clients begin to retry the failed requests. Typically, this type of amplification starts building after some amplification delay. This delay depends on several factors, such as the degree of overload in the system and request timeout. A short request timeout is good for latency when retrying due to a small transient issue. However, it can hurt the system's ability to handle larger problems by quickly starting the workload amplification. For example, AWS2 specifies that a small handshake timeout was a contributing factor to starting and sustaining the overload. The handshake timeout controlled the frequency of heartbeat messages and the duration a server can remain active without receiving a heartbeat. A longer timeout would have both reduced the heartbeat load and allowed for a longer heartbeat wait, potentially delaying workload amplification.

Capacity degradation amplification is another common type of sustaining effect. This effect occurs when the initial trigger overloads the system and causes the capacity to degrade or remain degraded. For example, a system experiencing a trigger where background interference from other co-located processes pushes it into an overloaded state may now need to also deal with an increased amount of garbage collection (GC) due to a queue buildup. In this case, the GC amplifying effect would degrade the system capacity beyond the capacity decrease from the trigger. The metastability arises when the capacity degradation from GC grows to be high enough such that the system remains overloaded even if the background interference is removed.

A sustained degradation is a special case of capacity degradation amplification. The CAS1 incident discussed earlier is an example of this. A different instance of this type of sustaining effect is the caching failure described in Bronson et al. [7]. In a system backed by a look-aside cache, a partial failure of a cache, such as a reboot of a caching server, may

result in a load spike on the underlying database and cause it to timeout. Because of timeouts, all operations effectively fail, preventing the system from filling the cache. This sustaining effect causes the capacity to remain degraded.

Figure 1 shows the impact of workload amplification (top scenarios) and capacity degradation amplification (bottom scenarios) on metastability. While the scenarios look different visually, they can all be understood under the metastability model of a sustaining effect that amplifies the load and/or capacity degradation to magnify an overload condition.

3.4 Metastability Scenarios

Figure 1 demonstrates four scenarios in which metastable failures occur. We introduce two types of triggers and two types of amplification mechanisms that impact the load and capacity of the system. We use the terms "load-spike" for triggers and "workload amplification" for amplification mechanisms impacting the load, and we use the terms "capacity-decreasing" for triggers and "capacity degradation" for amplification mechanisms impacting the capacity. In practice, both types of triggers and both types of amplification mechanisms can occur simultaneously.

In the upper left scenario, when there is a load-spike trigger, the organic load L_{org} increases beyond the system capacity C_{sys}, and thus the system is overloaded. The workload amplification (e.g., retries) further increases the system load L_{sys} above the triggers' effects (i.e., m_{trigL}) in the organic load L_{org}. When the system overload (i.e., $L_{sys}(t) - C_{sys}(t)$) is high enough (e.g., at time t_{meta}), even after removing the trigger (i.e., the dip of L_{org} and L_{sys}), the system remains overloaded and the workload amplification mechanism continues to exacerbate the overload, which indicates the system is in a metastable failure state.

In the upper right scenario, when there is a capacity-decreasing trigger, the organic capacity C_{org} decreases below the system load L_{sys}, and thus the system is overloaded. The workload amplification (e.g., retries) increases the system load L_{sys}. Once the amplification is high enough (e.g., at time t_{meta}), even after removing the trigger (i.e., the recovery of C_{org} by m_{trigC}), the system is still overloaded, and the workload amplification mechanism continues to exacerbate the system overload. Hence a metastable failure.

In the bottom left scenario, when there is a load-spike trigger, the organic load L_{org} increases beyond the system capacity C_{sys}, and thus the system is overloaded. The capacity degradation amplification (e.g., GC amplifying effect) decreases the system capacity C_{sys}. Once the amplification is high enough (e.g., at time t_{meta}), even after removing the trigger (i.e., the organic load L_{org} decreases by m_{trigL}), the system is still overloaded, and the capacity degradation amplification mechanism continues to exacerbate the system overload. Hence a metastable failure.

In the bottom right scenario, when there is a capacity-decreasing trigger, the organic capacity C_{org} decreases below the system load L_{sys}, and thus the system is overloaded. The capacity degradation amplification (e.g., GC amplifying effect) further decreases the system capacity C_{sys} below the triggers' effects (i.e., m_{trigC}) in the organic capacity C_{org}. When the system overload (i.e., $L_{sys}(t) - C_{sys}(t)$) is high enough (e.g., at time t_{meta}), even after removing the trigger (i.e., the recovery of C_{org} and C_{sys}), the system remains overloaded and the workload amplification mechanism continues to exacerbate the overload. Hence a metastable failure.

3.5 System States

Based on Bronson et al. [7], we define three states (stable, vulnerable, metastable failure) that a system operates in and describe the boundaries between these states.

3.5.1 Stable State

Assuming a system has a metastable amplification mechanism $\mathcal{W}(\alpha_L(t), \alpha_C(t), w_L(\Delta t_{trig}), w_C(\Delta t_{trig}), w_L^*, w_C^*)$ and trigger $\mathcal{T}(m_{trigL}, m_{trigC})$, it will never have a metastable failure if it's running under low enough load $L_{norm} < C_{stable}$. The demarcation line between stable and vulnerable states depends on the max amplification factors w_L^*, w_C^* and the normal capacity of the system, C_{norm}.

Theorem 2 (Stable region). Define $C_{stable} = \frac{C_{norm}}{(w_L^* * w_C^*)}$. If $L_{norm} < C_{stable}$, then the system will never have a metastable failure. (Proof in Section A.2.)

When the normal load is low enough relative to the normal system capacity, then even if the trigger overloads the system and causes the maximum metastable amplification, it will recover once the trigger is removed and hence is not a metastable failure. For instance, in the CAS2 incident, the Apache Cassandra cluster operated at a low load of 10% to 30% percent of the capacity. Despite a very significant trigger and workload amplification, the cluster recovered itself when the trigger was removed.

3.5.2 Vulnerable State

If the system has a normal load higher than C_{stable}, it's running in a vulnerable state. Bronson et al. [7] define the vulnerable state as the state when a system experiences a high enough load that temporary overloads can tip the system into a metastable failure state. However, based on our experiments, the vulnerable state is not a binary—there are many degrees to it and many factors determine this degree of vulnerability.

As an overloading trigger event $\mathcal{T}(m_{trigL}, m_{trigC})$ unfolds, the system (and engineers) are in a race to mitigate the overload before the feedback loop of the sustaining effect makes the failure unrecoverable without more drastic measures. In such a system, a combination of amplification and trigger factors impact the likelihood of a metastable failure.

Theorem 3 (Degrees of vulnerability). If the metastable amplification during the trigger overloading duration Δt_{trig} is small enough relative to the system headroom (i.e., $w_L(\Delta t_{trig}) * w_C(\Delta t_{trig}) < \frac{C_{norm}}{L_{norm}}$), then the system will never have a metastable failure. (Proof in Section A.3.)

Once the system is in a vulnerable state, a combination of factors determines its degree of vulnerability. First, how close L_{norm} is to C_{norm} impacts the vulnerability. The smaller the

C_{norm}/L_{norm} ratio, the easier it is to enter a metastable failure state (i.e., the higher degree of vulnerability). The smaller the $C_{norm} - L_{norm}$ difference, the smaller the trigger magnitude needed to overload the system and potentially trigger the metastable failure (Theorem 1). Second, the metastable amplification impacts the vulnerability. As described in Theorem 3, higher metastable amplifications ($w_L(\Delta t_{trig})$ and $w_C(\Delta t_{trig})$) increase the vulnerability to metastable failures. Since w_L and w_C increase with the overloading trigger duration Δt_{trig}, longer triggers also increase the vulnerability.

The amplification delay, if present, is the first mechanism to buy some time for mitigation efforts. Unfortunately, there is very little control over this delay interval, aside from timeouts in scenarios like retry-based workload amplification. The trigger overloading interval Δt_{trig} is another factor in determining whether an overload develops into the metastable failure. Intuitively, short triggers mean that amplification may not have started yet due to the amplification delay or has not escalated too far. Recall that entering a metastable failure state requires the system load to exceed the capacity even after fixing the trigger. This means that the amplification factors $\alpha_L(t)$ and $\alpha_C(t)$ play a role—a smaller amplification translates into a more moderate system load growth that can buy the engineers time to recover the trigger.

3.5.3 Metastable Failure State

The point when the trigger(s) cause the system to enter a metastable failure state depends on the current amplification factors $\alpha_L(t)$ and $\alpha_C(t)$ and trigger magnitudes.

Theorem 4 (Metastable failure boundary). If the metastable amplification causes the system overload to exceed the triggers' effects (i.e., $L_{sys}(t) - C_{sys}(t) \geq \alpha_L(t) * m_{trigL} + \alpha_C(t) * m_{trigC}$), then the system is in a metastable failure state. (Proof in Section A.4.)

Since the current amplification factors and trigger magnitudes change over time, we can use the current amplification factors and maximum trigger magnitudes to develop a metastable failure boundary. If the overload $L_{sys}(t) - C_{sys}(t)$ exceeds the boundary in Theorem 4, then there is a metastable failure because the system is overloaded even after the trigger is removed. If the overload $L_{sys}(t) - C_{sys}(t)$ is below the boundary in Theorem 4 while the trigger(s) are in full effect, then the system is not in a metastable failure state yet. This is because the removal of the trigger would result in a non-overloaded state where the system can recover.

Theorem 4 indicates the boundary in the general case where both types of triggers and amplifications occur simultaneously, but for simplicity, Figure 1 depicts the specific boundaries for each type of trigger and amplification in the four scenarios. That is, $m_{trigL} = 0$ or $m_{trigC} = 0$ depending on the trigger, and $\alpha_L(t) = 1$ or $\alpha_C(t) = 1$ depending on the amplification.

A practical takeaway from these results is that it is important to monitor the overload and take more drastic measures before it exceeds the metastable failure boundary. The key insight is that the overload should not be so bad that the system is overloaded even after the trigger is removed.

3.6 Recovery

Fixing the trigger is the first intuitive step many engineers take in recovery efforts. The intuition is likely the result of treating the trigger as the root cause of the failure. For instance, many incidents caused by deploying bad configuration involved rollbacks (GGL3, GGL4, AWS) or halting the deployments (GGL1). Similarly, many incidents triggered by software bugs involved hot-fixing the bug (AZR4, IBM1, SPF2). All incidents caused by load spikes included some form of load shedding (GGL1, AWS3, AZR3, CCI1, etc.).

However, once in the metastable failure state, the system cannot recover all by itself as the sustaining effect keeps it in the metastable failure state. Therefore, we need to remove the sustaining effect from the system to recover. Two broad strategies exist to recover from the failure. The first is load shedding—bringing the load down below the stable threshold C_{stable}. The second is to raise C_{stable} by increasing the system capacity.

Load shedding was the most popular mitigation effort used in over 50% of the incidents. This approach is intuitive in any kind of overload situation. However, without a proper understanding of the metastability and feedback loops, it is hard to know just how much the load needs to be reduced. This results in long mitigations and additional destructive steps, such as server reboots (AWS2, GGL2).

Raising C_{stable} is more nuanced than load shedding. One mechanism for changing the stable threshold is a policy change that impacts the amplification thresholds w_L^* and w_C^*. An example of such a policy change is decreasing the maximum number of retries per request. For instance, a policy with at most two retries will not amplify the work more than three times, while the policy with no cap effectively leaves the system with no stable region. A more popular way of increasing C_{stable} is to add the capacity to the system, essentially raising its C_{norm}. For a fixed w_L^* and w_C^*, increasing normal capacity will also raise the stable threshold, per Theorem 2. A few incidents in our study used this approach. For instance, AZR2 added more capacity after performing load shedding and fixing the trigger.

4 Metastability at Twitter

While publicly available incident reports provide enough high-level information to identify the metastable failures, they lack the depth and detail to understand the complex interactions between components in large systems. In this case study, we use insider information to describe in detail one specific metastable failure occurring at Twitter, a large internet company, due to garbage collection (GC). We identify a sustaining loop where high queueing increases memory pressure and mark-and-sweep processing during GC, causing job slowdowns and thus higher queueing. The effect is more pronounced at high system loads, where the system is more vulnerable to spikes. Specifically, we see that a peak load test

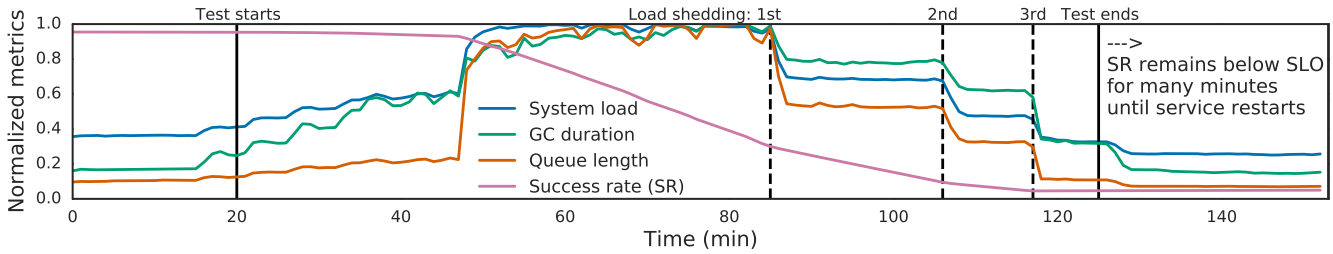

Figure 2: Timeseries of a core service under a peak load test at Twitter. Metrics are normalized except for the success rate, which is scaled to show the trend dropping below the SLO.

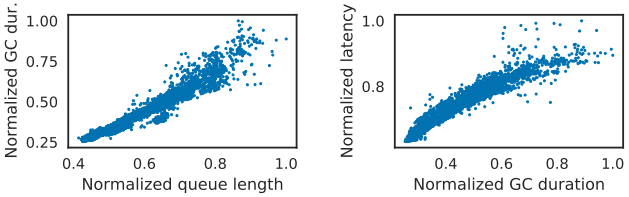


(a) Queue length vs. GC duration. (b) GC duration vs. Latency.

Figure 3: Correlation between metrics during 3 normal days.

during a busy day triggers the system to enter a metastable failure state where jobs start to fail, and it is only after sufficient load shedding that the success rate stops dropping.

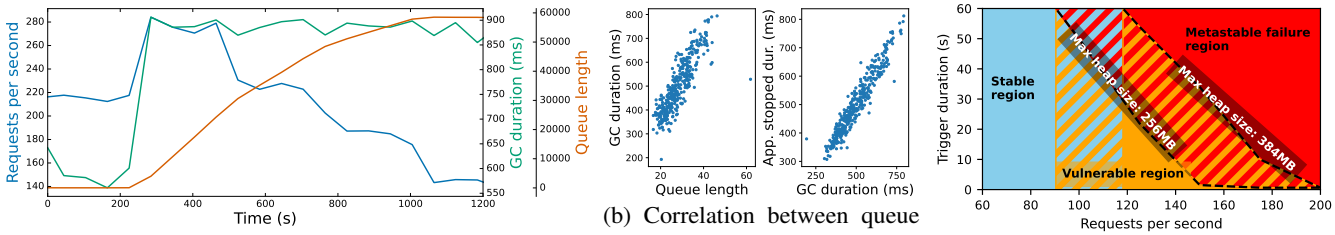
Peak load tests are one of the common types of tests used regularly in industry to expose potential problems and highlight the necessary steps to prevent incidents from happening. Figure 2 shows the timeseries of system metrics at a core service during a peak load test where we see a metastable failure. System load, GC duration, and queue length have been normalized to show the trend only, while success rate (SR) is scaled to demonstrate it dropping sharply below the SLO. All metrics are measured using the standard observability tools at Twitter, except for the (average) queue length, which is inferred using Little's Law [35]. By queue length, we mean the count of all the requests in the system. The service is a mature production service that's well-tuned and has been running for several years, under all the usual operating practices of frequent deployments, regular stress tests, and continuous monitoring and alerting.

In this incident, the peak load occurs around the 48-minute mark, and the SR starts to drop over time. Once the SR of this service drops below a critical threshold (i.e., the SLO), service operators are alerted to mitigate the problem. In this incident, the operators start load shedding at around the 83-minute mark and continue with more load shedding at 106 minutes. This had the desired effect of lowering the load, which also lowers GC and queue length. However, the SR still continues to drop and does not start to recover even when the load is back down to the level before the test. SR remains below the SLO until the service is restarted by operators. This is because even after the load shedding, a sustaining effect is still slowing down the system and causing it to remain in a metastable failure state.

Studying the internal system metrics from the test has shed some light on the problem. We find that the changes to GC duration are highly correlated with load fluctuations, as more load brings more memory allocation, thus requiring more GC. However, the GC is busier than normal during the peak load test. During the second load-shedding period between 106-118 minute marks, the load is more than 20% lower than that at the 40-minute offset, yet the GC is busier and SR is still dropping. At the same time, the queue length is also more than 50% higher, which implies that there are more jobs stuck in the system exacerbating GC. Thus, there is contention between arriving traffic and GC consuming resources, suggesting the metastability sustaining effect.

Specifically, the incident is caused by the sustaining effect in the following steps: (i) a load spike (i.e., a L_{org} increase) caused by peak load test introduces initial high queue length in the system; (ii) high queue length results in high GC behaviors; (iii) high GC behaviors slow job processing (i.e., C_{sys} decreases); (iv) more jobs get stuck in the system, which leads to higher queue length.

To demonstrate each of these steps, we further study data from this test as well as non-test data as a baseline. For (i), we can see the initial trigger in Figure 2 at around minute 48 where the load spike causes a sharp increase in queue length. For (ii), we see that queue length and GC duration are correlated over time in Figure 2. Additionally, we plot queue length vs. GC duration (Figure 3a) under 3 normal days without the test to show these metrics generally exhibit a positive correlation. One might wonder whether the system load affects these metrics, and we find that it is correlated to both queue length and GC duration. But to eliminate the impact of system load, we also filtered the data to only include results with approximately the same system load, and we still see a correlation between queue length and GC duration, which suggests that high queue length leads to high GC. Correlation does not imply causation, so we validate and reproduce these effects in Section 5.1 via a simple example. For (iii), we plot GC duration vs. latency (Figure 3b) during the same period without peak load testing and observe that the latency increases with GC duration. As GC consumes CPU cycles, there is CPU contention with job processing, which causes slowdowns to jobs as evidenced by the higher latencies. Naturally, job slowdowns will cause additional congestion and queueing, which completes the sustaining loop (iv).



(a) Timeseries of GC metastability.

(b) Correlation between queue length, GC, & application stalls.

(c) Degrees of vulnerabilities.

Figure 4: Metastability in Garbage Collection (GC).

Similar incidents recur many times, and engineers take different approaches to mitigate/fix this issue. For example, (i) observing unusually high latency spikes in backend services resulted in work to improve their performance to lower queue lengths, (ii) observing higher GC duration than normal resulted in adjusting the JVM memory configuration (e.g., increasing max heap size) to tweak GC behavior, and (iii) observing high resource utilization (e.g., CPU) resulted in adding more servers to lower per-server load. These approaches decrease system vulnerabilities and make it more robust to the trigger at the magnitude of the peak load test level.

5 Replicating Metastability

We introduce three example applications and experimentally reproduce metastable failures on them. One of these applications reproduces the failure in the Twitter case study (Section 4) at a small scale, and the other two reproduce failures due to retries and look-aside caching described in sections 2.1 and 2.2, respectively, of Bronson et al. [7].

5.1 Metastability due to GC

In this section, we develop a small-scale reproduction of the GC metastable failure seen in Section 4. This allows us to perform controlled experiments to validate the sustaining effect and study the factors that affect vulnerability. We confirm that GC can cause metastability and that the vulnerability increases with load. Since the sustaining effect is due to a high queue length causing memory pressure and GC slowdowns, we find that the memory size also impacts the degree of vulnerability.

5.1.1 Experiment Setup

Our reproduction is a multi-threaded java program compiled via JDK 8 under default GC settings except we experiment with MaxHeapSize. Each thread processes a job consisting of many memory allocations. Each job allocates a 0.5MB array of arrays and then proceeds to allocate each row in this 2D array, adding an additional 0.5MB of data. Once a job completes, the allocated memory is unreferenced and will eventually be garbage collected. The main thread launches jobs following a Poisson process with a configured request rate measured in requests per second (RPS). We launch the java program in a docker container configured with 1GB of memory running on an AWS EC2 m5.large instance.

5.1.2 Inducing Metastable Failures

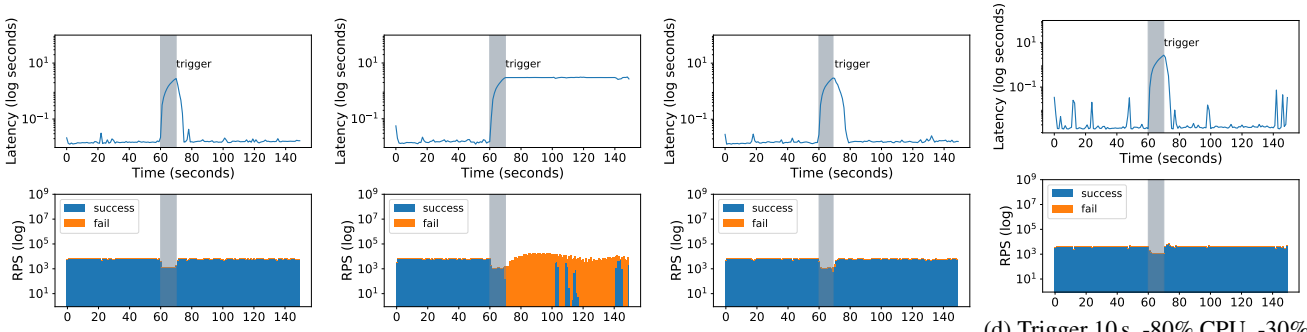
To illustrate the metastability, we vary RPS over time and plot the relevant metrics in Figure 4a. The initial RPS increase causes queue length and the GC duration to increase. Even as RPS is reduced over time, the sustaining effect causes the queue length and GC duration to remain high.

To gain a deeper understanding of the sustaining effect that causes the metastability, we extract detailed metrics from GC logs. Figure 4b shows that queue length, which we directly measure from arrival/completion timestamps, is correlated with GC duration. This is because there are more active objects to process during a GC cycle when there's a high queue length, and there is higher memory pressure as well. The figure shows a scatterplot of the normal behavior, though we see a similar correlation during metastable failures as well.

Figure 4b also shows that GC causes the application to pause, which slows down the jobs. Here, we configure the JVM to print a more detailed metric (PrintGCApplicationStoppedTime) to indicate how the JVM impacts the job's running time. We find that GC activity is causing the application to pause and slow down. As a result, the application isn't able to process jobs as efficiently, resulting in a higher queue length, thus completing the feedback cycle.

We next study the factors that affect vulnerability by exposing the example to varying trigger sizes. In our example, we generate triggers by injecting 100% stalls in the program for varying trigger durations. During the trigger, requests still arrive, but are not launched and do not begin processing. Once the trigger completes, there is effectively a large burst of backlogged requests that creates a large spike in the queue length until the backlog is handled. In our model, this corresponds to the bottom left scenario in Figure 1 where a load spike trigger (i.e., L_{org} increases) starts a capacity degradation amplification (i.e., C_{sys} degrades) due to GC.

Figure 4c shows how the vulnerability varies as a function of RPS. At high RPS, even small delays would cause the system to fall into a metastable failure state, whereas at low RPS, the system can mostly recover unless there is a very large trigger duration. The figure also shows how the vulnerability changes with the JVM memory size. Striped areas show regions where the metastability depends on the higher or lower memory size. For example, the striped region between the max heap (i.e., JVM memory) sizes indicates it is a metastable failure region for the smaller size and a vulner-



(a) Trigger 10 s, -78% CPU. (b) Trigger 10 s, -80% CPU. (c) Trigger 9 s, -80% CPU. (d) Trigger 10 s, -80% CPU, -30% RPS.

Figure 5: Metastability in a Replicated State Machine (RSM) due to retries.

able or stable region for the larger memory size (depending on RPS). Larger memory sizes decrease the memory pressure, which lowers the effect of GC. Thus, the system is less vulnerable with more memory and can sustain higher trigger durations and higher RPS. Nevertheless, the system is still subject to metastable failures, so understanding the degree of vulnerability is important for managing the system.

5.2 Metastability due to Retries

We next demonstrate an example of a metastable failure in a replicated state machine (RSM) model utilizing a popular NoSQL database. RSMs are prone to slowdowns [28,41] that can act as capacity-decreasing triggers for metastable failures. We use the slowdowns of varying magnitude and duration to induce metastable failures where retries create the sustaining effect.

5.2.1 Experiment Setup

For this experiment, we rely on MongoDB replicated database [64] based on the Raft [42] replication protocol. We operate the database in a strongly-consistent mode in a cluster of 3 replicas. A primary and two secondary MongoDB servers (version 4.4.9) are deployed on AWS EC2 m5a.large instances with 2 vCPU and 8 GiB of RAM each using Docker containers. A client application provides a constant baseline workload of insert operations against the replicated MongoDB database. We deployed the client on a bigger m5ad.2xlarge instance with 8 vCPU and 32 GiB of RAM.

We keep the RSM in a vulnerable state by running a constant client workload of approximately 6,200 successful RPS. A client uses a 3-second timeout for requests and will retry each operation up to 4 times after the timeout. To introduce the slowdowns, we temporarily restrict the CPU resources on the docker container running the primary node. In our model, this corresponds to the top right scenario in Figure 1 where a capacity-decreasing trigger (i.e., C_{org} decreases) causes a workload amplification (i.e., L_{sys} increases) due to retries.

5.2.2 Inducing Metastable Failures

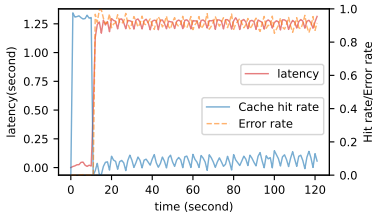
In Figure 5, we present the result of four experiments to demonstrate the relationship between trigger magnitude, trigger duration, and request rate. The figure truncates the experiments at 150 seconds, however, we ran the workloads for 500 seconds to ensure there is no delayed recovery from failure. We apply the capacity-decreasing trigger at the 60 second mark, as indicated by the gray shaded region in each of the subfigures.

(a) Baseline with no metastable failure. Figure 5a demonstrates a trigger of 10 seconds with a 78% reduction in CPU availability. This trigger briefly reduced the success rate of client requests, as observed by the dip in throughput with a corresponding increase in latency. The impact was brief with the occurrence of limited failures and retries towards the end of the trigger duration. The system does not enter a metastable failure state and recovers shortly after the trigger is removed.

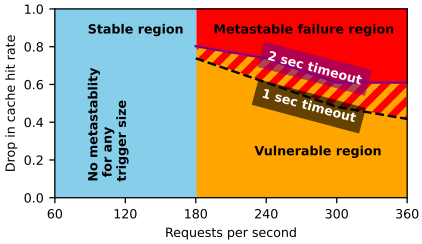
(b) Increased trigger magnitude causes metastable failure. Figure 5b demonstrates a metastable failure in an RSM. This result illustrates that even a slight increase in a trigger magnitude can push the system into metastability. In this instance, the trigger is of the same duration (10 seconds) against the same workload as (a) but with an 80% reduction in CPU availability (2% additional reduction). With this trigger magnitude, the system performance does not ever recover once the trigger is removed. Latency plateaus at approximately the client timeout of 3 seconds, and the total number of attempted requests peaks at around 20,000 RPS (a 3× increase over baseline), and goodput is reduced by ≈ 90% to 600 RPS. The client retry mechanism provides the feedback loop that prevents the system from resuming a normal state.

(c) Decreased trigger duration averts metastable failure. Figure 5c demonstrates that a minor change to a trigger duration, compared to the previous experiment (Figure 5b), can prevent a system from entering the metastable failure state. The experiment setup is the same as (b), except the trigger duration is reduced by 1 second from 10 seconds to 9 seconds. Similar to (a), we observe a transient increase in latency and a corresponding reduction in goodput. However, the system's performance recovers in this experiment, demonstrating the impact of trigger duration on vulnerability.

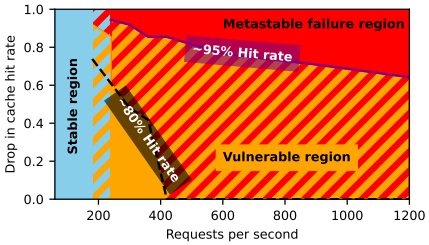
(d) Reduced load averts metastable failure. Figure 5d illustrates system performance when the base workload is reduced to about 4,200 RPS (≈ 30% lower than the baseline RPS) to show a system with more idle resources to handle triggers. We used the same trigger magnitude and duration as



(a) Trigger at 10s induces a metastable failure where a low cache hit rate causes the database to become overloaded. This results in high sustained error rates and latencies.



(b) Vulnerabilities for different request timeouts. Striped area between lines indicates it is a metastable failure region for 1 second timeouts and a vulnerable region for 2 second timeouts.



(c) Vulnerabilities for different steady state cache hit rates. Striped areas indicate the region is different for the hit rates (e.g., metastable failure for ~80% and vulnerable for ~95%).

Figure 6: Metastability in Look-aside cache.

in (b) (a trigger intensity of 80% and a trigger duration of 10 seconds) that pushed a more loaded system into a metastable failure. With more idle resources to handle the transient performance degradation, the system handled the trigger gracefully with only a temporary increase in latency.

Throughout our experiments on a replicated database, we have established that a trigger that sets off the retry process can lead to the feedback loop that prevents a distributed system from recovering. Moreover, even small changes to a trigger had a significant impact—a 2%-decrease in available CPU or a 1-second increase in duration separated successful recovery from a metastable failure. All experiments exhibit a small number of failed requests immediately before the trigger is removed. However, (b) demonstrates an increased level of failures and retries during the last second of the trigger. This suggests that timely removal of the trigger can prevent the transition into the metastable failure state.

5.3 Metastability due to Look-aside Cache

We next illustrate another type of metastable failures due to look-aside caching. Look-aside caching is a popular caching strategy where an application looks for data in a cache and will retrieve data from a backend system for cache misses. The application is then responsible for putting the data from the backend into the cache.

The metastability arises because the application is not always able to add the data from the backend into the cache. Specifically, if a trigger causes the cache hit rate to drop, then that would result in a higher rate of misses and an unexpectedly high rate of requests to the backend system. This amplified workload would in turn cause the backend to slow down, which would lead to timeouts in the application and/or backend. When there are timeouts, the application is unable to put data into the cache. As a result, the cache hit rate remains low, which sustains the metastability.

5.3.1 Experiment Setup

To replicate this metastability, we build an example web application with a MySQL database (34.6 million entries, totaling 15GB) and a memcached cache (1GB). If the web application is unable to find an item in the cache, it queries the database and stores the result in the cache. Items are requested following a Zipf distribution—a common distribution for representing cache entry popularity [6].

The arrival times are generated via a standard Poisson process at the desired RPS from our load generator. Our web server runs a standard Nginx + PHP setup, and we configure 1 second timeouts for the requests, which are much higher than the normal request processing times.

5.3.2 Inducing Metastable Failures

Figure 6a shows an example of a metastable failure when a trigger causes the hit rate to unexpectedly drop at time 10s. We see that the backend traffic sharply increases, which results in timeouts and errors. Since the application is unable to get the data before the timeout, no new data is added to the cache, which sustains the low hit rate for long periods of time.

We next run the system under different RPS and inject triggers of different magnitudes to evaluate whether the system is able to recover. We inject triggers by deleting the hottest items in the cache*. In our model, this corresponds to the bottom right scenario in Figure 1 where a capacity-decreasing trigger (i.e., C_{org} decreases) starts a capacity degradation amplification that causes the degradation to persist even after the cache memory is available for use (i.e., C_{sys} remains degraded). After the trigger, we run the system for an hour to see if it can recover or if the metastable failure persists. If the system doesn't recover within an hour, we mark this as a metastable failure. Caching systems by nature are self-healing, and we would expect the system to eventually recover if there's a non-zero chance that a request would successfully add data to the cache. However, long-term outages are catastrophic to companies so we still deem these cases as metastable failures.

Figure 6b illustrates the different degrees of vulnerability in our look-aside caching example. Under low RPS, the system is stable and can recover even if the entire cache is wiped. As the RPS increases, the system becomes more vulnerable where smaller drops in hit rate could cause the system to fall into a metastable failure region and not recover.

Figure 6b also illustrates the impact of the request timeout parameter. When increasing the timeout from 1 second to 2 seconds, the vulnerability at each RPS is decreased (i.e., a higher trigger magnitude is needed to cause metastable fail-

*Dropping the hottest items gives a conservative bound on the metastable region since these are the easiest items to recover.

ures). So there is a trade-off with setting the request timeout—a higher timeout decreases the vulnerability, but it takes longer to detect failed requests, whereas a lower timeout can quickly detect issues, but increases the metastable vulnerability.

Figure 6c demonstrates the impact of the steady state cache hit rate on vulnerability. When comparing a workload with a $\approx 80\%$ cache hit rate vs. a workload with a $\approx 95\%$ cache hit rate, we see that the higher hit rate is less vulnerable. This is because the workload has a more skewed popularity distribution where a small number of keys constitutes a large fraction of the requests. This skewness makes it easier to recover from a drop in hit rate. However, higher hit rates enable the system to operate at higher RPS where the system is vulnerable, and we see that the ~95% workload has a much wider range of vulnerability in terms of RPS. Thus one still needs to consider metastable issues at high hit rates.

6 Discussion

6.1 Multi-System Failures

Many metastable failures involve a combination of systems or components interacting together. Often, these failures are described as cascading failures (GGL1), where the failure of one system causes further faults in other components. The interactions between systems make it more difficult to identify the sustaining effect and enact quick fixes. Our caching example is a good illustration of such a multi-system failure.

In our caching example, the cache and storage systems are coupled together. When a cache fails, the result is a load spike in the storage system – a capacity degradation of one component cascades to a load increase in another. Even in the absence of workload amplification, this multi-system example has a sustaining effect. The complete cache-storage system needs the storage component to respond in time to fill the cache and reduce the load on storage. At the same time, the storage cannot do so due to the overload, creating a sustained condition where the overload cannot be alleviated even after the cache has all servers back up again.

6.2 Human Factors

Around 50% of the observed triggers have some direct human involvement, such as the deployment of buggy configuration (GGL3, GGL4, AWS1), rushed testing and deployment (AZR4), incomplete testing that fails to find bugs (GGL2, GGL4, AZR2, AZR3, IBM1), and regular maintenance (ELC1). For instance, in the AZR4 incident, engineers rushed a buggy code for deployment without proper testing. The bug would increase CPU consumption on some background tasks, essentially decreasing the system's processing capacity. Moreover, the deployment was happening on Friday before a long holiday weekend when the load on the system was lower than usual, potentially preventing the deployment procedure from catching the capacity degradation. After the holiday weekend when traffic returned to normal, the system was overwhelmed, which increased latency, caused timeouts, and failed user requests. This issue could have been avoided with more complete testing and better deployment practices. Another example of a human factor in metastability is the GGL4 incident where engineers bypassed the testing phase and released a buggy configuration to production.

6.3 Fix to Break

Misunderstanding the processes that cause the failure can lead engineers to adapt long-term fixes or changes that can further exacerbate the vulnerability for metastable failures. For example, not realizing the existence of a feedback loop may cause engineers to introduce changes that make the feedback loop more severe. In the AWS2 incident that brought down AWS SimpleDB, the storage servers frequently communicate with the locking service to ensure they are still part of the system. When an overload to the locking service occurred, the storage servers started to timeout and retry, further adding to the locking service overload. After several retries, the servers would demote themselves and stop serving the storage workload. The locking service remained overloaded for as long as enough storage servers were alive to keep the lock service busy. In the aftermath of the incident, engineers decided that servers must continue to retry the locking service instead of giving up, as the lack of prolonged retries was seen as the reason for botched recovery. Unlimited retries, however, can put a lot more workload amplification on the system and make the sustaining effect more severe. A similar incident (AWS3) happened to the DynamoDB database about a year later. The storage nodes did not back out of retrying to get updated membership data, causing a massive workload amplification and metastable failure.

Another example of this is the SPF1 and SPF2 incidents. In the aftermath of the first incident, engineers added significant logging to the error path of request execution to better understand the cause of the load spikes and retries. In SPF2, the additional logging after a load spike and initial retries increased the cost of each retry, adding more load to the system and causing more requests to retry.

6.4 Mild Metastable Failures

Many metastable failures are severe enough to cause a significant service disruption. However, this is not necessarily the case for all metastable failures. The CAS1 incident is an example of metastable behavior that did not cause a significant outage. Another example is our Twitter case study. While the metastable failure was severe enough to trigger internal alerts, it was very far from becoming an outage. This mildness was partly due to monitoring of key performance metrics and a timely response.

6.5 Prevention and Mitigation

A crucial aspect of preparing for metastable issues is understanding the system's vulnerability. As we have seen throughout our experiments with retries, caching, and GC, many factors impact the vulnerability of a system, ranging from the load to trigger magnitude and duration and to sustaining effect mechanisms, such as workload amplification growth. With a proper understanding of the processes involved, we can

have better control over both the triggers and sustaining effects. For example, our Twitter case study showed that even if the sustaining effect cannot be eliminated, knowing and understanding its characteristics can help engineers adjust parameters and reduce its impact in the future.

Similarly, systems may not be able to avoid all possible triggers, but they can often mitigate the trigger's impact. For instance, designing systems to be more resilient to component slowdowns [41] can help reduce the severity of triggers and reduce the system's vulnerability. Designing automated mitigation strategies can reduce the trigger duration, which result in a small performance blip instead of a metastable failure.

While autoscaling of resources can help mitigate metastable failures in some cases, it does not necessarily prevent metastable failures. Autoscaling is a way to increase the normal capacity C_{norm} of a system in response to load events, which should also raise the stable threshold C_{stable} and help the system recover sooner. However, autoscaling can be extremely costly for large systems and large work amplification factors. For instance, a loss of a cache with 99% hit-rate can result in a 100X amplification. Whether the current autoscaling techniques can scale up fast enough to avert a metastable failure requires further research. Furthermore, it is not always possible to autoscale services due to stateful components and system complexity (e.g., case Azure LL1H-9CZ).

7 Related Work

Since metastable failures were established as a class very recently [7], there have not yet been any studies particularly about them. However, researchers have discovered other classes of failures that we think are relevant to metastability. Specifically, the types of failures and bugs that we discuss below often act as triggers that lead to metastable failures.

One such class is *fail-slow* failures [27], which were extensively studied under different names: *fail-stutter* [3], *gray-failure* [29], and *limpware* [15, 16, 25]. Fail-slow failures happen when a hardware experiences a significant slowdown but is still functional. Since fail-slow failures can occasionally exhibit transient stops [27], they can trigger metastable failures. Unlike metastable failures, however, fail-slow failures are essentially subtle hardware failures that can be fixed by replacing the faulty hardware.

Another related class of failures is due to scalability bugs [34, 53]. These are latent software bugs that are scale-dependent—they only surface in large-scale deployments and are not discoverable in small-scale testing. As a result, load spikes can expose scalability bugs, which can trigger metastable failures. We have observed several incidents where load spikes exposed a bug that triggered a metastable failure.

Finally, there have been multiple studies on failures in distributed systems caused by configuration changes [40, 59] and software upgrades [63] both of which were predominant triggers of metastable failures in our study.

In general, most prior studies classify incidents according to their main root cause, for example, software bugs, hardware faults, misconfiguration, etc. The metastable failure model, where a service in the vulnerable state is tipped over to failure by a trigger, allows a richer, multi-dimensional characterization of bugs. Metastability would likely explain some of the bugs others have studied, but to date, researchers have lacked a framework for identifying such failures. It is notable that in [61] the authors observe that failures often "require an unusual sequence of multiple events with specific input parameters from a large space", which suggests that they may have in fact encountered metastable failures.

The cloud outage study of [26], which examines almost 600 publicly reported outages in popular Internet services, discusses the idea of "hidden single points of failure" and observes that the recovery process itself is often faulty or simply doesn't run because the right metrics are not being monitored. Our model for metastable failures may help identify the metrics that may act as triggers. They also note that the recovery process can be a source of metastable amplification, such as with retry storms or failover to cold caches.

In the Azure incidents studied by Liu et al. [36], running-environment mitigation techniques are commonly applied, such as restarting or migrating processes or adding capacity resources. The authors note that to date there has been little work on automation of such recovery methods – this would also be a fruitful direction in mitigating metastable failures.

What sets a metastable failure apart from all of the above is that its root cause is not a specific hardware failure or a software bug. It is an emergent behavior of a complex system that naturally arises from optimizations for the common case. Specifically, if the aforementioned failures do not trigger a metastable failure, then identifying and eliminating them restores the system functionality. If, however, they do trigger a metastable failure, then eliminating them will not restore the system's functionality.

8 Conclusion

Metastable failures are a class of system failures characterized by sustaining effects that keep systems in a degraded state and resist recovery. While relatively infrequent, metastable failures were behind big outages at large internet companies (including a recent AWS outage on December 7th, 2021). In this work, we confirm this observation by studying public incident reports. We then extend the metastability framework based on our observations for a more accurate metastability model. We validate our model by building three applications and reproducing different instances of metastability on them. We hope our work spurs further research into understanding and preventing metastable failures.

Appendix

A Proof of model theorems

A.1 Proof of Theorem 1

Assuming no overloading trigger, then by Definition 2 we have $C_{norm} - L_{norm} > m_{trigL} + m_{trigC}$. So,

$$\begin{aligned} L_{org}(t) &\leq L_{norm} + m_{trigL} && \text{(Definition 1)} \\ &< C_{norm} - m_{trigC} && \text{(assumption)} \\ &\leq C_{org}(t) && \text{(Definition 1)} \end{aligned}$$

Since $L_{org}(t) < C_{org}(t)$ for all t, then $\Delta t_{trig} = 0$. Since $w_L(0) = 1$ and $w_C(0) = 1$, then $\alpha_L(t) = 1$ and $\alpha_C(t) = 1$ for all t. Therefore, $L_{sys}(t) = L_{org}(t) < C_{org}(t) = C_{sys}(t)$ for all t by Definition 4. Thus, the system is never overloaded and never in a metastable failure state. □

A.2 Proof of Theorem 2

Assume $L_{norm} < C_{stable} = \frac{C_{norm}}{(w_L^* * w_C^*)}$. So,

$$\begin{aligned} L_{norm} * \alpha_L(t) &\leq L_{norm} * w_L^* && \text{(Definition 4)} \\ &< C_{stable} * w_L^* && \text{(assumption)} \\ &= C_{norm} * w_L^* / (w_L^* * w_C^*) && \text{(assumption)} \\ &= C_{norm} / w_C^* && \text{(algebra)} \\ &\leq C_{norm} * \alpha_C(t) && \text{(Definition 4)} \end{aligned}$$

Thus, under the normal conditions without triggers, the amplification factors are bounded such that the system is always stable even with the worst-case amplification factors. □

A.3 Proof of Theorem 3

Assume $w_L(\Delta t_{trig}) * w_C(\Delta t_{trig}) < \frac{C_{norm}}{L_{norm}}$. So,

$$\begin{aligned} L_{norm} * \alpha_L(t) &\leq L_{norm} * w_L(\Delta t_{trig}) && \text{(Definition 4)} \\ &< C_{norm} / w_C(\Delta t_{trig}) && \text{(assumption)} \\ &\leq C_{norm} * \alpha_C(t) && \text{(Definition 4)} \end{aligned}$$

Thus, under the normal conditions without triggers, the amplification factors are bounded such that the system is always stable. □

A.4 Proof of Theorem 4

Assume at time t, $L_{sys}(t) - C_{sys}(t) \geq \alpha_L(t) * m_{trigL} + \alpha_C(t) * m_{trigC}$. So,

$$\begin{aligned} & L_{norm} * \alpha_L(t) \\ &= L_{org}(t) * \alpha_L(t) - (L_{org}(t) - L_{norm}) * \alpha_L(t) && \text{(algebra)} \\ &\geq L_{org}(t) * \alpha_L(t) - m_{trigL} * \alpha_L(t) && \text{(Definition 1)} \\ &= L_{sys}(t) - m_{trigL} * \alpha_L(t) && \text{(Definition 4)} \\ &\geq C_{sys}(t) + \alpha_C(t) * m_{trigC} && \text{(assumption)} \\ &= C_{org}(t) * \alpha_C(t) + \alpha_C(t) * m_{trigC} && \text{(Definition 4)} \\ &\geq C_{org}(t) * \alpha_C(t) + \alpha_C(t) * (C_{norm} - C_{org}(t)) && \text{(Definition 1)} \\ &= C_{norm} * \alpha_C(t) && \text{(algebra)} \end{aligned}$$

Thus, if at time t we removed the triggers and reverted to the normal load and capacity, then the amplifying factors would cause the system to remain in an overloaded state. So the system is in a metastable failure state. □

Demystifying and Checking Silent Semantic Violations in Large Distributed Systems

Chang Lou Yuzhuo Jing Peng Huang

Johns Hopkins University

Abstract

Distributed systems today offer rich features with numerous semantics that users depend on. Bugs can cause a system to silently violate its semantics without apparent anomalies. Such silent violations cause prolonged damage and are difficult to address. Yet, this problem is under-investigated.

In this paper, we first study 109 real-world silent semantic failures from nine widely-used distributed systems to shed some light on this difficult problem. Our study reveals more than a dozen informative findings. For example, it shows that surprisingly the majority of the studied failures were violating semantics that existed since the system's first stable release.

Guided by insights from our study, we design Oathkeeper, a tool that *automatically* infers semantic rules from past failures and enforces the rules at runtime to detect new failures. Evaluation shows that the inferred rules detect newer violations, and Oathkeeper only incurs 1.27% overhead.

1 Introduction

Users' increasing reliance on distributed systems highlights the importance of ensuring they work correctly. Unfortunately, real-world distributed systems inevitably encounter failures. When a failure is recognizable through explicit signals such as crash, timeout, error code, or exception, timely actions can still be taken to detect [22,40,46] and mitigate [41,52,53] the failure. A vexing problem occurs when a system is operational but *silently* breaks its semantics without apparent anomalies.

Take a distributed notification service as an example, which provides an interface that promises to invoke the client callback whenever the status of some object changes. A bug may cause this system to miss invoking the callback upon a change or invoke the callback more than necessary. As another example, a distributed file system that is supposed to replicate data blocks by user-configured n copies may incorrectly under-replicate some blocks without any explicit errors.

Such failures can lead to severe consequences because they violate the guarantees a system provides to its users. They also break the contracts that other components or applications rely on, and result in amplified incorrectness. Moreover, since the violation is silent, the damage exacerbates over time. For example, as the buggy distributed file system that silently violates its replication policy continues to run, more and more newly created files will be subject to potential data loss.

System	Ver.	Client API	Public Method	Admin Command	Config.
ZooKeeper	3.4.6	38	219	13	30
ZooKeeper	3.6.2	78	2,853	18	128
HDFS	2.7.2	128	5,293	11	224
HDFS	2.10.0	162	6,306	12	449
Kafka	2.6.0	166	2,661	76	366
Kafka	2.8.0	171	3,107	86	379

Table 1: Number of public interfaces in popular distributed systems. An interface can have multiple semantics under different settings.

Distributed systems today have rich semantics (Table 1) exposed through client APIs, public methods including RPCs among internal components, administrator commands, configuration parameters, *etc.* One interface often encodes multiple guarantees. New interfaces and semantics are also continuously introduced as a system evolves. These characteristics together make it challenging to ensure that a distributed system conforms to its semantics in production settings.

Indeed, real-world evidence shows that semantic violations occur in practice. In a Google cloud incident [3], a traffic engineering subsystem that is supposed to throttle traffic upon congestion incorrectly throttled traffic even though the network was not congested. Another highly-impactful global outage [2] was caused by a quota system incorrectly reporting the usage for a user ID service as zero.

However, other than anecdotal evidence, the problem of silent semantic violations in distributed systems remains mysterious, despite its severe consequences. For instance, mature distributed systems include extensive test cases to check the correctness of their features. Thus, it is natural to assume silent semantic violations are rare in production because testing likely has eliminated most of them. In addition, while adding assertions and runtime verification [43,44,48,57] are potential solutions, the conventional wisdom is that they are expensive and semantic rules are difficult to get. It is also unclear what kind of semantics are violated in practice.

To systematically understand this problem, we present, to our best knowledge, the first empirical study on 109 *real-world* silent semantic violations from nine widely-used distributed systems. Through these cases, we analyze key questions such as *how prevalent are semantic violations in practice*, *what semantics are violated*, *why are these failures not caught in testing*, and *how are these silent violations detected*.

Our study provides quantitative data points to answer these

questions. The study findings also challenge some conventional wisdom and reveal gaps in the current practice. We highlight several findings:

- Contrary to the belief that silent semantic violations rarely occur in deployed systems, they have significant presence (39%) among sampled failures of all kinds.
- While the studied systems get more extensively tested over time and continue to add new features and semantics, their initial semantics do *not* become more bulletproof. On the contrary, more than two thirds of the failures violate semantics that have existed since the system's first stable release.
- Although these are distributed system failures, most (74%) violations can be determined locally in some component.
- The violated semantics are often *not* untested but rather well covered by existing test cases.
- Enabling assertions in release builds helps by converting semantic violations into crash failures. One studied system does this and has the lowest ratio of semantic failures.
- In many cases, although a semantic was initially honored, it was later violated, thus one-time assertions are insufficient.
- Many system semantics are vulnerable to violations during maintenance operations or node events.

Given the prevalence (as our study indicates) and severity of silent semantic violations, we design a tool Oathkeeper to help users check silent semantic violations at runtime. The tool design is directly guided by insights from our study.

Specifically, we find that in 73% of the cases, developers add regression tests after the failure is reported, which contain valuable information about the failed semantic. However, the majority of the studied cases still violate semantics that have been tested before. A major reason for the gap is that these regression tests are usually patch-driven: they only check if the specific bug is fixed in a particular setup using a bug-triggering workload. The underlying semantics can continue to be broken with different root causes in different scenarios.

Based on this insight, Oathkeeper leverages the regression tests and tries to infer the underlying semantic rules implied by the tests. To do so, Oathkeeper runs the tests on both the buggy version and patched version of the system, and takes a *template-driven* approach to automatically infer semantic rules from the two traces. Oathkeeper then deploys these semantic rules to production to catch future violations that are caused by different bugs under different conditions.

We evaluate Oathkeeper on ZooKeeper, HDFS, and Kafka. Oathkeeper infers hundreds to thousands of semantic rules from the old regression tests in these systems. With the inferred rules, we evaluate Oathkeeper on seven real-world semantic failures that were introduced long (9–34 months) after the old failures. Oathkeeper detects violations for six of them. With all rules enabled, Oathkeeper on average only incurs 1.27% throughput overhead to the target systems.

The contributions of this paper are two-fold: (i) the first study on *real-world* silent semantic violations in nine popular distributed systems; (ii) the design of Oathkeeper, which automatically infers semantic rules for large distributed systems to check silent semantic violations at runtime.

The source code of Oathkeeper is publicly available at:

`https://github.com/OrderLab/OathKeeper`

2 Background

2.1 Definition

We consider a distributed system $\mathcal{S}$ that provides services through a collection of operations. Each operation o has certain *semantics* [29]. The semantics encode guarantees that o makes about the output, system states, and results of subsequent operations, in response to some triggering condition c. The condition c can be a client request, an admin command (at the server side), a message from internal components, as well as an environment change including the passage of time. The semantics of $\mathcal{S}$ are all the guarantees provided by the history of operations $\mathcal{S}$ executes in response to a list of c.

A semantic violation (failure) occurs when $\mathcal{S}$ breaks some of its semantics in an execution. The failures may exhibit explicit error signals, such as crashes, timeouts, and exceptions. In such cases, the violations overlap largely with existing failure models and can be well addressed by existing techniques.

This work focuses on *silent* semantic violations, in which $\mathcal{S}$ violates its semantics but remains operational without exhibiting explicit error signals ($\mathcal{S}$ is unaware of its misbehavior). We focus on this class of failures because they are under-studied yet incur damaging consequences, and they pose significant challenges to testing, failure detection, and recovery.

Silent semantic violations differ from other failure modes in observability. Fail-stop failures cause complete loss of functionality, which can be observed with simple measures such as monitoring heartbeats. Fail-slow [32], partial failures [46] and gray failures [37] only cause some functionality to be broken (slow). But these issues can still be observed with generic approaches, *e.g.*, checking exceptions or timeouts [45]. In comparison, silent semantic violations are difficult to observe without a deep understanding of $\mathcal{S}$' semantics and execution.

Another way to interpret the "silent" aspect is on the semantics being violated. If $\mathcal{S}$ only has a few operations, all of which have well-defined and thoroughly checked semantics, semantic violations in $\mathcal{S}$ will be observable failures. Unfortunately, distributed systems have a large number of interfaces (Table 1), many of which have loosely-defined (or hidden) semantics that cannot be easily checked. Consequently, violations of such semantics are difficult to detect and address.

2.2 An Example

We show an example of silent semantic failures from our study (Section 3). ZooKeeper is a coordination service with a hierarchical data model. Its clients store data by creating `znode` in a namespace. A special type of `znode` is called ephemeral node. The semantics of the ephemeral node `create()` operation guarantees that the `znode` exists for as long as the creating

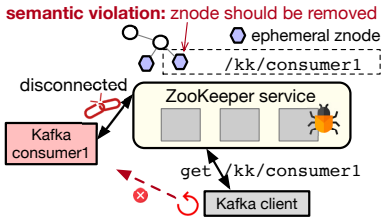

Figure 1: A silent semantic failure in ZooKeeper.

client's session and will be deleted once the associated session ends. The triggering conditions are the create request and the client session disconnection. Ephemeral nodes are commonly used to store membership information. For example, HDFS implements its leader election using ephemeral nodes [27].

In a production ZooKeeper failure [13], some ephemeral node still existed even though the client session that created them was long gone. Specifically, a Kafka consumer crashed but the associated `znode` was not deleted (Figure 1). As a result, when Kafka clients queried ZooKeeper to discover consumer information, they kept trying to connect to the crashed consumer. In other settings, this semantic violation can propagate to other dependent applications, *e.g.*, it will break HDFS namenode's automatic fail-over feature, which depends on the ephemeral node semantics, causing an HDFS service outage.

3 Study Methodology

Compared to other failure modes in distributed systems, silent semantic violations are not well understood. To fill this gap, we conduct a study on *user-reported* silent semantic failures from nine large-scale distributed systems (Table 2). We select these systems because they are representative, mature, widely used in production, and record many user-reported failures.

To collect the failure cases, we first query the study systems' issue trackers to find tickets that (1) are marked as "bugs", (2) have priorities higher than "minor", (3) are resolved, (4) involve the server components. This step returns a large number of tickets. We then *randomly* sample a subset (Table 2). Among this subset, some are not real failures, such as issues found in internal testing. The remaining ones (*valid* column in Table 2) are potential production failures. We then read their descriptions and check whether the failures violate system semantics. We filter crashes, aborts, out-of-memory errors, and semantic failures with clear error signals.

After the above step, we get a candidate set of production silent semantic failures (*Candidate* column). Due to time constraints, we perform in-depth analyses on a subset of the candidate cases, preferring those with sufficient information and discussions. This gives us the final study dataset (*Studied* column) of 109 production semantic failure cases.

Note that our sample sizes vary across systems. This is because the studied systems' tickets vary greatly in terms of their information, quality, and bug types. If using a fixed sample size or ratio, one system can dominate the study and produce extremely biased findings. Our sampling instead is done iteratively: for a particular system, if after an initial sampling, its number of *Candidate* cases is too small or 0, we sample more, until the candidate numbers for different systems are relatively balanced. Note that each iteration in this process is still randomly choosing from the *All* tickets.

Table 2: Studied systems, the tickets (of various kinds) in the issue tracker of each system, the cases we sampled, and cases studied.

Threats to Validity. Like all empirical studies, our study is subject to validity problems such as the representativeness and biases. We cover popular distributed systems of different types, such as database, file system, and search engine, to improve the representativeness. To minimize selection bias, we *randomly* sample the cases. We also spread the sampling across times so we are not biased by some specific version. To reduce the manual inspection errors, we write a detailed analysis document for each case and have multiple inspectors examine each document to reach a consensus.

Although our study provides informative findings on semantic failures in the studied systems, they may not be generalized to other systems beyond the scope this study was conducted. Our study is also biased by programming languages (Java and C++); the findings may not generalize to systems written in other languages such as Erlang or Elixir, which embrace "let-it-crash" error handling philosophy [18].

4 Are Silent Semantic Failures Rare?

Prevalence. An important question about silent semantic violations is whether they occur rarely in production. Getting accurate prevalence data requires examining thousands of tickets for each system, which is a daunting task. We instead obtain an approximate result by calculating the percentage of silent semantic failures in our sample set. Specifically, we calculate the percentages of the number of *candidate* cases in Table 2 over the number of *valid* cases in the sample. Note that the candidate cases are examined to be indeed silent semantic failures, even though we only study a subset of them.

Finding 1: *Silent semantic failures have significant presence across all studied systems, occupying 20%–57% (39% on average) of the sampled cases for all types of failures.*

The percentages vary in different systems. Systems such as ElasticSearch and Cassandra have a higher percentage of semantic failures (57% and 46%, respectively). MongoDB has the lowest ratio (20%). We will discuss in Section 8 these

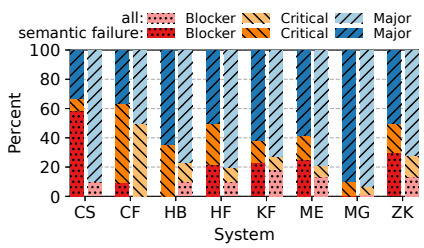

Figure 2: Issue priorities of semantic failure cases and all valid sampled cases.

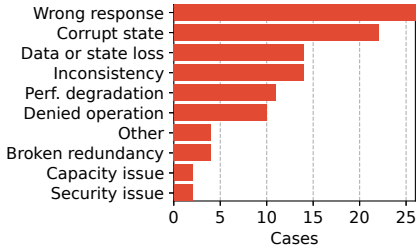

Figure 3: Consequence of the studied semantic failures.

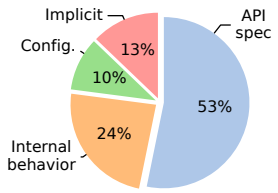

Figure 4: Sources of violated semantics.

systems' practices that may contribute to the differences.

Severity. How severe are these reported silent semantic failures? To answer this question, we analyze the severity levels that developers assign to the issues. Some systems use slightly different categories. We normalize them into three levels: *Blocker*, *Critical*, *Major*. Based on the official descriptions, *Blocker* means the issue "should block release until it is resolved"; *Critical* means the issue causes severe consequences like data loss; *Major* means a "major loss of function".

Overall, 45% of the studied cases have *Blocker* or *Critical* priorities. The ZooKeeper failure [13] described in Section 2.2 is an example *Blocker* issue. As another example *Blocker* issue, users reported that in their HDFS deployment, all the replicas of some blocks are residing on the same rack [8], which breaks the redundancy policy. This is clearly a severe violation because replica placement is critical to HDFS data.

We also compare the priority distribution of semantic failures with all failures in the sample. The result is shown in Figure 2. The average percentage of Blocker priority in semantic failures increases from 15% to 21%, and the percentage of Critical priority increases from 8% to 24%.

Interestingly, we find in some cases initially developers may not consider the symptoms to be severe, but after further investigation developers upgrade the priority level, *e.g.*, *"Marking as critical for 2.0. These 'unexpected behaviors' cause operator head-scratching and wasted hours of digging"* [5].

Finding 2: *Despite the lack of explicit error symptoms, silent semantic failures are considered severe by developers and users. Moreover, the sampled semantic failures are assigned with higher priorities compared to all sampled failures.*

Consequence. We next analyze the failure consequences. Figure 3 shows that besides incorrectness, semantic failures cause serious consequences such as corruption and data loss.

The consequences are damaging because clients or users are misled by the system's seemingly normal reactions. For example, Kafka guarantees that when a success response is sent to a producer, the produced message will be persisted by at least `min.isr` replicas. Otherwise, the producer will be notified of an error, so it may retry the request. In one failure [9], a leader replica switched to follower then back to leader. Some messages produced were lost while the client received responses with no error. This false success resulted in data loss for the users.

Note that Figure 3 is about the reported impact of failures, which is not always the semantic violation per se. For example, in a MongoDB case, the maximum cache usage configuration is not enforced. It takes a while for the violation to cause a performance problem—which is the consequence of this failure. But even before the system reaches the performance collapse, a cache limit violation has occurred.

Finding 3: *In addition to incorrectness (wrong responses), silent semantic violations often cause severe consequences including corrupt state, data or state loss, and security issues.*

5 What Kind of Semantics Is Violated?

5.1 Sources of Violated Semantics

The studied failures violate various system-specific semantics. We analyze where these semantics come from. There are four sources and Figure 4 shows their distributions:

- **API spec**: a system API promises certain effect will (not) occur, *e.g.*, a successful return of `removeWatch` API is supposed to remove the specified watcher.
- **Internal behavior**: the system's documentation explicitly guarantees that something should (not) occur about its *internal* behavior, which is not directly exposed to external APIs, *e.g.*, HDFS guarantees that if some Erasure Coding blocks fail, they should be detected and reconstructed.
- **User configuration**: user configurations regulate some system behaviors and the guarantees depend on the user settings. For example, the `max_hint_window_in_ms` parameter in Cassandra defines the maximum time window the coordinator will generate hints for a dead host.
- **Implicit**: the semantics are not explicitly defined or documented, but users expect them to hold for a correct system.

Finding 4: *Most (87%) studied failures violate semantics that are explicitly defined in API specs, system docs, or configs.*

Interestingly, in 10% of the studied cases, the system does not respect its configuration's semantics. For example, if users set `acl.inheritance` to `true`, HDFS should enable ACL inheritance; but in one case the inherited ACL permissions are masked [7]. This violation causes security issues. The problem of misconfiguration is extensively researched [20,21,35,56]. This finding suggests that even when users set configuration properly, a system can still misbehave.

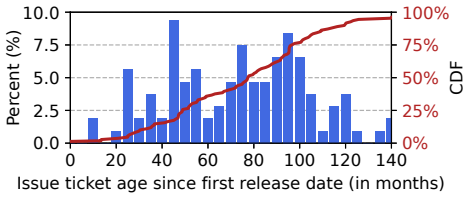

Figure 5: Issue ticket age (creation date minus first release date).

As an example of *Implicit* semantics, in one HBase case [4], a region is online in server A, but the region location registered in the meta table is server B. While this consistency semantics is a common sense, it is not explicitly declared.

Explicit documentation of semantics is indicative of developers' awareness of its guarantees and importance. One hypothesis is that if the semantics in a failure is not documented, it is understandable that developers did not make enough efforts to enforce the semantics. This finding disproves this hypothesis. However, the explicit documentations do *not* translate into fewer violations. One reason is that developers often document the semantics in a vague (*e.g.*, *"should produce correct results"*) or incomplete way. A more fundamental gap is that the documentation is designed to be human-readable but not machine-checkable. For example, the semantics for ephemeral `znode` in ZooKeeper is documented clearly, but the system does not have any mechanism or tool to enforce this semantics in deployment.

Implications: *Rich sources of documentation exist to leverage and judge semantic violations. Developers should move from documenting semantics in informal text to rigorously declare semantics that are mechanically checkable and enforceable.*

5.2 Categorizations of Violated Semantics

Old vs. New Semantics Modern distributed systems often keep adding new features. For example, the number of client APIs in ZooKeeper increased from 38 in version 3.4.6 (2016) to 78 in version 3.6.2 (2020). Similarly, HDFS' key APIs in `fs.FileSystem` increased from 128 in version 2.7.2 (2016) to 162 in version 2.10.0 (2019), along with significant increases of semantics in other interfaces such as RPC methods.

Since around 90% of our studied failures occurred after more than two years since the software's initial release (Figure 5), a natural hypothesis is that most of them violate some new semantics. We validate this hypothesis by analyzing the age of semantics in the studied failures. We define *old semantics* as ones that exist since the first major stable release of the system and others as *new semantics*.

Surprisingly, we find only less than one third (32%) of our studied failures violate relatively new semantics, while 68% of them violate old semantics. Old semantics usually represent the most fundamental functionalities the system provides since developers implement them first, and they usually undergo extensive testing already. However, our finding suggests that (1) even with new features added to the system, old semantics are still ones violated the most; (2) even with testing accumulating over the years, the reliability of old semantics is not necessarily higher in newer versions. Take ZooKeeper as an example. Its ephemeral `znode` interfaces and semantics have existed since the first major stable release (3.0.0) in October 2008 [1]. However, there are still production failures violating the guarantees of ephemeral `znode` reported by users even 10 years later [15].

We further investigate why old semantics still keep getting violated. There are three broad reasons: (1) *new implementation is buggy*, developers may optimize, refactor or refine the implementation of existing functionality, which contain bugs that break old semantics, *e.g.*, a concurrency bug introduced in changing an implementation to be multi-threaded; (2) *new feature adds buggy interactions*, when some new feature is added, developers may extend existing module to interact with or support the new feature. For example, after HDFS introduces the encryption zone feature, it needs to extend the original snapshot file function and the new handling path is buggy [6]; (3) *latent bugs are exposed*, as the most basic semantics, these old semantics' original implementations can be complex and contain latent bugs that can only be exposed in very specific scenario. In one ZooKeeper failure [14], users find the ephemeral `znodes` are not deleted when the system time changes unexpectedly. This bug exists for 6 years before it is discovered, because neither the testing nor most deployments would exercise the system with the time change.

Note that we did not count the numbers of semantics in the study, either for new or old semantics. This is because even with explicit documentation such as API specs, determining how many semantics are there for a given API can be subjective, which depends on the granularity of semantics. Instead, we objectively judge if the specific semantics violated in a failure were introduced in the initial release or not.

Finding 5: *68% of the studied failures violate old semantics.*

Implications: *Instead of having the false hope that old semantics are reliable, developers should invest efforts to prevent semantic violation regressions.*

Local vs. Distributed Semantics Since the study subjects are distributed systems, we analyze whether the semantic violations naturally require considering multiple distributed components. This question is important to the design of runtime verification techniques [43, 44, 48, 57].

We find that indeed 26% of the semantic violations require global information to judge, *e.g.*, whether the replica placement policy in HDFS is correctly enforced, or whether states in different Cassandra nodes match the consistency level.

However, interestingly, we find that the majority (74%) of the violations can be determined in a local scope. For example, `appendTo` in HDFS has the semantics of appending data to the end of a target file and making it persistent. A buggy node may fail to persist the new blocks or accidentally overwrite them. The violations can be determined in this node.

One reason is that a distributed system component often

keeps local copies of states for other components. For instance, even though ZooKeeper session is a global concept (a client connection to any follower or leader constitutes a session), such state is acknowledged to the ensemble. Thus, each node has a copy of the alive session and node list. The semantics of ephemeral `znode`, which require knowledge of the session information, can thus be checked locally in a ZooKeeper node.

Current runtime verification solutions typically aggregate global states across all nodes to check property violations. Obtaining such global information can be both expensive and tricky, *e.g.*, dealing with consistency issues in capturing distributed snapshots [23]. Our finding suggests it may be sufficient to use local checkers to expose many semantic failures.

Finding 6: *The violations in semantic failures can be usually (74%) determined in the scope of a single component.*

Implications: *Employing local checkers can potentially expose many semantic violations.*

Safety vs. Liveness Semantics Some failures break safety-related guarantees. For example, in Kafka, the maximum number of consumers in a group should not be larger than a configured limit, but users found more consumers joined the group.

In comparison, other semantics are liveness related. For example, ZooKeeper specifies that a container-type `znode` with no child `znodes` should *eventually* be deleted. Even when we observe some empty container node exists, it does not necessarily indicate this guarantee is violated because it might still hold some time later. Without context, one can interpret some safety guarantee, such as a correct response should be returned, to be involving liveness, because even if a response is not received, it could be still on the way. We refer to the system's official documentation for making the distinction. If the documentation explicitly states that when an operation returns, something (*e.g.*, a notification) will *eventually* happen, then a failure about its absence is a liveness violation.

It is generally challenging to check liveness properties [38], because there can be infinite possibilities in the execution that eventually produce the desired effect. Fortunately, we find most (86%) of our studied failures violate safety semantics.

Finding 7: *86% of the studied cases violate safety semantics.*

Implications: *There is usually a fixed time point to determine if a system has violated its semantics.*

6 Why Do Silent Semantic Failures Occur?

We analyze what causes a system to break its semantics. We are interested in identifying potential common bug patterns in the root causes, which can inform the designs of bug finding tools to eliminate semantic failures before production.

Some semantic failures are caused by bugs such as memory error, data race, and integer overflow, which are well studied with many tools designed to detect them. We find only 12% of the cases are caused by such bugs. The remaining failures are caused by system-specific logic bugs including design flaws, which are difficult to be caught by bug detection tools.

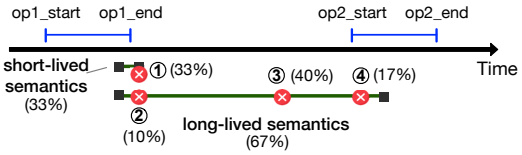

Figure 6: Timing of semantic violation.

An interesting finding is that even for failure cases that violate the same or related semantics, their root causes can be quite different. Take the ZooKeeper ephemeral `znode` as an example: (1) ZK-1208 is caused by a race condition: when ZooKeeper is handling the close session request, it deletes ephemeral `znodes` and then removes the session, in between a create operation causes new ephemeral `znodes` to be added; (2) In ZK-3144, the violations are caused by an incorrect order: during request processing, the `lastProcessedZxid` is updated before sessions are modified, so a snapshot may not include the change and the ephemeral node is not deleted after log replay; (3) In ZK-2355, the violations are caused by buggy error handling: follower fails while reading the proposal packet, but resetting `lastProcessedZxid` is missed in the error handler; (4) In ZK-2774, the system time of a server is changed unexpectedly, and session expiration codes rely the absolute system time, which causes the ephemeral `znodes` to persist after the client is disconnected for a long time.

Finding 8: *Only 12% of the studied failures are caused by well-defined bugs such as race conditions, while most cases are caused by a wide variety of logic bugs. Even for failures violating the same semantics, the root causes are diverse.*

Implications: *It can be challenging to exploit code patterns to eliminate semantic violations through static bug detection.*

7 How Are Semantic Failures Manifested?

Timing of Violation Understanding when semantics are violated can shed light on how to detect the violation.

As Figure 6 shows, some semantics only exist during the execution of its associated operation (at return point), *e.g.*, `read` operation should return the latest data. We call them *short-lived* semantics. In comparison, some semantics exist even after its associated operation finishes, *e.g.*, the specified file in `create` operation should be persisted and continue to be available after `create` returns. They often only cease to apply after some other event, *e.g.*, until a `delete` operation on the same file is executed. We call them *long-lived* semantics.

Interestingly, we find that 67% of the cases violate long-lived semantics. This is partly because these semantics have a larger "vulnerability" window compared to short-lived semantics: a violation can occur anytime in its lifespan. ZooKeeper ephemeral `znode` and watches are such examples. Essentially, the system must **maintain** the promise for a long time.

We categorize the violation timing into four scenarios: at the end of short-lived semantics (①), *e.g.*, wrong response, at the start (②) or in the middle (③) or near the end (④) for long-lived semantics. An example for ② is in HDFS-12217 the snapshot operation did not capture all open files, which

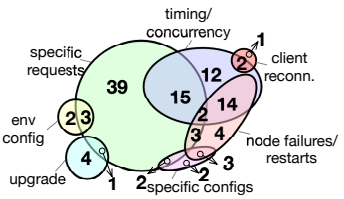

Figure 7: Distribution (# of cases) of the failure triggering conditions. Some combinations are omitted in the diagram for readability.

violates the long-lived snapshot semantics since the beginning. An example for ③ is HDFS-9083: at the block creation time, the block placement policy is honored; but after some node failures, all replicas of the block reside on the same rack. ④ happens when the semantics should cease to apply but did not, *e.g.*, ephemeral nodes should be removed when clients timeout. Figure 6 shows the distributions of the four scenarios.

Finding 9: *Near two thirds of the studied cases violate some long-lived semantics. In 40% of the cases, the semantics are initially honored but are violated in the middle.*

Implications: *It is crucial to* continuously *monitor semantic guarantees, even after the initial semantic check passes.*

Failure Triggering Conditions We further examine what triggers the semantic failures. Figure 7 shows the result.

Finding 10: *More than half of the studied failures are triggered by specific requests, while 39% of the failures require particular timing to trigger. Semantic failures often (41%) only manifest themselves under multiple types of conditions.*

HDFS-14514 is an example of semantic failure that requires multiple *types* of triggering conditions. The semantic violation (read out file size from snapshot is incorrect) can be only triggered when 1) `snapshot.capture.openfiles` is set; 2) create empty directory and encryption zone; 3) a client keeps a file open for write under the empty directory; 4) append several times; 5) perform a maintenance operation, snapshot.

We also find that in 23% of the cases, the triggering condition is certain system maintenance operation, such as compaction, cluster upgrade, node decommissioning. Such events do not occur frequently. They trigger semantic violations often because during the maintenance operation, the system execution enters a different mode, which exposes rare bugs.

Implications: *The reliability of semantics is vulnerable to maintenance operations or node events. Operators and the system should check violations during and after such actions.*

8 Current Practice for Semantic Failures

8.1 Testing

Since semantic violations concern functionality correctness, testing is responsible for catching them. The prevalence (Section 4) of many semantic failures in production seems to suggest a lack of testing. But that is not the case. The systems we study have extensive test cases—a median of 1309 test files. In addition, in 73% of the studied cases, the system has at least one test case covering the violated semantics.

Then *why the studied failures are not exposed during testing?* The earlier Finding 10 provides some clues. In many cases, even though there are related test cases, they lack some operations or arguments key to trigger the production failure. Even when the test cases have the proper operations and arguments, they only exercise the system under one timing, one configuration or normal scenarios, while the bugs are only triggered with unique timing, configuration, or node failures.

Are the failure triggering conditions so special that it is impossible for developers to foresee? Interestingly, we find that in many cases, similar triggering scenarios do exist in the test suite but they are not used in testing the violated feature.

Finding 11: *Semantic violations occur not simply due to a lack of testing. The violated semantics are usually (73%) covered by some existing test. In more than half of the studied failures, similar triggering conditions exist in the test suite.*

A fundamental gap is that developers tend to write tests driven by examples or fixes for a specific bug. Such tests are not expressive enough to preserve the underlying semantics and prevent regression. Consequently, developers spend repeated efforts to add tests. In HDFS-14514, the server reads snapshot file with incorrect length from encrypted zones. This exact semantics is already checked in an existing test case. If that test "copies" one line of test configuration `dfsAdmin.createEncryptionZone(...)` from other tests, the new bug will be triggered and exposed.

Implications: *Coverage of semantics alone is insufficient. Developers should introduce variances in existing test cases. It is also useful to "copy" triggering conditions across tests. More fundamentally, developers should write more general tests for the semantic properties rather than specific examples.*

8.2 Assertions

Assertions are a common method for catching logic bugs, which are major contributors to semantic failures (Section 6). They are typically only used in development and are turned off by default in release build for performance and stability.

Some of our studied systems use assertions in production: MongoDB has added many invariant checks since 2014 [11]. Interestingly, as Section 4 shows, MongoDB has the lowest ratio of semantic failures compared to other systems. While this practice may cause instability, *e.g.*, some users got infrequent crashes due to invariant check failures after upgrading to new versions [12], developers still prefer to fix the underlying bugs rather than turning off assertions completely.

We observe two gaps in the current practice. First, most existing assertions are pre-condition checks on the sanity of function arguments. They are too low-level to catch semantic violations, which require checking system functionalities and usually the operation history (*e.g.*, in checking consistency violations [48]). Second, existing assertions are usually only activated once during an operation, *e.g.*, the entry of a function. But many semantics are long-lived (Section 7), which require

continuous validation until the lifespan of semantics ends.

Finding 12: *Although in 51% of the failures the buggy functions have some sanity checks, few (9%) cases can be potentially detected by adding proper sanity checks.*

Implications: *Enabling assertions helps reduce silent semantic violations. However, developers should add more semantic-level invariant checks besides sanity checks.*

8.3 Observability

Since our studied failures are silent violations, *how do users notice these subtle failures then*? Understanding this question can reveal insights to improve the observability of semantic failures. We carefully examine the discussion threads in each ticket. In 34 cases, users mentioned their experience clearly.

For all of these cases, users discovered the issues through noticing something suspicious in some "side channels". We categorize them into two types: (i) benign errors in other requests (32%); (ii) anomalies in logs, files, or performance of other tasks (68%). In HBASE-11654, users find out the violations by noticing splitting directories in `/hbase/WALs/`, which is "very strange" because *"those logs should have been replayed and deleted"*. In KAFKA-9137, users observe the failure by seeing an increase in eviction rate in the logs. In CASSANDRA-6527, users found tombstones appeared even though they never used `delete` for a column family.

It might seem that we can rely on users to manually detect system semantic failures. Note that there is a survival bias: our studied cases by definition are identified, but in practice silent semantic violations can be easily missed because (i) users do not monitor the systems 24×7; (ii) when they check, they may not inspect the proper signals. When users notice the failures, the damage may be already done. In CASSANDRA-6527, users commented: "*Fortunately, we have noticed that quickly and canceled the migration. However, we were quite lucky.*"

How to make semantic failures more observable? First, if a system API has no interaction with others, it is hard to judge its correctness based on a single piece of information. In practice users often use multiple related APIs to cross-compare results. In HBASE-15236, users observe the violations because `Get` and `Scan` return different sizes for the same bulkloaded hfiles. Second, current systems often do not expose enough information about theirs internal states, thus users have to *ad-hocly* infer whether a promise is obeyed or not. Existing error messages (*e.g.*, a legitimate exception for another request) only focus on the current request, which is hard to link to the semantic violation in past correlated requests.

Finding 13: *Semantic violations are currently observed from "side channels": 32% from errors in other requests, 68% from anomalies in logs, files or performance of other tasks.*

Implications: *Designs of overlapping APIs improve observability of semantic violations. Systems should provide more admin APIs for convenient query of their internal states. Error messages should provide hints about past correlated requests.*

9 Oathkeeper: A Semantic Violation Checker

Guided by our study, we build a tool *Oathkeeper* to check semantic violations for large-scale distributed systems.

9.1 Design Overview and Workflow

Oathkeeper takes a runtime approach to check semantic violations in production. This choice is motivated by our findings that semantic failures have diverse root causes (Finding 8) and often difficult to expose in testing due to complex triggering conditions (Finding 10).

Central to a runtime verification approach is what invariants to use. Existing solutions rely on users to write distributed assertions to check the correctness of distributed protocols [43, 44] or network functions [57]. In those scenarios, the semantics to check are limited and well-defined. But in our cases, the systems have abundant (Table 1) and loosely-defined semantics. Even for semantics that can be described in simple expressions informally, mapping them to the concrete checkable invariants in the complex systems code is hard. These factors make manual construction a daunting task.

Insight and Key Idea. The insight behind Oathkeeper is based on our finding that the majority of the studied failures violate old semantics (Finding 5) despite the decent coverage of testing (Finding 10). When a semantic failure occurs, developers usually add regression tests. But these tests only check if the specific bug is fixed in a specific setup, while the same semantics can be violated repeatedly in other scenarios.

Based on this insight, Oathkeeper leverages the existing regression tests developers write for past semantic failures and automatically extracts the essence—the violated semantic rules. Oathkeeper then enforces these rules at runtime to detect future semantic violations, which may be caused by different bugs under different conditions.

Input and Output. To apply Oathkeeper to a new system, users supply a system-wide configuration and a list of past semantic failure metadata. The former provides basic information about the system such as the compilation command and test directory, and optionally the classes to include for analysis. The latter metadata is provided in the form of git commit id (for version switching) and regression test name.

Oathkeeper outputs the likely semantic rules (Section 9.3). Prior runtime verification tools focus on invariants expressed as predicates among key state variables in a system such as `lock_id` and `lock_mode`. This representation alone can be insufficient or complex to express the semantics of large distributed systems. Instead, Oathkeeper focuses on rules that describe relations among semantics-related events, particularly operation invocations and state updates. Such an *event relation* rule is expressive to capture various semantics.

Workflow. Figure 8 shows the tool's workflow. Oathkeeper operates in two stages. In the offline stage, Oathkeeper instru-

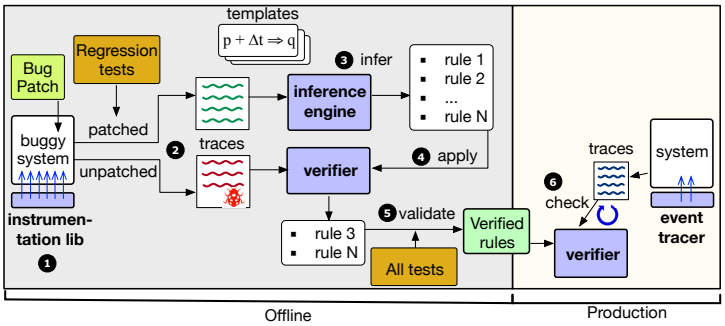

Figure 8: Workflow of Oathkeeper.

ments the target systems to record major events (❶). It then exercises the system twice with the regression tests: once using the patched version and the second time using the buggy version. This will generate two sets of traces (❷). The *inference engine* infers likely semantic rules from the traces of the patched version (❸). The *verifier* applies the inferred semantic rules against the traces of the buggy version and output rules that are violated in the buggy traces (❹). We assume these violated rules are potentially related to the semantic failure. Further optimizations are applied to remove noises and redundancies (❺). In the online stage, Oathkeeper only performs minimal instrumentation that is relevant to these final semantic rules from the offline stage. The event tracer ingests traces from the system in real time. The Oathkeeper verifier continuously checks the traces against the deployed semantic rules and reports violations (❻).

9.2 Instrumentation and Trace Generation

For both inferring semantic rules and runtime verification, we need to first instrument the system to obtain execution traces. The Oathkeeper traces use a uniform *event* schema that captures operation-related events and state-related events.

Oathkeeper designs a *load-time instrumentation library* that performs bytecode manipulation when a target system is loaded. This way of instrumentation is convenient (without re-compiling and re-packaging the system) and transparent.

To record operation events, the library adds hooks at the beginning, return and exception point of a method. To record state events, Oathkeeper takes a patch plus base approach. It analyzes the given semantic failure patch and automatically includes the list of classes involved in the patch file. Users can optionally specify names of some important system classes, such as `SessionTrackerImpl`. With the combined list of classes, Oathkeeper performs simple analysis at the loading phase of these classes to retrieve their member variables of primitive or collections types, and treat them as the state variables. It then identifies instructions that *update* these variables and insert a hook to emit a state update event with the relevant context (variable name, location, *etc.*).

For each given test, Oathkeeper switches the target system to the patched version. The tool executes the test with the instrumented system and generates the trace of events.

Template	Example
$p \Rightarrow q$	decommission a datanode should trigger reconstruction
$s\uparrow \Rightarrow p$	when datanode changes, associated watcher notifies clients
$s\uparrow \Rightarrow k\uparrow$	after session disconnection, ephemeral node is removed
$(s = c) \oplus q$	read-only server should not provide write access
$p + \Delta t \Rightarrow q$	inserted data should expire after the TTL is reached.
$s\uparrow \rightarrow q$	cf schema should be altered before alter command returns
$p \Rightarrow \odot(s\uparrow, k\uparrow)$	after snapshot renaming, either new snapshot creation and old snapshot deletion both occur or none of them occur

Table 3: Some templates integrated in Oathkeeper. p, q are operations, s and k are states, t is time, c is constant. $\neg p$ means p can not occur. $\uparrow$ means state changes. $p + \Delta t$ means time t after p occurs.

Then Oathkeeper reverts the target system to the buggy version (snapshot prior to the patch commit id). Since the buggy version does not contain the test, Oathkeeper copies the regression test from the patched version and executes it to get the buggy trace. If the test cannot directly run on the buggy version due to interface changes (*e.g.*, a function used in the test is not public in the buggy version), the tool supports user-provided patches to fix the compatibility issue.

The trace is stored in a JSON file for ease of deserialization. An example trace entry is `{"type": "OpTriggerEvent", "data":{"opName": "zookeeper.FileSnap.deserialize", "time": 1654026992, ...}}`. The trace scale is usually moderate, because it is generated from tests. For example, with ZooKeeper, even under the full instrumentation mode (instrumenting all classes), most end-to-end tests generate less than 10,000 events. A common scale is several thousands. We see large traces in only 5/273 tests that produce over 500,000 events. Under the diff mode (only instrument the classes affected by the patch), the trace typically has hundreds of events.

9.3 Template-Driven Inference

A key challenge in the semantic rule inference step of Oathkeeper is to integrate domain knowledge without requiring significant manual effort, while also having reasonable accuracy and efficiency. We take a template-driven approach to address this challenge. We first summarize general semantic rule patterns, such as happens-before relationship, atomicity, periodicity. For each pattern, we define one or more parameterized templates, such as a state change event for s must happen before the completion event of operation p.

```java
public abstract class InferScanner {
  //init state variables
  abstract void prescan(Set<Event> eventSet);
  //always need to go through the whole traces
  abstract void scan(Event event);
  //check states after scan, and generate invariants
  abstract List<Invariant> postscan();
}
public abstract class VerifyScanner {
  //init state variables
  abstract void prescan();
  //return true if continues to scan, otherwise break
  abstract boolean scan(Event event, Context context);
  //check states after scan, and judge
  abstract InvState postscan();
}
```

Listing 1: Inference and validation interfaces for each template.

Algorithm 1: Generic inference and validation workflow.

Input: L: a trace (list of events)
Output: a list of inferred invariants (one inv. is a template w/ context)
Func `Infer`(L)**:**
    `/* get unique events in the trace (we define equality individually for different types of events) */`
    `unique_events` ← Set(L)
    `prescan(unique_events)`
    foreach *event* ∈ L **do** `scan(event)`
    return `postscan()`

Input: L: a trace (list of events), *context*: parameters in templates, *e.g.*, if an invariant is $a1 \Rightarrow a2$, context is a1 and a2
Output: the checking result of invariant (pass, fail or inactive)
Func `Verify`(L, *context*)**:**
    foreach *event* ∈ L **do**
        if *scan(event,context)* **then break**
    return `postscan()`

Func `Main`($L_{patched}$, L_{buggy})**:**
    `inv_list` ← ∅

            `inv_list.add(inv)`
    return `inv_list`

Oathkeeper currently supports 18 templates. Table 3 shows several examples. Our technical report [47] shows the full list.

The inference engine implements an inference algorithm for each template. The algorithm checks if there are matches in a given trace and derives concrete values to each template parameter if so. We call each match a *context* for the template, which is a potential invariant. For one template (*e.g.*, $p \Rightarrow q$), a trace can have multiple contexts (*e.g.*, $a1 \Rightarrow a2$ and $a1 \Rightarrow a3$).

The templates allow encoding domain-specific semantics without significant specification effort. They also restrict the search space so the inference engine only analyzes trace events that match the template structure and parameter types. While these templates may not represent the exact or full semantics like a high-level specification does, they can capture the essential ingredients for making the semantics hold.

The inference engine takes the trace obtained from running the regression tests against the patched system. Each template class implements an `infer` function that returns a list of

Algorithm 2: Implementation for template $p \Rightarrow q$.

Func `ImplyTemplate::InferScanner::prescan`(S)**:**

    else return `InvState.INACTIVE`

rules from the trace. Most templates follow three phases in the `infer` function: *pre-scan*, *scan*, and *post-scan* (interfaces defined in Listing 1). The pre-scan step typically builds an index of the unique event set in the trace. The uniqueness is determined by a custom function we define for different types of events. For example, operation invocation events are unique based on the signatures of invoked functions. The scan step iterates through each event in the trace and updates bookkeeping data structures such as an event occurrence map. The post-scan step generates invariants based on the bookkeeping data structures. Templates that do not follow this pattern can customize the procedures. For example, the `AfterOpAtomicStateUpdateTemplate` iterates forward once and scans backwards once; the `StateEqualsDenyOpTemplate` scans the trace for each state type in the test.

The core inference algorithm for each template, while different, is relatively straightforward. It essentially involves identifying events in the trace that match the type of a template's parameter, enumerating hypotheses (candidates) from the contexts, and validating the hypotheses against the trace. Since the trace size is moderate, we can afford enumerations.

Example. We describe the inference of a representative tem-

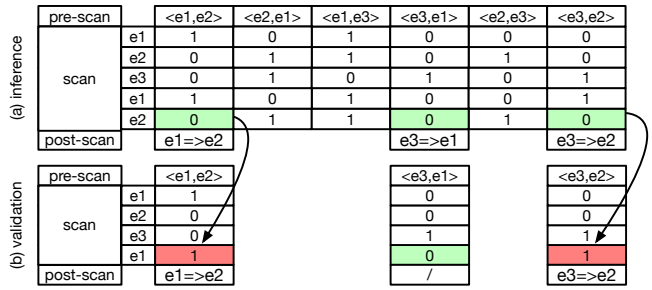

Figure 9: Inference and validation algorithm example.

plate $p \Rightarrow q$, which represents that every invocation of operation p implies a subsequent operation invocation of q. For example, `createSession` should usually imply `closeSession`. The steps are listed in Algorithms 1 and 2.

We use Figure 9 (a) to show the process of inferring rules of template $p \Rightarrow q$ from a patched trace $[e1, e2, e3, e1, e2]$. The algorithm assumes all pairs $<e_i, e_j>$ in the unique event set are candidate contexts to the template, in which e_i and e_j are of `OpTriggerEvent` type and the uniqueness is based on the operation name. Then it attempts to find counterexamples to invalidate wrong rules. The inference algorithm of this template uses a simple counting approach that runs in three steps. The *pre-scan* step constructs a nested map {`event`: {`event`: `int`}} to record the occurrences for the event pairs. For each event pair, the counter is initially zero. Then the *scan* step iterates through each event e in the trace in order. If e is e_i, *i.e.*, a key in the nested map, we increment the counters for all entries with $<e_i, *>$ keys; if e is e_j, we decrement the counters for entries that have $<*, e_j>$ keys *and* have positive counters. In the *post-scan* step, we check the final state of counters. If the final counter does not reach zero, there is an orphan e_i that does not have subsequent e_j. We get $e1 \Rightarrow e2$, $e3 \Rightarrow e1$ and $e3 \Rightarrow e2$ at the end. Rules like $e1 \Rightarrow e3$ are removed because no subsequent $e3$ occurs after the second $e1$.

9.4 Rule Validation

After step ❸, the inference engine could infer many likely semantic rules. Oathkeeper then applies these rules against the buggy traces (❹) and sees which rules are violated. Similarly to inference, each template class needs to implement a `verify` function. The `verify` function also usually consists of three phases: *pre-scan*, *scan*, and *post-scan*. The pre-scan step initializes auxiliary data structures specific to the template. The scan step goes over the events in the trace and updates the data structures. In some template, the scan step does not need to iterate through all events in the trace if a contradictory example is already found. The post-scan step checks the data structures and returns the result, which could be `PASS` (rule is activated and no contradiction is found), `INACTIVE` (the antecedent of the rule does not occur, *e.g.*, $p \Rightarrow q$ is inactive in a trace without occurrences of p), or `FAIL` (at least one contradiction is found). We only preserve rules that pass in the patched trace and fail in the buggy trace.

Example. Algorithms 1 and 2 show the steps to verify template $p \Rightarrow q$. We use Figure 9 (b) to show the process of validating inferred rules from (a) on a buggy trace $[e1, e2, e3, e1]$. There are three rules to verify: $e1 \Rightarrow e2$, $e3 \Rightarrow e1$, $e3 \Rightarrow e2$. In the *pre-scan* step, we first initialize a counter for each inferred rule. The *scan* step then updates the counter: for rule $e_i \Rightarrow e_j$, if a processed event e matches e_i, we increment the counter; if e matches e_j, we decrement the counter if it is positive. All three rules are active as both $e1$ and $e3$ appear in the trace. The *post-scan* step marks rules with non-zero counters as `FAIL`: $e1 \Rightarrow e2$ and $e3 \Rightarrow e2$.

However, there could still be a significant number of rules due to noises like unfinished tests (*e.g.*, an assertion failed in the middle of the test), new type events (new methods introduced), coincidence, and methods that are used for testing only. To reduce these noises, the verifier validates (❺) the candidate rules against traces obtained from all test cases, under the patched version, and *discards* rules that do not hold in all traces. In addition, we filter uninteresting rules about the system start-up or shut-down methods or thread run methods. This is achieved by inserting special marker events at the start and end of test method, and only running the inference algorithms on trace region within the markers.

9.5 Runtime Checking

Oathkeeper deploys the refined semantic rules with the target system in production, along with the verifier and event tracer. Oathkeeper performs load-time instrumentation to the production system in a wrapper class of the entry points. Different from the offline stage, the instrumentation is selective to only the deployed rules and is thus lightweight. The event tracer stores in-memory traces from the target systems.

The runtime verifier schedules periodical tasks that validate the current trace against *each* of the deployed semantic rules. It reuses the same checking logic defined in the function `verify` of the template. When the engine finds a semantic rule reported as `FAIL`, it records the counterexamples in the traces for debugging. It also schedules a second check on this violated rule again shortly to tolerate transient violations or inconsistencies in the trace. For high availability, Oathkeeper generates alerts in the log upon detection of potential semantic failures and does not attempt to crash the system.

9.6 Optimizations

The validation step can be time-consuming. With N (often thousands) candidate rules and M (often hundreds) test cases, we need to get M traces and check $N \times M$ times. To reduce the validation time, we introduce a survivor optimization. After a test finishes, we validate the rules, if some rule is already "killed" (invalidated) by this test's trace, it will not be carried over to the remaining tests. Therefore, only the survived rules will be validated to the end. Another optimization is to run more closely related tests first. The rationale is that some test takes a long time to run but is irrelevant to a given rule (thus the test's trace will not disprove the rule). By prioritization, we can potentially invalidate false rules faster.

We also add several optimizations to reduce the runtime overhead. First, the event tracer only preserves the most recent events within a time window, since always checking full traces from the start is wasteful. The time window is configured larger than checking frequency to avoid missing checking events. The events involved in time-related semantic rules are excluded as their expiration time is based on their parameters. Second, to achieve both high concurrency and low memory pressure, we decouple the checking from the event emission with a ring buffer design inspired by high-performance message queues [10]. Third, to avoid massive new object creation frequently triggering garbage collection, we reuse expired event objects in the ring buffers. Oathkeeper also pre-allocates buffers for each type of events at the instrumentation phase to prevent buffer initialization blocking.

9.7 Implementation

We implement Oathkeeper in Java (JDK 8). Its instrumentation library is built based on Javassist for class bytecode manipulation. Its test engine leverages JUnit to manage and execute test cases. The tool also includes a workflow script such as checking out patched and buggy versions and checking a semantic rule against given traces.

9.8 Limitations

Our approach makes several assumptions: 1) semantics should be expressible with simple relations of events; 2) the system has a number of test cases with good quality; 3) the failure patch should not involve significant redesign or interface interfaces. If some assumption does not hold, Oathkeeper may fail to deduce good semantic rules.

10 Evaluation

We have integrated Oathkeeper with ZooKeeper, HDFS and Kafka. We evaluate (1) whether Oathkeeper can leverage past semantic failures to check new violations; (2) what runtime overhead it incurs to the target system. The experiments are done in servers with 20-core 2.2 GHz CPUs, 64 GB memory, running Ubuntu 18.04. The Oathkeeper check engine is configured to schedule and check rule violations every second.

10.1 Generation Overview

Oathkeeper requires old semantic failures and their associated regression tests as input to extract semantic rules. We select old semantic failures and their regression tests to reproduce (8 for ZooKeeper, 10 for HDFS and 8 for Kafka). These tests cover major functionalities of the three systems. We add a switch in the system code to easily enable and disable the patch for the semantic failure bugs. We then apply Oathkeeper to the source code to add instrumentation points, run the regression tests with the patch switch turned on and off, and execute other steps in Oathkeeper (Section 9.1). For each case, Oathkeeper infers many raw semantic rules. After the validation and optimization step, the rule set is significantly reduced. In total, Oathkeeper extracted 285 rules for ZooKeeper, 1,209 rules for HDFS, and 150 rules for Kafka.

JIRA Id	Violated Semantics
ZK-1496	ephemeral node should be deleted after session expired
ZK-1667	watcher should return correct event when client reconnected
ZK-3546	container node should be deleted after children all removed
HDFS-14699	failed block need to be reconstructed
HDFS-14317	edit log rolling should be activated periodically
HDFS-14633	file rename should respect storageType quota
KAFKA-12426	partition topic ID should be persisted into metadata file

Table 4: Evaluated newer semantic failures.

10.2 Checking Newer Violations

We evaluate whether the inferred rules are useful to catch new semantic failures. Given Oathkeeper's approach, it is likely less effective with unseen semantics. We reproduce 7 newer (9–34 months later) failures (Table 4) that violate related semantics in the old cases, but with different root causes. With the inferred rules, Oathkeeper detects violations for 6 of them. These newer violations are known bugs by the time we conducted this experiment. However, their root causes and triggering conditions are completely different from the failures used to extract semantic rules. Oathkeeper detects these newer violations with only knowledge from the old failures, which demonstrates the tool's detection capability.

We show one example in Figure 10. ZK-1496 is not in our study dataset, but its symptom is similar to a studied failure ZK-1208 that was reported 9 months ago prior to ZK-1496 in an older release. Users found that the ephemeral `znodes` were not deleted long after the client exited. The root cause is a race condition bug that while the session tracker is removing the expired session, another thread is processing an ephemeral node creation request. In ZK-1208, developers added a fix to mark sessions as closing to prevent ephemeral node creation on expiring sessions, and introduced a regression test. Oathkeeper executes the regression test on ZooKeeper twice with patch enabled and disable, and generates two traces (c) and (d). Then Oathkeeper infers rules (e) from the patched traces. Not all inferred rules are useful. Oathkeeper only preserves rules that fail in buggy traces and pass all tests (f). Rules such as ③ are filtered when being validated on all tests. Finally, two verified rules ① and ② detect the violations (g).

Oathkeeper fails to detect ZK-1667: client A sets a watch on `/d` and then disconnects, client B deletes `/d` and recreates it; when client A reconnects, it receives a `NodeCreated` event instead of `NodeDataChanged` event. The violated semantics fits into one of our templates. However, due to the quality of the old watch test in our pool, Oathkeeper infers other rules.

The average detection time is 0.91 seconds. This result does not contradict with the long-lived semantics finding in Section 7. In the experiments, we trigger the conditions to reproduce the failure soon and measure the detection time from the start time of the violation.

We compare Oathkeeper with a state-of-the-art invariant

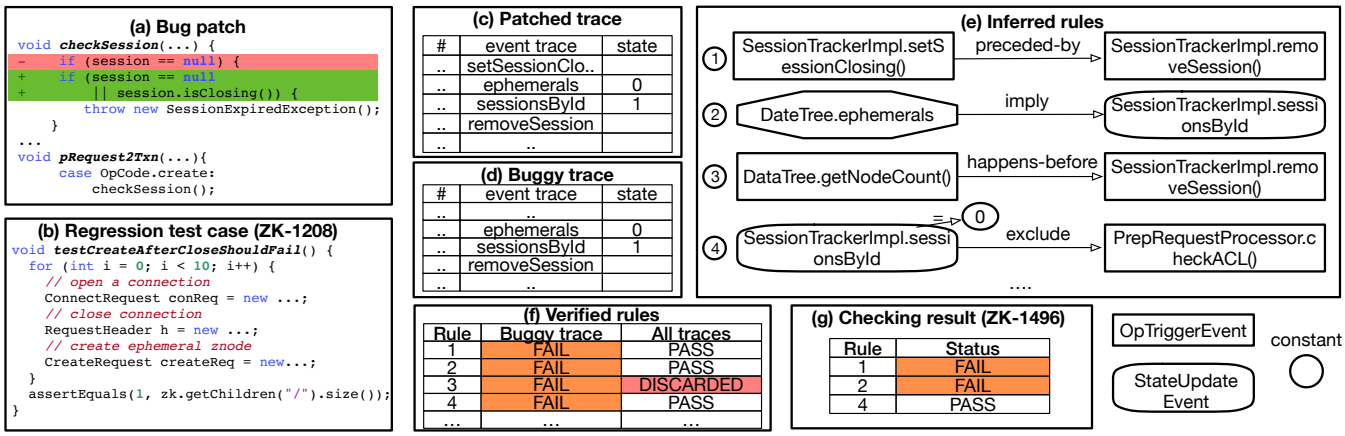

Figure 10: Example: Oathkeeper workflow of using ZK-1208 to detect ZK-1496.

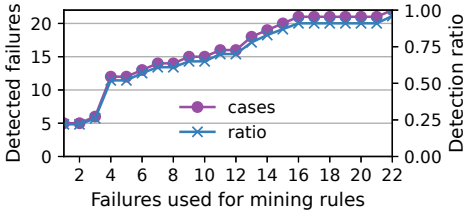

Figure 11: Detection of 22 semantic failures in ZooKeeper (sorted by the bug ticket time in ascending order) when applying Oathkeeper on a sliding subset of the failures for inferring semantic rules.

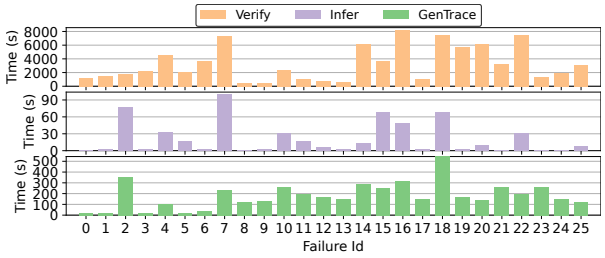

Figure 12: Time to generate trace, infer rules, and verify rules against test suite. ZK: Id 0–7, HDFS: Id 8–17, KF: Id 18–25.

checking tool, Dinv [30]. Dinv is designed for checking distributed protocols. Its core invariant inference component is based on Daikon [26] that mines variable-level relationship. We instrument the state variables in the two systems and apply Daikon to traces from the system test cases. The inferred invariants only detect 1 case (ZK-1496) and are highly noisy.

We conduct an additional "cross-validation" experiment. Specifically, we collect a larger pool of 22 semantic failures in ZooKeeper. The failures are sorted from older to newer. We feed each failure to Oathkeeper and measure how many of the 22 failures can be detected. For 16 cases, the rules inferred from one case only detect that case. It does not imply, though, these rules are useless. They might help detect failures outside the pool. Interestingly, for the remaining 6 cases, their inferred rules detect a median of 5 failures. For example, rules from ZK-2355 can detect 6 other failures besides itself. Figure 11 plots the aggregate detection result.

10.3 Performance

Figure 12 shows the performance of running Oathkeeper for the 26 old cases. Our template-based inference is fast. The median time to finish inference is 6.5 s. The median trace generation time is 153.5 s. The most time-consuming part is verifying the inferred rules against the system test suite, because running the full test for the three systems alone takes a long time. The end-to-end validation time is 2196 s (median). After discounting the original test execution time, the median validation time is 301 s. The survivor optimization we introduce (Section 9.4) helps. In one time-consuming case, it reduces the end-to-end validation time from 8104 s to 5024 s.

	Base	25%	50%	75%	100%
ZooKeeper	418.27	417.63	416.71	416.55	416.1
HDFS	174.55	174.56	172.10	172.10	172.06
Kafka	30,759.49	30,546.00	30,377.50	30,246.04	30,183.15

Table 5: System throughput (op/s) with varying percentages of semantic rules enabled. The 100% represents 285 rules for ZooKeeper, 1,209 rules for HDFS, and 150 rules for Kafka.

10.4 Runtime Overhead

We measure the overhead Oathkeeper introduces to the systems at runtime. The main source of overhead comes from the added instrumentation to emit traces; the rule checking does not impact the system much because it is done asynchronously. Oathkeeper only adds instrumentation relevant to the deployed rules to minimize the overhead. Naturally, more rules lead to higher overhead. We evaluate the overhead as a function of the percentage of enabled rules. For ZooKeeper, we run the workload of 15 clients sending 15,000 requests (40% reads, 60% creates and writes). For HDFS, we run the built-in benchmark NNBenchWithoutMR which creates and writes 100 files, each file has 160 blocks and each block is 1MB. For Kafka, we run the workload of producing 1 million 16KB messages. Table 5 shows the result. With all rules enabled, the average system throughput overhead is 1.27%.

Our initial event tracer used an array list with synchronization, which resulted in a 31% overhead under heavy workloads. We later implemented a more complex non-blocking queue, but the overhead is still large. After investigation, we

found the overhead mainly comes from memory and GC instead of synchronization, which motivated our ring buffer design (Section 9.6) that significantly reduced the overhead.

10.5 Rule Activation and False Positive

We deploy the inferred rules to a cluster of ZooKeeper, HDFS, and Kafka instances. We run a set of workloads against the instances. We first measure the rule activation ratio during the experiment. A rule is activated if the check engine finds the antecedent of the rule has occurred. For ZooKeeper, 11% of the rules are activated. The remaining rules are not activated due to the lack of workloads, faulty conditions, *etc.*, to trigger the antecedent events. For HDFS and Kafka, the activation ratio is 66% and 48%. We then measure the false positive ratio among the activated rules. The result is 4% for ZooKeeper, 9% for HDFS, and 12% for Kafka. This result benefits from the validation steps described in Section 9.4: Oathkeeper eliminates falsely inferred rules by validating the rules against both the buggy trace and the traces from all test cases of a target system. Adding profile runs or a dynamic ban mechanism can further remove the false rules.

11 Related Work

Semantic Bugs. Several studies [42,55,58] analyze the prevalence of semantic bugs in open-source server software. Our study analyzes *semantic failures* in distributed systems. Beyond the difference that we investigate distributed systems, the study of *bugs* is in general a complementary effort to the study of *failures*. The former focuses on analyzing the static code patterns, while the latter focuses on the dynamic manifestations and system misbehavior.

Several solutions are proposed to detect semantic bugs in file systems and DBMS, including cross-checking multiple file system implementations [50], fuzzing [39], and testing using pivoted query [54]. Both cross-checking and fuzzing focus on finding bugs offline. Oathkeeper focuses on a complementary direction of inferring semantic rules for runtime checking. We hope our study can motivate future work to extend these solutions to detect semantic bugs in distributed systems. We observe some open challenges to cross-check distributed systems: distributed systems usually provide a wide variety of semantics that are less rigorously specified compared to file systems, which have well-defined semantics (*e.g.*, POSIX standard) and many implementations. Each distributed system has its unique semantics and may not be cross-checkable. In addition, they often contain many internal and background mechanisms that provide semantic guarantees but the semantics are not easy to be tested. For fuzzing, the challenge is that many silent semantic violations require external faulty events (*e.g.*, node restarts, network error) to trigger besides input. Thus, fault injection testing is needed.

Distributed Systems Failure Study. Understanding failures has been an important theme in distributed system literature, with a series of empirical studies [16, 17, 19, 25, 31, 32, 36, 37, 46, 51], *e.g.*, on fail-slow faults [32], gray failures [37], and network partitions [17]. These failures usually have some error signals such as timeouts. Our study complements these studies and focuses on the under-explored silent semantic failures in distributed systems.

Runtime Verification. Prior works have explored runtime assertions to verify distributed protocols [43, 44], file systems [28], and network functions [57]. Runtime verification [34] is also studied in embedded systems and Java benchmark programs [24]. Recent works [45, 46] propose intrinsic watchdogs that detect partial faults with clear error signals. Lu *et al.* propose a runtime checker for consistency violations [48]. Overall, there is a lack of runtime verification solutions for monitoring the semantic correctness of large-scale distributed system implementations. Our proposed tool Oathkeeper explores automatically extracting semantic rules to check a variety of semantics for large distributed systems.

Invariant Mining. Inferring likely invariants from software execution traces have been studied, *e.g.*, Daikon [26] and DIDUCE [33]. They mainly focus on mining invariants on the relationship of program variables for single-component software, *e.g.*, `off < array.length`. These invariants are too low-level to capture the semantics of distributed systems.

Dinv [30] is proposed to infer protocol invariants of program variables across nodes. It runs complex program slicing to instrument program variables influenced by network communication. It then uses Daikon to infer invariants from the logs of running the system's test suite. I4 [49] infers inductive invariants for verifying distributed protocols.

Oathkeeper is complementary to the two efforts. Instead of protocols and variable relations, we focus on inferring high-level semantic rules for large distributed systems, most of which are not about protocols. Also unlike Dinv, Oathkeeper does not rely on complex static analysis to work and thus does not suffer from analysis inaccuracies and scalability limitations. Oathkeeper takes a unique approach of leveraging past failures and semantic templates to extract semantic rules.

12 Conclusion

Silent semantic violations pose a severe challenge to distributed systems reliability. This paper sheds light on this under-explored yet important problem by presenting a study on real-world failures in popular distributed systems. It reveals that sadly "a promise is often *not* a promise". Guided by our study, we design a tool Oathkeeper that automatically extracts semantic rules from past semantic failures, and enforces these rules at runtime to check future violations.

Abstract

Memory leak is a notorious issue. Despite the extensive efforts, addressing memory leaks in large production cloud systems remains challenging. Existing solutions incur high overhead and/or suffer from high inaccuracies.

This paper presents RESIN, a solution designed to holistically address memory leaks in production cloud infrastructure. RESIN takes a divide-and-conquer approach to tackle the challenges. It performs a low-overhead detection first with a robust bucketization-based pivot scheme to identify suspicious leaking entities. It then takes live heap snapshots at appropriate time points in carefully sampled leak entities. RESIN analyzes the collected snapshots for leak diagnosis. Finally, RESIN automatically mitigates detected leaks.

RESIN has been running in production in Microsoft Azure for 3 years. It reports on average 24 leak tickets each month with high accuracy and low overhead, and provides effective diagnosis reports. Its results translate into a 41× reduction of VM reboots caused by low memory.

1 Introduction

Memory leak is a prevalent issue in software, from applications [13] to OS kernels and device drivers [46]. At Microsoft Azure, its infrastructure contains many complex software components running on a massive number of machines with various workloads. Unsurprisingly, these components encounter memory leak issues from time to time. When a process leaks memory, the direct consequence is performance degradation and crash. Worse still, its impact often affects other components running on the same machine, such as causing excessive paging, innocent processes being killed, and node reboots.

Memory leak is notoriously difficult to deal with, especially in a production cloud infrastructure setting. The issues are usually only triggered by rare conditions and occur slowly, thus they easily escape testing and failure detectors [20]. After leak symptoms are detected, it is time-consuming and sometimes impossible to reproduce them offline. Unlike other failures like crashes that have clear points to start diagnosis, developers are often clueless in finding the leak's root cause.

Extensive solutions have been proposed to detect memory leak bugs. One approach uses static analysis techniques [10, 15, 18, 36, 47] to analyze the software source code and deduce potential leaks. The second approach detects memory leaks dynamically by instrumenting a program and tracking the object references at runtime [16, 21, 25, 39, 49].

While helpful, these solutions are insufficient to address the memory leak challenges in Azure. Static approach is limited by the well-known accuracy and scalability issues with static analyses. It also only focuses on leaks in which allocated objects are unreachable [24]. If memory objects are reachable but never accessed again, it still incurs the consequences of leaks. Such leaks are hard to detect statically. Moreover, memory leaks in cloud infrastructure can be caused by cross-component contract violations, which require too much domain knowledge to recognize statically.

Dynamic approaches better fit Azure's requirements. However, while the existing dynamic detection solutions are generally more accurate, they are intrusive and require extensive instrumentations that are cumbersome to apply to complex components [16, 21]. They also incur high runtime overhead that is prohibitive for deployment in production [6].

In this paper, we present RESIN, an end-to-end service designed to holistically address memory leaks in large cloud infrastructure, from detection to diagnosis and mitigation. RESIN is highly scalable—it analyzes all the host software components, including kernels, drivers, and system processes, on millions of nodes in Azure. RESIN has low overhead while running in production environment. At the same time, RESIN provides good accuracy and helps developers pinpoint the root causes of memory leak issues.

Two key insights motivate the design of RESIN and enable it to achieve the above properties. First, the conundrum of existing solutions is in part because they mix detecting a leak and pinpointing the leak bug in one step, so they have to make trade-offs among accuracy, scalability, and overhead. In our experience, we should decompose the detection and pinpointing into multi-level stages to catch memory leaks at production scale. Second, taking a centralized service approach that

leverages low-level system mechanism is essential to support many components transparently in a non-intrusive way. It also enables gathering valuable information from many nodes in the cloud to address the accuracy challenges.

Based on these insights, RESIN performs non-intrusive, low-overhead leak detection first. When a process is suspected of experiencing leaks, RESIN triggers a live heap-snapshot mechanism to capture sufficient evidence and runs diagnosis. RESIN leverages kernel-level monitors and profilers as its building blocks, so it directly supports all the running processes without cumbersome integration. Furthermore, RESIN builds a centralized service that analyzes processes across all hosts in Azure fleet together to capture complex leaks.

A key challenge for dynamic leak detection is the highly noisy nature of memory usage in modern software affected by the workload characteristics. Using simple static thresholds can easily generate many false alarms or false negatives. For instance, in an impactful real-world cloud service outage caused by memory leaks, no alarm was triggered despite the existence of a memory monitoring service [4].

RESIN addresses this challenge by designing a robust *bucketization-based pivot* scheme. It aggregates the memory usages of processes across machines, and groups them into different buckets. Then by performing a pivot analysis on the process name, bucket, and other attributes, RESIN can reliably detect leaks without being prone to fragile thresholds. Essentially, we focus on analyzing a component's global memory usage behavior, rather than the microscope of an individual process. The rationale is that a true memory leak comes down to some buggy release. Although the memory usage of an individual process is highly dependent on workloads, the workload effect is likely canceled out when inspecting the usage of the same component running in all machines.

Once a suspicious memory leak is detected, RESIN activates the second stage of taking *live* heap snapshots of the suspected processes, which contain information about the active allocations and their stack traces. This stage is more heavyweight but provides more evidence to help developers confirm and diagnose the issue. Since a leak is often sporadic, RESIN aims to "hit" the leak again and capture useful evidence. It carefully chooses the snapshot time points so that the obtained snapshots have a high chance of localizing the root causes while minimizing the snapshot cost. Besides taking heap snapshots of the suspected leaking process, RESIN performs a *fingerprinting step* that periodically takes heap snapshots of representative processes to build a reference database. This reference database is used in the diagnosis algorithm to further improve the diagnosis accuracy.

Finally, RESIN automatically mitigates a detected leak to minimize its impact on the service availability and performance. The mitigation engine in RESIN leverages the information from the detection and diagnosis engines, and determines the appropriate actions to resolve the leak symptoms while developers investigate the root causes and fixes.

RESIN has been running in production in Azure for more than 3 years. RESIN reported many memory leaks, helped developers diagnose the issues, and automatically mitigated the leaks before their impact becomes visible to customers. Within the recent year at the timing of writing, the unexpected VM reboots in Azure caused by out of memory are reduced by 41×, and the new VM allocation errors due to low memory are reduced by 10×. In addition, no severe outages in 2020 and 2021 at Azure were caused by memory leaks.

In summary, the main contributions of this work are:

- A holistic memory leak solution for cloud infrastructure.
- A novel bucketization-based pivot scheme to robustly detect memory leaks with low overhead.
- A live heap snapshot algorithm to effectively capture evidence in production and diagnose memory leaks.
- A lightweight automated leak mitigation design.
- Deployment of RESIN in a production cloud service.

2 Background and Motivation

2.1 Host Memory Compositions

In IaaS cloud infrastructure, servers are equipped with large memory, a significant portion of which is used by the virtual machines (VMs), while the other portion is used by the host software. The latter includes the hypervisor, host OS kernel, drivers, system processes, and various host agents, *e.g.*, an agent that manages networking of the VMs. In this work, we focus on memory leak issues in host software, not leaks in customer VMs. Unless otherwise specified, the kernel, drivers and processes hereafter refer to those in host software stack.

Leaks in the host software can cause severe performance degradation and even instability of the host OS. They can further impact the running VMs, because memory between VMs and the host is not strictly partitioned, typically controlled by a soft threshold [45]. They can also cause potential VM start-up failures due to insufficient physical memory available.

The host memory is divided into user-mode memory and kernel memory. The host OS in Azure's infrastructure distinguishes four states for pages in a process' virtual memory: *free*, *reserved* (for future use but no physical page is allocated), *committed* (memory has been allocated from physical memory or paging files), and *shared*. For memory leak detection, we only need to consider pages in the committed and shared states. For kernel memory, the kernel creates two types of memory pools: *non-paged* pools and *paged* pools. Virtual memory in the non-paged pool is guaranteed to reside in physical memory as long as the kernel objects are alive, whereas memory in paged pool can be paged out. Memory leaks in the kernel can happen in both types of pools.

2.2 Memory Leaks

Memory leak occurs when heap-allocated objects are not freed at appropriate time. It is manifested in two forms: (i) *unreachable* leak, in which an allocated object is no longer

```
1  // ConfigMonitorThread          5-sec timeout, previously
2  while (cm->running) {           it was set to INFINITE
3    waitStatus = WaitForSingleObject(
4                      fileChangeHandle, 5 * 1000);
5    if (waitStatus == WAIT_OBJECT_0) {
6      // object is signaled, config file has changed
7      ::Sleep(200);
8      cm->ReadConfig(); // read the file
9  +   if (!FindNextChangeNotification(fileChangeHandle))
10 +     throw ServerBaseException(
11 +         "Failed to get handle to config directory");
12   }
13 - FindNextChangeNotification(fileChangeHandle);
14 }
```

Figure 1: A production memory leak example in Azure from a host process that caused leaks of objects allocated at the kernel side.

reachable from the root objects such as global and stack variables; (ii) *forgotten* leak, in which an allocated object is still reachable but no longer accessed. The first type does not occur in managed languages like Java. For the second type, since the program still keeps references to the leaked object, it cannot be reclaimed even with managed languages [12]. Such leak is challenging to be detected because whether an object will be accessed in the remaining execution is undecidable. Thus, a leak detection solution can only output conservative (correct) answers, *e.g.*, the objects that are definitely dead at a given time point, or approximate answers (which may be incorrect) such as inferring based on the object's *staleness* [17].

Memory leaks in cloud software have further complications. For instance, while existing solutions focus on detecting leaks in an individual component, a memory leak in cloud infrastructure often happens because of API contract violations between different components, which is not well addressed. This type of leak is hard to expose in pre-production environment, because software components are often tested separately and integration testing cannot cover all possible interactions. Slow leaks also unlikely get detected due to testing time constraints.

Figure 1 shows a real example of such a leak in Azure (this case was successfully caught by RESIN). The process has a thread that monitors the configuration file updates using `WaitForSingleObject` with a 5-second timeout. In each loop iteration, it calls the `FindNextChangeNotification` API (line 13). Each invocation causes the kernel to allocate I/O request kernel objects from the non-paged pool memory. The contract of the `FindNextChangeNotification` is that it must be followed by a call to a wait function, and if the wait function returns for any reason other than the change notification handle being signaled (*e.g.*, timeout), the wait must be retried. In this case, although the process calls the wait function, it unconditionally calls `FindNextChangeNotification` even if the wait returns timeout. Thus, the kernel objects are allocated every 5 seconds without being cleaned up. In this incident, the culprit process' memory usage was not high. The kernel was experiencing memory leak in its non-paged pool, not because of kernel bugs but rather the improper API usage in the process' code. This memory leak was introduced during a bug fix for another issue: previously the process waits for the updates using an `INFINITE` parameter in line 4, but this caused service restart operations to be blocked, so developers changed the wait parameter to a timeout of 5 seconds.

2.3 Requirements

There are several challenges and requirements for addressing memory leaks in cloud infrastructure software:

- *Highly scalable.* Cloud system is large in the number of components, codebase size, and deployment scale.
- *Versatile.* Memory leaks in cloud infrastructure manifest themselves in various ways—in processes, kernel, unreachable leaks, forgotten leaks, cross-component leaks, *etc.*
- *Non-intrusive and low-overhead.* Solutions that require intrusive modifications or incur high runtime overhead are hard to be deployed in production.
- *Accurate.* True leaks should be detected. False positives should be minimized, because they would cause developers to waste significant time investigating false issues.
- *Timely.* If the leak detection is too slow, significant damage to customers may already occur.
- *End-To-End.* Only alerting memory leaks is insufficient. Developers also need considerable help in confirming the issue, pinpointing the root cause, and mitigating the leak.

Additional constraints include generality and efforts of integrating a solution. The software components in cloud infrastructure are written in different programming paradigms, and may depend on proprietary libraries. The millions of nodes in Azure also have heterogeneity with different OSes, libraries, and hardware versions. Supporting all of these varieties is challenging. For example, we made an experimental effort of integrating the LeakSanitizer [1], a popular run-time memory leak detector from the LLVM project, into one Azure host component's codebase. The integration effort was difficult (took one person month) due to complex compilation flags, and library compatibility issues. The MSVC compiler's full support for LeakSanitizer is still pending [3].

3 Overview of RESIN

Despite the extensive efforts to address memory leaks in conventional settings, they are insufficient to satisfy the unique requirements for tackling memory leaks in large cloud infrastructure (Section 2.3). To address this gap, we propose RESIN. RESIN is a holistic system running in the Azure production infrastructure to detect memory leaks in host software and provide diagnosis support to developers easily pinpointing the leak's root causes. RESIN further performs automatic leak mitigation to reduce the impact of detected leaks.

Approach A large cloud infrastructure can have hundreds of components owned by different teams. Prior to RESIN, tackling memory leaks in Azure is a team-by-team effort. Some teams started investigating after incident reports about slow or failing VMs, and developers discovered leak bugs in their components during manual investigation. Some teams added telemetry monitors in their testing cluster and used

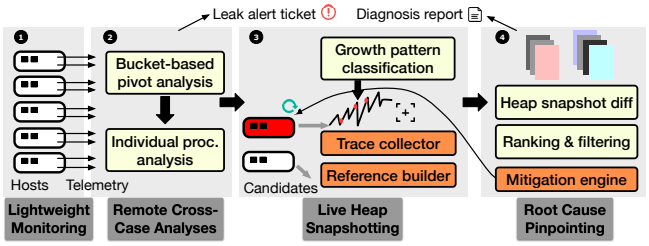

Figure 2: Workflow of the RESIN system.

hard-coded thresholds to trigger leak alerts in testing. Similarly, diagnosing leaks in Azure used to rely on developers to manually inspect the leaking nodes and run profiling tools. These individual practices were tedious and costed repeated engineering efforts. They also incurred significant false positives and could not handle cross-component leak issues.

RESIN takes a centralized approach instead. It does not require access to a component's source code, nor extensive instrumentation or re-compilation. RESIN uses a monitoring agent to each host that leverages low-level OS features to collect memory telemetry data. It automatically supports all components including the kernel. The data analysis is offloaded to a remote service, which minimizes the overhead to the hosts. By aggregating data from different hosts, RESIN can run more sophisticated analyses to catch complex leaks.

In addition, RESIN decomposes and tackles the memory leak problem in multi-level stages. It performs lightweight leak detection first and triggers more in-depth inspections on the fly when necessary for confirmation and diagnosis. This divide-and-conquer approach allows RESIN to achieve low overhead, high accuracy, and scalability together.

Workflow Figure 2 shows the workflow of RESIN. It starts with low-overhead monitoring (❶) at each host. A remote service analyzes (❷) the collected data across different hosts using a bucketization-pivot scheme. If a bucket is suspected of leaking, RESIN triggers an analysis on the process instances from that bucket. After the two steps identify a highly suspicious software component, RESIN automatically generates an alert ticket for that component along with a list of leaking process instances belonging to that component. Meanwhile, RESIN performs live heap snapshotting (❸) for the suspected processes. RESIN carefully chooses the snapshotting time using a growth pattern based algorithm to ensure the collected snapshots would be helpful. RESIN also samples normal processes to take regular heap snapshots and build a reference database. After generating multiple heap snapshots, RESIN tries to pinpoint the root causes (❹) by running a diagnosis algorithm on the snapshots. The analysis report will be attached to the alert ticket thread to assist developers. Finally, RESIN automatically mitigates the leaking processes.

4 Design of Leak Detection

In this section, we describe the RESIN's design for detecting memory leaks. In existing literature, the term "detection" refers to detect both (i) if a program or a process has a leak, and (ii) the bug in code or leaked objects. RESIN separates these as two tasks and uses the term detection to refer to (i) specifically. The diagnosis component (Section 5) targets (ii).

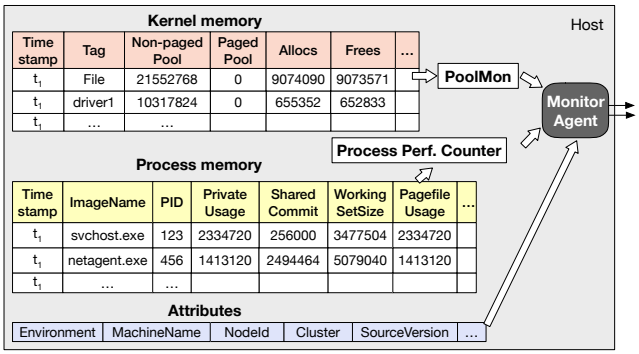

Figure 3: Monitor agent in each node collecting memory usage data.

4.1 Challenges

RESIN needs to address several challenges. First, cloud infrastructure software has highly noisy memory usage due to changing workloads and interference in the environment. Using static thresholds would generate many false positives. Standard anomaly detection algorithms [40, 41] do not work well either, because it is common for a component to exhibit memory usage spikes that are not leaks but legitimate increases in handling certain workloads.

Second, memory leaks in production systems are usually fail-slow faults [14] that last days, weeks, to even months (rapid leaks are likely caught in testing or deployment). Inspecting memory usage in a short time window would miss these slow leaks. It is necessary but challenging to capture gradual changes over a long period and still raise timely alerts.

Third, given the scale of Azure, collecting fine-grained data for a long time is impractical because of storage and overhead concerns. Therefore, RESIN can only collect limited, coarse-grained data and must work well under this constraint. Still, even with coarse-grained signals, the data volume is enormous. The detection algorithms must run efficiently.

4.2 Lightweight Memory Usage Monitoring

RESIN deploys a privileged monitoring agent on each host (Figure 3). This agent communicates with the host OS to track memory usage. It collects both kernel memory usage and per-process memory usage. The kernel usage is obtained from a pool monitor kernel module (`PoolMon`), and includes the usages of non-paged memory pool and paged memory pool for each *tag*. The tag is passed as an argument by the callers of the kernel allocation API [32] and represents a sub-system that has requested memory from the kernel allocator, *e.g.*, the file system, a driver. The per-process usage is obtained by querying the per-process performance counters from the host. It includes breakdowns of a process's memory, such as the private commit, working set size, paging file usage, *etc.*

We collect the memory usage breakdowns and tags instead of simply a single total memory usage metric, because mixing

different memory usage sources can introduce noises and miss important changes. For example, a 20 MB increase can be a leak for a driver but may be negligible for another component. Reporting the specific memory portion or tag that is leaking helps developers localize the buggy code. The breakdowns also help RESIN take more effective mitigation actions.

In addition to memory usages, the monitoring agent also records attributes such as the software version, hardware generations, node id, and cluster id. The attributes are used during leak detection analyses to increase accuracy. RESIN includes the common attributes of the leaked process in the detection report to give developers troubleshooting hints.

The monitoring agent is scheduled to run every 5 minutes. However, the data points from different hosts may not be perfectly synchronized. Some special events in a host such as node reboots also introduce missing or invalid data. Therefore, RESIN aggregates the time-series data into hourly granularity by removing extreme outliers and computing the mean of the remaining data points. This pre-processing step reduces the noises as well as the data volume. Using an hourly window is not too coarse-grained because most software components in cloud infrastructure are long running, and production leaks typically occur in a large time scale.

4.3 Detection Algorithms

RESIN uses a two-level scheme to detect memory leak symptoms: a global bucketing-based pivot analysis to identify suspicious components, and a local individual process leak detection to identify leaking processes. The detection output includes the suspected component, the list of top leaking processes of that component, the leak start and end times, severity scores, *etc.* The detection algorithms are language agnostic.

4.3.1 Bucketization-based Pivot Analysis

To address the challenges described in Section 4.1, our insight is that we should inspect at the *component* granularity across processes. This is because although an individual process' memory usage is influenced by workloads and highly noisy, the noises can be "canceled out" *en masse*. For a normal component, its process instances on different hosts may experience different workload effect at any time slice. But for a leaky component, the memory leak must be caused by some buggy release. Therefore, its processes should exhibit some global trend at certain time slices despite the workload effect.

Based on this insight, we design a simple yet robust bucketization-based pivot detection scheme (Figure 4). RESIN first groups the raw memory usage telemetry data into a number of buckets. In our implementation, we use 20 buckets (50 MB, 100 MB, 200 MB, ..., 40 GB, 50 GB). RESIN then applies pivoting to the data with a unique attribute tuple as the index and memory usage bucket as columns. The attribute tuple is (`ProcessImageName`, `ServiceName`) for user-level software, and (`TagName`, `PoolType`) for kernel subsystems, where `Type` is paged memory or non-paged memory. The aggregation function is the count of distinct nodes. Thus, each summary

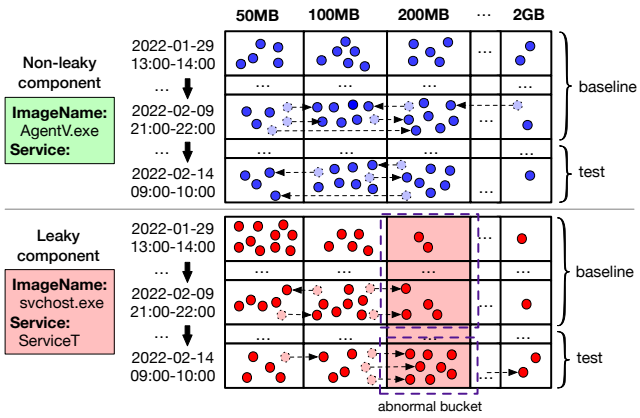

Figure 4: Group the memory usage into buckets and pivot by image name, service, and bucket size. Each circle represents one process. Shaded circle represents a process moving to another bucket.

cell represents the number of nodes that have running processes with a particular attribute tuple and these processes' memory usages fall into the specific bucket. RESIN computes the summary periodically and incrementally for data in each time interval. The results are saved into a database table.

We basically transform the memory usage data into summary about numbers of nodes in different buckets, which can more robustly represent the trends and tolerate noises due to workload effect (*e.g.*, the non-leaky component in Figure 4). RESIN then runs anomaly detection on the time-series data of each bucket for each component. It uses the most recent time period of summary data (default 15 days), with the first $2/3$ portion as the baseline and the remaining data points as the test. If a bucket's test period has data points that exceed the $\mu + 3\sigma$ of the baseline data (μ and σ represent the mean and standard deviation of the distribution), it is considered to be an anomaly. The start time and end time in the test period when the node count becomes the outlier are recorded.

One caveat is that if many processes of a component experience a sudden *drop* in memory usage, the node count would shift from a higher bucket to a lower bucket. But the lower bucket's node count significant increase is not an anomaly. To handle such scenarios, RESIN calculates cumulative bucket values during the anomaly detection. In other words, if the 100 MB bucket has a node count of n, it means there are n nodes that have the particular processes with memory usage equal to or larger than 100 MB, including processes (if any) that fall into the 200 MB bucket. In this way, a significant increase in a bucket almost always suggests an anomaly.

The bucketization approach also helps address the computation challenges. Before introducing this approach, it can take RESIN more than one day to run anomaly detection on the enormous data points from millions of nodes. After the pivot summary, RESIN only needs to run anomaly detection for the time-series data in each bucket, which can finish in less than one hour for all data (even without parallelization).

RESIN calculates a severity score for each bucket based on the deviations and node count in the bucket. It considers a

component is leaking based on a <*size_mb*, *score*> threshold: if a bucket is of size equal to or larger than *size_mb* and its severity score exceeds *score*. RESIN generates intermediate reports for the abnormal buckets. It de-duplicates the intermediate reports by only keeping the one for the largest bucket of a unique attribute tuple, and generates a ticket for that report.

4.3.2 Localizing Individual Processes

The bucketization pivot analysis works at the component granularity. RESIN uses a second-level detection scheme that works at the process[1] granularity. The motivation for this scheme is that a component has many process instances. It is important to localize the truly leaking processes in the alerting bucket. If we simply include all the processes in the abnormal bucket, developers can waste significant effort investigating innocent processes that fall into that bucket by coincidence.

The second-level detection scheme computes the leak likelihood and severity for a process based on its memory usage. RESIN uses all the memory usage data of a component in the most recent month to train two parametric models: (i) the *absolute usage model* and (ii) the *usage difference model*. Since different clusters and regions can exhibit drastically different characteristics, the tool builds separate models for each combination of region name and cluster type for a component.

Let $U_c(n_i,t_j)$ denote the memory usage value for a process of component c on node n_i at time t_j. RESIN assumes *absolute usage* $U_c(n_i,t_j)$ follows a Gaussian distribution $\mathcal{N}(\mu_1,\sigma_1^2)$ and fits the memory usage data by calculating the maximum likelihood estimators for μ_1 and σ_1. The absolute memory usage values can be severely distorted by occasional events such as VM creations. To account for such events, we consider the differential memory usage, *i.e.*, $\Delta U_c(n_i,t_j) = U_c(n_i,t_j) - U_c(n_i,t_{j-1})$. Based on our observations, when noisy events such as VM creations occur, $\Delta U_c(n_i,t_j)$ usually significantly deviates from its normal range. Thus, RESIN also builds a parametric Gaussian distribution $\mathcal{N}(\mu_2,\sigma_2^2)$ model for *usage difference* $\Delta U_c(n_i,t_j)$ and calculates the μ_2 and σ_2.

With the offline models, RESIN uses a *moving suspicious interval* algorithm (Algorithm 1) to examine a suspected process' memory usage in *real time*. This algorithm works by keeping a *suspicious leak time interval* $[T_0,T_1]$. The basic idea is to assume the leak still continues at the end of the time series and try to find the earliest time the leak trend starts by skipping over low-confidence points. This interval is initialized as $[t_1,t_1]$ upon reading the first data point in a time series. At the j-th step, RESIN reads $U_c(n_i,t_j)$, calculates the $\Delta U_c(n_i,t_j)$, and adjusts the time interval by moving T_1 and update T_0 adaptively. If $\Delta U_c(n_i,t_j)$ has a significant increase or drop (based on the 3-sigma rule for μ_2 and σ_2), T_0 is updated to t_j because the system status is likely changed by some event. If $U_c(n_i,t_j)$ is lower than $U_c(n_i,T_0)$ or there are few increasing points in the current interval, T_0 is also updated to t_j because a leaking trend should have enough increasing values. For other situations, we keep the T_0 intact. The loop stops when T_1 hits the last time point t_n. If the final T_0 is equal to T_1, this process is not considered as leaking.

[1] Here we use the term "process" to also include a running instance of a kernel subsystem in a particular host for kernel memory leak detection.

Algorithm 1: Moving suspicious interval algorithm

Input: $U_c(n_i,t)$: time-series memory usage for node n_i of component c; $\mathcal{N}(\mu_2,\sigma_2^2)$: offline usage difference model for component c.
Output: T_0, T_1: leak start and end time; no leak if T_0==T_1. N_{inc}: number of increasing data points

```
t_n ← max(t) in U_c(n_i,t), N_inc ← 0
T_0 ← t_1, T_1 ← t_1
for j ← 2 to n do
    T_1 ← t_j
    ΔU_c(n_i,t_j) ← U_c(n_i,t_j) - U_c(n_i,t_{j-1})
    if IsOutlier(ΔU_c,N) || U_c(n_i,t_j) < U_c(n_i,T_0) || N_inc/n < ε then
        T_0 ← t_j
    if T_0 == T_1 then
        N_inc ← 0          /* empty interval, no leak, reset */
    else if IsLarger(U_c(n_i,t_j),U_c(n_i,t_{j-1}),N) then
        N_inc ← N_inc + 1  /* a new increasing data point */
return T_0, T_1, N_inc
```

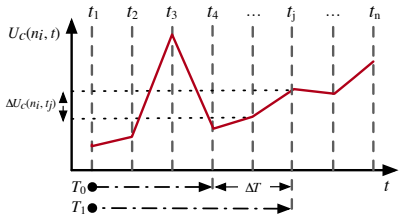

Figure 5: Applying the moving suspicious interval algorithm.

Figure 5 shows an example of applying the algorithm. $[T_0,T_1]$ are initially set to $[t_1,t_1]$. When T_1 is set to t_2, $\Delta U_c(n_i,t_j)$ is positive thus we keep T_0 unchanged and continue to move T_1 forward. When T_1 is set to t_3, $\Delta U_c(n_i,t_j)$ is an outlier in the offline model $(\mathcal{N},\mu_2,\sigma_2^2)$, which we consider an occasional event instead of a leak. We reset T_0 to t_3 accordingly. When T_1 is set to t_4, $U_c(n_i,t_j)$ is significantly lower than $U_c(n_i,T_0)$ thus we also reset T_0 to t_4. After t_4 we did not encounter scenarios to reset T_0 (the memory usage drops slightly later but it is unnecessary to reset for such cases), so eventually T_1 reaches the end t_n, and $[T_0,T_1]$ is $[t_4,t_n]$.

RESIN calculates a severity score (Equation 1) for a process to indicate its leak probability and impact. Several factors are considered, including the normalized memory usage difference ($\Delta U_c = U_c(n_i,t_n) - U_c(n_i,t_1)$), the length of the suspicious leak interval ($\Delta T = T_1 - T_0$ in the unit of month), the increasing rate (number of increasing data points over the number of all data points), and the final memory usage at t_n.

$$SevScore = \frac{\Delta U_c}{\sigma_1} + \frac{N_{inc}}{n} + \Delta T + \frac{1}{1+e^{-U_c(n_i,t_n)/\mu_1}} \qquad (1)$$

For efficiency, the above analyses are run proactively. When the bucketization-based pivot detection step identifies a leaking bucket, RESIN triggers the individual process analysis for the processes in the bucket and can usually inspect the results without waiting. It outputs the suspected leaking processes, the leak start and end time, and the severity scores.

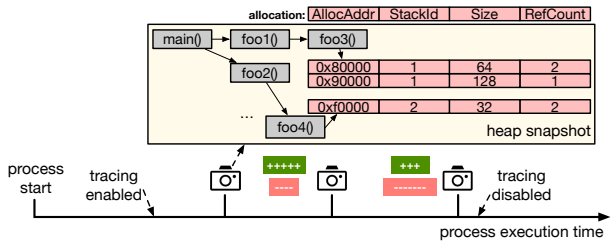

Figure 6: Periodic heap snapshot collection.

5 Diagnosis of Detected Leaks

Only detecting a leak is not enough. Without sufficient evidence and diagnosis support, developers are likely stuck in confirming and diagnosing the issue. RESIN designs a solution that automatically takes *live* heap snapshots and analyzes the snapshots to pinpoint the root cause of a detected leak.

5.1 Background: Heap Snapshot

RESIN provides diagnosis information at stack trace granularity. In our experience, if developers are presented with a stack trace containing the problematic allocations, they can often quickly debug the issue. RESIN leverages the Windows heap manager's snapshot capability to perform live profiling. The heap manager exposes APIs such as `HeapAlloc`, `HeapReAlloc`, and `HeapFree`, which are used by applications and C/C++ runtime to allocate heap objects. Thus the heap manager has the ability to collect the heap allocation sizes and stack traces.

RESIN uses the Windows Performance Recorder [2] to notify the kernel to start tracing heap allocations, typically for a specific process ID and occasionally for an image name (which enables tracing for all processes with the image). Then RESIN instructs the heap manager to take a snapshot at a certain time. Our current heap snapshotting mainly focuses on C/C++, which are the primary language choices for host software on Azure. Extending to other languages would take extra effort but are still straightforward, as their runtime typically already provides the functionality to capture allocation events.

To minimize overhead, the heap manager only stores limited information in each snapshot. Specifically, it stores (1) the stack trace and size for each *active* allocation after the tracing was enabled (if an allocation has been freed, no information is stored), (2) the total allocation sizes for each unique stack trace, and (3) the number of times a unique stack trace is invoked. It does *not* store more detailed information such as the allocation time or a pointer graph.

The information in a single snapshot is usually too noisy, as it includes all active allocations from the tracing start to the snapshot point. To get more accurate information for a time window, RESIN periodically takes *multiple* heap snapshots (Figure 6) to increase the chance of capturing truly leaking allocations between snapshots. RESIN uploads the snapshot files to a remote storage service. The diagnosis engine uses these snapshots to deduce the leaking allocation points.

5.2 Choosing Candidate Hosts to Profile

Picking the right hosts to take heap snapshot is vital for diagnosis effectiveness. Because heap snapshot incurs overhead, RESIN cannot afford to enable snapshot on all hosts containing the leaking processes the detection engine outputs. Simply choosing the hosts randomly is not a good strategy either, because the workloads on different hosts vary widely. For the same leak bug, it can exhibit in quite different patterns on different hosts. Thus, we may choose a candidate host in which the buggy allocations are triggered rarely.

We rank the candidate hosts in the suspected list based on three factors: 1) *severity*: choose processes with higher severity scores as described in Section 4.3.2, since more obvious symptoms suggest a better chance to be diagnosed; 2) *noisiness*: choose processes with a clearer growth pattern, which we will discuss in more detail in Section 5.3; 3) *impact*: choose hosts that have fewer user activities to minimize impact of profiling events. By default RESIN triggers snapshot collection for the top three hosts in the list in case the collection fails unexpectedly (*e.g.*, due to target process restart).

5.3 Deciding Trace Collection Strategy

With the candidate hosts selected, the next step is to decide if a *new* leak happens in the most recent snapshot interval and whether to take the snapshots. This step is different from the analysis in Section 4.3, which only finds leaking processes in *past* time. The decision making has two main challenges.

First, many production leaks are only triggered by specific events. Some leaks only occur once in several days. If we take snapshots at other times, the collected traces would not be helpful. To ensure rare leaks are captured, RESIN attaches the profiling workflow to the process for a long time and periodically (every half hour) takes snapshots in hope of capturing the leak. However, we cannot afford to keep uploading snapshots due to storage and overhead concerns. RESIN addresses the challenge with a *long-term, trigger-based* strategy: it uses a circular buffer that only keeps the most recently taken snapshots, and completes tracing once certain trigger is met.

Second, how to decide when the trace collection should complete, *i.e.*, the trigger. At the completion time, we should ideally (1) have snapshot(s) containing the buggy allocation; (2) have snapshot(s) for non-leaking scenarios; (3) minimize noisy allocations in the snapshot(s). One potential trigger is to complete the collection once the memory usage difference exceeds some threshold. This trigger can easily complete the tracing prematurely (fails to capture the buggy allocation) due to a legitimate memory usage spike, and/or produces snapshots that have many noisy allocations and mislead diagnosis.

To gain some insights on how to choose the triggers, we study the memory usage data of 51 real leak cases. Interestingly, most cases fall into three common patterns (and a mixture of them). Additionally, one leaking process in a specific host often has a *consistent* pattern. In 63% of the cases, the leaking process shows a *steady* pattern. One example is

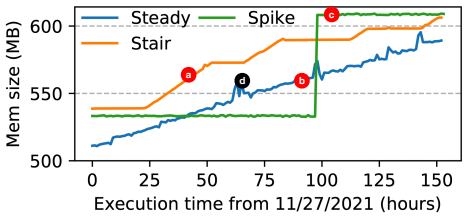

Figure 7: Memory growth patterns and completion point choices. Each data point is real memory usage from production processes.

Pattern	Characteristics	Completion Trigger
Steady	Almost linear growth	$R_j^2 > \lambda_a$.
Stair	Steady growing and flat curves alternately appears.	$\lvert 1 - slope_j/slope_k \rvert < \lambda_b$ && $R_j^2 < \lambda_c$
Spike	A few large allocations in a short period of time	$\Delta U_c(n_i,t_j)/\Delta U_c(n_i,t_k) > \lambda_d$

Table 1: Leak patterns, characteristics and their completion triggers.

the bug shown in Figure 1, in which the leak exists in periodical update tasks. The other two common patterns are *stair* (the memory usage occasionally grows only when the procedure containing leaks is activated) and *spike* (the leak only occurs once in a while due to rare events). Each pattern has its unique usage growth characteristics and clear completion point candidates ⓐ, ⓑ, ⓒ shown in Figure 7. ⓓ is not a good completion point as it is right after a period of some noises.

Guided by the findings, RESIN takes a pattern-based approach to decide the trace completion triggers. It uses the target process' memory usage data in the most recent week and classifies it into one of the three patterns. Specifically, RESIN first identifies nearly flat segments in the time-series data and removes them. It then performs linear regression on the remaining growing segments and outputs results including the slope $slope_k$, coefficient of determination R^2, and absolute memory usage increase $\Delta U_c(n_i,t_k)$. If the data contains no flat segments, RESIN marks it as a *steady* pattern. If the data has flat segments in between growing segments, it is marked as a *stair* pattern. If a large increase in memory usage only occurs in a few data points, it is marked as a *spike* pattern.

After the pattern is classified, the workflow starts to monitor and analyze the recent memory usage. We compute the $slope_j$, R_j^2, and $\Delta U_c(n_i,t_j)$ for the most recent six hours and check the pattern's completion trigger based on rules listed in Table 1 (λ_a, λ_b, λ_c and λ_d are set to 0.8, 0.1, 0.1, and 0.5, respectively). Once the trigger is satisfied, RESIN stops tracing and uploads the trace file that contains the most recent few snapshots. It ensures each trace has at least three snapshots.

5.4 Collecting Reference Snapshots

One challenge in using snapshots for diagnosis is the presence of many noisy but benign allocations. Even with multiple snapshots, they may remain active and mislead the diagnosis. RESIN collects *reference snapshots* to address this challenge.

For the reference snapshots to be useful, they should be comparable to the snapshots from the leaking process. A poor choice of a reference snapshot may be even counter-

Algorithm 2: Heap snapshot diagnosis algorithm

Input: A_{n-1},A_n: sets of allocations in two heap snapshots, S^r: a list of outstanding stacks from reference hosts, *pattern*: classified pattern, *estimate_leak*: upper bound of estimated leaking size
Output: S^o: a list of top N stack traces that likely caused leaks

```
S^o ← [], S^diff ← []
S^n ← A_n.groupBy(alloc=>alloc.stackid)
S^{n-1} ← A_{n-1}.groupBy(alloc=>alloc.stackid)
foreach stack ∈ S^n do
    if stack ∈ S^{n-1} then A^diff ← S^n[stack.id] \ S^{n-1}[stack.id]
    else A^diff ← S^n[stack.id]
    if A^diff ≠ ∅ then
        foreach a ∈ A^diff do stack.size ← stack.size+a.size
        S^diff.add(stack)
S^diff.orderBy(stack=>stack.size)
if pattern ≠ SPIKE then
    S^diff.removeAll(stack=> stack.size > estimate_leak)
S^diff.removeAll(stack=> stack ∈ S^r)    /* filter references */
S^o ← S^diff.top(N)                      /* only keep top N stack traces */
return S^o
```

productive and filter out the culprit allocations. RESIN uses a periodical *fingerprinting* process to build reference snapshots. It randomly samples hosts for common leaking services to take heap snapshots. We currently define the fingerprints to be the attribute tuple `(cluster_id, OS version, service version, date)`. This is based on our observations on the locality of memory leaks. These snapshots are saved in a reference database and cleaned up when they become stale.

At the diagnosis stage, after RESIN chooses the candidate leaking hosts to profile (Section 5.2), RESIN checks if the database already has reference snapshots with similar fingerprints. If not, RESIN triggers reference collection. It first scans the qualified hosts (not in the detection engine's suspicious list and have similar fingerprints to the leaking hosts) and samples a few that have active memory activities and modest memory usage. Then RESIN applies the growth pattern analysis (Section 5.3) to check if this host is leaking. If not, it takes snapshots and uploads the traces to the reference database.

5.5 Trace Analyses for Diagnosis

The next step is to analyze the collected snapshots to output the root cause stack traces. The challenge is to handle many noisy allocations and localize the buggy allocations.

RESIN designs a diagnosis algorithm listed in Algorithm 2. The inputs are the allocations from the two most recent snapshots of a trace file (A_{n-1}, A_n), stack traces from reference snapshots, and the estimated leaked size upper bound calculated in the pattern analysis. For the *steady* and *stair* patterns, we estimate the leaked size upper bound by multiplying the slope with the time interval of the growing segments and a coefficient (by default 2). The goal is to find the stack traces that allocate objects of sizes closest to the estimated leak.

The diagnosis engine first groups allocations in A_{n-1}, A_n by the stack trace id and get two maps S^n and S^{n-1}. Each map value is all the allocations that come from a stack trace. It then traverses each stack trace in S^n to calculate the aggre-

gated allocation size. The engine then identifies stack traces that contain unique allocations, and ranks these traces based by their allocated object sizes. Stack traces allocating sizes larger than the estimated leak size are likely noises and thus removed. Finally, the diagnosis engine cross-checks the reference snapshots to filter out benign stack traces. If the output list is empty, the engine repeats the analysis for the next snapshot pairs (A_{n-2}, A_{n-1}), *etc.*

6 Mitigating Leaks

When a memory leak is detected, it can take time for developers to come up with and deploy the bug fix. To avoid further customer impact, RESIN attempts to automatically mitigate the detected leak issues. Depending on the nature of the memory leak, mitigation can be done in several ways. Rebooting the host OS in general can mitigate all kinds of leaks. However, this is costly and potentially causes VM downtime.

RESIN leverages the results from its detection engine and uses a rule-based decision tree to choose a mitigation action that can minimize the impact. If the memory leak is localized to a single process or Windows service, and this process or service is not required to be always alive to provide services to customers, RESIN attempts the lightest mitigation by simply restarting the process or Windows service.

For some processes, the mitigation requires additional steps. RESIN allows component teams to define custom scripts and invoking conditions. If the leak is located in buggy drivers, RESIN unloads and reloads the driver to mitigate the issue.

For safety, RESIN uses allowlists for each action category to make sure auto-mitigation is not misused. It defines an initial allowlist for the processes and drivers that are known to be safe to restart. A feature team can opt in auto-mitigation by adding the name of the process or tag to the allowlist.

For leaks in the OS kernel memory such as I/O request objects and file objects, if the detection engine can attribute the leak to a process or a service, RESIN attempts to restart the culprit process or service. This action is usually effective because it allows the leaked kernel objects to be properly freed without the need to reboot the OS.

OS reboot will resolve any software memory leak but takes a much longer time and can cause VM downtime. Thus, it is the last resort when a leak cannot be mitigated by the above actions or the name is not in the allowlist. RESIN checks if the host is empty and does the OS reboot if so. Empty hosts could also leak memory due to past user activities or current background processes. For a non-empty host, RESIN first performs live VM migrations [8]. Then it attempts a kernel soft reboot, which skips hardware initialization. If the soft reboot is ineffective, a full OS reboot is performed.

To minimize the impact of mitigation actions, RESIN closely monitors the leaking hosts. It prioritizes the actions on 1) nodes that fire low-memory related events, such as E2004 (low virtual memory) from the Windows resource exhaustion detector, E3122 (not enough memory to start VM) from Hyper-V; 2) nodes in regions with capacity issues; 3) nodes with host memory reservation overage; 4) nodes ordered by the leak size, leaking rate, and the predicted time-to-failure.

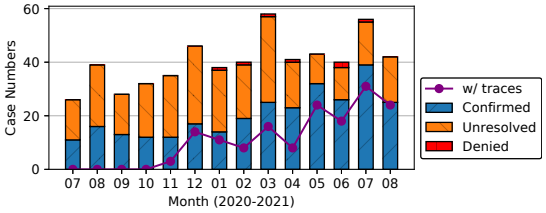

Figure 8: Memory leak cases RESIN detected and reported.

RESIN stops applying mitigation actions to a target when the detection engine no longer considers the target leaking. This typically occurs *without* manual intervention. For example, after developers identify the root cause and apply a fix, the leak symptom disappears, so RESIN stops the mitigation. Sometimes, after a mitigation action, the leak symptom no longer re-appears, which naturally stops further mitigation.

RESIN also coordinates with its diagnosis engine (Section 5) in performing the mitigation actions. If the diagnosis engine plans to or is taking heap snapshots for a candidate host, RESIN defers the mitigation actions to avoid losing the critical opportunities for capturing the leaking allocations.

7 Evaluation

Our evaluation answers several questions: (1) how effective is RESIN in detecting memory leaks? (2) how accurate is the detection? (3) can RESIN help developers diagnose and mitigate leaks? (4) what is the overhead of trace collection?

7.1 Deployment Status and Scale

RESIN has been running in production in Azure since late 2018. It covers millions of hosts, over 600 different host processes and over 800 different kernel pool tags daily. The detection engine in RESIN analyzes more than 10 TB memory usage data every day. The diagnosis module collects 56 trace files on average (10–200 MB) daily. Every month, the mitigation engine performs a median of 1,592 process restarts, 1,290 kernel soft reboots, and 4,649 node reboots.

7.2 Detecting Production Memory Leaks

Azure has various solutions that help eliminate memory leak bugs before production, including code reviews, static bug finding tools, testing, and safe deployment policies. As a result, only complex memory leak bugs occasionally escape these solutions. RESIN serves as the last defense to effectively catch these bugs in production.

Figure 8 shows the memory leak tickets RESIN reported in Azure from July 2020 to August 2021. Overall, RESIN reported 564 tickets in 14 months, among which developers explicitly resolved 291 tickets.

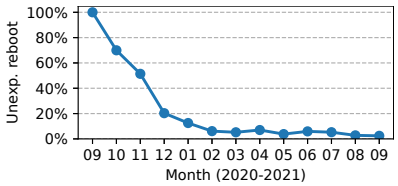

Figure 9: Unexpected VM reboot.

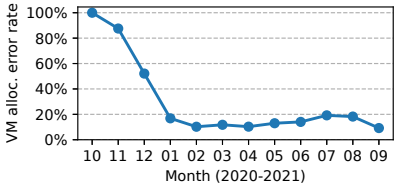

Figure 10: VM allocation error rate.

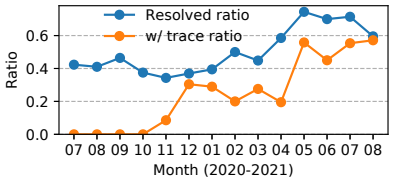

Figure 11: Ticket resolved and w/ trace ratio.

7.3 End-to-End Impact

The end-to-end benefits brought by RESIN are clearly demonstrated by two key metrics: (1) *VM unexpected reboot*[2]: the average number of reboots per one hundred thousand hosts per day due to low memory; (2) *VM allocation error*: the ratio of erroneous VM allocation requests due to low memory.

As shown in Figures 9 and 10 (data is normalized for confidentiality), the improvement RESIN provides is significant. Both metrics show large decreases: VM reboots are reduced by 41× from September 2020 to September 2021, and allocation error rates are reduced by 10× from October 2020 to September 2021. Note that these key metrics have been continuously dropping before the starting points in Figures 9 and 10. We omit to plot these earlier points because the raw data are no longer in the database due to data retention policies.

The improvement also shows in the reduction of service incidents. In 2020 and 2021, no severe outages in Azure were caused by memory leaks (such outages occurred previously).

7.4 Effectiveness of Detection

Detecting memory leaks in a complex, frequently changing cloud infrastructure like Azure is challenging. RESIN aims to minimize the false positives and false negatives.

Precision To evaluate the detection accuracy, we count how many cases RESIN reported are flagged by developers as false alarms. Overall, RESIN only incurs 7 false positives out of 291 resolved cases in 14 months.

There are two common patterns of false positives: (i) after a component adds a new feature that consumes significantly more memory; (ii) after a configuration change, *e.g.*, *"we are collecting and correlating lot more counters and # of disks per node have also increased"*. The memory usages in these cases typically stabilize and become new baselines, which RESIN automatically picks up without requiring adjustment.

Recall We count how many cases RESIN misses or fails to detect in time. The criterion is a memory leak causing noticeable service impact and getting reported by users, developers, or other monitoring services before RESIN detects it. We search keywords including "memory leak" and "leak" on Azure's issue tracker used by all teams. We compare them with tickets automatically created by RESIN. Overall the false negatives are few: only 4 cases are not on RESIN's ticket list.

We also inspect the reason for each case. One case in July 2020 was caught by us manually when analyzing a heap snapshot trace, before the issue triggered RESIN's alert. In other two cases, the leak impact was not significant, but developers found the leaks when they were closely monitoring their new deployment. The last case was both found by developers and RESIN, but developers found the issue faster. This happened because the issue manifested itself earlier on a testing cluster that had a different workload from the production clusters RESIN monitored; developers were also using an aggressive threshold in that cluster to expose potential issues.

Timeliness It can be difficult to determine the exact starting time of a leak and hence the exact detection delay. We observe that RESIN's detection typically occurs within two hours of a leak's clear manifestation. In general, a too-long detection delay would be reflected in a false negative since developers or other monitoring tools would detect the issue earlier.

Resolution rate Not all cases are eventually resolved by developers. On average, RESIN reports a resolution rate of 52% within reported date range. We believe this resolution rate is underestimated compared to actual responsive rate: in many cases, developers took actions but did not update the open tickets (only tickets tagged with a high severity level are mandatory to resolve according to ticket platform's policy). "Unresolved" also does not necessarily mean the ticket is unimportant. We observed that some teams tend to have lower response rates, likely due to their limited resources and the overwhelming number of urgent tickets.

This result is also influenced by our design goal. RESIN is designed to catch memory leaks early before the leak escalates to catastrophic issues. RESIN further provides automatic leak mitigation. Thus, a could-have-been-severe leak would appear to be low-risk. When developers prioritize resolving high-impact tickets, it adversely affects the resolution rate for our leak tickets. Due to the large volume of reported cases from various groups, we could not afford to inspect all unresolved tickets and check with their owners.

7.5 Effectiveness of Diagnosis

The diagnosis module of RESIN in total collects traces and generates reports for 157 cases from July 2020 to August 2021 (Figure 8). For tickets related to kernel leaks or clusters with legacy OSes, RESIN is unable to collect traces. Before November 2020 the diagnosis module was in trial runs and diagnosis reports were not appended to tickets. We gradually enabled it for more clusters after the trial run was over.

Figure 11 shows how the ratio of tickets with collected traces (and diagnosis reports) increases, which correlates with

[2]In this paper, we only count those VM unexpected reboots and allocation errors caused by low memory and memory exhaustion.

```
virtual void AddDsmsCertificate(CertificateStore& ... {
-   for (; certHead != nullptr; certHead = certHead->Next) {
+   for (auto currentCert = certHead; currentCert != nullptr;
+        currentCert = currentCert->Next) {
-       if (certHead->Versions == nullptr)
+       if (currentCert->Versions == nullptr)
          continue;
-       auto latest = certHead->Versions->Latest;
+       auto latest = currentCert->Versions->Latest;
        if (latest == nullptr)
          continue;
        ...
    freeCertLst(certHead)
```

Figure 12: The fix for ServiceH leak.

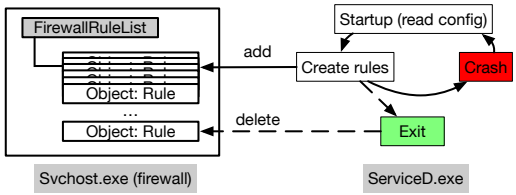

Figure 13: Contract violation induced leak on ServiceD.

the improvements on the ratio of resolved tickets.

Usefulness To evaluate the usefulness of the diagnosis reports RESIN generates, we randomly sample 14 issue tickets and closely follow up with the developers (all cases are eventually resolved and fixed). In 11 cases (79%), developers directly use the diagnosis reports to pinpoint root causes. Among them, in 5 cases the bug fix is in the same function in the allocation stack; in 5 cases the allocation stack and bug fix are in the same source file; in only 1 case the allocation stack and bug fix are in different components. Out of the other three cases, two are solved by memory dumps because the developers are quite experienced: upon seeing the sizes of leaked memory objects, they immediately realized which function the leaks came from. In one case the traces captured in the production cluster are not particularly useful. Instead, developers successfully captured some snapshots consisting of leaking stack on their own testing cluster.

Feedback Over time, developers build up high confidence in RESIN. We receive many pieces of positive feedback:

"(The result is..) incredibly useful. The information I had was enough."

"Thanks for pinpointing out the memory leak that we had been trying so hard to find over the past few days."

"Stack trace was sufficient for debugging this, it included the API call that was problematic."

Case studies We share two representative cases. The first case occurs in ServiceH[3]. This process' memory usage keeps increasing and gets restarted every few days. The diagnosis module in RESIN collects heap snapshots and pinpoints the root cause stack trace. After the diagnosis report is attached to the ticket, developers confirm and fix the issue in 3 hours.

In this case, the program uses a pointer to manage the list of certificates, and frees the pointer at the end of the function. However it also uses the pointer to traverse the list. In the end the pointer has moved and only a part of the list is freed (Figure 12). This is a day-0 bug introduced a long time ago, but is recently triggered due to added certificates to the machines.

[3]The service names are anonymized for reasons of confidentiality.

Mitigation	Count	50%	75%	90%	99%
Process restart	27,039	1.62	5.74	6.50	30.70
Kernel soft reboot	8,292	24.64	34.47	49.14	141.69
Node reboot	278,005	248.58	274.36	362.10	1382.61

Table 2: Single mitigation action execution time (seconds).

The second case represents another common (6 out of 14 cases we studied) type of leaks in cloud infrastructure: leaks due to contract violations in cross-component interactions. After RESIN reports a firewall-related `svchost` is leaking, the diagnosis module collects traces and reports a function in the rule list adding procedures after analyses.

Developers do not find bugs in this specific function at first, but the report prompts them to check the firewall rule lists on these machines. They then find the rule lists on these machines have been flooded with redundant rules. The reason is that the `svchost` process gets a firewall configuration from another program ServiceD. This program creates firewall rules at startup. Due to another bug, ServiceD keeps crashing, which causes it to miss deleting created rules and repeatedly recreate rules upon restarts (Figure 13). This in turn causes significant memory usage increases for the `svchost` program. Such a bug is hard to be detected statically.

Timeliness The diagnosis timeliness is also important to help developers. We measure the latencies of RESIN's heap snapshot collection and analysis. The median trace collection time is 61 minutes. For more than 80% of cases, the collection finishes within 10 hours. Note that the trace collection time is influenced by when a leak recurs in a suspected process. If the leak is sporadic, RESIN has to wait until the symptom reappears to capture the snapshot. For trace analysis, the median latency of the analysis jobs is 10 minutes.

7.6 Effectiveness of Mitigation

Mitigation procedure duration on leaked services Figure 14 shows the number of mitigated nodes of a kernel leak due to a buggy driver. At first, RESIN applied mitigation actions on a few nodes per day to test possible side effects. Once the mitigation actions reached production, RESIN applied mitigation to at most around 2,000 nodes per day with some fluctuations. The mitigation action volume then gradually dropped as the fix was being rolled out. Eventually the volume dropped to a few nodes a day, which were primarily nodes that failed in driver upgrading or other fix actions.

Mitigation action duration on single host We collect the frequencies and durations of each mitigation action between July 2020 to September 2021. As Table 2 shows, process restart is the most lightweight mitigation action. In most cases, it finishes within 6.5 seconds. Kernel soft reboot is also fast and in most cases finishes in a minute. Node reboot takes a longer time, with a median time of 4.6 minutes.

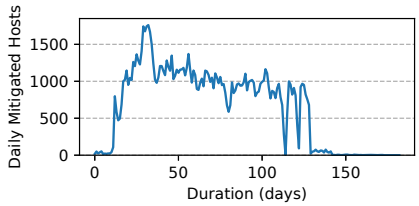

Figure 14: Mitigation for a leaking driver.

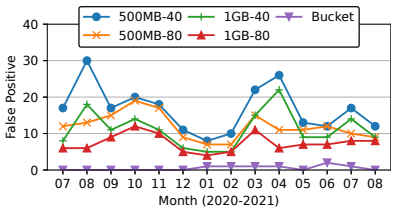

Figure 15: False positive of detection algo.

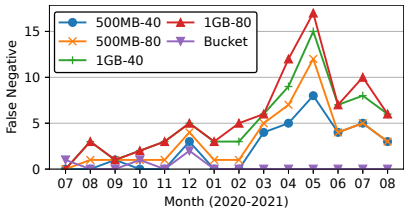

Figure 16: False negative of detection algo.

7.7 Comparison of Different Algorithms

Bucketization-based detection We first compare our core detection algorithm, the bucketization-based pivot analysis, with the practice of static threshold-based memory usage monitoring. We use four threshold policies, *e.g.*, policy "500MB-40" means generating leak alerts if a service's memory usage exceeds 500 MB on more than 40 nodes. We apply these hard thresholds to historical data and count how many cases will be wrongly reported as leaking (false positive) and how many leaking cases will be missed (false negative).

Figures 15 and 16 show the results. Our algorithm performs the best: it has both the lowest false positives and the lowest false negatives. In comparison, for other policies, it is often a dilemma to balance precision and recall. For example, policy "1GB-80" has the lowest false positives among the baselines at the cost of having the highest false negatives.

Pattern-based collection We compare our pattern-based collection with random collection. The experiment is conducted on ServiceS, ServiceV, and ServiceW. They have ongoing memory leaks on some hosts. We randomly choose six hosts and apply pattern-based collection on three hosts and random collection on the other three hosts. For the random strategy, we implement a workflow that periodically collects snapshots with at least two snapshots and completes the trace collection with a probability $1/6$. We inspect the collected heap snapshot traces to see if the leaking allocation exists in the snapshot.

Our pattern-based collection successfully captures leaking allocation stacks for all three services. Interestingly, the root cause of ServiceW was still unknown at the time we conducted the experiment. RESIN successfully captures an outstanding allocation that contains the bug within a real-time event processing function. In comparison, random collection only captures the buggy allocation for ServiceS, which has a frequent leaking interval (less than 1 hour).

Reference-assisted analysis We then evaluate the usefulness of reference snapshots with a controlled experiment on the ongoing leaking component ServiceS, which has the most noises among the three ongoing leak cases. We randomly sample eight hosts that have leaking patterns and collect snapshots until the leaking stack appears. We feed eight collected trace files to RESIN and compare the analysis results with and without reference snapshots. Figure 17 shows the result. Without the reference snapshots, the root cause stack trace ranks below the top three in all traces. With the reference snapshots, in 7 out of 8 traces, the root cause rank improves.

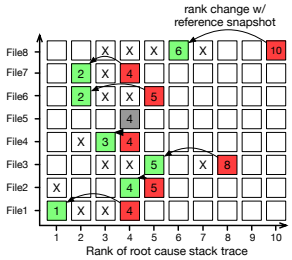

Figure 17: Ranks of root cause stack trace in diagnosis analyses on 8 trace files, w/ (green colored) and w/o (red colored) using reference snapshots. Cell with a number represents the rank. "X" marks the stack trace that gets filtered with the reference snapshots.

HasOverlap	Sessions	Nodes	25%	50%	75%	90%	95%	99%
FALSE	102,627	315	28	49	94	164	202	869
TRUE	165	31	38	50	59	86	241	888

Table 3: VM deployment time (seconds) impact by trace collection.

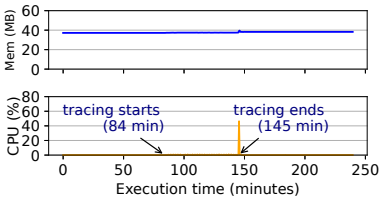
In four traces, the rank rises to the top three, which largely narrows down the code regions developers need to investigate.

7.8 Runtime Overhead

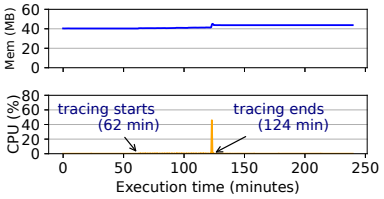
As a production service, RESIN should not impose significant overhead on the hosts. For the detection component, since RESIN leverages the kernel to collect performance counters infrequently and offloads the analyses remotely, the overhead is minimal. The main source of overhead is the heap snapshot trace collection. We use the VM deployment performance to quantify the end-to-end cost of trace collection, because VM deployment is the most important event for hosts and involves nearly all host services and triggers many critical code paths. A large overhead will be reflected in long deployment time.

We first check how many hosts RESIN performs trace collection on in November 2021. The result shows only 346 hosts are collected at least once, which is less than 0.1% of all nodes in a cluster. We then collect start and end timestamps of all VM deployment sessions and the heap snapshot tracing requests. We compare the timestamps in the two sets of events. In 315 (91%) of the 346 hosts, the deployment sessions do not have any overlap with tracing sessions, thus the tracing has no impact on these sessions.

Table 3 shows the end-to-end latency of the overlapped sessions compared to non-overlapped sessions: by 1 s for the median, and by 10 s for the 25th percentile. The latency increase could be notable for some short-duration deployments. However, this impact is limited to only a few sessions (0.16%) from a relatively small number of host nodes.



(a) host A



(b) host B

Figure 18: Memory size and CPU usage changes through tracing.

To measure the impact on memory size and CPU, we conduct experiments on two hosts that have active workloads. We trace one of the critical host processes. Figure 18 shows the memory and CPU usage during the experiment. Enabling tracing both slightly increases the average memory usage, 0.25 MB for host A and 0.53 MB for host B, and the CPU usage, 0.23% for host A and 0.22% for host B. When doing snapshot and dumping the trace, there is a clear spike for CPU usage: around 46% in both hosts. The memory usage also increases, but not significantly: 1.93 MB for host A and 3.89 MB for host B. After the tracing, the memory usage remains at a slightly increased level due to a one-time initialization required by tracer. Overall, the CPU and memory usage costs are acceptable in production deployment.

7.9 Tuning Effort

The software components and workloads in Azure infrastructure undergo frequent changes. As part of RESIN's design goals of minimizing false positives and false negatives, we aim to build robust algorithms that avoid fragile parameter tuning. For the detection part, throughout RESIN's production operation, we only made one major parameter change. We updated the alert threshold for the final result <*BucketSize*, *SeverityScore*> (Section 4.3.1) from <50 MB, 10> to <200 MB, 40> around 3 months after deploying RESIN. There has not been further tuning since then. For the diagnosis part, except for the initial trial runs in which we were experimenting with the snapshot algorithms, the parameters for the completion triggers have not been tuned after the diagnosis engine was enabled in production.

8 Lessons and Limitations

Lessons While memory leaks are generally taken seriously, developers tend to postpone the investigation if there are no convincing hints. Presenting clear evidence in results is critical, and significantly improves developers' responsiveness.

Many teams write extensive test cases that check if allocations are freed. Some teams also implement their own version of memory leak detection tool in their testing cluster. Developers mentioned a major pain point is that the testing environment has significant discrepancies with the production environment. For example, in one case, developers mentioned *"We don't have an environment where ServiceH runs for a really long time with hosts undergoing reboots."*, otherwise, their testing would have caught the memory usage anomaly.

Our initial thought in designing the diagnosis module is to analyze the source code of the detected leaking component. We later found that finding the root cause stack traces is usually good enough for developers to debug the issue based on their own experience and domain knowledge.

For production services, safety is of high priority. The cloud infrastructure is a complex and dynamic environment. Some workflow in RESIN can be interrupted abruptly, *e.g.,* due to transient network issues, interference with other profiling tools. On one occasion, RESIN accidentally left the trace collection running and triggered alarms in the detection engine. We set three lines of protection to prevent similar issues: (i) limit collecting on same cluster within one hour five times at maximum to reduce side effects; (ii) a forced cleanup operation whether the profiling succeeds or not; (iii) a workflow that periodically checks logs and cleans up for runaway hosts.

Limitations The telemetry data RESIN analyzes is relatively coarse-grained. Even the heap snapshot only contains limited information about allocations. Therefore, it has inherent inaccuracies and may miss detection of minor leak bugs. RESIN can be further enhanced by collecting more fine-grained signals, and leveraging semantic information from source code.

Developers may need to reproduce a reported memory leak issue for investigation or confirming bug fixes. But this is often challenging, because the issues are often triggered by complex workloads and rare conditions. RESIN does not address this challenge. We plan to automatically capture production triggering workloads for developers to reproduce leaks.

The patterns used in our heap snapshot trigger are based on empirical observations, which may be incomplete. Our classification method is simple. They can be improved with more comprehensive case studies and more advanced methods.

9 Related Work

Detecting memory leak bugs has been extensively studied in the context of conventional software. Our work focuses on addressing memory leaks in production cloud infrastructure, which face unique challenges as described earlier. Indeed, the memory leaks addressesed by RESIN are usually the ones that escape the bug detection and extensive testing practice in Azure and are only triggered in complex production workloads. The main research contribution of RESIN is its novel multi-stage approach and algorithms including the bucket pivot analysis and moving suspicious interval algorithm for leak detection, the live heap snapshot collection and analysis for leak diagnosis, and the decision tree based leak mitigation.

Dynamic leak detection. Many solutions have been proposed to dynamically detect memory leaks. There are broadly two approaches. In one approach, the tool records memory-related metadata by inserting checks to object code [16], using performance monitoring units in processors [24], instrumenting bytecode [39, 49], instrumenting intermediate representation [25, 34], instrumenting source code [21], modifying garbage collector or memory allocators [23, 35] or using metrics such as object staleness [17] as indicators to examine object lifetime. These works usually record fine-grained memory object information and have high accuracy, but they require rewriting codes or special hardware support, which is difficult and unsafe to apply in production settings.

Another approach analyzes heap snapshots/dumps [31, 33, 38, 44]. They are designed for interactive offline debugging and do not work well for long-running processes and services in production systems. They also rely on user-defined workloads as oracles to judge if memory growth is a leak. Obtaining such oracle workloads is difficult in practice. RESIN continuously monitors components in production cloud, designs robust algorithms to detect leaks without requiring oracles, and performs low-overhead live trace collection on-demand.

Some solutions [22, 40, 41] analyze memory usage patterns. They propose complex models to detect leaks in a single process or VM. The memory usage behavior of an individual process can be highly noisy due to workload effect and interference. Thus, they can have false positives and false negatives when applied in production cloud. Building complex models for each process in cloud scale also faces significant computation challenges. In comparison, RESIN focuses on the memory usage summary and global trend across processes, which enables accurate detection and efficient computation. RESIN additionally takes live heap snapshot and analyzes the snapshots to help developers localize the root cause.

Static leak detection. A wealth of work uses static analysis to find memory leak bugs. Many of them focus on improving the accuracies of static analyses [10, 15, 18, 36, 47]. Some other work focuses on finding specific leak code patterns. LeakChecker [50] finds objects created by the iteration are unnecessarily referenced by objects external to the loop. MLEE [46] finds leaks from early-exit paths by cross-checking the presence of memory deallocations on different early-exit paths and normal paths. Heapster [5] adopts a hybrid approach to leverage dynamic information to help static analysis. In general, while static approaches have the advantages of not requiring running a program, they face well-known scalability and accuracy challenges. They are also typically designed for a specific type of program. The software components in cloud infrastructure are highly complex and are written in a wide variety of programming paradigms. Also, static analyses cannot handle the forgotten leaks.

Leak fix and recovery. Some research work focuses on helping developers fix leak in addition to detecting them. LeakPoint [9] points developers to the potential fixable locations by taint analysis. LeakChaser [48] provides three layers of abstractions to assist programmers to diagnose memory leaks. Some other work focuses on automatically recovering the program from leaking. LeakSurvivor [42] and Melt [7] reclaim memory resources by swapping out objects to disks. LeakFix [11] inserts deallocations for leaks.

Statistical debugging. Statistical debugging [28, 29] uses statistical methods to identify predictors in the source code that correlate with a program failure. It requires instrumenting all predicates and re-running a program many times with normal runs and buggy runs. The diagnosis design in RESIN is complementary to statistical debugging. It collects live heap snapshots from production directly. Its algorithm identifies buggy stack trace based on the allocation information.

Failure detection and mitigation. Detecting memory leaks in production cloud is related to the topic of failure detection and mitigation in distributed systems [14, 19, 20, 27, 30, 43, 51]. Memory leaks are difficult to detect compared to other types of failures. IASO [37] detects fail-slow issues and supports mitigating slow issues with VM or node reboots. Narya [26] predicts node-level failures and performs mitigation actions. RESIN focuses on catching on-going memory leak issues, and provides a holistic solution. Its mitigation module leverages results from the detection engine to perform targeted mitigation to a specific process, service, driver, or host OS.

10 Conclusion

This paper presents RESIN, an end-to-end service designed to tackle memory leaks in production cloud infrastructure. RESIN takes a divide-and-conquer approach to decompose the memory leak problem, and designs a multi-level solution with novel algorithms including bucketization-based pivot analysis, live heap snapshot strategy, and diagnosis analysis. RESIN has been running in Azure for more than 3 years, and successfully reduces low-memory-induced VM reboots and new VM allocation errors by 41× and 10×, respectively.

Acknowledgments

We would like to thank our shepherd, Kathryn S. McKinley, and the anonymous reviewers for their thoughtful comments. We thank our colleagues who partnered with us on building the overall solution and providing feedback to us, including but not limited to Nathan Ernst, Anupama Vedapuri, Rui Ding, Carl Zhou, Francis David, Gaurav Jagtiani, Rakkimuthukumar Nallore Ponnusamy, Jayjit Phadke, Dustin Douglas, Matt Sebek, Harish Srinivasan, Kevin Broas, and Heejin Son. We would like to thank the strong support from Igal Figlin, Dongmei Zhang, Marcus Fontoura, Melur Raghuraman, Mark Russinovich, and Girish Bablani. Cancellation in Systems

An Empirical Study of Task Cancellation Patterns and Failures

Abstract

Modern software applications rely on the execution and coordination of many different kinds of tasks. Often overlooked is the need to sometimes prematurely terminate or cancel a task, either to accommodate a conflicting task, to manage system resources, or in response to system or user events that make the task irrelevant. In this paper, we studied 62 cancel-feature requests and 156 cancel-related bugs across 13 popular distributed and concurrent systems written in Java, C#, and Go to understand why task cancel is needed, what are the challenges in implementing task cancel, and how severe are cancel-related failures. Guided by the study, we generalized a few cancel-related anti-patterns and implemented static checkers that found many code snippets matching these anti-patterns in the latest versions of these popular systems. We hope this study will help guide better and more systematic approaches to task cancellation.

1 Introduction

Task cancellation is critical to the performance and availability of modern concurrent and distributed systems. Unlike fault handling, which reacts to the failure of a software or hardware component, task cancellation proactively stops the execution of a software component (i.e., a task) that no longer needs to run. Concurrent applications use task cancellation for better resource management, task coordination, and system responsiveness [6, 7, 20, 22]. For instance, when a user aborts a long-running operation, the underlying system may want to cancel the relevant tasks to save resources; when a high-priority request comes, a busy system may want to cancel a low-priority task for the greater good. Task cancellation is crucial for today's systems that concurrently execute a large number of complex and resource-consuming tasks under stringent quality of service requirements.

Unfortunately, supporting efficient and correct task cancellation in modern applications is nontrivial. Tasks need to be designed such that they can be aborted at certain points of execution without undesirable side-effects (e.g., without corrupting the system state). Moreover, the application needs to decide when to safely cancel a task, and once decided to cancel, the decision needs to be correctly propagated to the target task to be canceled.[1] Last but not least, a system may contain dozens or hundreds of concurrent tasks, with complex dependencies among the tasks as well as on the system environment. If not carefully implemented, canceling a task may break a dependency or introduce concurrency errors such as races. It is therefore not surprising that implementing task cancellation can be error-prone.

As it stands, there have been no studies on task cancel problems in concurrent and distributed systems—how cancel is used and implemented, the various types of cancel-related bugs, the impact of those cancel-related bugs, and so on, although various other types of bugs and problems have been heavily studied for distributed systems [11, 16, 18, 26, 27].

This paper attempts to provide an in-depth analysis of cancellation usage and problems in popular software applications across multiple languages, which we hope will help guide cancellation-related systems research and design.

Why do applications cancel tasks? To understand why cancellation may be desirable to system operation, we reviewed 62 *feature requests* in 13 popular open-source applications, such as HBase, Hive, Cassandra (Java); Roslyn, ASP.NET Core (C#); CockroachDB, and InfluxDB (Go).

We found that about half of the cancel-feature requests aim to terminate tasks that no longer produce useful results upon a change in system or user state (e.g., the finish of a related task and the end of a user session); close to half of the requests aim to improve operational flexibility and enable users to cancel a job, particularly the time-consuming ones, at any time; a small number of requests aim to enable stopping a low-priority task prematurely to support the launching and running of other more important tasks.

Our study confirms our understanding that task cancellation is a crucial feature that facilitates efficiency and operation flexibility in concurrent systems. It shows that the trigger of a cancel can be a variety of events (far beyond

[1] This is in contrast to fault-handling where the external environment decides *when* a fault is generated.

	Task	Task Cancellation
C#	`Task,Thread`	`CancellationToken` struct
Go	`goroutine`	`Context` type
Java	`Thread`	`interrupt()` on `Thread` itself

Table 1. Task constructs and cancellation mechanisms

system shutdown and component failures), and the target of cancellation is often a small number of selective tasks (rarely bulk cancellation), which can all bring complexity to the implementation of task cancellation.

What causes cancel-related bugs? To understand the challenges in implementing task cancellation correctly, we studied 156 bug reports across the same set of 13 popular open-source applications in Java, C#, and Go to understand what are common cancellation-related bugs.

Our study shows that problems routinely occur at all phases of cancel: 1) deciding when and which task to cancel (about one third of the bugs), 2) propagating the cancel request from the initiator to the target task (about one quarter of the bugs), and 3) fulfilling the cancel in the target task (about one third of the bugs). Some classes of problems are particular to the type of mechanism used to issue cancel, such as bugs in the use of Java's `interrupt` API, and bugs in passing cancellation tokens through function parameters in C# and Go. Many other classes of problems are due to the overall complexity of implementing cancel, such as determining which tasks conflict, which system state changes must be reverted before task termination, etc. For each type of bugs, we discuss potential solutions to tackle them.

Impacts of cancel-related bugs. The impact of cancel bugs varies, but can in some cases be severe. Among issues with specified symptoms, a few common categories are resource leaks, performance issues, broken task APIs, data corruption or loss, and incorrect user reporting.

Cancellation anti-patterns. Through the study above, we have generalized and implemented static checkers for five cancel-related anti-patterns using the CodeQL [1] static analysis framework, including (1) missing interrupt handling inside a loop (Java); (2) using the wrong built-in API to check or reset the interrupt flag on threads (Java); (3) failure to propagate cancel to child tasks (Java); (4) ignoring cancel-token parameters (C#); and (5) not propagating cancel tokens (C#)[2]. We find around 200 instances of these anti-patterns across the latest versions of the 13 applications we studied, which further motivates future work to improve the support for correct cancel implementation.

2 Background

Task. This paper defines a task as a unit of concurrent execution. As summarized in Table 1, in Java, all code that implements a `Runnable` interface qualifies (e.g., `Thread`). In C#, tasks are objects of type `Thread` or `Task`. In Go, execution inside a `goroutine` is a task [4, 5, 22]. Tasks are not limited to any specific programming model: for example, some issues we study involve tasks as part of an event-driven design. Some tasks execute with a clear end, like a user-request task launched by a server application; some execute with an open end and cease only on system shutdown or explicit request to terminate, like a task that provides an in-memory cache service for others. Tasks can also initiate work on other nodes, e.g. by issuing an RPC call.

[2]This particular checker is a re-implementation of an existing C# checker.

```
1  public void run() {
2       try { ...
3       } catch (InterruptedException e) {
4       // receiver handles the cancel request
5       }
6       ...
7       if (Thread.currentThread().isInterrupted()) {
8       // receiver handles the cancel request
9       }
10   }
```

Listing 1. Handling cancel requests in Java

Task Cancel. Cancel is the deliberate attempt of one task to terminate another task in a *cooperative* way. We will refer to the former as the cancel initiator and the latter as the cancel target. All the instances of cancel we study are *cooperative*, which means that the target task, upon receiving the request, chooses how and when to terminate [15]. Note that the alternate way of task cancel - *abortive*, where the initiator forces the target to terminate - is prone to semantic errors and is not supported by the three languages that our study focuses on (Java, C#, Go). For example, the abortive Java `Thread.stop()` method is deprecated now.

Cancel vs Fault Handling. Task cancel and fault handling have some similarities in that they both involve a task finishing earlier than expected, but they also have fundamental differences. Cancel can be considered part of the regular operation of the system: the conditions that cause cancel to be issued are known and expected with some regularity, such as to proactively prevent performance problems, as we will discuss in Section 4; the cancel process involves the cooperation between at least two running parties, the initiator and the target; after the cancel is conducted, the system is expected to remain functioning as normal or even at a higher capacity. This is in contrast to failure handling, in which failure events are unexpected; the handling is reactive after a component failure; and the expectation for system functioning may be lower - e.g. to function at reduced capacity, or to terminate safely.

Cancel mechanisms. Although the built-in cancel mechanisms in C#, Go, and Java take different forms, as listed in Table 1, they all essentially offer a "flag": the initiator sets the flag when requesting cancel, and the target can check the flag and respond to the cancel request.

```
var tokenSource = new CancellationTokenSource();
var token = tokenSource.Token;
var mytask = Task.Run(() => {
// the receiver checks the token before starting
// to handle a potential cancel request
    ...
    if (token.IsCancellationRequested) {
    // receiver handles the cancel request
    }
}, token);
```

Listing 2. Handling cancel requests in C#

Specifically, in Java, any thread can execute `t.interrupt()` to set an internal flag of thread `t`. Any code executing in thread `t` can use APIs like `isInterrupted()` to check this flag and see if an cancel request has been delivered to it. Alternatively, any execution of a blocking API, like `sleep()` or `poll()`, will throw an `InterruptedException` upon the setting of its thread's cancel flag, as shown in Listing 1.

C# and Go offer more flexible ways of cancel. Instead of limiting each thread to have one flag, they allow the software to declare any number of `CancellationToken` structs (C#) or `Context` variables (Go) that each contains a cancel flag. In C#, a `CancellationToken` object, generated from a `CancellationTokenSource` is typically passed through function parameters. An invocation of `Cancel()` on the token's source would set the flag inside the token object, which is visible to any task that has access to the token, as illustrated in Listing 2. Cancel in Go is similar: the `Context` type provides a `CancelFunc` to issue a cancel signal, which can be checked via ctx.Done() on the Context ctx. Like `CancellationToken`, `Context` is typically passed via function parameters. In the remainder of the paper, we will refer to `Context` variables also as cancellation tokens for simplicity.

The `CancellationToken` in C# also allows registering a callback function to be called when the token is canceled. This functionality is rarely used in the applications that we study and hence will not be discussed in this paper.

Finally, developers can implement custom means of cancel. In many Java programs, shared Boolean variables are used as cancel flags. Threads explicitly read and write these flags to carry out cancel. This essentially allows multiple cancel flags for one thread and hence can embed more semantic information inside each flag. However, it is also prone to bugs, as we will discuss in Section 5.

3 Methodology

Application selection. We study applications written in three different languages: Java, C# and Go, as shown in Table 2. These languages were chosen as they have widespread use of different built-in cancel mechanisms, and as such provide a useful point of comparison for this study.

In choosing which Java applications to study, we focus primarily on the most popular, as indicated by GitHub stars, open-source distributed applications in various categories,

Table 2. Applications included in our study

Application	Category	Stars	Bugs	CFR[2]
Java (distributed apps)				
Cassandra	Database	7K	14	2
Elasticsearch	Full-text search	57K	15	20
Hadoop[1]	Distri. storage; distri. processing	12K	10	3
HBase	Database	4K	26	3
Hive	Data warehousing	4K	21	5
Kafka	Stream processing	20K	9	2
Solr/Lucene	Full-text search	4K	9	2
Spark	Data processing	31K	6	6
Java - subtotal			110	43
C# (single-instance apps)				
ASP.NET Core	Web framework	26K	6	1
Roslyn	Compiler	15K	14	8
C# - subtotal			20	9
Go (distributed apps)				
CockroachDB	Database	22K	12	6
etcd	Key-value store	38K	8	0
InfluxDB	Database	22K	6	4
Go - subtotal			26	10
Total			156	62

[1] Including Hadoop Common, HDFS, YARN, MapReduce
[2] Cancel-Feature Requests

as listed in Table 2. Our selection is more limited for Go and C#, since there are much fewer applications written in these two languages on GitHub. For Go, we study applications that are analogous to categories studied in Java: InfluxDB and CockroachDB (distributed databases), and etcd (distributed application serving and coordination). For C#, there do not exist any widely-used applications in those categories. So, as an alternative, we chose the top 2 applications/frameworks, out of the 50 most popular C# applications on GitHub, that utilize cancel extensively: Roslyn (compiler suite) and ASP.NET core (web framework).

Cancellation Issue Study. For these selected applications, we checked their Jira issue trackers or GitHub issue-and-pull systems, if they do not use Jira. We searched for *resolved* and *valid* issues, up to June 2021, using the following keywords: *abort*, *cancel*, *interrupt*, and *terminate*. We then manually checked the reports to exclude issues that do not have a clear description or are unrelated to task cancel.

From the remaining, we get 156 issues that are labeled by developers as "bug" or are clearly fixing a bug, although not labeled. They will help us understand the root causes and symptoms of cancel-related bugs, as presented in Section 5 and 6. We should note that although an issue might belong to multiple root causes or symptom categories, it

Table 3. Reasons underneath Cancel-Feature Requests (CFR)

Why should a task T be canceled?	#CFR
A. Efficiency: T no longer produces useful results	**30**
- A1. Upon system shutdown	5
- A2. Upon a user disconnection or time-out	6
- A3. Upon a system or user event	19
B. Flexibility: T is no longer wanted by users	**28**
- B1. Cancel through an API call	20
- B2. Cancel through user interface or keyboard	7
- B3. Cancel through timeout parameter	1
C. Priority: More important tasks need to run	**4**
Total	**62**

is classified by its primary category only, **without double-counting**. In addition, we study 62 issues that are requests to add the capability of canceling some tasks and are labeled as "improvement" or "feature", instead of "bug", and contain patches approved or already merged. They will help us understand the motivation of task cancel, as in Section 4.

We believe cancel problems are under reported, as cancel code can be difficult to exercise during testing. From the discussion in cancel-feature requests, we also see that the complexity in correctly implementing task cancel sometimes drives developers away from implementing cancel, which of course comes with performance and efficiency loss.

Threats to validity. Our study does not cover all task cancel mechanisms, and may not generalize to those issues and systems not covered in our benchmark suite. Particularly, we have skipped those cancel-feature requests and cancel-related bugs whose description is not clear enough for us to conduct further categorization. We may also have missed cancel-related requests or bugs whose reports do not contain the search keywords used by us. Furthermore, since there are many more issue reports and pull requests about adding cancel features than those about cancel-related bugs, we limit our study of cancel-feature requests to those that contain cancel-related keywords in the issue/pull titles. Thus, we likely have missed many requests that have those keywords in the issue/pull body, but not the title.

4 Why Do Applications Cancel Tasks?

To understand why tasks may require cancel and what triggers a task cancel, we studied 62 cancel-feature requests in Java, C#, and Go systems, following the methodology described in Section 3, and generalized three main reasons for task cancel as shown in Table 3.

Reason-A: Efficiency. Close to half of the cancel-feature requests originate from developers' efficiency concerns, as the computation of a task T no longer produces useful results upon (A1) a system shut-down, (A2) a user-session termination, or (A3) a particular system or user event. Among these three different cancel-trigger scenarios, A3 is the most common and triggers cancel at a finer granularity than A1 and A2. For example, when a user navigates away from a web page P, the system still runs many tasks related to the user, but can cancel all the tasks initiated by page P (e.g., influxdb-19029); when one attempt of a task finishes, all other speculative or parallel attempts of this task can be canceled (e.g., SPARK-25773 and roslyn-8050); when a job is canceled or finished, its related tasks can be canceled (e.g., roslyn-25620 and roslyn-51816). In all these cases, continuing the execution of T does not affect functional correctness but wastes system resources and affects request latency.

Reason-B: Flexibility. Another common reason is to offer users the flexibility to prematurely terminate a user operation and all its related tasks, which contribute to about 40% of the cancel-feature requests. In a number of cases, the requests explicitly mention that the target task may take a long time (e.g., elasticsearch-72644 and elasticsearch-73818 and SOLR-6122) or even hang for unknown reasons (e.g., KAFKA-1506), and hence should be cancellable. In other cases, the exact reasons why a user may want to cancel a task is not explained. The requested cancel features typically get implemented as task-cancel commands or as handlers of certain user interface events, like the Ctrl+C keyboard combination.

Reason-C: Priority. Interestingly, sometimes, developers want to enable the system to sacrifice T for the benefit of other more important tasks. For example, in HDFS-2507, a feature is added to cancel an ongoing checkpoint task of a standby NameNode when the active NameNode fails. This would allow the standby NameNode to immediately start the fail-over task instead of waiting for the long checkpointing to finish, minimizing the system downtime. Similar decisions of sacrificing long-running low-priority tasks for the benefit of high-priority tasks also occur in other systems (e.g., CASSANDRA-14397, elasticsearch-56009).

Observations. *Trigger variety.* A task cancel can be triggered by a variety of events, as shown in Table 3. This variety adds complexity to the implementation of cancel: the program may miss a trigger and fail to initiate the cancel. Even when a trigger is sensed, the trigger information may not be included in the cancel request, e.g., in Java's built-in cancel mechanism, making it difficult for the cancel handler to process the cancel request properly.

Fine granularity. Task cancel is often targeted; bulk cancel scenarios like system shutdown are rare. This fine granularity can make it difficult to decide which task to cancel.

Heavy coordination. In a system that involves many concurrent components, cancel may involve a lot of coordination across tasks: a task's cancel could be due to the launch, the progress, or the termination of another task. This heavy coordination requirement demands careful synchronization and shared-state clean-up during task cancel.

Proactive instead of reactive. Unlike fault handling, task cancel rarely reacts to an already exposed component failure. It is more about the system efficiency, request latency, operational flexibility, and resource balancing, which, although do not immediately precipitate system outages, are crucial to the service quality and robustness.

5 Root Causes of Cancel-Related Bugs

We divide the whole procedure of cancel into three phases, and categorize cancel bugs' root causes accordingly:

1) *Initiating Cancel* - the cancel initiator senses a cancel-trigger event and decides which task to cancel.

2) *Propagating Cancel* - the cancel request propagates from the initiator to the target.

3) *Fulfilling the Cancel* - the cancel target responds to the cancel request, releasing resources, restoring system states, and ending its own execution.

Note that there are 9 bugs caused by miscellaneous semantic errors that are not related to the core functionality of task cancel. We put them in the "Other" category in Table 4 and skip discussion about them below.

Table 4. Cancel-related bugs: root causes

Root Cause Category	Java	C#	Go
Buggy cancel initiation			
- Overlooking triggers	22	3	9
- Broken trigger checking	7	0	0
- Excess cancel	7	1	0
Buggy cancel propagation			
- Untimely delivery	15	3	4
- Dropped cancel	17	5	2
Buggy cancel fulfill			
- Cancel not checked	8	0	4
- Cancel not carried out	6	0	0
- Defective cleanup	23	5	6
Other	5	3	1

5.1 Cancel-initiation bugs

As discussed in Section 4, a variety of conditions might trigger a cancel. Deciding when to initiate a cancel to which target task is complex and susceptible to problems, contributing to about 30% of cancel-related bugs (Table 4).

In some cases, a cancel is not initiated when it should be, either because the system completely overlooks a cancel trigger ("Overlooking triggers") or because the system checks the existence of a cancel trigger incorrectly ("Broken trigger checking"). In other cases, a cancel is incorrectly or unnecessarily initiated ("Excess cancel"). We describe each type in more detail below.

5.1.1 Overlooking triggers. This type of bug occurs when a cancel should be initiated upon a specific trigger, but no logic exists to do so. This is the most common type of cancel-initiation bug, contributing to more than 20% of all the cancel-related bugs.

The most common scenario is that a running task T is canceled or has failed but a dependent task, which is no longer necessary, is not canceled. As an example, in SPARK-21738, expensive jobs would continue to run on a Spark cluster even after a user session was closed, wasting computation resources to produce irrelevant results. While Spark does provide support for canceling jobs, the system did not realize that a session closure should be treated as a trigger for job cancel.

As another example, in roslyn-1086, the failure of a compilation task will prevent a "completion" event from ever being published to an event queue, while a task listening to the queue, *AnalyzerDriver*, will continue to run and wait for the event which will never arrive. The solution in this case was to include a reference to the *AnalyzerDriver* in the compilation task, which is canceled via cancellation token upon compilation failure.

Other types of triggers could also be overlooked. For example, in CASSANDRA-8805, developers realized that the launch of high-priority tasks like *repair* often gets blocked by long-running low-priority tasks like *index-summary redistribution*, as these tasks access *sstables* in a conflicting way and cannot run in parallel. To solve this problem, developers added the logic to allow any *repair* to check for and cancel any running *index-summary redistribution* tasks.

Note that bugs of this type share similar root causes with those cancel-feature requests for efficiency or priority reasons, which were discussed in Section 4. The difference seems to be the impact: the ones that cause more severe failure symptoms are reported as bugs, instead of feature requests.

The patches to these bugs are straightforward: adding the logic to initiate a cancel upon the occurrence of the trigger.

Lessons learned. A fundamental challenge here is to track the dependency relationship among all the concurrent tasks, a daunting task in modern concurrent and distributed systems: which tasks conflict with each other and cannot run in parallel; which tasks depend on which task and hence should not continue if the latter is canceled; which tasks are redundant copies of which task and hence should not continue if the latter finishes successfully; etc. In all systems that we have checked, this is conducted in an ad-hoc way. There is an unmet need for coherent tool/framework and possibly programming language support for capturing these dependencies.

One particular type of dependency, the parent-child relationship, is feasible to track through static program analysis. Consequently, we can build a static checker to automatically identify code snippets where the parent task is canceled, and

yet no cancel is initiated towards the children tasks. We will present more details about this checker in Section 7.3.

Other types of dependencies, like *repair* versus *index-summary redistribution* or a speculative task versus the original task, depend on application-specific semantics and are much harder to track systematically. We noticed that these semantic-rich dependencies are often centered on some key shared data, like the `sstables` that are updated by conflicting tasks or the common `job-ID` shared between multiple job attempts (e.g., HIVE-12307). Consequently, future work may automatically infer task dependencies by analyzing access patterns on key data.

5.1.2 Broken trigger checking. Sometimes, the program anticipates the existence of a trigger. However, it checks the trigger occurrence in a wrong way. For example, in SOLR-10525, if a duplicate task is submitted while a previous instance of a task is still running, the previous instance should be canceled. However, the logic to recognize whether a previous instance of a task is running is incorrect and so a cancel is never issued, leading to the execution of duplicate tasks.

Lessons Learned. Many bugs of this type are related to checking whether a particular task is running. Often, the task performing the check does not have a direct reference to the task under check, and hence needs to refer to an intermediary, like a shared collection of task status. The logic to store and retrieve the task status information is custom implemented in each system and hence prone to bugs: some accesses to the task registry are not thread safe; different types of tasks may store their information in different ways in the collection and hence got mis-checked later; etc. Some standard library support would help.

5.1.3 Excess cancel. Converse to "Overlooking triggers", sometimes triggers are correctly sensed and yet tasks are wrongly or unnecessarily canceled. For example, upon the launch of a task T, the software may incorrectly cancel tasks that are actually not conflicting with T (CASSANDRA-13142, CASSANDRA-15024) or tasks that are indeed conflicting but have higher priority than T (HBASE-17674). Upon the finish of a task T, the software may incorrectly cancel tasks which are related to T but whose results are still needed (roslyn-11470, HADOOP-6762).

Lessons Learned. Similar as "overlooking triggers", these bugs originate from the challenge of tracking the dependency among tasks. Future research should study how to track which tasks conflict with or depend on each other, potentially through data dependency analysis.

5.2 Cancel-propagation bugs

Once a cancel trigger is correctly sensed and the cancel target is correctly identified, the initiator issues a cancel request. For about a quarter of the cancel-related bugs in our study, the propagation from the initiator to the target went wrong.

```
1  // Cancel initiator
2  class Initiator {
3    Task myTask;
4    main() {
5      ...
6      myTask.cancelFlag = true;
7    }
8  }
9
10 // Cancel recipient
11 class Task {
12   public boolean cancelFlag = false;
13   private BlockingQueue Bqueue;
14
15   run() {
16       while(cancelFlag == false) {
17         ...
18         Bqueue.take(); // blocks until an element is
                available
19       }
20   }
21 }
```

Listing 3. An example of late cancel (SPARK-1582)

5.2.1 Untimely delivery. It is important that a cancel can be issued at any time to the cancel target without delays or mis-handling. However, this is often not the case when a custom cancel mechanism is used.

Cancel race. In many systems, a "task manager" is implemented to coordinate tasks and relay cancel requests: the cancel initiator notifies the task manager about its cancel request; the task manager then sends the request to the cancel target. In several Java and Go systems, such as Cassandra (CASSANDRA-9070), Spark (SPARK-4097), HBASE (HBASE-13146), InfluxDB (influxdb-9018), and etcd (etcd-8443), the implementation of task managers contain concurrency bugs that manifest when cancel is issued at a special moment, like shortly after the target task is submitted, or in parallel with another cancel request towards the same target. As a result of these bugs, cancel requests may be dropped.

Occasionally, such cancel-related concurrency bugs also occur when a standard cancel mechanism is used. For example, in aspnetcore-11757, a cancel initiator disposes a `CancellationTokenSource` right after it requests a cancel on the token. As a result, when the target task checks the token, a use-after-disposal error occurs.

Lessons Learned. It is alarming that similar cancel-concurrency bugs occur in so many different systems. On one hand, standard task-manager library support could help. On the other hand, existing concurrency bug detection and testing tools [10, 13, 14, 17, 19] should be applied to check the correctness of cancel-related implementation.

Late polling. As discussed in Section 2, many custom cancels are conducted through a shared flag variable. Unfortunately, without system support, such a cancel request cannot be delivered timely when the target task conducts frequent blocking operations. For example, Listing 3 illustrates a simplified version of bug SPARK-1582. A task checks

```
// Cancel recipient
class Task {
  run() {
      ...
      commitSync() // interrupt lost inside commitSync
      ...
      if (isInterrupted()) {
        // cleanup steps here will not be performed
      }
  }
  commitSync() {
   sleep(1000); // unsets interrupted flag
    ...
    catch (InterruptedException ex) {
      // does not reset flag, cancel gets dropped
     }
  }
}
```

Listing 4. An example of dropped delivery (KAFKA-4375)

```
class Task {
  ...
  void checkStale() {
       ...
    // current thread is interrupted somewhere
     } catch (InterruptedException e) {
-      Thread.currentThread().interrupted(); // Wrong
+      Thread.currentThread().interrupt(); // Fixed
     }
  }
}
```

Listing 5. API Misuse Example (SOLR-8066)

whether a cancel is delivered to it at the beginning of every work-loop iteration through a custom `cancelFlag` variable. Unfortunately, since every iteration of the loop executes a `BlockingQueue::take()` operation, the flag may not be checked for a long or even unlimited amount of time, causing severe delays in Spark job cancellation. Similar issues also exist in KAFKA-5697, KAFKA-5896, and others.

These problems are typically fixed by using a language built-in cancel mechanism instead of, or in addition to, the custom flag to carry out the cancel. In Java, the built-in `Thread.interrupt()` would terminate blocking operations such as `sleep()`, `BlockingQueue::take()`, and `poll()`, with an `InterruptException` thrown. In C# and Go, many system operations such as `sleep()` accept cancellation tokens as parameters, allowing the timely delivery of cancel.

Lessons Learned. The key takeaway here is to avoid using a custom cancel flag, particularly when the nearby code region conducts blocking operations. We can use static program analysis to identify these vulnerable custom-cancel loops and warn the developers. Having said that, the pervasive use of custom-cancel loops in Java programs is probably due to the limitation of Java's built-in cancel mechanism, which we will discuss more in Section 5.4.

5.2.2 Dropped cancel.

Depending on the different cancellation mechanisms, a cancel request could be dropped before it propagates to the right target in different ways.

Cleared interrupt (Java). A tricky aspect of Java's built-in mechanism is that the interrupt received by a thread can be silently unset by methods along the call chain. As a result, the interrupt may fail to reach the code that is prepared to fulfill the cancel request, contributing to about 15% of cancel-related bugs in Java programs in our study.

For example, in KAFKA-4375, function `run` contains a well written cancel handler that stops child tasks and exits. Unfortunately, at run time, the cancel is often intercepted by the `sleep` method inside its callee `commitSync`, as shown in Listing 4. The Java `sleep` method, just like many other Java blocking methods, silently unset the interrupt and throw an `InterruptedException`. Without rethrowing the exception or resetting the interrupt flag, the interrupt is dropped before reaching the right handler in function `run`. Similar problems also occur in other systems, like HBASE-5243, HIVE-13858, HBASE-10650, HBASE-10651, HBASE-10652, etc. Patches for these bugs simply re-throw the interrupt in the catch block.

A related mistake is that developers sometimes get confused about a few similar Java APIs: `t.interrupt()` interrupts a thread `t`; `t.interrupted()` checks whether `t`'s interrupt flag is set *and* clears the flag; `t.isInterrupted()` conducts the same checking but *does not* clear the flag. When `interrupted()` is mistakenly used, the cancel could be dropped before reaching the intended cancel handler, as illustrated in Listing 5. This type of mistake occurred at multiple places across different systems (KAFKA-9415, KAFKA-5665,HBASE-10455, SOLR-8066). Patches for these problems are straightforward, as shown in Listing 5.

Lessons Learned. Many bugs of this type can be automatically detected. As we will discuss in Section 7.1 and 7.2, static checkers can search for the catch blocks of `InterruptedException` that neither terminate the execution nor re-throw the exception, and search for incorrect use of the `interrupted()` API.

Invisible token (C#/Go). In C# and Go, once a cancel is issued on a cancellation token, the status of the token cannot be reverted. Consequently, the type of mistaken clearance in Java does not exist in C# or Go. However, a cancel request may still get dropped during its propagation: since the cancellation token is typically not a global object, developers need to pass the token through function parameters to ensure the token is available through the chain of method calls. If the token is not passed to a long-running function f, cancel would be greatly delayed until the execution returns to a caller of f that has access to the token. This contributes to close to 15% of cancel-related bugs in C# and Go.

Making things more complicated, unlike Java, C# and Go allow canceling a thread through different cancellation tokens, each representing different semantics—one token

```
// Cancel recipient
class SomeTask {
  private CancellationToken systemCancelToken;

  void doWork(CancellationToken userCancelToken) {
        ...
        libraryMethod(userCancelToken); //
             systemCancelToken invisible to libraryMethod
  }
}
```

Listing 6. One type of invisible token (aspnetcore-5936)

might represent requests from end users; one might represent requests from a periodic timer; and so on. As a result, programmers may pass some tokens to a function, but forget some others, causing certain cancel requests to be dropped, as shown in Listing 6. Note that, a function typically only allows one cancellation-token parameter. Consequently, the onus is on developers to be aware of what tokens exist in the current context and when or how to combine them into one token to pass to a callee function—not a trivial task.

Lessons Learned. This type of bug can be detected by static checkers: if a function f has a cancellation-token parameter, its caller function F should pass every cancellation token *tok* visible in F to f. In fact, such a checker is included in the .NET SDK, a set of libraries that provide support for development for C#[23]. We apply this checker to the latest versions of ASP.NET Core and Roslyn, and report the results in Section 7.5.

5.3 Cancel-fulfill bugs

Once a cancel is correctly initiated and propagated to the target, the target task must process the cancel request, stopping its execution, releasing resources, and reverting or invalidating shared states so that other tasks, including a potential re-submission of the current task, can proceed correctly. This is unsurprisingly the most difficult aspect of cancel, contributing to about one third of all the bugs in our study.

5.3.1 Cancel not checked. Sometimes, a successfully delivered cancel request is not immediately checked by the target task, causing severe cancellation delays.

In Java, the complexity is that explicit cancel checking is not always needed. Once the internal cancel flag is set by the system, the target thread will throw an `InterruptedException` once it executes a blocking Java API like `sleep`, `poll`, and others. Consequently, if the target thread invokes some of these APIs from time to time, explicit checking is not needed. However, if a long-running code-region, like a loop, does not call any such APIs, explicit checks using APIs like `isInterrupted` or `interrupted` are needed. Lacking such explicit checks are the root causes behind several bugs in Java systems, like HIVE-16078 and HBASE-10575.

In C# and Go, similar problems occur if a long-running function never checks its parameter cancellation token.

Table 5. Cleanup issues breakdown

	Count
What type of cleanup defect?	
- Incorrect: wrong API or cleanup semantics	10
- Incomplete: did not clean up all data	14
- Missing: no cleanup performed	4
- Unordered: clean up data in a wrong order	3
- Other	3
Where is data requiring cleanup located?	
- Heap	27
- Persistent data	7
How should data be cleaned up?	
- Invalidate, revert or reset data	13
- Release resource (lock, thread, etc.)	13
- Delete file from disk	2
- Other	6

Lessons Learned. For C# applications, we have implemented a static checker to detect this type of bug (Section 7.4). For Go applications, implementing an accurate checker is difficult, as the `Context` variables contain many fields and could be used for many different purposes other than cancel. Automatically detecting this type of bug in Java programs is feasible. We leave this to future work.

5.3.2 Cancel not carried out. This type of bug occurs when the target task makes no attempt to stop its execution after it becomes aware of the delivered cancel request.

Our study has only seen this type of bugs in the context of the Java built-in mechanism. Specifically, an `InterruptedException` is thrown by a Java library API. This exception is caught by the caller function but the handling block is essentially empty. There are many bugs of this type (e.g., HBASE-3064, HBASE-10472, HIVE-15997, KAFKA-5833, KAFKA-1886).

Comparing with other cancel mechanisms, an `InterruptedException` contains the least semantic information—it is unclear which task initiated the cancel and for what reason. This may be why some of these catch blocks are empty.

Lessons Learned. Although the root cause here differs slightly from the "Cleared interrupt" bugs in Section 5.2.2[3], they both can be detected by a checker that searches for problematic catch blocks of `InterruptedException`, which we will discuss in Section 7.1.

5.3.3 Defective cleanups. When responding to a cancel request, a task needs to not only stop itself, but also to release resources that it acquired earlier and clean up changes it made to shared data. Doing so in a coordinated, correct, and

[3]The cancel-target task has no cancel handling across the call chain for bugs here, but has the right handling in a caller in "Cleared interrupt" bugs.

efficient way is challenging. Unsurprisingly, bugs that occur during this process are particularly common, contributing to more than 20% of all the bugs in our study.

What went wrong? There are mainly four types of mistakes in a cancel cleanup, as shown in Table 5.

First, the cancel handler changes the values of some variables in an attempt at cleanup, but the resulting values lead to failures (10 bugs in our study). For example, in SOLR-8372, upon the cancel of a *recovery* task, the *update log* this *recovery* task has been working on should remain in "inactive" state until recovery is restarted. However the cleanup logic mistakenly puts the update log into "active" state, which had the serious consequence of potential data loss. The fix was simply not to make that state change.

Next is incomplete cleanup, where the task attempted to clean up data but did not do so comprehensively (14 bugs). For example, in CASSANDRA-7803, *compaction result* files were written during the *compaction* task. The files could be written in a regular location or a temporary location, depending on the configuration. The cleanup logic removed the regular files but not the temporary ones, which could quickly fill the disk and make the application unusable.

Completely missing cleanup, where no steps are taken to clean up any data related to the task, occurred in 4 bugs. In HBASE-13877, a *TableFlushProcedure* task is canceled. However the task simply ceases execution without any additional steps taken. The data modified by the task (*Memstore Snapshot*) is not invalidated and may get reused by subsequent tasks, causing data corruption or data loss.

Finally, there are 3 bugs where the cleanup routine works on shared variables in an incorrect order, causing coordination problems with other tasks.

What data is at the center of defective cleanup? Unlike crash handling, cancel handling is carried out by the cancel target, an actively running task, and hence needs to clean up not only persistent but also heap data it has touched. In fact, for the majority of clean-up bugs (80%), heap, instead of persistent data, is the target of defective cleanup.

In our study, a canceled task T typically does not hold a close dependency with other running tasks—otherwise, T typically would not be canceled, or its dependent tasks would be canceled altogether. Consequently and fortunately, there is typically not too much heap data to clean. What needs to be cleaned are mainly low-level resources, such as locks or thread pools; or shared data structures related to system activities or persisted information. The latter includes things like task tracking, i.e. what tasks are running, have run, or about to run in the system, e.g. the `ZoneSubmissionTracker` object in Hadoop; pointers to persisted user data e.g. the `DataTracker` object in Cassandra, which maintains references to all database tables; and other system metrics or metadata, such as the `StorageMetrics` object in Cassandra which tracks disk usage, and the `RoutingNode` object in Elasticsearch, which maintains shard status information. This relatively focused target of cleanup may help future research to automate data cleanup.

Occasionally, a task which produces a large amount of intermediate results needs to be canceled. Fortunately, in most cases we have seen, the system already has a transaction-style design, where all intermediate data is buffered in a cache. The cleanup only needs to update the cache metadata correctly.

In the cases where persistent data is the target of defective cleanup, most often the data are temporary files local to a task, which are not properly deleted or invalidated. In three cases, however, the persistent data are shared by other system activities, and defects in cleaning up this data prevent the broader system from performing correctly.

What does the patch do? Most commonly, the patch releases resources, invalidates or reverts the data modified by the task. Releasing resources, such as locks, threads, and cancellation tokens, is straightforward. Often, the original task already has the correct resource release routine. However, upon a task cancel, that routine is short circuited. The patch simply makes sure the complete release routine is followed.

How to correctly invalidate or revert the data varies from case to case. Sometimes, the task needs not keep track of the modifications it has performed: for example, in CASSANDRA-5481, a task needs to reset a shared connection/cursor object on cancel, which does not require information about the history or the state of the task. But in other cases, a task must track information about modifications it has made: in CASSANDRA-15674, a task makes a single modification to *totalDiskSpaceUsed* on the shared *SystemMetrics* object, and should remember to decrement by this same value upon cancel. One challenge in performing this type of clean up is knowing, among the various heap data modified by a task, which requires cleaning and which type of cleaning.

Lessons Learned. As evidenced by the examples above, defective cleanups have severe consequences and are common. It is important to tackle these bugs.

Detecting the complete absence of cleanups is relatively easy. Whenever a cancel handler only ceases the execution and performs no cleanup, a warning should be issued. Some of these bugs can even be automatically fixed: in many cases, one just needs to re-throw the interrupt to the caller that contains the correct clean-up logic (e.g., HBASE-7711).

Some incomplete cleanups are caused by short-circuiting a correct clean-up routine. Particularly, exceptions may be thrown during the clean up, either due to unexpected task states or a system API hitting the original interrupt signal again. Incorrect handling of such a double-exception may skip the remainder of the cleanup routine, causing incomplete cleanups (HIVE-15997). Automated checkers can be developed to search for this type of bug.

Existing tools that detect resource leaks during exception handling [25] and cancellation-token leaks [21] can be applied to detect those resource leak problems.

Detecting incorrect cleanup or general missing cleanup is the most challenging and requires more research. One possible research direction is to consolidate cleanup steps to help detect and fix defective cleanups. In many bugs, the related cleanup steps were interspersed across the task. However, when they were combined or compared together, it was clear that they were not comprehensive or correct. Sometimes cleanup for one task should have been identical to another. For example, in SPARK-1396, a scheduler had two methods, *handleCancel* and *abortStage*. These should have performed the exact same cleanup steps, but for each method steps were implemented separately and non-comprehensively. The fix was to combine the cleanup logic so that it was shared. Or, the cleanup on task cancellation was very similar to the steps performed on task completion (e.g. removing a task from a registry when it is completed or canceled), and deficiencies were clear on consolidation.

Finally, given our observation that the target of cleanup is often a small set of system data structures, future research may use data-flow analysis to remind developers about what data should be cleaned, and to potentially synthesize invalidating/reverting methods for the small number of data structures that are the target of most cleanup.

5.4 Discussion: cancel mechanisms

5.4.1 Built-in mechanisms. A natural question to ask is whether different built-in cancel mechanisms cause different cancel usage issues. Some types of bugs are common no matter what mechanism is used. For example, "overlooking triggers" contribute to 19% and 26% of bugs in Java and C#/Go, respectively; "defective cleanup" contribute to 20% and 24% of bugs in Java and C#/Go, respectively.

However, there are also many types of bugs that occur particularly often in Java systems, reflecting limitations of Java's built-in cancel mechanism:

1) "Cleared interrupt" bugs (Section 5.2.2) only occur in Java programs, as neither C# nor Go allows clearing an already issued cancel request. Note that, it is natural for Java to allow clearing a cancel signal received by a thread, because each thread has only one internal cancel flag no matter how many different cancel initiators and how many different cancel contexts there might be. This limitation also influences the next two types of bugs in Java.

2) The "Late polling" bugs (Section 5.2) in theory could exist in programs written in any languages, but were only seen in Java programs by us: the use of custom cancel-flag loops is very common in Java programs and yet very rare in C#/Go programs, probably due to the limitation of Java built-in cancel mechanism as discussed above.

3) "Cancel not carried out" bugs (Section 5.3) in theory could exist in programs written in any language, but were only seen by us in Java programs. We believe this is again related to the above limitation of Java cancel mechanism. In C# and Go, a nice effect of using a `CancellationToken` as one of a task's function parameters is that it makes clear from the function protocol that the task is designed to be cancellable. The rich semantics behind cancel tokens also helps developers decide how to treat each cancel request. In contrast, in Java, `interrupt()` is available on threads by default but there is no guarantee threads respond to the interrupt, and indeed often do not.

Of course, the mechanisms in C# and Go are not perfect either. In addition to the common problems they face, such as "defective cleanup", they are particularly susceptible to "invisible token" problems (Section 5.2.2). Furthermore, the design of mixing cancel signals with other information in the `Context` variable in Go introduces challenges for both developers and researchers in designing cancel-related analysis tools.

5.4.2 Custom mechanisms. Some of the systems we studied contain components specially built to assist with cancel functionality. These components offer features that may mitigate root cause cancel issues discussed previously, and so may be of interest. We share examples of a few such constructs here.

Cancellable Task interfaces. While Java threads by default provide a method to cancel tasks, i.e. built-in `interrupt()`, a few systems provide an alternative interface to be used by cancellable tasks. At a bare minimum these interfaces declare a "cancel" method that task developers must implement, in some cases encouraging developers to sidestep built-in "interrupt" and associated problems.

For example, the *Interruptible* interface in Cassandra's "concurrent" package declares, in addition to the main task method `run()`, a method named `interrupt()` that requires implementation by developers. Though simple, this design advantageously makes explicit the task should be cancellable and actively requires cancel implementation, whereas for other task constructs, for example a generic thread, the need for cancel might not be apparent, and developers might not check for interrupts or passively ignore interrupt exceptions as we have seen. (And, an examination reveals all existing implementers of this interface do indeed handle cancel).

Some interfaces go further and include partial mechanism implementation. The abstract class *CancellableTask* in Elasticsearch's *tasks* package provides a non-overridable, pre-implemented `cancel` method which sets a member field cancel flag `isCanceled` to false (and which task execution code should check). The class also includes the status method `isCanceled()`, which may help avoid misuse problems that occur when using the built-in API to check interrupted status. We must note, however, there is a downside to side-stepping built-in interrupt entirely: if the task uses built-in blocking Java methods - e.g. sleep - it will not be able to exit these methods prematurely, as we have seen.

Interfaces may also include post-cancellation methods that developers can implement to perform cleanup or other

related tasks. *LifecycleTransaction* in Cassandra's *db* package provides, in addition to a cancel method, an `onAbort()` hook which is called after cancellation is processed. This may encourage developers to implement or consolidate cleanup logic, helping prevent missing or incorrect cleanup issues.

"Uninterruptible" interfaces. Conversely one system provides an "uncancellable" interface that allows users to run code sections without interruption: the *UninterruptibleThread* abstract class in Spark's "util" package allows users to define "uninterruptible" code sections that will complete in their entirety - if `interrupt()` is called on the thread, it will be suppressed until the uninterruptible code section completes. One area where this might be useful is for cleanup steps which must be executed in their entirety after the task is canceled: some issues we have seen arise from cleanup steps failing to complete due to interrupt during cleanup itself. An examination reveals that some implementations of this interface indeed use this functionality for cleanup. However, this design is susceptible to problems if not used carefully: if an uninterruptible code section uses an operation that blocks indefinitely, the thread may never respond to a cancellation request.

Task dependency tracking. One of the biggest categories of cancel issues is overlooking triggers, of which a common trigger is cancellation of a parent or associated task. Thus using constructs that track related or dependent tasks and help propagate cancel between them may be valuable.

For example, some systems provide a task tracking service or "task manager" that maintains a list of scheduled or running tasks, usually by requiring that all task executions be launched through the manager. The task manager may additionally be designed to track task dependencies: e.g. the *TaskManager* shared class in Elasticsearch's "tasks" package require that submitted *Tasks* contain an "id" and "parentId". All task executions are initiated through the task manager using the manager's `register` or `registerAndExecute` methods. Running tasks and their children can thus be tracked and cancellations, which must also go through the manager (via `cancelTaskAndDescendants` method), can be propagated to all dependent tasks.

6 Symptoms of Cancel-Related Bugs

Not all the bug reports specify the exact failure symptoms. We categorize the ones that describe the symptoms in Table 6. As we can see, the symptoms vary, and can be severe.

Resource leaks. Resources acquired during task execution, including locks, buffers, and others, might not be released due to defective cleanup (Section 5.3.3). Furthermore, if a cancel does not take effect, the task thread itself may be leaked, which may be especially problematic if the thread pool has a fixed size. For example in SPARK-1582, work done by a Spark *Executor* thread was no longer needed, but a cancel was delayed (sometimes indefinitely) and the thread was not made available to perform other work.

Table 6. Cancel-related bugs: symptoms

Symptom Category	Issues
Resource leaks	30
Performance issues	29
Broken task API	17
Data corruption/loss	5
Incorrect reporting	10
Unspecified	65
Total	156

Broken Task API. Unsurprisingly, incorrect cancellation might break the API used to submit or manage tasks. For example, in HDFS-12518, a critical task cannot be re-executed, due to the task not cleaning up its status when canceled. In SPARK-8132, *no* subsequent task for a multi-stage user job is able to be launched due to incorrect cleanup.

Data corruption/data loss. Many tasks might perform operations on user data, and a broken cancel can corrupt in-memory data used to service user requests, as well as cause persistent data to be lost - a very serious issue. For example, a silently dropped cancel signal in a callee led a caller to put incomplete (i.e. corrupted) in-memory values of user computations into a shared cache. Later user jobs would use these invalid values and give wrong results. (SPARK-1602).

Performance issues. While cancellation itself should generally lead to improved performance, as resources previously used by a task can be freed for other work, broken cancel handling can put the system in an unanticipated state that causes degraded performance or unresponsiveness.

In HIVE-13858 an interrupt signal was dropped, leading to an infinite loop in a task, which made access to a portion of system I/O impossible. This could cause unavailability of the entire cluster. Similarly, in CASSANDRA-11373, incomplete cleanup led to an infinite loop and CPU saturation.

In elasticsearch-75316, how frequently cancel would be used was underestimated, and inefficient cancel handling led to a 50x increase in latency for normal user requests. The patch was to make cancel handling more efficient.

Incorrect reporting to users. Lastly, mistakes in cancel functionality might lead to incorrect reports to users. For example a system might report to the user that a job has been canceled when in fact it was not (HIVE-14942, SPARK-18665, influxdb-13681). Or, conversely, the system might report that a job has not been canceled when indeed it has (SPARK-2666).

7 Task Cancel Anti-Patterns

Root causes of cancel bugs are varied and sometimes complex, but we find that a few types of bugs are associated

Table 7. Anti-pattern instances found in Java and C# applications

	HBase	Hive	Spark	Kafka	Solr	Cassandra	Hadoop	es	ASP.NET Core	Roslyn
Unhandled IE in loop (Java)	5	2	0	0	0	1	13	0	-	-
API misuse (Java)	3	2	0	7	5	0	0	0	-	-
Uncanceled child tasks (Java)	1	2	0	0	0	0	9	0	-	-
Ignored tokens (C#)*	-	-	-	-	-	-	-	-	34/112	120/179
Tokens not passed (C#)**	-	-	-	-	-	-	-	-	9	9

* Our analyzer result / CodeRush analyzer (simulated) result
** .NET analyzer (simulated) result

with clear anti-patterns that are detectable by static code analysis. This section presents our experience of designing and evaluating a few anti-pattern checkers.

We have implemented a checker for each of the anti-patterns below using CodeQL [1], a publicly available static analysis tool. CodeQL takes as input *queries* which are a set of conditions on the application source code's call graph, control flow, dataflow graph and other information (e.g. object hierarchies). Queries are language specific, so for each anti-pattern and language, we have constructed a single query that describes the anti-pattern and can be run on all applications of that language, using CodeQL's command line tool or web interface. The results of queries are references to problematic section of source code (file and line number). The queries associated with each anti-pattern can be viewed at a publicly available repository [3].

Note that, code snippets that match an anti-pattern may not all cause severe failures, but are frequently harmful to the software in the long run if not fixed. We will discuss this in detail when we comment on the severity of each anti-pattern.

Also note that, these checkers mainly tackle low hanging fruits of cancel-related bugs, with more complicated bugs waiting to be tackled by future work. We are aware of similar checkers for the two C# anti-patterns, which we will discuss in details in Section 7.4 and 7.5. There may be similar checkers for the Java anti-patterns, although we are currently not aware of them. Our main goal here is to show that it is feasible to detect cancel-related code defects through simple static checking, and that many cancel-related defects exist even in the latest versions of these popular Java and C# applications.

7.1 Unhandled Interrupt Exception (Java).

Anti-pattern. An `InterruptedException` is caught inside a loop body, but in the catch block there is no handling - no control flow to exit the loop (i.e. no `break` statement, `return` statement or rethrown exception in the AST), and the interrupt flag is not reset via `t.interrupt()` on thread `t`. In addition, we also check via dataflow analysis that the thread is indeed interrupted somewhere in the codebase.

Rationale. This anti-pattern is closely related to "cleared interrupt" bugs (Section 5.2.2) and "cancel not carried out" bugs (Section 5.3.2). Its severity has been explained in these earlier sections. Note that, in this anti-pattern, we particularly look for problems inside a loop, as it is especially problematic there: without proper cancel handling inside a loop, a task may never cease execution or incur particularly long delays (HADOOP-6221,HBASE-3064).

Severity. There is one scenario where the impact of this anti-pattern may be mitigated: the program may use a custom cancel flag together with an `interrupt` call to cancel a task. In that case, an unhandled interrupt exception may not have a big impact, as long as the remainder of the loop iteration does not take long time to execute. Having said that, this type of implementation is still problematic and makes code maintenance difficult: what if an expensive operation is added near the end of the loop iteration? What if the task initiator deems the use of flag redundant in the presence of the interrupt call and removes the former?

Results. Our checker finds 21 cases of this anti-pattern in the latest versions of 4 Java applications in our benchmark suite (Table 7). Our manual checking of these 21 cases shows that 14 of them are truly instances of this anti-pattern; 2 of them are false positives (a corner case in CodeQL control-flow analysis misses the fact that the exception handler does stop the task execution); 5 of them may be considered false positives: the exception handler sets a flag, which defers the actual handling to a later point in the loop, which may or may not cause perceivable delay in the cancel handling.

7.2 Interrupt API Misuse (Java).

Anti-pattern. A thread calls `Thread.interrupted()` inside an `InterruptedException` catch block.

Rationale. This anti-pattern is inspired by a few API-misuse bugs discussed in Section 5.2.2 (e.g., Listing 5). When an `InterruptedException` is triggered by a library method in thread `t`, the interrupt flag is almost always cleared and should be reset by invoking `t.interrupt()` if the exception is to be handled by the caller. If a `t.interrupted()` is invoked instead, this is frequently a typo, as this API is

designed to clear the interrupt flag, effectively a no-op inside the catch block. It may also be used inside a condition check, as it returns the status of the flag before clearing - `e.g. if (t.interrupted())`, - but when such checking occurs inside the catch block it is even worse, as library methods likely will have unset the flag before the check, and the logic inside the condition will never execute.

Severity. This API misuse can cause an interrupt to be dropped. Consequently, handling/cleanup logic that exists elsewhere may not be executed, causing functional problems.

Results. Our script finds 17 instances of this anti-pattern in 4 applications, as shown in Table 7. Our manual examination did not find any false positives.

7.3 Cancel not propagated to dependent tasks (Java)

Anti-pattern. A task instantiates a Java `Timer` and starts a child task (wrapped in a `TimerTask` interface) using a Java `Timer` object but does not cancel the `Timer` and `TimerTask`: either it does not maintain the reference to the `Timer` or it does not explicitly call `cancel()` on the `Timer` or `TimerTask`.

Rationale & Severity. This anti-pattern is related to some of the "Overlooking triggers" bugs discussed in Section 5.1.1. Java's built in `Timer` is one of the mechanisms used for scheduling single or periodic task executions on a separate thread. If the child task launched using the `Timer` (or `Timer` itself) is not canceled when the parent is canceled, then at a minimum, this lack of cancellation will leak resources. Note that, this anti-pattern focuses on `Timer`-based parent-child task dependency, because these type of child tasks are typically scheduled periodically and hence lead to more severe impact if not properly canceled.

Results. Our script finds 12 instances where a timer and associated tasks are started but not canceled. Three of these instances are false positives: in 2 cases, the reference to the `Timer` is embedded in a nested class, and hence is missed by our CodeQL-based static checking; in one case, the `Timer` task is only started during system shut down, and hence its leakage does not really cause problems.

7.4 Ignored cancellation tokens in loop (C#)

Anti-pattern. A method containing a loop accepts a `CancellationToken` parameter `ct`, but does not check the token via `ct.IsCancellationRequested`, `ct.CanBeCanceled` or `ct.ThrowIfCancellationRequested()`, anywhere inside a loop. Nor does it pass the token as an argument to any function calls inside the loop.

Rationale & Severity. The rationale of this anti-pattern has been discussed in Section 5.3.1. For a similar reason as discussed in Section 7.1, we focus on loops in this anti-pattern, for their bigger performance impact.

Results. Our analyzer found 154 cases of this anti-pattern (34 in ASP.NET Core and 120 in Roslyn). Manual checking finds 4 of these to be false positives: in 3 cases, a token is used via an indirect reference or reflection; in 1 case, a method that operates on a token instead of using it as a signal.

We also investigated a similar analyzer that is part of CodeRush [2], a popular debugging and code analysis extension for VisualStudio. The CodeRush analyzer warns if a token is not checked anywhere inside in a method. We have simulated the CodeRush analyzer using CodeQL and find 112 and 179 instances in ASP.NET Core and Roslyn, respectively. In one regard, our analyzer is stricter: if a token is checked somewhere in a method but not in a loop, our analyzer will flag it as a warning but the CodeRush analyzer will not. But, unlike the CodeRush analyzer, our analyzer does not check methods that do not contain loops.

7.5 Token not passed - .NET analyzer (C#)

We also applied an analyzer included as part of the .NET compiler platform (Roslyn). That Roslyn built-in analyzer checks if a `CancellationToken` is passed via parameter to a method M, but M does not pass the token to its calee C which optionally accepts a token parameter (optional arguments are a feature of the C# language). This anti-pattern is related to the "invisible token" bugs discussed in Section 5.2.2.

Simulating this anti-pattern using CodeQL, we find 9 instances each in the latest version of ASP.NET Core and Roslyn. Our manual checking finds no false positives.

7.6 Anti-pattern limitations

While these checkers have been inspired by and cover some of the bugs in our study, there are still many bugs that cannot be covered by our checkers, for various reasons. In some cases a bug manifests due to reasons logically different from those covered by our checkers: for example, a cancel is dropped due to a semantic bug in a custom mechanism, rather than API misuse or an unhandled interrupt exception.

In other cases, conditions added to our antipatterns to reduce false positives thereby introduce false negatives: for example, we search for empty interrupt exception handling specifically inside loops, but empty handling outside loops can also cause bugs.

Finally, our checkers are designed around common usage patterns and may miss other valid forms of usage: for example, we assume a cancel-supporting method is one that accepts a context or token explicitly as a top-level parameter; our checkers will ignore methods where the context or token is passed implicitly, say as a member field of another parameter.

8 Related Work

Our study is the first empirical study of task cancellation patterns and failures in concurrent systems to the best of our knowledge. Nevertheless, several related works have discussed general exception handling problems in the past.

The problem of empty exception handlers was discussed by Yuan et al. in the study of real-world failures of distributed

systems and by Fu and Ryder in the context of analyzing exception-chain of Java programs [8, 26]. Our work is orthogonal to their research, as we particularly focus on bugs related to task cancel. As discussed in Section 5, only a small portion of cancel-related bugs are due to empty exception handlers — those 6 "Cancel not carried out" bugs in Java and some of those 16 "Dropped cancel" bugs in Java. Because of the task-cancel context, why these bugs' catch blocks are empty, how to fix them, their failure symptoms, and how to generalize them into anti-patterns are all different from generic empty handler problems (e.g., the anti-pattern in Section 7.1 does not just look for empty catch blocks).

While our work discusses how cancel signals may fail to propagate to the target tasks (Section 5.2) in concurrent systems, previous work studied how incomplete error propagation could occur in file systems and storage device drivers [12, 24]. Since previous work looks at propagation through function error-code return, it is orthogonal to our study.

Past studies about general cloud system failures [11, 18] have identified error/fault handling to be a common cause, contributing to 18% of software-related failures in one study [11] and 31% of software-bug incidents in another study [18]. Both categorized error/fault handling problems into two or three major categories, including "error/fault detection", "error propagation", and "error handling". This taxonomy is similar to how we categorize cancel-related bugs at the highest level. The similarity ends here. Since both previous studies focus on general cloud failures, neither goes deep into the error/fault handling problems. The examples of detection, propagation, and handling problems there are very different from the cancel initiation, propagation, and fulfillment bugs discussed in this paper.

A Java textbook [9] has listed five possible reasons behind task cancel: (a) user-requested cancel, (b) time-limited activities, (c) application events, (d) errors, (e) shutdown. In our cancel feature study, we want to see what are the common reasons and trigger events behind task cancel in modern concurrent systems. Our study led to a categorization (Table 3) that is related but not the same as the textbook listing.

9 Future Research Directions

In this section we highlight a few potential areas for future research.

Cancellation in other languages. Different languages may have attributes which affect what types of cancel issues manifest. For example, our study focuses on garbage-collected languages; languages with manual memory management (e.g. C++) may see other cancel issues, e.g. stemming from explicit deallocation.

Cancel programming models and language features. As discussed in Section 5.4, different built-in cancel mechanisms and language constructs offer different support and challenges to developers. While we present some examples of custom cancel constructs in Section 5.4, more extensive exploration and evaluation of cancel-related designs and models are needed.

Bug-detection and other developer tools. Although this work presents static tools to detect certain classes of cancel bugs, there are still many cancel bugs that are not covered by our static checkers. More static or dynamic detection and diagnosis tools are needed.

Other kinds of developer tools may also assist in cancel implementation. For example, in Section 5.3.2 we describe how `InterruptedException` often contains the least semantic information about the source of cancel; it may be worth exploring whether developer tools, such as IDE plugins that detect and provide this contextual information, can help guide proper implementation.

10 Conclusions

Task cancellation is critical to the efficiency, availability, and operational flexibility of concurrent systems. This paper presents a comprehensive study about how task cancel is used and what type of bugs are related to task cancel in popular distributed and concurrent systems written in Java, C#, and Go. This study reveals the complexity of implementing correct and efficient task cancel, and motivates future research to offer better system support for task cancel.

Automatic Reliability Testing for Cluster Management Controllers

Abstract

Modern cluster managers like Borg, Omega and Kubernetes rely on the *state-reconciliation* principle to be highly resilient and extensible. In these systems, all cluster-management logic is embedded in a loosely coupled collection of microservices called *controllers*. Each controller independently observes the current cluster state and issues corrective actions to converge the cluster to a desired state. However, the complex distributed nature of the overall system makes it hard to build reliable and correct controllers – we find that controllers face myriad reliability issues that lead to severe consequences like data loss, security vulnerabilities, and resource leaks.

We present Sieve, the first automatic reliability-testing tool for cluster-management controllers. Sieve drives controllers to their potentially buggy corners by systematically and extensively perturbing the controller's view of the current cluster state in ways it is expected to tolerate. It then compares the cluster state's evolution with and without perturbations to detect safety and liveness issues. Sieve's design is powered by a fundamental opportunity in state-reconciliation systems – these systems are based on state-centric interfaces between the controllers and the cluster state; such interfaces are highly transparent and thereby enable fully-automated reliability testing. To date, Sieve has efficiently found 46 serious safety and liveness bugs (35 confirmed and 22 fixed) in ten popular controllers with a low false-positive rate of 3.5%.

1 Introduction

Modern cluster managers like Kubernetes [11], Borg [80], Twine [77], Omega [72], and vSphere [20] break down cluster-management logic into a fleet of microservices, called *controllers* [27]. For example, in Kubernetes, *all* the cluster-management logic is encoded in different controllers. Today, thousands of controllers are implemented by commercial vendors and open-source communities to extend Kubernetes with new capabilities [42, 68, 74, 78]. Controllers manage everything from application lifecycles (e.g., provisioning, upgrades, autoscaling) to stateful services, storage, networking, and integrations with cloud providers [41, 53, 57, 60, 71].

These cluster managers follow the *state-reconciliation principle* for resilience and extensibility [7, 27]. In this design, each controller continuously monitors a subset of the cluster state and reconciles the *current* state of the cluster to match a *desired* state. The cluster state is typically hosted in a logically centralized, highly available data store (e.g., etcd or ZooKeeper). In Kubernetes, entities like pods, nodes, volumes, and application instances are represented as objects in the cluster state. An auto-scaling controller might thereby monitor an application-group object for the number of currently active replicas and scale it to match the desired replica count. The design allows cluster managers to be 1) *resilient*: controllers can independently fail and pick up from where they left off, and 2) *extensible*: supporting a new feature or application is a matter of adding a custom controller that manages a set of custom objects as part of the cluster state.

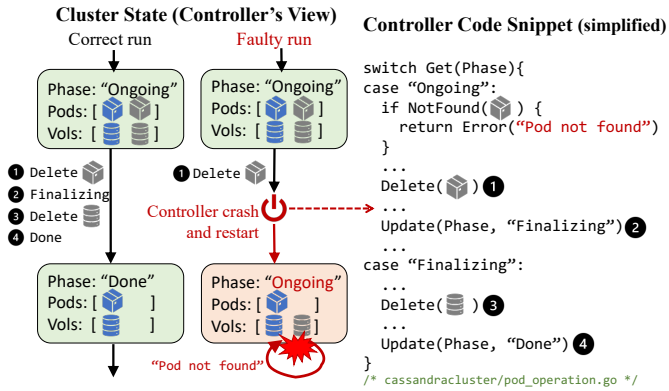

Figure 1: **A bug in a Cassandra controller detected by our tool, Sieve [30].** The controller cannot recover from an intermediate state introduced by Sieve using a crash. As a consequence, the controller cannot auto-scale the Cassandra cluster and leaks storage resources. The bug has been fixed. The code snippet is significantly simplified for clarity; the real code spans 70+ functions and 2,000+ lines of Go.

Despite the importance and prevalence of custom controllers, ensuring their reliability is challenging. Controllers run within complex, dynamic, and distributed environments. They must safely drive the system to desired states while tolerating unexpected failures, network interruptions, and asynchrony issues. If controllers are not robust to these circumstances, they lead to severe consequences such as application outages, data loss, and security issues. Buggy controllers have indeed caused many real-world problems [31, 38, 51, 52].

For example, Figure 1 shows a bug in a Kubernetes controller for managing Cassandra [30]. The bug prevents the Cassandra cluster from auto-scaling and leaks storage resources (decommissioned volumes in gray are never deleted). This is because the controller lacks crash safety – it fails to recover from an intermediate state due to a crash between deleting a Cassandra pod and updating the `Finalizing` phase.

The above crash-safety bug is only one of the myriad kinds of reliability issues that affect controllers. We find that controllers also experience bugs caused by state inconsistencies due to asynchrony effects and bugs caused by uncoordinated concurrent interactions between controllers. Existing testing techniques are either too specialized for certain types of bugs or require expert guidance in the form of formal specifications or carefully-crafted test inputs (§8). We instead seek a solution that is broadly applicable across controllers and is capable of *automatically* detecting a wide range of bugs.

Contributions. In this paper, we present Sieve, the first automatic reliability-testing technique for cluster-management controllers. Sieve drives unmodified controllers to their potentially buggy corners by systematically and extensively perturbing the controller's view of the cluster state in ways it is expected to tolerate. Sieve then compares the cluster state's evolution with and without perturbations to automatically detect safety and liveness issues.

Sieve is highly usable. It does not require 1) formal specifications of the controller or the cluster manager, 2) hypotheses about vulnerable regions in the code where bugs may lie, or 3) highly specialized test inputs. It does not rely on expert-written assertions either. Sieve requires only a manifest for building the controller image and basic test workloads. Sieve's testing is then fully automatic. This degree of usability is key to making reliability testing broadly accessible to the rapidly increasing number of custom controllers.

Sieve is powered by a fundamental opportunity in state-reconciliation systems – controllers interact with the cluster state via *state-centric interfaces*. State-centric interfaces perform semantically simple operations on the cluster state (e.g., reads and writes) and deliver notifications about cluster-state changes; the objects that flow through the interfaces typically have a uniform schema. Therefore, state-centric interfaces are highly introspectable and hence an ideal vantage point to observe and perturb a controller's view of the cluster state.

Sieve leverages the fact that a controller's actions are strictly a function of its view of the current cluster state. We thus test a controller by exhaustively introducing state perturbations through failures, delays, and reconfigurations. These are circumstances that reliable controllers are expected to tolerate. Currently, Sieve supports three typical perturbation patterns that expose controllers to 1) intermediate states (Figure 1), 2) stale states (or past cluster states), and 3) unobserved states due to missing some cluster state transitions (§3.1).

For each pattern, Sieve automatically generates test plans that cover all possible perturbations during an execution of the controller under test. Test-plan generation is based on analyzing a controller's behavior and the cluster-state evolution during reference executions. Sieve effectively avoids redundant and futile test plans to maximize test efficiency.

Sieve automatically detects buggy controller behavior using differential test oracles that compare the cluster-state transitions with and without perturbations. This comparison is feasible because a controller's behavior is reflected in the sequence of cluster-state transitions. The differential oracles are often more effective than searching for errors in logs and more comprehensive than human-written assertions (§3.6).

Key results. We implemented Sieve for Kubernetes controllers. Sieve requires only a manifest for building the controller image and basic workloads (e.g., a scale-up-and-down workload for an autoscaling feature). Sieve's testing is then fully automatic. We evaluated Sieve on ten popular open-source controllers of various kinds, from either commercial vendors or official projects. Sieve found 46 new bugs in total, among which 35 have been confirmed (22 fixed) after we reported them. Notably, these are deep semantic bugs that Sieve detected without any expert guidance. The bugs have severe consequences, including application outages, security vulnerabilities, resource leaks, and data loss. Sieve is highly efficient—all controllers could be tested in under seven hours on a cluster of 11 machines, representing a typical nightly test. Sieve also has a very low false-positive rate of 3.5%, making its testing results trustworthy.

Summary. The paper makes four main contributions:

- We present the first automatic reliability-testing technique for state-reconciliation systems: exhaustively perturbing the controller's view of cluster states and using differential oracles on the cluster state evolution to detect bugs.
- We design and implement Sieve, a system that uses our proposed technique to automatically test *unmodified* cluster-management controllers in Kubernetes.
- Sieve has already improved reliability for ten popular open-source controllers by virtue of bugs it found that were then fixed by developers. It is practical to run Sieve regularly.
- We have made Sieve publicly available at `https://github.com/sieve-project/sieve`, with instructions to reproduce all discovered bugs.

2 Background and Motivation

Modern cluster management and control plane designs follow the state-reconciliation pattern, where control loops reconcile the current state of the cluster to conform to a desired state. Kubernetes, like its predecessors Borg and Omega, follows the idea of reconciliation control loops for resiliency [27]. Similarly, vSphere [81] and NSX [82] continuously monitor and correct deviations from declaratively-specified desired

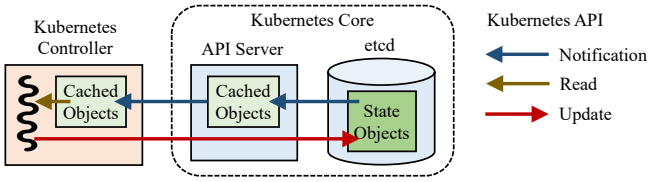

Figure 2: **Interactions between a controller and other Kubernetes components and the state-centric APIs.**

states to manage virtual machines and networks. These systems rely on a clean separation between the cluster state and the control plane logic [27]; the state is represented as mere data (e.g., JSON objects), and the control plane logic queries and manipulates the state programmatically.

We now give a brief overview of state reconciliation and cluster-management controllers. We also present the urgent need for automated reliability testing and our insights.

State reconciliation by example. We use Kubernetes as a representative example to present the basics of state reconciliation. Figure 2 illustrates Kubernetes' architecture. Kubernetes' core comprises an ensemble of *API servers* and a highly available, strongly consistent data store (etcd) that houses the *cluster state*. The cluster state is represented by a collection of *objects*. Every entity in the cluster has a corresponding object in the cluster state, including pods, volumes, nodes, and groups of applications. All other components in Kubernetes interact with the cluster state via API servers.

All cluster-management logic is encoded in *controllers* that are clients of the API servers. The controllers continuously monitor a part of the cluster state and perform state reconciliation whenever the current state does not match the desired state. The controllers perform reconciliation by querying and manipulating the state objects via a client library that exposes a state-centric interface. This interface provides notifications, reads, and writes involving the cluster state objects.

This design enables Kubernetes to be highly extensible: supporting a new application or feature is a matter of adding a new controller and a corresponding set of custom object types to the cluster state; it does not require changes to the client library or interface. The design also allows controllers to be loosely coupled, which improves resilience: controllers can independently fail and new controller instances can resume reconciliation without fail-over logic.

Figure 3 shows how a collection of controllers coordinate in a loosely coupled manner. To deploy a ZooKeeper cluster running on Kubernetes, the user creates a ZooKeeper object which specifies the desired state of the ZooKeeper cluster (e.g., replica count, version, storage size) via the Kubernetes command-line tool. The ZooKeeper controller receives a notification that a ZooKeeper object was created. To drive the system to the desired state, it updates the cluster state by creating a StatefulSet object (an abstraction to run stateful applications). Then, a StatefulSet controller is subsequently

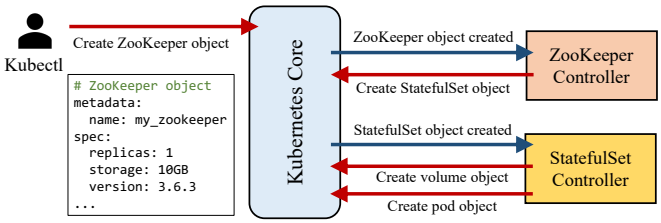

Figure 3: **The workflow of deploying ZooKeeper on Kubernetes using a ZooKeeper controller.**

notified about the StatefulSet object being created, which in turn creates pod and volume objects to run the containerized ZooKeeper nodes. While not shown in the figure for brevity, this subsequently leads to more controllers like a scheduler, a storage controller, and worker nodes being activated to bring up the actual containers and volumes. Similarly, if the user then edits the desired state of the ZooKeeper object (e.g., the number of replicas), it triggers a similar sequence of reconciliations by different controllers, as each tries to make minor adjustments to get to its appropriate desired state.

The need for automated reliability testing. Kubernetes' extensibility has led to a thriving ecosystem with *thousands* of domain-specific controllers implemented by commercial vendors and open-source communities [41, 42, 53, 60, 68, 71, 74]. For example, OpenShift, an enterprise Kubernetes platform from Red Hat, provides 130+ custom controllers that extend Kubernetes [17]. All these controllers represent critical infrastructure, making their correctness paramount. As shown by many real-world problems [31, 38, 51, 52] and our evaluation results, designing and implementing reliable controllers is challenging – many popular, mature controllers misbehave under faults, delays, and asynchrony with severe consequences.

However, controller reliability is notoriously hard to ensure. A developer faces the fundamental challenge of 1) anticipating all possible *views* of the cluster state at the controller (compounded by asynchrony) and 2) safely reconciling to the required desired states from any of these points. We observe that manually-written test suites do not sufficiently test a controller's reliability (§6).

Unfortunately, existing testing techniques are either too specialized for certain bug types (e.g., crash-recovery bugs or concurrency bugs) and cannot address the broad range of controller bugs; or require expert guidance in terms of formal specifications of the system, crafted heuristics, or hypotheses on vulnerable code regions (§8). We seek a solution that is easy to use and broadly applicable to unmodified controllers.

Our insight. To overcome the above challenges, we 1) automatically and extensively perturb an unmodified controller's view of the cluster states in ways it is expected to tolerate, and 2) automatically flag safety and liveness issues using differential oracles that compare the evolution of cluster states with and without perturbations. This degree of automation

and unintrusiveness is enabled by the fundamental nature of state-reconciliation systems. That is, these systems often have a simple and highly introspectable state-centric interface with which controllers interact with the cluster state. Such interfaces essentially do no more than reads and writes, or receive notifications regarding state-object changes. All objects share a common schema, which makes any arbitrary object highly introspectable. For example, all objects in Kubernetes have an identical set of fields representing their metadata. This enables a degree of automation that is hard to achieve otherwise.

3 Sieve Design

Sieve is an automatic reliability testing tool for cluster management controllers. It checks whether the controllers under test can correctly operate the system under common perturbations (due to unexpected faults and inherent asynchrony) and detects bugs that lead to safety and liveness issues at the development time. Sieve is automatic—it tests unmodified controllers and does not rely on formal specifications or controller-specific assertions. Sieve is effective—it focuses on well-defined, highly-targeted perturbations that reliable implementations are required to tolerate.

Sieve perturbs the controller's view of the cluster state based on three broad patterns that expose the controller to 1) intermediate states, 2) stale states, and 3) unobserved states. We discuss the three patterns and their rationales in §3.1. Note that these are not the only patterns in which faults can occur, but cover a broad range of faults that a component in a distributed system is expected to handle gracefully. Sieve can be extended to incorporate other patterns in the future.

Sieve tests controllers with the following workflow:

- *Collecting reference traces* (§3.2). Sieve starts by learning how a controller behaves in the absence of faults (under test workloads) and records the state transitions in reference traces. To do so, it instruments the state-centric interfaces used by the controller to interact with the cluster state.
- *Generating test plans* (§3.3). Sieve then analyzes the reference traces to generate *test plans*. A test plan describes a concrete perturbation. The test plan specifies *what* faults to inject and *when* to inject them to effectively drive the controller to see a target cluster state.
- *Avoiding ineffective test plans* (§3.4). To achieve high test efficiency, Sieve prunes redundant or futile test plans. For example, it avoids a test plan if it is clear that it cannot causally lead to a target cluster state.
- *Executing test plans* (§3.5). Sieve executes each test plan using a test coordinator. The test coordinator monitors the cluster-state transitions during testing and injects the specified faults according to the test plan's specification.
- *Checking test results* (§3.6). Sieve has generic, effective, differential oracles to automatically check test results. The oracles detect buggy controller behavior by comparing the cluster-state evolution between the reference and test runs.

Sieve deals with non-deterministic elements of the cluster state during testing to minimize their impact on test plan generation and test oracles (§3.7). Specifically, Sieve identifies non-deterministic state objects and fields and excludes them.

Usage. To use Sieve, one needs to provide two inputs: 1) a manifest that specifies how to build and deploy the controller under test, and 2) a set of test workloads that exercise end-to-end behavior of the controller under test. The two inputs are mostly available in mature controller projects, as they are needed for controller development and deployment. In our experience, finding them is straightforward.

3.1 Perturbing A Controller's View of The State

Sieve operates under the assumption that a controller follows the state-reconciliation principle, which receives a sequence of *notifications* about the changes to the cluster states and outputs a corresponding sequence of *updates* to the cluster states. Sieve aims to affect the outputs of a controller by perturbing its view of the cluster state. These perturbations are produced by injecting targeted faults (e.g., crashes, delays, and connection changes) when specific cluster-state changes (*triggering conditions*) happen.

Notably, the perturbation strategy allows Sieve to *decouple policy from mechanism*. The decoupling makes it easy to extend existing policies or add new policies by orchestrating the underlying perturbation mechanisms. Specifically, a policy defines a view Sieve exposes to the controller at a particular condition, while the mechanism specifies how to inject faults to create the view. Sieve automatically generates test plans for each policy; each test plan introduces a concrete perturbation based on a specification of a triggering condition and a fault to inject when that condition happens.

Sieve currently supports three patterns to perturb a controller's view. Crucially, these perturbations drive a controller to states that it is expected to tolerate. They represent valid inconsistencies in the view that a controller could see due to common faults as well as the inherent asynchrony of the overall distributed system. Over time, we hope to add more perturbation patterns.

Intermediate states. Intermediate states occur when controllers fail in the middle of a reconciliation before finishing all the state updates they would have otherwise issued. After recovery (e.g., Kubernetes automatically starts a new instance of a crashed controller), the controller needs to resume reconciliation from the intermediate state left behind.

Figure 4 illustrates how Sieve tests the official RabbitMQ controller with intermediate-state perturbations and reveals a new bug. The test workload attempts to resize the storage volume from 10GB to 15GB. The resizing is implemented with two updates: 1) updating `VolCur` to 15GB; 2) updating

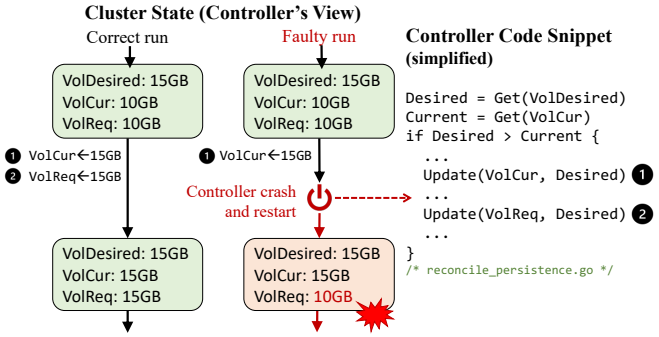

Figure 4: **An intermediate-state bug in a RabbitMQ controller detected by Sieve [70].** The controller fails to recover from the intermediate state introduced by Sieve; the controller does not successfully resize the storage volume.

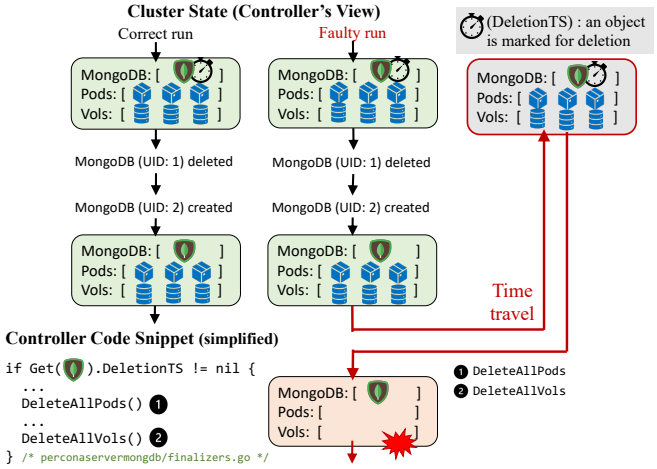

Figure 5: **A stale-state bug in a MongoDB controller detected by Sieve [43].** The controller experiences a "time-travel" and observes a stale state. It makes wrong reconciliation action based on the stale state (deleting all the pods and volumes) which leads to application outages and data loss.

`VolReq` to 15GB which triggers Kubernetes to resize the volume. The controller issues updates when `VolCur` is smaller than the desired volume size. During testing, Sieve crashes the controller between the two updates, which creates an intermediate state where `VolCur` is updated, but `VolReq` is not. The controller cannot recover from the intermediate state and the resizing never succeeds. The bug has been fixed with 700+ lines of Go code to revamp the volume resizing logic. In addition, the developers added eight new tests along with the fix to exercise how the controller handles different intermediate states, which is what Sieve performs automatically.

Stale states. Controllers often operate on stale states, due to asynchrony and the extensive uses of caches for performance and scalability [26]. As shown in Figure 2, controllers do not directly interact with the strongly consistent data stores, but are connected with API servers. The states cached at API servers could be stale due to delayed notifications. Controllers are expected to tolerate stale views that lag behind the latest states maintained in the data store.

Tolerating stale views correctly is nontrivial. For example, a Kubernetes controller's view may "time travel" to a state it observed in the past. Time traveling occurs when there are multiple API servers operating in a high-availability setup, when the controller reconnects to a stale API server that has not yet seen some updates to the cluster state. The reconnection can be triggered by failover, load balancing, or reconfigurations. Controllers are expected to recognize the stale state [18], instead of treating it as a new, unseen state.

Figure 5 illustrates how Sieve tests Percona's MongoDB controller with stale-state perturbation and reveals a new bug that leads to both application outages and data loss. To support graceful MongoDB cluster shutdowns, the controller waits to see a non-nil deletion timestamp (`DeletionTS`) field attached to the state object representing the MongoDB cluster (a common practice to give systems time to react to an impending deletion [23]). When the controller sees this change, it deletes all the pods and volumes of the MongoDB cluster.

Sieve drives the controller to mistakenly delete a live MongoDB cluster by introducing a time-travel perturbation. With a workload that first shuts down a MongoDB cluster and then recreates a new instance of the same cluster, Sieve waits till the cluster is recreated and then introduces a time-travel perturbation. The perturbation causes the controller to see the deletion timestamp being applied to the *already-deleted cluster*. Consequently, the controller mistakenly shuts down the newly created cluster. This revealed that the controller should be checking for the UIDs of clusters, not just their names.

Unobserved states. By design, controllers may not observe every cluster-state change in the system. The full history of changes made to the cluster state is prohibitively expensive to maintain and expose to clients [76]. Controllers are hence expected to be designed as *level-triggered* systems (opposed to being *edge-triggered*), i.e., a controller's decision must be based on the currently observable cluster state (level) [21], not on seeing every single change to the cluster state (edge).

Figure 6 illustrates how Sieve tests Instaclustr's Cassandra controller using unobserved-state perturbations and reveals a new bug that leads to resource leaks and service failures. The test workload first scales down and then scales up storage volumes of the Cassandra cluster. During scale-down, the controller removes volumes when it learns that the corresponding pods were marked for deletion (a non-nil deletion timestamp field is set on the pod object, similar to the previous example). The pods' lifecycles (including deletions) are managed by a built-in controller called a StatefulSet controller. Sieve pauses notifications to the Cassandra controller for a window such that it does not see these deletion marking events by the StatefulSet controller. This causes the Cassandra controller to not delete the corresponding volumes even though it has the

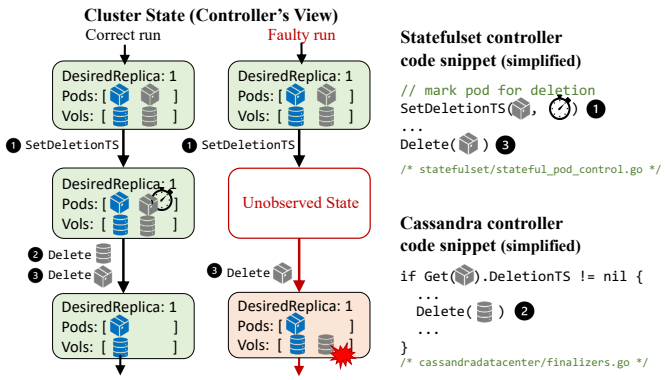

Figure 6: **An unobserved-state bug in a Cassandra controller detected by Sieve [29].** The controller misses a transient state where the pod has a non-nil deletion timestamp. It thus fails to delete the volumes, leaking storage resources. The bug also prevents new Cassandra pods from rejoining.

right information to make that call (i.e., its view has volumes created by it that do not have pods attached to them).

Hence, the volume never gets deleted, leaking the storage resource. The bug also prevents the controller from scaling the Cassandra cluster – newly-created pods try to reuse the dangling volumes and cannot rejoin using the cluster metadata already in them (as it represents a node that was decommissioned). The bug has been fixed by adding a pre-deletion hook – a coordination mechanism in Kubernetes that allows the Cassandra controller to complete the required cleanup operations before the pods can be deleted [9].

3.2 Collecting Reference Traces

Sieve starts by learning how a controller behaves in the absence of faults. To do so, Sieve interposes around the state-centric interfaces used by the controllers to interact with the cluster state. All modern cluster managers have unified, well-defined client libraries based on state-centric interfaces. Taking Kubernetes as an example, any interaction with the cluster state (exposed by the API servers) goes through a small, well-defined set of client APIs that read, modify, or receive notifications about state objects. They are used by every controller that interacts with the Kubernetes API servers. To support Kubernetes controllers, Sieve decorates 10 functions in the client library and this interposition is fully automated (§4).

With the interposition in place, Sieve learns every cluster-state change notification that the controller receives, as well as any reads and writes attempted by the controller to the cluster state or to the local cache of the cluster state maintained by the client. Sieve then runs each test workload supplied by the developer and collects the following two reference traces:

- *Controller trace.* A series of events observed via the interposition of client APIs, including notifications about state changes, entry and exits of each reconciliation cycle, and client-API invocation by the controller and their arguments.
- *Cluster state trace.* The initial cluster state and the sequence of state changes (object creations, modifications, and deletions), collected using public APIs of the cluster manager.

The controller trace is used for generating test plans (§3.3) and the cluster-state trace is used by test oracles (§3.6).

3.3 Test Plan Generation

Sieve generates a set of test plans for each test workload for which it has collected reference traces. Each test plan specifies a perturbation to inject during the workload.

A test plan is represented by a self-contained file that describes a test workload, a list of faults to inject during the workload run, and the triggering condition for when to inject each fault. Sieve currently supports several primitives that test plans can compose to introduce complex faults: 1) crash/restart a controller, 2) disconnect/reconnect a controller to an API server, 3) block/unblock a controller from processing events, and 4) block/unblock an API server from processing events. When an executed test plan reveals a bug, the test-plan file is sufficient to reproduce the bug.

Figure 7 shows a simplified test-plan file generated by Sieve. Each element in `faults` specifies the fault to inject (`faultType`) and the triggering conditions (`triggers`). Each element in `triggers` specifies a triggering condition, that causes the specified fault to be injected before or after a particular cluster state change if executed. A composite triggering condition can be specified in `compositeTrigger` by combining multiple conditions in `triggers` with boolean operators. For example, `t1 & t2` means the fault is only injected when both `t1` and `t2` are triggered. In Figure 7, `trigger1` is the only required condition to inject the fault. Similarly, composite faults can be constructed (e.g. crashing a controller after `t1` and restarting it after `t2`).

We now present the basic rules Sieve applies to compute test plans that exercise one of the three patterns in §3.1. We later describe how Sieve avoids ineffective test plans in §3.4. Optionally, one can customize patterns by implementing new rules or manually writing test plans.

Intermediate-state rule. For a controller, Sieve generates test plans that force all possible intermediate states and exposes them to the controller. To do so, Sieve analyzes the reference controller trace and marks the sequence of state updates made by the controller within each reconciliation loop. Concretely, for every reconciliation that issues multiple state updates, $U_1, U_2, ..., U_n$, Sieve generates one test plan per state update U_i, where Sieve crashes the controller after it issues U_i. When the controller restarts after the crash, it is presented with the target intermediate state.

Stale-state rule. For stale states, Sieve generates test plans that make the controller travel back in time and see stale states that it has already observed. Concretely, Sieve checks the controller trace for a notification-update pair (N, U), such that observing N results in an update U (see §3.4.1). It then

```
testWorkload: resizePVC
faults:
- faultType: crashController
  triggers:
  - triggerName: trigger1
    triggerAt: afterControllerIssues
    stateChange:
      beforeChange: 'VolCur:10GB'
      afterChange: 'VolCur:15GB'
  compositeTrigger: trigger1
```

Figure 7: **A test plan generated by Sieve.** This is a simplified view of the test-plan file that detected the bug in Figure 4. This test plan crashes the RabbitMQ controller right after the controller updates `VolCur` from 10GB to 15GB. Sieve learns every state change issued by the controller via the state-centric interfaces (e.g., `Update` in Table 1).

searches for a subsequent state-change notification N' which has a conflicting effect with U (e.g., U deletes an object and N' creates the same object). With time traveling, if the controller mistakenly issues U after seeing the stale state N, it could corrupt the newer cluster state as notified by N'.

Sieve generates test plans that 1) block a reserved API server to prevent it from advancing its own state after it sees N, 2) after the controller sees N', time-travel the controller to see N by reconnecting the controller to the reserved stale API server, and 3) unblock the stale API server; so, the introduced staleness is only transient—both the API server and the controller catch up eventually. We focus on deletions for U because they are destructive operations.

Unobserved-state rule. For unobserved states, Sieve generates plans that skip states that a controller might observe during normal executions, but could potentially miss in the presence of faults. Sieve checks the controller trace to find pairs of notifications (N, N') in which N' is the closest subsequent notification that cancels the effect of N. Sieve generates test plans that 1) block the controller to prevent it from seeing N, and 2) unblock the controller when N' arrives. Such a test plan causes the controller to miss cluster states from N (inclusive) up to N' (exclusive).

3.4 Avoiding Ineffective Test Plans

Sieve may potentially generate a large number of test plans using rules specified in §3.3. For example, in stale-state testing, Sieve might identify every notification the controller receives as a point to inject staleness, therefore generating test plans for every received notification. For example, the naïve rule above for stale states would generate 140,000+ test plans for the MongoDB controller in Figure 5. It is therefore key to prune ineffective test plans.

As a guiding principle, we prune a test plan if the test plan does not introduce an intermediate-, a stale- or an unobserved-state that can affect the controller's outputs, or the introduced state is identical to states introduced by other test plans. This naturally requires Sieve to have a clear notion of what input events affect the controller's outputs.

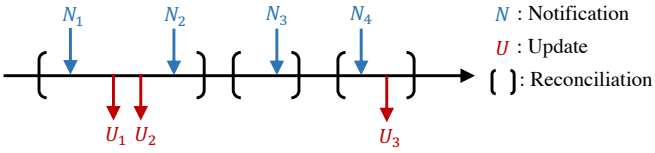

Figure 8: **Causality rules used by Sieve.** For simplicity, in this figure the object pertaining to each notification is immediately read by the controller. (N_1, U_1), (N_1, U_2), (N_3, U_3) and (N_4, U_3) are causally related according to the rules in §3.4.1. N_2 is *not* causally related to any update, given the earliest-reconciliation rule.

3.4.1 Pruning by Causality

If a controller makes an update U based on a notification N, we consider N and U to be causally related. We consider a pair (N, U) that is not causally-related to be irrelevant from a testing standpoint, because perturbing N will not affect U.

Inferring causality between events is generally a challenge in distributed systems. By focusing on the "narrow waist" of state-centric input and output events of the controller under test, we are able to design simple yet effective rules for Sieve to infer whether a pair (N, U) is causally related. These rules are lenient and only introduce false positives at best, but not false negatives. False positives increase testing times by generating redundant test plans, whereas false negatives risk reducing test coverage that could miss bugs. While causal tracing support [58] for Kubernetes is currently in its infancy [6], we might be able to leverage it in the future.

Sieve currently considers a pair (N, U) to be causally related if both the following conditions holds (Figure 8 exemplifies the two causality rules):

- *Read-before-update rule:* the object pertaining to N is read by the controller before it issues U;
- *Earliest-reconciliation rule:* N and U happen in the same or adjacent reconciliation cycles. The rationale is that controllers always issue updates relevant to N in the earliest possible reconciliation cycle after N is received.

For stale- and unobserved-state testing, Sieve only generates test plans involving a N if it has at least one causally-related U. We find pruning test plans by causality effective, especially when there are many notifications due to other activities irrelevant to the controllers under test.

3.4.2 Pruning Unsuccessful Updates

Sieve ignores any update U that does not change the current cluster state. Sieve checks whether an update U is successful based on whether U triggers a state change ΔS of the cluster state. This information is typically encoded in the return value of the U operation.

For stale-state testing, Sieve further ignores an update U that, if issued again, does not change any of the subsequent cluster states, (i.e., there does not exist an N' that is affected by U). Sieve checks whether the state objects updated by U would later be conflicted with N'.

The rationale for the above pruning is straightforward. If an update does not change the current cluster state, it is unlikely to cause new states in the execution. If an update U cannot affect any future cluster states, it would not perturb the controller's execution under the time-travel pattern either, i.e., if U is issued again, it would not corrupt any future state.

In practice, we found that many controllers issue unsuccessful updates that do not actually change the cluster state, including pathologically frequent ones caused by inefficient but benign behavior (see Section 5.2).

3.5 Test Plan Execution

Every test plan is executed by the Sieve test coordinator running in the testing cluster. The coordinator faithfully executes the test plan by running the test workload and injecting the faults specified in the test plan. Specifically, the test coordinator monitors state transitions of both the controller's view of the cluster state as well as the cluster state as seen by API servers. This is done based on the interposition described in §3.2; it allows the test coordinator to intercept and take actions (e.g., injecting faults) when state transitions happen. If the observed state transition matches the triggering condition ΔS specified in the test plan, the coordinator marks the condition as matched. The coordinator injects a fault (e.g., a controller crash) once all the corresponding conditions are matched. Most of the interposition and injection are done through the client APIs. But, for stale-state testing, the coordinator also needs to interpose at the API server (to make an API server stale).

As a concrete example, to execute the test plan in Figure 7, the test coordinator monitors every state transition issued by the RabbitMQ controller. The coordinator marks `trigger1` in the test plan as matched when it observes a state transition that updates `VolCur` from 10GB to 15GB. Since `trigger1` is the only required condition in the test plan, the coordinator injects a controller crash right after `trigger1` is matched. If the test plan specifies multiple faults, the coordinator injects them one by one according to the specified order.

The test coordinator also records the cluster states in a trace during testing, which will be compared with the reference cluster-state trace (§3.2) to detect buggy behavior.

3.6 Differential Test Oracles

Sieve has generic, effective oracles to automatically detect safety and liveness issues. The oracles detect buggy controller behavior based on the *cluster states* during and at the end of the test run. The goal is to validate that the testing traces are free of safety and liveness issues, in addition to monitoring anomalous controller behavior (e.g., crashes and hangs). Developers can also add domain-specific oracles.

In our experience, many buggy controller behaviors do not show immediate or obvious symptoms (e.g., crashes, hangs, and error messages). Instead, they lead to data loss, security issues, resource leaks, and unexpected application behavior which is hard to check with oracles typically used by prior art [55, 75, 84, 88, 89]; in our evaluation, only five (out of 46) bugs can be flagged by checking for exceptions or crashes.

We therefore develop differential test oracles that compare cluster states in a reference run versus those in test runs—with inconsistencies typically indicating buggy behavior. This methodology means we need to exclude nondeterministic states and state objects affected by the perturbation (§3.7).

We found that Sieve's differential oracles vastly outperform developer-written assertions in the test suites of the controllers we evaluated, because Sieve's oracles systematically examine all the state objects and their evolution during testing. It is challenging for developers to manually codify oracles that comprehensively consider the large number of relevant states.

Note that Sieve does implement regular error checks for obvious anomalies, including exceptions, error codes and timeouts. Sieve scans the controller's log and checks whether the controller encountered any unexpected exception (i.e., `panic` in Go). Sieve also checks whether the operations in the test workload return error codes or fail to complete on time.

3.6.1 Checking End States

Sieve systematically checks the end state after running a workload. Specifically, our oracles check the count of state objects by type and the field values of all the objects after accounting for nondeterminism (§3.7). It compares the end state of the test run versus the reference run. Sieve fails the test if it finds inconsistencies between the end states and prints human-readable messages to pinpoint inconsistencies.

Such checking is effective compared to the simpler assertions that we found in test suites for the controller projects we studied. For example, in an intermediate-state bug [46], the MongoDB controller fails to create an SSL certificate used for securing communications inside the MongoDB cluster. This causes the controller to fall back to insecure communications. Such security issues do not manifest in the form of crashes or error messages. Sieve however automatically catches the bug, because the certificate object in the faulty run does not exist in the cluster state, which is different from a normal run. The bug was detected by Sieve and confirmed by the developers.

We found that none of the 71 test cases shipped with the controller has an assertion that checks the certificate object, despite the fact that enabling TLS is recommended and is the default configuration [66]. We would not be able to repurpose the assertions in these test cases to catch this bug.

3.6.2 Checking State-Update Summaries

Besides the end state, Sieve also checks how the controller updates the cluster state over time. It does so by comparing summaries of constructive and destructive state updates for each object (e.g., `CREATE` and `DELETE` operations). Such checks are complementary to the end-state checks, because a correct end state does not imply that the controller behavior is always correct during the test. We find that buggy behavior can end in correct states (same as in the reference runs).

For example, in a stale-state bug [47], the XtraDB controller mistakenly deletes the front-end proxy (which routes user requests to the XtraDB cluster), causing service unavailability. After the staleness ends, the API server and the controller eventually catch up with updated states and recreate the proxy. In this case, the end state of the proxy in the test run is the same as in the reference, but the update that deleted the proxy in the test run is buggy. Sieve detects the bug by noting that the proxy pod receives 2 `CREATE` and 1 `DELETE` operations in the faulty run, but only 1 `CREATE` in the reference run.

In another intermediate-state bug [62], the NiFi controller fails to reload configuration files. The end state is the same as a normal run; however, in the faulty run, the controller did not restart the NiFi pod to reload the configuration. Sieve flags this by noting the NiFi pod receives a `CREATE` and a `DELETE` operation (to reload the configuration) in the normal run, but neither appears in the faulty run.

Note, comparing the *sequence* of state-update is unreliable and would lead to false alarms—the sequences are not strictly the same due to concurrent controller operations. The summaries instead are robust to different event orderings.

3.7 Dealing with Nondeterminism

The shape of a state object (the set of fields and their values) might be nondeterministic. This nondeterminism affects Sieve's test plan generation and the differential test oracles. We now describe how Sieve combats this problem.

All objects have identifying metadata (e.g., a type, namespace, and name). This is key for Sieve to identify two instances of the same object, both within a run (e.g., checking for conflicting operations in the stale-state rule) and across runs (e.g., comparing configurations of objects across runs).

Sieve identifies nondeterministic field values by running the test workloads without perturbation multiple times when generating reference runs, and then comparing the values of each field in each state object.

Objects whose identifying metadata is nondeterministic are excluded from test plan generation and subsequent steps, because Sieve cannot reliably match them across runs or setup triggering conditions for them. If other kinds of fields have nondeterministic values (typically IP addresses, timestamps, or even random port numbers), Sieve does not exclude the object but simply masks the field values. Note that these two rules still allow Sieve to spot unexpected changes to the set of fields on the object (e.g., missing deletion timestamp fields).

API	Component	Instrumentation
`reconcileHandler`	Client	Log entry and exit
`Get`, `List`	Client	Send objects to coordinator
`Create`, `Update`, `Patch`	Client	Send objects to coordinator
`Delete`, `DeleteAllOf`	Client	Send objects to coordinator
`HandleDeltas`	Client	Send objects to coordinator
`processEvent`	API server	Send objects to coordinator
`Get`, `List`	Client	Add delay
`processEvent`	API server	Add delay

Table 1: **Instrumentation performed by Sieve to monitor and perturb states.** The instrumentation is automated.

In addition, Sieve provides an API for Sieve users to exclude specific state objects or fields from test plans or oracles based on domain knowledge, if needed.

4 Implementation

We implement Sieve for Kubernetes controllers. Sieve uses `kind` [10] to run a Kubernetes cluster on a single machine, so every test plan can be run entirely on one machine. Sieve configures two API servers for stale-state testing. Sieve is implemented in 5,500 lines of Python code (for test plan generation and oracles) and 3,100 lines of Go code (for automated instrumentation and fault injection).

Sieve instruments 10 API methods, representing the state-centric interface, for monitoring and perturbing states (Table 1). Those methods are in Kubernetes client libraries [13, 14] and the API server. Sieve implements an automated procedure to instrument the 10 methods using `dst` [8] to work with different versions of Kubernetes client libraries and API servers. Sieve analyzes the syntax tree for each method to insert monitoring and fault-injection code. Sieve applies the instrumentation when building the controller image. Sieve does not need to analyze or instrument the controller code.

In Kubernetes, level-triggered controllers do not immediately read notifications when they arrive [21]. Instead, the controller first updates a locally-cached view of the state objects; the controller reads from this cache when it uses `Get` or `List` APIs to query the cluster state. In causality analysis (§3.4.1) Sieve needs to know whether a notification is read before an update. To do so, Sieve analyzes the state objects updated by each notification and those read by each `Get`/`List`.

Some controllers are multi-threaded, where each thread calls a different reconcile function. Sieve uses the instrumented client libraries to obtain stacktraces whenever the controller reads or updates the cluster state (e.g., `Get`, `Create`). These stacktraces are used to differentiate between controller threads when generating and executing test plans.

5 Evaluation

Sieve's premise is that automatic and effective reliability testing for unmodified controllers is viable, by a) exhaustively

Controller	Systems	Dev.	#Stars	#Commits	#WL
cass-operator	Cassandra	DataStax	287	477	2
cassandra-operator	Cassandra	Instaclustr	227	337	2
casskop	Cassandra	Orange	177	1643	3
elastic-operator	Elasticsearch	Official	1832	3375	2
mongodb-operator	MongoDB	Percona	142	1407	5
nifikop	NiFi	Orange	101	232	3
rabbitmq-operator	RabbitMQ	Official	343	1679	3
xtradb-operator	XtraDB	Percona	302	1693	5
yugabyte-operator	YugabyteDB	Official	41	36	4
zookeeper-operator	ZooKeeper	Pravega	242	220	2

Table 2: **Kubernetes controllers used in our evaluation.** "#WL" stands for the number of different test workloads.

perturbing a controller's view of the cluster states and b) using differential oracles to flag safety and liveness issues.

We validate this hypothesis with three evaluation questions: 1) Can Sieve find new bugs in real-world controllers? 2) Does Sieve do so efficiently? 3) Are Sieve's testing results trustworthy? We answer these questions in the affirmative:

- §5.1: Sieve finds *new* bugs in *all* ten evaluated controllers, resulting in a total of 46 *new* bugs, which represent a swathe of safety and liveness issues. So far, 35 of them have been confirmed and 22 have been fixed by the developers.
- §5.2: All controllers can be tested in seven hours on a cluster of 11 machines, representing a typical nightly test. This is attributed to the effective reduction techniques which reduce test plans by 46.7%–99.6% across the controllers.
- §5.3: Sieve poses a low false positive rate of 3.5%.

Tested controllers We evaluated Sieve on ten popular controllers from the Kubernetes ecosystem for managing widely-used cloud systems (Table 2). The controllers are either developed by the official development team of the corresponding system, or by companies that have production-grade offerings around said systems. The term *operator* [12] in the project names refers to the Kubernetes design pattern of using a custom controller to manage an application.

Sieve employs 2–5 basic test workloads for each controller (Table 2). Each workload exercises a feature of the controller. Every evaluated controller supports software deployment and autoscaling, and therefore has at least two workloads. Sieve also employs workloads for controllers that support more features, such as sharding, storage resizing, reconfiguration, and load balancing. A test workload is typically implemented in 6–12 lines of code and takes 4–12 minutes to run.

It took us on average three hours to apply Sieve to each controller, which was mostly spent on understanding how to build the controller. We expect controller developers to expend much less effort to integrate Sieve in their workflow.

5.1 Finding New Bugs

Sieve finds a total of 46 *new* bugs in the evaluated controllers (Table 3). Those bugs include 11 intermediate-state bugs, 19 stale-state bugs, 7 unobserved-state bugs, and 9 bugs indirectly detected by Sieve during testing. Sieve finds new bugs in *all* the evaluated controllers. We have reported all these bugs. So far, 35 of them have been confirmed and 22 have been fixed. No bug report was rejected.

Controller	Interm. State	Stale State	Unobser. State	Indirect	Total
cass-operator	2	1	0	0	3
cassandra-operator	0	2	1	2	5
casskop	1	2	1	0	4
elastic-operator	0	2	0	0	2
mongodb-operator	2	3	1	3	9
nifikop	2	0	0	1	3
rabbitmq-operator	1	2	1	0	4
xtradb-operator	3	3	1	0	7
yugabyte-operator	0	2	1	2	5
zookeeper-operator	0	2	1	1	4
Total	11	19	7	9	46

Table 3: **New bugs detected by Sieve in each controller.**

Sieve can consistently reproduce all the 37 intermediate-, stale-, and unobserved-state bugs—running the test plan always reproduces the buggy behavior. In our experience, Sieve's reproducibility is invaluable for debugging test failures. It helps developers localize bugs in the source code and continuously iterate on bug fixes (§6).

Table 4 shows the consequences of the 46 controller bugs and an exemplar bug for each kind of consequence. We see that many bugs have severe consequences, such as application outages, security issues, service failures, and data loss. Note that these controllers are all mature projects (Table 2 and §6), suggesting that controller reliability is challenging to achieve.

The bugs that Sieve finds are deep and highly unlikely to be detected by manual testing or imprecise techniques like chaos testing or randomized fault injection tools [1, 2, 4, 5]. For example, a bug [63] in nifikop is triggered only when the controller crashes between issuing two specific state updates within one reconciliation loop (the time window between the two updates is about 0.7 milliseconds). In contrast, the test workload used for detecting the bug takes about 440 seconds to finish, and causes 481 reconciliation loops and 1,687 state updates issued by the controller. Sieve is able to detect and consistently reproduce the bug because it relies on injecting a fault precisely when a specific cluster-state change happens.

5.1.1 New Bugs Detected by Sieve

Intermediate-state bugs. Sieve found 11 intermediate-state bugs. Sieve stresses a common pattern among controllers, where they issue multiple updates per reconciliation, after the controller checks for a certain condition to hold in the cluster state. However, Sieve finds bugs when these condition checks only detect states from running the reconciliation loop in its entirety; that is, when the checks do not account for intermediate states that may arise due to controller crashes. For

Consequence	Example	# Bugs
Application outage	rabbitmq-operator-648: The RabbitMQ cluster is mistakenly turned down [69].	12
Service failure	K8SPSMDB-433: Sharding service for the MongoDB cluster wrongly terminated [44].	5
Data loss	K8SSAND-559: Storage volumes of Cassandra replicas wrongly deleted [49].	8
Reduced reliability	zookeeper-operator-314: The ZooKeeper cluster scaled down unexpectedly [90].	7
Misconfiguration	nifikop-49: The NiFi pod is not updated with new configuration [62].	6
Security issue	K8SPXC-896: TLS is not enabled for the XtraDB cluster [48].	6
Resource leak	cassandra-operator-398: Volumes used by deleted replicas never recycled [29].	7
Controller malfunc.	casskop-370: The controller stops serving scaling requests [30].	8

Table 4: **Consequences of the bugs found by Sieve (Table 3).** One bug can lead to multiple consequences.

example, in the intermediate-state bug in Figure 4, rabbitmq-operator compares `VolCur` and `VolDesired` to check whether the volume has been expanded already. However, this check assumes that all subsequent steps in the reconciliation succeed whenever this condition is satisfied. In the bug in Figure 1, the condition check cannot differentiate an intermediate state versus an unexpected faulty state. Part of the challenge is that controllers lack mechanisms analogous to write-ahead logging or journaling to guarantee atomicity of each reconcile action to enforce crash consistency. Controllers typically run as Kubernetes pods themselves and the newly created controller pod instance lacks any memory of its past execution (as they *should* – controllers must only depend on the *current state*). Sieve exposes those bugs without the need to understand source code—it systematically tests a controller with all possible intermediate states and checks for correctness.

Stale-state bugs. Sieve found 19 stale-state bugs. In our experience, it is notoriously challenging to anticipate all possible stale states. That said, we found controllers were not adequately using Kubernetes' mechanisms to tolerate asynchrony and staleness: like object versioning and unique IDs (instead of referring to objects by names, that need not be unique), or using coordination mechanisms to enforce ordering between events. Controllers also have the option to avoid staleness by using quorum reads to API servers, but this creates a scalability bottleneck as it drives more load to etcd – developers therefore choose to synchronize selectively. In general, we do not believe there is a shortcut to reasoning about any given update under all possible staleness or time-travel scenarios. Sieve therefore aids developers by systematically testing controllers under all possible time-traveling scenarios.

Unobserved-state bugs. Sieve found 7 unobserved-state bugs. We find that all of them are rooted in latent edge-triggering behavior in the controllers, that go against the Kubernetes philosophy of designing controllers to be level-triggered (§3.1). That is, these bugs arise when the controller's correctness relies on observing a specific state transition (edges), as exemplified by Figure 6. By identifying states that would be later overwritten and preventing those states from being observed by the controller, Sieve is effective at exposing unobserved-state bugs in controllers.

Bugs indirectly detected by Sieve. Sieve also finds 9 bugs that were not directly triggered by input states Sieve generated but *were still correctly flagged* by its differential oracles. All these bugs could (and do) happen in reference runs as well; but because Sieve executes many test plans, some test traces inevitably *differ* from the reference traces due to these bugs, allowing Sieve to detect them. These bugs are caused by a range of issues, including 1) controllers making incorrect assumptions about the Kubernetes API (e.g., assuming a list of pods from a query have stable ordinals); 2) spurious, dangling object creations, masked by Kubernetes' garbage collection (e.g., accidentally creating ZooKeeper pods after deleting the high-level ZooKeeper cluster object); 3) the applications managed by the controller being buggy and failing. Sieve can be extended with new perturbation patterns to systematically force out some of those bugs. For example, after understanding the root causes, we were able to reproduce two of these bugs consistently with manually written test plans.

5.1.2 Oracle Effectiveness

Sieve's differential oracles are crucial to detect buggy executions. Of the 46 newly found bugs, 45 were flagged by the differential test oracles. Checking logs for errors only flagged 5 bugs of which 4 were also found by our differential oracles.

Our end-state checker (§3.6.1) finds 28 bugs by comparing the end states of a test workload with and without perturbation. The state-update summaries checker (§3.6.2) finds 17 more bugs by checking the number of object updates through an execution. These oracles allow Sieve to detect bugs such as security and reliability issues (see §3.6) that do not manifest as simple failure symptoms (e.g. exceptions or process crashes).

The only bug that the differential oracles fail to find but is found by a regular error check in log files, is a null-pointer dereference bug [45] that causes an unexpected controller crash. Since Kubernetes automatically restarts the controller, it does not affect the end states or the state updates.

5.2 Test Efficiency

Table 5 shows the total time Sieve takes to test each controller in terms of machine hours. All experiments were run on 11 Amazon EC2 virtual machines, each with 8-core Intel(R) Xeon(R) Platinum 8259CL CPU with 2.50GHz and 32 GB memory, running Ubuntu 20.04.2 LTS.

Sieve's total testing time varies from 11.07 to 67.24 machine hours across the controllers. Sieve runs tests in parallel because every test plan is independent. With eleven virtual

Controller	Testing Time (Machine Hours)			# Test Plans
	Generation	Execution	Total	
cass-operator	0.60	43.67	44.27	218
cassandra-operator	0.49	10.72	11.21	81
casskop	0.57	12.40	12.97	125
elastic-operator	0.43	30.10	30.53	245
mongodb-operator	1.00	66.24	67.24	584
nifikop	1.17	41.61	42.78	239
rabbitmq-operator	0.47	10.60	11.07	133
xtradb-operator	1.40	62.96	64.36	395
yugabyte-operator	0.67	17.38	18.05	196
zookeeper-operator	0.33	13.75	14.08	164

Table 5: **Sieve's total testing time for each controller.**

machines, the total testing time for each controller is no more than 7 hours. Therefore, it is practical to run Sieve as a regular nightly test.

Over 95% of the testing time is spent on executing test plans. With the perturbations introduced by Sieve, a workload takes 8.8% longer to run on average. The overhead mainly comes from delays injected by Sieve for stale- and unobserved-state testing. In a few cases, when Sieve triggers bugs that lead to liveness issues, the controller hangs and triggers a timeout (by default, 10 minutes).

Sieve also spends 0.33–1.40 hours to 1) collect the reference trace and 2) generate test plans for each controller. The collected trace for each workload contains 3,386 events of notifications, updates, or reads on average. Generating test plans takes only 20 seconds for each workload on average.

Test reduction. Sieve's techniques to avoid ineffective test plans are key for tractability. Figure 9 breaks down the cumulative contribution of each technique. The baseline represents the basic rules described in §3.1 without any of the pruning techniques in §3.4. Overall, Sieve prunes away 46.7%–99.6% possible test plans across the evaluated controllers.

Specifically, pruning by causality (§3.4.1) reduces test plans by up to 95.0% across the controllers. This reduction is particularly effective for controllers that receive many notifications that are not causally related to any update. For example, mongodb-operator receives 700+ notifications regarding 20+ state objects, which are not causally related to most of its updates. This allows Sieve to prune *136,000*+ causally *unrelated* pairs of notifications and updates.

Pruning unsuccessful updates (§3.4.2) further prunes up to 75.8% of test plans across the controllers. In casskop, 60.0+% of updates issued by the controller do not affect the cluster state because the controller redundantly recreates two `service` objects that already exist. As none of these updates are relevant, Sieve excludes them when generating test plans.

Sieve finally prunes up to 72.9% of test plans across all controllers by focusing on deterministic triggering conditions (§3.7). This makes Sieve robust to many peculiar behaviors. For example, zookeeper-operator has an inefficient but benign behavior – it regularly clears the `NodePort` field of a `service`

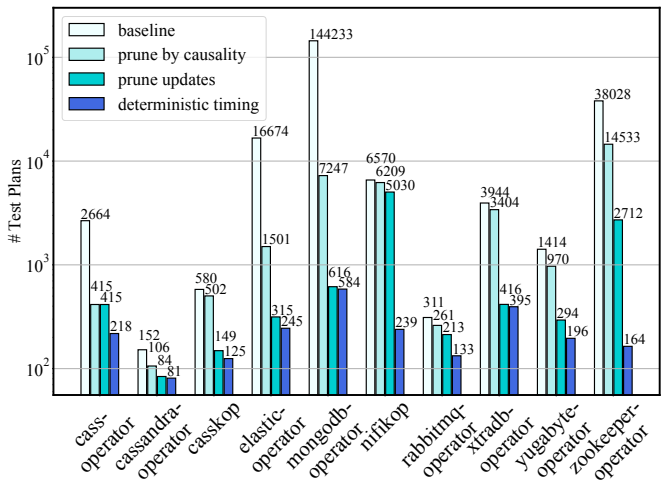

Figure 9: **Effectiveness of Sieve's test plan reduction techniques (§3.4).** The number of generated test plans is reduced by 46.7%–99.6% compared with the baseline.

object in every reconciliation, forcing Kubernetes to randomly allocate a port. This leads to thousands of state transitions with random port numbers. Sieve identifies these transitions to be nondeterministic and avoids related test plans.

5.3 False Positives

Sieve has a low false positive rate of 3.5%. It reports a total of 227 test failures for the ten evaluated controllers. 219 of them were true alarms—the test failures are caused by the 46 bugs described in §5.1 (one bug might fail multiple tests). The other eight test failures are false alarms.

The eight false alarms come from test results of three controllers (casskop, nifikop and xtradb-operator). All of them are caused by benign state transitions introduced in the faulty runs that did not happen in the reference runs.

The false alarms do not lead to opaque test failures—Sieve pinpoints the inconsistent fields. In all eight cases, the false alarms are easy to identify based on the identified fields and we could validate them by running the vanilla workload.

6 Discussion

In this section, we reflect on our experience building Sieve and studying the root causes of bugs it found (§5.1).

We find that all the evaluated controllers adopt mature software testing practices and have numerous unit, integration, and end-to-end test cases. Some even test scenarios involving faults. However, it is prohibitively difficult for developers to anticipate all possible cluster states that may occur, let alone codify them into test cases. Sieve fills this gap by exhaustively testing input states according to patterns of interest. For two bugs, Sieve detects that the initial bug fixes are deficient in covering all the conditions. *We run Sieve on the patched controllers and Sieve still detects the bugs!*

We also find that it is challenging for developers to comprehensively check test results, given the enormous state objects and their fields. Developers typically check a few fields of interest but such assertions can easily miss subtle, but serious issues (e.g., security vulnerabilities as discussed in §3.6).

We also observe that certain bugs are likely rooted in misunderstandings of Kubernetes' design and API semantics. For example, some unobserved-state bugs are caused by incorrectly assuming that every state change can be observed by the controller; some stale-state bugs can be prevented by using Kubernetes' mechanisms like resource versioning and precondition checking. We expect such problems to be more prevalent as engineers implement more and more custom controllers for their cluster management needs.

While cluster managers may avoid some classes of bugs, they come with hard tradeoffs. For example, not caching state objects at the controllers and API servers (Figure 2) could avoid stale-state bugs. However, it would introduce significant performance overheads to the controllers (memory accesses become network round trips) and make the data store a scalability bottleneck [26]. Also, transactions are not a solution for intermediate-state bugs – it would complicate the state-centric interface and prevent controllers from independently making progress regardless of failures, a key factor for resilience.

Since there is no silver bullet to implementing reliable controllers, we believe that automatic tools like Sieve are critical to cluster management reliability.

7 Limitations

Like other testing tools, Sieve is neither sound nor complete. Sieve uses specific perturbation patterns and exhaustively drives controllers to input states according to those patterns.

Sieve's differential oracles can yield both false negatives and positives. Sieve only applies its oracles on cluster states exposed by the state-centric interface. It is possible that certain application-specific states cannot be observed by the interface, which would lead to false negatives. In addition, Sieve reports false positives if the inconsistencies captured by the differential oracles are caused by benign state transitions that did not happen in the reference runs (§5.3). We found the false positive rate low (3.5%) in our evaluation.

The way Sieve deals with nondeterminism also leads to false negatives. Sieve excludes objects with nondeterministic metadata and masks nondeterministic field values in test plan generation and the differential test oracles (§3.7). This approach effectively avoids many irreproducible test plans and false positives, but also misses bugs that are triggered by states involving nondeterministic fields.

Lastly, Sieve depends on test workloads provided by the user for coverage. Implementing a test workload only takes 6-12 lines of code from our experience, but it requires domain knowledge about the controller and the system.

8 Related Work

Testing control-plane software. Modern SDNs have state-reconciliation based elements [15, 16, 19, 73] that could be tested using Sieve's methodology. A body of orthogonal work tests [28, 83] or verifies [37] how an SDN controller affects a network topology. For example, NICE [28] focuses on the boundary where controllers process packet-in/out events and uses that vantage point to automatically test for bugs. To the best of our knowledge, Sieve is the first work to focus on automatic reliability testing for cluster-manager controllers.

Testing distributed systems. Fault-injection tools [3, 25, 32, 34, 35, 55, 59, 79] have been developed for distributed systems, including chaos testing tools from the industry for cluster managers [1, 2, 4, 5]. Sieve's goals differ from those in the fault injection literature. Sieve seeks to expose controllers to as many input states as possible to test their reliability. For us, faults just happen to be a good mechanism to drive controllers to the required states. Compared to randomized chaos testing approaches that are unaware of cluster state transitions, Sieve can precisely force specific bug-triggering state transitions and consistently reproduce bugs. Furthermore, unlike prior art [32, 55, 87], Sieve is not based on an expert's hypotheses about vulnerable regions in the code under test.

A few prior tools can, in principle, expose some bugs found by Sieve. For example, concurrency-testing tools [61, 64, 65, 88] may expose bugs triggered by unobserved states (which in essence occur due to reordering of events). Similarly, tools that check for crash safety [22, 32, 55, 67] could expose bugs caused by the intermediate states. Finally, tools that inject network partitions [3], with expert guidance, could find some bugs caused by the stale-state pattern, i.e., a partition might force a controller to talk to a lagging API server (after talking to an up-to-date one). In contrast to these tools, Sieve does not target one class of bugs. Through exhaustive state perturbations, Sieve finds many kinds of bugs, essentially combining the power of prior targeted tools. Further, the chances that prior tools will find the bugs Sieve does are small, as they lack the context required to efficiently drive controllers to their buggy corners (e.g., a network-partition injector is unlikely to reliably orchestrate time-travel bugs).

Model checking. Sieve bears similarities to implementation-level model checking [40, 50, 54, 56, 61, 85, 86], in that we drive an unmodified implementation to a range of states to find bugs. Unlike model checking, Sieve does not seek to exhaustively cover the controller's state space. It instead executes developer-supplied test cases and exhaustively perturbs these test cases according to some fault patterns. Additionally, model checkers typically rely on a specification for correct behavior. While Sieve intentionally does not require hand-crafted specifications, it leans on reference traces as a partial specification of expected correct behavior.

Automation and ease-of-use. Sieve treats automation and ease-of-use as first-class design goals. Our automation is pri-

marily enabled by state-centric interfaces, which Sieve uses to produce perturbed states. Prior work has leveraged similar interface boundaries (e.g., the system-call interface [36,67]), enabling a general scheme to test multiple applications. For ease of use, Sieve does not require formal specifications [28,33,39], special test input [3, 24], code modifications [34, 61, 65], or whitebox analysis [54]. It also uses differential oracles to avoid the additional effort to supply domain-specific oracles [3, 22, 39]. However, Sieve's efficacy can be further improved with such expert guidance.

9 Conclusion

We present Sieve, the first automatic reliability testing technique for cluster management controllers. We find that Sieve is effective and practical. Sieve's usability and reproducibility play a critical role in understanding, debugging, and fixing reliability bugs. Sieve's testing technique is general and easy to extend – it separates the policy (how to perturb a controller's view of state) from mechanisms (how to realize perturbations). Hence, we are able to use the technique to detect a wide range of bugs without brittle heuristics, specifications or hypotheses. Our goal is to make Sieve a part-and-parcel of every controller developers' toolkit, and to harden the growing number of controllers that power today's data centers. We have made Sieve publicly available at https://github.com/sieve-project/sieve.

Abstract

Due to the latency difference between DRAM and non-volatile main memory (NVMM) and the limited capacity of DRAM, incoming writes are often stalled in LSM tree-based key-value stores. This paper presents *ListDB*, a write-optimized key-value store for NVMM to overcome the gap between DRAM and NVMM write latencies and thereby, resolve the write stall problem. The contribution of ListDB consists of three novel techniques: (i) byte-addressable *Index-Unified Logging*, which incrementally converts write-ahead logs into SkipLists, (ii) *Braided SkipList*, a simple NUMA-aware SkipList that effectively reduces the NUMA effects of NVMM, and (iii) *Zipper Compaction*, which moves down the LSM-tree levels without copying key-value objects, but by merging SkipLists in place without blocking concurrent reads. Using the three techniques, ListDB makes background compaction fast enough to resolve the infamous write stall problem and shows 1.6x and 25x higher write throughputs than PACTree and Intel Pmem-RocksDB, respectively.

1 Introduction

Non-Volatile Main Memory (NVMM) is a new tier in the memory/storage hierarchy. NVMM has latency comparable to DRAM, but ensures non-volatility of data, similarly to secondary storage. Because NVMM is installed in the memory slot, it is byte-addressable and operates at memory bus speeds.

In order to locate and retrieve data from large datasets in NVMM, an efficient persistent index that takes into account the characteristics of NVMM is required. In the past few years, various NVMM-only persistent indexing structures [11,13,24,35,45,49,56,63] and hybrid DRAM+NVMM persistent indexing structures [38,40,49,63] have been proposed. In addition, several key-value stores that manage large datasets using such persistent indexes and background worker threads have been developed [12, 29, 30, 57, 60]. While NVMM-only indexing structures such as Fast and Fair B+tree [24], CCEH [45], and PACTree [32] provide orders of magnitude higher performance than their disk-based counterparts, their performance is still lower than a DRAM index because commercial NVMM products, e.g., Intel's Optane DC Persistent Memory Module, a.k.a., DCPMM [26], fall short of the performance of DRAM. Specifically, DCPMM has (i) latency higher than DRAM, (ii) bandwidth lower than DRAM, (iii) high sensitivity to NUMA effects, and (iv) a larger media access granularity (i.e., 256-byte *XPLine*) [62], which transforms a small write into a larger read-modify-write operation.

To benefit from DRAM performance and avoid the shortcomings of NVMM, the hybrid DRAM+NVMM indexing structures and key-value stores proposed in previous studies [12,49,57,60] place the complexity of indexing in volatile DRAM. In this work, we question whether such a hybrid approach that ignores the byte-addressability, keeps the entire index in DRAM, and uses NVMM only as log space is desirable, because it has two major limitations. First, the capacity of DRAM is small. If a dataset's index does not fit in small DRAM, or if DRAM is shared with the working sets of other processes, the existing hybrid DRAM+NVMM approaches may suffer from memory swapping of large indexes. Second, a volatile DRAM index needs to be reconstructed from scratch when recovering from a system failure. If a large number of key-value objects are stored without a persistent index that can survive system crashes, the recovery time can be significant. To improve the recovery performance, a volatile index can be periodically checkpointed [12]. However, such a periodic synchronous checkpointing results in very high tail latency because it blocks concurrent writes.

We advocate *asynchronous incremental checkpointing*, merging small, high-performance DRAM indexes into a persistent index in the background for data recovery. *ListDB* is a write-optimized LSM (log-structured merge) tree-based key-value store for NVMM. ListDB achieves high performance comparable to DRAM indexes, and prevents a DRAM index from growing indefinitely by flushing to NVMM at high throughput exceeding that of a DRAM index. ListDB buffers bulk insertions in a small DRAM index, and runs background *compaction* threads to incrementally checkpoint the buffered writes to NVMM without data copy. Instead, ListDB restruc-

tures log entries as a SkipList rather than flushing the entire volatile index to NVMM. Simultaneously, such SkipLists are merged in place, reducing NUMA effects, without blocking concurrent read queries.

Specifically, ListDB proposes the following three novel techniques - *Index-Unified Logging*, *Zipper Compaction*, and *Braided SkipList*. Our contributions are as follows.

- **Fast Write Buffer Flush:** ListDB unifies the write-ahead log with SkipList. Using *Index-Unified Logging* (IUL), ListDB writes each key-value object to NVMM only once, as a log entry. Taking advantage of NVMM's byte addressability, IUL converts a log entry into a SkipList element in a lazy manner, which masks the logging and MemTable flush overhead. Therefore, it makes the MemTable flush throughput higher than the write throughput of the DRAM index, thus resolving the write stall problem.
- **Reducing NUMA Effects:** *Braided SkipList* effectively reduces the number of remote NUMA node accesses by making the upper layer pointers point only to the SkipList elements on the same NUMA node.
- **Fast Compaction with In-Place Merge-Sort:** *Zipper compaction* merge-sorts two SkipLists in-place without blocking read operations. By avoiding copy, Zipper compaction alleviates the *write amplification* [21, 41, 53] problem and reduces the number of SkipLists fast and efficiently to improve read and recovery performance.

Our performance study shows that the write performance of ListDB outperforms state-of-the-art NVMM-based key-value stores. For read performance, ListDB relies on classic caching techniques.

The rest of the paper is organized as follows. In Section 2, we present the background and motivation. In Section 3, we present the design of ListDB. In Section 4, we compare the performance of ListDB against state-of-the-art key-value stores. Finally, we conclude the paper in Section 5.

2 Background and Motivation

2.1 Hybrid DRAM+NVMM Key-Value Store

Intel's Optane DCPMM is much faster than block device storage. However, its performance is still worse than that of DRAM in terms of latency, bandwidth, NUMA sensitivity, and access granularity [62]. Furthermore, byte-addressable persistency complicates failure-atomicity (i.e., reusability after a system crash) because the CPU cache replacement mechanism may evict dirty cachelines that are not ready to be persisted. When a system recovers, such prematurely written cachelines may corrupt data structures. To guarantee failure-atomicity despite such unexpected cacheline flushes, NVMM-only data structures carefully order machine instructions using memory fence instructions and call expensive `clflush` instructions frequently to persist dirty cachelines, which incurs significant overhead in NVMM [24, 39, 56]. To avoid this, several hybrid DRAM+NVMM indexing structures and key-value stores have been proposed. For example, NV-tree [63] and FP-tree [49] are variants of B+tree that store internal tree nodes in DRAM and leaf nodes in NVMM. The internal nodes are lost upon a system crash but can be reconstructed from persistent leaf nodes. With this approach, writes to internal nodes do not need to be failure-atomic.

FlatStore [12] takes a rather radical approach, i.e., NVMM is used only as a log space where key-value objects are appended in insert order rather than key order, whereas the index resides in DRAM. Therefore, FlatStore has to reconstruct a volatile index from persistent log entries after a system crash. To mitigate the expensive recovery overhead, FlatStore proposes to checkpoint the DRAM index onto NVMM periodically. However, a naive synchronous checkpointing, as in FlatStore, takes a global snapshot while blocking incoming writes, leading to unacceptably high tail latency.

2.2 Log-Structured Merge Tree

2.2.1 Asynchronous Incremental Checkpointing

A better approach is *asynchronous incremental checkpointing* [28], which checkpoints only the difference between the current checkpoint and the last checkpoint state. Log-Structured Merge (LSM) tree [47] is a classic index that consolidates checkpoint data over time [10, 17, 20, 33, 36, 48, 54].

2.2.2 Write in LSM Tree

An LSM tree buffers multiple write operations in an in-memory buffer space called *MemTable*, which sorts key-value objects using an ordered index such as SkipList [10, 17, 20, 33, 36, 48, 54]. Since a MemTable is volatile, a key-value object is written to a write-ahead log (WAL) for crash consistency before it is inserted into the MemTable. If the MemTable size exceeds a certain threshold, it is marked as immutable and a new MemTable is created so that the new MemTable can serve incoming clients' requests while a background thread transforms the immutable MemTable into a sorted array called SSTable (Sorted String Table), flushes it to disk, and then deletes the corresponding log entries. This design leverages the high performance of DRAM for random writes and the high sequential write bandwidth of block devices.

The key range of a MemTable is not disjoint with those of SSTables on disk. If a large number of MemTables are converted into SSTables and the overlap between SSTables increases, background threads merge-sort them to incrementally construct fewer, eventually into one large sorted array for fast search. This process, called *compaction*, is the most significant performance bottleneck because the same key-value object is repeatedly written to new SSTables [2, 9, 21, 29, 37, 41–43, 46, 53, 55].

2.2.3 Search in LSM Tree

For a read query, an LSM tree looks up a mutable MemTable, immutable MemTables, and then SSTables from level 0 to

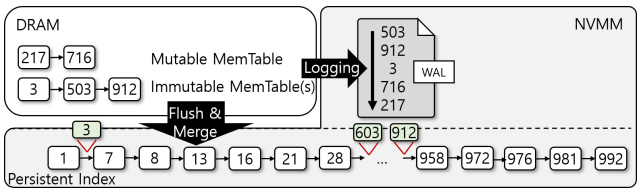

Figure 1: *Two-Level LSM Tree without Level 0 Buffer Indexes*

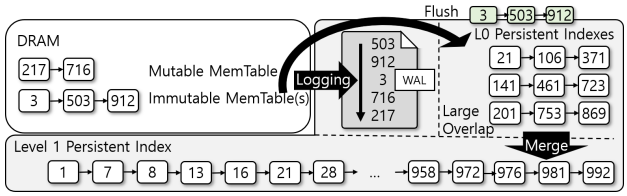

Figure 2: *Three-Level LSM Tree with Level 0 Buffer Indexes*

the upper levels, i.e., the recently stored objects are searched first. The search performance of LSM trees is affected by the degree of overlap between SSTables within and across levels because a read query searches all SSTables whose key range overlaps the search key until it finds a matched key. To reduce the overlap and improve the search performance, compaction threads merge-sort SSTables despite the high cost. Due to overlap and multiple levels, the read performance of LSM trees is worse than B+trees [27]. Nevertheless, LSM trees are more popular than B+trees in NoSQL systems because simple caching techniques can improve read performance. However, improving write performance is not easy.

2.2.4 Side Effect of Write Buffer: Write Stall

The in-memory MemTable is effective in buffering writes. However, despite buffering write bursts in the MemTable, tail latency can be very high if the workload is write-intensive because incoming writes can be blocked by *artificial governors* [31]. For instance, if compaction is slow, immutable MemTables will not be flushed to storage fast enough and the number of immutable MemTables will increase. Similarly, if SSTables are not merge-sorted quickly, the number of overlapping SSTables will increase, and search performance will degrade. Most LSM tree-based key-value stores [10, 17, 20, 33, 36, 48, 54] block clients from inserting new objects into the MemTable until compaction finishes and makes space for a new MemTable. This *write stall* problem occurs frequently in disk-based LSM tree-based key-value stores because of the high latency of the disk. If the write stall problem occurs, the insertion throughput is bounded by persistent storage performance, failing to benefit from the fast write buffer (DRAM) performance.

2.2.5 Write Amplification in LSM Trees

2.2.5.1 Multi-Level vs. Two-Level Compaction

As SSTables accumulate in storage, LSM trees perform compaction to merge-sort SSTables and reduce the overlap. Compaction is particularly expensive in disk-based key-value stores because they copy key-value objects between SSTable files. That is, compaction threads select a set of overlapping SSTables at level k and another set of SSTables that overlap at the next level $k+1$, and merge-sort them to create a new set of SSTables at level $k+1$. Such copy-based compaction allows concurrent read queries to access old SSTables while new SSTables are being created. However, copy-based compaction requires the same objects to be repeatedly copied to new SSTables. The number of times a key-value object is copied to a new file, called *write amplification* factor, has been reported to be as high as 40 [41, 53, 55]. The write amplification is particularly serious if key-value stores use *leveled compaction* and a large number of levels [53, 55]. The leveled compaction limits the number of SSTables per level and prevents any overlap between the SSTables at the same level.

NVMM allows byte-addressable updates. Therefore, there is an opportunity to avoid write amplification and improve compaction performance by replacing multiple levels of SSTables with a high-performance single-level persistent index. In particular, SLM-DB [29] uses two levels, i.e., MemTables and a single persistent B+tree in NVMM. Using the two-level design (shown in Figure 1), MemTables buffer multiple key-value objects and later insert them into a large persistent index in ascending order of keys, such that the large persistent index is traversed only once for multiple writes and it yields a higher write throughput than a single persistent index.

2.2.5.2 Decoupling Merge-Sort from Flush

The main problem with the two-level design is that the size of the persistent index affects the performance of merging volatile indexes into a persistent index, i.e., it fails to make write performance independent of NVMM performance. This is because MemTables are not flushed[1] *as-is*, but merge-sorted into the large, slow persistent index. Because NVMM has higher latency than DRAM, merge-sort throughput is much lower than insert throughput of volatile indexes, especially when the persistent index is large.

To alleviate this problem, most key-value stores including LevelDB [36] and RocksDB [54] employ an intermediate persistent buffer level (level 0, *L0*) in storage. That is, they flush MemTables to the intermediate buffer level without doing merge-sort. Figure 2 shows such a three-level design. By separating merge-sort from flush, MemTables can be flushed to NVMM faster; the flush throughput becomes independent of the database size.

A drawback of this design is that it results in a large number of overlapping SSTables, which hurts search performance. Given its poor indexing performance, the intermediate persistent buffer level does not appear to be very different from write-ahead log. Furthermore, key-value objects are written

[1] To avoid confusion with the cacheline flush instruction (e.g., `clflush`), writing a MemTable to NVMM is henceforth referred to as *flush*, and the cacheline flush is referred to as *persist*.

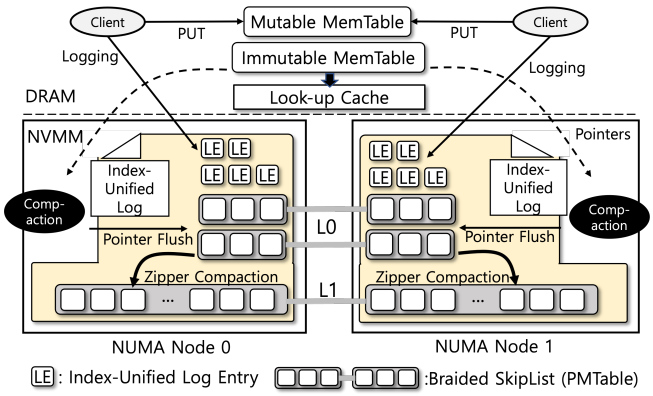

Figure 3: ListDB Architecture

to storage at least twice, i.e., once for WAL and once again for MemTable flush.

TRIAD [3], WiscKey [41], and FlatStore [12] prevent the same key-values (or just values) from being repeatedly written. TRIAD is particularly inspiring because it considers the commit log as an unsorted *L*0 SSTable. To enable efficient search in the unsorted *L*0 SSTables (the commit log), TRIAD creates a small index file for each *L*0 SSTable. The index file does not store keys and values, only the offsets for each object in sorted order of the keys. Although TRIAD reduces the I/O traffic, each MemTable flush creates an index file and calls the expensive `fsync()` to make it durable. However, given the high overlap between *L*0 SSTables and also the fact that *L*0 SSTables will be quickly merged into *L*1 SSTables, it is questionable whether a separate index file for each *L*0 SSTable should be created and persisted at a very high cost.

2.3 NUMA Effects

NVMM is more sensitive to NUMA effects than DRAM because of its lower bandwidth (1/6 for writes and 1/3 for reads) [16, 57, 62]. As such, state-of-the-art persistent indexes, such as FAST and FAIR B+tree [24] and CCEH [45] do not scale with the number of threads due to irregular cacheline accesses and NUMA effects [32, 57].

To mitigate the NUMA effects, Daase et al. [16] suggest limiting the number of write threads to 4-6 per socket. Nap [57] hides NUMA effects by overlaying a DRAM index on top of NVMM-resident indexes such that the DRAM index can absorb remote NUMA node accesses. However, data stored in NVMM is already in the memory address space, and NVMM has latency comparable to DRAM. Therefore, using DRAM as a fast cache layer over NVMM and copying data between DRAM and NVMM back and forth can be wasteful. For example, NVMM file systems such as EXT4-DAX and NOVA [61] do not use the page cache but directly access NVMM.

To mitigate NUMA effects in DRAM, various approaches, including *Delegation* with hash-based sharding [4, 6, 7, 44] and *Node Replication* (NR) [7] methods, have been investigated. In Delegation methods, a designated worker thread is assigned for all operations on a specific range of keys. Therefore, client threads have to communicate with worker threads and delegate operations using message passing. Due to the significant message passing overhead, Delegation performs sub-optimal, especially for lightweight tasks such as indexing operations [7]. Node Replication (NR) [7] implements a NUMA-aware shared log, which is used to replay the same operations for the data structures replicated across NUMA nodes. However, this consumes memory for replicating the same data structure across multiple NUMA nodes. Besides, the performance falters due to cross-node communication, as the number of NUMA nodes increases [7]. Considering that the bandwidth of Optane DCPMM is much lower than that of DRAM [62], replication can aggravate the low bandwidth problem.

3 Design of ListDB

ListDB is a write-optimized key-value store with an LSM tree structure that resolves the write stall problem. In this section, detailed descriptions of ListDB's key designs are provided. First, the overall architecture of ListDB is presented (§3.1). Then, its key designs, i.e., *Index-Unified Logging* (§3.2), NUMA-aware *Braided SkipList* (§3.3), in-place *Zipper Compaction* (§3.4), *lookup cache* (§3.5), and recovery algorithm (§3.6) are presented.

3.1 Three-Level Architecture

Figure 3 shows the three-level architecture of ListDB-volatile MemTables, and *L*0 and *L*1 Persistent MemTables (*PMTables*). MemTables and PMTables are essentially the same SkipLists, but the node structure of PMTable has additional metadata that MemTable does not need because PMTable is a data structure transformed from the write-ahead log. ListDB uses SkipList as the core data structure for all levels because it enables byte-addressable in-place merge-sort and avoids the *write amplification* problem [21, 41, 53], as will be presented throughout the paper.

ListDB employs an intermediate persistent buffer level - *L*0 (level 0) in NVMM. With level 0, a MemTable is flushed to NVMM without being merge-sorted, making the flush throughput independent of the next level persistent index size. MemTables accumulated at *L*0 (*L*0 PMTables) are gradually merged into the large *L*1 PMTable by compaction. To manage multiple PMTables, ListDB uses a metadata object called MANIFEST to point to the beginning of each SkipList.

3.2 Index-Unified Logging

ListDB aims to flush MemTables to NVMM without copying key-value objects. As discussed in Section 2.2.5.2, all key-value objects in MemTables are already persisted in the commit log in NVMM [3]. Besides, *L*0 indexes are known to have very poor indexing performance due to large overlap.

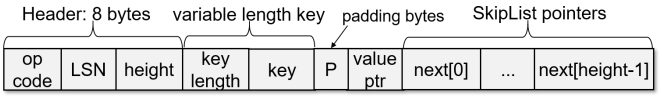

Figure 4: Index-Unified Log Entry Layout

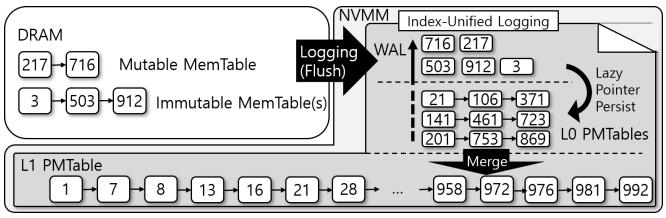

Figure 5: Index-Unified Logging

3.2.1 Conversion of IUL into SkipList

Index-Unified Logging (IUL) unifies write-ahead log entries and SkipList elements by allocating and writing log entries in the form of SkipList elements. Figure 4 shows the structure of an IUL entry, which serves both as a log entry and as a SkipList element. When a key-value object is inserted into a MemTable, the object and its metadata (i.e., operation code `op_code` and log sequence number `LSN`) are written and persisted as a log entry in NVMM with SkipList pointers initialized to NULL (Algorithm 1). Later, when a compaction thread flushes its corresponding MemTable from DRAM, the log entry is converted into a SkipList (*L*0 PMTable) element, reusing the key and value stored in the log entry.

The information that *L*0 PMTable needs, but the log does not have, is the sorted order of keys, which is managed as SkipList pointers in MemTables. When converting the log into an *L*0 PMTable, the addresses of the corresponding MemTable elements are simply translated into NVMM addresses, i.e., the log entry offsets, as shown in Algorithm 2. When the SkipList pointers in IUL entries are set to NVMM addresses, the IUL entries become SkipList elements.

Finally, the MANIFEST is updated to validate the new *L*0 PMTable and invalidate the immutable MemTable in a failure-atomic transaction.

3.2.2 MemTable Flush without `clflush`

When writing SkipList pointers to log entries, there is no need to call persist instructions (e.g.,`clflush`) because the key-value objects are already persistent in the log, and because the order of keys can be recovered without difficulty in case of a crash. Instead of explicitly persisting cachelines for updated pointers, Index-Unified Logging leaves that to the CPU cache replacement mechanism, i.e., it waits until the CPU evicts updated pointers from its cache. Through the CPU cache replacement mechanism, multiple pointer updates to the same 256-byte XPLine can be buffered and batched. That is, each 8-byte small write is not eagerly transformed into a 256-byte read-modify-write operation. Not only does it defer the read-modify-write problem, but also prevents background compaction threads from being affected by the read-modify-write problem and high NVMM write latency.

Algorithm 1 *Put(kvObject)*

```
1:  mutex.lock();
2:  iul_entry ← iul_tail;
3:  iul_entry.LSN ← GetNextLSN(); /* log sequence number */
4:  iul_entry.height ← RandomHeight(); /* SkipList element height */
5:  iul_tail ← iul_tail + sizeof(kvObject) + height*8 + 8;
6:  mutex.unlock();
7:  iul_entry.op_code ← OP_INSERT; /* operation type (insert, delete) */
8:  iul_entry.kvObject ← kvObject;
9:  iul_entry.next[0..height] ← NULL; /* initialize pointers */
10: pmem_persist(iul_entry, sizeof(iul_entry)); /* calls clwb */
11: memTable.Insert((SkipListElement)iul_entry); // classic SkipList insert
```

Algorithm 2 *FlushImmutableMemTable(memTable)*

```
1:  element ← memTable.head[0].next[0]; // smallest MemTable element
2:  while element≠NULL do
3:      L0_element ← element.iul_address;
4:      lookup_cache.Insert(L0_element);
5:      for layer ← 0; layer < element.height; layer++ do
6:          L0_element.next[layer] ← element.next[layer].iul_address;
7:          /* no need to persist */
8:      end for
9:  end while
10: new_L0.iul_address ← memTable.head[0].next[0].iul_address;
11: new_L0.next ← MANIFEST.L0List().GetFront();
12: MANIFEST.L0List().PushFront(new_L0); /* CAS */
13: freeMemTable(memTable);
```

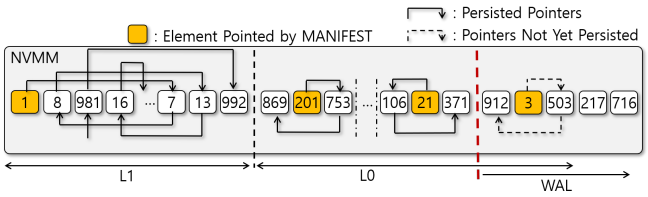
3.2.3 Walk-Through Example

Let us walk through MemTable flush illustrated in Figure 5. Suppose foreground client threads insert keys into the currently mutable MemTable in the order of 503, 912, and 3. Each client thread persists the object, its metadata, and NULL pointers in the log before it commits. Then, a background thread marks the MemTable as immutable and creates a new MemTable. Client threads insert two more keys, 716 and 217, into the new mutable MemTable.

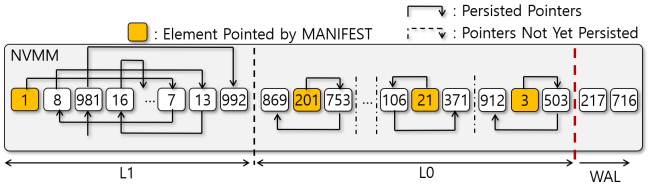
When a background compaction thread flushes the immutable MemTable, i.e., (3, 503, 912), the pointers of each MemTable element are simply translated into the IUL offsets of the corresponding log entries and the NULL pointers are replaced with the IUL offsets so that the log entries become a SkipList, as shown in Figure 6(a). As described in Section 3.2.2, the updated pointers in the new *L*0 PMTable may remain in the CPU cache and may be lost upon a system crash, but the pointers are not required for crash consistency.

3.2.4 Checkpointing *L*0 PMTable

Although the log entries are now converted to *L*0 PMTable elements, the boundary between logging space and *L*0 PMTable space (denoted as a thick dotted line in Figure 6(a)) has not moved, because it is not guaranteed that the pointers of the new *L*0 PMTable are persistent. The boundary can only move if `clflush` instructions are explicitly called for the updated pointers. In our implementation, a background thread persists dirty cachelines for *L*0 PMTables in batches. This op-



(a) NVMM Layout Before Checkpointing



(b) NVMM Layout After Checkpointing

Figure 6: NVMM Layout of Index-Unified Logging

eration is referred to as *checkpointing*. Figure 6(b) shows the NVMM layout after the pointers are explicitly persisted. Once a PMTable is checkpointed, it is possible to move the boundary of the logging space to reduce the number of log entries to recover, as shown in Figure 6(b).

3.2.4.1 Lazy Group Checkpointing

Checkpointing reduces recovery time. However, ListDB defers checkpointing as much as possible, because calling `clflush` instructions is very expensive. Even if *L*0 PMTables are not persisted at all, it does not affect crash consistency because all the elements in all *L*0 PMTables will be treated as log entries if the system crashes, and the key order of *L*0 PMTable elements can be reconstructed from the log.

In our implementation, multiple *L*0 PMTables are grouped and dirty cachelines for them are persisted in batches. We call this *lazy group checkpointing*. Note that there is a trade-off between lazy group checkpointing and recovery time. Infrequent checkpointing increases the log size and it takes longer to recover. In contrast, if checkpointing frequency is high, recovery will be fast, but flush throughput degrades.

Zipper compaction, which will be described in Section 3.4, persists pointers fast enough to prevent the number of *L*0 PMTables from increasing. That is, even if IUL does not persist any *L*0 PMTable, Zipper compaction persists pointers fast when merging an *L*0 PMTable into the *L*1 PMTable, and the recovery time of IUL is much shorter than synchronous checkpointing, as will be shown in Section 4.

3.3 NUMA Effects for SkipList

ListDB employs a NUMA-aware data structure, which is more scalable and effective in minimizing NUMA interconnect contention than Delegation and Node Replication [7].

3.3.1 NUMA-aware Braided SkipList

A SkipList has the invariant that the list at each layer[2] is a sorted sub-list of the bottom layer [52]. Unless this invariant

[2]To avoid confusion with the *level* of LSM trees, the level of SkipList will be referred to as *layer*.

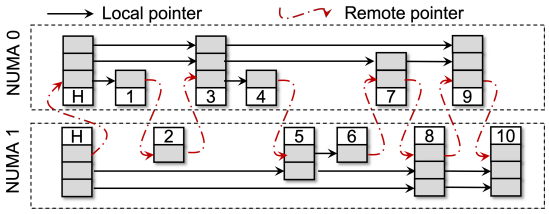


Figure 7: NUMA-aware Braided SkipList

is violated, correct search results are guaranteed because the upper layer pointers are probabilistic shortcuts, which do not affect the correctness of search results. However, an upper layer does not need to be a sub-list of the next layer, as long as it is a sub-list of the bottom layer. Even if a search does not find a key closer to the search key in an upper layer, the search falls back to a lower layer and eventually to the bottom layer which contains all sorted keys.

The Braided SkipList of ListDB leverages this property to mitigate NUMA effects in a simple and effective way. Upper layer pointers ignore SkipList elements in remote NUMA nodes; i.e., upper layer pointers of each element point to an element with a larger key in the same NUMA node. Compared to NUMA-oblivious conventional SkipLists, Braided SkipList reduces the number of remote memory accesses to $1/N$, where N is the number of NUMA nodes, as will be shown in Section 4.

Figure 7 illustrates an example (The upper layers in NUMA node 1 are illustrated upside down for ease of presentation). Observe that the second layer pointer of element `3` on NUMA node 0 points to element `7` on the same NUMA node, instead of element `5` on NUMA node 1. Nonetheless, a correct search is guaranteed. For example, suppose a client thread running on NUMA node 0 searches for element `5`. It will follow the top layer to element `3`, then `9`. Since `9` is greater, the thread moves down one layer in element `3`, and then the search visits element `7`. Since `7` is greater than `5`, the thread moves down again and follows the bottom layer pointer to element `4`. Since the search key is greater than `4`, it follows the bottom layer to a remote SkipList element `5`. The search then completes.

In our implementation of Braided SkipList, a NUMA ID is embedded in the extra 16 bits of the 64-bit virtual address, as in *pointer swizzling* [59], such that it can use 8-byte atomic instructions instead of expensive PMDK transactions [50]. For direct reference, Braided SkipList restores the virtual memory address of a SkipList element by masking the extra 16 bits.

3.4 Zipper Compaction

With byte-addressable NVMM, Zipper compaction merge-sorts *L*0 and *L*1 PMTables in-place by only updating pointers, but without blocking concurrent read queries. The in-place merge-sort avoids write amplification, thus it improves the compaction throughput.

Leveraging the SkipList invariant (§3.3.1), various lock-free SkipLists have been studied in the literature [22, 23], and the Java™ SE `ConcurrentSkipListMap` class has been

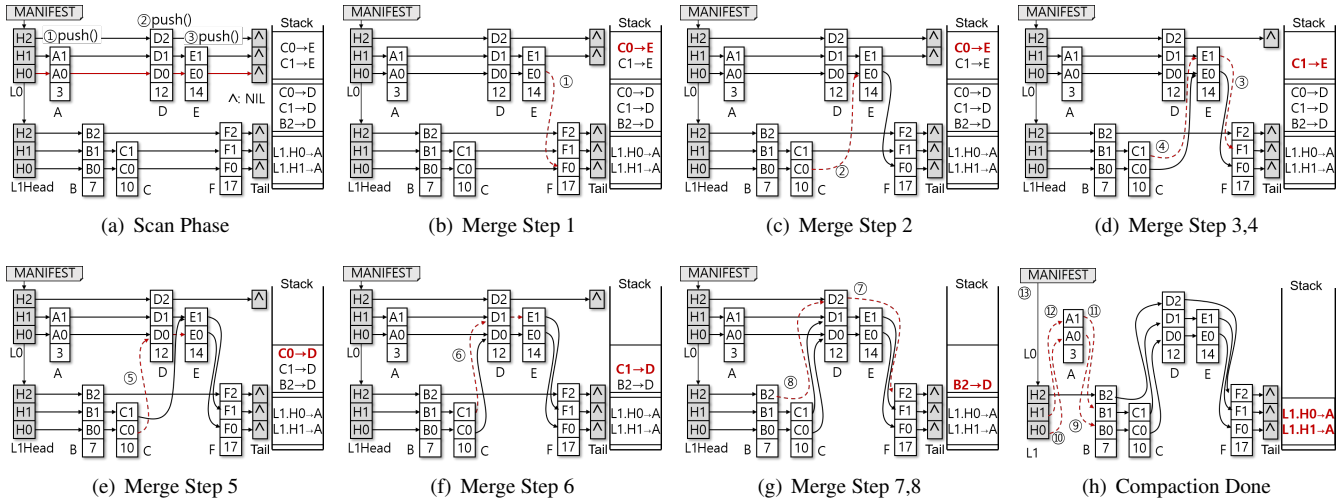

Figure 8: *Zipper Compaction: Merging SkipLists from Tail to Head*

shown to perform well in practice [34]. Zipper compaction algorithm allows concurrent read operations to access $L0$ and $L1$ PMTables while merging them without violating the invariant of SkipList.

A classic lock-free SkipList avoids locks for multiple writers. In contrast, ListDB does not perform concurrent writes; the only writers are the compaction threads, and ListDB coordinates them to avoid write-write conflicts. For parallelism, multiple compaction threads write to disjoint *shards*. A shard is a disjoint key range from an element with the maximum height to the next element with the maximum height in $L1$ PMTable. To merge $L0$ elements into $L1$, a compaction thread must acquire a lock on the corresponding shard.

Zipper compaction proceeds in two phases; (i) a forward *scan* from head to tail and (ii) a backward *merge* from tail to head, hence the name. To guarantee correct search results without blocking concurrent readers, $L0$ PMTable elements are merged into $L1$ PMTable from tail to head while concurrent read operations are traversing them from head to tail.

3.4.1 Scan Phase

In the forward scan phase, a compaction thread traverses $L0$ and $L1$ PMTables from head to tail and determines where each $L0$ PMTable element should be inserted in the $L1$ PMTable. However, in this phase, it does not make any change to the PMTables but pushes necessary pointer updates on a stack. The backward merge phase pops the stack to apply and persist the updates to the $L1$ PMTable.

The scan phase follows the bottom layer of $L0$ PMTable. For each $L0$ element, it searches the $L1$ PMTable to find where to insert the $L0$ element. For this, it keeps track of the rightmost element smaller than the current search key ($L0$ element) in each layer to avoid repeatedly traversing $L1$ PMTable. Since keys are sorted in both PMTables, the next larger key in $L0$ PMTable can reuse the previous rightmost elements, and backtrack to the top-layer rightmost element for the next search. Therefore, the complexity of the scan phase is $O(n_0 + \log n_1)$ where n_0 and n_1 are the sizes of $L0$ and $L1$ PMTables, respectively.

Algorithm 3 shows the pseudo-code of Zipper compaction. For NUMA-aware Braided SkipLists, Zipper compaction requires a two-dimensional array - `rightmost[numa_id][layer]` to keep as many rightmost elements in each layer as the number of NUMA nodes for Braided SkipList. But, note that a Braided SkipList element does not need more pointers than a conventional SkipList element as it embeds NUMA node ID in the 8-byte address.

Figure 8(a) shows an example of Zipper scan. For ease of presentation, all SkipList elements are assumed to be on the same NUMA node. The first element `A` in $L0$ will be placed in the first position in $L1$. Hence, `H0` and `H1` of the head element in $L1$ are the current rightmost pointers that need to be updated for `A`. This information is stored on the stack. Note that `A0` and `A1` need to point to `B`, but they are not pushed onto the stack because `B` is pointed by the current rightmost elements that are already pushed on the stack. Each $L0$ element is inserted between two $L1$ elements and only the previous (i.e., rightmost) element in each layer needs to be pushed on the stack because the next element can be found from the previous elements. Next, the scan phase visits the second element `D` in $L0$ and searches $L1$. Inserting `D` requires updating `B2`, `C1`, and `C0`. Again, they are pushed onto the stack. Finally, it visits the last element `E` in $L0$ and searches $L1$. Note that $L1$ PMTable has not changed and the current rightmost pointers are still `B2`, `C1`, and `C0`. Thus, the scan phase pushes `C1` and `C0` on the stack to make them point to `E`.

3.4.2 Merge Phase

The merge phase applies pointer updates from tail to head. When a compaction thread pops a pointer update $X_N \rightarrow Y$ from the stack, the Nth layer pointer in element Y is updated to the current value of X_N. Then, X_N is set to the address of Y.

Algorithm 3 *BraidedZipperCompaction(L0SkipList, L1SkipList)*

```
1: LogZipperCompactionBegin(L0SkipList); // micro-logging
2: L0_element ← L0SkipList.head[0].next[0]; // smallest L0 element
3: local_numa_id ← DecodeNumaId(L0_element); // not always 0
4: for i ← 0; i < NumNUMA; i++ do
5:     rightmost[i][] ← L1SkipList.head[i].next[]; // array copy
6: end for
7: bottom_L1_element ← L1SkipList.head[0].next[0];
8: L1_element ← L1SkipList.head[local_numa_id]; // local head
9: // I. scan phase: from head to tail
10: while L0_element≠NULL do
11:     // NUMA-aware local search for upper layer pointers
12:     for layer ← L0_element.height−1; layer > 0; layer−− do
13:         while L1_element.next[layer] ≠ NULL &&
                  L1_element.next[layer].key < L0_element.key do
14:             L1_element ← L1_element.next[layer];
15:             // update the rightmost for the current layer
16:             rightmost[local_numa_id][layer] ← L1_element;
17:         end while
18:     end for
19:     // NUMA-oblivious search for bottom-layer pointer, i.e., layer = 0
20:     L1_element ← bottom_L1_element;
21:     <<same while loop with line 13–17 >>
22:     // push an array of NUMA local upper-layer pointers and a NUMA-
        oblivious bottom layer pointer
23:     stack.push(L0_element, rightmost[local_numa_id][]);
24:     // fetch the next L0_element and update local NUMA ID
25:     L0_element ← L0_element.next[0];
26:     local_numa_id ← DecodeNumaId(L0_element);
27:     bottom_L1_element ← L1_element;
28:     L1_element ← rightmost[local_numa_id][L0_element.height−1];
29: end while
30: // II. merge phase: from tail to head
31: while stack is not empty do
32:     (L0_element, rightmost2update[]) ← stack.pop();
33:     for layer ← 0; layer < L0_element.height; layer++ do
34:         // Pop and apply the updates without worries about NUMA IDs
35:         L0_element.next[layer] ← rightmost2update[layer].next[layer];
36:         if layer = 0 then
37:             persist(L0_element.next[layer]);
38:         end if
39:         rightmost2update[layer].next[layer] ← L0_element;
40:         if layer = 0 then
41:             persist(rightmost2update[layer].next[layer]);
42:         end if
43:     end for
44:     second_chance_cache.Insert(L0_element);
45: end while
46: MANIFEST.L0List().PopBack(); /* CAS */
47: LogZipperCompactionDone(L0SkipList); // micro-logging
```

In the example, shown in Figure 8(b), the compaction thread pops `C0`→`E` and sets `E0` to `F`, which is the current value of `C0`. At this point, the upper layer pointer of element `E` (`E1`) is not pointing to element `F`. However, as described earlier, upper layer pointers are probabilistic shortcuts, which do not affect the correctness of search. Therefore, there is no need to update `E0` and `E1` atomically. In the next step, shown in Figure 8(c), the compaction thread sets `C0` to the address of `E`. In the next step, shown in Figure 8(d), the compaction thread pops `C1`→`E`, sets `E1` to `F`, and makes `C1` point to `E`. Each pointer update is removed from the stack one by one, and is applied in order, as shown in Figures 8(e), 8(f), 8(g), and 8(h). Zipper compaction assumes 8-byte pointer updates are atomic. To make the updates failure-atomic, it persists each bottom layer update immediately using memory fence and cacheline flush instructions. In the final step, the compaction thread deletes the head element of *L*0 PMTable from the MANIFEST object, thus completing compaction.

3.4.3 Lock-Free Search

Zipper compaction does not violate the correctness of concurrent search, i.e., a read thread will not miss its target SkipList element without acquiring a lock. This is because a read thread accesses PMTables from head to tail and from *L*0 to *L*1, whereas a compaction thread merges them from tail to head. During Zipper compaction, every element is guaranteed to be pointed by at least one head. Consider the example shown in Figure 8, which shows how a sequence of atomic store instructions merges the two example SkipLists. Even if a concurrent read thread accesses the PMTables in any state shown in Figure 8, it returns a correct result.

The algorithm remains correct even if a read thread is suspended during compaction thread is making changes to SkipLists. For example, suppose a read is suspended while accessing an *L*0 element. When it resumes, the element might have been merged into *L*1. When the read thread wakes up, it will continue traversing to the tail if it does not find the search key. Once it reaches the tail, it is done with *L*0 and will start searching *L*1, into which *L*0 elements have been merged. Consequently, the read thread might visit the same elements multiple times, but it will never miss the element it is searching. Multiple visits might hurt search performance. To avoid this, a read stops searching the *L*0 if it detects the level of the current element is *L*1.

3.4.4 Updates and Deletes

An update in LSM trees duplicates the same key because writes are buffered in MemTables and gradually flushed to the last level. ListDB does not eagerly delete the older version in *L*1. Instead, when a compaction thread scans *L*0 and *L*1 levels for Zipper compaction, it marks the older version in *L*1 obsolete. Similarly, a delete in ListDB does not physically delete an object but inserts a *key-delete* object into the MemTable. If an LSM tree physically deletes the most recent version of a key from MemTables or *L*0 PMTables, older versions of the key will come back to life. Zipper compaction places a more recent key-value or key-delete object before its corresponding old objects. Therefore, a read query always accesses the more recent object before older ones, and thus returns a correct search result.

3.4.5 Fragmentation and Garbage Collection

Using `libpmemobj` library [50], ListDB allocates and deallocates a *memory chunk* (e.g., 8 MB) for multiple IUL entries in PMDK's failure-atomic transaction so that the number of calls to expensive PMDK transactions can be reduced. ListDB deallocates a memory chunk if all elements in the chunk are marked obsolete or deleted. Note that ListDB does not relocate SkipList elements for garbage collection. To address

the lasting fragmentation, a compaction thread may perform CoW-based garbage collection. We leave this optimization for our future work.

Memory management for lock-free data structures is a hard problem because there is no easy way to detect whether deallocated memory space is still being accessed by concurrent reads [5, 14, 19]. ListDB employs a simple epoch-based reclamation [14]; ListDB does not deallocate memory chunk immediately but waits long enough for short-lived read queries to finish accessing the deallocated memory chunk. A background garbage collection thread periodically checks and reclaims a memory chunk if all objects in the memory chunk are obsolete or deleted. For obsolete objects, the garbage collection thread checks its newer version's LSN. If it is also old enough, it considers the obsolete objects are not accessed by any reads, removes them from $L1$ PMTable, and physically deallocates the memory chunk.

3.4.6 Linearizability

Theorem 1. *Zipper compaction is linearizable with a single writer and multiple readers.*

Proof. For some element e, there is a single *linearization point* [23] for a writer when its level changes from $L0$ to $L1$, by atomic update of the bottom-layer next pointer. We denote this linearization point as $e.merge\_to\_L1$.

There are two linearization points $e.search\_L0$ and $e.search\_L1$ for a reader, as it searches $L0$ and then $L1$ PMTable in order. Let $a \rightarrow b$ if an event a happens before another event b. There are three cases to consider.

1. $e.merge\_to\_L1 \rightarrow e.search\_L0 \rightarrow e.search\_L1$
2. $e.search\_L0 \rightarrow e.merge\_to\_L1 \rightarrow e.search\_L1$
3. $e.search\_L0 \rightarrow e.search\_L1 \rightarrow e.merge\_to\_L1$

In case 1, $e.search\_L1$ will find e in $L1$. In case 2, $e.search\_L0$ will find e in $L0$. If the search does not stop after finding e in $L0$, $e.search\_L1$ will also find e in $L1$. In case 3, similarly, $e.search\_L0$ will find e. Since all three cases succeed in finding e, Zipper compaction is linearizable, meaning a read always succeeds in finding an element if the element was inserted by a committed write transaction, regardless of whether the element is in $L0$ or $L1$ PMTable. □

3.5 Look-up Cache

ListDB requires that a read query accesses at least two indexes, i.e., a mutable MemTable and $L1$ PMTable. Therefore, the read throughput of ListDB is significantly lower than a highly-optimized persistent B+tree, as we show in Section 4.

To mitigate this problem, ListDB uses a *lookup cache* in DRAM. Flushing a MemTable hashes each element into a fixed-sized static hash table. Unlike disk-based designs, the lookup cache does not duplicate the element in it, but only stores its NVMM address because the element in NVMM is already in the memory address space and its address never changes. Hence, regardless of the level at which the PMTable element is present, the lookup cache can locate the PMTable element. SkipList pointers are frequently updated by compaction threads in ListDB. By caching immutable addresses, not mutable content, the lookup cache can avoid frequent cache invalidation. If a hash collision occurs on a bucket, the old address is overwritten (i.e., FIFO replacement policy).

Algorithm 4 *Get(key)*

```
1: iter ← MANIFEST.GetTableIterator();
2: table ← iter.GetTable(); // get mutable MemTable
3: while table ≠ NULL && table.IsPMTable() = false do
4:     value ← table.Search(key); // SkipList lookup
5:     if value ≠ NULL then
6:         return value; // Found: return value
7:     end if
8:     table ← (++iter).GetTable(); // immutable MemTables
9: end while
10: /* L0 Cache Lookup */
11: cached ← lookup_cache.Lookup(key);
12: if cached ≠ NULL && cached.GetElement().key = key then
13:     return cached.GetElement().value;
14: end if
15: /* L0 Search */
16: while table ≠ NULL && table.Level() = 0 do
17:     value ← table.Search(key); // SkipList lookup
18:     if value ≠ NULL then
19:         return value; // Found: return value
20:     end if
21:     table ← (++iter).GetTable(); // L0 PMTables
22: end while
23: /* L1 Search */
24: rightmost ← second_chance_cache.Lookup(key);
25: value ← table.SearchFromElement(key, rightmost);
26: if value ≠ NULL then
27:     return value; // Found: return value
28: end if
29: return NOT_FOUND;
```

ListDB constructs a SkipList in DRAM as a second chance lookup cache for tall elements evicted from the hash table. The purpose of the second chance lookup cache is to accelerate PMTable search. Even if a key is not found in the second chance cache, a query can start the search from the closest PMTable element found in the cache. Algorithm 4 shows how a read query uses the lookup caches. Suppose a read searches for key 100 but finds element 85 is the closest smaller element in $L1$. Then, the search continues from element 85 in $L1$ PMTable instead of the beginning of $L1$. ListDB does not use the second chance lookup cache for $L0$ search because small $L0$ PMTables are merged into $L1$ fast, and $L0$ elements are mostly cached in the lookup hash table, The second chance lookup cache uses the SIZE replacement policy [58], i.e., it compares heights and evicts elements with shorter heights.

3.6 Recovery

A system may crash while $L0$ and $L1$ PMTables are being merged by Zipper compaction. To recover from such failures, a compaction thread performs micro-logging to keep track of which $L0$ PMTable is being merged into $L1$ PMTable. When a system restarts, ListDB checks the compaction log to redo unfinished compactions. For redo operations, Zipper compaction has to check duplicate entries since many entries in the tail of

Algorithm 5 *RecoverDB()*

```
1:  ScheduleUnfinishedZipperCompactionJob();
2:  curr_table ← NULL;
3:  while log_iter.Valid() do
4:      iul_entry ← log_iter.GetIULEntry();
5:      table_id ← GetTableIdByLSN(iul_entry.LSN);
6:      if curr_table = NULL || table_id ≠ curr_table.Id() then
7:          curr_table ← MANIFEST.GetTableById(table_id);
8:          curr_table.ResetSkipListHead();
9:      end if
10:     curr_table.InsertEntry(iul_entry); /* SkipList Insert */
11:     log_iter.Next(); /* from old to latest */
12: end while
```

*L*0 PMTable can be shared with *L*1 PMTable.

The recovery algorithm of ListDB, shown in Algorithm 5, is similar to that of conventional LSM trees. First, a recovery process locates the boundary of WAL, which is recorded by compaction threads in the compaction log. Then, it sorts log entries and restores *L*0 PMTables. At this point, the system returns to the normal execution mode and starts processing clients' queries. Compaction between *L*0 and *L*1 will be done in the background as normal.

As for the lookup cache, ListDB can process clients' queries without restoring the cache although the search performance will be poor until the cache is populated. By avoiding the reconstruction of DRAM cache and index, the recovery performance of ListDB is superior to synchronous checkpointing [12], as we show in Section 4.

4 Evaluation

4.1 Experimental Setup

Experiments are conducted on a four-socket NUMA server with Intel Xeon Gold 5215 CPU (2.50 GHz, 20 vCPUs) per socket, 256 GB of DDR4 DRAM (16x 16 GB), and 2 TB (16x 128 GB) Optane DCPMM (4 DCPMM's and 4 DRAM's per each socket) in app-direct mode. Our testbed server supports only the *directory coherence* protocol, but not *snoop* protocol, despite its known NUMA bandwidth meltdown issues [32].

All implementations are compiled using gcc 7.5.0 with `-O3` optimization. Using PMDK [50], ListDB creates an auto-growing directory-based persistent memory poolset (`pmempool`) on each NUMA node [50]. For NUMA-oblivious designs, we use the device mapper to create a single persistent memory poolset interleaved on four sockets.

We evaluate the performance of ListDB[3] using two individual sets of experiments. First, the performance effects of each part of the design of ListDB are quantified. Second, the performance of ListDB is compared against that of state-of-the-art persistent indexes, including FAST and FAIR B+tree [24] and PACTree [32], and LSM tree-based key-value stores for NVMM, i.e., NoveLSM [30], SLM-DB [29], and Intel's industry-optimized Pmem-RocksDB [51]. Pmem-RocksDB [51] is a variant of RocksDB for NVMM that Intel has optimized in two respects. First, Pmem-RocksDB separates keys and values to mitigate write amplification issues, as in WiscKey [41]. Second, Pmem-RocksDB mmaps SSTables and writes directly to NVMM by using non-temporal stores (i.e., `ntstore`) to bypass the cache hierarchy and eliminate context switching.

[3] Source code is available at http://github.com/DICL/listdb.

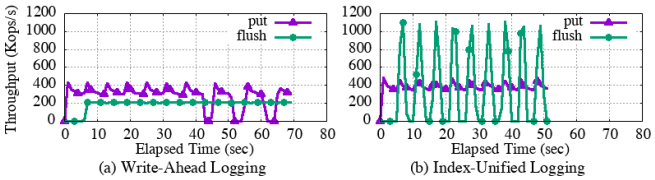

Figure 9: *Low Flush Throughput Results in Write Stalls*

Our experiments use YCSB [15] and the Facebook benchmark [8]. The Facebook benchmark generates more realistic workloads than YCSB as it emulates real-world RocksDB workloads in Facebook/Meta datacenters. Specifically, the Facebook benchmark adds mathematical models (e.g., sine distribution) to db_bench [18] such that it can vary key sizes, value sizes, and query arrival rates over time.

4.2 Evaluation of Index-Unified Logging

4.2.1 IUL vs. WAL: Flush Throughput

This section compares the performance effect of IUL to standard WAL with respect to write stalls. For the experiments shown in Figure 9, a single YCSB [15] client thread (Load A) and a single compaction thread are used to evaluate how fast a MemTable absorbs bursts of 20 million writes (8-byte key and 8-byte value objects), and how fast a single background compaction thread flushes MemTables to NVMM. To prevent memory usage from increasing indefinitely, the maximum number of immutable MemTables is set to 4. Zipper compaction threads are disabled to evaluate only the effect of IUL, i.e., *L*1 is not used. `put` denotes the client's query processing throughput over time (i.e., the number of records inserted into MemTables per second), and `flush` denotes how many records are flushed from MemTables to NVMM by the compaction thread.

Figure 9 (a) shows that with standard WAL, `put` throughput is higher than `flush` throughput because inserting key-value objects into a SkipList in DRAM is much faster than flushing (i.e., copying key-value objects from DRAM to NVMM) and persisting a SkipList in NVMM. Each spike in `put` throughput indicates that a new empty mutable MemTable was created; it takes about 5 seconds to fill a 64 MB MemTable. In 40 seconds, the number of MemTables exceeds the threshold, and subsequent writes are blocked. Even if the threshold is set to a higher value than four, it is only a matter of time before a write is stalled, because `flush` throughput is lower than `put` throughput.

In contrast, Figure 9 (b) shows that with IUL, `flush` throughput is much higher than `put` throughput. `flush` throughput of IUL fluctuates because each flush takes less time than filling a MemTable, i.e., the compaction thread be-

(a) Load A (b) Workload A (c) Workload B (d) Workload C (e) Workload D

Figure 10: Performance Effect of Index-Unified Logging

comes idle. This high `flush` throughput is because IUL does not copy key-value objects from DRAM to NVMM and does not call cacheline flush instructions. So, write stalls do not occur and the compaction thread often becomes idle, allowing the CPU to perform other work.

4.2.2 Evaluation of IUL using YCSB

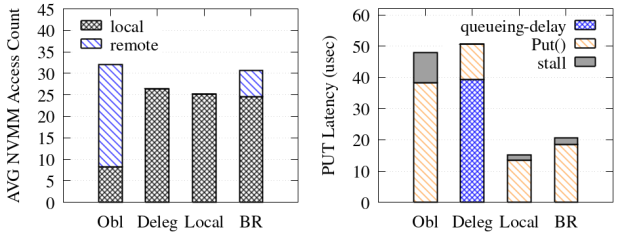
The experiments shown in Figure 10 compare the performance of IUL to standard WAL with varying the number of client threads for YCSB workloads. The number of background compaction threads is set to half the number of client threads. The MemTable size and the maximum memory usage for MemTables are set to 256 MB and 1 GB, respectively, i.e., a maximum of 4 MemTables are allowed. We set the lookup cache size to 1 GB (979 MB hash-based lookup cache and 45 MB for the second chance lookup cache). For the experiments, Braided SkipList and Zipper compaction are enabled so that $L0$ PMTables are merged into $L1$ PMTable and read queries can run faster. The `Load A` workload populates the database with 100 million records (8-byte keys and 8-byte values). All other workloads submit 100 million queries each.

Figure 10(a) shows that increasing the number of client threads increases the write throughput of both logging methods, up to 80 threads. With 80 client threads, the throughput of IUL (14.513 million ops/sec) is approximately 1.8x higher than that of WAL (8.101 million ops/sec). However, when the number of client threads exceeds the number of logical cores throughput degrades due to the high overcommit rate. That is, 100 client threads and 50 background compaction threads compete for 80 logical cores. Still, the throughput of IUL is 99% higher than WAL.

For Workload B (95% reads), Workload C (100% reads), and workload D (read latest), WAL has similar or slightly better performance than IUL because WAL does copy-on-writes to store records in ascending order of keys, and read operations benefit from higher memory access locality than IUL. Nevertheless, IUL outperforms WAL in Workload A (50:50 Read:Write) due to its better write performance.

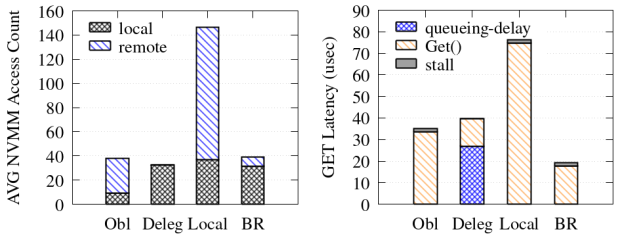
4.3 Evaluation of Braided SkipList

This section evaluates NUMA effects in NVMM using a single PMTable. The performance of the NUMA-aware Braided SkipList (denoted as `BR`) is compared with three other methods that were discussed in Section 2.3; i.e., (i) NUMA-oblivious SkipList (denoted as `Obl`), (ii) delegating client



(a) Memory Access Count (b) Response Time Breakdown

Figure 11: PUT Performance (80 Clients)



(a) Memory Access Count (b) Response Time Breakdown

Figure 12: GET Performance (80 Clients)

queries to a worker thread, using shared memory (denoted as `Deleg`), and (iii) a write-optimal local SkipList (denoted as `Local`), which manages a SkipList per NUMA node. `BR` and `Obl` manage one large PMTable, whereas `Deleg` and `Local` create four smaller PMTables. `Deleg` partitions key-value records according to hash keys, but `Local` allows a write client to insert data into the SkipList on its local NUMA node regardless of the key. Consequently, a read query has to search all four SkipLists. Even if a key is found in the local index, it must search remote indexes because a remote index may have a more recent update. Therefore, when there are n NUMA nodes, the ratio of local accesses is always $1/n$.

Our experiments, shown in Figures 11 and 12, run YCSB Load A (100 million inserts, 5-25 bytes string keys, 100-byte values) and Workload C (10 million queries).

PUT: Figure 11(b) shows that `Local` has the lowest write response time because it always inserts into the local PMTable. This eliminates remote NUMA node access for writes as shown in Figure 11(a). Braided SkipList (denoted as `BR`) has a higher write response time than `Local` because `BR` accesses remote NVMM via bottom layer pointers. Figure 11(a) shows that most NVMM accesses using `BR` are local, unlike NUMA-

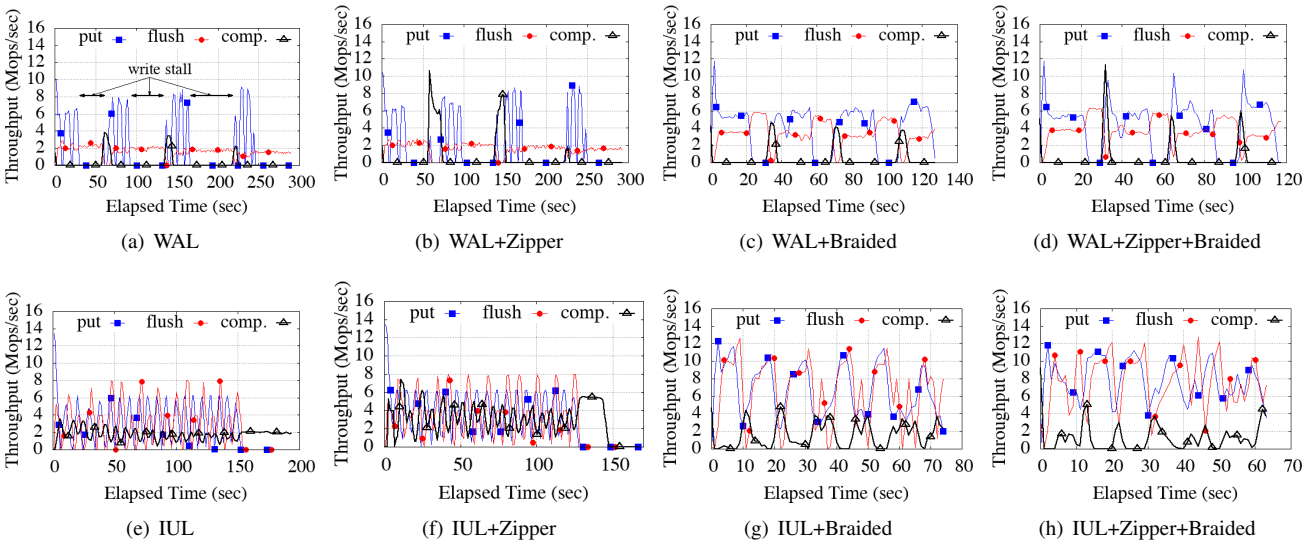


Figure 13: Put/Flush/Compaction Throughput over Time (YCSB Load A)

oblivious SkipList (20.1% vs. 74.1% remote accesses). `Obl` and `BR` access NVMM more than `Deleg` and `Local`.

Similar to `Local`, `Deleg` also completely removes remote NVMM access, but the write response time is significantly higher due to delegation overhead. That is, threads use slow atomic instructions to access the shared queue and make a memory copy for queries and results. Figure 11(b) shows that the queueing delay accounts for 77.1% of query response time with 80 client threads. Because put/get operations on a lock-free index are very lightweight, the synchronization overhead incurred by delegation dominates the overall response time.

GET: Figure 12(a) shows that the response time of `BR` for read queries is lower than the other methods. While `Local` outperforms `BR` for writes, the read response time of `Local` is about 4x higher than `BR` because `Local` must search all 4 PMTables. Although `BR` avoids visiting a more efficient search path that follows remote elements, Figures 11(a) and 12(a) show that it has almost no effect on the traversal length. `Deleg` shows the fewest memory accesses. However, due to synchronization overhead, its query response time is about 2x higher than `BR`, so its performance is even lower than `Obl`.

4.4 Putting It All Together

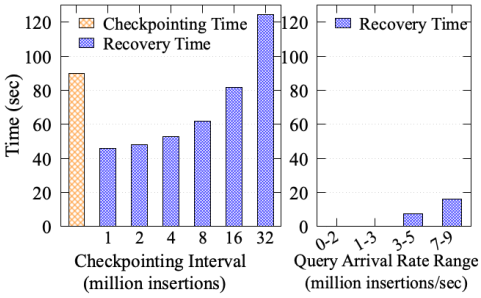
Figure 13 presents a factor analysis for ListDB. [4] We enable and disable each design feature of ListDB and measure write throughput (denoted `put`), flush throughput (MemTable $\rightarrow$ $L0$ PMTable, denoted `flush`), and compaction throughput ($L0 \rightarrow L1$ PMTable, denoted `comp.`) over time. We run 80 client threads and 40 background compaction threads for YCSB Load A, inserting 500 million 8-byte keys and 8-byte values. Figure 13(a) shows that disabling all three optimizations causes client threads to stall for more than 50 seconds. Enabling Zipper compaction improves the $L0 \rightarrow L1$ compaction throughput as shown in Figure 13(b), but the write stall problem still occurs because of the memory copy overhead for flushing the MemTable. If Braided SkipList is used, accessing remote NUMA nodes can be avoided when flushing the MemTable. Therefore, flush throughput doubles, which results in less frequent write stalls, as shown in Figure 13(c). Enabling both Zipper compaction and Braided SkipList results in shorter write stall times, and the workload completes in less than 120 seconds (Figure 13(d))

If IUL is used instead of WAL, `flush` throughput becomes comparable to `put` throughput, as shown in Figure 13(e). By avoiding expensive memory copy, write stalls are less frequent than WAL. However, note that compaction throughput is much lower than flush throughput. This increases the number of $L0$ PMTables and degrades search performance. As shown in Figure 13(f), if additionally IUL and Zipper compaction are enabled, the NVMM bandwidth improves by reducing the number of memory copies. Thus, it improves compaction and flush throughput. Enabling IUL and Braided SkipList, as shown in Figure 13(g), avoids NUMA effects, which improves both compaction and flush throughput. Finally, with all three optimizations enabled, the workload completes in under 65 seconds with virtually no write stalls (Figure 13(h)) compared to 300 seconds in figure 13(a).

4.5 Recovery Performance

We evaluate the recovery performance of asynchronous incremental checkpointing for ListDB and periodic synchronous checkpointing. Using the Facebook benchmark, we populate a database with 100 million objects and measure the time to recover using a checkpoint and write-ahead log entries. Despite using the same workload, the recovery performance of synchronous checkpointing is affected by the checkpointing interval, whereas asynchronous checkpointing is only affected by the query arrival rate. This is because the number of the

[4] Note that the scale of the x axis differs between the subfigures.



(a) Synchronous Checkpointing (b) ListDB

Figure 14: Recovery Performance

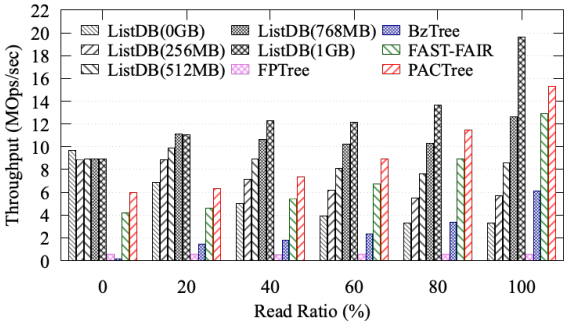


Figure 15: Comparison with Other Designs

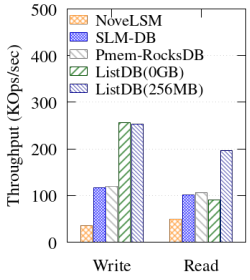

Figure 16: Comparison with NoveLSM and SLM-DB

log entries varies with asynchronous checkpointing, which background compaction threads have not yet merged into *L*1. If the query arrival rate is higher than the Zipper compaction throughput, the number of the IUL entries increases and the recovery process has to create a larger *L*0 PMTable with more log entries.

Figure 14 shows that a synchronous checkpointing takes about 90 seconds to serialize and flush the in-memory B+tree using the `binary_oarchive` class from the Boost library. This causes concurrent queries to block for 90 seconds while the checkpointing is being performed, resulting in unacceptably high tail latency. To alleviate the problem, checkpointing can be performed less frequently, but that increases the recovery time (i.e., the time to restore the checkpointed index and insert log entries to it) as more log entries accumulate.

In contrast, Figure 14 (b) shows that ListDB recovers instantly if it crashes when the write query arrival rate is lower than 3 million insertions/sec. If the query arrival rate varies between 7 and 9 million insertions/sec, ListDB takes about 19 seconds to recover. With a higher query arrival rate, the recovery time of ListDB increases.

4.6 Comparison with Other Designs

The experiments shown in Figure 15 compare the performance of ListDB with state-of-the-art persistent indexes; i.e., BzTree [1], FP-tree [49], FAST and FAIR B+tree [24], and PACTree [32], We run the experiments on a two-socket machine, because PACTree is hardcoded for two sockets. The two-socket machine has the same Intel Xeon Gold 5215 CPUs (40 logical cores in total), 128 GB DRAM (8x 16GB), and 1 TB (8x 128 GB) DCPMM. The database is pre-loaded with 100 million key-value records and then 40 clients submit 10 million queries with uniform distribution (generated from YCSB Workload A) with various read-write ratios. These tree-structured indexes are not optimized for (or do not support) large variable-length string keys and values. Therefore, we generated 8-byte numeric keys and 8-byte pointer values for the workload, which is favorable for tree-structured indexes with large fanouts.

Figure 15 shows that ListDB outperforms tree-structured persistent indexes for write-intensive workloads. For the write-only workload, `ListDB(0GB)` shows 79x, 17x, 2.3x and 1.6x higher throughput than BzTree, FPTree, FAST and FAIR B+tree, and PACTree, respectively. However, for the read-only workload, tree-structured indexes benefit from faster search performance. In particular, FAST and FAIR B+tree and PACTree show 3.88x and 4.61x higher search throughputs, respectively, than `ListDB(0GB)`. With the lookup cache enabled, ListDB outperforms or shows comparable performance to tree-structured indexes. The numbers in parentheses in the graph key show the lookup cache size. With a lookup cache larger than 768 MB, ListDB outperforms PACTree unless the read ratio is higher than 80%.

These results confirm that standard caching techniques can easily improve read performance. However, the lookup cache that indexes the location of key-value records cannot be used for PACTree, FAST FAIR B+tree, FPTree, etc. because they frequently relocate key-value records to different tree nodes due to tree rebalancing operations. That is, employing a DRAM cache for a tree-structured persistent index is not as simple as our address-only lookup caching. For example, Nap [57] has a very complicated caching mechanism.

4.6.1 Write Amplification

Although LSM trees have better write performance than tree-structured indexes, they have higher write amplification, as a critical limitation in block device storage [21, 41, 53]. To compare write amplification, we used Intel PMwatch [25] to measure the total number of accessed bytes in the experiments shown in Figure 15. All indexing methods suffer from high write amplification. DCPMM's internal write combining buffer transforms a small write (8-byte key and 8-byte value) into a 256-byte read-modify-write operation, resulting in at least 16x write amplification. In ListDB, the writes are further amplified by merge-sort operations in *L*0 and *L*1 PMTables. However, the write amplification of ListDB (104.4) is lower than that of FAST and FAIR B+tree (126.789) and comparable to that of PACTree (91.5) because ListDB merge-sorts SkipLists in-place.

4.7 Comparison with NoveLSM and SLM-DB

Figure 16 shows the single-threaded read and write throughput of NoveLSM, SLM-DB, Pmem-RocksDB, and ListDB.

The experiments run a single client thread (`db_bench`, 100 million random 8-byte keys and 1 KB values) because NoveLSM crashes when multiple threads concurrently access the database. NoveLSM and SLM-DB were designed to use NVMM as an intermediate layer on top of the block device file system, but our experiments store all SSTables in NVMM formatted with EXT4-DAX for a fair comparison.

NoveLSM shows the worst performance, not because of its design but because it is implemented on top of LevelDB, which is known to have poor performance. SLM-DB is also implemented on top of LevelDB but shows better performance because it uses FAST and FAIR B+tree as its core index. Since SLM-DB is not yet ported to use PMDK, it has no overhead imposed by run-time flushing or transactional updates, i.e., it shows DRAM performance and does not survive a system crash. Nonetheless, SLM-DB does not show better performance than Pmem-RocksDB, a fully persistent key-value store. Compared to Pmem-RocksDB, `ListDB(0GB)` shows twice the write throughput, but read performance is slightly worse unless the lookup cache is enabled. This is because Pmem-RocksDB benefits from memory locality by storing keys contiguously in NVMM in sorted order, whereas ListDB does not relocate data.

4.8 Comparison with Pmem-RocksDB

Finally, we compare the performance of ListDB with Intel's Pmem-RocksDB using the *Prefix Dist* workload in the Facebook benchmark. The experiments shown in Figure 17 run 80 client threads and use the default key and value sizes of the benchmark (48-byte string keys and variable-length values ranging from 16 bytes to 10 KB). The workload submits queries according to a query arrival rate (QPS parameter) that follows a sine distribution with a noise factor of 0.5. The put/get ratio of the workload is 3 to 7.

For various parameter settings, ListDB consistently outperforms Pmem-RocksDB. The results of two different settings are presented in Figure 17 - an `idle` workload (0.1 $\sim$ 0.3 million write queries and 0.2 $\sim$ 0.7 million read queries arrive per second; 200 million queries in total), in which the throughput of Pmem-RocksDB is saturated, and a `heavy` workload (2.4 $\sim$ 7.2 million write queries and 5.6 $\sim$ 16.8 million queries arrive per second; 5 billion queries in total), in which the throughput of ListDB is saturated. The lookup cache is disabled for ListDB while setting the maximum DRAM usage for both key-value stores to 1 GB and allowing Pmem-RocksDB to use the default 8 MB block cache.

For the `idle` workload, Pmem-RocksDB suffers from excessive NVMM writes, so its `put` throughput saturates at 200 Kops. For the Facebook benchmark, a `get` query has to wait for its previous `put` query to commit. Therefore, the `get` throughput of Pmem-RocksDB saturates at 400 Kops in the experiment. In contrast, Figure 17(b) shows that the throughput of ListDB follows the sine distribution, i.e., the query arrival rate, without blocking queries.

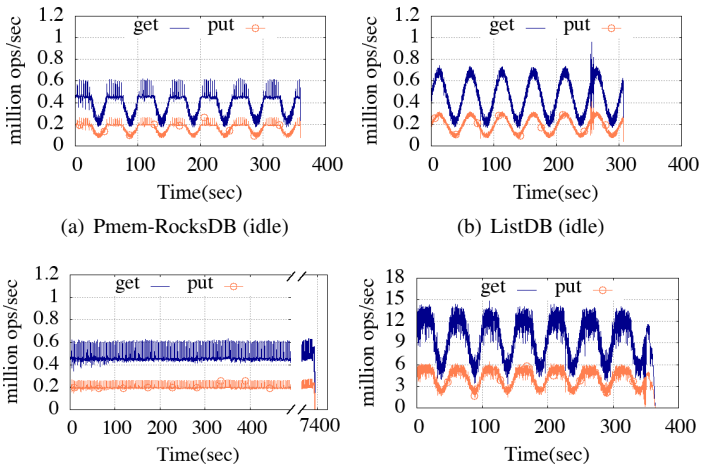

Figure 17: Throughput over Time (Facebook Benchmark)

For the `heavy` workload, Pmem-RocksDB's throughput is still saturated. On the other hand, the `put` throughput of ListDB is 25x higher than that of Pmem-RocksDB, i.e., 5 million ops. Similarly, the `get` throughput of ListDB is up to 22x higher than that of Pmem-RocksDB (i.e., 13 million vs. 0.6 million ops). As such, ListDB completes the workload 19.4x faster than Pmem-RocksDB (i.e., 380 vs. 7400 seconds).

5 Conclusion

In this work, we design and implement ListDB - a key-value store that leverages the byte-addressability to avoid data copies by restructuring data in-place and high-performance of NVMM to reduce the write amplification and avoid write stalls. We show that ListDB significantly improves write performance via asynchronous incremental checkpointing and in-place compaction. With its three-level structure, ListDB outperforms state-of-the-art persistent indexes and NVMM-based key-value stores in terms of write throughput. A standard lookup cache can help mitigate the problem of having multiple levels. For future work, we are exploring the possibility of improving search performance by introducing another level, namely L2 PMTable, to opportunistically rearrange L1 PMTable elements for spatial locality and garbage collection.

Abstract

Existing file systems for persistent memory (PM) exploit its byte-addressable non-volatile access with low latency and high bandwidth. However, they do not utilize two unique PM properties effectively. The first one is contention awareness, *i.e.*, a small number of threads cannot thoroughly saturate the PM bandwidth, while many concurrent accesses lead to significant PM performance degradation. The second one is NUMA awareness, *i.e.*, exploiting the remote PM efficiently, as accessing remote PM naively leads to significant performance degradation.

We present OdinFS, a NUMA-aware scalable datapath PM file system that addresses these two challenges using a novel ***opportunistic delegation*** scheme. Under this scheme, OdinFS decouples the PM accesses from application threads with the help of background threads that access PM on behalf of the application. Because of PM access decoupling, OdinFS automatically parallelizes the access to PM across NUMA nodes in a controlled and localized manner. Our evaluation shows that OdinFS outperforms existing PM file systems up to 32.7× on real-world workloads.

1 Introduction

Persistent memory (PM), a storage-class memory, breaks the traditional dichotomy of storage and memory. It offers byte addressability, non-volatility, low latency, and high bandwidth [8, 14, 23, 43]. Recent characterization studies show that PM has many subtle performance characteristics [18–20, 23, 27, 29, 37, 39, 40, 43], posing a significant challenge for storage stacks to utilize PM performance efficiently.

Such a challenge arises from two unique PM characteristics. The first factor is the tension between concurrent accesses and PM performance. In particular, a small number of threads underutilize PM bandwidth, while a high number of concurrent access threads[1] lead to PM performance meltdown [39]. The meltdown happens because a high number of concurrent access threads render the caching and prefetching in PM inefficient [14, 43]. The second factor is the pronounced NUMA impact on PM, as several prior works found that remote NUMA accesses on PM are much slower than DRAM, leading to at least 2× bandwidth reduction [14, 27, 38]. Supporting multiple NUMA domains is currently the primary way to increase PM's capacity and aggregated bandwidth. Unfortunately, the pronounced NUMA impact defeats the purpose of PM NUMA architecture.

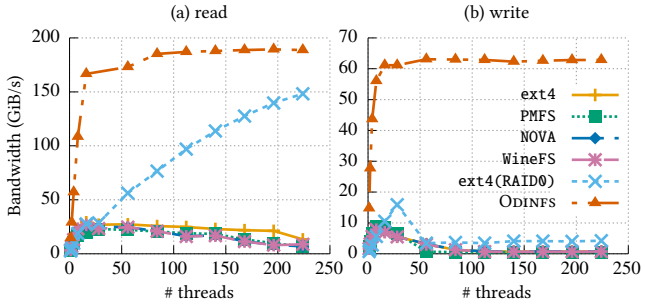

Figure 1: The maximal PM read and write bandwidth of four PM file systems and OdinFS. `ext4(RAID0)`: `ext4` mounted on a RAID0 built from PM across all NUMA nodes. Benchmark: `fio`, in which each thread accesses a private file at the granularity of 2MB sequentially, on an eight-socket machine.

Several proposed PM file systems exploit various characteristics of PM [10, 12, 16, 17, 24, 25, 28, 34, 41]. However, none of the existing PM file systems considers the tension between concurrent accesses and PM performance. Moreover, the conventional approach to mitigate the PM NUMA impact is to migrate data to CPUs or vice versa [25, 42], which incurs a high migration overhead, and cannot efficiently utilize the aggregated PM bandwidth. Figure 1 illustrates the issues for several PM file systems [2, 17, 25, 41]. The bandwidth of these file systems highly depends on the thread counts. Except for `ext4(RAID0)` performing the read workload, the read and write bandwidth of these file systems collapse after the thread count exceeds a certain threshold. In summary, existing PM file systems cannot efficiently utilize PM in a NUMA setup and incur performance collapse if multiple threads of

[1] In this paper, we use the term "access thread" to denote a thread that directly accesses PM. It could be an application thread or a kernel thread.

the application (*e.g.*, file server software and video streaming software) access PM concurrently.

This paper presents OdinFS: (Opportunistic DelegatIoN File System), a NUMA-aware PM file system that maximizes PM performance by controlling concurrent accesses, minimizing the NUMA impact, and parallelizing PM accesses to utilize the aggregated bandwidth. To design OdinFS, we first holistically analyze the behavior of existing PM file systems on an eight-socket NUMA machine. We analyze two issues specifically: maintaining maximum PM performance within a NUMA node and minimizing the PM NUMA impact. For the first issue, we find that both read and write performance of PM collapse with high thread counts, while prior work only reports the write performance collapse [14, 43]. For the second issue, we provide a detailed analysis and quantitatively confirm that placing the access threads in the same NUMA node as PM minimizes the NUMA impact.

Motivated by our performance analysis, we design OdinFS with three major design goals: (1) **Limit concurrent PM accesses (access arbitration)**: OdinFS controls the number of PM access threads to maintain the maximal PM performance within a NUMA node. (2) **Localized PM accesses (NUMA-awareness)**: OdinFS ensures threads always access the local PM within a NUMA node, thereby avoiding the PM NUMA impact. (3) **Automatic parallel PM accesses (automatic parallelization)**: OdinFS automatically parallelizes applications' PM access requests across all NUMA nodes without application modification. OdinFS thus efficiently utilizes aggregated PM bandwidth, thereby improving application performance.

OdinFS achieves these goals by proposing a new approach—***opportunistic delegation***—that decouples PM data accesses from application threads. Specifically, on each NUMA node, OdinFS creates multiple background kernel threads (delegation threads) that access PM on behalf of the application threads. Therefore, OdinFS limits the maximum concurrency within PM by controlling the number of delegation threads. Moreover, the delegation threads are local to each NUMA node, leading to NUMA-aware localized accesses. OdinFS thus departs from the conventional NUMA-mitigation approaches in PM file systems that mainly involve data or thread migration.

Furthermore, the delegation threads enable servicing bulk data requests by efficiently utilizing aggregated PM bandwidth across all NUMA nodes. Specifically, OdinFS first stripes the file data across PM in all NUMA nodes. Exploiting the well-designed system call interface, OdinFS services data system calls (*e.g.*, `read()` and `write()`) by transparently dividing them into multiple disjoint access requests based on the stripe size and sending such access requests to the corresponding delegation threads. The delegation threads thus access PM in different NUMA nodes in parallel to serve the system call. We further enhance OdinFS with fine-grained parallelism for data operations. Our evaluation shows that OdinFS outperforms other file systems by up to 32.7× for real-world workloads and has up to two orders of magnitude performance improvement for scalability microbenchmarks.

This paper makes the following contributions:

- **Analysis.** We thoroughly analyze the behavior of existing PM file systems on a large NUMA machine and reveal two new findings.
- **Opportunistic delegation.** We propose an opportunistic delegation scheme for PM file systems that decouples PM data accesses from application threads, thus efficiently utilizing both local and remote PM.
- **OdinFS** We design and implement OdinFS: a PM file system that builds on the opportunistic delegation scheme with state-of-the-art concurrency control mechanisms. OdinFS maximizes the performance and further scales data operations with increasing threads.

2 PM Performance Analysis

Prior study has shown that the underlying architecture of PM is quite complicated [39], and PM has limited bandwidth and higher latency compared to DRAM [14, 40]. Moreover, naively utilizing PM in NUMA machines often underutilizes PM or leads to performance collapse [14, 25, 27, 38]. To showcase the issues of concurrent NUMA accesses in PM, we first provide an overview of the current hardware (§2.1). We then analyze why existing PM file systems fail to handle many concurrent requests (§2.2) and the impact of different types of accesses in a NUMA machine (§2.3).

2.1 Intel Optane internals

The Intel Optane [8] PM is the only publicly available nonvolatile memory technology so far. A memory controller accesses PM at the granularity of a cache line (64 bytes). However, the access size of the internal 3D-Xpoint storage media is 256 bytes. Such an access size mismatch results in read or write amplification. The 3D-Xpoint media includes a buffer (*XPBuffer*) and an associated prefetcher (*XPPrefetcher*) to address this issue and mitigate its long latency. The XPBuffer combines adjacent accesses to PM, and the XPPrefetcher prefetches blocks in the 3D-Xpoint media to XPBuffer based on the access pattern. In addition, the 3D-Xpoint media also stores the inter-NUMA node coherence information [6, 27]. Hence, inter-NUMA accesses may involve writing to the 3D-Xpoint media to update the coherence information, which is the root cause of the slow inter-NUMA PM accesses (§2.3).

2.2 Concurrent accesses to PM

Prior work [14, 43] finds that PM performance depends on the access size and the number of concurrent access threads. The impact of access size is well understood. Applications accessing PM perform well as long as the access size is large enough to stress all the interleaved PM DIMMs. To understand the impact of concurrent access threads, we run `fio` [4], in which each pinned thread sequentially accesses a private 1GB file at a 2MB granularity. We evaluate on an eight-socket

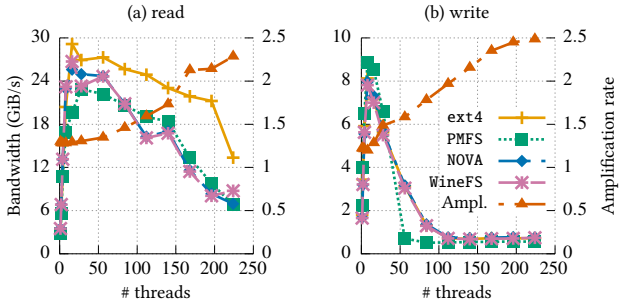

Figure 2: PM read and write bandwidth of PM file systems with increasing threads for sequential 2MB access size. Results show that both read and write performance collapse after exceeding a specific limit. We observe a dramatic increase in read/write amplification due to cache thrashing in the PM storage device.

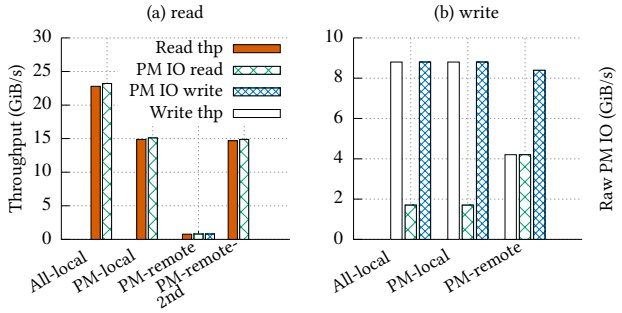

Figure 3: Application throughput and the raw PM I/O for reading data from PM (left) and writing data to PM (right) with the same workload in §3.6 and the following configurations. *All-local*: Access threads, PM, and DRAM (I/O buffer) are in NUMA node 0. *PM-local*: Access threads and PM are in NUMA node 0; DRAM is in NUMA node 1. *PM-remote*: PM is in NUMA node 0; access threads and DRAM are in NUMA node 1. *PM-remote-2nd*: A consecutive run with *PM-remote*.

NUMA machine, with each socket having six interleaved Optane DIMMs and a processor with 28 cores.

Figure 2 shows the read and write bandwidth of PM file systems with increasing threads. Both read and write reach their peak bandwidth with sixteen and eight threads, respectively. After that, increasing threads severely degrades the overall bandwidth. Specifically, with 224 threads, the read and write bandwidth degrades by 3.7× and 17.2× compared to the peak bandwidth, respectively.

Such performance collapse occurs because high concurrent accesses thrash the underlying cache of PM.[2] Specifically, a mismatch exists between the CPU access size (64 bytes) and the underlying PM storage access size (256 bytes). PM minimizes the read/write amplification overhead by batching writes (XPBuffer) and prefetching (XPPrefetcher) (§2.1). However, with high concurrent accesses, the sequential accesses from different threads convert into non-adjacent accesses. These accesses arrive at the PM simultaneously, which reduces the efficiency of both caching and prefetching. As a result, it increases read and write amplification, as XPBuffer cannot keep up with the requests and the underlying PM media latency starts to dominate for fetching or writing data, leading to performance collapse. The read collapse threshold is higher than write since reads perform better than writes with the 3D-Xpoint media. Thus, PM can sustain the read bandwidth despite reducing caching and prefetching efficiency up to two NUMA nodes.

We find that both read and write bandwidth crashes after a certain point. The results for writes are consistent with prior works [14, 43]. However, we find that read bandwidth also starts to collapse after two NUMA nodes. This is contrary to prior work, which reports that the read bandwidth scales with increasing threads.

Insight #1. A file system must control the number of threads that concurrently access PM for both reads and writes to preserve the maximal performance within a NUMA node.

[2]We verify that the performance collapse is not due to the scalability bottleneck in the file systems by confirming that most of the CPU cycles are spent in accessing PM.

2.3 NUMA impact on PM

We now analyze the NUMA effect on PM. `WineFS` [25] proposes to migrate a thread to a PM NUMA node to mitigate the NUMA impact [25]. Unfortunately, there is no in-depth analysis of the effectiveness of this mechanism. Specifically, suppose a thread copies data between remote PM and local DRAM. In this case, migrating the thread to the respective PM NUMA node still involves remote memory access, and thus it is not clear why or how the thread migration can improve performance.

We answer the aforementioned question by investigating the performance impact of NUMA placements of thread, DRAM, and PM. We configure `fio` with three setups. In the *All-local* setup, threads, PM, and DRAM (*i.e.*, I/O buffer) are in the same NUMA node (node 0), which serves as the best-case scenario. In the *PM-local* setup, threads and PM are in the same NUMA node (node 0), while DRAM is in a remote NUMA node (node 1). In the *PM-remote* setup, PM is in NUMA node 0, while threads and DRAM are in the same NUMA node (node 1). We evaluate this experiment using `PMFS` with 28 threads for read and 8 threads for write. Other file systems or thread counts produce similar results.

Figure 3 shows the PM read and write throughput with the three setups. We note that both *PM-local* and *PM-remote* perform the same task of copying data between PM on NUMA node 0 and DRAM on NUMA node 1. However, *PM-local* achieves nearly 19.1× and 2.1× higher throughput than *PM-remote*. Furthermore, *PM-local* achieves 60% and almost 100% of *All-local* read and write throughput, respectively. The above results are due to the implementation of the *directory coherence protocol* in Intel machines [6, 27]. Specifically, Intel maintains intra-NUMA and inter-NUMA directory information separately [5]. The processor cache and memory store the intra-NUMA directory and inter-NUMA directory information, respectively. With the *PM-local* setup, the PM cache blocks become NUMA-local: data is written to the processor

cache; while the DRAM cache block moves between NUMA nodes. Hence, the system updates the PM directory locally, while writing to DRAM to update its directory information. However, with the *PM-remote* setup, the processor updates DRAM directory information on the processor cache, while updating its directory information on PM. Hence, the performance difference between DRAM and PM leads to the performance difference between *PM-local* and *PM-remote*.

To verify the above claim, we used Intel PCM [7] to measure the PM device level read/write IO, as shown in Figure 3. For *All-local* and *PM-local*, the total bytes written and read from the PM device match the actual I/O bandwidth, indicating no directory information update. However, *PM-remote* incurs extra read and write traffic to the PM device. Furthermore, a consecutive read with *PM-remote* (*PM-remote-2nd*) can restore the performance, while a consecutive write in *PM-remote* still suffers from NUMA impact. The above evidence confirms that *PM-remote* involves directory coherence updates. Specifically, the extra read and write traffic is due to updating the coherence information. The *PM-remote-2nd* setup can only restore the read performance since, in this case, coherence information update is not needed for read but is still required for write. In summary, our performance analysis quantitatively confirms that placing the access threads and PM in the same NUMA node minimizes the NUMA impact on PM.

Insight #2. To minimize the pronounced PM NUMA impact, and efficiently utilize remote PM, a file system should place the access threads local to the PM.

3 OdinFS Design

Following our performance analysis on PM (§2), we present OdinFS, a NUMA-aware PM file system that maximizes PM performance within and across NUMA nodes through opportunistic delegation. This section first presents the design goals that enable OdinFS to maximize PM performance (§3.1), an overview of OdinFS (§3.2), followed by the design of each individual component.

3.1 OdinFS Design Goals

We design OdinFS to meet the following goals:

- **Limiting concurrent PM access (access arbitration).** To avoid the PM performance collapse with many concurrent PM accesses (§2.2), OdinFS should limit the concurrency to maximize PM performance within a single NUMA node.
- **Localized PM access (NUMA-awareness).** To avoid the performance collapse due to the PM NUMA impact, OdinFS only allows threads to access local PM (§2.3). This minimizes the PM NUMA impact and opens the opportunity for OdinFS to utilize remote PM efficiently.
- **Automatic parallel PM access (automatic parallelization).** The access arbitration and NUMA-aware design goals allow OdinFS to maximize the local and remote PM performance. To fully benefit from the aggregated PM bandwidth, OdinFS further parallelizes large PM accesses across all NUMA nodes automatically without application changes.
- **Scalability.** Scalability is the overarching goal of OdinFS. Modern machines have multiple NUMA nodes and hundreds of CPUs. The above three design goals allow OdinFS to scale PM performance with an increasing core count. Beyond that, OdinFS should maximize concurrent accesses within the same file.

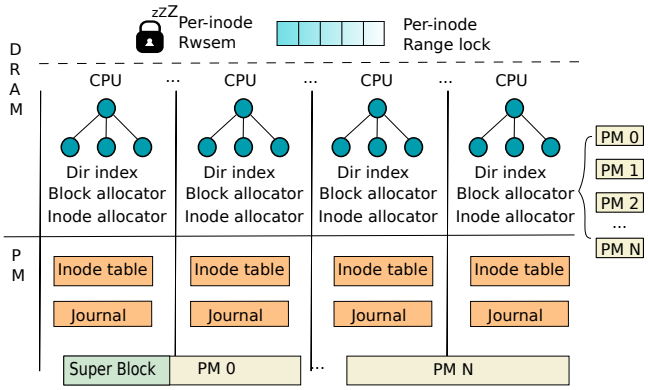

Figure 4: OdinFS architecture. OdinFS maintains per-CPU data structures to minimize the synchronization overhead. Furthermore, OdinFS maintains the directory index, block allocator, and inode allocator in DRAM to maximize performance. OdinFS enhances the per-inode readers-writer semaphore with our optimized range lock to increase concurrency.

3.2 OdinFS Architecture

Figure 5 shows the key components of OdinFS and their typical workflow. We next present the key design of OdinFS and explain how they meet the design goals of OdinFS (§3.1).

(1) NUMA-striped data layout for cumulative PM bandwidth utilization. Unlike other NUMA-aware PM file systems that try to localize file accesses within a single PM NUMA node [25, 42], OdinFS stripes the data of every file across PM on each NUMA node in a round-robin manner. OdinFS makes this design choice since it can minimize the PM NUMA impact *with delegation*, as detailed below. Furthermore, stripping file data across PM enables OdinFS to exploit all available PM bandwidth to handle application requests, which opens the door for automatic request parallelization.

(2) Delegation-based PM accesses to maximize PM performance. A key insight in OdinFS is that the access arbitration, NUMA-awareness, and automatic parallelization design goals can be simultaneously achieved by decoupling PM data accesses from application threads through delegation. In particular, for each NUMA node, OdinFS creates several background threads (delegation threads). Only the delegation threads can access PM. When the application thread needs to access PM, it first checks which NUMA node the PM address belongs to and then sends the PM access requests to one of the delegation threads on that NUMA node. The delegation thread performs the access on behalf of the

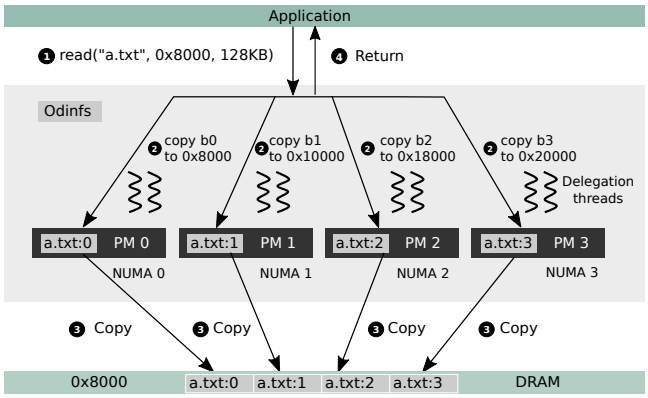

Figure 5: Overview of Odinfs. Each NUMA node has delegation threads that access local PM on behalf of application threads. Odinfs stripes the file data across all PM NUMA nodes. ❶ An application thread issues a read system call. ❷ Odinfs divides the system call into multiple access requests based on the stripe size and sends them to the delegation threads. ❸ The delegation threads read from PM in different NUMA nodes in parallel to service the access requests. ❹ The application thread returns.

application thread and informs the application thread when the access completes.

Since only the delegation threads can access PM, they effectively act as a central entity to *arbitrate* PM access. Regardless of the application thread count, delegation threads decide the level of concurrent accesses to PM. Thus, Odinfs accesses PM with a thread count that avoids the PM performance collapse with many concurrent access threads (§2.2). This effectively achieves the *arbitration* design goal. Since the delegation threads are in the same NUMA node as PM, Odinfs always access PM locally, in either *All-local* or *PM-local* setup (§2.3). Thus, Odinfs minimizes the PM NUMA impact, achieving the *NUMA-aware* design goal.

(3) Automatic parallelization at the system call boundary. The data striping and the delegation threads allow Odinfs to serve IO requests from applications in parallel across all the NUMA nodes. Moreover, the POSIX interface enables Odinfs to *automatically* parallelize the requests without modifying applications. Specifically, Odinfs divides all data system call (*e.g.*, `read`, `write`, `pread`, `writev`) requests into multiple independent sub-requests based on the stripe size, and sends them to the corresponding delegation threads. The delegation threads then execute these requests by accessing PM in different NUMA nodes in parallel. Figure 5 illustrates the case. In this way, Odinfs achieves the *automatic parallelization* design goals.

(4) High scalability with full PM performance. Delegating PM access allows Odinfs to maximize PM performance. Odinfs further maximizes concurrent accesses to ensure applications can benefit from the performance gains even under the high contention case. Specifically, most existing PM file systems globally protect the inode [2, 17, 25, 41]. Odinfs further increases the disjoint data access parallelism with a readers-writer range lock for each inode. This enables concurrent writes to disjoint regions and concurrent reads from the same file region. The use of range lock poses a significant challenge for enforcing crash consistency. Odinfs overcomes this issue by preserving the whole inode lock and falling back to it for concurrency control if needed. (§3.7).

Odinfs design novelty. To the best of our knowledge, Odinfs is the first PM file system that addresses the goal of access arbitration and automatic parallelization. While some NUMA-aware file systems mitigate PM NUMA impact [25], they either move computation to data [25], or move data to computation [42]. Odinfs proposes a fundamentally different approach by using the delegation to minimize the NUMA impact. Furthermore, Odinfs extends the scope of the NUMA-aware file systems. Instead of focusing only on minimizing the NUMA impact, Odinfs takes a radical approach of parallelizing and striping data across all PM NUMA nodes for the best performance. Moreover, our controlled PM access approach also minimizes I/O amplification (§2.2), leading to low write amplification. Lower write amplification further increases the life of the PM device and minimizes the long latency that happens due to wear leveling [39].

3.3 Handling system calls

Odinfs is a POSIX-compliant in-kernel file system. A key novelty in Odinfs is the PM access delegation. However, since delegation incurs communication overhead, Odinfs does not delegate small PM accesses (§3.5). As a result, the delegation threads only perform data operations, while the metadata operations (*e.g.*, `open`, `close`) are handled by application threads. Furthermore, application threads directly access PM for small data operations.

Handling bulk data operations with delegation. After issuing a data system call (*e.g.*, `write`) and entering into the kernel space, the application thread divides the requests into multiple sub-requests, each consisting of a data stripe (§3.4). For each access request, the application thread walks the indexing structure and obtains the corresponding address on PM and the NUMA domain. It then enqueues the request (*e.g.*, source and destination memory address, access length) on a corresponding ring buffer of the PM NUMA node. After enqueueing all requests, the application thread waits for delegation threads to complete and then returns to the user space. Meanwhile, a delegation thread receives the request via the ring buffer. The delegation thread dequeues the request and accesses PM on behalf of the application thread by copying the data between PM and the specified DRAM buffer. After completing the request, the delegation threads notify the application threads.

3.4 NUMA-aware PM allocation

NUMA-aware allocator. To operate on multiple PM NUMA nodes and stripe file data across them (§3.2), Odinfs designs a NUMA-aware PM allocator. Odinfs inherits the performant and scalable allocator design from `NOVA` and `WineFS` and ex-

tends the allocator design to handle multiple PM NUMA nodes. OdinFS uses a per-CPU allocator residing on DRAM, in which each CPU owns multiple private PM pools, each corresponding to one PM NUMA node (Figure 4). Block allocation works as follows: The allocator receives the allocation request with a block size and a NUMA node as arguments. It first tries to serve the request from its own per-CPU PM pool. If that fails, it tries to serve the requests from the pool in the specified NUMA node having the largest free space. If both attempts fail, the allocator returns an error.

Layout policy. OdinFS employs different layout policies for file data, indexing structure, and other metadata. OdinFS stripes the file data across all PM NUMA nodes to enable parallel access (§3.2). Since OdinFS does not delegate small PM accesses (§3.5), it optimizes for small files by placing the first stripe of each file in the local PM node as the creation thread, if possible. This assumes that the following accesses are likely from the same NUMA node thanks to temporal locality. OdinFS places the remaining stripes in a round-robin fashion across all PM NUMA nodes. With our system, the memory controller in each NUMA node interleaves six PM DIMMs at 4KB granularity. Therefore, we set the stripe size as 32KB to maximize PM performance. Since OdinFS does not delegate access to the indexing structure, OdinFS places it in PM local to the CPU that creates the file, leveraging temporal locality. Regarding other metadata, OdinFS places the superblock in the first PM NUMA node and per-CPU metadata (*e.g.*, journaling) in the local PM node (Figure 4).

3.5 Opportunistic delegation

Since delegating PM accesses involves communication overhead, it is not always beneficial, especially for small accesses. Thus, OdinFS performs opportunistic delegation only for PM accesses that might improve the performance. Based on our performance analysis (§2), OdinFS uses different delegation policies for PM reads and writes.

Write access. OdinFS always delegates write accesses with an access size larger than 256 bytes (XPBuffer size) to limit the performance collapse and minimize the NUMA impact.

Read access. Unlike writes, OdinFS chooses a more relaxed policy for delegating reads. Specifically, PM read performance starts to collapse with a high thread count (> 56). Furthermore, the PM read performance can be restored after repetitive remote reads (PM-remove vs. PM-remote-2nd in Figure 3). Thus, OdinFS checks the number of threads that read from each PM NUMA node for every fixed interval. If it finds that for one PM NUMA node, the number of threads is constantly higher than the collapse threshold (56), OdinFS arbitrates access to that PM device by using the same policy as write. Otherwise, OdinFS only delegates the read accesses that may benefit from the automatic parallelization (*i.e.*, those with access size larger than the stripe size: 32KB). We find this policy is enough to achieve good performance.

Saving CPU cycles. A delegation thread uses a variant of the spin-then-park strategy to 1) avoid wasting CPU cycles when there is no request and 2) minimize the long latency due to naively parking and waking up threads [26]. OdinFS uses the IO size of application threads as a heuristic to decide the length that a delegation thread should spin before parking. The spinning is inversely proportional to the IO request size. For example, for large IO requests, delegation threads spin for a shorter duration because they can amortize the parking/wake-up latency by handling long requests. On the other hand, delegation threads spin for a longer duration for small IO requests, since we assume that application threads are likely to issue sparse requests in this case. We find that this heuristic works well for every evaluated workload.

3.6 Concurrency control

Prior in-kernel PM file systems [17, 25, 41] rely on VFS's inode lock for concurrency control. Inspired by recent works [12, 36], OdinFS increases fine-grained access to a file with a per-inode readers-writer range lock. The lock allows parallel writes to disjoint regions, while concurrent reads on the same region in a file. The existing concurrency control mechanisms still protect other operations.

3.7 Crash consistency

Consistency mode. OdinFS currently supports two consistency modes: POSIX and sync [24]. The POSIX mode guarantees that all metadata operations are synchronous and atomic (*e.g.*, `ext4`). The sync mode is the default setup that in addition to POSIX mode, further ensures that all data operations are synchronous but not atomic. Specifically, when the system call returns, the data is guaranteed to persist on PM. However, a crash may cause data operations being partially completed. This provides the same guarantee as `PMFS` and the "relaxed mode" of `NOVA`. If required, we can extend OdinFS to provide other consistency modes [24, 25, 41].

Atomic updates and per-CPU journaling. OdinFS provides metadata crash consistency with atomic updates [17] and per-CPU journaling [41]. Intel architecture only supports 8 bytes as atomic updates and (aligned) 16 bytes with the double compare-and-exchange operation. OdinFS leverages this to update simple metadata whenever possible. For complex metadata updates, OdinFS leverages journaling for crash consistency. Note that OdinFS does not need to journal file data for its current consistency models. OdinFS inherits the per-CPU undo journal design from `WineFS` [25]. As detailed below, OdinFS ensures a file can only be in one per-CPU journal at any time. Hence, OdinFS can recover from the per-CPU journals by using a global transaction ID.

Ensuring crash consistency with range locks. Since the range lock allows multiple threads to access the same file (§3.2), ensuring crash consistency becomes a challenge. OdinFS addresses this issue by maintaining an invariant that a file can only be in one per-CPU journal. The key idea is that if a thread performs any operation that requires jour-

naling, it must acquire the writer lock of the whole inode lock for exclusiveness, even if this may reduce concurrency. Specifically, we classify data operations into three types: *read*, *overwrite* (writes to an existing file block), and *unallocated write* (writes to an unallocated file block, such as appending a file or writing to holes in a sparse file). Only the metadata stored in the inode, such as access or modification time, needs to be updated for read and overwrite. Following PMFS strategy, OdinFS stores these fields in a 16-byte PM block and updates them atomically without journaling. Hence, OdinFS can allow concurrent reads and overwrites to the same file. However, an unallocated write updates both inode and multiple blocks in the indexing structure and thus requires journaling. Hence, OdinFS only allows one thread to perform unallocated write at a time to maintain the invariance.

Thus, for reads, OdinFS acquires the reader lock of the whole inode lock and reader lock of the relevant range in the range lock. For writes, OdinFS distinguishes between overwrite and unallocated write. OdinFS first acquires the reader lock of the whole inode lock and walks the indexing structure to identify whether the write involves writing to unallocated blocks. No journaling is required if the write only updates allocated blocks (*i.e.*, overwrite). Hence, the thread can proceed by acquiring the writer lock of the relevant range in the range lock. Otherwise, it is an unallocated write and requires journaling. The thread then upgrades from the reader lock to the writer lock of the whole inode lock to ensure the inode is only in one per-CPU journal.

4 OdinFS implementation

File system implementation. We modify and extend PMFS [17] to design and implement OdinFS, while also referring to NOVA [41] and WineFS [25]. In summary, the inode table consists of multiple blocks forming a linked list. The directory data structure is similar to a linked list. The indexing structure of a regular file is a B-tree. Crash consistency is achieved with atomic updates and undo journaling (§3.7). OdinFS maintains the inode allocator, block allocator, and cached directory entries in DRAM with red-black trees. The state of the inode and block allocator needs to persist across power cycles. Thus, OdinFS writes their state to PM during unmount and reads from PM during mount. Upon crash, OdinFS recovers the state by scanning used inodes and their indexing structures. To minimize the synchronization overhead, inode allocator, block allocator, inode table, and journaling use per-CPU data structures. To handle complex metadata operations, such as `rename` or `mmap`, OdinFS follows PMFS by using the synchronization mechanisms in both VFS and the file system. We implemented OdinFS as a kernel module for the 5.13.13 Linux kernel and thus, its deployment challenges and manageability are similar to other in-kernel file systems. OdinFS is publicly available at https://github.com/rs3lab/Odinfs.

Efficient communication with delegation threads. Application and delegation threads communicate via a ring buffer (§3.3). To minimize communication overhead, we adopt the scalable ring buffer implementation from Solros [32]. Furthermore, each delegation thread has its private ring buffer to reduce the contention. The application threads send requests to a random delegation thread in the target NUMA node to load balancing delegation threads. We choose this algorithm since it incurs minimal runtime overhead without central coordination while achieving good performance. For PM access request notification, we use a pair of per-NUMA counters: issued counter and completed counter. The application thread increases the issued counter for each request, and sends the pointer of the completed counter. After issuing all the requests, the application thread waits until the number of issued request count on each NUMA node equals the per-NUMA completed count, which is atomically updated by delegation threads.

Accessing userspace memory via delegation. Delegation threads do not have access to the application address space, even though both of them are in the kernel space when handling a system call. We resolve this issue by first letting the application thread pre-faults and pins the user buffer pages in the kernel. It then passes the user buffer along with its root page table information (`mm->pgd`) to the delegation thread. Upon receiving the request, the delegation thread walks the page table for each user buffer page to figure out the physical page. Since the Linux kernel maps all physical pages into its address space linearly, the delegation threads can obtain the corresponding kernel virtual address by adding an offset. The delegationt threads can then access the user buffer with the kernel virtual address.

Minimizing synchronization overhead. To achieve the scalability design goal (§3.1), OdinFS further adopts state-of-the-art synchronization mechanisms to minimize the synchronization overhead. Specifically, OdinFS enhances the readers-writer range lock (§3.6) with BRAVO [15]. BRAVO optimizes the reader side performance of a readers-writer lock by leveraging a hash table, thus avoiding updating the shared reader counters. As discussed in §3.7, since a thread only acquires the writer lock of the whole inode lock for unallocated-write, we use the readers-writer semaphore in [30] for the whole inode lock. The per-CPU readers-writer semaphore optimizes the reader side performance of the semaphore with a per-CPU counter.

CPU usage fairness with delegation. To ensure fairness, OdinFS charges the request serving time of delegation threads to the application thread. Specifically, the application thread passes a pointer to its CPU usage time (`vruntime`) in each request, and the delegation threads thus atomically update it accordingly.

Implementation limitations. In the current implementation, we pin each delegation thread on a particular CPU.

Furthermore, with the current Linux scheduler, if application threads are also pinned to the same CPU, both the delegation and the application threads' performance will degrade. We plan to explore a lightweight and more efficient thread scheduling algorithm to address this issue.

5 Evaluation

We evaluate OdinFS by answering the following questions:

- How does opportunistic delegation affect OdinFS' performance? (§5.2)
- What is the I/O amplification factor of OdinFS? (§5.3)
- Does OdinFS scale with different delegation thread counts and PM NUMA nodes? (§5.4)
- Does OdinFS scale data operations? (§5.5)
- How does OdinFS perform with real-world applications? (§5.6)

5.1 Evaluation methodology

Evaluation environment. We conduct our evaluation on an eight-socket server. Each socket equips a 28-core Intel Xeon processor (224 cores in total) and six 128GB Intel Optane DIMMs interleaved at 4KB (768GB on each NUMA node). The machine has a total DRAM size of 768GB, with two A100 and two A5000 Nvidia GPUs. The server is running Linux kernel v5.13.13 and hyper-threading is disabled.

OdinFS configuration and target comparisons. Unless otherwise mentioned, we configure OdinFS to run on all eight NUMA nodes with twelve delegation threads on each NUMA node. We evaluate and compare OdinFS with four PM file systems: `ext4` [2], `PMFS` [17], `NOVA` [41], and `WineFS` [25]. We configure `ext4` with the DAX option and all the other file systems with the default setup. They provide weaker or the same level of consistency as OdinFS (§3.7). Since these four file systems operate on a single PM NUMA node, we further include one setup: `ext4(RAID0)`. Specifically, we create a RAID0 across all eight PM NUMA nodes using dm-stripe [1] and mount `ext4` on top of it. We cannot run RAID0 with the other file systems because unlike `ext4`, other PM file systems access the PM storage device by memory mapping it into the kernel address space and accessing it with load and store. The RAID0 device created by PM block devices does not support memory mapping to the kernel address space. Because of this, existing PM file systems crash at the time of mounting.

To the best of our knowledge, `ext4(RAID0)` is the only available setup that utilizes all the PM NUMA nodes.[3] However, we further emulate a non-existent setup: `NOVA(MN)` (`NOVA` with multiple nodes) to estimate the performance of a NUMA-aware `NOVA`. Specifically, we mount a single instance of the `NOVA` file system on each NUMA node and evenly distribute the testing files among instances.

Workload. Our workloads include a wide range of file system use cases, covering both data- and metadata-intensive ones. For microbenchmarks, we chose `fio` [4] and FxMark [31] to measure throughput, latency, and scalability, respectively. We configure `fio` to let each thread access a 1GB private file. We only show the results of sequential access due to space limitations and confirm that random access yields similar results. We evaluate `fio` with both small (4KB) and large (2MB) access sizes. For macrobenchmarks, we use Webserver, Fileserver, Videoserver, and Varmail in Filebench [3] and DNN checkpointing.

[3] `WineFS` crashed when mounting on multiple PM NUMA nodes on our server.

5.2 Throughput and latency

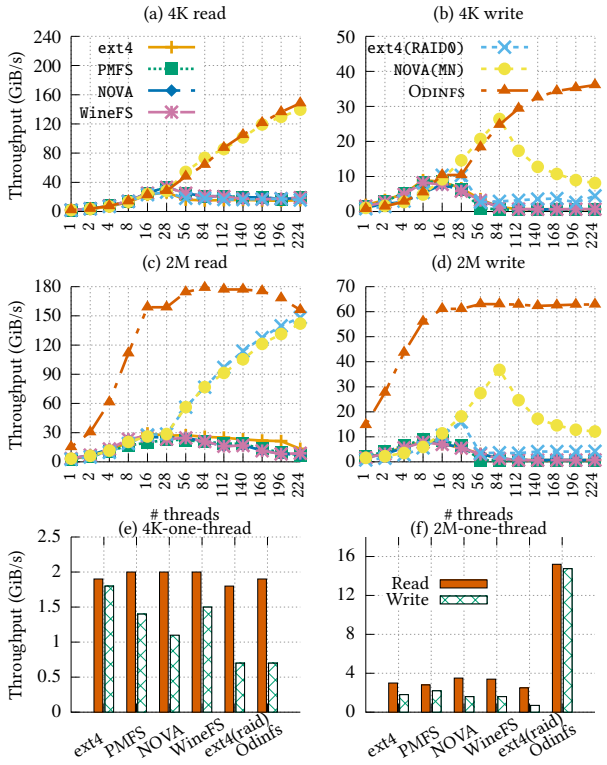

Figure 6: Throughput of evaluated file systems with up to 224 threads. OdinFS scales and outperforms others by up to 24.7×, as it utilizes all PM NUMA nodes and controls concurrent PM accesses.

Throughput. We use `fio` to evaluate OdinFS's throughput and latency. Figure 6 shows the throughput of all evaluated file systems. For `4K-read`, when the thread count is low ($\leq$ 28), all the evaluated file systems perform similarly. However, only OdinFS and `NOVA(MN)` scale beyond one NUMA node, outperforming other file systems by 9.4× with 224 threads. For `4K-write`, when the thread count is less than eight, OdinFS suffers from the communication overhead due to delegation and is up to 62% slower than other file systems. However, when the thread count reaches a certain threshold, the throughput of `ext4`, `PMFS`, and `NOVA` starts to collapse due to the reducing efficiency of XPBuffer and XPPrefetcher (§2.2). Instead, OdinFS can maintain its throughput thanks to limiting PM accesses, outperforming others by up to 8.1×.

With the 2MB access size, OdinFS benefits from accessing all PM NUMA nodes in parallel to serve IO requests. As a result, OdinFS outperforms other file systems even with a

low thread count. OdinFS allows applications to utilize most PM bandwidth with eight threads for write and 28 threads for read. OdinFS similarly scales both read and write throughput, outperforming other file systems by 1.1× to 24.7×, and up to 14.8× for `2M-read`, and `2M-write`, respectively. The throughput drop in OdinFS with `2M-read` is likely due to the increasing contention in the ring buffer or the shared counters §4. We plan to address this issue by investigating mechanisms to further increase the scalability of the communication mechanisms.

OdinFS scales because (1) OdinFS utilizes all the PM NUMA nodes in the system , and (2) it limits the number of PM access threads to avoid the performance collapse. `ext4(RAID0)` and `NOVA(MN)` similarly utilize all the PM NUMA nodes and thus performs closest to OdinFS. However, `ext4(RAID0)` and `NOVA(MN)` only scale read operations. `ext4(RAID0)` cannot scale `4K-read` due to a scalability bottleneck in small reads (§5.5). With `2M-read`, they only reach the throughput of OdinFS with a high thread count.

Summary: For small I/O requests, OdinFS incurs overhead with a small thread count but preserves PM performance with a large thread count. For large I/O requests, OdinFS benefits from handling them by paralleling accesses to PM NUMA nodes. This allows an application to utilize most of the PM bandwidth even if it has a small thread count. In summary, OdinFS scales both read and write operations for both small and large I/O sizes.

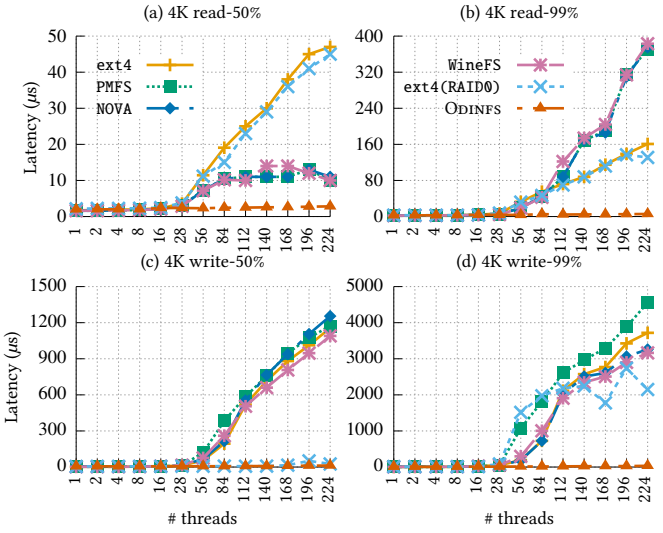

Figure 7: The median and 99 percentile latency of the evaluated file systems with a 4KB access size. OdinFS constantly maintains the low latency due to delegating PM accesses, avoiding the performance collapse within and across NUMA nodes.

Latency. Figure 7 presents the mean and the 99 percentile latency of all the evaluated file systems. For all the other file systems, increasing threads lead to either contention on PM or suffering from PM NUMA impact, resulting in skyrocketing latency. Thanks to delegation, OdinFS constantly maintains low latency. Its median and 99 percentile are 2.8µs and 5.7µs for `4K-read`, 5.4µs to 12.0µs and 6.3µs to 32.4µs for `4K-write`, respectively, outperforming the other file systems by up to 190×. OdinFS consistency has lower latency than `ext4(RAID0)`. The lowest median latency of other file systems is 1.6µs for `4K-read` and 2.6µs for `4K-write` with one thread. However, their latency quickly worsens after sixteen read threads and eight write threads. With a 2MB access size, the trend is similar. The performance advantage of OdinFS is even higher due to parallelization.

Summary : Delegating PM accesses enables OdinFS to maintain low latency.

5.3 IO amplification

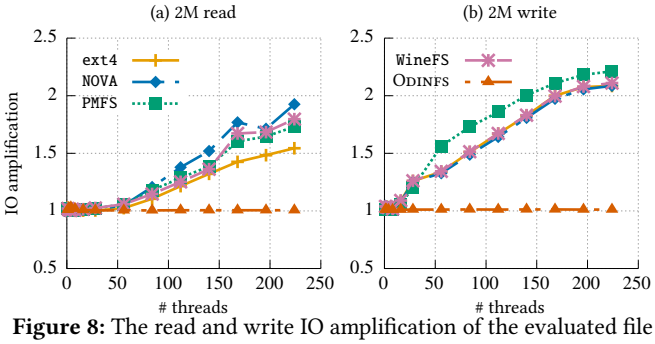

Figure 8: The read and write IO amplification of the evaluated file systems. OdinFS achieves low IO amplification since delegation maintains the caching/prefetching efficiency.

The conventional wisdom is that IO amplification is relevant for traditional storage devices (especially SSD) but not for PM since it is byte-addressable. However, due to the access size mismatch between the memory controller and the PM storage media, PM also suffers from IO amplification if the internal caching/prefetching becomes inefficient (§2.2). A high IO amplification reduces the PM lifetime and causes a latency spike triggered by the internal wear-leveling operation [43]. Thus, a PM file system must reduce it.

We report the I/O amplification as the number of bytes read from (or written to) the underlying PM media divided by the number of bytes requested (or issued) by the CPUs. We use Intel PMWatch [9] to obtain the relevant data. Figure 8 shows the I/O amplification for different file systems with the same setup in §5.2. OdinFS constantly achieves a low IO amplification (*i.e.*, less PM-level IO incurred for the same workloads) with increasing threads since delegation limits concurrent accesses and thus preserves the caching/prefetching efficiency. All other file systems suffer from a high IO amplification rate (*i.e.*, more PM-level IO incurred for the same workload), validating their low throughput (Figure 6) and high latency (Figure 7).

Summary : I/O amplification is still relevant for PM. OdinFS maintains a balance of amplification and high PM utilization. Our delegation scheme limits concurrent accesses, which maintains the caching/prefetching efficiency.

5.4 Sensitivity analysis

This section presents how delegation thread counts and PM NUMA nodes affect OdinFS's performance. We use the same experimental setup in §5.2.

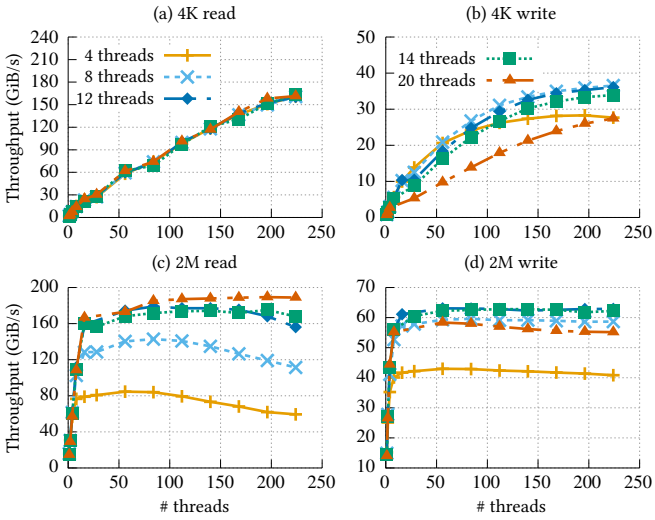

Figure 9: OdinFS's throughput with different delegation threads.

OdinFS with varying delegation threads. The optimal number of delegation threads for OdinFS depends on many factors, such as the relative speed between the processor and PM. Thus, we run experiments that vary the delegation thread counts to find the optimal one for our system.

Figure 9 shows the results. With `4K-read`, the delegation thread counts have no impact because OdinFS does not delegate read accesses (§3.5). With `2M-read`, the throughput is close to being saturated with twelve delegation threads but continues to increase until twenty delegation threads. With `4K-write` and `2M-write`, the throughput of OdinFS increases with up to eight or twelve delegation threads, respectively. Hence, we chose twelve delegation threads as the default setup for OdinFS since it performs well in all four setups.

Summary : The optimal delegation thread number in OdinFS depends on many factors and thus should be decided with experiments. Twelve delegation threads achieve a balanced performance in our system.

OdinFS with varying PM NUMA nodes. Figure 10 shows OdinFS's throughput with a different number of PM NUMA nodes. For `4K-read`, OdinFS enables delegation to prevent throughput collapse after 56 threads with one PM NUMA node and 112 threads with two PM NUMA nodes (§3.5). For the other three setups, OdinFS always delegates PM accesses. The results show that (1) OdinFS can maintain the throughput with a high thread count for different numbers of PM NUMA nodes, and (2) OdinFS scales PM performance with increasing PM NUMA nodes.

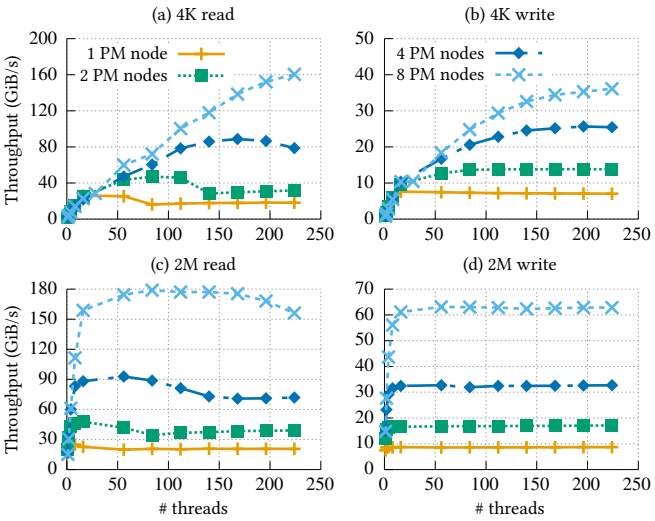

Figure 10: OdinFS with different numbers of PM NUMA nodes.

Name	Description
`DRBL`	Each thread reads a private block in a private file.
`DRBM`	Each thread reads a private block in a shared file.
`DRBH`	Each thread reads a shared block in a shared file.
`DWOL`	Each thread overwrites a private block in a private file
`DWSL`	Same as `DWOL` plus an `fsync()` after each writes
`DWAL`	Each thread appends to a private file
`DWOM`	Each thread writes to a private block in a shared file

Table 1: Summary of microbenchmarks in the FxMark suites [31]. Each thread repetitively performs the corresponding operations in each microbenchmark.

Summary : OdinFS scales PM performance with increasing PM NUMA nodes because of its efficient delegation scheme, showing the generality of its design.

5.5 Datapath scalability

To test whether OdinFS achieves the scalability design goal, we evaluate it with FxMark [31] microbenchmark suites. OdinFS mainly focuses on data operations and partially reuses the scalable data structures in `NOVA` and `WineFS` for metadata scalability. Hence, we focus on evaluating the scalability of data operations. Table 1 summarizes the FxMark microbenchmarks used in the evaluation. We use all the data operation microbenchmarks from FxMark except `DWTL`, where each thread concurrently truncates a private file; `DWTL` does not involve typical data operations (*i.e.*, read or write), and thus we view it as a metadata microbenchmark.

Figure 11 shows the scalability results of the evaluated file systems. Among the compared file systems, only `PMFS` and `NOVA` can scale one microbenchmark: `DRBL`. Instead, OdinFS scales all seven evaluated microbenchmarks. For read microbenchmarks, OdinFS is 12% slower than `PMFS` in `DRBL`. However, OdinFS outperforms other file systems by around 233× and 269× in `DRBM` and `DRBH`, respectively. For `DRBM` and `DRBH`, all other evaluated file systems suffer from the

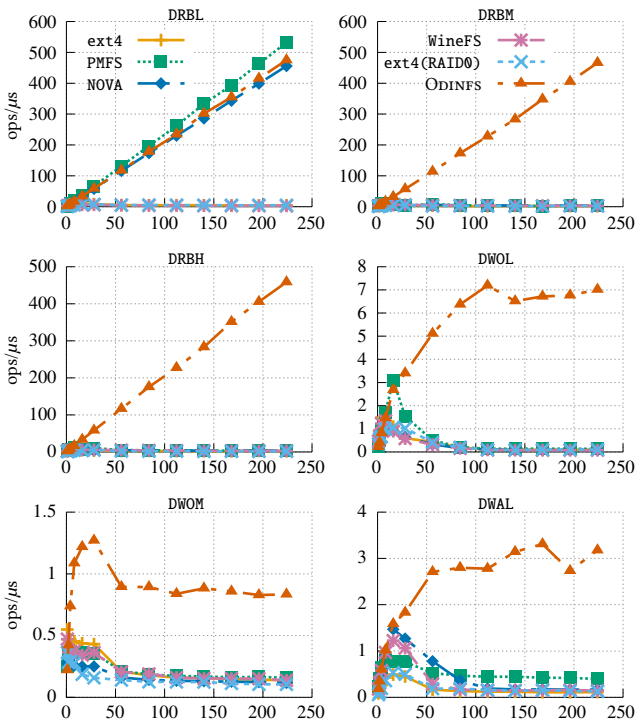

Figure 11: Scalability of data operations with the evaluated file systems. DWSL is not shown since its result is the same as DWOL. Other evaluated file systems only scale DRBL while OdinFS scales all microbenchmarks, thanks to controlling PM accesses, scalable metadata structures and concurrency control mechanisms, and the unique readers-writer range lock.

default readers-writer semaphore implementation in the Linux kernel, resulting in high locking overhead. The scalability of OdinFS comes from the unique scalable synchronization mechanisms (per-CPU readers-writer semaphore and BRAVO on top of the range lock) that minimize the synchronization overhead (§3.6, §4).

For write microbenchmarks, OdinFS outperforms other file systems by 53.8×, 8.2×, and 8.3× in DWOL (DWSL)[4], DWAL, and DWOM, respectively. OdinFS scales DWOL and DWSL due to arbitrating PM accesses and thus prevents performance collapse caused by concurrent writes. OdinFS scales DWOL due to arbitrating PM accesses and the scalable allocator design. In addition to arbitrating PM accesses and the scalable allocator, OdinFS scales DWOM with the readers-writer range lock.

Summary : While other evaluated file systems only scale DRBL, OdinFS scales all seven evaluated microbenchmarks with PM access control, scalable metadata structures, scalable concurrency control mechanisms, and the unique readers-writer range lock.

Name	# Files	Avg. file size	I/O size (r/w)	R/W
Fileserver	10K	2MB	1MB / 256KB	1:2
Webserver	20K	4MB	1MB / 256KB	10:1
Videoserver	226	512MB	1MB / 1MB	27:1
Varmail	100K	16KB	1MB / 16KB	1:1

Table 2: Configuration of the Filebench workloads. Fileserver, Webserver, and Videoserver is data-intensive with large I/Os. Varmail is metadata-intensive with small I/Os, representing the worst case for OdinFS. Webserver and Varmail are write-intensive while Fileserver and Videoserver are read-intensive.

5.6 Macrobenchmarks

We use a set of benchmarks from Filebench [3] as macrobenchmarks to evaluate OdinFS. We select four benchmarks: Fileserver, Webserver, Videoserver, and Varmail with configurations shown in Table 2. We configure Fileserver, Webserver, and Videoserver to work on relatively large files, reflecting the trend of growing sizes with these types of files. Varmail works on a large number of small files and performs small IO, representing the worst case for OdinFS. Webserver and Videoserver are read-intensive while Fileserver and Varmail are write-intensive. For Videoserver, since not all the threads are doing the same task, we measure the overall read and write throughput. For the other benchmarks, we measure the number of operations per second.

Figure 12 shows the result. For Fileserver, OdinFS outperforms other file systems by 4.8× to 25.3×. For Webserver, OdinFS outperforms all the single PM file systems and ext4(RAID0) by at least 3.8× and 1.6× to 3.1×, respectively. For Videoserver, OdinFS outperforms single PM file systems by around 6.6× and at least 5.4× for read and write throughput, respectively. OdinFS outperforms ext4(RAID0) by up to 2.3× for read throughput and around 7.3× for write. For these benchmarks, OdinFS's performance advantage comes from delegating PM accesses to preserve the maximum performance and utilizing the bandwidth of all the PM NUMA nodes. For read-intensive benchmarks: Webserver and Videoserver, ext4(RAID0)'s performance matches OdinFS with large thread counts, which is consistent with results in §5.2. However, OdinFS still outperforms ext4(RAID0) by 1.6× with 224 threads for Webserver. ext4(RAID0) achieves the same read throughput for Videoserver with high thread counts. However, this is because OdinFS still maintains around 4GiB/s write throughput while ext4(RAID0) completely starves the write threads.

Varmail is the worst case for OdinFS since delegating small I/Os incurs large communication overhead. However, the results show that OdinFS can maintain the similar performance as NOVA and WineFS. OdinFS outperforms PMFS, ext4, and ext4(RAID0) by 6.0× to 32.7×. The performance advantage of OdinFS, NOVA, and WineFS comes from the scalable

[4]The DWSL result is the same as DWOL since all evaluated file systems treat fsync() as a no-op.

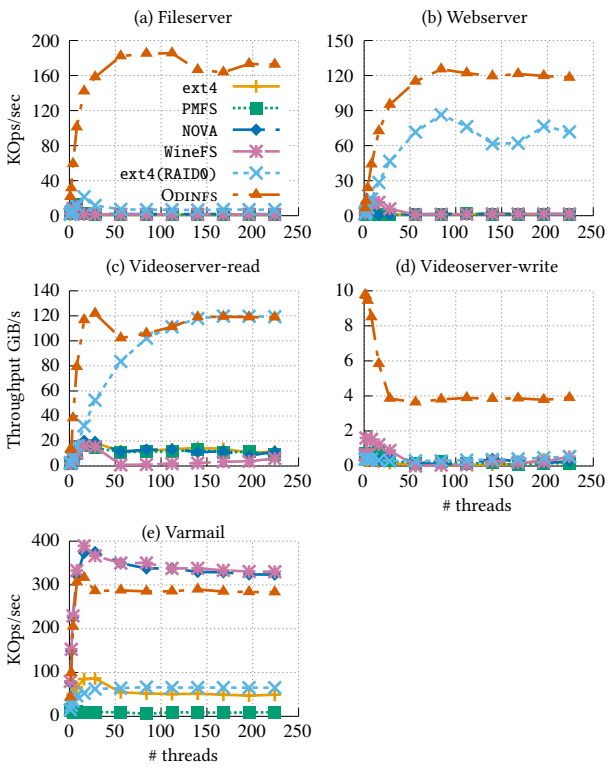

Figure 12: Results of the Filebench benchmarks. See Table 2 for configurations. Results show that OdinFS continue to scale PM performance with macrobenchmarks. OdinFS behaves the same as NOVA in the worst-case scenario: Varmail.

metadata structures (*e.g.*, in-memory directory indexing and per-CPU inode table).

Model	VGG16-ImageNet1K	BERT-SQuAD
Frequency (Steps/ckpt)	34	86
Checkpoint Size (MB)	1055	3828

Table 3: Machine learning checkpointing workloads setup. We use the same frequencies as [33]. A step refers to a training mini-batch.

Machine learning checkpointing. We also evaluate OdinFS with deep neural networks (DNN) checkpointing. DNN training is a time-consuming process and thus must checkpoint its state into persistent storage for fast failure recovery [33]. PM allows high frequency checkpointing and thus minimizes the window of losing work. Table 3 lists models and datasets we use. We measure the end-to-end execution time of training one epoch with checkpointing and the time spent in the file systems. Figure 13 shows the result. OdinFS results in end-to-end execution time reduction over the evaluated file systems by at least 2.6% on VGG16 and 12.3% on BERT. When looking into the time spent in the file systems, OdinFS outperforms evaluated file systems by at least 3.9× on VGG16 and 5.7× on BERT.

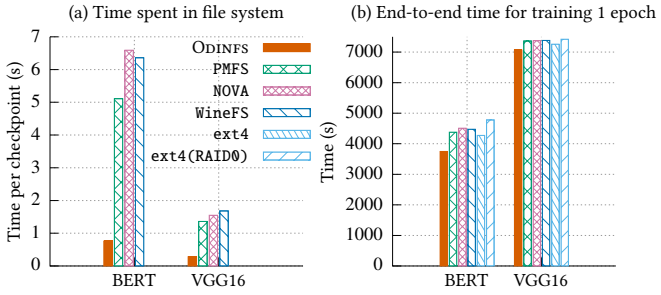

Figure 13: Machine learning checkpointing benchmark.

Summary : OdinFS continues to scale PM performance with macrobenchmarks. OdinFS achieves similar performance to state-of-the-art PM file systems in its worst-case scenario.

6 Discussion

6.1 PM I/O scheduling

The Videoserver result in §5.6 indicates that PM file systems similarly need to employ I/O scheduling as traditional file systems do to, for example, ensure fairness among applications [21, 44]. An I/O scheduling algorithm can be implemented in the system call, page cache, or block layer. Prior research has shown that an I/O scheduling algorithm is more effective if implemented across the various layers of the storage stack [44]. Existing PM file systems [2, 17, 25, 41] bypass the page cache and access PM directly with loads and stores. Hence, they can only implement the I/O scheduling algorithm in the system call layer, limiting the effectiveness of the scheduling algorithm.

Since OdinFS forces application threads to delegate bulk PM accesses to the delegation threads, the delegation threads thus become a central entity to access PM, acting similarly to the block layer in the traditional storage stack. Hence, the delegation enables OdinFS to perform I/O scheduling in both the system call layer and block layers. Exploiting this unique feature, we plan to extend OdinFS to support various I/O scheduling algorithms to ensure fairness or prevent head-of-line blocking to further improve its performance.

6.2 Comparison against RAID0

OdinFS's data layout policy is similar to RAID0 in that it stripes data across multiple PM NUMA nodes in a round-robin manner (§3.4). However, unlike RAID0, OdinFS employs PM-specific optimizations for small files (*i.e.*, put the first file stripe in the local PM of the creation threads). Furthermore, OdinFS stripes in the file level while RAID0 stripes in the disk level. OdinFS thus maximizes parallelization by ensuring adjacent file stripes are highly unlikely in the same PM NUMA node.

A fundamental difference between OdinFS and RAID0 is that OdinFS delegates PM access. As discussed across the paper, this enables OdinFS to avoid the bandwidth collapse with many access threads, minimize the PM NUMA impact,

and access PM in parallel, thus maximizing the PM performance. A typical RAID0 implementation achieves none of the above tasks. As a result, OdinFS consistently outperforms `ext4(RAID0)` with the evaluated benchmarks (§5).

6.3 Applicability to future PM hardware

Two of OdinFS's design goals: localized PM access and access arbitration, are based on the current implementation of PM hardware (§2). Although there is a possibility that future PM hardware may mitigate the above issues, we believe that many of OdinFS' designs will remain effective. Specifically, the PM NUMA impact is mostly due to the implementation of directory coherence information. Some of the recent Intel two-socket machines support snoop protocol for PM, and a prior work [27] has reported that the snoop protocol can significantly mitigate the PM NUMA impact. However, we find that many (large) multi-socket machines, only support directory coherence protocol. Hence, we believe that localized PM access is still a practically important design consideration.

Excessive concurrent access leads to performance collapse since it renders the on-DIMM caching and prefetching inefficient (§2.2). Furthermore, the access size mismatch between the CPU (64 bytes) and the underlying storage media (256 bytes) exacerbates the performance collapse. It also reduces the lifetime of the PM device due to the incurred I/O amplification. While it is difficult to predict the feasibility of changing the PM access sizes in future PM hardware, we expect that such changes would be non-trivial, especially making the PM access size as small as the CPU access size. This would require changes to other critical components in a PM DIMM, such as the address indirection table (AIT) and the DIMM-level prefetching logic. Furthermore, despite the reduced PM access size, limiting concurrent access might still be needed to avoid the performance degradation caused by DIMM-level cache thrashing.

In summary, we expect that both localized PM access and access arbitration will still be relevant for future PM hardware. Moreover, since OdinFS only incurs a small delegation overhead, it provides a "cost-effective" solution to the above problems without hardware changes. In addition, OdinFS' automatic parallelization design will remain useful to utilize the aggregated PM bandwidth across NUMA nodes without modifying the application code. We believe that the automatic parallelization design can be further generalized to other present or future storage systems (*e.g.*, CCIX-based storage systems [13]).

7 Limitations

Extra CPU usage. OdinFS's design incurs additional CPU usage due to parallelizing large PM accesses and the communication between the application thread and the delegation thread. OdinFS's current design reduces the CPU usage by pausing the delegation threads if there is no incoming request (§3.5). In addition, OdinFS can further trim down the CPU usage by (1) offloading PM accesses to I/OAT DMA and (2) disabling the delegation when there is no idle CPU on one NUMA node.

Stripping overhead. OdinFS stripes the data of a file across all NUMA nodes so that even a single-threaded application can benefit from the aggregated PM bandwidth through automatic parallelization (§3.2). However, since the stripping often involves remote access, while the delegation mechanism already significantly mitigates the NUMA impact, the stripping may reduce the best-case throughput and latency. Specifically, without stripping, a best-case scenario occurs when the application and the PM data are in the same NUMA node. However, benefiting from such a scenario requires extra code development to remember the NUMA node where the data resides and pin application threads to the NUMA node, which also limits scheduling flexibility.

If an application does not benefit from the automatic parallelization and wishes to enjoy the best-case performance, we expect OdinFS can work without stripping by placing the data of a file on a single NUMA node. In this case, OdinFS still achieves the other two design goals: (1) limiting concurrent accesses and (2) minimizing the PM NUMA impacts. Large I/O accesses can still be parallelized to one NUMA node but not all NUMA nodes as before.

Memory mapping. Due to stripping, OdinFS's memory mapping (mmap) performance is lower than other single-NUMA-node PM file systems in the best-case scenario as described above. To optimize this, OdinFS can use a copy-then-mmap model similar to `NOVA` [41]. Specifically, upon `mmap`, OdinFS allocates PM pages in the same NUMA node, copies the file content in remote NUMA nodes to these pages, and `mmap` the PM pages to the applications. Upon `msync` or `munmap`, OdinFS propagates the changes in the replicated PM pages back to the files.

8 Related work

PM file system. Unlike OdinFS, most existing PM file systems are designed to work on a single PM NUMA node and do not limit the number of access threads [12, 16, 17, 24, 28, 34, 41], leading to PM performance collapse. In terms of NUMA-aware PM file systems, Xu *et al.* proposed a new `ioctl` command that allows applications to specify the preferred NUMA node of a file [42]. This approach requires application changes and relies on the application to avoid the NUMA impact. `WineFS` [25] assigns a home NUMA node to each application thread and migrates the thread to the home NUMA node before writing to PM. As acknowledged by the authors, thread migration is expensive. Furthermore, it still suffers from the NUMA impact when two threads from different home nodes share the same file. Unlike OdinFS, none of these works focuses on utilizing both local and remote PM simultaneously as OdinFS does. `ext4(RAID0)` [1, 2] does not control the number of access threads nor resolve the PM NUMA impact, leading to lower performance than OdinFS in most cases.

Other NUMA-aware PM systems. PACTree uses the snoop protocol to minimize the PM NUMA impact [27]. However, the snoop protocol is unlikely to scale on large NUMA machines and may thus impact the performance of memory-intensive applications. Nap caches frequently accessed items in DRAM to avoid remote PM accesses [38]. However, Nap relies on a skewed access pattern to benefit from caching and still suffers from the PM NUMA impact upon cache misses. OdinFS proposes a fundamental different approach that uses delegation to address the PM NUMA impact.

Scalable file system. There are scalable file systems for both traditional storage devices [11, 30, 36] and PM [12, 41]. NOVA designs several scalable metadata structures, and OdinFS inherits them. Similar to OdinFS, there are file systems scaling the data operations with range locks [12, 36]. The closest work to OdinFS is KucoFS [12]. KucoFS is a PM file system that scales metadata operations through bypassing the VFS and scales data operations with range locks and versioned read. However, KucoFS shows that it cannot scale data operation benchmarks in FxMark beyond fifteen threads, while OdinFS scales all of them up to 224 threads. The difference is that (1) OdinFS uses delegation to prevent PM performance collapse while minimizing the NUMA impact. (2) OdinFS uses state-of-the-art concurrency mechanisms which minimize the synchronization overhead.

Localized I/O threads. Since PCIe devices also conform to NUMA topology, utilizing localized I/O threads (*i.e.*, placing I/O threads in the same NUMA code as the I/O devices) is a relatively common design in many non-PM systems [22, 35, 45]. To realize the old wisdom in PM systems, OdinFS has encountered and resolved many unexplored challenges (§3, §4), leading to a design significantly departs from the other PM systems (§3.2).

9 Conclusion

This paper presents OdinFS, a file system that maximizes PM performance in NUMA machines. A key novelty in OdinFS lies in decoupling the PM data accesses from the application threads by offloading them to a set of delegation threads in each NUMA node. Such decoupling simultaneously allows OdinFS to preserve the maximum PM performance with a single NUMA node, efficiently utilize PM in remote NUMA nodes, and service system calls by accessing PM in all NUMA nodes in parallel, thus maximizing the PM performance. OdinFS further includes fine-grained synchronization control mechanisms to scale all typical file system data operations. Extensive evaluation shows that OdinFS constantly outperforms existing PM file systems by several times to orders of magnitude.

Abstract

Non-volatile memory (NVM) has promoted the development of *concurrent crash-consistent* data structures, which serve as the backbone of various in-memory persistent applications. Durable linearizability defines the correct semantics of NVM-backed concurrent crash-consistent data structures, in which linearizability is preserved even in the presence of a crash event. However, designing and implementing a correct durable linearizable data structure remain challenging as developers are to manually control durability (persistence) using low-level cache flush and store fence instructions.

We present DURINN, to the best of our knowledge, the first durable linearizability checker for concurrent NVM data structures. DURINN is based on the novel observation on the gap between linearizability point – when the changes to a concurrent data structure become publicly visible – and durability point – when the changes become persistent. From the detailed gap analysis, we derive three durable linearizability bug patterns that render a linearizable data structure not durable linearizable. To tame the huge NVM states and thread interleaving test space, DURINN statically identifies likely-linearization points and actively constructs adversarial NVM state and thread interleaving settings that increase the likelihood of revealing durable linearizability bugs. DURINN effectively detected 27 (15 new) durable linearizability bugs from 12 concurrent NVM data structures without a test space explosion problem.

1 Introduction

Non-volatile memory (NVM) is becoming widely adopted in various computer systems thanks to its storage-and-memory-like characteristics. Like storage, NVM is persistent across a power cycle and has a high density. Like memory, NVM provides byte-addressability and low-latency properties. A program can persist data in NVM using `load` and `store` instructions without paying storage stack overhead. Notably, Intel's Optane DC Persistent Memory [13, 47] has already been deployed in cloud [3] and supercomputer [2]. ARM also has announced its support for NVM [12, 14]. The upcoming Compute Express Link (CXL) [20] standard introduces cache-coherent CXL-attached NVM card with on-device cache.

The persistence and low-latency properties of NVM have promoted the development of various NVM-backed *concurrent crash-consistent* data structures, which serve as the key enabler of the application-level crash-consistency guarantee. For instance, concurrent NVM hash table is the backbone of NVM-backed `memcached` [7] and `redis` [10]. Concurrent NVM B+tree and hash map are the cores of `pmemkv` [4]. Concurrent NVM B-trees are used in NVM-backed file systems [19, 24–26]. In the event of an application or system crash, or a sudden power failure (a crash hereafter for brevity), an NVM program built on crash-consistent data structures can seamlessly resume its execution from the (recovered) NVM state as if nothing has happened.

Durable linearizability [40] defines the correct semantics of NVM-backed concurrent crash-consistent data structures, as linearizability [33] is the norm correctness standard for traditional (non-NVM) concurrent data structures. At a high level, durable linearizability requires that the effects of completed operations before a crash should remain completed and visible (like linearizability). Additionally, durable linearizability requires that the operation upon a crash be either fully executed ("all" semantic) or not at all executed ("nothing" semantic). However, designing and implementing correct durable linearizable data structures remain very challenging.

The fundamental challenge in developing a durable linearizable NVM data structure lies in *the gap between the linearization point (visibility) and the durability point (persistence).* Concurrent data structures use a synchronization operation (*e.g.*, `compare-and-swap` (`CAS`) in lock-free ones and `lock`/`unlock` in lock-based ones) as *the linearization point* to make one thread's effect visible to other threads. However, the completion of a synchronization operation does not guarantee durability. When the new value of a store (or `CAS`) instruction reaches a cache, it becomes visible, but it is not yet durable until it is written back to the NVM. A data staying in a volatile

cache[1] (as a dirty line) is lost upon a crash, and a cache may evict cache lines in an arbitrary order that is different from the program (store) order. As a result, *the durability point* may come later in time and may appear in a different order with respect to the preceding stores within the same thread or the remote loads from other threads. To ensure durable linearizability, developers have to manually control durability using cache line flush and store fence instructions (*e.g.*, `clwb` and `sfence` in x86 architecture), making durable linearizable NVM programming error-prone.

Unfortunately, existing solutions are not sufficient in testing durable linearizability of concurrent NVM data structures. Prior linearizability testing tools [15, 63] do not consider crash and recovery semantics. NVM-specific crash consistency testing tools either require user-defined custom oracles [22,31,35,43,45,46,51] or are limited to single-threaded NVM programs [30]. It is non-trivial to extend them for durable linearizability because testing space grows exponentially in two dimensions: *crash states* and *thread interleaving*.

This paper presents DURINN, an active and scalable durable linearizability checker for concurrent NVM data structures. DURINN is based on the novel observation on the gap between linearizability point where the changes to a data structure becomes visible and durability point where the changes become persistent and thus remain visible even after a crash. After analyzing what could go wrong if a crash occurs before, after, or between the linearizability and durability points, we derive three durable linearizability (DL) bug patterns that render a linearizable data structure not durable linearizable.

To tame the huge test space, DURINN uses two novel techniques: 1) *adversarial crash state and thread interleaving construction*, and 2) *likely-linearization point inference*. DURINN serves as an adversary of the three DL bug patterns, and actively constructs adversarial crash scenarios that specify which stores to (or not to) persist and which thread interleaving to consider. The intuition behind adversarial crash state construction is to maximize the difference between a constructed crash state and a consistent state preserving DL conditions, thus increasing the likelihood of revealing DL bugs. Furthermore, DURINN employs static program analysis to identify *likely-linearization points* and focuses on testing a program crash before and after those linearization points.

We evaluate DURINN with 13 concurrent NVM data structures, which are highly optimized for NVM and have shown to be more scalable than (simple) NVM hash tables and B-trees used in `memcached`, `redis`, `pmemkv`, etc. DURINN detected 27 (15 new) durable linearizability bugs in 12 data structures. 7 of 15 new bugs have been confirmed by the developers so far. Our evaluation also shows that DURINN can detect concurrent DL bugs (better detection effectiveness) with fewer tests (better scalability), compared to Witcher [30], the state-of-the-art NVM crash-consistency bug detector.

[1] We discuss the implications of (future) persistent cache later in §7.2.

The paper makes the following scientific contributions:

- We present three durable linearizability bug patterns after performing detailed analysis on how a linearizable data structure may violate durable linearizability.
- To our best knowledge, DURINN is the first durable linearizability checker designed for concurrent NVM data structures. The proposed adversarial crash state and thread interleaving construction and likely-linearization point inference allow DURINN to detect DL bugs in an active and scalable manner.
- DURINN reports 27 (15 new) bugs and outperforms the state-of-the-art NVM testing tool in terms of bug detection effectiveness and test space reduction.

2 Background

In this section, we first provide background on linearizability (§2.1) and durable linearizability (§2.2), and then discuss the persistence model used in this paper (§2.3).

2.1 Linearizability

Linearizability [33] is the widely-used correctness standard for concurrent data structures. Formally, linearizability is defined over an existence of an equivalent legal sequential history. Informally, a concurrent data structure is *linearizable* if each operation appears to take effect instantaneously at some moment between the operation begin and end events. If one operation precedes another, then the earlier operation must have taken effect before the next one. If two operations overlap, then their order can be serialized in any arbitrary order. Some pending operations can be thought to be complete.

A *linearization point* (LP) is a program point where an operation takes effect and its effects become visible to other operations. In a lock-based data structure, a critical section (or an `unlock` point) often serves as the linearization point. In a lock-free data structure, the linearization point is typically a single-step atomic instruction (*e.g.*, `CAS`) that makes its change visible to others. We refer to the variable used to make an operation's effect visible as a *synchronization variable* (SV). Atomically updating SV is a linearization point for a writer operation (*e.g.*, `insert`), while reading SV is a linearization point for a reader operation (*e.g.*, `get`).

2.2 Durable Linearizability

Durable linearizability [40] extends linearizability with the notion of a crash. With durable linearizability, a history may include a system-wide crash event (which does not belong to a specific thread) in addition to the operation begin and end events. The definition of precedence order is also extended to incorporate a crash. In durable linearizability, an operation makes its effects visible to others at the linearization point (like linearizability). Additionally, an operation makes its effects persisted at the *durability point* (DP) so that its effects remain completed and visible after a crash.

A *completed operation* refers to an operation whose instructions are all executed, end event is observed, and result

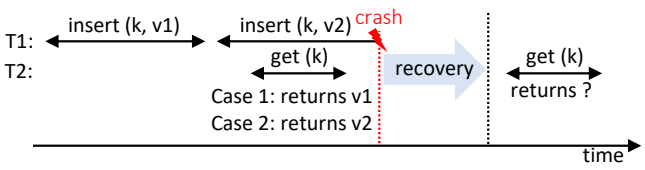

Figure 1: Durable linearizability example. The result of the second `get` (after a crash) depends on the result of the first `get` (before a crash), which also determines if the crashed `insert` takes effect.

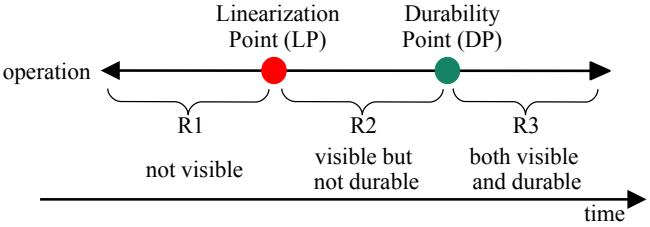

Figure 2: Linearization point and durability point split an operation into three-time intervals as per its visibility and durability guarantees.

is returned. Some crash-consistent programs that can recover from inconsistent NVM state using a custom crash consistency protocol may not require a completed operation to be fully durable.

Durable linearizability requires the following conditions:

- **(C1)** Without a crash, all operations are linearizable.
- **(C2)** If a crash happens, all previously completed operations (before a crash) should remain completed and their effects should remain visible after a crash.
- **(C3)** The operations that have not completed upon a crash could be considered either completed or not. When considered completed, its effect should be visible. In other words, the crashed operation should provide all-or-nothing semantics (fully executed or not at all executed).

Figure 1 illustrates a durable linearizable example. Thread `T1`'s first `insert` completes before a crash, so it should remain visible even after a crash by (C2). If `T2`'s first `get` returns `v1` before a crash, the second `get` after the crash could return either `v1` or `v2`, with a flexibility to follow all or nothing semantics in (C3). However, if `T2`'s first `get` returns `v2` (*i.e.*, it completes) before a crash, then the second `get` after the crash should return `v2`, according to (C1) and (C2).

Prior works such as Line-up [15] and Round-up [63] have demonstrated the practicality of (C1) linearizability testing. DURINN assumes a data structure under test is linearizable without a crash, and focuses on checking if it satisfies the (C2) and (C3) conditions in the presence of a crash.

2.3 Persistence Model

This paper assumes a volatile cache. This is the case for the current Intel x86 architecture with Optane NVM [39, 58] and ARM [12, 14]. The future Compute Express Link (CXL) [20] standard also introduces a cache-coherent interconnect and a CXL-attached NVM card with a volatile on-device cache. We will discuss the implications of persistent cache later in §7.2.

Given a volatile cache, dirty cache lines are lost upon a crash. To control durability, Intel provides cache flush instructions such as `clflush`, `clflushopt`, and `clwb`. When the asynchronous flush `clwb` instruction is used for performance, the store fence `sfence` instruction should be used together to ensure the completion of preceding `clwb` instructions [58]. Similarly, ARM supports `dc cvap` cache flush and `dsb` fence instructions [12, 14]. CXL introduces Global Persistent Flush (GPF) to enforce the persistence ordering on emerging CXL-attached NVM card [20].

3 Durable Linearizability Bugs

This section discusses the gap between linearization point and durability point (§3.1), and presents three durable linearizability bug patterns derived from the gap analysis, along with real-world examples detected by DURINN (§3.2-§3.4).

3.1 The Gap Between LP and DP

As illustrated in Figure 2, the duration of an operation can be partitioned into three regions (`R1`, `R2`, and `R3`) based on the linearization point (LP) and the durability point (DP). At LP, the effect of an operation becomes visible to other threads. At DP, the effect of an operation becomes durable (persisted) so that it can survive a crash and remain visible after a crash.

The bug patterns presented in this section assume that LP is known given an operation. We later in §5.2 discuss the static methods we used to identify *likely-linearization points*. For example, a lock-free `insert()` operation often uses an atomic instruction on a synchronization variable to make its effect visible in a single step. The atomic update (*e.g.*, `CAS`) forms LP, and the following cache line flush and fence instructions (*e.g.*, `clwb` and `sfence`) become DP.

The gap between LP and DP leads to different visibility and durability guarantees. Before LP (region `R1`), the effect of an operation is neither visible nor durable. Between LP and DP (region `R2`), the effect of an operation is visible but not durable. After DP (region `R3`), the effect of an operation is visible as well as durable. Durable linearizability defines different correct/wrong behaviors depending on when a crash occurs: after DP (region `R3`), before DP (regions `R1` and `R2`), and between LP and DP (region `R1`). From the classification, we derive the following three DL bug patterns.

3.2 DL Bug Pattern 1: An Incompletely-Durable Bug

The first *Incompletely-Durable* bug pattern considers a crash *after DP* (in region `R3`). As a crash happens after DP, all the changes made by the crashed operation should be completed and persisted as if no crash has happened. In other words, the crashed operation should provide the "all" (fully-executed) semantic guarantee. After resuming from a crash, if another operation may observe *incompletely durable* effects, then it may produce wrong output violating durable linearizability. Figure 3 illustrates the Incompletely-Durable bug pattern. Since the crash happens after DP of `T1`'s `insert(K,V)`, to be

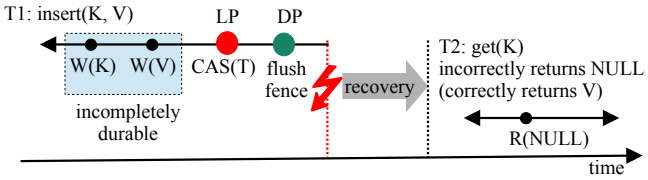

Figure 3: An *Incompletely-Durable* bug pattern. If a crash occurs after DP, the `insert` operation should make all its effects durable completely. Otherwise, the `get` operation after a crash may not be able to see its effect, producing wrong output.

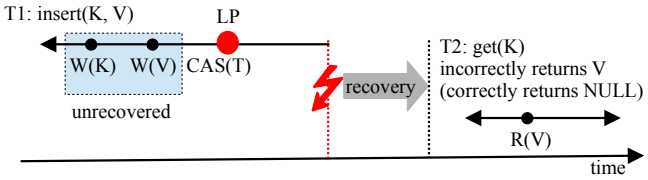

Figure 4: An *Unrecovered-Durable* bug pattern example. If a crash happens before DP, the `insert` operation should recover (undo) any partially durable effect. Otherwise, the `get` operation after a crash may see its partial effect, producing wrong output.

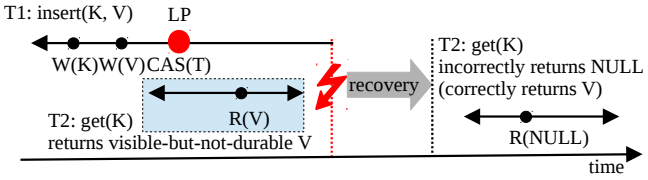

Figure 5: A *Visible-But-Not-Durable* bug pattern. For a crash between LP and DP of `insert`, the concurrent `get` may observe and return the visible-but-not-durable value. However, the second `get` after a crash may not be able to return the same value as the effect of `insert` is not durable.

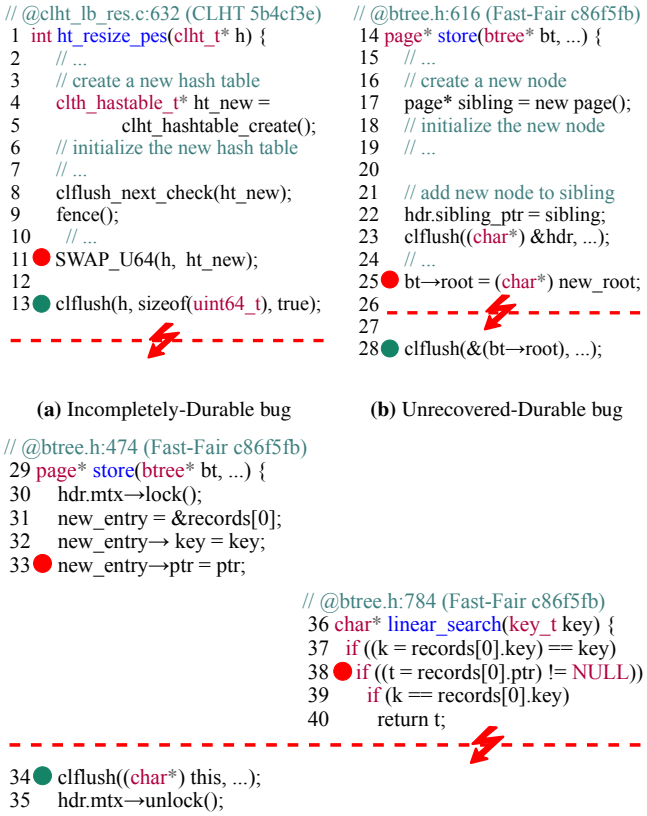

(a) Incompletely-Durable bug

(b) Unrecovered-Durable bug

(c) Visible-But-Not-Durable bug

Figure 6: Durable linearizability bug examples in P-CLHT [44] (a) and Fast-Fair [34] (b) and (c). A red circle represents LP; green represents DP; and a red lightning bolt represents a crash.

durable linearizable, `T2`'s `get(K)` should return `V` after the recovery.

To avoid *Incompletely-Durable* bugs, all the preceding stores must be persisted before the store (or `CAS`) on a synchronization variable becomes persisted (DP), using cache line flush and fence instructions. This is analogous to the linearizability programming idiom in which all the preceding stores must be visible before the store (or `CAS`) on a synchronization variable become visible (LP), using a fence instruction.

Figure 6(a) shows a part of rehashing code in P-CLHT [44], a concurrent NVM hash table. The code first allocates a new hash table (line 4), updates/persists the new hash table (lines 6-7), and then atomically sets the root pointer `h` to the new hash table, making its effect visible (line 11, which is LP). However, `clflush_next_check` at line 8 does not flush all the updated NVM data in the new hash table and leaves a part unpersisted (an Incompletely-Durable bug). If a crash happens after DP – after persisting the root pointer `h` (line 13), the inserted key-value data after a crash may be lost, violating durable linearizability.

3.3 DL Bug Pattern 2: An Unrecovered-Durable Bug

The second *Unrecovered-Durable* bug pattern considers a crash *before DP* (in regions `R1` and `R2`). As a crash happens before DP, any temporal change made by the crashed operation should not be visible after the resumption. That is, the crashed operation should support the "nothing" (not-at-all-executed) semantic. After resuming from a crash, if another operation may observe *unrecovered durable* effects, it may produce wrong output violating durable linearizability. Figure 4 illustrates the Unrecovered-Durable bug pattern. Since the crash happens before DP of `T1`'s `insert(K,V)`, to be durable linearizable, `T2`'s `get(K)` should not return `V` after the recovery.

To avoid *Unrecovered-Durable* bugs, a durable linearizable data structure may opt to buffer/undo the effects of preceding stores before DP, or embed a custom logic to safely ignore partial NVM updates: *e.g.*, read key `K` and value `V` only if token `T` is set. This pattern is called "guarded protection" [30] and we discuss it in detail in §5.2.

Figure 6(b) shows an *Unrecovered-Durable* bug from Fast-Fair [34], a lock-based NVM B+tree. While splitting a node, it first creates a new node (line 17) and initializes the new node

(lines 18-19). Then it adds the new node to the sibling of the current node (line 22) and persists the change (line 23). Later, it sets the new root (line 25, which is LP). The `new_root` in line 25 is the new root node of the B+tree after a node split. The node, which the `hdr` belongs to, is a child of the new root. If a crash happens before persisting the new root node (line 28, DP), the B+tree will be in an illegal state in which the root node has a sibling node. Any further operation leads to a program crash and will lose all previously completed operations, violating durable linearizability.

3.4 DL Bug Pattern 3: A Visible-But-Not-Durable Bug

The last *Visible-But-Not-Durable* bug pattern considers a crash *between LP and DP* (in region `R2`). If a crash happens between them, the effect of the current operation may be *visible but not yet durable*. As it is visible, another concurrent operation can see the effect and take an action based on the observation: *e.g.*, returning a non-durable value.

Figure 5 illustrates an example. While thread `T1` is performing an `insert(K,V)` operation and just finishes executing its LP but not DP, thread `T2` performs a concurrent `get(K)` operation. The concurrent `get(K)` sees the non-durable effect of `insert(K,V)` and returns the value `V`. As the `get(K)` is completed before a crash, to be durable linearizable, `T2`'s second `get(K)` after the recovery should return `V` as well, but it cannot as the effect of `insert(K,V)` has not been persisted. Note that Visible-But-Not-Durable bugs may also occur between concurrent writers, say two `insert(A)` and `insert(B)` operations in a sorted linked list. The later `insert(B)` operation in the linearizable order may see the effect of the earlier `insert(A)` operation, adding `B` after `A`. Durable linearizability may be violated if a crash occurs after `insert(B)` completes but before `insert(A)` finishes.

To avoid *Visible-But-Not-Durable* bugs, an operation (later in the linearizable order) may be designed to wait until the earlier operation passes its DP. Alternatively, a lock-free design may use a "persistence-helping" mechanism [21, 28]. Suppose operation `A` updated `X` but did not persist it yet. Another concurrent operation `B` wants to take actions (*e.g.*, takes a different branch, persists other data) based on the value of `X`. Then `B` "helps" persist `X` on behalf of `A`. If a lock-free data structure does not implement a similar helping mechanism correctly and if `B` relies on unpersisted updates from `A`, then a Visible-But-Not-Durable bug may happen. The helping logic is analogous to the linearizability programming idiom in which one thread helps fix temporal inconsistency on behalf of another thread.

Figure 6(c) shows a *Visible-But-Not-Durable* bug from Fast-Fair [34]. The left code (`store`) and the right code (`linear_search`) are parts of `insert` and `get` operations, respectively. An `insert` operation first acquires the lock (line 30) then writes `key` and `ptr` (lines 31-33). It then persists the writes (line 34) and releases the lock at the end (line 35). Since Fast-Fair allows concurrent (non-blocking) `get` operations while splitting a node, linking a new node is LP for `insert` (line 33). On the other hand, the `get` operation refers to `ptr` (line 38, which is LP for `get`) while checking if there is any key change in-between by reading it twice (lines 37, 39). Suppose `linear_search` is scheduled between the LP (line 33) and DP (line 34) of `store` as shown in the figure. The concurrent `get` operation can read visible-but-not-durable data. If the crash happens before `insert`'s DP (line 34). After the recovery, the previously returned data cannot be accessed anymore because unpersisted data will be lost upon a crash. Thus, Fast-Fair violates durable linearizability.

4 Overview of Our Approach

In this section, we will first discuss the huge testing space as the main challenge in detecting durable linearizability bugs (§4.1). We then provide an overview of our two major techniques – (1) adversarial NVM state and thread interleaving construction (§4.2) and (2) likely-linearization point inference (§4.3) – designed to address the test space challenge.

4.1 Challenges in Detecting DL Bugs

Existing solutions are not sufficient in testing durable linearizability of concurrent NVM data structures. Traditional linearizability testing tools, such as Line-up [15] and Round-up [63], do not consider crash and recovery semantics. Most NVM-specific crash consistency bug detection tools (*e.g.*, Yat [43], PMTest [46], XFDetector [45], Agamotto [51], Jaaru [31], and PMDebugger [22]) are not designed for durable linearizability, and instead require user-defined custom oracles or consistency checkers. Some (*e.g.*, Witcher [30]) are limited to testing single-threaded NVM programs. We discuss related work in detail in §9.

It is non-trivial to extend existing NVM testing tools such as Yat and Witcher for durable linearizability because testing space grows exponentially in two dimensions: *NVM crash states* and *thread interleaving*. The crash state test space is huge since a crash can happen any time during an execution and a volatile cache can evict cache lines in an arbitrary order. For example, Yat [43], an exhaustive crash consistency testing tool, attempts to test 10^{31} crash states for an NVM hash table with 2000 operations [30]. Moreover, the number of thread interleaving grows exponentially (n^k) with the number of threads (n) and the number of steps (k) in each thread.

4.2 Adversarial NVM State and Thread Interleaving

We propose an adversarial technique to effectively explore the huge testing space in finding durable linearizability bugs. Instead of exhaustively or randomly exploring the testing space, we actively construct adversarial NVM states and adversarial thread interleavings, which are likely to trigger the three DL bug patterns discussed in §3. To the best of our knowledge, DURINN is the first work using an adversarial testing approach for bug detection in NVM programs.

Adversarial NVM state construction. For each DL bug pattern and a given crash location (*e.g.*, before or after DP),

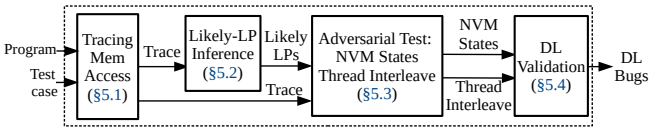

Figure 7: The overall architecture of DURINN.

DURINN determines which preceding stores should be or should not be persisted to increase the likelihood of triggering the DL bugs. For example, when testing an Incompletely-Durable bug after DP, DURINN adversarially constructs the (worst-case) NVM state where an update on a synchronization variable is persisted (at DP) but the preceding stores are not as persisted as possible. This way, DURINN can maximize the incompleteness of durability of a target operation, increasing the chance to break its "all" (fully-executed) semantic guarantee. Note that DURINN constructs only feasible NVM states while obeying the persistence model of a processor and program order semantics (*e.g.*, TSO for x86).

Adversarial thread interleaving construction. DURINN constructs adversarial thread interleaving only when thread interleaving is indispensable to trigger the DL bug patterns. The Incompletely-Durable and Unrecovered-Durable bugs do not require concurrent operations to trigger, so DURINN tests those bug patterns in a single-threaded mode. On the other hand, Visible-But-Not-Durable requires concurrent operations. The main challenge in triggering the Visible-But-Not-Durable bug is that two (or more) concurrent operations must be precisely scheduled in a very narrow window between LP and DP. DURINN adversarially constructs a thread interleaving such that a concurrent operation is scheduled between LP and DP of another operation.

4.3 Likely-Linearization Point Inference

Our adversarial NVM state and thread interleaving construction requires the knowledge of LP locations. Manual annotation of LPs would be error-prone and it makes DURINN not automatic. A naive approach, considering all stores as LPs, would lead to too many tests.

To address the problem, DURINN infers likely-LPs from source code based on the common concurrent NVM programming practices: (1) atomic instructions are used in concurrent programs for synchronization; (2) concurrent programs usually make a memory region visible to other threads after initialing the memory region; (3) NVM programs usually use guarded-protection [30] to ensure persistence atomicity. DURINN employs static program analysis to identify the above programming practices and infer likely-LPs. They are then fed to our adversarial NVM state and thread interleaving construction. The inferred likely-LPs are not necessary to be precise. A false positive LP will only lead to more tests. As far as we know, DURINN is the first work that statically infers linearization points from concurrent NVM programs.

```
// writer
 1  *key_ptr = key;
 2  *val_ptr  = val;
 3  flush(key_ptr);
 4  flush(val_ptr);
 5  fence();
 6
 7  flag = 1; // set guardian
 8  flush(&flag);
 9  fence();

// reader
10  // guardian read
11  if ( flag == 1)
12     func(key_ptr, val_ptr);
```

(a) Guarded-Protection

```
 1  // Memory allocation
 2  Node* new_node = alloc(sz);
 3  // Initialization
 4  new_node→key = key;
 5  new_node→val =  val;
 6  new_node→next = NULL;
 7  flush(&new_node→key);
 8  flush(&new_node→val);
 9  flush(&new_node→next);
10  fence();
11
12  // Add node to the core
13  core→tail = new_node;
14  flush(&core→tail);
15  fence();
```

(b) Publish-after-Initialization

Figure 8: Examples for *Guarded-Protection* and *Publish-after-Initialization* from (a) CCEH [50] and (b) NVTraverse [28]. Likely-linearization points are at line 7 and 13 in (a) and (b), respectively.

5 Design of DURINN

We present the overall architecture of DURINN at Figure 7. DURINN takes as input a target NVM data structure and a test case (a sequence of operations, such as `insert`, `delete`, and `get`) and reports detected durable linearizability bugs. DURINN first instruments a program and runs a test case to collect a memory trace (§5.1). DURINN then infers likely-linearization points from the trace (§5.2). Given the memory trace and the identified likely-linearization points, DURINN performs adversarial NVM state and thread interleaving construction (§5.3) to generate a collection of crashed NVM images and thread schedules to test. Lastly, DURINN validates the generated crashed NVM images along with the generated thread schedules to detect durable linearizability bugs (§5.4).

5.1 Tracing Memory Accesses

DURINN instruments all NVM memory accesses (load, store[2]) and NVM heap allocation. DURINN also traces control flow transfers (branch, function call) because our likely-linearization point inference (§5.2) relies on program dependence analysis. To track the persistent state (*i.e.*, whether an NVM address is persisted or not) for adversarial NVM state construction (§5.3), we instrument all flush and memory fence instructions. We also trace lock operations for adversarial thread interleaving construction (§5.3). For durable linearization validation (§5.4), we trace the value of each store instruction.

We implement an LLVM compiler pass [11] for the instrumentation and execute the instrumented binary with a test case to collect an execution trace. To ensure the total ordering in the execution trace for the analysis of multi-threaded programs, we protect our tracing code using a global mutex.

5.2 Likely-Linearization Point Inference

DURINN infers likely-linearization points by analyzing three concurrent NVM programming practices: *Atomic instruction*, *Guarded-Protection* and *Publish-after-Initialization*.

Atomic Instruction. In lock-free data structures, atomic instructions are typically used to update a synchronization variable and to make the effect of an operation atomically visible to other threads. Thus, DURINN identifies atomic instructions (*e.g.*, `CAS`, `fetch-and-add`) as likely-linearization points for lock-free writer operations (*e.g.*, `insert`).

Guarded-Protection. Guarded protection is a widely used NVM programming pattern (*e.g.*, key-value store, persistent data structure, file systems) to ensure atomic persistence of data [30]. A flag variable called *"guardian"* denotes whether the *"guarded data"* is valid or not. Thus, writing or reading a guardian is a linearization point. In Figure 8(a), for instance, a writer ensures that key and value are persisted before the `flag`, a guardian, is persisted. Also, a reader check if the `flag` (line 11) is set before reading the key and value (*"guarded read"*). Writing to the `flag` (line 7) is writer's linearization point since the changes become visible after setting the `flag`.

Based on this observation, DURINN performs program analysis to identify any stores to guardians. DURINN first finds out the guarded read pattern in the code to identify guardian candidates from conditional branch instructions. From the branch condition variables, DURINN performs the backward dataflow analysis to identify NVM memory addresses that are data-dependent on the branch condition variables. Then DURINN marks the stores to those NVM memory addresses as likely-linearization points.

Publish-after-Initialization. As an optimization to reduce persistence overhead, many NVM program follows so-called publish-after-initialization steps when adding a new memory object in the global data structure: (1) first allocating an NVM memory, (2) initializing the memory, and finally (3) linking (publishing) the memory to the global structure. For example, in Figure 8(b), a node is allocated first (line 2), then initialized (lines 4-10), finally is linked to the global list (`core→tail` at lines 13-15). The benefit of the publish-after-initialization idiom is that any writes to the new memory (lines 4-10) are not externally visible so that the persistence ordering of the writes in the initialization phase is relaxed until the new memory is published (line 13), improving performance (only one `fence` is needed at line 10).

Based on this NVM programming idiom, we filter out all the stores to newly allocated memory regions within an operation, and exclude them from likely-linearization points. We found that this pruning is highly useful for operations requiring many writes, such as node split/merge operations for a tree and a rehashing operation for a hash table.

[2]Non-temporal stores are supported/modeled as store+flush.

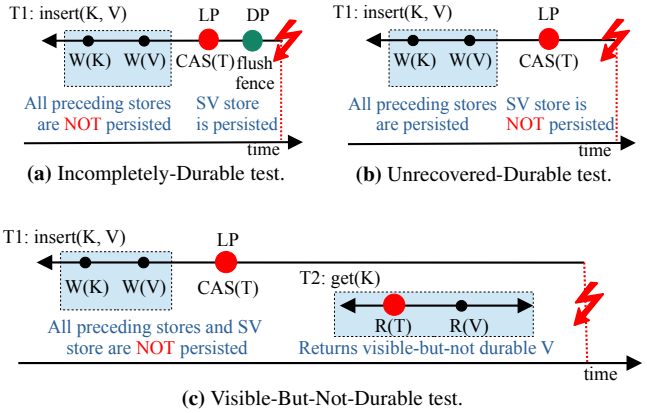

Figure 9: Adversarial test strategies for Incompletely-Durable, Unrecovered-Durable, and Visible-But-Not-Durable bugs. LP: linearization point. DP: durability point. SV: synchronization variable.

5.3 Adversarial NVM State and Thread Interleaving Construction

In this section, we first describe our adversarial construction approaches for each DL bug pattern (§5.3.1, §5.3.2, and §5.3.3). We then introduce our cache/NVM simulations to generate feasible NVM states (§5.3.4) for the validation.

5.3.1 Incompletely-Durable Bug Pattern

Testing Incompletely-Durable bugs can be performed for each operation in isolation without considering concurrent operations. When a crash happens after DP, to be durable linearizable, the crashing operation should provide the "all" (fully-executed) semantic and ensure that its effect remains visible after a crash (Figure 3). Then, the adversarial NVM state that increases the chance to trigger Incompletely-Durable bugs for a crash after DP would be to make all the preceding stores as unpersisted as possible. In other words, we artificially attempt to create a feasible yet worst NVM state that many updates made by an operation are not persisted.

Figure 9a illustrates our adversarial NVM state construction for `insert(K,V)` in which an atomic update to a synchronization variable `T` serves as LP and persisting it serves as DP. The adversarial NVM state would be to make the change to `T` persisted, but leave the changes to key and value unpersisted so that the new key and value data is not visible after a crash even though the synchronization variable `T` says differently. Note that we attempt to leave stores unpersisted only if possible. We do not force. We obey memory consistency and persistence model (*e.g.*, the semantics of fence, flush).

5.3.2 Unrecovered-Durable Bug Pattern

Testing Unrecovered-Durable bugs can also be performed for each operation in isolation. If a crash happens before DP, for durable linearizability, the crashing operation should provide the "nothing" (not-at-all-executed) semantic and ensure that any partial update is not visible after a crash (Figure 4). Then,

the adversarial NVM state that stress-tests the data structure under test to expose Unrecovered-Durable bugs for a crash before DP would be to make all the preceding stores as persisted as possible. That is, we are interested in constructing a feasible yet worst NVM state that many updates made by an operation are persisted, stress-testing its recovery logic.

Figure 9b shows our adversarial NVM state construction for the same `insert(K,V)` example in which `CAS(T)` is LP and persisting it is DP. We construct the adversarial NVM state such that the changes to key and value are persisted, but not the synchronization variable `T`. This way, the new key and value data may be visible after a crash when the synchronization variable `T` says they should not.

5.3.3 Visible-But-Not-Durable Bug Pattern

The Visible-But-Not-Durable bugs are related to the case where an operation takes an action after observing a visible-yet-not-durable state of another concurrent operation (Figure 5). Unlike the prior two bug patterns, testing Visible-But-Not-Durable bugs should be performed in a context sensitive manner. Figure 9c illustrates our adversarial NVM state and thread interleaving method for Visible-But-Not-Durable bugs, which requires the following three conditions.

Requirements. First, DURINN needs *(1) racy operations*. In Figure 9c, thread T1's `insert(K,V)` writes (`CAS`) on `T` and T2's `get(K)` reads `T`. Second, DURINN needs some *(2) prefix operations* (a sequence of other operations to execute before testing racy operations) that construct the preconditions for a race condition to be triggered. For example, an NVM data structure should be in a certain state (*e.g.*, initiating a resizing or node splitting process) to exhibit a race condition. Last, DURINN needs to control *(3) precise thread interleaving* in which a thread makes a progress based on another thread's visible-but-not-durable effect and a crash happens between LP and DP as illustrated in Figure 9c.

Challenges. However, constructing the test scenarios that satisfy all the three conditions is very challenging because not only search space is huge but also the three conditions are inter-dependent. For example, two racy operations with one sequence of prefix operations may not be racy any more with another sequence of prefix operations.

Our Approach. We propose techniques to find out adversarial (1) racy operations, (2) prefix operations, and (3) thread interleaving in a scalable manner by analyzing a *single-threaded* execution trace. Figure 10 shows the overall workflow. First, DURINN detects potentially racy two operation by analyzing a single-threaded memory trace. Second, if two racy operations are not consecutive, DURINN reorders the operations of the test case, places the two operations consecutively, and checks whether the same race can be triggered: *i.e.*, the new memory trace with the re-ordered operations still include the same race. Last, if two re-ordered operations are still racy, DURINN generates adversarial thread interleaving for these two operations. In the rest, we discuss each step in detail.

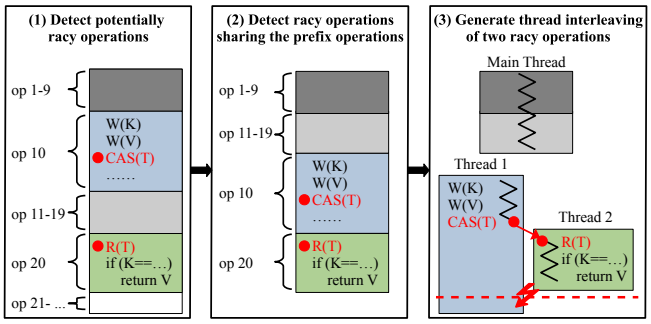

Figure 10: The workflow of adversarial NVM state and thread interleaving construction for Visible-But-Not-Durable bugs.

(1) Finding racy operations. The first step is to find potentially race operations. The inputs for the analysis are a single-threaded execution trace (§5.1) and the inferred likely-linearization points (§5.2). DURINN finds a pair of potentially racy operations that write-write or write-read synchronization variables (updated at likely-linearization points). These two potentially racy operations are not necessary to be consecutive in a single-threaded execution trace. In Figure 10 (1), operation 10 and 20 are such potentially racy operations.

(2) Finding prefix operations. A pair of potentially racy operations from the first step may not be racy when run in parallel. One main reason is that these two operations ran with different preceding operations (*i.e.*, prefix operations). In Figure 10 (1), the prefix of operation 10 is operation 1-9 but the prefix operations of operation 20 is operation 1-19. Hence, the precondition of an NVM data structure when running these two operations may be different, so these two operations may not be racy when run in parallel.

To filter out such spurious racy operations, DURINN reorders operations such that the two operations have the common prefix operations and places two potentially racy operations consecutively. In Figure 10 (2), operations 1-9 and 11-19 becomes the prefix of operation 10 and 20. We then run the instrumented program with the prefix and the two racy operations in a single thread and generate a new execution trace. If two candidates (operation 10 and 20) are still racy with the re-arranged operations, the prefix and racy operations will be fed in to the last step to construct thread interleaving of the two racy operations.

(3) Controlling thread interleaving and generating NVM state. For a given prefix operations, DURINN should precisely control thread interleaving of two concurrent racy operations. For example, in Figure 10 (3), thread 1 writes synchronization variable `T` first, which is LP, then thread 2 preempts and reads `T` then returns `V` to user. A crash should happen right after when the operation in thread 2 finishes and before thread 1 executes DP to trigger a Visible-But-Not-Durable bug.

In order to precisely control thread interleaving, DURINN uses a runtime technique using breakpoints. DURINN sets

breakpoints at the load and store of the synchronization variable (*e.g.*, `T` in Figure 10). After executing the prefix operations in a single-threaded manner, DURINN lets thread 1 run until reaching to the breakpoint of the `store` instruction to the synchronization variable. Then DURINN lets thread 2 run until it reaches the breakpoint of the `load` instruction of the synchronization variable. Then DURINN lets thread 2 resume and injects a crash right after finishing its operation.

Upon the crash, DURINN leaves all stores in thread 1 unpersisted as an adversarial NVM state. Note that thread 2 may not be able to finish its operation if other synchronization with thread 1 is involved (*e.g.*, deadlock). DURINN detects such a case with a timeout, and regards such thread interleaving infeasible. DURINN generates a `gdb` command script to automate the whole process. Using a hardware breakpoint makes DURINN's adversarial thread interleaving control efficent, though DURINN serializes a multi-threaded execution.

5.3.4 Cache and NVM Simulation

DURINN generates NVM crash images according to the adversarial NVM state and thread interleaving testing methods. To consider only feasible NVM states, DURINN simulates cache behaviors while obeying processor's memory consistency and persistence models. DURINN starts from the empty cache and NVM states and simulate the effects of `store`, `flush`, and `fence` instructions along an execution trace. Particularly, we implemented Intel's x86-64 architecture model following total store order (TSO) memory model consistency model [39, 56].

5.4 Durable Linearizability Validation

DURINN runs the NVM data structure under test from an NVM crash image (generated in §5.3) and checks if it violates durable linearizability by executing a sequence of validating operations. At a high level, the validating operations checks whether all operations before crash take effects (DL's C2 condition in §2.2); and whether the crashed operation is either fully executed or not at all executed (C3 condition). DURINN runs recovery code before running validation operations.

More specifically, for an NVM index data structure (*e.g.*, hash table, B-tree), the validating operations comprise:

1. A list of `get` operations to check all previously inserted but not deleted key-values exist,
2. A `get` operation to check the crash operations follows all or nothing semantics,
3. A list of `delete` operations for all inserted keys, and
4. A list of `get` operations to check all the deleted keys in the previous step are indeed deleted.

Note that for each crashed image, a list of completed operations and the crashing operation are known, so we know which key has been inserted or deleted. DURINN provide similar validating operations for other data structures: *e.g.*, array and queue.

6 Implementation

We implemented tracing and data flow analysis in LLVM [11]. We automatically generated `gdb` command files based on the locations of breakpoints. To control the progress of each thread in `gdb`, we set `scheduler-locking` on. Our LLVM-related code comprises around 1900 lines of C++ code. Other DURINN components are written in 2700 lines of Python code. Our current prototype supports an NVM program built on PMDK `libpmem` or `libpmemobj` libraries to create/load an NVM image from/to disk. To ensure the virtual address of the `mmap`-ed NVM heap are the same across different executions, we set `PMEM_MMAP_HINT` environment variable [38]. The DURINN prototype is available at https://github.com/cosmoss-jigu/durinn.

7 Discussion

7.1 False Negatives and False Positives in DURINN

DURINN may have false negatives (*i.e.*, missing bugs) for three reasons. First, DURINN is a trace-based dynamic tool that takes a test case as input. DURINN may miss DL bugs that did not appear in a trace.

Second, DURINN's likely-LP inference is based on heuristics and may miss true LPs in theory. Missing LP means no adversarial testing, so DURINN may miss DL bugs. However, the proposed heuristics are built on common NVM programming practices, namely Guarded-Protection and Publish-after-Initialization presented in §5.2. As a result, our empirical study (§8.4) shows that the inferred likely-LPs do not miss manually-identified (true/oracle) LPs and DURINN does not miss any DL bugs detected with the oracle LPs.

Last, DURINN performs adversarial testing and does not explore all possible NVM states and thread interleaving. In theory, for Incompletely-Durable and Unrecovered-Durable bugs, some more complex combinations of persisted and unpersisted stores may be required to trigger a DL bug. For Visible-But-Not-Durable bugs, more than two concurrent thread interleaving may be needed to expose a DL bug. However, our empirical study (§8.5) shows that DURINN detects all the bugs reported by the state-of-the-art Witcher [30] and indeed found more new bugs with significantly fewer tests.

On the other hand, for a given trace under test, DURINN does not have false positives as DURINN performs durable linearizability validation (§5.4). Any crash NVM image (constructed by adversarial testing) that violates durable linearizability is indeed a definite clue of a true DL bug (by definition). We note that multiple durable linearizability violations may stem from one root cause.

7.2 Persistent Cache

Intel architecture is expected to adopt eADR support (Extended Asynchronous DRAM Refresh) [37] that includes a cache into the persistent domain. For an eADR-enabled Intel architecture, there will be no gap between LP and DP because once the effect of a store reaches a cache, it is guaranteed to

be written back to the NVM.

We expect DURINN remain useful when eADR is available for the following three reasons. First, eADR is unlikely to be added to all product lines due to the high cost of battery size. In the current Intel platforms (Optane 200), eADR support is optional and requires an additional backup battery [36]. As eADR is not expected to be available in all machines, NVM programmers would need to write a code to support both eADR and non-eADR machines. Second, eADR is not the panacea if non-temporal stores (`ntstores`) are used. `Ntstores` place data in the store buffer and bypass caches, which is outside eADR persistent domain. For example, PMDK `pmemcpy()` prefers to use `movnstore` for better performance. An NVM program may lead to an inconsistent state when data in a store buffer is not flushed into NVM before a crash. Last, the Unrecovered-Durable bug pattern is still an issue even with eADR because it requires recovering or tolerating any partial updates made before linearization point. eADR has nothing to do with such a recovery logic. Developers still need to design and implement inconsistency-recoverable data structures.

7.3 Relationship to ACID

Three DL bug patterns can be disucssed using traditional database/filesystem's ACID terms. One can view *Incompletely-Durable* and *Unrecovered-Durable* bugs as ACID-atomicity/consistency/durability violations *Incompletely-Durable* bug pattern considers a crash after DP and tests ACID-atomicity/consistency/durability's fully-executed "all" semantic. *Unrecovered-Durable* bug pattern considers a crash before DP and tests ACID-atomicity's not-at-all-executed "nothing" semantic.

On the other hand, *Visible-But-Not-Durable* bug is related to ACID-isolation violation. *Visible-But-Not-Durable* bug pattern considers a crash before DP. However, a concurrent operation observed unpersisted data, and it completed, violating ACID-isolation and forcing the crashed operation to ensure the "all" semantic. A naive durability checker cannot detect *Visible-But-Not-Durable* bugs because they require a completed, ACID-isolation-violating, concurrent operation.

8 Evaluation

For evaluation, we first present our methodology (§8.1), then present the following experimental results.

- We report and analyze the DL bugs detected by DURINN (§8.2) along with detailed statistics, including the number of tests and testing time (§8.3).
- We evaluate the effectiveness and (empirical) soundness of DURINN's likely-linearization inference technique (§8.4).
- We compare DURINN with other NVM crash-consistency testing tools in terms of bug detection effectiveness and test space reduction (§8.5).

LL: low-level persistence primitives **TX**: transactional persistence

Table 1: Tested concurrent NVM data structures

8.1 Evaluation Methodology

Tested NVM data structures. We evaluate DURINN with 13 concurrent NVM data structures, as listed in Table 1 with tested version, data structure type, its concurrency control mechanism, and persistence programming model. There are two concurrency control mechanisms: lock-free and lock-based. For persistence (durability) control, most data structures use low-level (LL) persistence primitives such as `flush` and `fence` instructions, while `pmdk-queue` uses PMDK's transactional (TX) persistence programming model.

All the tested data structures have been highly optimized for NVM, and most of them have shown to be more scalable than (simple) NVM hash tables and B-trees used in NVM-backed key-value stores such as `memcached`, `redis`, `pmemkv`, etc. All tested data structures use `libpmemobj`, the PMDK library for persistent memory allocation or transaction. As some data structures originally used a volatile memory allocator and emulated NVM using DRAM, we modified them to use the PMDK's persistent NVM memory allocator. Our changes do not add or delete any new/existing persistence primitives, or memory operations. Thus, the changes do not affect the bug detection evaluation.

Test Cases. We use AFL++ fuzzer [1] to generate a test case for our evaluation. We first feed a randomly generated seed into ALF++ fuzzer. Our random seed generator assigns a higher probability to create a new unused key for `insert`; and to reuse existing keys for other dependent operations such as `delete`, `update`, `query`. Then we run the fuzzer and picked the generated test case with the highest code coverage, which consists of 1,000 operations. We found that 1,000 operations are large enough to achieve a reasonable and stable code coverage (50%-80%) for our tested NVM data structures. Missing code coverage is due to unused features (*e.g.*, garbage collection) and debugging codes. The generated test cases are used for both likely-LP inference and adversarial testing.

Experimental setup. We ran all experiments on a 64-bit Fedora 29 machine with two 16-core Intel Xeon Gold 5218 processors (2.30GHz), 192 GB DRAM, and 512 GB NVM.

Table 3: The detailed statistics of DURINN bug finding.

8.2 Detected Durable Linearizability Bugs

In summary, DURINN detected 27 (15 new) durable linearizability bugs from 12 NVM data structures. There were 10 Incompletely-Durable bugs, 7 Unrecovered-Durable bugs and 10 Visible-But-Not-Durable bugs. 7 out of 15 new bugs have been confirmed by the developers so far. Table 2 shows the source code locations, impacts and fix strategies of the detected bugs.

(DL1) Incompletely-Durable bugs. DURINN detected 10 Incompletely-Durable bugs. Figure 6(a) discussed in §3.2 is a representative example (Bug ID 19) found in P-CLHT, leading to a lost key-value. As another instance, in P-LF-List (Bug ID 3), a new node is not fully persisted before it is added to the list using a `CAS` operation (which is LP). If a crash happens before DP (and after LP in this particular case), the list may contain a garbage node leading to an inconsistent structure. To fix Incompletely-Durable bugs, developers need to persist all the changes using additional cache line flush and fence instructions before DP.

(DL2) Unrecovered-Durable bugs. DURINN detected 7 Unrecovered-Durable bugs. Figure 6(b) illustrates a case detected in Fast-Fair (Bug ID 12). For another example, in CCEH (Bug ID 7), if a crash happens while rehashing the table and before adding a new segment into the table, the hash table will be in an illegal state: *i.e.*, all the metadata assumes there is a new segment added but it is not. To fix Unrecovered-Durable bugs, an NVM data structure should be able to recover from or tolerate partial updates before LP of an operation. Designing an inconsistency-recoverable design is one solution. Using logging or transaction is another.

(DL3) Visible-But-Not-Durable bugs. DURINN detected 10 Visible-But-Not-Durable bugs. Figure 6(c) shows a Visible-But-Not-Durable bug in Fast-Fair (Bug ID 8). For another example, Bug ID 6 from CCEH is due to incorrect usage of locks. While both `insert` and `get` operations use a lock to protect a critical section, the write to the synchronization variable (LP) is inside the critical section but the persistence of the synchronization variable (DP) is ensured outside the critical section in `insert`. Since the DP is not protected by a lock, the `get` operation is able to observe the visible but not durable writes from a concurrent `insert` operation. We observed two ways to fix Visible-But-Not-Durable bugs. Some

choose to fix the concurrency control mechanism to guarantee that every data read by concurrent threads is persisted. Others made one operation that reads unpersisted data help persist the data on behalf of another concurrent operation.

8.3 Statistics of DL Bug Detection

Table 3 shows the detailed statistics of DURINN when tested with 1000 operations. The second column reports the number of stores and the third column lists the number of inferred likely linearization points. On average, using static analysis described in §5.2, DURINN infers about 2,000 likely-LPs, which is 13% of 15.3K NVM stores traced while running 1000 tested operations. More detailed analysis on likely-LP inference will follow in §8.4.

The next three columns show the number of DL tests performed by DURINN to detect three DL bug patterns. The number of Incompletely-Durable and Unrecovered-Durable tests are the same as the number of inferred LPs because for each LP, DURINN performs one adversarial test for Incompletely-Durable bugs and for Unrecovered-Durable bugs. On the other hand, the number of Visible-But-Not-Durable tests depends on the number of co-schedulable racy operations. The second last column shows that the number of Visible-But-Not-Durable tests varies by data structures up to a few thousand. Intuitively, lock-free data structures tend to have more co-schedulable racy operations than (coarse-grained) lock-based ones, requiring more tests. The last column reports the execution time, which mostly depends on the number of tests. Testing all three test cases typically takes a few minutes. `P-LF-Queue` took the most time (around 40 mins) due to the large number of concurrent Visible-But-Not-Durable testing.

Lastly, for each test case violating durable linearizability, we manually analyze each case and report the details in Table 2. DURINN provides sufficient information for root cause analysis, including execution trace, crash location, persisted and unpersisted writes, and a crash NVM image. We loaded the crash image in `gdb` and followed the DURINN-generated schedule to inspect the root causes of detected DL bugs.

8.4 Likely-Linearization Point Inference

DURINN infers likely-linearization points using *Guarded-Protection* and *Publish-after-Initialization* heuristics described in §5.2. The number of likely-LP determines the number of DL tests that DURINN performs, so in terms of scalability, the less the better. At the same time, ideally, likely-LPs should not miss true LPs because missing LPs may lead to missing true DL bugs (false negatives).

We performed a detailed case study with CCEH and Fast-Fair in which we manually analyzed the true LPs (oracle) for comparison. They both use lock-based concurrency control in which the store instructions serving as LPs are not explicit. They are non-trivial concurrent data structures including balancing operations such as rehashing (CCEH) and node split/merge (Fast-Fair) operations.

Figure 11 shows the effectiveness of the proposed likely-LP inference techniques, compared to the manually identified LPs. The first bar represents the number of total stores. The second and third bar represent the number of likely-LPs when only Guarded-Protection or Publish-after-Initialization heuristics is used, respectively. The fourth bar shows the number of likely-LPs of DURINN where both are considered. The last bar is the number of LPs from our manual source code analysis. The result shows that DURINN effectively reduces the number of likely-LPs using two heuristics. The number of likely-LPs inferred by DURINN is twice as the number of manually-identified LPs. Note that as listed in Table 3, CCEH and Fast Fair are the most difficult data structures in terms of the reduction ratio between the stores and the likely-LPs.

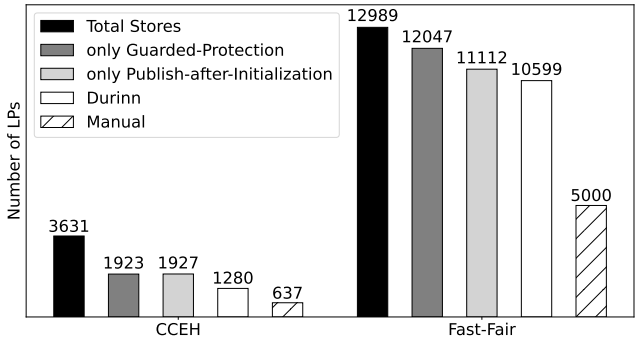

Figure 11: A case study of likely-linearization point inference.

Additionally, we compared the bug detection effectiveness and found that DURINN's inferred likely-LPs detect the same DL bugs as manually-identified (true) LPs. Though DURINN's likely-LP inference heuristics do not guarantee soundness in theory, this experiment empirically shows that likely-LP inference did not miss true LPs (at least) for the CCEH and Fast-Fair. We believe the same case for other data structures given that the heuristics are designed based on common NVM programming patterns.

8.5 Comparison with Other Tools

We present the detailed comparison with Witcher [30], the state-of-the-art NVM crash-consistency bug detector, and Yat [43], an exhaustive crash-consistency testing tool.

Bug Detection. We compared the bug detection effectiveness with Witcher. In their paper, Witcher claims that it can detect all the crash-consistency bugs that prior tools (*e.g.*, PMTest, XFDetector and Agamotto) found for a common set of NVM programs, along with some new bugs. For comparison, we run Witcher with the same test case with 1000 operations for six common data structures: CCEH, Fast-Fair, P-ART, P-CLHT, P-HOT and P-Masstree. Both Witcher and DURINN detected 11 bugs in common. Beyond them, DURINN reports 10 Visible-But-Not-Durable bugs that Witcher missed. Detecting Visible-But-Not-Durable bugs requires scheduling concurrent operations, which is not supported by Witcher.

Test Space Reduction. We compare the number of tests

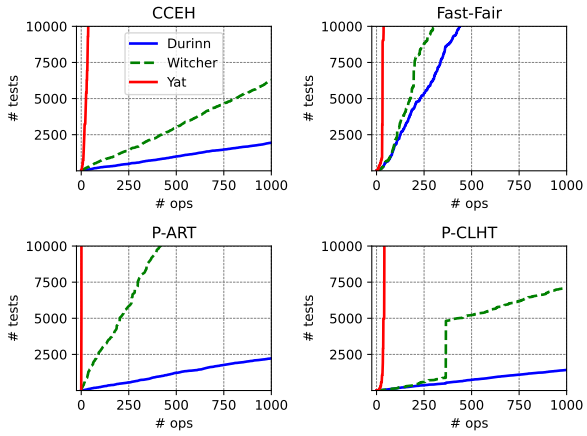

Figure 12: Test space comparison.

performed by DURINN, Yat, and Witcher over the same 1000 operations. Figure 12 shows how the number of tests grows (y-axis) as the number of tested operations increases (x-axis) for four data structures: CCEH, Fast Fair, P-ART, and P-CLHT. The other NVM data structures demonstrate a similar pattern. Yat is an exhaustive testing tool, so the test space explodes within the first ten operations. Witcher performs several times more tests than DURINN. The sudden spike in P-CLHT is due to a rehashing operation. On the other hand, DURINN performs adversarial testing for three DL bug patterns, reduces the number of tests, yet still detects more bugs than Witcher.

9 Related Work

File system/database Consistency Checking. File system consistency checking [17, 18, 32, 41, 48, 49, 54, 57, 60–62] deals with block-grained files, and logging/journaling is the norm for crash consistency. On the other hand, DURINN deals with concurrent data structures backed by byte-addressable NVM. DURINN analyzes load/store instructions along with cacheline flush and fence instructions, controlling durability in NVM. NVM data structures often come with custom (log-free) crash consistency and lock-free logic, making NVM test space huge. For file systems, CrashMonkey [49] bounds search space using heuristics learned from a bug study. EXPLODE [61] and FiSC [62] use in-situ model checking. In contrast, DURINN reduces test space with adversarial crash state and thread interleaving construction.

For correctness conditions, strict serializability and durable linearizability are equivalent from the ACID properties perspective. (PMDK "transaction" does not provide "isolation", though). Yet, we believe durable linearizability is the appropriate framework to use as many NVM data structures are derived from volatile concurrent data structures, where linearizability is the norm. Others [28, 42] also use durable linearizability. Equivalently, the asynchronous commit mechanism in database systems (Salt [59] and Hekaton [23]) can be mapped to "buffered durable linearizability" [40]. For performance, both do not eagerly make the changes durable as long as they can resume from one of the old consistent states.

Linearizability Checker. Line-up [15] is the first complete and automatic checker for deterministic linearizability. It detects thread-safety violations by comparing the concurrent execution to linearizable executions of a test. Similarly, Round-up [63] checks quasi linearizability. Quasi linearizability intentionally introduces non-determinism into the parallel computations and exploits such non-determinism to improve the performance. Pradel *et al.* [53] detects concurrency bugs in thread-safe classes. It generates tests in which multiple threads call methods on a shared instance of the tested class and check if the execution matches any linearizable execution.

Bug Detector for NVM Software. Most existing NVM bug detectors are not designed for durable linearizability bugs. PMDebugger [22] targets universal bugs such as missing persistence primitives. To detect application-specific bugs, such as persistence ordering/atomicity bugs, Yat [43], PMTest [46], XFDetector [45] and Agamotto [51] require user-defined custom oracles or consistency checkers. Jaaru [31] only identifies bugs that have visible manifestation, such as a segment fault or an assertion failure. Witcher [30] leverages all or nothing semantics for validation like DURINN, but it is limited to single-threaded NVM programs.

Active Testing. AtomFuzzer [52] is a randomized active atomicity violation detector, which modifies the thread scheduler behavior to create atomicity violations with high probability. RaceFuzzer [55] uses potential data race information obtained from an existing dynamic analysis technique to control a random scheduler of threads for actively detecting race conditions. Jumble [27] uses adversarial memory to classify race conditions as destructive or benign on systems with relaxed memory models. Relaxer [16] detects sequential consistency violations in a relaxed memory model by actively leading execution to predicted violations.

10 Conclusion

We present DURINN, the first durable linearizability checker for concurrent NVM data structures. We explore the gap between linearizability point and durability point, and define three novel durable linearizability bug patterns. We propose adversarial crash state and thread interleaving construction and likely-linearization point inference to detect durable linearizability bugs in an active and scalable manner. DURINN detected 27 (15 new) durable linearizability bugs.

Abstract

Sparsity is becoming arguably the most critical dimension to explore for efficiency and scalability, as deep learning models grow significantly larger and more complex. After all, the biological neural networks, where deep learning draws inspirations, are naturally sparse and highly efficient.

We advocate an end-to-end approach to model sparsity via a new abstraction called Tensor-with-Sparsity-Attribute (*TeSA*), which augments the default Tensor abstraction that is fundamentally designed for dense models. TeSA enables the sparsity attributes and patterns (*e.g.,* for pruning and quantization) to be specified, propagated forward and backward across the entire deep learning model, and used to create highly efficient, specialized operators, taking into account the execution efficiency of different sparsity patterns on different (sparsity-aware) hardware. The resulting SparTA framework can accommodate various sparsity patterns and optimization techniques, delivering 1.7x∼8.4x average speedup on inference latency compared to seven state-of-the-art (sparse) solutions with smaller memory footprints. As an end-to-end model sparsity framework, SparTA facilitates sparsity algorithms to explore better sparse models.

1 Introduction

As deep neural network (DNN) models become large and complex, they are inevitably getting sparse (or made sparse) for efficiency, just as manifested in the highly sparse biological neural networks [89]. A DNN model is usually modeled as a data flow graph (DFG), where each node is an operator with one or multiple input and output tensors. *Model sparsity* involves introducing some sparsity patterns on the tensors; for example, to quantize some tensors with lower precision (*e.g.,* 16 to 8-bit); to prune the model by setting the value of some (or all) parts of some tensors to zero (*e.g.,* block sparsity [61, 63] or fine-grained sparsity [43, 54, 55]); or to apply the combination of pruning and quantization to a model. With careful pruning and quantization, a DNN model can be compressed into a smaller memory footprint without losing too much accuracy. With DNN operators customized for the sparsity patterns, the resulting model will, hopefully, come with a lower inference latency.

Unfortunately, deep learning systems are not yet effective in exploiting sparsity: the increase in sparsity might not translate into actual gains in efficiency for a variety of reasons. First, the computation kernels for general sparse operations remain far from optimal. For example, cuSPARSE [3], the CUDA library for sparse matrix operations, has been shown to underperform cuBLAS, its dense counterpart, even when the sparsity of the matrices reaches 98% (Table 1). Second, as DNN computation usually takes multiple stages, the sparsity pattern might vary significantly across stages, making it hard to develop sparsity-aware optimizations for end-to-end gains. Finally, any effective sparsity-aware optimization might involve additional support across the vertical stack, from the deep learning framework, compiler, optimizer, operators and kernels, and all the way to hardware. Insufficient support at any of the layers could lead to inefficiency.

We therefore propose SparTA, a new framework that treats sparsity as a first-class citizen, with the following design principles. The design is *customizable and extensible* to accommodate new innovations on model sparsity; it is *end-to-end* and covers the *whole-stack*, rather than being limited to one operator or to one layer; it aims for *extreme performance* without sacrificing general applicability; it can facilitate existing sparsity algorithms to explore sparse models more efficiently.

At the core of SparTA is a new abstraction, *Tensor-with-Sparsity-Attribute* or *TeSA*, which augments the standard tensors with attributes to describe sparsity properties and patterns. Examples include low-precision weights, block (structured) sparsity, and fine-grained (unstructured) sparsity. A set of *TeSA propagation rules* guides the forward and backward propagation of sparsity attributes for end-to-end coverage. The rules can either be defined by the proposed TeSA algebra,

*: Equal contribution.

Table 1: Speed of matrix multiplication ($1024 \times 1024 \times 1024$) in cuSPARSE and cuBLAS on NVIDIA 2080Ti (unit: us).

Sparsity Ratio	50%	90%	95%	99%
cuSPARSE	1652.5	633.9	463.0	181.7
cuBLAS	208.3	208.3	208.3	208.3

or be inferred in a probabilistic way (§3.2).

With the sparse attributes in TeSA, SparTA can generate an efficient execution plan, taking into account the sparsity-aware hardware and specific sparse operators/kernels in certain sparsity patterns and conditions. SparTA may transform an execution plan to decompose complex sparsity attributes into a combination of simple ones with known effective optimizations. In the execution plan, SparTA can perform *code specialization* to generate efficient kernels for simple and regular sparse attributes, instead of resorting to generic but less efficient sparse kernels. This is how SparTA achieves extreme efficiency without sacrificing generality (§3.3).

Due to the whole-stack support (all the way to the codegen on accelerators), SparTA is able to provide the ground-truth performance metrics (*e.g.,* latency) that can help evaluate different execution plans given a TeSA with fixed sparsity attributes and also offer valuable feedback for practitioners to search for the set of sparsity attributes with the ideal tradeoff between performance and accuracy (§5.4).

SparTA is highly customizable and extensible. With TeSA, one can define new sparsity properties and patterns for new ways of exploiting sparsity, provide new TeSA propagation rules, and incorporate new sparsity-aware operators, kernels, and (sparsity-aware) hardware accelerators.

We have implemented SparTA based on Rammer [60], a state-of-the-art open-source DNN compiler with no special support for sparsity. We extensively evaluate SparTA on three popular DNN models with four representative sparsity patterns on three accelerators (*i.e.,* CUDA GPU, ROCm GPU, Intel CPU). Our evaluation shows that SparTA achieves up to 8.4x average speedup on model inference latency with less memory consumption, compared to seven state-of-the-art solutions (§5). We have also used SparTA to speed up sparse DNN model training and achieved more than 2x speedup than previous solutions (§5.5). By open sourcing SparTA[1], we hope that this work can bring the community together in this extensible and unified framework to accelerate innovations on model sparsity.

2 Background and Motivation

The size of deep neural networks grows significantly over the past years [25, 37], which incurs large inference latency and heavy memory burden. Model sparsity is arguably the most critical dimension to explore for efficiency and scalability.

[1]Code available at https://github.com/microsoft/SparTA

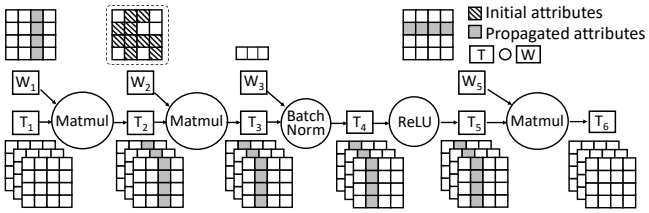

Figure 1: The sparsity attribute of one tensor can be propagated along the deep learning network.

Various forms of sparsity. Deep learning model sparsity is an active and extensively studied research topic. Currently, there are various sparsity patterns being studied. Structured (coarse-grained) sparsity, including channel-granularity sparsity, and block sparsity [56, 59, 61, 63], involves pruning a channel or a sub-block of tensors (e.g., weight or activation tensor) associated with some operators. With unstructured (fine-grained) sparsity, any element of a tensor [43, 54, 55] might be pruned. Quantization algorithms represent models at different levels of precision (*e.g.,* binarized models [31], 8-bit models [52, 92]), and even with different, mixed precision across neural network layers [36, 57, 77] or within a single tensor [66, 84]. Some research further combines pruning and quantization in order to achieve high accuracy under the strict latency and memory constraints [42, 74, 75, 78, 83, 90]. Overall, pruning and quantization have been shown effective in reducing the size and computation complexity of certain deep learning models, sometimes by more than 10 times, without losing much accuracy [42, 76].

The myth of FLOPs. Model sparsity does not translate directly into performance benefits. The existing practice of using "proxy metric" (*e.g.,* FLOPs, or Floating point operations) to evaluate the effect of their proposals such as model inference latency is flawed and leads to inaccurate results. For example, when an operator's weight is pruned by 50% with fine-grained sparsity, even though in theory its FLOPs can be reduced by half, the actual inference latency may become higher with a default sparse kernel (§5.3).

One reason is the sub-optimal implementation of current *generic* sparse kernels. A generic sparse kernel tends to apply a few default sparse encoding schemes (*e.g.,* Compressed Sparse Row [26]) to any sparse tensors. This may miss optimization opportunities in a tensor with a specific sparsity pattern, such as structured sparsity. As a result, a generic sparse kernel library like cuSPARSE [3] can outperform cuBLAS, its dense counterpart [2], only in some extreme sparse case (98%), as shown in Table 1. This motivates the need to find a general framework to implement *specialized* kernels tailored for individual sparsity schemes.

The diminishing end-to-end returns. Sparsity algorithms often focus on exploring the sparsity of a certain DNN operator (*e.g.,* convolution [64]). However, when placed in an end-to-end deep learning model, the sparsity pattern across the whole model can be impacted by each of the operators in the model. This may introduce sophisticated sparsity pat-

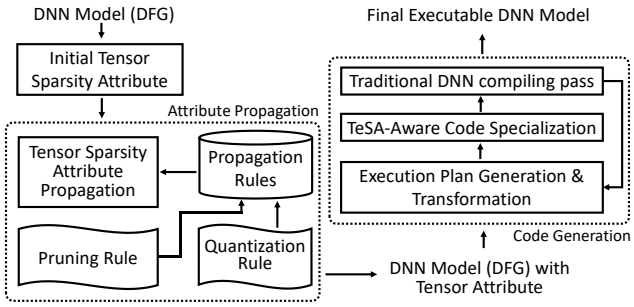

Figure 2: The system architecture of SparTA.

terns that are difficult for existing solutions to understand or optimize, leading to diminishing end-to-end return from sparsity.

In Figure 1, tensor W_2 illustrates a fine-grained sparsity pattern (63% sparsity). Such an initial sparsity pattern of W_2 incurs ripple effects. W_2 would propagate its sparsity attribute to the down-stream and up-stream tensors, including W_1, T_2, T_3, T_4, T_5, and W_5. For example, because the second column of W_2 is pruned, the second column of T_3 is destined to be all zero, hence can be pruned too (as $T_2 \times W_2 = T_3$). Likewise, as the third row of W_2 is pruned, the third column of T_2 can also be pruned. It is therefore desirable for a deep learning compiler to understand such *propagation* of sparsity so as for further sparsity-aware optimization.

Across-stack sparsity innovations in silos. Due to the above limitations, sparsity innovations either are constrained to individual operators and evaluated with proxy metrics without knowing the end-to-end effects, or have to be implemented manually on a few neural models, difficult to be ported to other models [42, 77]. More problematically, individual solutions are hard to be extended to or combined with other proposals. All these motivate SparTA, a common foundation to facilitate sparsity innovations, which can be evaluated end-to-end.

3 SparTA Design

Figure 2 summarizes the overall architecture of SparTA. At the core of SparTA is the TeSA abstraction, which augments the existing tensor abstraction with *sparsity attribute* (§3.1). An algorithm designer can specify the sparsity patterns in selected tensors of a deep learning model as "Initial Tensor Sparsity Attribute".

Given the initial sparsity attribute, SparTA performs *attribute propagation* to infer the sparsity attributes of all other tensors in the deep learning model, according to the propagation rules (§3.2). Sparsity attribute propagation exposes more optimization opportunities than the original sparse tensors, as shown, for example, in Figure 1.

After attribute propagation, SparTA runs a multi-pass compilation process to generate efficient end-to-end code (§3.3). Compared to a traditional DNN compiler, SparTA conducts two additional compilation passes to exploit model sparsity fully. The first pass transforms the original execution plan of a DNN model into a new one that takes advantage of the given sparsity patterns. A further compilation pass then performs sparsity-aware code specialization. The awareness of tensor sparsity patterns allow SparTA to generate highly customized code. This process may be iterated for further improvement.

Finally, with the final compiled code, model designers can profile the DNN model to obtain authentic performance metrics, including memory consumption and inference latency. Given the feedback, model designers may further update the sparsity attributes in some tensors and repeat this process iteratively to find the best tradeoff. Thus SparTA enables a feedback loop, facilitating the innovation in model sparsity.

3.1 The TeSA abstraction

TeSA augments a traditional tensor with an additional tensor with the same shape, where each element is a scalar value, representing the sparsity attribute of the corresponding element in the original tensor. This allows a user to specify arbitrary sparsity patterns in a tensor, a key requirement of the evolving research on model sparsity [40, 47, 72]. Figure 3 shows an example of TeSA. The left shows the original dense tensor. The right shows the corresponding sparsity attribute, where one prunes the second row in the tensor, uses 8-bit to quantize the bottom-right element and 4-bit for the remaining elements. This example shows that TeSA can unify tensor quantization and pruning in one abstraction. The unified abstraction facilitates the co-optimization of pruning and quantization, *e.g.,* picking the right block size to cover (represent) the remaining (non-pruned) elements while aligning with low-bit hardware instructions (*e.g.,* `wmma` [5]). With TeSA, SparTA can understand the sparsity pattern at compile time, which enables further optimizations. Note that the sparse attribute will only be used in the compile phase, thus it does not impose additional resource burden to the actual compute phase.

3.2 Sparsity Attribute Propagation

The number of tensors in a deep learning model is usually large. A user can only set the sparsity attribute for a subset of the tensors. To maximize end-to-end sparsity, SparTA performs attribute propagation along the DFG of the DNN model

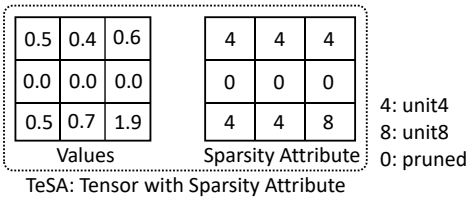

Figure 3: An example of TeSA. Sparsity Attribute denotes the sparsity pattern, including quantization (4 means `uint4`, 8 means `uint8`) and pruning (0 means the element is pruned).

Algorithm 1: TeSA attribute propagation.

```
   Data: G: DFG of TeSA annotated DNN model.
   Result: G with updated TeSAs.
1  Function Propagate(G):
2      S = Set(AllNodesOf(G));
3      while S ≠ ∅ do
4          N = S.PopOne() ;   /* can start from any node */
           /* I_s (O_s) is node N's input (output) TeSA  */
5          I_s, O_s = TeSAOf(N);
6          I_updated, O_updated = PropOneNode(N, I_s, O_s);
7          foreach T ∈ ( I_updated ∪ O_updated ) do
8              B = NeighborNodesOf(T);
9              S.Insert(B.Remove(N));
10     return G;
```

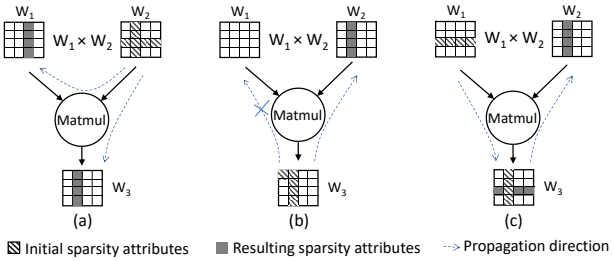

Figure 4: The propagation of sparsity attribute. The gray blocks are propagated sparsity attributes.

to derive the TeSA of other tensors, shown in Algorithm 1. Given a node, if the TeSA of any input or output tensor of a node is updated (`TeSAOf` in Line 5), `PropOneNode` (Line 6) updates the TeSA of other tensors associated with this node, according to a certain propagation rule (as discussed later, the propagation could be bidirectional). The propagation repeats until no TeSA requires further update.

Note that if being propagated multiple times, a sparsity attribute will be updated to increase the sparsity until convergence. Multiple pruning updates lead to the union of the pruned elements in all the updates (The tensor W_3 in Figure 4(c) is an example). For quantization, the attribute will be converged to the fewest quantization bits (or 0-bit, *i.e.,* being pruned). As each propagation monotonically increases sparsity and both the propagations of pruning and quantization are commutative and associative, Algorithm 1 is guaranteed to terminate.

Intra-operator propagation. The propagation behavior of `PropOneNode` varies across different type of operators and attributes. In Figure 4(b), the pruned element [0,0] in tensor W_3 cannot propagate to W_1 and W_2 through the operator `Matmul`, while it does propagate to upstream tensor if the operator is element-wise computation like `ReLU`. Propagation could be bidirectional. Figure 4(a) shows that the input W_2 can affect the output W_3 and another input W_1. And in Figure 4(b), W_2 becomes sparse due to the TeSA of the output W_3.

The sparsity attribute of the quantization type propagates differently. If an output tensor has a low precision (*e.g.,* 4bit) while the input tensor's precision is high (*e.g.,* 16bit), the input may use fewer quantization bits with little impacts on output (*i.e.,* information bottleneck [73]).

Type	Computation	Computation in TeSA Algebra
Unary $f(x) \Rightarrow y$	$sin, cos,$ $\lvert x\rvert, ReLU, \ldots$	$(x=\phi) \rightarrow (y=\phi)$ $(x=\alpha) \rightarrow (y=\alpha)$
Binary $f(x,y) \Rightarrow z$	$+, -$	$((x=\phi) \wedge (y=\phi)) \rightarrow (z=\phi)$ $((x=\alpha) \vee (y=\alpha)) \rightarrow (z=\alpha)$
	$\times, \div, x^y$	$((x=\phi) \vee (y=\phi)) \rightarrow (z=\phi)$ $((x=\alpha) \wedge (y=\alpha)) \rightarrow (z=\alpha)$

Table 2: TeSA algebra on a set of attribute values. ϕ and α represent pruned and non-pruned element respectively.

Next, we show two propagation rules used by SparTA for pruning and quantization attribute. Note that it is possible to extend `PropOneNode` to support more rules as shown in line 27-line 36 of Algorithm 2. New propagation rules can be registered and invoked in `PropOneNode`.

Pruning rule. The propagation of pruning attributes depends on the computation logic of an operator (*e.g.,* $+$, $\times$ in `Matmul`). To capture such property, SparTA defines a TeSA algebra that maps the an operator's element-wise computation to a set with two elements, {*pruned*, *non-pruned*}. The TeSA algebra is shown in Table 2. Given an input TeSA, its output TeSA can be computed using the TeSA algebra, following the same computation flow of the operator. Note that Table 2 can be extended to support new operators.

SparTA also proposes *Tensor Scrambling*, a probabilistic propagation rule that handles black-box or complex operators, where the detailed computation logic is unavailable or unclear. This rule derives the pruned elements of a tensor by scrambling the values of other related tensors. Specifically, the rule sets the pruned elements in the input tensor to zeros, and assigns random values to the remaining elements (*i.e.,* scrambling). It then runs the operator to obtain its output tensor (assuming at least the dense version of the operator is available). By repeating this process enough times (see §5.2), the rule treats those elements that always stay zero as pruned elements in an output tensor.

In addition, the sparsity also propagates from the output to the input, or from one input tensor to another. To achieve this, SparTA leverages the auto differentiation (AD) of DNN computation. An operator's backward operator is also available for the back-propagation in the AD. Let $I_{1\ldots n}$ and $O_{1\ldots n}$ denote an operator's inputs and outputs respectively. Its backward operator's inputs are $I_{1\ldots n}$ and $gO_{1\ldots n}$, with its outputs being $gI_{1\ldots n}$, where the prefix g denotes the gradient of the corresponding tensor. According to AD's property, gI_i and gO_i should have the same TeSA of I_i and O_i (both shape and value). To infer the TeSA propagated from tensor I_i (or O_t) to I_j, SparTA applies TeSA algebra or Tensor Scrambling to the backward operator: using the TeSAs of $I_{1\ldots n}$ and $gO_{1\ldots n}$ as the input, SparTA applies either rule to compute (`PropOneNode`)

Algorithm 2: TeSA attribute propagation rules.

```
   Data: N: a node in DFG, I_s: node N's inputs, O_s: node N's outpus.
   Result: Updated input/ouput TeSAs after propagation on N.
11 Function PruningPropRule(N, I_s, O_s):
12     S_updated = ∅;
13     foreach T ∈ ( I_s ∪ O_s ) do
14         T_updated = TensorScrambling(N, (I_s ∪ O_s)\T);
15         if T_updated != T then
16             S_updated.Update(T_updated);
17     return SplitToIsOs(S_updated);
18 Function QuantizationPropRule(N, I_s, O_s):
19     S_updated = ∅; S = ( I_s ∪ O_s );
20     D_calib = GetCalibrationDataOf(N);
21     foreach T ∈ ( I_s ∪ O_s ) do
22         T_updated = LowerBitAndFinetune(N, S, T, D_calib);
23         if T_updated != T then
24             S.Update(T_updated);
25             S_updated.Update(T_updated);
26     return SplitToIsOs(S_updated);
27 RegisterPropRule(PruningPropRule);
28 RegisterPropRule(QuantizationPropRule);
29 Function PropOneNode(N, I_s, O_s):
30     I_updated = O_updated = ∅;
31     foreach RegisteredPropRule do
32         I_proped, O_proped = RegisteredPropRule(N, I_s, O_s);
33         I_s.Update(I_proped); O_s.Update(O_proped);
34         I_updated.Update(I_proped);
35         O_updated.Update(O_proped);
36     return I_updated, O_updated;
```

gI_j's TeSA, which has the same shape and value of that of I_j.

We use Operator $Y = AX + B$ as an example to illustrate output-to-input and input-to-input propagation, where Y is output tensor, and A, B, and X are input tensors. To derive the TeSA of A, B, X, we take the derivative of the operator with respect to A, B, and X, *i.e.,* $gA = gY \times X^T$, $gB = gY$, $gX = A^T \times gY$, respectively. The sparsity propagation from output tensor Y to input tensor A uses $gA = gY \times X^T$. gY has the same TeSA as Y. Given the TeSA of Y and X, gA's TeSA can be inferred using either TeSA algebra or Tensor Scrambling. The propagation from X to A also uses this backward computation, which is input-to-input propagation. Similarly, the TeSA of B and X can be inferred from Y using $gB = gY$ and $gX = A^T \times gY$, respectively. It is obvious from $gB = gY$ that B has the same TeSA as Y.

The propagation rule of pruned elements can be realized in line 11 of Algorithm 2. Every input/output TeSA of node N is computed (line 14), *i.e.,* propagating the sparsity in other TeSAs (*i.e.,* $(I_s \cup O_s)\backslash T$) to this TeSA (*i.e.,* T). This function returns the updated input and output TeSAs separately (*i.e.,* line 17). Note that here Tensor Scrambling can be replaced with tensor algebra.

Quantization rule. For propagation of quantization attributes, the key is to find tensors with unnecessarily high quantization precision. SparTA defines a quantization rule (line 18 of Algorithm 2) that borrows the idea of knowledge distillation [45,46] to identify such tensors. That is, to identify whether the information passed through an operator can be distilled into a lower precision with acceptable information loss. Since the information loss can be measured through the operator's input and output tensors, we first perform inference on the corresponding DNN model using train/test dataset, and collect the resulting input and output tensors of that operator to construct *calibration data* (line 20). Next, we gradually reduce the quantization precision (*e.g.,* 32-bit to 16-bit) of one tensor of this operator while keeping other tensors unchanged. The operator is then quantized and fine-tuned using the calibration data under the new precision. The fine-tuning is to minimize Mean Squared Error (MSE) between the output tensors in calibration data and the output tensors of that operator after lowering the precision. If the drop of model accuracy is smaller than a predefined threshold (*e.g.,* 1% in our experiment), the new quantization attribute of that operator is accepted (line 22). The process repeats for other tensors in the operator, until all tensors are evaluated. To reduce the cost of collecting calibration data, SparTA works through all the operators in a DNN model in a topological order and caches the activations computed in earlier quantization propagations. Collecting an operator's calibration data only needs partial inference from the nearest cached activations to this operator. For example, consider a sequential model with two layers L_a and L_b. The propagation on L_a has collected its output activations in its calibration data. When working on L_b, its calibration data can be collected by doing partial inference from the collected output activations of L_a. Our evaluation results in §5.2 show the effectiveness of this propagation rule.

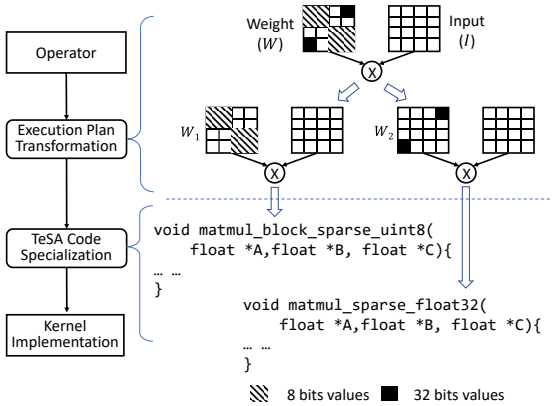

Figure 5: Two-pass compilation to generate an efficient kernel for an operator (`MatMul`).

3.3 Code Generation with TeSA

After attribute propagation, tensors in the DNN model may show a mixture of different sparsity patterns [42, 57, 74, 84]. Such complex patterns make it difficult to generate efficient kernel code. SparTA therefore transforms a tensor with a complex sparsity pattern to multiple tensors, each with a simpler sparsity pattern. Correspondingly, SparTA rewrites the execution plan of the associated operator to accommodate

new operators that compute the transformed tensors. Finally, SparTA performs code generation for the transformed execution plan, with sparsity-aware specialization.

Figure 5 shows an example of such a two-pass compilation process for `Matmul`. The weight tensor W is a tensor with a mixed precision, where two structured blocks use 8bit quantization and one fine-grained element uses 32bit. SparTA transforms W into W_1 and W_2, each using a simpler quantization scheme. Consequently, two operators are introduced to compute $W_1 \times I$ and $W_2 \times I$, respectively, using the hardware instructions fit for the specific sparsity attribute. As a result, the original execution plan with one operator is transformed into a new plan that requires more tensor operations.

Execution-plan transformation. This compilation pass transforms a tensor with a complex sparsity pattern to "regular" (simple) sparsity patterns, which facilitates further optimizations in later passes. In SparTA, a regular sparsity pattern means the TeSA of a tensor shows only one type of quantization attribute and one block size of pruning attribute.

The detailed execution plan transformation for a DNN model is performed operator-by-operator, shown in Algorithm 3. For simplicity, we assume the operator has m inputs and a single output. The process starts from the operator's input and output TeSAs, each of which could be transformed to one or multiple TeSAs using `TransformTeSA`. Correspondingly, the operator is transformed to $|T_o|\prod_{i=1}^{m}|T_i|$ sub-operators, which are the Cartesian product of those decomposed TeSAs. The sub-operator usually has the same computation logic as the original operator (*e.g.,* the operators that can be expressed with *Einstein summation* [7]), an approach that has also been taken in the context of DNN model partitioning [82]. The system performs code generation for each sub-operator (line 45), profiles the resulting kernel in the real hardware, and records the profiled result (line 47).

Note that the transformation is a repetitive search process. Given a TeSA, `TransformTeSA` may have multiple transformation plans. The process iterates over each plan to find the satisfied one (line 38). Figure 6 shows an example. On the left, a mixed precision TeSA can be decomposed to multiple TeSAs each of which has one precision. It can also be transformed to one TeSA where all the elements are aligned to the highest precision. Similarly, for the right example, the sparse TeSA can be decomposed to two TeSAs, one with a block size of 2x2 and the other with a block size of 1x1. It can also be transformed to one TeSA of block size 2x2 with the pruned elements set to zero, or transformed to one TeSA of block size 1x1. Note that the algorithm may decide not to decompose a tensor and choose a block size of 1x1, indicating that the TeSA has a fine-grained sparsity that is hard to be transformed to regular sparsity.

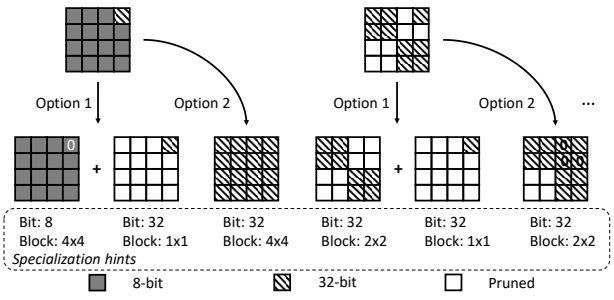

Figure 6: Multiple transformation plans produced by a transformation policy. The specialization hints are used by the second pass compilation for code specialization.

64 **return** *DecomposedTeSAs*(T, B_{chosen});

`TransformTeSA` (line 49) implements the logic of transforming a TeSA. It first decomposes TeSA in `BitRounding`, based on both the quantization bit width that the TeSA contains and the possible quantization bit width supported by the hardware. For example, if the hardware supports both 4-bit and 8-bit instructions, there are at least two rounding options: (i) rounding to 4-bit and 8-bit accordingly, (ii) all rounding

to 8-bit. For each TeSA returned by `BitRounding`, function `WeightedBlockCover` chooses one or multiple proper block sizes to cover the non-pruned elements, which we treat as a *weighted set cover* problem [19]. The weight of each block size corresponds to the cost of computation with the block size on the underlying hardware (see §4 for details). We use a simple greedy algorithm to pick the blocks with the lowest cost (*i.e.,* $\frac{block\_weight}{num\_covered\_elements}$), until all non-pruned elements are covered (line 56).

Transformation policy P can be further customized to incorporate new optimizations (*e.g.,* supporting Sparse Tensor Cores [1] detailed in §5.3).

To help codegen, each transformed TeSA is attached with the information about the bit width and block size, named as *specialization hints* (illustrated in Figure 6). The hints will be passed to the second pass, elaborated next.

TeSA code specialization. The second compilation pass specializes kernel code for each (sub)operator (*i.e.,* line 45 in Algorithm 3). The specialization hints generated from the previous pass guide the specialization strategy. For example, the bit-width of an operator suggests whether to leverage a specific hardware instruction (*e.g.,* `DP4A`). And the loop tiling of the operator should be aligned with the block size for effective dead code elimination (DCE). In addition, SparTA can leverage traditional DNN compilers for dense computation. For example, some intra-block computation is dense and thus can use a dense implementation generated by existing DNN compilers [29, 60, 91].

The specialization process starts from a dense version of the operator, implemented as multi-level loops generated by a traditional DNN compiler [29]. It first specializes under the guidance of the block size in the specialization hints. It searches from the outermost loop until the level (say l) of inner loop body aligns with the block size. Since the pruning sparsity attribute is specified at the granularity of block size, many runs of the loop body within level l are dead computation. To eliminate the dead computation, we introduce a new schedule primitive `dismantle` that jointly performs loop unrolling and DCE. When `dismantle` is applied on a loop, this loop and all its outer loops are unrolled and specialized with the given sparsity attribute. An example is shown in Figure 7(b). `dismantle` is applied on the third loop, thus the top three loops are unrolled, generating eight small Matmuls (*i.e.,* [2,2]x[2,2]). According to the sparsity pattern in Figure 7(a), six of them are dead computation and can be eliminated. In essence, `dismantle` embeds a specific sparsity pattern into the code, which eliminates the need of sparsity encoding, *e.g.,* compressed sparse row (CSR) [26]. As the index to the non-pruned blocks/elements is specialized in the code, the overhead of indirect addressing on the index is removed.

Given a different transformation plan (and the specification hints), the code can be specialized differently. The hint in Figure 7(c) show a smaller block size. In this case, the loop body is a smaller Matmul (*i.e.,* [2,1]x[1,1]), which enables

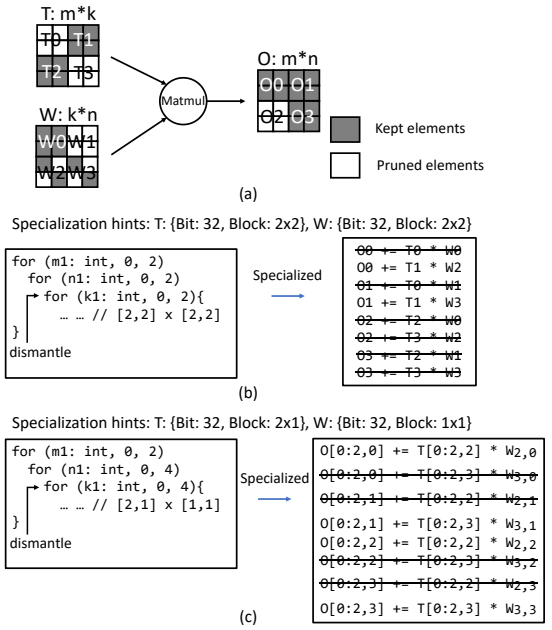

Figure 7: Sparsity-aware code specialization, leveraging specialization hints generated during execution plan transformation. (a) is a sparse Matmul, (b) and (c) are its specialized kernel code with different transformation plans. $T[x:y,z]$ denotes the elements on row x to y and column z, $W_{x,y}$ denotes the value on row x and column y of W.

more DCEs. Besides the dead computations eliminated in the previous case, four computations of the small Matmul can be removed. Furthermore, as the small Matmul only accesses one value in W, the value can be directly specialized to the code (*i.e.,* $W_{x,y}$) without maintaining a sparse tensor W in memory.

A specialization hint could also specify the block size equal to the tensor's shape (*i.e.,* one block covers the whole tensor). In this case, SparTA can directly use the existing state-of-the-art general sparse kernel implementation (*e.g.,* cuSPARSE [3], taco [53]) or even use the dense kernel implementation if it perform better. SparTA's specialization framework is general to incorporate any sparsity-aware techniques, including the off-the-shelf sparse kernel and even its dense version.

Specializing operators with quantization attributes also works on the multi-level loops, but starting from the innermost loop. SparTA picks a proper hardware instruction based on the bit-width denoted in TeSA, *e.g.,* `DP4A` [13] or `wmma` [5] for 8bit, `wmma` for 4bit. The specialized tiling of the innermost loop(s) is then aligned to the computation shape of the instruction. For example, one supported computation shape of `wmma` is the Matmul [16,16]x[16,16]. To specialize for this instruction, the tiling should rearrange the innermost loop body to align with the shape, and then replace the rearranged loop body with the instruction. The tiling for the instruction `DP4A` with a shape [1,4]x[4,1] can be done similarly.

4 Implementation

We implemented SparTA on Rammer [60], a state-of-the-art open-source DNN compiler with no special support for sparsity. We implemented sparsity attribute propagation as a dedicated compilation pass over Rammer. A DNN model is converted to an ONNX graph [14] before compiling. Each TeSA element has a two-byte attribute: 7 bits record the bit width of the element, 4 bits specify the element's data format (*e.g., unsigned int*, *float32*, *bfloat16*), and the rest 5 bits are reserved. The bit-width zero means the element is pruned. TeSA exists only during compile time and therefore incurs no runtime memory cost. We implemented the execution plan transformation within Rammer, with an additional compilation pass that rewrites the graph with a better execution plan. The specialized sub-operators are injected into Rammer's kernel DB for constructing the whole executable.

For the efficient execution of weighted block cover in execution plan transformation (§3.3), SparTA calculates the weight of different block sizes. Specifically, we implemented a kernel template for block sparsity, and evaluated 13 different block sizes on that template. The overhead of each block size is profiled by measuring the latency of the kernel with zero sparsity and dividing the latency with the number of blocks. The overhead is used as the weight of the block sizes. When an operator is too sparse to saturate available cores, the weights may become less accurate. In such cases, we enumerate all the combinations of block sizes to run the weighted block cover algorithm and pick the best one. For kernel specialization, we implement the *dismantle* primitive based on loop unrolling. When a loop is unrolled with *dismantle*, we read the corresponding TeSA and eliminate dead computations accordingly.

SparTA, as a full-stack solution for model sparsity, has supported 21 model sparsity algorithms, including 16 pruning algorithms and 5 quantization algorithms (full list omitted due to page limit). Those algorithms can run on SparTA with little code modifications, and benefit from SparTA not only on sparsity exploration but also on model fine tuning, which will be demonstrated in §5.4.

5 Evaluation

We evaluate SparTA on three popular DNN models with four different sparsity patterns on NVIDIA GPU, AMD GPU, and Intel CPU. Overall, our key findings include:

- SparTA significantly reduces the inference latency of sparse DNN models with less memory consumption. The speedup is up to 10.6x, 5.0x, 7.5x, 20.1x, 5.8x, 5.6x, 1.7x over PyTorchJIT, TensorRT, TVM, TVM sparse[2], Rammer, Rammer sparse[3], and OpenVINO (CPU), respectively. The average speedup is 3.8x, 2.6x, 4.2x, 8.4x, 3.0x, 3.2x, 1.7x. (§5.1)

[2]Excluding cases where kernel tuning failed for TVM and TVM sparse.
[3]The state-of-the-art sparse kernels wrapped in Rammer.

Model	Type	Sparsity	Ratio	Acc (%)
BERT [34]	NLP {*Matmul*}	Structured [87]	95%	89.7->88.49
		Unstructured [43]	95%	89.7->88.67
		Structured+8bit [52]	95%	89.7->88.03
		Mixed Sparsity [48, 84]	94.99%	89.7->88.63
MobileNet [49]	CV {*Conv*}	Structured [94]	60%	78.27->75.62
		Unstructured [43]	95%	78.27->64.15
		Structured+8bit [52]	60%	78.27->75.13
HuBERT [50]	Speech {*Conv*, *Matmul*}	Structured [56, 62]	80%	95.61->95.1
		Unstructured [43]	95%	95.61->95.55
		Structured+8bit [52]	80%	95.61->94.3

Table 3: Evaluated DNN models with different sparsity patterns and their resulting accuracy. The second column lists the major operators of each model. The column **Ratio** denotes the initial sparsity ratio for pruned weights.

- Sparsity attribute propagation increases the end-to-end sparsity ratio by up to 39.7%. With execution plan transformation and code specialization, SparTA can achieve up to 6.7x speed up over the state-of-the-art sparse kernel implementation for a sparse DNN operator (*e.g.,* Matmul) with complex sparsity patterns. (§5.2, §5.3)
- SparTA facilitates the development and exploration of sparse DNN models, producing DNN models with lower inference latency and/or higher accuracy. (§5.4)

5.1 End-to-End Experiments

We evaluate SparTA on the inference latency and memory usage of three popular DNN models across different task domains, shown in Table 3. We evaluate four representative sparsity patterns, covering different pruning and quantization schemes and their combination. *Unstructured* sparsity prunes model weights in the granularity of an element in weight tensors to reach the desired sparsity ratio [43, 54, 55]. *Structured* sparsity prunes weights in the granularity of column, row, channel, or block, depending on specific models [44, 56, 59]. We apply different sparsity patterns to the three selected models to show SparTA's effectiveness under various patterns. BERT is pruned in row combined with a block of size 32x32 [87]; MobileNet gets pruned in the output channel [94]; for HuBERT, it is a combination of channel pruning in the Conv layer and head pruning in the transformer layer [56, 62]. To further demonstrate the powerful expressiveness of TeSA, we apply structured sparsity, based on which 8bit quantization is further applied on the remaining tensor elements to construct the third sparsity pattern, *i.e., Structured+8bit*. Finally, we introduce an even more complicated *Mixed Sparsity* for BERT. On top of the *Structured+8bit* sparsity, we apply unstructured sparsity with 32bit quantization back to 0.01% of the pruned elements [48, 84]. This leads to a total sparsity ratio of 94.99%.

We trained the models (BERT on dataset QQP [51], MobileNet on ImageNet-Dogs [33], HuBERT on SUPERB [85]) applied with the above sparsity patterns, the accuracy change

of those sparse models is shown in the **Acc** column of Table 3. Overall, the accuracy drops are consistent to those reported in the corresponding papers. The accuracy of sparse BERT drops around 1%. Mixed sparsity has the accuracy of 88.63% at 94.99% sparsity, nearly the same accuracy as unstructured sparsity, but is much easier to be accelerated. For MobileNet, unstructured sparsity has a higher accuracy drop, as its sparsity is high (*i.e.,* 95%). For HuBERT, 95% unstructured sparsity can outperform the structured ones with 80% sparsity ratio.

The models are evaluated on three types of accelerators: NVIDIA GeForce RTX 2080 Ti, AMD Radeon VII, and Intel Xeon Silver 4210 CPU. We compare SparTA with seven representative solutions, including one popular deep learning framework: PyTorch (v1.7) with JIT [67], two vendor-specific toolkits: TensorRT (v7.2) for NVIDIA GPUs [18] and OpenVINO (v2021.4.1) for Intel CPUs [15], two DNN compilers: TVM (0.9.dev0) [29] and Rammer [60] (which offers the state-of-the-art performance). To evaluate the state-of-the-art sparse kernels/libraries in an end-to-end model, we create Rammer sparse (or Rammer-S) by wrapping in Rammer these sparse kernel libraries/implementations, including cuSPARSE [3], taco [53], and Sputnik [39] for NVIDIA GPU, hipSPARSE [17] for AMD GPU, MKL Sparse Linear Algebra [12] for Intel CPU. For TVM, we also evaluate its sparsity support [22] (denoted by TVM-S). Each model on TVM is tuned with 1,000 trials per task using Ansor [91], aligned with the common practice [91]. The batch size we used in the end-to-end experiments (except Figure 12) is 32.

5.1.1 SparTA on CUDA GPUs

Structured sparsity. The first row of Figure 8 shows the inference latency of the three models on the structured sparsity. PyTorch, TensorRT, TVM, and Rammer treat them as three dense models. TensorRT performs the best among them. Compared to TensorRT, SparTA is 3.7x, 2.9x, 2.4x faster on BERT, MobileNet, and HuBERT, respectively. TVM-S and Rammer-S are aware of sparsity. TVM-S incurs high inference latency, as the kernel templates it uses cannot efficiently support different sparsity patterns. Rammer-S performs marginally better than TensorRT on MobileNet and HuBERT. The SOTA sparse kernel uses Sputnik, which performs better than cuSPARSE and taco on those models. SparTA performs 1.7x, 2.6x, and 2.3x faster than Rammer-S. Its performance gain comes mainly from sparsity propagation, which increases the whole model's sparsity (see §5.2) and sparsity transformation, *i.e.,* covered with different block sizes on different layers (see §5.3).

Memory footprints in the inference are shown in the first row of Figure 9. SparTA shows the smallest footprint. For MobileNet, PyTorch and TensorRT consume much more memory, because they use cuDNN, which requires additional memory to store weights and activations. SparTA's memory usage is smaller than TVM-S and Rammer-S due to sparsity propagation, which increases the sparsity ratio.

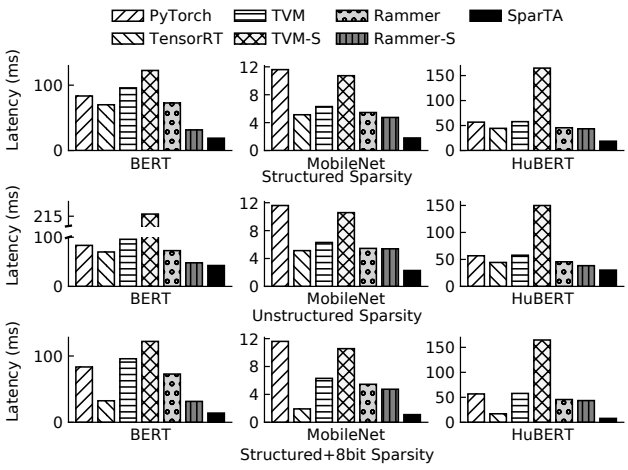

Figure 8: Inference latency of different models with three sparsity patterns on NVIDIA 2080 Ti.

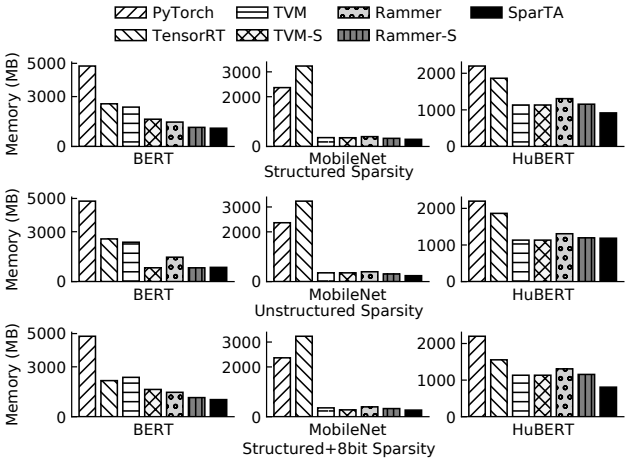

Figure 9: GPU memory usage of different models with three sparsity patterns on NVIDIA 2080 Ti.

Unstructured sparsity. For unstructured sparsity (*i.e.,* second row of Figure 8), TensorRT also performs the best among those dense baselines, marginally better than Rammer. SparTA is 1.6x, 2.2x, 1.5x faster than TensorRT on BERT, MobileNet, HuBERT, respectively. Rammer-S still uses Sputnik. SparTA outperforms Rammer-S by 1.13x, 2.4x, 1.3x on BERT, MobileNet, HuBERT, respectively. The speedup on MobileNet is high because the sparsity is easier to be propagated on depthwise and pointwise convolution even with unstructured sparsity. On BERT and HuBERT, the performance gain over Rammer-S mainly comes from code specialization (*i.e.,* weight values are embedded into kernel code). For the memory usage (*i.e.,* the second row of Figure 9), SparTA shows a usage similar to TVM-S and Rammer-S, and performs better than the other baselines.

Structured+8bit. Shown in the third row of Figure 8, Ten-

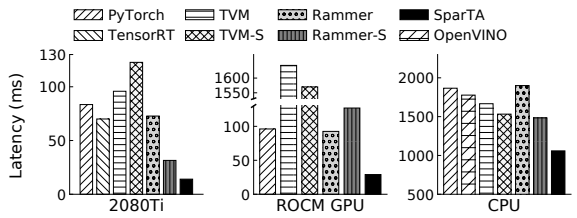

Figure 10: Mixed Sparsity end-to-end latencies.

sorRT performs much better than PyTorch, TVM, and Rammer, because it supports low-bit computations with Tensor Cores. SparTA outperforms TensorRT by 2.3x, 1.7x, 2.2x on BERT, MobileNet, HuBERT, respectively. This is because, besides leveraging the hardware instruction `wmma` of Tensor Core, SparTA further combines the optimization for structured sparsity. Compared to Rammer-S (also using Sputnik), SparTA is 2.3x, 4.3x, 5.6x faster on BERT, MobileNet, HuBERT, respectively, because Rammer-S has limited optimization (*e.g.,* missing low-bit instructions) for each single sparse operator, while SparTA does holistic optimizations on the model, *e.g.,* sparsity propagation, operator transformation and specialization. The speedup shows the combined gain from structured sparsity (*i.e.,* the first row of Figure 8) and low-bit instructions. The memory usage of SparTA (*i.e.,* the third row of Figure 9) is the lowest: the memory saving comes from both low-bit values and pruned elements. This highlights the benefit of SparTA and in particular TeSA that uses a unified abstraction for pruning and quantization to make such a joint optimization possible.

Mixed sparsity. The left figure in Figure 10 shows the latency of BERT with Mixed Sparsity. SparTA is 5.9x, 5.0x, 6.8x, 8.7x, 5.2x, 2.2x faster than PyTorch, TensorRT, TVM, TVM-S, Rammer, Rammer-S, respectively. Unlike structured+8bit, TensorRT shows slight advantage over other baselines on mixed sparsity, although most elements are 8-bit.

Latency Breakdown. Figure 11 shows the performance breakdown of BERT on the four sparsity patterns. "+Sparse Kernel" applies our generated sparse kernels following the original sparsity ratio without operator transformation and kernel specialization. It can be treated as Rammer-S. "+Propagation" applies sparsity propagation on the model and regenerates the sparse kernels without transformation and specialization. "+Transformation" tunes the block size for covering non-pruned elements of each sparse operator, and for mixed sparsity it also decomposes sparse tensors to multiple ones. "+Specialization" tunes intra-block implementation and embeds values into codes when necessary.

For mixed sparsity, the latency reduction brought by each optimization is 55.8%, 19.7%, 37.7%, and 12.6%, respectively. The other three sparsity patterns could be viewed as a type of breakdown of mixed sparsity. In structured sparsity and structured+8bit, transformation brings 20.5% and 26.5% latency reduction, respectively, while propagation brings 19.7% and 15.8% latency reduction, respectively. Finally, intra-block specialization brings 8.2%, 11.4%, and 13.7% latency reduction for structured, unstructured, and structured+8bit, respectively. The significance of a certain optimization depends on DNN models and sparsity patterns. For BERT in Figure 11, "+Sparse Kernel" brings 2.1x gain on average, SparTA brings an extra 2x gain. For MobileNet to be illustrated in §5.2, "+Propagation" brings the most gain (*e.g.,* increasing sparsity from the 50% to 89.7%).

Latency of different batch sizes. Figure 12 shows the performance of BERT under different batch sizes on NVIDIA 2080Ti. When batch size varies from 8 to 64, SparTA is on average 4.1x-4.6x, 2.4x-2.7x, 4.2x-6.3x, 5.9x-13.8x, 3.6x-4.1x, 2.2x-2.6x faster than PyTorch, TensorRT, TVM, TVM-S, Rammer, Rammer-S, respectively on three sparsity patterns. The overall speedup of SparTA is similar across different batch sizes. The range of the speedup over TVM-S is relatively large, because large batch size induces large tuning space that makes the kernel tuning in TVM less effective.

Compiling overhead. The overhead of SparTA comes from the compiling phase, which consists of three parts: propagation, transformation, specialization. The overhead is positively related to the number of operators in the model. Taking BERT as an example, the propagation, transformation, and specialization take 3 minutes, 2 hours and 1.5 hours respectively using a single thread. It is possible to reduce the overhead by leveraging more prior knowledge in transformation policy and pre-tuned kernels. We leave it as future work.

5.1.2 SparTA on Other Accelerators

ROCm GPU. Figure 13 shows inference latency of the three models on AMD Radeon VII. The speedup of SparTA over PyTorch on the three sparsity patterns is up to 3.5x, 4.2x, 2.2x for BERT, MobileNet, and HuBERT, respectively. The kernel tuning of TVM on ROCm GPUs does not function properly (always stuck in Debug mode), the performance of TVM and TVM-S on BERT and HuBERT suffers a lot. They show reasonable performance on MobileNet, because they

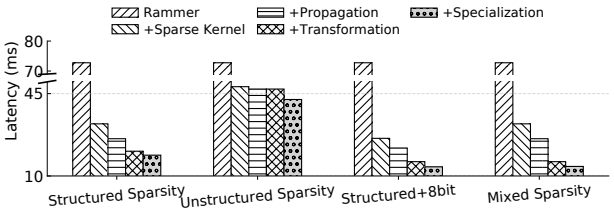

Figure 11: Performance breakdown of SparTA for different sparsity patterns of BERT on 2080 Ti. Each bar shows the result of applying the additional optimization labeled on this bar from the previous one.

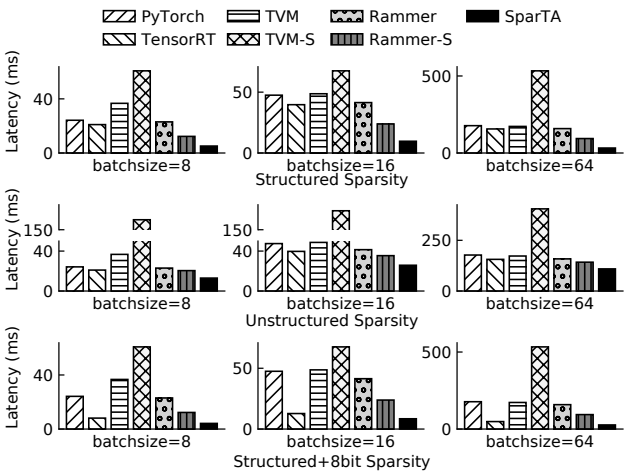

Figure 12: Inference latency of BERT under different batch sizes on NVIDIA 2080Ti.

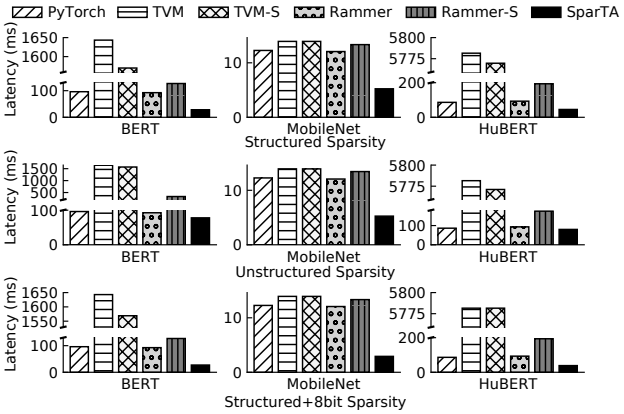

Figure 13: Inference latency of different models with three sparsity patterns on AMD Radeon VII.

have provided reasonably good default kernel schedules for some popular DNN models including MobileNet. Compared to Rammer, SparTA is up to 3.4x, 4.1x, 2.4x faster for BERT, MobileNet, and HuBERT, respectively, on the three sparsity patterns. Rammer-S uses hipSPARSE on ROCm GPU, the speedup of SparTA over Rammer-S is up to 4.7x, 4.6x, 5.0x for BERT, MobileNet, and HuBERT, respectively.

For mixed sparsity of BERT shown in the middle of Figure 10, SparTA is 3.3x, 56.7x, 54.1x, 3.2x, 4.4x faster than PyTorch, TVM, TVM-S, Rammer, and Rammer-S, respectively. Although Rammer-S with hipSPARSE has higher latency than Rammer, it has a lower memory footprint.

Intel CPU. We evaluated mixed sparsity pattern of BERT on CPU, the result is shown in the right of Figure 10. Compared to OpenVINO, a high-performance inference engine for Intel CPUs, SparTA achieves 1.7x speedup. For PyTorch, TVM, TVM-S, the speedup of SparTA is 1.8x, 1.6x, 1.5x, respectively. Rammer-S uses the MKL library, which leverages

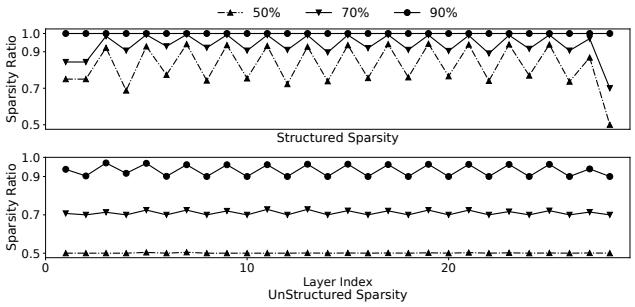

Figure 14: Propagated sparsity across the layers for different sparsity patterns on MobileNet

the sparsity, thus faster than other baselines. SparTA still has 1.4x performance gain over Rammer-S, because it leverages low-bit instruction (*i.e.,* AVX512 VNNI [10]) and further optimizes the model with sparsity propagation and execution plan transformation in a holistic way.

5.2 Sparsity Attribute Propagation

Propagation of pruned elements. The performance gain brought by propagation on BERT has been illustrated in Figure 11. The propagation has higher potentials on MobileNet, as convolution's filter size is small (*e.g.,* 3x3). Figure 14 shows how sparsity is propagated across layers on MobileNet, which increases each layer's sparsity ratio. In this experiment, we tested three sparsity ratios (*i.e.,* 50%, 70%, 90%) pruned by the same algorithm used in the end-to-end experiment. For each sparsity ratio, we prune every layer of MobileNet to the target ratio. Then the propagation rule is applied. The accuracy results of inference on train/test dataset are exactly the same before and after propagation, as the propagation rule for pruned elements does not affect computation logic.

For structured sparsity, the total sparsity ratio is increased from 50% to 89.7% after propagation. The curve's zigzag is caused by different propagation potential of the interleaving depthwise convolution and pointwise convolution in MobileNet. Interestingly, when the original sparsity ratio is 90%, after propagation the sparsity ratio becomes 100%, which explains the anomaly that, although there are 10% filters left on each convolution (before propagation), the model's accuracy is similar to a random image classifier. The propagation ability on unstructured sparsity is lower. Only high sparsity ratio could bring an obvious increase of sparsity ratio. For example, with 90% original sparsity, the total sparsity is increased to 95.3% after propagation. With Tensor Scrambling, our experiences show 256 randomly sampled tensors can identify sparsity correctly.

Propagation of quantization bit. In this experiment, we evaluate the propagation rule for quantization described in §3.2. We follow the same approach proposed in HAQ [77] to quantize MobileNet. Specifically, it uses reinforcement learn-

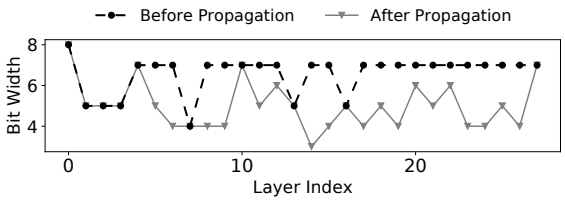

Figure 15: The quantization (bit width) of each layer in MobileNet before and after propagation.

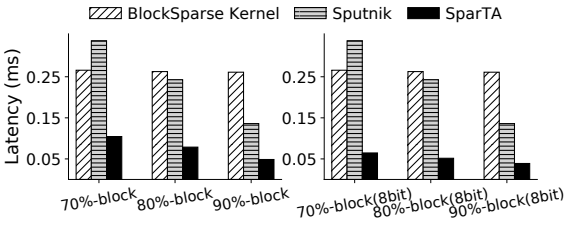

Figure 16: The performance of execution plan transformation for mixed sparsity patterns. B is sparsified for the matrix multiplication $A \times B$ (1024x1024x1024). "X%-block" means X% block sparsity mixed with 1% unstructured sparsity.

ing to explore the bit width on each weight and activation tensor. The candidate bit width is between 0 to 8. After exploring 50 different configurations of bit width, we pick the best one, whose accuracy on ImageNet is 64.6%. The propagation rule is then applied to that configuration. The experiment result is shown in Figure 15: 18 out of 28 layers reduces its bit width (from 7bit to around 4bit), while the model accuracy after propagation only drops slightly, from 64.6% to 64.2%. From another point of view, our propagation rule for quantization is complementary to the search algorithm (*e.g.,* reinforcement learning, simulated annealing [58]) on quantization bits. A proper combination of them could improve search efficiency, which is an interesting future work.

5.3 Efficient Code Generation with TeSA

Effectiveness of execution plan transformation. The sparsity-aware execution plan transformation in SparTA could handle complex sparsity patterns efficiently. We test two sophisticated sparsity patterns: (1) Mix of structured sparsity with block size 32x32 and unstructured sparsity (*i.e.,* 1x1) [48, 53]. There are 1% unstructured elements, and the structured sparsity ratio varies from 70% to 90%. (2) Based on the first sparsity pattern, we further make the structured sparsity 8bit, and make unstructured sparsity 32bit [84]. To show the effectiveness of transformation, we compare SparTA with two baselines: one is our specialized kernel for structured sparsity (denoted by BlockSparse), where the unstructured elements are covered with 32x32 blocks; the other is Sputnik, which is optimized for unstructured sparsity.

The results are shown in Figure 16. For the first sparsity pattern, SparTA transforms the operator into two sub-operators with structured sparsity and unstructured sparsity, respectively. After transformation, SparTA becomes 2.5x, 3.3x, 5.4x faster than BlockSparse on the three sparsity ratios, respectively. The performance of BlockSparse has little change, because the blocks to cover those unstructured elements construct the major of the blocks in the computation. The speedup of SparTA over Sputnik is 3.2x, 3.1x, 2.8x, respectively. Sputnik performs the worst on 70%-block, because it treats each block as 1,024 unstructured elements, missing optimization opportunities. For the second sparsity pattern, the performance gain of SparTA is much higher, *i.e.,* 4.1x, 5.1x, 6.7x faster than BlockSparse, 5.2x, 4.7x, 3.5x faster than Sputnik. This is because SparTA further leverages low-bit instructions for the computation of those 32x32 blocks.

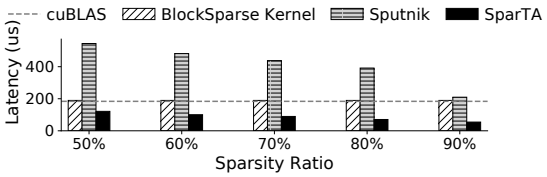

Figure 17: The performance of execution plan transformation leveraging Sparse Tensor Cores. B is sparsified with different sparsity ratios for $A \times B$ (1024x1024x1024).

The transformation can effectively leverage special hardware like Sparse Tensor Core [1]. Sparse Tensor Core has a strict requirement on tensor's sparsity pattern, *e.g.,* one element should be pruned in a $[1 \times 2]$ tile (50% sparsity ratio). To leverage Sparse Tensor Cores for the generic unstructured sparsity, we develop a new transformation policy to decompose an unstructured sparse tensor into two: one follows the sparsity requirement of Sparse Tensor Cores, the other contains the elements not included in the first one. The first one uses Sparse Tensor Cores, while the other uses our specialized sparse kernel. To evaluate the transformation, we randomly generate an unstructured sparse tensor whose sparsity ratio ranges from 50% to 90% in one input of Matmul. The experiment runs on NVIDIA A100, the result is shown in Figure 17. SparTA performs better than both BlockSparse and Sputnik, as it leverages cuSPARSELt [6], a library optimized for Sparse Tensor Cores, for sub-Matmul that costs around 40 us. The other sub-Matmul has 12.5%, 8%, 4.5%, 2.0%, 0.5% sparsity ratio respectively. BlockSparse shows a similar performance to cuBLAS. As the sparsity is randomly introduced, it actually computes a dense Matmul.

Sparsity Pattern	1	2	3	4	5
Origin Latency(ms)	1.293	0.361	2.808	1.263	0.189
SparTA Latency(ms)	0.436	0.191	0.599	0.569	0.101
Best Block Size	32x128	128x32	32x128	32x64	128x64

Table 4: Block size transformation

During the transformation, SparTA also finds the best

block size to cover those non-pruned elements. We picked 5 sparse tensors with different sparsity patterns in BERT, apply `WeightedBlockCover` to find the best block size of the 5 tensors. Table 4 shows the found block sizes. The chosen block sizes are all different from the original 32x32 block size and they all perform much better than the kernel implemented with the original block size. Essentially, the block covering makes a trade-off between the efficiency that a certain block size is optimized for the underlying hardware and the ratio of the computation wasted using that block size.

Effectiveness of TeSA code specialization. We evaluate SparTA's specialized matrix multiplication kernel under different unstructured sparsity ratios, ranging from 50% to 99%. We compare the specialized kernels with cuSPARSE, taco [16, 53], and Sputnik [39]. The result is shown in Figure 18. At 99% sparsity, cuSPARSE outperforms cuBLAS, but incurs 2.2x slowdown at 95% sparsity. In most cases, cuSPARSE performs much worse than cuBLAS on latency, although it has a lower memory footprint due to encoded sparse tensors. taco performs worse than cuSPARSE due to its inefficient utilization of shared memory [70]. It is 15.6x slower than cuSPARSE for 99% sparsity; the slowdown is reduced to 4.0x when the sparsity is 50%. SparTA is up to 6.0x faster than cuSPARSE. It outperforms cuBLAS when the sparsity is only 70%. Sputnik also performs better than cuSPARSE and taco. SparTA is up to 1.7x faster than Sputnik.

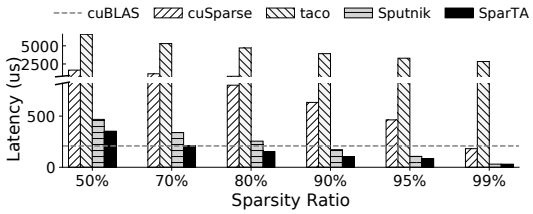

Figure 18: Comparison of cuSPARSE, taco, Sputnik, and SparTA on matrix multiplication (1024x1024x1024) with fine-grained sparsity under different sparsity ratios. B is sparse for $A \times B$.

5.4 Augmented Model Sparsity Exploration

SparTA, as a full-stack solution for model sparsity, facilitates the exploration of existing model sparsity algorithms. In this section, we demonstrate this from the following two aspects.

Actual latency vs. FLOPS as proxy-metric for latency reduction in model pruning. In this experiment, we use Simulated Annealing [58] to prune MobileNet to reduce 30% and 40% inference latency, respectively, *i.e.,* the two dash lines in Figure 19. Our baseline uses FLOPS as the metric to filter out the disqualified models: the model whose FLOPS is larger than 70% of the original FLOPS. In contrast, SparTA uses the real latency to filter models. The result is shown in Figure 19. The best sparse models found by the two approaches have similar accuracy. However, the model found via FLOPS does not meet the latency target, 23.8% and 51.4% higher than the target, respectively. This shows FLOPS cannot faithfully reflect real inference latency. In contrast, the sparse models found by the algorithm on SparTA successfully satisfy the latency requirement.

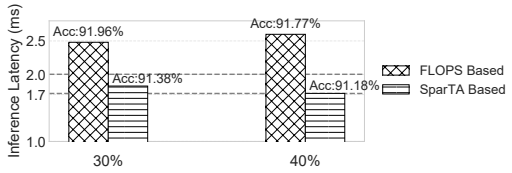

Figure 19: The comparison of using real latency or FLOPS as metric to explore sparse models by Simulated Annealing.

Speeding up sparsity exploration. With high-performance sparse kernels, SparTA can speed up the exploration process of a sparsity algorithm, which usually searches for a sparsity pattern iteratively [58, 86]. In each iteration, the algorithm "sparsifies" a proportion of the model (*e.g.,* 30%) and fine-tunes it. It repeats the iteration until achieving the targeted sparsity (*e.g.,* 90%). In this process, model fine-tuning consumes significant exploration time. With SparTA, model fine-tuning can be accelerated. Figure 20 runs Simulated Annealing, an iterative sparsity algorithm, on ResNet50. The algorithm prunes 50% of the remaining weights and fine-tune 300 epochs in each iteration. SparTA reduces 31.8% of the total exploration time, compared to the baseline that always uses the original dense model.

5.5 Accelerating Sparse Model Training

In addition to model pruning and quantization, some DNN models are designed to be sparse from the beginning, *e.g.,* sparse attention [72]. SparTA can also be used to speed up the training process of such sparse models.

We show this by applying SparTA to the training of NÜWA [81], a state-of-the-art visual synthesis pretrain model that adopts a novel 3D Nearby Attention (3DNA) mechanism. In 3DNA, each token computes the attention to the nearby tokens within a small 3D window, instead of to all the tokens (*i.e.,* full attention).

We implement 3DNA using SparTA and compare the performance with its previous PyTorch implementation (a dense version), and another version implemented using OpenAI's Triton (v1.1.1) [21], a compiler that supports sparse attention. As the two baselines are PyTorch-based, we integrate SparTA-based 3DNA into PyTorch for a fair comparison. The result is shown in Figure 21. Both Triton and SparTA perform much faster than the default PyTorch version, and consume less GPU memory. The default PyTorch version encounters out-of-memory when the batch size grows beyond 16. SparTA is 2.15∼2.24x faster than Triton across different

Figure 20: The improvement on exploration time when using SparTA-accelerated sparse model.

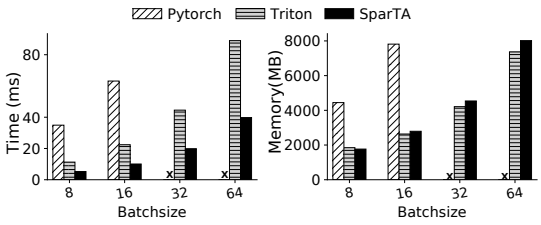

Figure 21: The time of training one batch and GPU memory consumption of 3DNA on NVIDIA 2080Ti.

batch sizes, mainly because SparTA specializes the block sizes (*e.g.,* 32x64, 32x32) covered on non-zero values in the matrix multiplications of 3DNA. The memory usage of SparTA and Triton are similar. As the SparTA-based version currently relies on PyTorch for the management of some intermediate tensor, it is possible to further improve the memory usage by moving it to the SparTA side.

6 Related Works

Sparsity support in DNN frameworks and compilers. Deep learning frameworks like PyTorch [67] and TensorFlow [23] or compilers like TVM/Ansor [29, 91] exploit sparsity by vendor-specific libraries like cuSPARSE/cuSPARSELt [3] or user-provided sparsity kernel templates [29]. The lack of understanding to the specific sparsity pattern across a sparse model leads to a subpar performance. In contrast, with TeSA, SparTA can capture arbitrary sparsity patterns and enable various sparsity-aware optimizations to generate efficient end-to-end code.

SparTA's design incorporates several classic compiler techniques. For example, sparsity attribute propagation is similar to type qualifiers [38] and type inference [32]. OpenMP [35] also leverages attribute propagation in a different problem domain with a different mechanism. Code specialization based on value profiling [27] is also a well-known technique. Zeroploit [69] and PGZ [71] also use a similar idea, but focus on gaming applications. Instead of values, SparTA uses more general attributes for code specialization. And SparTA offers a complete framework for DNN model sparsity.

Sparsity acceleration of DNN models. Sparse matrix multiplication has been studied for decades in scientific computing [68,80]. With the emerging accelerators (*e.g.,* GPU [8,20], TPU [4], FPGA [11], GraphCore [9]), some research optimizes sparse matrix multiplication for a certain type of hardware [24, 26, 39, 80, 95]. Another type of works study an efficient sparse data format (*e.g.,* CSR, CSB, and DIA) to reduce memory footprint and improve cache efficiency. taco [30, 53, 70] generalizes various sparse data formats with a unified expression. It generates sparse kernel code using the proper data format best fit for a class of sparsity pattern (*e.g.,* 99% sparsity). Unlike taco, SparTA proposes a holistic framework for sparsity, including sparsity propagation, execution plan transformation, and code specialization.

To optimize sparse kernels on GPU, SparseRT [79] embeds sparse weight values into kernel codes rather than stored in a sparse data format. It can be seen as a special case of code specialization in SparTA, *i.e.,* unrolling all the loops. Hong et. al [48] reorders elements in a sparse tensor and uses an adaptive tiling strategy to enhance the performance of sparse matrix multiplication. These optimizations are complementary to SparTA.

Some works [28, 88] co-design sparsity algorithms with hardware, which balance sparsity for efficient parallel execution on a GPU. Similar design has been incorporated in Sparse Tensor Core [93]. EIE [41] designs a new data encoding/decoding node and a new Processing Element (PE) to speed up matrix-vector multiplication. SCNN [65] designs another architecture of PE, which supports sparse convolution in a compressed format. SparTA can leverage these new accelerators with new transformations and specialization passes.

Sparsity exploration on DNN models. Research on both neural science and deep learning suggests that a deep neural network is sparse [54, 89]. Various model compression algorithms are shown to construct sparse models with little accuracy degradation. Unstructured pruning prunes model weights without a regular pattern [43, 54, 55], while other works prune DNN models in a regular granularity, such as in the filter [44], channel [56, 59] in CNN, and block level [61, 63]. Quantization is another way to sparsify a model, including single-precision [31,52,92], mixed-precision among layers [36, 57, 77], and mixed-precision within each tensor [66, 84]. Recent works further combine the pruning and quantization techniques [42, 74, 75, 78, 83, 90]. SparTA's TeSA abstraction could capture the sparsity patterns in all these works and generate efficient code for the sparse model.

7 Conclusion

SparTA takes a principled system approach to model sparsity in deep learning, centered on the new TeSA abstraction. SparTA is designed to accommodate a rich set of sparsity patterns, work end-to-end and across the stack to support propagation of sparsity patterns and the optimizations that take advantage of those patterns, and leverage compiler technology and hardware support, all in an extensible framework. SparTA can not only contribute to superior sparsity-induced speedup, but also accelerate model sparsity innovations within a unified framework, for the first time.

A Artifact Appendix

Abstract

SparTA proposes the new TeSA abstraction which enables the sparsity optimization across the compiler stack. This artifact reproduces the main results of the evaluation on NVIDIA 2080Ti and A100.

Scope

This artifact will validate the following claims:

- End-to-end performance: By reproducing the experiments of Figure 8, 9, 10, 11, we can validate the end-to-end latency and memory footprint of SparTA claimed in §5.1.
- Effectiveness of the propagation: By reproducing the experiments of Figure 14, 15, we can validate the effectiveness of the propagation.
- Effectiveness of the transformation: By reproducing the experiments of Figure 16, 17, we can validate the effectiveness of the transformation.
- Effectiveness of the specialization: By reproducing the experiments of Figure 18, we can validate the effectiveness of the specialization.
- Augmentation of model sparsity exploration: By reproducing the experiments of Figure 20, we can validate that SparTA can augment the model sparsity exploration for the algorithms.

Contents

In this artifact, we will reproduce the Figure 8-11, 14-18, 20 on NVIDIA 2080Ti and A100. Each figure has a shell script to reproduce and visualize the experimental results automatically. In addition, there are many baselines compared in our evaluation, therefore, we also provide a Dockerfile containing all dependent environments for 2080Ti and A100 respectively. Users can quickly set up the experiment environment with the Dockerfile we provided.

Hosting

The artifact is hosted at https://github.com/microsoft/SparTA/tree/sparta_artifact. To get the code, please git clone the SparTA repository and checkout to the *sparta_artifact* branch.

Requirements

- **Hardware requirements:** Figure 17 requires a NVIDIA A100 GPU and the other Figures requires a NVIDIA 2080Ti GPU.
- **Software requirements:** Please use docker to build the *image/Dockerfile* to set up the environment for 2080Ti and *image/Dockerfile.a100* to set up the environment for A100.
- **CUDA Driver:** Larger than 11.2.

Tutorial

Environment setup To set up the environment, please first clone the code and build the docker image based the Dockerfile we provided. Second, please start a docker instance and install the SparTA in the python environment. Finally, please run the *init_env.sh* to initialize the environment variables and download the datasets. Listing 1 shows the commands used to set up the experiment environment.

Listing 1: Commands to set up the environment

```
# get the source code
git clone -b sparta_artifact https://github.com/microsoft/SparTA.git
cd SparTA/image
# build the docker image
sudo docker build . -t artifact
# start a docker instance
sudo docker run -it --gpus all --shm-size 16G artifact

# Execute following commands in the docker instance
# install the sparta
mkdir workspace && cd workspace
git clone https://github.com/microsoft/SparTA && cd SparTA && git checkout sparta_artifact
conda activate artifact
python setup.py develop
# initialize the environment
cd script && bash init_env.sh
```

Run experiments SparTA provides the end-to-end scripts to reproduce all the experiments with one command on NVIDIA 2080Ti and A100 respectively. Listing 2 shows the commands to start all the experiments. The reproduced results will be visualized and saved automatically.

Listing 2: Commands to run the experiments

```
# go into the script directory
cd script
# for 2080Ti
bash run_all_2080ti.sh
# for A100
bash run_all_a100.sh
```

ROLLER: Fast and Efficient Tensor Compilation for Deep Learning

Abstract

Despite recent advances in tensor compilers, it often takes hours to generate an efficient kernel for an operator, a compute-intensive sub-task in a deep neural network (DNN), on various accelerators (e.g., GPUs). This significantly slows down DNN development cycles and incurs heavy burdens on the development of general kernel libraries and custom kernels, especially for new hardware vendors. The slow compilation process is due to the large search space formulated by existing DNN compilers, which have to use machine learning algorithms to find good solutions.

In this paper, we present ROLLER, which takes a different construction-based approach to generate kernels. At the core of ROLLER is *r*Tile, a new tile abstraction that encapsulates tensor shapes that *align* with the key features of the underlying accelerator, thus achieving efficient execution by limiting the shape choices. ROLLER then adopts a recursive *r*Tile-based construction algorithm to generate *r*Tile-based programs (*r*Program), whose performance can be evaluated efficiently with a micro-performance model without being evaluated in a real device. As a result, ROLLER can generate efficient kernels *in seconds*, with comparable performance to the state-of-the-art solutions on popular accelerators like GPUs, while offering better kernels on newer accelerators like IPUs.

1 Introduction

Deep neural networks (DNN) have been used extensively in intelligent tasks like computer vision and natural language understanding. As DNN computation is known for its complexity, the compute intensive sub-tasks (e.g., matrix multiplication) in a DNN model are abstracted as operators and implemented as kernels, executed on modern accelerators (e.g., GPUs, TPUs) to speed up the computation. DNN compilers play an important role in producing high-performance kernels for the development of DNN models. It reduces the burden of (often hand-crafted) library-based kernel development (e.g., cuDNN [6] and cuBLAS [2]) and provides a flexible way to cover the fast-growing number of custom operators, which libraries struggle to catch up with and optimize, a growing pain especially for new hardware vendors.

DNN compilers treat a DNN operator as tensor computation, which is then translated into nested multi-level loops iterated over the computation on each tensor element along different axes (dimensions). Compiler optimization techniques like loop partitioning/fusion/reordering are applied to nested loops. Due to the inherent complexity of loop rearrangement, it is a combinatorial optimization problem to find a good solution among a large search space, often with millions of choices. Therefore, advanced compilers [15, 33, 35] propose to adopt machine learning algorithms to search for a good solution. This usually takes thousands of search steps, each evaluated in a real accelerator, to find a reasonable solution. Our own experience shows that tuning an end-to-end DNN model using state-of-the-art compilers [15, 33] often requires days, if not weeks. The tuning time may be even longer if the DNN model runs on less mature accelerators (e.g., AMD GPU or Graphcore IPU [4]) (§2). To make the matter worse, a DNN model need to re-compile whenever its structure, operator types, tensor shapes and configurations are changed. This is often required when trying different configurations in model training or inference. Given that an operator could have arbitrary input shapes and configurations, such compilation could significantly slow down the overall DNN model development cycle.

In this paper, we propose ROLLER, a deep learning tensor compiler that addresses the problem in a radically different way. ROLLER is built on the following insights. First, instead of multi-level nested loops, ROLLER treats the computation in a DNN operator as a *data processing pipeline*, where data tiles (a fraction of a tensor) are moved and processed in an abstracted hardware with parallel execution units and multi-layer memory hierarchy. The goal of generating efficient kernel programs then becomes that of improving the throughput of the pipeline.

*Work is done during the internship at Microsoft Research.

Second, for an accelerator to execute efficiently, the shape of a data tile should *align* with the hardware characteristics, including memory bank, memory transaction length, and minimum schedulable unit (e.g., warp size in GPUs). To achieve the full alignment across multiple hardware features, the available tile shapes are limited. More importantly, with alignment as a constraint, to maximize the throughput of a pipeline, one only needs to *construct* an aligned tile shape that saturates the execution unit of the accelerator. This construction process is significantly more efficient than solving the original unconstrained combinatorial optimization problem.

Third, the performance of an aligned pipeline is highly predictable. Key performance metrics under the aligned pipeline (e.g., memory throughput) can be derived from the hardware specification (or through micro-benchmarking). This greatly simplifies the performance evaluation under various aligned configurations, eliminating the need of a complex cost model and/or expensive hardware-based evaluation on each aligned configuration.

With these insights, ROLLER proposes *r*Tile, a new abstraction that encapsulates data tile shapes that *align* with the key features of the hardware accelerator and the input tensor shapes (§3.1). A data processing pipeline can then be described as an *r*Tile-based program (a.k.a. *r*Program) composed by three interfaces: `Load`, `Store`, and `Compute`, acted against *r*Tile. To construct an efficient *r*Program, ROLLER follows a *scale-up-then-scale-out* approach. It first performs the scale-up process, which adopts a recursive *r*Tile-based construction algorithm (Figure 8) to gradually increase the size of the *r*Tile shape to construct an *r*Program that saturates a single execution unit of the accelerator (e.g., an SM, a streaming multi-processor in a NVIDIA GPU). It then performs the scale-out process, which simply replicates the resulting *r*Program to other parallel execution units, thanks to the homogeneity of both the computation pattern of deep learning and the parallel execution units in an accelerator.

ROLLER can evaluate the performance of different *r*Tiles without significant overheads. The peak (saturate) compute throughput can simply be measured *once per operator type*. And due to the alignment, other key performance factors like memory pressure of an *r*Tile can be derived analytically from hardware specifications. This leads to an efficient micro-performance model, avoiding the expensive online profiling on each configuration required by existing DNN compilers, thereby significantly speeding up the compilation process. In addition, due to the strict alignment requirements, the recursive construction process can produce a few desired *r*Tiles (and *r*Program) quickly. Combined, ROLLER can generate efficient kernels *in seconds*.

We have implemented ROLLER on top of TVM [15] and Rammer [26], and open-sourced the code[1]. Our evaluation on 6 types and 119 popular DNN operators from several mainstream DNN models shows that ROLLER can generate highly-optimized kernels in *seconds*, especially for large expensive custom operators. This achieves *three orders of magnitude improvement* on compilation time. The performance of ROLLER-generated kernels is comparable to and often better than the state-of-the-art tensor compilers and even vendor-provided DNN libraries. With the three *r*Tile-based interfaces (`Load`, `Compute`, `Store`) describing an *r*Program, ROLLER can easily adapt to different accelerators like AMD GPU and Graphcore IPU. ROLLER has been used to develop custom DNN kernels internally and shown to significantly speed up our development cycle. It offers potentially disruptive opportunities to new players in the compute accelerator market, who previously have to spend significant engineering efforts on efficient kernels.

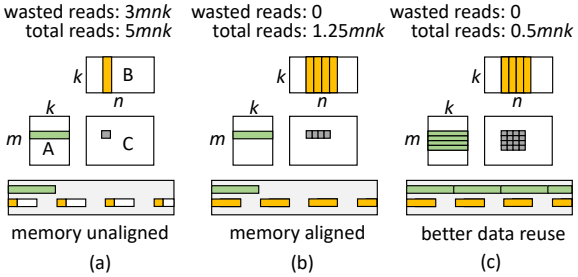

Figure 1: Access pattern of different tile shape. Matrix multiplication, $C_{m,n} = A_{m,k} \times B_{k,n}$.

2 Motivation and Key Observations

Excessive compilation time. Our own experience in a set of DNN operators (detailed setting in §5) shows that the average compile time for a single operator using Ansor [33], a state-of-the-art tensor compiler, is 0.65 hours. Among them, one convolution operator in ResNet model takes 2.17 hours. A DNN model may contain hundreds of operators, thus it easily takes days to compile the model. For example, to compile a NASNet model (§5), we reach only 32% of the overall searching progress after tuning for 41.8 hours. Our experience also shows the compilation speed is even worse on less mature devices, the compiler takes much longer time for a kernel.

Observation and insights. We observe that there exists a different view to the computation of an DNN operator. Taking matrix multiplication (MatMul), $C_{m,n} = A_{m,k} \times B_{k,n}$, as an example to illustrate our observation. Unlike existing compilers that treat MatMul as a 3-level loop iterated over each axis m,k,n, the computation process is also a data processing pipeline. One can `Load` each sub-matrix (i.e., a tile) from A and B, `Compute` the two tiles, and `Store` the resulting tile of C to memory. Thus, the performance of the computation depends on how fast one can move the data tiles in the `Load-Compute-Store` pipeline.

The key factor affecting the performance in all steps in the pipeline is the *shape* of tiles and the corresponding layout

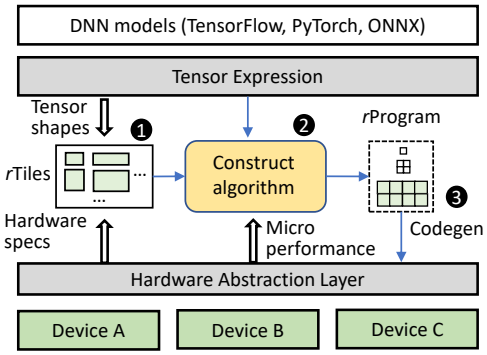

Figure 2: System overview of ROLLER.

in the one-dimension memory space. Figure 1(a) illustrates the computation of one element in C (in the top part) and the memory accessing pattern (in the bottom part). Assuming all matrices stored in a row-major layout, loading a column from B causes strided accesses in length of 1. Suppose the memory transaction length is 4, there will be $3/4$ of total redundant data reads. Thus, the data tile shape should align with the memory transaction length for efficient memory access. In Figure 1(b), when computing B in the granularity of 1×4 tile, there will be no memory bandwidth waste. Besides memory alignment, the tile shape should also align with the hardware execution unit, e.g., the parallel threads number, to avoid waste in computing cycles. Moreover, the tile shape also affects data reuse opportunities due to caching, a common feature in modern accelerators. For example, Figure 1(a) needs $2mnk$ data reads when computing a 1×1 tile each time. However, in Figure 1(b), only $1.25mnk$ reads are required, as one read from A can be reused 4 times. If setting the tile size along M dimension to 4×4, as shown in Figure 1(c), the total reads can be reduced to $0.5mnk$. A $10\times$ improvement over Figure 1(a).

These observations motivate ROLLER, a system that identifies the aligned tile shapes and constructs an efficient tile processing pipeline to improve the end-to-end throughput.

3 System Design

Figure 2 shows the system overview. ROLLER takes an operator described as a tensor expression (§3.1). The expression is generated by users or from a graph-level DNN compiler [15, 26, 33], which might further fuse multiple operators into a single expression. ROLLER extracts the tensor shapes from the tensor expression and leverage hardware specifications to construct *r*Tiles, i.e., a hardware-aligned building block (§3.1). Based on *r*Tiles, ROLLER proposes a *scale-up-then-scale-out* recursive construction algorithm to generate efficient tensor programs (named *r*Program) that describes the data processing pipeline (§3.2). When generating *r*Program, the construction algorithm identifies good *r*Tile configurations by evaluating the performance of a constructed *r*Program through a micro-performance model. It is built on top a device described through a hardware abstraction layer exposing only *r*Tile-related interfaces: `Load`, `Compute`, and `Store` (§3.3). The constructed *r*Program is finally realized through a code generator to emit the final kernel code corresponding to the specific device.

```
class rTile {
  TensorExpr expr;
  TileShape shape;
  TileShape storage_padding;
  vector<TileShape> GetInputDataTiles();
  vector<TileShape> GetOutputDataTiles();
};
```

Figure 3: The data structure of *r*Tile.

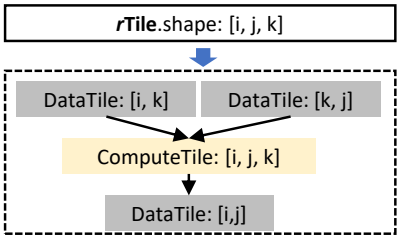

Figure 4: The data tiles and computing tile inferred by an *r*Tile for MatMul expression.

3.1 Tensor Expression and *r*Tile

ROLLER takes input of a tensor computation as an index-based lambda expression, i.e., tensor expression [15, 27]. It describes how each element in the output tensor is computed based on the corresponding elements in the input tensors. For example, a MatMul operator with output tensor C of the shape $M \times N$ can be expressed as,

```
C = compute((M,N), lambda i,j:sum(A[i,k]*B[k,j])),
```

where the element indexed by (i, j) in C is computed by a sum reduction over the elements in row i of A and column j of B, and k is the reduction axis. Such an expression can cover the majority of operators in DNN models and is widely used in existing DNN compilers including TVM [15], Ansor [33], and FlexTensor [35].

ROLLER introduces *RollingTile* (*r*Tile for short) as the basic computing unit to compose a tensor computation. As shown in Figure 3, an *r*Tile encapsulates a multi-dimensional tile `shape` defined along each loop axis of a given tensor expression `expr`. Given `shape` and `expr`, an *r*Tile can statically infer the involved input and output data tiles. For example, a tile shape $[4, 4, 2]$ along axes i, j, k denotes an *r*Tile for the above MatMul expression, where each *r*Tile loads a 4×2 data tile from A and a 2×4 tile from B, conducts total $4 \times 4 \times 2$ multiply-add computations, and stores a 4×4 data tile to C, as illustrated in Figure 4.

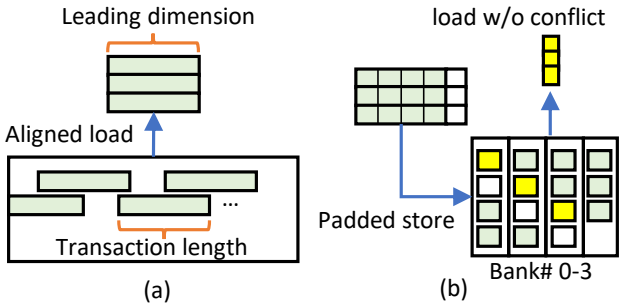

Figure 5: Illustration of (a) transaction aligned memory load and (b) bank conflict-free padding.

A unique property of an *r*Tile is that it must align with both the underlying hardware features and the tensor shapes in a given tensor expression. All these alignments are controlled by the *r*Tile *shape* and the *storage_padding* fields in Figure 3, which represent the logical form and the physical layout of an *r*Tile, respectively. We elaborate the detailed requirements of alignment next.

Alignment with the hardware execution unit. First, the shape of an *r*Tile must align with the parallelism of the execution unit it runs on. For example, if running on a warp of threads in a GPU, the size of `shape` in the *r*Tile should be a multiple of the warp size, e.g., 32, for maximal computing efficiency. When using TensorCore in NVIDIA GPUs, the *r*Tile shape should be a multiple of $16 \times 16 \times 16$. Similarly, an *r*Tile executed on a streaming multi-processor (SM) should align its size as a factor of execution unit number on the SM.

Alignment with memory transaction. Second, a data tile's shape should align with the length of memory transaction for optimal memory access. Specifically, for each data tile of an *r*Tile, we should guarantee that its leading dimension (e.g., the inner-most dimension in a row-major tensor) is a multiple of the memory transaction length, as illustrated in Figure 5(a). In ROLLER, tensors are allocated in a cache-aligned way. Thus, an *r*Tile can avoid any wasted transaction read, as its shape is aligned with the memory transaction.

Alignment with memory bank. Third, the memory layout of a data tile should align its stride with the memory bank to avoid read conflicts. For example, a $[3,4]$ data tile is kept in the memory across 4 banks and is read by an upper-memory-layer tile with a shape of $[3,1]$, as shown in Figure 5(b). A naive approach that stores all the $[3,1]$ values in the same bank will result in conflicted loading. *r*Tile avoids such inefficiency by padding a data tile. Given a data tile with a leading dimension of size N, which is read by another tile with a leading dimension of size n, we add a padding size of $(BL - N\%(BL) + L\lceil n/L \rceil)\%(BL)$ along N when storing this tile, where B and L are the bank number and the bank width, respectively. The padding sizes along each axis are calculated and stored in the `storage_padding` field in Figure 3. For the case in Figure 5(b), by a padding size of 1, all the $[3,1]$ values are distributed in different banks and can be read efficiently.

Alignment with tensor shape. Finally, an *r*Tile's shape should align with the tensor shape of an input tensor expression. Otherwise, the computation cannot be evenly partitioned by the *r*Tile, wasting compute resources or incurring heavy boundary checking overheads. A simple solution is to add a padding size P_i along a tensor dimension i with size of N_i, which makes $N_i + P_i$ a multiple of the *r*Tile shape's dimension size at axis i. However, a large padding might waste computation. ROLLER therefore restricts tensor padding under a range ε, where an *r*Tile's shape dimension size S_i has to satisfy that $\frac{S_i - N_i \% S_i}{N_i} \leq \varepsilon$, where N_i is the tensor size at dimension i. This ensures the wasted percentage of computation is bounded by ε. With this restriction, we can enumerate all the valid *r*Tile shapes that satisfy this condition.

Deriving all *r*Tiles. Given the above alignment requirements, for a specific tensor expression and hardware device, ROLLER incrementally derives all the conforming *r*Tiles using the following interface:

```
vector<int> GetNextAlignedAxisSize(rTile T, Dev d),
```

which returns the next aligned size for each axis in the `shape` of *r*Tile T given the specific device specification d. This is calculated by gradually increasing the dimension size along each axis until it satisfies all the alignment requirements. The *r*Tile abstraction allows ROLLER to be extended to support new alignment requirements (e.g., new hardware features). This is achieved by adding new alignment rules to the `GetNextAlignedAxisSize` interface.

Calculating data reuse score. An interesting property of *r*Tile is that we can implicitly control the memory traffic by adjusting its `shape`. Increasing the *r*Tile size usually brings more *data reuse* opportunities at the cost of occupying more memory space. Given an *r*Tile T and its next aligned size in each axis, we can calculate the data reuse score S_i for axis i by $S_i = \frac{Q(T) - Q(T_i')}{F(T_i') - F(T)}$, where T_i' is a newly enlarged *r*Tile by replacing the dimension size at axis i with the next aligned size from `GetNextAlignedAxisSize`. Functions $Q(T)$ and $F(T)$ calculate the memory traffic and memory footprint when the computation is executed in the granularity of T, which can be directly inferred based on the given tensor expression and hardware memory specification (§3.3). A larger S_i means better cost-efficiency, i.e., more memory traffic can be saved with the same memory usage. The memory reuse score plays a critical role in constructing an efficient *r*Program (using *r*Tiles), as shown in the next subsection.

3.2 Tensor Program Construction

***r*Tile program.** Given *r*Tile and the hierarchical memory structure of modern accelerators, a tensor computation can be naturally treated as a streaming data processing pipeline. The computation loads data tiles (specified in *r*Tile) from the lowest memory layer through the memory hierarchy to the highest layer, performs *r*Tile computation on the execution

```
for L1_iter in L2_rtile.split(L1_rtile):
  L1_input_tiles = Load(L1_iter); //L2 to L1
  for L0_iter in L1_rtile.split(L0_rtile):
    L0_input_tiles = Load(L0_iter) //L1 to L0
    L0_out_tile = Compute(L0_input_tiles);
    Store(L0_out_tile, L2_out_tile);//L0 to L2
```

Figure 6: The pseudo code of an *r*Program on a device with a 3-layer memory hierarchy (Bottom-up: layer `L2` to layer `L0`).

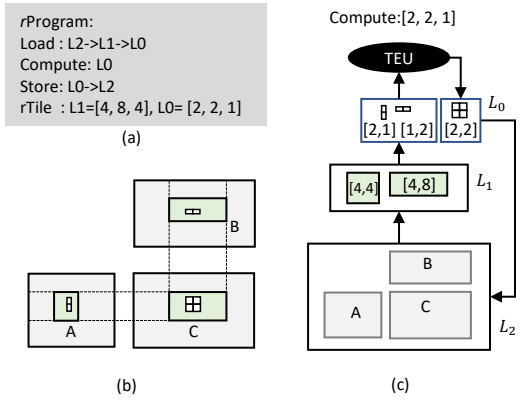

Figure 7: ROLLER computation model. (a) An *r*Tile program; (b) *r*Tiles on matrix multiplication; (c) Execution of the *r*Tile program on a hardware memory hierarchy.

units of the accelerator, and stores the resulting data tiles back to the lowest memory. For each memory layer, a specific *r*Tile is defined to align with the characteristics of this memory layer. Thus, ROLLER describes tensor computation as a data processing pipeline with a hierarchical *r*Tile configuration, which is called an *r*Tile program (i.e., *r*Program).

Figure 6 shows an *r*Program on a device with three memory layers (L0, L1 and L2). The *r*Program is described by the *r*Tile at each layer and the *r*Tile instructions (i.e., `Load`, `Store`, and `Compute`) at each memory layer. Figure 7(a) shows a MatMul *r*Program illustrated in Figure 7(b). Figure 7(c) illustrates how the *r*Program is mapped to each memory layer of a device. Specifically, each time it loads a $[4,4]$ data tile in A and a $[4,8]$ tile in B from memory L2 to L1; and then it loads the data tiles from memory L1 to memory L0 (i.e., registers) in shapes of $[2,1]$ and $[1,2]$. After each `Compute`, the resulting $[2,2]$ tile will be directly stored from L0 to L2.

Given a data processing pipeline, the optimization goal of the corresponding *r*Program is to maximize the throughput of the pipeline. The goal can be translated into three conditions: 1) the computation and memory movement should fully leverage the hardware features; 2) the throughput should saturate the bottleneck stage; and 3) there needs to be sufficient parallelism to leverage all the parallel execution units. Thus, ROLLER proposes the following *r*Program construction policy: first scale-up on one core by constructing a single-core *r*Program to saturate the core's hardware utilization and then

```
1  Func ConstructProg(expr:TensorExpr, dev:Device):
2      T = rTile(expr);
3      Results = [];
4      EnlargeTile(T, dev.MemLayer(0), rProg());
5  Func EnlargeTile(T:rTile, mem:MemLayer, P:rProg):
6      if mem.IsLowestLayer()
7          Results.append(P);
8          if (Results.Size() > TopK) Exit();
9          Return();
10     for T' : GetNextRTileShapes(T, mem) do
11         if Visited(T')
12             Return();
13         if MemFootprint(T') > mem.Capacity()
14             P.Add(mem, T);
15             EnlargeTile(T, mem.Next(), P);
16         else
17             if MemPerf(T') > MaxComputePerf(T'.expr)
18                 P.Add(mem, T');
19                 EnlargeTile(T', mem.Next(), P);
20             EnlargeTile(T', mem, P);
21 Func GetNextRTileShapes(T:rTile, mem:MemLayer)
22     alignedSizes = GetNextAlignedAxisSize(T, mem);
23     SortedRTiles = OrderedMap();
24     for d : T.Dimensions() do
25         T' = T.Replace(d, alignedSizes[d]);
26         SortedRTiles.Insert({T', DataReuseScore(T')});
27     Return SortedRTiles;
```

Figure 8: ROLLER's *r*Program constructing algorithm for a single core (e.g., an SM).

scale-out to leverage the multi-core parallelism by replicating the constructed single-core *r*Program.

Scaling up an *r*Program. Since the alignment properties of *r*Tile ensure hardware efficiency, ROLLER can just focus on maximizing the throughput at each memory layer by constructing the right *r*Tile shape. By leveraging the data reuse score defined in §3.1, the single-core *r*Program construction algorithm starts from an initial *r*Tile and gradually enlarges it towards the most cost-effective axis in the *r*Tile (i.e., with the maximum data reuse score). Note that the construction algorithm does not require an absolute data reuse score, it just picks the largest one to maximize the throughput. During the process, the memory performance improves until it hits the computational bound or the maximal memory capacity. The above process repeats for each memory layer from top to bottom, until a desired *r*Program is constructed. Note that if the data reuse score remains constant for some tensor expressions, e.g., element-wise operators, ROLLER will just construct *r*Tiles for the top layer and loads them directly from the bottom layer memory.

Figure 8 shows the detailed construction algorithm. Given a tensor expression `expr` and a target device `dev`, the algo-

rithm constructs an initial *r*Tile T at the top memory layer and enlarges T recursively (`EnlargeTile` in line 4). At each step, it enumerates the next larger *r*Tile T' that improves the data reuse score most (`GetNextRTileShapes` in line 10). If T' hits the memory capacity (line 13) or the data tile loading throughput $MemPerf(T')$ exceeds the peak computing throughput $MaxComputePerf(T')$ (line 17), the algorithm records the current *r*Tile T and goes on to `EnlargeTile` at the next memory layer. Otherwise, it continues to enlarge T' at the current layer (line 20). The construction finishes at the lowest memory layer (line 6), producing one result and repeating, until it obtains K (e.g., 5-20) *r*Programs (to tolerate the hidden factors affected by the device compiler). Note that $MemPerf(T')$ and $MaxComputePerf(T')$ are derived based on `dev`, based on the micro-performance model (§3.3).

Scaling out an *r*Program. Given the homogeneity of both the computation pattern of most DNN operators and the parallel execution units in an accelerator, ROLLER simply replicates the *r*Program constructed on one execution unit to other units, by uniformly partitioning the computation into *r*Tiles of the size equals to the lowest layer *r*Tile. We achieve this by distributing all the partitions evenly to all execution units. Note that ROLLER prefers to assign the partitions split along a reduction axis on the same execution unit, as they can share the reduction results in the higher memory layers. Note that ROLLER does not assume an *r*Program will exclusively occupy all computing units, the system can explicitly control the parallelism of a *r*Program when scaling out.

Small operator and irregular tensor shape. The scale-out algorithm inherently favors operators with sufficient parallelism, e.g., where the partition number is significantly larger than the number of execution units. For a small operator, the overall performance of the algorithm could suffer from the low utilization of parallel execution units. In general, this can be addressed by co-scheduling with other operators in compilers like Rammer [26], if there exists sufficient inter-operator parallelism. Otherwise, for each *r*Program, ROLLER will try to shrink its *r*Tiles along the axis that has the smallest data reuse score to achieve sufficient parallelism. Note that this enumerating process returns the next aligned tile size each time just like other alignment rules, which is an efficient process and incurs negligible costs compared to the overall construction process.

In addition, a large operator may contain irregular tensor shapes with small dimensions, whereas ROLLER might not generate a sufficient number of *r*Programs due to the alignment requirements. To address this issue, ROLLER transforms a tensor expression into a canonical form by an axis fusion pass. Specifically, for all the involved tensors, if there exist two adjacent axes in one tensor, which are either both existing and still adjacent or both missing in all other tensors, ROLLER can safely merge these two axes. For example, an element-wise operator with the tensor shape $[17, 11, 3]$ in both input and output tensors, ROLLER will transform it into the tensor shape $[561](17 \times 11 \times 3)$ by fusing the three axes. Besides axis fusion, ROLLER will also try to greedily increase the parameter ε in the tensor padding mechanism (§3.1) until K *r*Programs have been constructed.

```
// compute interface
int Load(T* src, rTile st, T* dst, rTile dt);
int Store(T* dst, rTile dt, T* src, rTile st);
int Compute(TensorExpr e, rTile t, T** args);

Spec GetDeviceSpec(); // Spec query interface

// interfaces of the micro-performance model
size_t MemFootprint(rTile t);
size_t MemTraffic(rTile t);
double MaxComputePerf(TensorExpr expr);
double MemPerf(rTile t);
```

Figure 9: The interface of ROLLER's hardware abstraction

3.3 Efficient Evaluation of an *r*Program

In the construction algorithm, ROLLER needs to evaluate the performance of *r*Program. Instead of evaluating the end-to-end *r*Program in a real hardware device, ROLLER only needs to evaluates the performance of the corresponding *r*Tile, e.g., `MemPerf` and `MaxComputePerf` in Figure 8.

To this end, ROLLER builds a micro-performance model against a device described in a hardware abstraction layer (HAL). The HAL models an accelerator as multiple parallel execution units with a hierarchical memory layer. The HAL exposes three *r*Tile-based interfaces: `Load`, `Compute`, and `Store` (Figure 9). An execution unit is abstracted as an *rTile Execution Unit (TEU)*, which computes the data tiles through the `Compute` interface. Multiple TEUs can be organized as a group, which `Load` and `Store` tiles cooperatively. The HAL treats different memory layers, e.g., register, shared memory, DRAM, as an unified type exposing the hardware specifications that affect the performance of tile movement. The specifications include memory capacity, transaction lengths, cache line size, and number of memory banks, which can be obtained by the `GetDeviceSpec` interface in Figure 9.

Micro performance model. With the hardware abstraction layer, ROLLER can easily derive the performance of a *r*Tile (and hence the *r*Program). First, given an *r*Tile, the incurred memory footprint (including padding) and the memory traffic volume across different layer can be statically inferred from the *r*Tile's tensor expression `expr` and the `shape`, i.e., the `MemFootprint` and `MemTraffic` interfaces in Figure 9. They are used to calculate the data reuse scores and check if an *r*Tile exceeds the memory capacity. Second, to calculate `MaxComputePerf` of an *r*Tile, ROLLER conducts a one-time profiling to measure the peak compute throughput by aggressively enlarging the compute tiles (e.g., multiple of warp size in an SM) to saturate the TEU. This performance data is cached in ROLLER for future query in the construction al-

gorithm. Finally, for a given *r*Tile, ROLLER also estimates `MemPerf`, the performance on loading data tiles from a memory layer to a higher layer. Given the aligned memory access in *r*Tile, the latency of loading a regular chunk of data can be simply modeled by the division of the total traffic to the memory bandwidth. For the memory layer shared by all TEUs, we split the bandwidth evenly. For the smaller accessing sizes, ROLLER also conducts a one-time offline profiling for each device type and cache the results. It is worth noting that the micro-performance model only *needs* to be accurate when the tile shapes are fully aligned, a key requirement of ROLLER.

4 Implementation

Our implementation of ROLLER is based on TVM [15] and Rammer [26], two open-source DNN compilers. ROLLER's core mechanisms, including expression optimization, construction algorithm, micro-performance model, etc., are implemented with 8K lines of code. ROLLER's compilation pipeline is as follows. Its input is an ONNX graph [9] or a TensorFlow frozen graph [13]. ROLLER first leverages Rammer to conduct graph level optimizations (e.g., inter- and intra-operator co-scheduling). Next ROLLER derives the TVM tensor expressions for each (fused) operator extracted from the optimized graph, and generates corresponding *r*Program by ROLLER's construction algorithm, and performs kernel generation. Finally, the generated kernels are injected to Rammer's runtime and generate the end-to-end model code.

Code generation. Given the fixed code structure in an *r*Program (in Figure 6), ROLLER generates the kernel code through a predefined template, implemented as a TVM schedule with its built-in scheduling primitives. Loading and storing data tiles at each memory layer are implemented by TVM's `cache_read` and `cache_write` primitives. Partitioning on *r*Tile is done through `split` and `fuse`. Some primitive *r*Tile computation is implemented with TVM's intrinsic API. With the template, a given *r*Program can be directly generated into device codes, e.g., CUDA kernels.

Tensor padding. ROLLER relies on tensor padding to align *r*Tiles with tensor shape. In practice, most tensors in the lowest memory (e.g., DRAM) are allocated by external program (e.g., DNN framework), thus we just apply padding in the upper layer memory (e.g., shared memory). Our tensor padding currently requires the input tensor expression to specify whether it allows to pad, as well as the default padding value (e.g., 0 for MatMul operator). For the storage padding for memory bank alignment, we leverage TVM's `storage_align` primitive to add padding.

Performance profiling. ROLLER implements two profilers: a *micro-performance profiler* and a *kernel profiler*. The former generates device specifications, e.g., memory bandwidth, computing throughput, etc., through a set of micro-benchmarks, which is a one-time offline profiling for each device type and tensor expression types (regardless of the tensor shapes). The latter profiles the fastest kernels among the top K *r*Programs and is used for each compilation result if the K is larger than 1. In practice, the performance of a specific kernel code is also slightly affected by some device-compiler and hardware related hidden factors, which ROLLER can hardly control. These factors include instruction density of different instruction types, register allocation behaviors, device compiler optimizations, warp scheduling overhead, etc. Particularly, on NVIDIA GPUs, ROLLER relies on nvcc [3] to compile the generated CUDA codes into machine code. However, nvcc's proprietary optimizations might undesirably affect the program execution behaviors. Thus, ROLLER leverages the kernel profiler to quickly evaluate top performing *r*Programs and select the best one. A larger K could generally increase kernel quality. After evaluating the top 10, 20, and 50 results, our experiences show that top 10 could recall the optimal results for most cases. Note that ROLLER's kernel profiler differs from the evaluation process driven by a machine learning algorithm in previous compilers [15,33,35]. The ML-based approach usually requires hundreds even thousands of *sequential* evaluation steps, while ROLLER only profiles tens of candidates *in parallel*. In future, we plan to implement assembly-level code generation to alleviate the hidden issues in a high-level device compiler.

ROLLER's HAL allows us to support different accelerators easily. User can configure the corresponding HAL for each device type. ROLLER also provides built-in configurations for most common device types. Some detailed configurations, e.g., memory bandwidth, rely on micro-benchmark profiling or derive from published device specifications. Next, we share our experiences in implementing the HAL on several popular DNN accelerators, including NVIDIA GPUs, AMD GPUs and Graphcore IPU.

ROLLER on NVIDIA CUDA GPUs. An NVIDIA GPU usually employs a centralized memory architecture. We implement ROLLER on V100 and K80, two CUDA GPUs with different architectures on the *streaming multi-processors (SMs)*. Their memory architecture contains global memory, L2 cache, L1 cache, shared memory, and register. In ROLLER's HAL, we abstract them into 3 memory layers: L2 layer for global memory and L2 cache, L1 layer for only the shared memory, and the L0 layer for register. We ignore L1 cache because it shares the space with shared memory and cannot be controlled by user programs. The memory bandwidths of all levels are measured by our micro-benchmarks. The transaction length at the global memory layer is set to 32 Bytes, i.e., 8 float elements, for both GPUs. For V100 GPUs, the bank number and the bank length of the shared memory is 32 and 4 Bytes respectively. For K80 GPUs, the bank length is 8 Bytes. The shared memory capacities are set as 48KB for both GPUs (based on `deviceQuery`).

We implement the TEU on CUDA GPUs as a warp of 32 threads, which is also the basic unit to execute the TensorCore WMMA instructions. The size of a TEU Group on a HAL

(e.g., a SM) is set to the warp scheduler number, which is 4 for both GPUs. The SM number is 80 for V100 [21] and 13 for K80. On CUDA GPUs, each thread has a limited register capacity, e.g., 255 registers for V100. Exceeding this limit will lead to register spilling, causing significant performance degradation. This sets a limit to the size of an *r*Tile at register layer. We notice that the *nvcc* compiler will implicitly declare more registers (for loop variables or other purposes). Given that this behaviour is hard to predict, we reduce the register limit empirically to only 96 registers for both V100 and K80 per thread to avoid unexpected performance impacts.

ROLLER on AMD ROCm GPUs. We also implement ROLLER on MI50 [12], AMD's second-generation Vega series GPU. MI50 shares a similar memory architecture as V100: the centralized global memory can be accessed by all *compute units (CUs)*. Like SMs in NVIDIA GPU, each CU has its own scratchpad memory, registers, and computation cores. The data movement of a ROCm [1] kernel program is also similar. The memory transaction size for the global memory is set as 64 Bytes. The memory bank number is 32 and bank length is also 4 Bytes. We also implement the TEU as a warp of threads, which is 64 threads on MI50 GPUs. The maximal register size is empirically limited to 70 registers per thread. All other specifications such as the memory bandwidths at each layer, peak computing throughput, etc., are measured with our micro-benchmark.

ROLLER on Graphcore IPUs The Graphcore IPU [22] is a massive parallel MIMD processor with 1216 parallel processing cores. Distinct from NVIDIA and AMD GPUs, an IPU employs a distributed memory architecture. There is only 256KB on-chip local memory attached per core, and no unified global memory. When the local memory is unable to hold all the input data, by default, the initial data of a kernel program is stashed in the on-chip local memory and evenly distributed across the nodes. Thus, ROLLER's HAL for IPUs also abstracts three memory layers: L2 for all the remote memories across all cores, L2 for the local memory on each core, and L0 for the register. We take advantage of prior benchmarking work [22], which has successfully measured peak memory bandwidth and computation throughput. The size of the register files per IPU core is not publicly available. Considering that we have no prediction for behaviours of the IPU program compiler, we allow each upper-level *r*Tile to use only 10 registers, which safely guarantee that the tiling algorithm does not emit invalid tiling configurations.

5 Evaluation

We evaluate ROLLER on both DNN operator benchmarks and end-to-end models by comparing with state-of-the-art DNN compilers and frameworks. We first summarize our findings: 1) ROLLER achieves *three orders of magnitude speedup* on compilation time, compared to TVM and Ansor. On V100 GPU, the most expensive operator takes 43 seconds, while all other operators take only around 13 seconds to compile. 2) ROLLER matches the state-of-the-art performance of vendor libraries and other compilers on a wide range of operators. It even outperforms others for more than 50% of operators. 3) For operators with smaller sizes and irregular shapes, ROLLER's results are sub-optimal because of the difficulty in aligning with the hardware. However, their kernel execution time is usually small (around or below 1ms). 4) We have conducted the most extensive evaluations (119 ops in total) covering different operator types over different accelerators.

Table 1: A subset of operator configurations in our benchmark.

Experimental setup. ROLLER is evaluated on four types of servers equipped with different accelerators. The CUDA GPU evaluations use two types of servers: an Azure NC24s_v3 VM equipped with Intel Xeon E5-2690v4 CPUs and 4 NVIDIA Tesla V100 (16GB) GPUs and an Azure NC24_v1 VM with 24 Intel(R) Xeon(R) CPU E5-2690v3 CPUs and 4 NVIDIA Tesla K80 GPUs. Both running on Ubuntu 16.04 with CUDA 10.2 and cuDNN 7.6.5. The AMD ROCm GPU evaluations use a server equipped with Intel Xeon CPU E5-2640 v4 CPU and 4 AMD Radeon Instinct MI50 (16GB) GPUs, installed with Ubuntu 18.04 and ROCm 4.0.1 [1]. The IPU evaluations use an Azure ND40s_v3 VM equipped with Intel Xeon Platinum 8168 CPUs and 16 IPUs with Poplar-sdk 1.0.

We compare ROLLER against other tensor compilers, vendor libraries and DNN frameworks, including TVM [15] (v0.8) and Ansor [33] (v0.8), two state-of-the-art tensor compilers; cuDNN, cuBLAS, rocBLAS (ROCm GPUs), POPLAR library (Graphcore IPU), which are vendor libraries; TensorFlow (v1.15), a state-of-the-art DNN framework; TensorFlow-XLA a state-of-the-art DNN full-model compilers; and TensorRT (v7.0) (with TensorFlow integration version), a vendor-specific inference library for NVIDIA GPUs. We validate our compilation results by comparing them against Ansor's.

Benchmarks. Our evaluation benchmark uses four typical DNN models, including ResNet-50 [19] (CNN), LSTM [20] (RNN), NASNet [36] (a state-of-the-art CNN model obtained

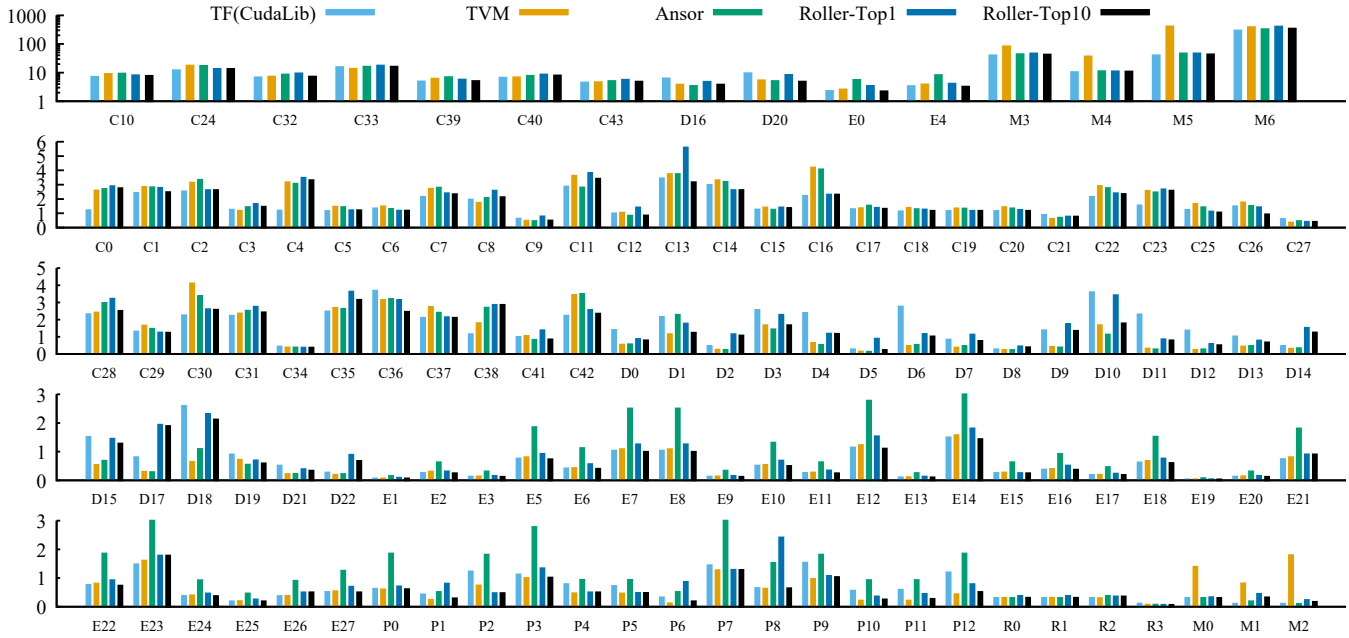

Figure 10: Operator performance on V100 GPUs (y-axis: average kernel execution time in ms).

by the neural architecture search), and BERT-Large [17] (transformer-based). We set the default batch size of each model to 128. From each model, we choose the most-frequently used operators to construct our operator benchmark. It contains 6 classes of operator type with total 119 operator instances with different configurations (7 MatMul operators, 44 Conv2D operators, 23 DepthwiseConv operators, 28 element-wise operators, 13 pooling operators, and 4 reduction operators). Table 1 lists a representative subset of operators as well as their configurations. The last column lists the corresponding abbreviation of each operator. The full list of the operator configurations is omitted due to page limit.

5.1 Evaluation on NVIDIA GPUs

This section first evaluates ROLLER's operator performance, compilation time, and scalability on large operators by comparing against the state-of-the-art tensor compilers and vendor libraries. We also evaluate the performance of ROLLER on TensorCore. Finally, we show the end-to-end model performance compared to existing DNN compilers and framework.

Operator performance. We first evaluate the performance of ROLLER generated kernels by comparing against TVM (i.e., AutoTVM with XGBoost tuning algorithm [16]), Ansor, cuBLAS (for matrix multiplication operators) and cuDNN (for convolution operators). Vendor libraries like cuBLAS and cuDNN are wrapped in TensorFlow to evaluate the performance. For the rest of operators (e.g., element-wise, reduce), we use TensorFlow's built-in kernel implementations. To amortize the overhead of data feeds/fetches in TensorFlow's session, we repeat the kernel running for 1,000 times in each session and calculate the average. We set the tuning steps for TVM and Ansor to 1,000 for each operator, same as Ansor's evaluation setup [33], and report the best results. We compare both the top-1 and the best from the top-10 kernels constructed by ROLLER, the latter can tolerate some hidden performance impacts from device compilers.

Figure 10 plots the average kernel performance for all the 119 operators in our benchmark, ordered by the operator type and ID. We plot the large operators (e.g., kernel time is larger than 5ms) in the top sub-figure in a log-scale for y-axis, and the other medium and small operators in the bottom 4 sub-figures [2]. First, compared to CUDA libraries (CudaLib), ROLLER could get comparable performance (i.e., within 10% performance) for 81.5% of the total operators, and can be even faster for 59.7% of them. We observe that the majority of operators that ROLLER performs worse are convolution operators with 3×3 or larger filters, which are usually implemented with a more efficient numerical algorithm (e.g., Winograd [23]) in cuDNN and hard to be expressed by the tensor expression. This is the reason Ansor and TVM are also slower than CudaLib in these cases. Second, compared to TVM and Ansor, ROLLER could also get comparable performance for 72.3% and 80.7% of the total operators respectively. The rest 27.7% and 19.3% of them are mainly small operators or with irregular tensor shapes, which are by natural hard to align with the hardware. However, these operators usually have relatively short kernel time, e.g., only 1.65ms and 1.16ms on average. Among 54.6% and 65.5% of the total

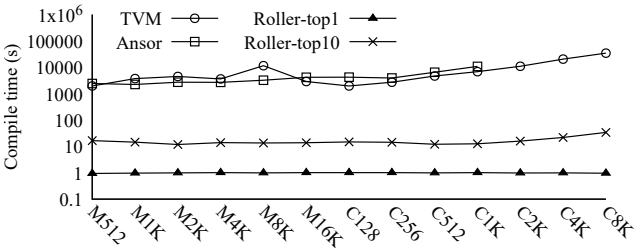

Figure 14: Compilation time for both MatMul and Conv2d operator with different batch sizes.

operators, ROLLER can even produce faster kernels than TVM and Ansor, respectively. We observe that the majority of these operators are large and time-consuming ones. As it shows in the top sub-figure where operators are larger than 5ms (up to 343ms), ROLLER could achieve better performance for most of these operators, e.g., by 1.85× and 1.27 × speedup over TVM and Ansor on average.

Compilation time. Given the comparable kernel performance, the major advantage of ROLLER is its fast compilation. Figure 11 compares ROLLER's compilation time against TVM and Ansor for all the operators. The operator ID is sorted by the compilation time for each line. The average operator compilation time for TVM is 0.65 hours and up to 7.89 hours. For the first 40 operators, which are mainly the element-wise, reduction, and pooling operators, TVM's compilation takes less than 10 seconds. This is because TVM's manually-written code templates for these operators can directly emit code without searching. However, Ansor generates search spaces for all the operators. Its compilation time takes 0.66 hours on average and up to 2.17 hours. In contrast, ROLLER's top-1 kernel results can be generated in 1 second for most operators and in 0.43s on average, which is *more than three orders of magnitude* faster. The major time is spent on the recursive constructing algorithm, which increases slightly with the growth of operator size, but quickly stabilizes as the recursive depth (to enlarge the *r*Tiles) is bounded by the limited memory capacity. To get the optimal kernels from the top-10 candidates, ROLLER's average compilation time is only 13.3 seconds. The major cost comes from the kernel code compilation with the device compiler and the evaluation on target devices.

Scale-out with operator size. We evaluate the scalability of ROLLER on larger operators by comparing with both CUDA libraries, TVM, and Ansor. We select a MatMul operator from the BERT model and a Conv2D operator from the ResNet mode, and scale them by setting different batch sizes. Figure 12 and Figure 13 show the performance comparisons. For the MatMul operator, both Ansor and ROLLER have a linear scalability over the batch sizes and comparable performance with CudaLib (i.e., cuBLAS). However, TVM's performance is relatively non-stable. For example, ROLLER can outperform TVM by average 11.2× and up to 36.1× for the batch size of 1024. For Conv2D operators, ROLLER can still achieve linear scalability over the batch size, and get slightly better performance than Ansor and TVM (by 1.25 and 1.54× on average). Note that Anosr is unable to search for a valid kernel for the batch size over 2048 using its default configurations. TVM can generate valid kernels, but the performance is scaled sublinearly for the larger batch sizes, e.g., ROLLER can achieve more than 1.9 × speedup for batch sizes greater than 2048.

Finally, Figure 14 compares the compilation time for the two operators with different batch sizes. The average compilation time of TVM and Ansor is 2.36 (up to 9.55) hours and 1.19 (up to 3.0) hours respectively. Moreover, their compilation time grows constantly with the growing of batch size. This is because that they are both based on ML-based search approach, whose search space usually increases exponentially with the operator size. In contrast, ROLLER produces the top-1 kernel in 1 second, and 16 seconds (up to 34 seconds) on average for the top-10 kernel.

Compile on TensorCore. ROLLER could easily support hardware tensor ISAs (e.g., TensorCore) by aligning the *r*Tile shape with the hardware instruction shape. We use the 16×16×16 WMMA instruction in ROLLER. We remove An-

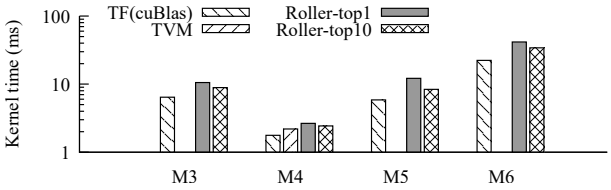

Figure 15: Matmul kernel time on TensorCore.

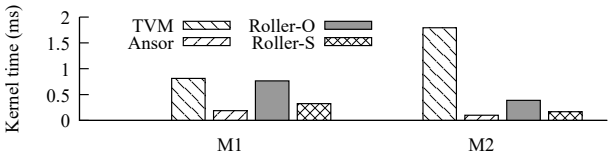

Figure 16: Performance for small operators.

sor in this experiment as it does not support TensorCore to our best knowledge. We select 4 large MatMul operators that are friendly to TensorCore in this experiment. Figure 15 shows the performance comparisons. As it shows, by constructing from the aligned *r*Tile shape, ROLLER can quickly produce good kernels on TensorCores, e.g., within a 43% performance gap to cuBLAS. Note that cuBLAS is highly optimized with a lot of hand-crafted optimizations on TensorCore. As a comparison, TVM fails to generate valid kernels for 3 of the 4 total operators with the default configurations. We try to increase the tuning steps from 1,000 to 10,000, it is still unable to find a legitimated kernel due to its poorly-defined search space.

Small operators and irregular tensor shape. ROLLER optimizes performance for small operators by shrinking the *r*Tile when there is insufficient parallelism. We demonstrate the performance of this optimization for the two small MatMul operators. Figure 16 compares the performance of the original *r*Tile configuration without sufficient parallelism (Roller-O), and the shrunken *r*Tile configuration (Roller-S) which matches the SM parallelism. As it shows, shrinking *r*Tile could significantly improve performance than the original kernel, e.g., by 2.3× on average. However, ROLLER is still slower than Ansor, e.g., by 50% on average, on small operators, even it is significantly faster than TVM by 6.6×. For such operators, we can further leverage search-based approach to fine-tune the configurations to obtain a better performance.

ROLLER compiles operators with irregular tensor shapes with two optimizations: i.e., *axis fusion* and *tensor padding* with bound parameter ε. We demonstrate their benefits on a representative set of irregular convolution operators, as shown in Figure 17. We compare the performance of ROLLER without any optimizations (Roller-B), with axis fusion (Roller-F), and further with tensor padding of ε from 0.4 to 1.0 (Roller-P0.4 and Roller-P1.0). All ROLLER's performances are the best one selected from the top-10 candidates. First, with axis fusion optimization, ROLLER is able to have more *r*Tiles that aligns with the tensor shapes, which improves the kernel performance by 1.5× on average. Moreover, with the tensor

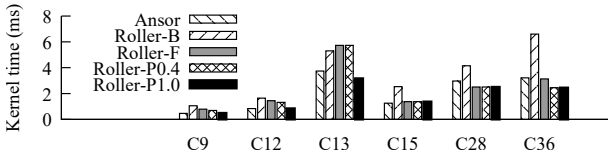

Figure 17: Performance for operators with irregular shapes.

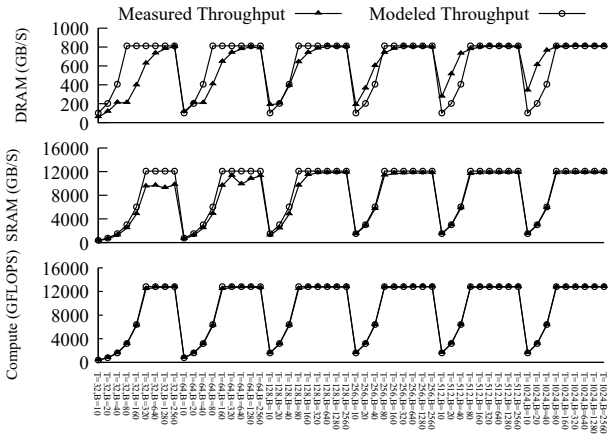

Figure 18: Memory throughput (DRAM and shared memory) and compute throughput from our micro-performance model and real measurement (X-axis: kernel configurations with different number of threads per block (T) and blocks (B)).

padding optimizations (e.g., at ε of 1.0), ROLLER can further improve performance than Roller-F by 1.4×. This is mainly because the number of legitimated kernels is very limited with smaller ε for irregular shapes. Increasing the ε allows ROLLER to have chance to select from more candidate kernels.

Micro-performance model. We conduct extensive experiments to validate the micro-performance model, including global memory throughput, shared memory throughput, and compute throughput, under different kernel configurations (i.e., different thread block and grid size). Figure 18 compares the performance estimated by our micro-performance model with that measured on real device. As shown, when the configuration is not aligned with the parallelism of execution units, i.e., thread number per block is less than 128 (4 warps), our model produces a relatively estimation error, especially for the DRAM throughput. This is also the case when there is insufficient parallelism (i.e., block number is less than 80). Thus, we can see our micro-performance model is accurate only for those shape-aligned configurations (i.e., *r*Tiles), as they fully exploit hardware efficiency. This also motivates us to choose only the aligned *r*Tiles, which greatly reduces the complexity of micro-performance model.

Kernel performance. We further study how close the performance of ROLLER generated kernels can approach the optimal. Since ROLLER's data pipeline model can naturally identify the bottleneck layer, e.g., DRAM, shared memory, or

Resource utilization	60-70%	70-80%	80-90%	90-100%
Operator #	6	13	22	78
Percentage	5%	11%	18%	66%

Table 2: The distribution of resource utilization at the saturated layer for different kernels.

Baseline	MemAlignn	EUAlign	ShapeAlign	BankAlign
1.0x	1.42x	1.88x	1.92x	1.94x

Table 3: Average accumulated performance improvement with different alignment optimization.

computation, we profile each generated kernel and compare the corresponding resource utilization at the saturated layer with the theoretical hardware limit. Table 2 lists the distribution of the resource utilization for the total 119 operators. The table shows most kernels saturate hardware resources, e.g., 66% of them utilize more than 90% of the theoretical limit. For the few under-utilized kernels, especially whose utilization is less than 80%, our investigation shows that they are mostly small operators with insufficient parallelisms.

To understand the impact of different alignment rules, we incrementally turn on each alignment optimization and evaluate its performance improvement. Table 3 shows the average speedup compared with the baseline (without any optimization). For example, EUAlign shows the kernels with the alignment on execution units and memory transaction alignment (MemAlign) can together improve the performance by 1.88x than the baseline. Bank alignment (BankAlign) has relatively small improvement because most kernels are already bank conflict free.

End-to-end model performance. We evaluate the end-to-end model performance of ROLLER by comparing against TensorFlow (TF), TensorFlow-XLA (TF-XLA), TensorRT (TF-TRT), and Ansor, which represent the state-of-the-art DNN framework, graph-level compiler, vendor-provided DNN engine, and DNN compiler with tensor compilation, respectively. Note that TensorRT is also the core engine in NVIDIA Triton inference server [8]. We omit TVM in this experiment as it usually requires an order of magnitude longer compilation time on tuning end-to-end models than Ansor [33]. ROLLER's end-to-end model compilation is implemented in Rammer (i.e., Rammer+Roller) by feeding the generated kernels into it. To create a fair baseline, we manually feed both the TVM and Ansor generated kernels for the same set of operators into Rammer, which are denoted as Rammer+TVM and Rammer+Ansor.

Table 4 lists the model execution time for each model compiled or executed by each compiler and framework. Note that TF-XLA fails to compile the BERT-Large and NASNet model (out-of-memory). TF-TRT also fails to run the BERT-Large model due to exceeding the maximum protobuf size limit (2GB) in its graph loading stage. For Ansor, we set the total tuning steps as 1,000 multiplied with the number of subgraphs for each model. However, Ansor also fails to produce

	BERT-Large	ResNet	NASNet	LSTM
TF	5,186	131	1,041	141

TF-TRT	N/A	137	883	31
Ansor	46,847 (TVM)	122	927	84
Rammer+TVM	17,730	143	1,168	43
Rammer+Ansor	5466	137	1036	48
Rammer+Roller	4,850	142	1,005	20
Ansor compile-time	30.9h (TVM)	33.4 h	41.8h	11.3 h
Roller compile-time	371s	352s	668s	298s

Table 4: End-to-end model execution time (in milliseconds) and compilation time on V100 GPUs.

	TF(CudaLib)	TVM	Ansor
Better Performance	82.4%	65.5%	71.4%
Perf. within 5%	82.4%	67.2%	75.6%
Perf. within 10%	83.2%	73.1%	79.0%
Perf. within 50%	99.2%	93.3%	94.1%
Perf. within 90%	100.0%	100.0%	100.0%

Table 5: The percentage of better and comparable performant operators on NVIDIA K80 GPUs.

a legitimate program for BERT-Large models. Thus, for this case, we use TVM to compile the model. Note that, the performance of TVM for BERT-Large is about 2.6× slower than Rammer+TVM, as the default layout of the dense operator in TVM (i.e., NT) is different from that in Rammer (i.e., NN). First, for the ResNet and NASNet models, ROLLER can only achieve comparable and mostly slower performance than TF, TF-XLA, and TF-TRT (up to 26.7% slower compared to TF-XLA for ResNet). This major overhead in ROLLER is caused by the less efficient convolution kernels compared to cuDNN as explained before. However, for the BERT-Large and LSTM models, ROLLER can outperform all other frameworks and compilers, e.g., by 1.07× and 1.55× faster than the state-of-the-arts, i.e., TF for BERT-Large and TensorRT for LSTM. This mainly due to ROLLER's kernel construction favors large and regular operator shape, which are heavily used in the BERT-Large model. For both the BERT and LSTM models, since ROLLER can control to generate resource-efficient kernels by the scaling-up policy, it provides more opportunities for Rammer to co-schedule parallel kernels on the parallel SMs on GPUs. They together produce an efficient end-to-end program, which can even outperform TF-TRT by 1.55× for LSTM. Among all the implementations, Ansor can also produce very efficient programs for all the rest 3 models except for the BERT. However, it requires a long compilation time (29.3 hours on average). For the NASNet model, it reaches only 32% of the overall searching progress after tuning for 41.8 hours. In contrast, ROLLER only takes 422s on average to compile these models. This includes the graph-level optimization and the full-model compilation time in Rammer, which occupies about 41% of the total time on average.

Operator performance on K80 GPUs. We also evaluate ROLLER on the K80 GPUs. Table 5 shows the percentage of better or comparable performing operators (e.g., within 10%

	TF(RocLib)	TVM	Ansor
Better Performance	73.1%	58.8%	70.6%
Perf. within 5%	79.0%	62.2%	72.3%
Perf. within 10%	81.5%	62.2%	73.9%
Perf. within 50%	94.1%	84.0%	86.6%
Perf. within 90%	100%	100%	100%

Table 6: The percentage of better and comparable performant operators on AMD ROCm MI50 GPUs.

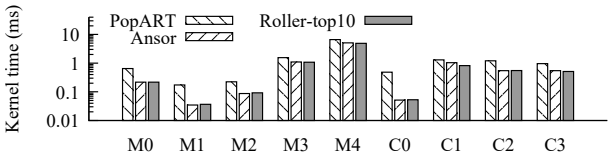

Figure 19: Operator performance on Graphcore IPU (y-axis in log-scale).

differences or 1.1× slow down) ROLLER generates for our operator benchmarks. Compared to CUDA libraries, TVM, and Ansor, ROLLER produces 82.4%, 65.5% and 71.4% better kernels for the whole operator benchmark. The percentage is relatively low for TVM mainly because the manual-crafted element-wise kernel templates in TVM are already highly-optimized. Finally, the average compilation time for all operators is 0.65 hours for TVM and 0.95 hours for Ansor respectively. In contrast, ROLLER's average compilation time is only 5.24 milliseconds for top-1 kernel and 12.3 seconds for top-10 kernel.

5.2 Evaluation on Other Accelerators.

Operator performance on AMD ROCm GPUs. We evaluate ROLLER on AMD ROCm GPUs by comparing it against ROCm libraries, TVM, and Ansor. Table 6 shows the percentage of operators that ROLLER can produce better or comparable performance (e.g., within 5% and 10% differences) in our operator benchmarks. Compared to the ROCm libraries (e.g., rocBlas), 73.1% of the total operators ROLLER can produce better kernels. This percentage is much higher than that on CUDA GPUs (59.7% and 54.6% for V100 and K80 GPUs). This is mainly because the libraries on CUDA GPUs are more mature than the ROCm GPUs, where ROLLER can help significantly. Compared to TVM and Ansor, ROLLER can also produce 58.8% and 70.6% better kernels. Similar to CUDA GPUs, the kernels that are slower by more than 10% are mostly small operator and those with irregular tensor shapes: the average execution time of these kernels are only 1.69ms and 1.57ms for TVM and Ansor, respectively. Finally, the average compilation time for all operators is 0.85 (up to 4.2) hours for TVM and 0.99 (up to 3.4) hours for Ansor, respectively. In contrast, ROLLER's average compilation time is 0.24 (up to 0.63) seconds for top-1 kernel and 7.69 (up to 49.0) seconds for top-10 kernel.

Operator performance on Graphcore IPU. We evaluate ROLLER on Graphcore IPUs. Due to the limited on-chip memory capacity, we only evaluate a set of small MatMul and Conv2D operators with different configurations. Figure 19 shows the average kernel time of each operator in log-scale, comparing against the Poplar-sdk library (i.e., PopART) provided by Graphcore and Ansor. Since TVM and Ansor do not have Graphcore backends, we use a modified version of Ansor in this experiment. As it shows, ROLLER can generate faster kernels than PopART for all operators, with an average of 3.1× and up to 9.2× speedup. Even comparing to Ansor, ROLLER can still construct comparable or even better kernels in most of operators, i.e., 2.9% average improvement. Note that Ansor still requires hours of tuning for each operator, as the device compiler on IPUs could take up to minutes to compile a program. However, ROLLER usually produce good kernels from the top-10 constructed candidates in several minutes. This time is mainly bottle-necked by the less-matured device compiler. It also brings more challenges to adopt the ML-based tensor compilers on these devices.

6 Discussion and Future Work

Optimization space compared with loop-based compiler. The abstraction of *r*Tile and data processing pipeline allows ROLLER to construct an optimization space overlapped with, but different from, existing DNN compilers (e.g., Ansor) [15, 33, 35]. As mentioned previously, these compilers view tensor compilation as nested loop optimizations. For example, Ansor allows only divisible tiling sizes along a tensor dimension to partition a loop axis evenly. This makes it usually perform worse for tensor shapes with prime dimensions. ROLLER instead focuses on maximizing hardware efficiency from the data-processing-pipeline view, allowing more aggressive optimizations, e.g., exploring non-divisible but hardware-aligned tiling sizes with fused adjacent axis and padded tensor shapes. Driven by our observation that most DNN operators are memory-bound, ROLLER fundamentally differs from existing DNN compilers by first optimizing data-tile throughput, i.e., maximizing reuse score rewards and aligning with hardware features, and then for parallelism. Such a trade-off inherently leads to fast compilation and good performance for operators with sufficient parallelism.

Optimization trade-off. ROLLER's design philosophy is based on an observation: large and dense operators tend to be major contributors to the execution time. This leads to a design trade-off: optimizing data reuse (i.e., maximizing pipeline throughput) as the primary optimization goal, and turning other hardware related optimizations into alignment constraints. Such trade-off results in fast compilation and high kernel quality for a majority of operators in mainstream workloads. For small operators, ROLLER further employs some adaptive mechanisms to trade-off among different optimiza-

tion goals, e.g., using a threshold to limit redundant work (§3.1) when there are insufficient results, employing an adapting *r*Tile shrinking process to increase parallelism (§3.2), etc.

Future work. ROLLER currently relies on high level device compiler, e.g., nvcc, to compile kernel code to executable. This sometimes introduces undesirable performance impacts and forces ROLLER to allocate registers conservatively. This is because the device compiler will implicitly allocate registers for intermediate values (e.g., loop variables). ROLLER cannot detect implicit register allocation beforehand, hence it is difficult to estimate and decide the precise register usage. One of our future work is to generate assembly (e.g., PTX for NVIDIA GPUs) code directly to avoid the side effects from the high level device compiler.

Moreover, although the key hardware information that affects performance, including memory bandwidth, capacity, and transaction length, is often available in the hardware specification, there are still some devices (e.g., mobile GPUs) lacking such information. Another future work is to leverage some profiling techniques [25] to disclose and quantify those hardware features.

ROLLER's HAL assumes hardware contains homogeneous computing units and symmetric memory accessing. However, we also observe that some devices have NUMA architecture. This makes it difficult for the micro-performance model to estimate *r*Tile performance, as the same tile will perform differently at different locality under NUMA architecture. We leave this issue as future work.

Finally, the optimization for sparse kernel may also violate the assumption of homogeneous workload in a DNN kernel and make the micro-performance model inaccurate. Some tiles with a larger degree of sparsity may perform differently from dense tiles. ROLLER assumes a higher level, sparsity-aware compiler (e.g., SparTA [34]) will address this issue.

7 Related Work

Most tensor compilers treat DNN operators as nested multi-level loop computation, which essentially defines a large space with a combinatorial complexity. TVM [15] inherits the insight from Halide [27] and describes DNN operators as loop optimization schedule primitives. Later, AutoTVM [16] extends TVM to apply an ML-method to search for the best configurations from manually written code templates. FlexTensor [35] proposes to automatically explore the space without manual templates. Ansor [33] further advances such automation. It generates an even larger search space considering a hierarchical code structure and adopts an evolution algorithm to find performant kernels. Compilers like Tiramisu [14], AKG [32], and Tensor Comprehensions [29] apply polyhedral-based techniques to loop optimization, which transforms the loop into an integer programming problem and finds a good configuration with a solver. All these approaches rely on a huge search space to provide good kernel, which leads to long compilation/solving time. ROLLER explores a different approach to construct *r*Tiles that align with hardware features.

Tensor Processing Primitives (TPPs) [18] define a set of 2D-tensor operators to compose complex operators on high-dimensional tensors, providing limited expressiveness. In contrast, ROLLER does not limit the dimension of tile shape and can be applied to general tensor expressions. The OpenAI Triton [28] is a programming framework and compiler for developing block-based GPU kernels. Triton relies on programmers to decide the block size and block scheduling, while this is the key problem ROLLER addressed by considering both hardware features and tensor shapes. MLIR [5] and Tensor IR [10] plan to support block-level (i.e., tile) computation representation in their IRs. ROLLER's *r*Tile abstraction and the *r*Program construction are compatible with these initiatives.

Graph-level DNN compilers like XLA [11], TVM [15], and Rammer [26] focus on cross-operator optimizations, e.g., operator fusion/co-scheduling. ROLLER's kernel generation is compatible with these compilers. ROLLER's *r*Tile abstraction complements the rTask concept in Rammer [26] as it provides an efficient way to construct an rTask.

Finally, some works focus on operator-specific optimizations. CUTLASS [7] is a template for implementing matrix-multiplication. An analytical model [24] is proposed to find the best loop-level optimization configuration only for convolution operators on multi-core CPUs. And DREW [30] proposes a new way to optimize Winograd convolution using data compression [31]. ROLLER's optimization approach is general for DNN operators on various devices.

8 Conclusion

ROLLER takes an unconventional approach to deep learning compiler. Instead of relying on costly machine learning algorithms to find a good solution in a large search space, ROLLER generates efficient kernels using a recursive construction-based algorithm that leverages the new *r*Tile abstraction with much fewer shapes that align with multiple hardware features. The constructed program can be evaluated by a micro performance model, without running on a real device every time. As a result, ROLLER can compile high-performance kernels in seconds, even in less mature accelerators. More importantly, ROLLER offers a unique and significantly more efficient approach for new AI hardware vendors to build competent vendor-specific DNN libraries, bridging the ecosystem gap to market leaders and thereby facilitating innovations in AI accelerators.

Abstract

To break the bottlenecks of mainstream cloud-based machine learning (ML) paradigm, we adopt device-cloud collaborative ML and build the first end-to-end and general-purpose system, called Walle, as the foundation. Walle consists of a deployment platform, distributing ML tasks to billion-scale devices in time; a data pipeline, efficiently preparing task input; and a compute container, providing a cross-platform and high-performance execution environment, while facilitating daily task iteration. Specifically, the compute container is based on Mobile Neural Network (MNN), a tensor compute engine along with the data processing and model execution libraries, which are exposed through a refined Python thread-level virtual machine (VM) to support diverse ML tasks and concurrent task execution. The core of MNN is the novel mechanisms of operator decomposition and semi-auto search, sharply reducing the workload in manually optimizing hundreds of operators for tens of hardware backends and further quickly identifying the best backend with runtime optimization for a computation graph. The data pipeline introduces an on-device stream processing framework to enable processing user behavior data at source. The deployment platform releases ML tasks with an efficient push-then-pull method and supports multi-granularity deployment policies. We evaluate Walle in practical e-commerce application scenarios to demonstrate its effectiveness, efficiency, and scalability. Extensive micro-benchmarks also highlight the superior performance of MNN and the Python thread-level VM. Walle has been in large-scale production use in Alibaba, while MNN has been open source with a broad impact in the community.

1 Introduction

To provide intelligent services for millions or even billions of smartphone users in industry, the mainstream paradigm lets mobile devices send requests with raw data and lets the cloud return results after data processing and model execution. However, this paradigm encounters three major bottlenecks: (1) *High Latency:* The network latency between each mobile device and the cloud plus the request processing latency of the cloud is in seconds, which is unacceptable for some real-time interactive applications. For example, the practical latency requirements of computer vision (CV), natural language processing (NLP), and recommendation tasks are in hundreds or even tens of milliseconds; (2) *High Cost and Heavy Load:* On the device side, uploading raw data will incur high cellular data usage, if Wi-Fi is not available. On the cloud side, receiving and storing enormous amounts of raw data from a massive number of mobile devices, processing data with diverse and sophisticated ML algorithms, and returning results in time, inevitably cause high overhead. For example, the size of 60s-long video or audio is in tens of MB, and the size of raw data for recommendation per user per day is in MB. Further multiplied by the scale of mobile devices, the total size of raw data is huge; and (3) *Data Security and Privacy:* Uploading the raw data with sensitive contents (e.g., personal information and user behaviors) may raise serious security and privacy concerns of users. Storing and processing raw data on the cloud may suffer from the risk of data breach.

By deconstructing the cloud-based ML paradigm, we can find that it simply regards mobile devices as interactive interfaces, but ignores the fact that mobile devices after 10 years of development can now undertake an appropriate load of data processing and model execution. Therefore, it does not leverage the natural device-side advantages of being close to users and data sources, thereby reducing latency and communication cost, mitigating the cloud-side load, and keeping private data on local devices. To overcome the bottlenecks of the mainstream cloud-based ML paradigm, the device-cloud collaborative ML paradigm emerged, which advocates offloading part of ML tasks to mobile devices and letting the cloud and the mobile devices collaboratively accomplish the ML tasks. Existing work tends to focus on the algorithmic decisions (e.g., device-cloud task splitting strategy [29] and collaboration/interaction paradigm [34]) in either inference or training phase and normally for a specific application (e.g., video analytics [6,11,31], text processing [5], recommendation [17,44]).

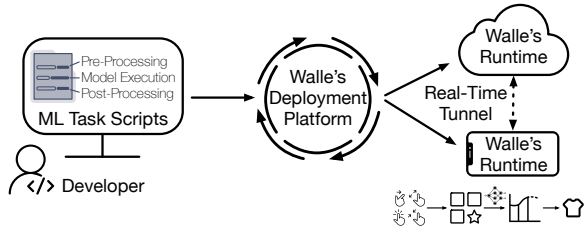

Figure 1: Walle from the perspective of an ML task developer.

However, practical industrial scenarios tend to involve the full cycle of diverse CV, NLP, and recommendation applications to serve millions or even billions of mobile devices, building a general-purpose system to put device-cloud collaborative ML in large-scale production becomes a new requirement.

We build an end-to-end system, called Walle, the overall goal of which is to support general device-cloud collaboration (e.g., single device-cloud and multiple devices-cloud) in each phase of diverse ML tasks through exchanging any necessary content (e.g., data, feature, sample, model, model update, and intermediate result). As shown in Figure 1, Walle supports the whole cycle of ML tasks (i.e., pre-processing, model training and model inference, and post-processing) on both mobile devices and cloud servers in both development (e.g., the practical need of frequent experimentation and deployment for daily ML task iteration) and runtime (i.e., ML task execution and device-cloud data transfer) stages. By following the philosophy of building a general-purpose system rather than integrating massive application-specific or platform-specific solutions, Walle functions as a fundamental ML infrastructure with standard APIs and keeps the light-weight limit of mobile APPs, having supported 1,000+ kinds of CV, NLP, and recommendation tasks in large-scale production.

During building Walle, we encounter several practical requirements and challenges that motivate our design decisions. Walle is oriented by ML tasks and consists of a deployment platform, a data pipeline, and a compute container, catering to ML task deployment, input preparation, and execution, respectively. (1) For the compute container, one major requirement is to decouple ML task iteration from the monthly/weekly update of mobile APPs, making the classical method of integrating new functionalities into APPs infeasible. Another key requirement is to support diverse ML tasks with high performance across different operating systems (OS) and heterogeneous hardware of mobile devices and cloud servers. This requires to build a tensor compute engine in C/C++ and do operator-level and computation graph-level optimizations for each hardware backend. Two dominant strategies are manual optimization (e.g., in almost all ML engines), the workload of which is quite heavy that only some common cases can be covered; and auto tuning (e.g., in TVM [9]), which cannot support runtime optimization and is infeasible in industrial scenarios that involve massive heterogeneous devices or require frequent/quick ML task iteration. Based on the tensor compute engine, the libraries should be implemented to cover pre-processing, model training and inference, and post-processing as well as mobile devices and cloud servers in a unified way, rather than in a separate and incomplete way, like NumPy, OpenCV, TensorFlow (Lite), and PyTorch (Mobile). Without integrated design, the high performance of the tensor compute engine cannot be exposed to different libraries, the workload of optimizing each library on heterogeneous backends is heavy, and the package is large; (2) for the data pipeline, the overarching goal is to prepare raw data, which can come from different sources and are structured in various formats, as device-side or cloud-side ML model input. The mainstream paradigm of uploading all the device-side raw data to the cloud for aggregate processing is inefficient and error-prone; and (3) for the deployment platform, its key requirement is to manage, release, and deploy ML tasks for numerous mobile devices in a fine-grained, timely, and robust way, given massive ML task deployment requirements, intermittent device availability, and potential task failure.

We overcome the key challenges above and build Walle. (1) We choose dynamically-typed, widely-used Python as the script language for developing ML tasks in Walle and implement a Python VM as the core of the compute container by refining CPython in two aspects: one is to abandon the global interpreter lock (GIL) and support task-level multi-threading with VM isolation and data isolation; and the other is to perform tailoring for practical device-side need. Such design enables daily ML task iteration. At the bottom of the compute container, we implement a tensor compute engine along with standard data processing and model execution libraries, called MNN [2]. MNN first introduces a novel geometric computing mechanism to decompose the transform and composite operators into atomic operators, thereby dramatically reducing the workload of manually optimizing hundreds of operators for tens of backends; and then introduces a novel semi-auto search mechanism to quickly identify the best backend with runtime optimization for a series of operators. At the top of the compute container, we expose MNN to Python thread-level VM as standard APIs, supporting the whole cycle of diverse ML tasks with standard data input. (2) For the data pipeline in Walle, we mainly build a new on-device stream processing framework to enable processing user behavior data at source. The key novelty is managing the trigger conditions of multiple stream processing tasks to generate different features with a trie structure for concurrent triggering. We also establish a real-time tunnel to transfer device-side fresh features to the cloud for use. (3) Regarding the deployment platform of Walle, we propose to manage task entity with git, categorize task-related files into shared and exclusive ones to facilitate multi-granularity deployments, and release tasks with an efficient push-then-pull method and in steps.

Walle is now part of Alibaba's ML backbone infrastructure, being invoked more than 153 billion times per day and supporting more than 0.3 billion daily active users, 30+ mobile APPs, and 300+ kinds of ML tasks. MNN is open source now

with 6,600+ stars and 1,300+ forks on GitHub, and also is in production use in 10+ other companies. Evaluation of Walle in example real applications (i.e., livestreaming and recommendation) and platform statistics demonstrate effectiveness, efficiency, and scalability. Micro-benchmarks of MNN and Python thread-level VM show superiority.

We summarize the key contributions as follows: (1) Walle is the first end-to-end, general-purpose, and large-scale production system for device-cloud collaborative ML, masking hardware and software heterogeneity at the bottom, and supporting diverse ML tasks with daily iteration cycle and high performance at the top; (2) the compute container in Walle comprises MNN, which introduces geometric computing to sharply reduce the workload of manual operator-level optimization, and semi-auto search to identify the best backend with runtime optimization; and a Python VM, which is the first to abandon GIL and support task-level multi-threading, and also is the first to be ported to mobile devices; (3) the data pipeline in Walle introduces on-device stream processing with trie-based concurrent task triggering to enable processing user behavior data at source; and (4) the deployment platform in Walle supports fine-grained task release and deployment to billion-scale devices with strong timeliness and robustness.

2 Preliminaries

In this section, we first expound the background and motivation of building a general-purpose system for device-cloud collaborative ML. We then elaborate on the major design challenges. We finally draw the system requirements.

2.1 Background and Motivation

Machine Learning Task. From a developer's perspective, an ML task comprises scripts (e.g., codes in Python), resources (e.g., data, models, and dependent libraries), and configurations (e.g., trigger conditions mainly for specifying where and when to trigger the ML task). The whole workflow of an ML task can be divided into three phases or sub-tasks[1]: pre-processing, model execution, and post-processing. In the pre-processing phase, raw data from multiple sources are cleaned, integrated, and processed to extract features and generate samples, which are then fed into models. In the model execution phase, a model is loaded to do training or inference. In the post-processing phase, the results of model inference are processed (e.g., by applying some ranking policies or business rules) to finally serve users.

Motivating Industrial Applications for Walle. In Alibaba, there are now at least hundreds of online ML tasks to serve billion-scale daily active users with mobile devices in tens of business scenario, where CV, NLP, and recommendation tasks roughly account for 30%, 10%, and 60% of the total tasks and run billion, one hundred billion, and billion times every day, respectively. In particular, (1) typical CV-type application scenarios include livestreaming, visual image search, short video analysis, augmented reality, and security checkup, where the major tasks include key frame detection, image segmentation and classification, item recognition, facial recognition and effects, human keypoint and pose detection, and porn detection; (2) typical NLP-type application scenarios include livestreaming and voice navigation, where the major tasks include automatic speech recognition, text to speech, text analysis, and text generation; and (3) typical recommendation-type application scenarios include item re-ranking, intelligent refresh, message popping, and page rearrangement, where the key tasks include click-through-rate prediction, click-conversion-rate prediction, user state recognition, and user intent detection.

Need for Device-Cloud Collaborative System. The applications raise strict latency requirements on ML tasks. In general, (1) CV tasks need to process each image in 30ms; (2) NLP tasks require to process a 5s-long audio segment in 500ms or process an audio stream with latency less than 100ms; and (3) recommendation tasks need to generate outputs in 300ms. In addition, the raw data from massive users input to ML tasks are huge. For example, (1) for CV tasks, the size of a 60s-long, 1080p, and 8Mbps video is roughly 60MB; (2) for NLP tasks, the size of a 60s-long WAV/PCM audio is around 10MB; and (3) for recommendation tasks, one user normally generates thousands of pieces of raw data per day, each piece in the size of KB. Furthermore, raw user data are more or less sensitive, raising security and privacy concerns.

The practical requirements above make the mainstream cloud-based ML paradigm infeasible and motivate us to adopt device-cloud collaborative ML. The key principle is that an ML task can be executed not only on the cloud but also on mobile devices, rather than purely on the cloud. During the execution of an ML task, mobile devices can work as a relay of the cloud, and vice versa. The choice of which side to execute which phase is flexible and should incorporate the practical need of the ML task and the characteristics of the cloud and mobile devices. For example, choosing which side for pre-processing should consider whether the side is near data source. Further observing the industrial need to support diverse ML tasks and massive devices, we are motivated to build an end-to-end and general-purpose system that can put device-cloud collaborative ML in large-scale production.

2.2 Practical Challenges

A device-cloud collaborative ML system faces some practical challenges that span the execution, input preparation, and deployment stages of ML tasks as follows.

Execution Challenges. (1) *Long Iteration Cycle:* The common update cycle of a mobile APP includes development, testing, and integration of new functionalities (e.g., ML tasks to be deployed in our context), as well as APP store review and release to massive mobile devices in batches. As a result, most APPs is updated weekly, while some super APPs (e.g., Mobile

[1] We call ML sub-tasks also as ML tasks for convenience.

Taobao, a shopping APP owned by Alibaba with 0.3 billion daily active users) are updated monthly. However, ML tasks require frequent experiments/deployments in nature, such that the effectiveness of different ML algorithms and models can be quickly verified, and the optimal feature combination and hyper-parameters can be identified; (2) *Heterogeneous Backends:* The cloud servers and mobile devices significantly differ in hardware (e.g., CPU, GPU, NPU, instruction set architecture (ISA), and memory) and OS (e.g., Android, iOS, Windows, and Linux). Among mobile devices, the ecosystem is even more fragmented; (3) *Diverse ML Tasks:* Industrial applications involve many kinds of ML tasks, requiring diverse model structures (e.g., convolutional neural network (CNN), recurrent neural network (RNN), transformer, generative adversarial network (GAN), and deep interest network (DIN)). Meanwhile, pre-processing and post-processing also involve lots of image, text, and numerical processing methods; and (4) *Limited Device Resources:* Each mobile APP has only one process. For Mobile Taobao, the maximum RAM is only 200MB, and the package size cannot exceed 300MB.

Input Preparation Challenges. (1) *Atypical User Behavior Data:* For CV and NLP tasks, most raw data (e.g., image, video, text, and audio) are in standard formats, the pre-processing of which can be supported by standard libraries. Another major data source, the pre-processing of which cannot be directly supported, is each user's diverse behaviors in time and page series during interacting with a mobile APP and is essential to many ML (especially, recommendation) tasks. Conventionally, all the users' behavior data are uploaded to the cloud, far away from source, for stream processing with Flink. To enable pre-processing at source, there, however, does not exist an on-device stream processing framework; (2) *Diverse Trigger Conditions:* ML tasks tend to need many features. Each feature corresponds to a stream processing task and its trigger condition. How to efficiently manage multiple trigger conditions for concurrent task triggering is non-trivial.

Deployment Challenges. (1) *Massive Task Deployment Requirements:* In Alibaba, the size of active ML tasks is at least in hundreds, and the mobile devices to be covered can reach the scale of billion. The release of each ML task also needs to incorporate APP versions, device-side and user-side differentiation; (2) *Intermittent Device Availability:* Mobile devices are with unstable wireless connections and allow only one APP to run on the foreground, while users tend to switch APPs frequently. Therefore, from the perspective of a certain APP, each device's availability is dynamic. Conventional push (e.g., based on persistent connection) or pull (e.g., based on polling) deployment method cannot guarantee timeliness and incurs high load on the cloud; (3) *Potential Task Failure:* A mobile APP runs as a single process. The failure of any task will lead to the crash of the whole APP, seriously impacting user experience. Further, due to the massive task deployment requirements, it is impractical to test each pre-release task on all relevant types of real devices.

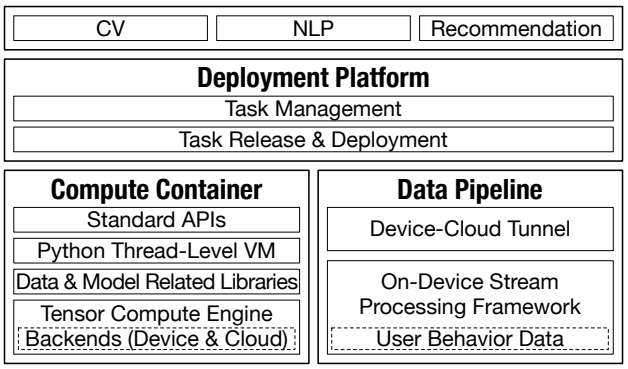

Figure 2: Architecture of Walle.

2.3 System Requirements

Given the challenges above, the design of an device-cloud collaborative ML system should meet some requirements.

The ML task execution environment needs to satisfy: (1) *Quick Task iteration:* ML tasks can be iterated daily on a mobile APP, reliving the dependence on the APP's original update cycle; (2) *Cross Platform:* OS-level and hardware-level heterogeneity should be masked; (3) *High Performance*: Optimization need to be specific to heterogeneous hardware backends of mobile devices and cloud servers; (4) *Universality:* Diverse CV, NLP, and recommendation tasks should be supported. The pre-processing, model execution, and post-processing phases of each ML task should be supported in an end-to-end way; and (5) *Light Weight:* The whole package size needs to be small, especially for mobile devices.

The ML task input preparation pipeline needs to first introduce *a new on-device stream processing framework* with concurrent task triggering ability to enable processing user behavior data at source. To enable the cloud to consume the generated features (e.g., for feature fusion or model inference) far away from source with low latency, a real-time tunnel between mobile devices and the cloud also needs to be built.

The ML task deployment platform should guarantee: (1) *Multi-Granularity:* Task release needs to support uniform, device-level grouping, user-level grouping, or even extremely device-specific policy; (2) *Timeliness:* A large number of mobile devices can be covered in short time; and (3) *Robustness:* Task deployment must put stability in the first place.

3 Walle: Architecture and Design Rationale

Guided by the system requirements, we build Walle. We first introduce the whole architecture and then design rationale.

3.1 Architecture Overview

As shown in Figure 2, the compute container in Walle comprises: (1) a cross-platform and high-performance tensor compute engine at the bottom; (2) data processing and model execution libraries based on the tensor compute engine; (3) a

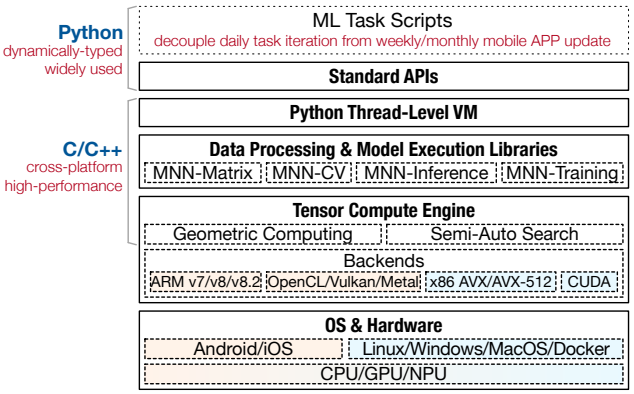

Figure 3: Architecture of compute container.

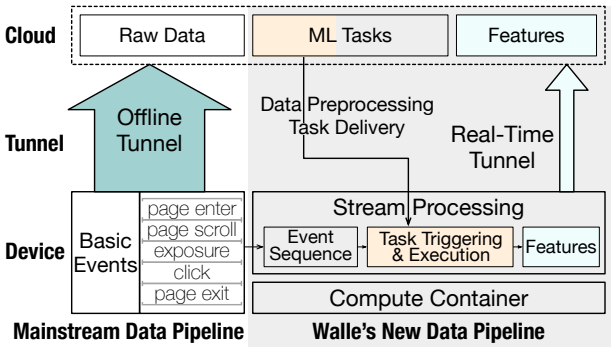

Figure 4: Architecture of data pipeline.

Python thread-level VM; and (4) standard APIs at the top. The data pipeline introduces: (1) an on-device stream processing framework; and (2) a real-time device-cloud tunnel. The deployment platform in Walle comprises: (1) a task management module; and (2) a task release and deployment module.

3.2 Design Rationale

Rationale of Compute Container. As shown in Figure 3, on the top, we choose Python as the script language, because Python is widely used in developing ML algorithms and also is a dynamically-typed and interpreted language. To support executing the Python scripts of ML tasks on different platforms, especially on resource-constraint mobile devices, we implement a Python VM by refining CPython and perform tailoring for the practical need of a mobile APP. Further considering the characteristics of ML task execution, including concurrent triggering of many tasks, independence across different tasks, and sequential execution of different phases in each individual ML task, we abandon GIL in Python VM and support task-level multi-threading by first binding each ML task with a thread and then conducting thread isolation. Such Python VM-based design endows the compute container with the capability of dynamic task delivery, decoupling daily ML task iteration from monthly/weekly mobile APP update.

At the bottom, we implement a tensor compute engine in C/C++ for cross-platform and high-performance considerations. The cores are the novel mechanisms of geometric computing and semi-auto search, as shown in Figure 5. In particular, geometric computing extracts a new atomic operator from transform operators, by leveraging the nature of coordinate transformation as well as the linear mapping between an element's coordinate and its memory address. As a result, all the transform and composite operators, accounting for roughly 49% of all the operators, can be decomposed to the atomic operators, reducing 46% of the workload of manually implementing and optimizing 124 operators for 16 kinds of backends from algorithm, ISA, memory, and assembly. Then, to quickly identify the backend available on a mobile device or a cloud server to execute a computation graph with a series of operators at the minimum cost, semi-auto search is applied in runtime to find the optimal implementation algorithm with the optimal parameters for each operator on each available backend. The parameter search is converted to solving a constrained optimization problem, by incorporating the hardware properties of the backend and the sizes of the implementation algorithm's inputs. Based on the tensor compute engine, we implement the libraries of scientific computing, image processing, model inference, and model training, and expose them to Python VM as standard APIs, supporting the whole cycle of diverse ML tasks with standard data input.

Rationale of Data Pipeline. The architecture is depicted in Figure 4. First, a user's behaviors are naturally recorded as a time-level event sequence, based on which the page-level event sequence can be created by aggregating the events in the same pages. Then, the trigger condition of a stream processing task can be specified by a sequence of event/page ids. To support concurrent triggering, we model matching multiple trigger conditions with the event sequence as a string matching problem with multiple wildcard patterns and propose to organize trigger conditions with a trie, such that if a new event comes, all the triggered tasks can be picked out for execution. Given a stream processing task can be triggered frequently over the continuously generated event sequence, while the size of one-time output is small, we design a collective storage mechanism to reduce the frequency of write. Finally, to upload the output of on-device stream processing with low latency, we leverage persistent connection to implement a real-time tunnel, transferring up to 30KB data within 500ms.

Rationale of Deployment Platform. We first manage the task entity with git and categorize task-related files into shared and exclusive ones, according to how many devices can use the files in common. The file categorization further facilitates the uniform and customized policies of task deployment. To guarantee the timeliness of task deployment, we propose a novel push-then-pull method based on transient connection, where the push functionality reuses the existing client-side http request for business services, while the pull functionality is via content delivery network (CDN) and Alibaba cloud enterprise network (CEN). For the robustness of task deployment, we introduce task simulation test with the cloud-side

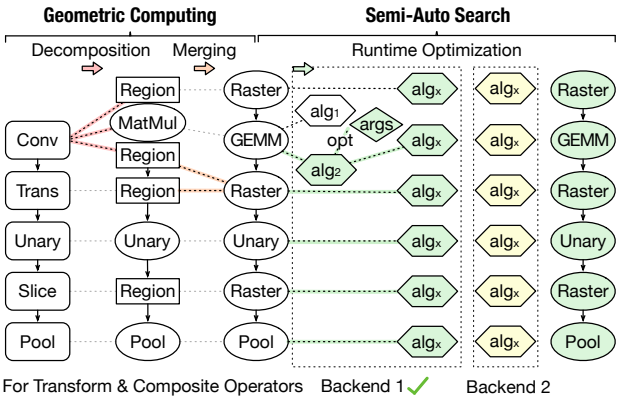

Figure 5: Geometric computing and semi-auto search.

compute container before release and enforce releasing task in steps, while allowing rollback in the case of task failure.

In what follows, we present the design and implementation details of the compute container in Section 4, the data pipeline in Section 5, and the deployment platform in Section 6.

4 Compute Container in Walle

We introduce the compute container in a bottom-up way: MNN, a tensor compute engine along with the data processing and model execution libraries; Python thread-level VM; and standard APIs of MNN.

4.1 Tensor Compute Engine

Tensor computation can be viewed as the basis of data processing and ML, and the operators of underlying tensor computation can be divided into four categories: (1) *Atomic Operators*, which function as the basic unit of backend optimization, such as some common unary operators (e.g., taking square) and binary operators (e.g., addition, subtraction, multiplication, and division); (2) *Transform Operators*, which change the shape and/or reorder the elements, such as transpose, slicing, concatenation, and permutation; (3) *Composite Operators*, which can be decomposed into the atomic and transform operators, such as 3D convolution and pooling, normalization, exponential linear unit, and long short-term memory cell; and (4) *Control-Flow Operators*, including if and while.

Geometric Computing. Currently, MNN can support $N_{aop} = 61$ atomic operators, $N_{top} = 45$ transform operators, $N_{cop} = 16$ composite operators, and $N_{fop} = 2$ control-flow operators. The workload of implementing and optimizing the operators for all $N_{ba} = 16$ backends in MNN is $O((N_{aop} + N_{top} + N_{cop}) \times N_{ba} + N_{fop} = 1954)$. Further considering the workload involving the atomic and control-flow operators is unavoidable, we turn to reducing the workload involving the transform and composite operators, which roughly accounts for half of the whole load and will grow in the future (e.g., as more composite operators are required to support more kinds of deep neural network (DNN)). Our key idea is to extract a new atomic operator, called "raster", from the transform operators. Then, both the transform operators and the composite operators can be decomposed into the raster operator and the atomic operators. Since only the atomic and raster operators need to be optimized for each backend, the whole workload becomes $O((N_{aop}+1) \times N_{ba} + N_{top} + N_{cop} + N_{fop} = 1055)$, reducing roughly 46% of the workload. Now, the problems become what is the raster operator and how to implement it. We propose a geometric computing mechanism as follows.

In essence, the basic functionality of the transform operators is to move an element from a memory address to another memory address, or from geometry, is to transform the coordinate of the element to another coordinate. In addition, the memory address is a deterministic linear function of the coordinate. Moreover, given a certain transform operator, the formula of coordinate transformation can be determined. As a result, with the coordinate of an element in the input or output tensor, typically the element's index in the input or output tensor, the original memory address and the memory address after movement can also be determined. The raster operator is introduced to move the elements between the input and output tensors according to the memory addresses and by traversing the coordinates. We take slicing for example. A is a 2×4 matrix, placed in contiguous memory addresses with a unique identifier/pointer. The slicing of A by leaving only the second row is denoted as B, which is a 1×4 matrix. For an element $B_{i,j}$ with the row index i and the column index j (i.e., the coordinate (i, j)) in B, its memory identifier relative to B's unique identifier is $i \times 4 + j$, which is linear with the coordinate, where the coefficients $(4, 1)$ are called the strides. According to the definition/rule of slicing (i.e., $B_{i,j} = A_{i+1,j}$), the coordinate of the corresponding element $A_{i+1,j}$ in A is $(i+1, j)$, and the relative memory identifier is $(i+1) \times 4 + j = 4i + j + 4$, where the coefficients $(4, 1)$ are the strides, and the intercept 4 is called offset. The raster operator can realize the functionality of slicing by iterating the coordinates $\{(i, j) | 0 \le i < 1, 0 \le j < 4, i, j \in \mathbb{Z}\}$ and moving each $A_{i+1,j}$ to $B_{i,j}$ using their memory addresses.

In practical implementation of the raster operator, we introduce a supporting concept, called "region", which contains an input tensor, the range of coordinate, as well as the linear mappings between an element's coordinate and its memory addresses in the input and output tensors, which are called "views" and can be specified by the strides and offsets. In addition, after operator decomposition, some raster operations can be merged for optimization. One policy is called vertical merging, which mainly deals with two successive raster operations, skips indirect references, and operates on the original tensor; and the other policy is called horizontal merging, which handles two parallel raster operations with the same region and keeps only one raster operation.

Atomic Operator Optimization. Specific to the atomic operators, including the raster operator, we incorporate hardware heterogeneity and optimize the implementation from the

perspectives of algorithm, ISA, memory, and assembly. (1) The algorithm-level optimization is specific to some compute-intensive operators, typically convolution and matrix multiplication. We take more efficient algorithms, including Winograd and Strassen algorithms, to sharply reduce the number of multiplications; (2) the ISA-level optimization leverages single instruction multiple data (SIMD), such as ARM Neon and x86 AVX512, for speedup. To adequately exploit data-level parallelism in SIMD, we carefully design data layout and data packing. Specifically, we take a new NC/4HW4 layout [35] and a channel-major packing for convolution; (3) the memory-level optimization focuses mainly on reducing the number of read and write as well as improving the contiguity of memory allocation. In particular, for matrix multiplication, we apply tiling and memory reordering; and (4) the assembly-based optimization can achieve instruction-level speedup. We implement core operators with hand-written assembly codes and carefully apply some optimizations, such as loop unrolling, software pipelining, and instruction reordering.

Semi-Auto Search. Data processing and model execution normally involve a series of operators (i.e., the atomic, raster, and control-flow operators after decomposition). Meanwhile, different backends have different implementations and optimizations for the operators, and a mobile device or a cloud server tends to have several backends available. The global goal of semi-auto search is to identify the backend with the minimum cost. The cost of each backend is the sum of all the operators with the optimal implementations. To identify the optimal implementation algorithm for a certain operator on a certain backend, the optimal parameters of each possible algorithm need to be found. This is converted to a constrained optimization problem that can be quickly solved, where the objective is computation or memory cost, and the constraints incorporate the hardware constraints of the backend and the sizes of the algorithm's inputs. We formulate the whole process of semi-auto search and introduce the details as follows.

We let BA denote the set of all available backends and let $op_1 \rightarrow op_2 \rightarrow \ldots \rightarrow op_n$ denote the series of n operators for execution. The cost of a backend $ba \in BA$ is defined as

$$C_{ba} = \sum_{i=1}^{n} C_{op_i,ba}, \tag{1}$$

where $C_{op_i,ba}$ denotes the cost of the operator op_i with the optimal implementation on the backend ba. The goal of semi-auto search is to find the backend with the minimum cost, which can be expressed as

$$\arg\min_{ba \in BA} C_{ba}. \tag{2}$$

Then, the problem is how to compute each $C_{op_i,ba}$. For each operator op_i and the backend ba, we let $algs(op_i, ba)$ denote all feasible implementation algorithms with the optimal parameters. Then, $C_{op_i,ba}$ is defined as

$$C_{op_i,ba} = \min_{alg \in algs(op_i,ba)} \frac{Q_{alg}}{P_{ba}} + S_{alg,ba}, \tag{3}$$

where (1) Q_{alg} denotes the number of elementary calculations in the algorithm alg, which can be obtained given the ("optimal" here) parameters and the sizes of the inputs; (2) P_{ba} represents the performance of the backend Ba. In MNN, for a CPU-type backend, if the backend ba supports ARMv8.2-FP16, P_{ba} empirically takes 16 times the frequency; otherwise, P_{ba} takes 8 times the frequency. For a GPU-type backend, P_{ba} is empirically set to the number of floating point operations per second (FLOPS) by manual testing; and (3) $S_{alg,ba}$ denotes the scheduling cost of the algorithm alg on the backend ba. In MNN, for a CPU-type backend, $S_{alg,ba}$ is set to 0; and for a GPU-type backend, $S_{alg,ba}$ is empirically set and mainly considers the time of data transfer. Now, the remaining problem is for an operator op_i, a backend ba, an implement algorithm alg, and the sizes of the inputs, how to determine the optimal parameters of the algorithm. In practice, we formulate it into a constrained optimization problem, where the objective is to minimize the computation or memory cost, and the constraints mainly include the width of SIMD unit, the number of registers, the number of threads, and the sizes of the inputs. In addition, we focus mainly on optimizing the following parameters: the packing size in SIMD, the tile size in matrix multiplication, the block unit in the Winograd algorithm, and the reduction of the elementary calculations using the Strassen algorithm. We take the optimization of the title size in matrix multiplication for example. We let A denote an $a \times e$ matrix, let B denote an $e \times b$ matrix, let t_e denote the tile size along the axis with the equal size, let t_b denote the tile size along the axis of B's columns, and let N_r denote the number of registers. The optimization objective is minimizing the times of memory read and write. The formula of the optimization problem is given as follows:

$$\begin{aligned} \min_{t_e,t_b} \quad & \frac{e}{t_e} \times \frac{b}{t_b} \times (a \times t_e + a \times t_b + t_e \times t_b), \\ \text{s.t.} \quad & t_e \times t_b + t_e + t_b \leq N_r, \end{aligned} \tag{4}$$

which can be solved efficiently in runtime.

Compared with manual search, which optimizes the implementation algorithms with some common parameters for each operator case by case, semi-auto search not only can sharply reduce the workload but also can find the optimal parameters with higher probabilities. Regarding why not adopt auto tuning in TVM, it does not exploit manual experience in operator optimization, consumes long time of static compilation due to the large search space at the operator and graph levels for a certain backend, and cannot support runtime optimization. Most importantly, given the restriction on executable files and just-in-time (JIT) compilation on iOS devices for security [4], the compiled models generated by TVM must be linked into mobile APPs with monthly/weekly update and cannot be daily iterated as desired. Therefore, TVM is infeasible in industrial applications that involve a large number of heterogeneous devices or require frequent/quick task iteration (e.g., updating the deployed ML models). In contrast, our design of the tensor

compute engine essentially leverages manual operator-level optimization for heterogeneous backends to narrow down the space of semi-auto search, thereby supporting deploying models as regular resource files and further facilitating runtime optimization and daily ML task iteration in Python VM. Another benefit is that the package size of mobile APPs will not increase in the long term for more and more ML tasks.

4.2 Data and Model Related Libraries

With the tensor compute engine, we implement the libraries of scientific computing and image processing for the pre-processing and post-processing phases of an ML task, as well as the libraries of model inference and model training. In particular, the scientific computing and image processing libraries can be regarded as the optimized implementations of NumPy [21] and OpenCV [28] in terms of light weight and high performance. The light weight means that the sizes of libraries can be reduced without manual tailoring. The original sizes of NumPy 1.9.3 and OpenCV 3.4.3 are 2.1MB and 1.2MB, and decrease to 51KB and 129KB in MNN, respectively. The high performance indicates that the performance optimization of the underlying tensor compute engine can be inherited to the libraries, avoiding the extra workload. We introduce the implementations of the libraries as follows.

Scientific Computing & Image Processing. We use the atomic, raster, and control-flow operators to support array creation and manipulation routines, binary operations, linear algebra, logic functions, padding arrays, random sampling, mathematical functions, etc, in the scientific computing library; and to support image filtering, geometric and miscellaneous image transformations, drawing functions, color space conversions, etc, in the image processing library.

Model Inference & Model Training. We currently provide two modes of model inference in MNN, called session and module. The module mode can support the control-flow operators, which are required by transformer, dynamic RNN, etc, whereas the session mode cannot. The session-based model inference can be divided into four steps: (1) load a model, create a session, arrange all the operators in the computation graph according to the topological ordering, and apply for the tensors that all the operators need; (2) given the shape of each input tensor and the definition of each operator, compute the shapes of all the tensors; (3) perform geometric computing, particularly, first decompose the transform and composite operators into the atomic and raster operators, and then do vertical and horizontal merging for raster operators; and (4) identify the optimal backend with semi-auto search, request memory for each operator and execute in sequence, and return the inference result. In the second step, the control-flow operators require the intermediate result to determine the following execution order and thus cannot be supported in the session mode. To solve this problem, when loading the model in the first step, the module mode splits the computation graph into modules (i.e., sub-graphs) iteratively, according to the positions of the control-flow operators. Then, the execution of each module is the same as that of the session.

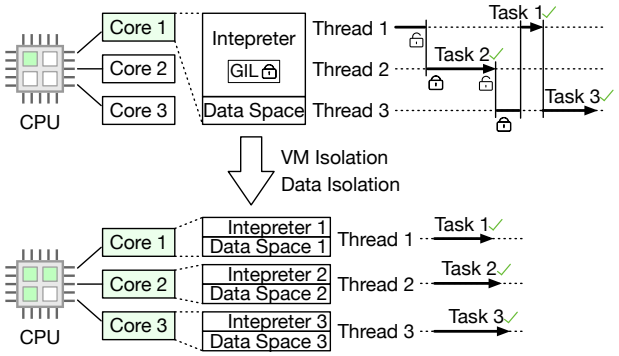

Figure 6: Python thread-level virtual machine.

We implement model training by adding two common optimizers: stochastic gradient descent (SGD) and adaptive moment estimation (ADAM). At the bottom, we add the gradient operators of all the atomic operators and one raster operator.

4.3 Python Thread-Level Virtual Machine

Most ML tasks are implemented in Python and require a Python VM to execute the Python scripts. We choose the official and the most widely-used Python compiler and interpreter, called CPython [43]. However, there exist two key problems in the porting process of CPython, especially for resource-constraint mobile devices. The first problem is that the size of the package is large. For example, CPython 2.7.15 contains 500+ scripts in C and 1,600+ libraries, including many redundant functionalities for mobile APPs. The second problem is that CPython cannot support multi-threading to improve efficiency. CPython originally cannot support concurrent programming and introduces GIL for multi-processing. GIL allows only one thread to be processed at one time within a process. However, each mobile APP has only one process and does not allow multi-processing. How to support task-level multi-threading in Python VM becomes a problem.

To reduce the package size, we tailor the functionalities, libraries, and modules for the practical need of Mobile Taobao. (1) *Functionality Tailoring:* CPython first compiles Python code into bytecode with the file suffix ".pyc" and then interprets the bytecode for execution. By leaving the compile phase on the cloud and sending only the bytecode to mobile devices for execution, we can delete all the compile modules, saving 17 scripts in C. (2) *Library and Module Tailoring:* We keep 36 necessary libraries (e.g., abc, type, re, and functools) and 32 modules (e.g., zipimport, sys, exceptions, and gc). After package tailoring, we implement a light-weight Python interpreter for mobile devices, which is the first in industry. For example, on ARM64-based iOS, the package size decreases from 10MB+ to only 1.3MB.

Regarding multi-threading, we abandon GIL and further design and implement the first Python thread-level interpreter in

industry, supporting the concurrent execution of many tasks. As shown in Figure 6, each task is scheduled to a certain thread, which creates an independent VM and contains the VM runtime and task-related data. For thread safety, the key is to perform thread-level VM isolation and data isolation, which pin a VM to its thread and further pin the context of VM runtime to the thread. (1) *VM Isolation:* The lifecycle of the original Python VM is pinned to the process, each process having one VM. We need to modify the creation of VM instances such that a process can hold multiple thread-level VMs, each VM having its independent lifecycle. In CPython, VM is defined as a struct in C, called PyInterpreterState. When CPython starts, one PyInterpreterState instance will be initialized. We modify the initialization of CPython, particularly creating and initializing a PyInterpreterState instance for each thread. (2) *Data Isolation:* Besides VM itself, the context of VM runtime (e.g., type system, module, and task-related data) should also be isolated on the level of thread, avoiding the concurrency problem of multi-threading without the protection of GIL. We adopt the thread-specific data (TSD) technique for data isolation, such that each thread has its own data space, and different threads cannot access the same data simultaneously. We mainly apply TSD to type system, buffer pool, object allocation, and garbage collection.

4.4 Standard APIs

We expose the cross-platform libraries of data processing and model execution through Python VM to support ML tasks. For pre-processing and post-processing, the scientific computing and image processing APIs are consistent with the original APIs of NumPy and OpenCV to be developer-friendly, such as matmul, swapaxes, concatenate, split, resize, warpAffine, warpPerspective, cvtColor, GaussianBlur, etc. For model inference and model training, the APIs of common model-level and data-level operations are exposed, such as data loading, model loading and saving, session creation and execution, optimizers, hyper-parameter setting, loss computing, etc.

5 Data Pipeline in Walle

We detail the on-device stream processing framework and the real-time device-cloud tunnel in the data pipeline.

5.1 On-Device Stream Processing Framework

The key design goal is to support stateful computation over unbounded data stream on single device. A user's behavior data in a mobile APP tracked with accurate timestamps form stream. The processing of user behavior data is stateful, where the intermediate results are buffered in memory or stored locally for later usage. The resources of single device are limited, which implies that the trigger conditions of many stream processing tasks should be well managed. We introduce on-device stream processing from event sequence

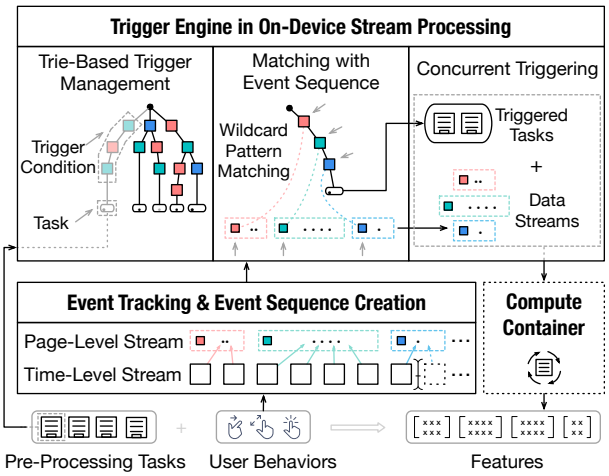

Figure 7: Workflow of on-device stream processing.

creation, trigger management, task triggering, task execution, and collective storage. The workflow is depicted in Figure 7.

Event Sequence Creation. When a user interacts with a mobile APP, the user's behaviors will be tracked as events. There are five major kinds of basic events: page enter, page scroll, exposure, click, and page exit. Each kind of event is recorded with a unique event id, a page id, a timestamp, and event contents (e.g., the item id for exposure-type event and the graphical widget id for click-type event). Since a user's behaviors are naturally in time series, the time-level event sequence can be directly created. To further benefit processing the events within a certain page or cross pages, the page-level event sequence is created by aggregating the events between the enter and exit events of the same pages.

Trigger Management. A stream processing task over the event sequence contains scripts and configurations, where the scripts implement the data processing algorithm, and the configurations mainly include a trigger condition. In particular, the trigger condition can be specified by a sequence of trigger ids, where a trigger id can be an event id or a page id.

For a certain mobile device, it needs to efficiently maintain multiple pre-processing tasks to generate different features for diverse ML tasks, such that as an event comes, all relevant tasks can be triggered immediately. The key is to organize trigger conditions for quick matching. The trivial method of storing trigger conditions in a list is inefficient, because of the need to traverse the entire list each time. In fact, the matching of multiple trigger id sequences with the event sequence (with both event and page ids) can be modeled as a string matching problem with multiple wildcard patterns. Therefore, we leverage the data structure of prefix tree, called a trie, for efficient trigger management. More specifically, the trie has three kinds of nodes: start, middle, and end nodes. The trie's root is the unique start node. A trigger id is a middle node. An end node, which stores the stream processing tasks, is a leaf node of the trie, and vice versa. When a new stream processing task comes, the trigger id sequence will be extracted as a sequence

of middle nodes, and a pair of start and end nodes will be added to the first and the last places of the node sequence, respectively. Then, the depth-first search is performed over the current trie from the root. If a path is completely matched with the node sequence, then the stream processing task will be added to the leaf node; otherwise, the mismatched nodes will be added to the trie as a new sub-tree, the root of which is the last matched node in the depth-first search process. We note that each path of the trie corresponds to a unique trigger condition, and the leaf node stores the stream processing tasks with the same trigger condition. If two trigger id sequences have common prefixes, then they will be put in the same sub-tree, and the middle nodes in the path from the trie's root to the sub-tree's root correspond to the common trigger ids.

Task Triggering. When a new event (with an event id and a page id) comes, the set of triggered tasks will be returned. First, two lists of trie nodes are introduced to record the concurrent matching states of multiple trigger conditions and to avoid being blocked by wildcard pattern matching. The static pending list stores all the children of the trie's root, which correspond to the first trigger ids in all the trigger conditions and always keep active for matching. The dynamic pending list stores the desired next nodes of the trigger conditions in the ongoing matching. For an event in the stream, if its event/page id matches the trigger id of any node in the static or dynamic list, then each child of the node will be checked for whether it is an end node. If the child is an end node, then the stream processing tasks in the end node will be returned; otherwise, the child, as a new desired next node, will be added to a buffer of the dynamic list. At the end of task triggering for the event, the dynamic list will be replaced by the buffer, and the buffer will be refreshed.

Task Execution. When a task is triggered, the scripts will be run in the compute container to process relevant events. Besides standard data processing and mode execution APIs of the compute container, to facilitate the extraction of relevant events from the event sequence and the processing of event contents, the stream processing framework also provides some basic functions as follows: (1) *KeyBy*, which returns the events matched with a given key; (2) *TimeWindow*, which returns the events in a given time window; (3) *Filter*, which returns the events filtered by a defined rule; and (4) *Map*, which processes the event contents with a defined function.

Collective Storage. For each stream processing task, its outputs, typically features, are saved as a table using SQLite. Considering the fact that a stream processing task can be triggered for several times, while the size of one-time output is small, a collective data storage API is encapsulated over SQLite to reduce the number of write, thereby improving performance. In particular, a buffering table will be created in memory, and the output of a stream processing task is first written to the buffering table. If the number of write reaches a certain threshold or a read operation is invoked, the buffering table will be written into the database once.

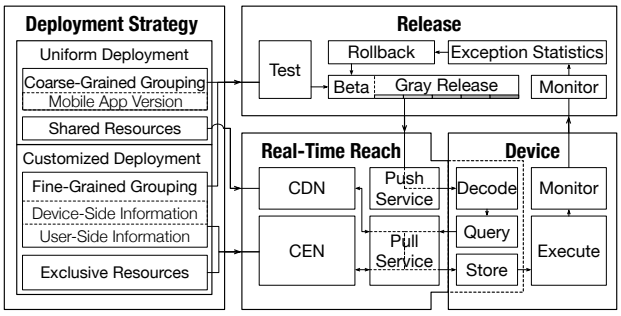

Figure 8: Workflow of deployment platform.

5.2 Real-Time Device-Cloud Tunnel

Besides for local use, the output of on-device stream processing can also be uploaded to the cloud for real-time use. We implement a device-cloud tunnel based on the persistent connection. The secure sockets layer (SSL) protocol is optimized to reduce the time of connection establishment, encryption, and decryption. The data are compressed before transfer and are decompressed after transfer. To deal with high throughput, a fully asynchronous service framework is built on the cloud.

6 Deployment Platform

We introduce the details of ML task management, release, and deployment. The whole workflow is shown in Figure 8.

Task Management. Git [41] is adopted to achieve the isolation of different tasks and the version control of a certain task, while supporting collaborative development with access control. In particular, the entire task management is regarded as a git group; each business scenario corresponds to a git repo (repository); each task in a business scenario corresponds to a branch; and each version of a task corresponds to a tag.

Besides the management of task entity, the task-related files, especially the resources (e.g., data and model) which can be large in size, are also managed in a fine-grained way to support uniform and customized deployments. The files are divided into two categories: one is the shared files, which can be used by a large number of mobile devices (e.g., the devices with a certain version of APP); and the other is the exclusive files, which can be used only by a small number of devices or even a specific device. The shared and exclusive files can be requested efficiently via CDN and CEN, respectively.

Task Release & Deployment. A uniform or customized policy can be taken to deploy tasks on targeted devices. The uniform policy supports task release grouped by the APP version, while the customized policy can further support grouping by device-side information (e.g., OS and its version or device performance) and user-side information (e.g., age or habit). According to the number of devices in a group, the coarse-grained uniform deployment normally involves only shared files, whereas the fine-grained customized task deployment not only can involve shared files but also can involve exclusive files. In the extremely personalized scenarios, the

customized policy supports deploying a certain kind of task but with user-specific/exclusive files to each individual device.

Regarding task release, we take a novel push-then-pull method. We reuse the existing client-side business request to implement push, by adding a mobile device's local task profile into the http header and letting the cloud compare it with the latest task profile. If a new task needs to be released and takes the uniform deployment policy, then the cloud responds with the CDN address of the shared task files. If the new task takes the customized deployment policy, the cloud first determines which group the mobile device belongs to by rule matching and then responds with the CDN address of the shared files or the CEN address of the exclusive files. After receiving the response from the cloud, the mobile device can pull the task files using the CDN or CEN address from the nearest node. Considering the fact that the client-side business request is frequent, while the speeds of CDN and CEN are fast in practice, the timeliness of task deployment can be guaranteed.

To guarantee the stability of task release and deployment, the simulators of the mobile APP with different versions for different OS can be created with the compute container on the cloud for testing a pre-release task extensively. Upon passing the simulation testing, a beta release is conducted to deploy the task only on a few targeted devices. After passing the beta release, the gray release is forced to be performed in steps, covering all the targeted devices incrementally. The deployment platform is also equipped with an exception handling module, which can monitor the failure rate of the task in real time and also can rollback immediately if the failure rate exceeds a certain threshold.

7 Evaluation of Walle

We evaluate Walle in two major application scenarios of Alibaba. We also extensively conduct benchmark testing for MNN, Python thread-level VM, and real-time tunnel. We finally report the statistics of the deployment platform.

7.1 Performance in E-Commerce Scenarios

Compute Container in Livestreaming. E-commerce livestreaming has brought a brand new form of online shopping to billion-scale users. In 2020, the gross merchandise value (GMV) of livestreaming in Mobile Taobao exceeded 400 billion RMB. One key ML task in this scenario is highlight recognition, which is to locate the time points of a streamer in introducing attractive information about items.

Under the conventional cloud-based ML paradigm, a video stream is uploaded from each streamer's mobile device to the cloud for highlight recognition, which mainly includes the detection and recognition of items as well as the facial detection and the voice detection of streamers. Due to the large number of online streamers, the long length of their video streams, and the stringent latency requirement of highlight recognition, the load of the cloud is so heavy that only part of video streams and only a few sampled frames can be analyzed, which becomes a key bottleneck in practice.

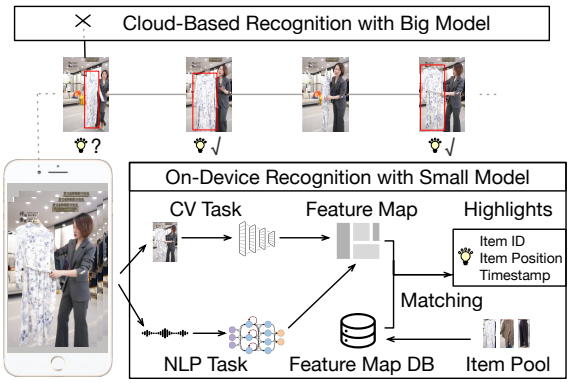

Figure 9: Workflow of device-cloud collaborative highlight recognition in e-commerce livestreaming.

Table 1: Model information and inference latency in device-side highlight recognition.

	Item Detection	Item Recognition	Facial Detection	Voice Detection
Model	FCOS [40]	MobileNet [25]	MobileNet [25]	RNN
Parameter Size	8.15M	10.87M	2.06M	8K
Huawei P50 Pro	56.92ms	25.68ms	41.42ms	0.07ms
iPhone 11	33.71ms	29.74ms	22.58ms	0.01ms

With Walle, we can offload the highlight recognition task with light-weight models to a streamer's mobile device and implement a device-cloud collaborative workflow, as shown in Figure 9. If the device-side models can recognize the highlights in a video stream with high confidences, then these highlights can be directly shown to users after post-processing. Only those highlights, which are recognized with low confidences on the mobile device and account for roughly 12% in practice, need to be processed by cloud-side large models. After passing cloud-side recognition, the rate of which is around 15%, the highlights will be delivered to the mobile device.

Through device-cloud collaboration, the numbers of streamers and video streams covered with highlight recognition dramatically increase, while the load of the cloud is also sharply relived. In particular, business statistics show that compared with the cloud-based paradigm, the new device-cloud collaborative workflow increases the number of streamers with highlight recognition by 123%; reduces the computing load of the cloud per highlight recognition by 87%; and increases the size of daily recognized highlights per unit of cloud cost by 74%. We also evaluate the performance of the compute container in Walle, when supporting highlight recognition on Huawei P50 Pro and iPhone 11. The total latency is 130.97ms and 90.42ms, respectively. In particular, the network architectures, the parameter sizes, and the inference latency of the adopted models are listed in Table 1. The results above demonstrate the high performance of our compute container and the practical effectiveness of device-cloud collaboration.

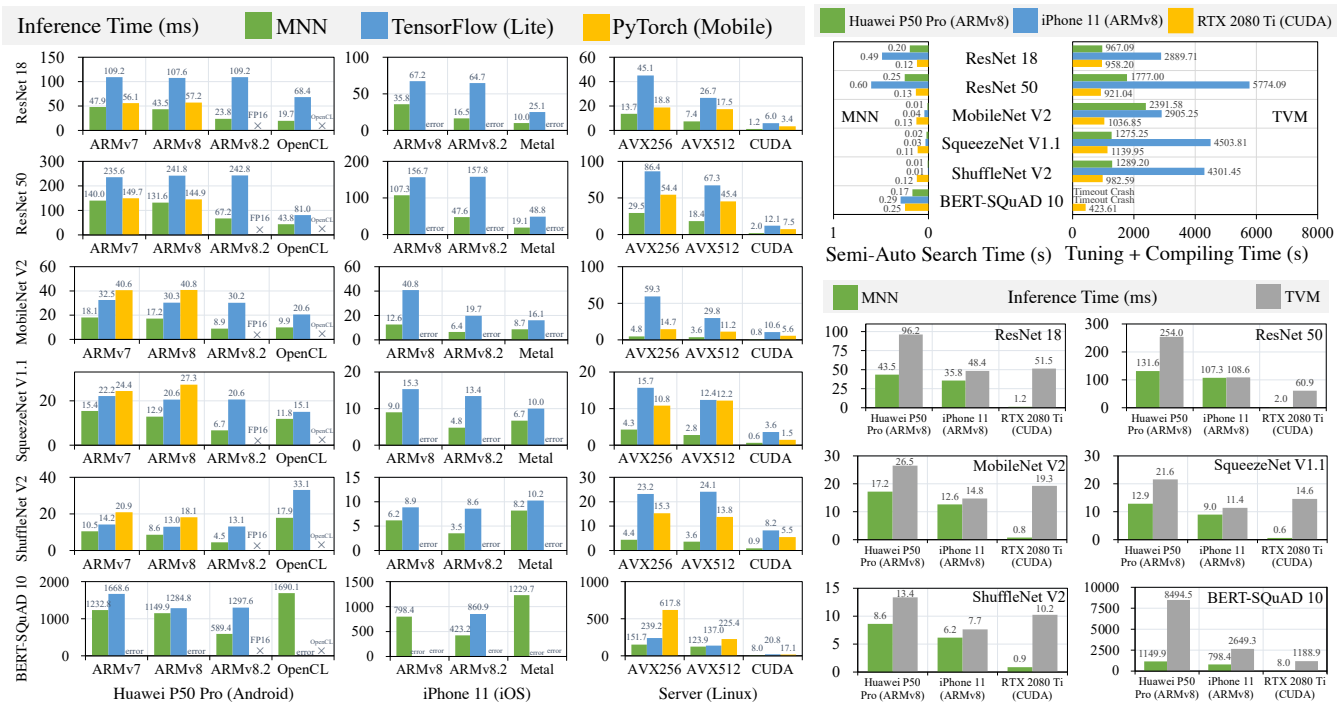

Figure 10: MNN vs. TensorFlow (Lite), PyTorch (Mobile), and TVM on different backends of mobile devices and cloud servers.

Data Pipeline in Recommendation. In Alibaba's cloud-side and device-side recommendation models, item page-view (IPV) feature, which records a user's behaviors (e.g., add-favorite, add-cart, and purchase) in the detailed page of an item, is of significant importance. To generate IPV feature, under the conventional cloud-based paradigm, all the users' raw event data are uploaded to the cloud for stream processing and mixed with user ids for explicit identification. The time-level event sequence from each mobile device is split into multiple homogeneous sequences, one sequence containing a certain kind of event. To obtain the IPV feature of each individual user, the cloud performs join operations with user id and page id as keys over all the users' events, which is quite time-consuming, resource-consuming, and error-prone.

With the on-device stream processing framework in the data pipeline, each mobile device needs to process only a small size of the corresponding user's local events, which is more efficient and more natural. In fact, the IPV feature invokes the generation process of the page-level event sequence. The input is the time-level event sequence. The trigger condition is the page exit event. The triggered stream processing task is to aggregate all the events (i.e., to cluster the same kind of events and gather statistics between the enter event and the exit event of the page). Since the raw contents in each event contain redundant fields (e.g., device status), a filtering is applied to the event contents. Further considering the fact that the IPV feature is first encoded (e.g., through RNN) in recommendation models, by using the model inference API of the compute container, the encoding process can also be offloaded to mobile devices.

We first show the size reductions from raw event data, to IPV feature, and to IPV encoding. On average, one IPV feature is around 1.3KB in size, involving 19.3 raw events in the size of 21.2KB, and one IPV encoding is only 128 bytes. This indicates that compared with the conventional paradigm of transferring raw event data to the cloud for stream processing, our new IPV data pipeline can save more than 90% of communication cost. Besides communication efficiency, we also compare the latency of on-device and cloud-based stream processing. By analyzing over 10,000 practical cases (randomly sampled from the case pool of 2 million online mobile clients) of processing raw events into IPV features, the average on-device latency is only 44.16ms. In contrast, using Alibaba's internal version of Flink, called Blink, the average latency of producing one IPV feature is 33.73s. In particular, the cloud-based stream processing is over 2 million online users' raw events and consumes 253.25 compute units (CU), where 1 CU denotes 1 CPU Core plus 4GB memory; the error rate of IPV feature generation is 0.7%; and the average latency is analyzed over 10,000 randomly sampled normal cases. These results reveal that compared the mainstream cloud-based data pipeline, Walle's new data pipeline can indeed reduce device-cloud communication cost and cloud-side load, while improving the timeliness and validity of feature.

7.2 Benchmark Testing

We first compare MNN with TensorFlow (Lite) and PyTorch (Mobile) on Android and iOS devices as well as Linux servers. For device-side testing, we use Huawei P50 Pro and iPhone 11, covering the backends of ARMv7, ARMv8, and ARMv8.2

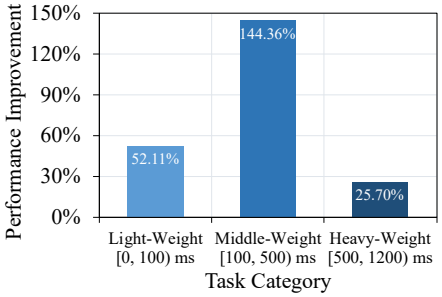

Figure 11: Python thread-level VM vs. CPython (30 million ML task executions).

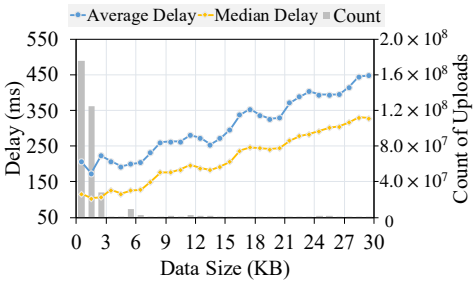

Figure 12: Delay of real-time tunnel (analyzed over 364 million uploads).

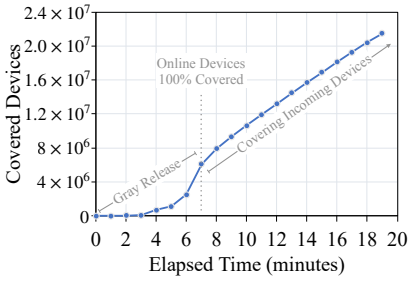

Figure 13: Timeliness of ML task deployment (22 million devices).

with single thread as well as OpenCL and Metal. For server-side testing, we use AMD Ryzen 9 3900X (x86), Alibaba Cloud's ecs.g6e.4xlarge (Intel Xeon (Cascade Lake) Platinum 8269CY, 16 vCPU, 64GiB memory), and NVIDIA GeForce RTX 2080 Ti, covering the backends of AVX256 and AVX512 with 4 threads, and CUDA, respectively. We take ResNet 18 [22], ResNet 50 [22], MobileNet V2 [38], SqueezeNet V1.1 [27], ShuffleNet V2 [33], BERT-SQuAD 10 [10], and DIN [46], as the testing models, which are commonly used in CV, NLP, and recommendation applications. The input size of CV models is set to $1 \times 3 \times 224 \times 224$, the input size of BERT-SQuAD 10 is set to $(1 \times 256, 1 \times 256, 1 \times 256, 1)$, while the input size of DIN is set to $1 \times 100 \times 32$. We show the inference time of the CV and NLP models in the left part of Figure 10, and omit the results of DIN, which are quite low (e.g., less than 0.2ms on iPhone 11 using MNN). We can observe that MNN significantly outperforms TensorFlow (Lite) and PyTorch (Mobile) in almost all the test cases. Besides higher performance, MNN is also more full-featured on the side of mobile devices, given that MNN can support all the models on each device-side backend, whereas TensorFlow Lite and PyTorch Mobile fail to support some backends and/or models.

We continue to compare MNN with TVM. We take MacBook Pro 2019 and NVIDIA GeForce RTX 2080 Ti as the host machines of TVM to do auto-tuning and compiling for the mobile devices and the GPU server, respectively. The number of trials in TVM auto-tuning is set to 30. Since TVM auto-tuning for BERT-SQuAD 10 on two mobile devices incurs timeout crash, we take the default parameter settings for model inference. From the evaluation results depicted in the right part of Figure 10, one key observation is that the auto-tuning and the compiling of TVM roughly cost thousands of seconds. In contrast, the semi-auto search of MNN for runtime optimization costs roughly hundreds of milliseconds. Further incorporating the comparative analysis in Section 4.1, we can draw that MNN can support the industrial scenarios that involve numerous heterogeneous devices and require frequent and quick task iteration, whereas TVM cannot. The second key observation is that the inference time of MNN is lower than TVM for each model on each backend, especially on the GPU server. Such superiority is mainly due to the manual operator-level, backend-level optimization in MNN.

We next compare Walle's Python thread-level VM with the original Python VM (i.e., CPython with GIL) using roughly 30 million online ML task executions. We define performance as the reciprocal of task execution time and show the average performance improvement in Figure 11. For the light-weight, middle-weight, and heavy-weight tasks, Python thread-level VM gains 52.11%, 144.36%, and 25.70% of performance improvement, respectively. We can draw that task-level multi-threading without GIL is the key of performance boosting.

We finally evaluate the latency of the real-time tunnel over roughly 364 million uploads. Figure 12 shows the latency and the number of uploads for varying data sizes. We can observe that more than 90% uploads are under 3KB with less than 250ms on average. Even when the sizes of 0.1% uploads grow to 30KB, the average delay increases only to around 450ms.

7.3 Deployment Platform Statistics

The deployment platform in Walle has supported 30+ mobile APPs (e.g., Mobile Taobao, AliExpress, Xianyu, Youku, Cainiao Guoguo) in Alibaba since the end of 2017, running for roughly 1,500 days. It has deployed 1,000+ kinds of ML tasks in total, each with 7.2 versions on average. Currently, the deployment platform is maintaining and monitoring 348 kinds of active tasks on more than 0.3 billion mobile devices. To demonstrate the timeliness of task deployment, we randomly select an ML task, monitor its release process, and depict in Figure 13 how the number of covered devices changes as the elapsed time grows. The first segment of the curve shows the gray release stage, which takes 7 minutes to cover all the 6 million online devices. In particular, roughly 4 million devices are incrementally covered within the last minute. Then, the number of covered devices increases as more mobile devices become online. Until 19 minutes later, almost 22 million devices have been covered. The statistics show the scalability and timeliness of the deployment platform in Walle.

8 Related Work

In this section, we briefly review some related work in both academia and industry.

Cloud-Based ML System. Many companies have built their ML systems on the cloud, which are backed by their

cloud computing platforms, such as Amazon Web Services, Microsoft Azure, Alibaba Cloud, and Google Cloud. The architecture is clear and comprises the standard modules of data storage (e.g., HBase [14] and HDFS [13]), batch and stream processing (e.g., Storm [42], Spark [45], and Flink [7]), ML engines (e.g., TensorFlow [1], PyTorch [36], and MXNet [8]), virtualization and containerization (e.g., KVM [37] and docker [26]), and elastic orchestration (e.g., Kubernetes [15]).

On-Device ML System. Some modules are open source with rapid development in terms of well balancing light weight, necessary functionality, and high performance, including on-device inference engines (e.g., TensorFlow Lite [16], PyTorch Mobile [12], Core ML [3], and NCNN [39]); and SQLite [24], which is a small and self-contained SQL database engine. However, the whole architecture is still in the dark, and several core capabilities are absent, such as an on-device execution environment that supports quick development and concurrent execution of multiple ML tasks, and light-weight data processing and model training libraries for diverse CV, NLP, and recommendation tasks.

Device-Cloud Collaborative ML. The concept can stretch back to edge/mobile computing, but focuses on the collaboration of the cloud and mobile devices in executing complex ML tasks, rather than offloading simple data analysis tasks from the cloud to edge servers or mobile devices. Previous work focused on the algorithmic framework or solution and was normally specific to a certain kind of application. In contrast and in parallel, Walle targets at the general-purpose and large-scale production system support. We review some representative work as follows.

An initial paradigm is to keep model training on the cloud but offload model inference (e.g., facial recognition, photo beautification, and question answering) to mobile devices, validating the on-device advantages in reducing latency and protecting privacy. The key of this paradigm's proliferation is the advances of model compression algorithms to reduce model size and optimize model structure, such as quantization [19], pruning and sparification [20], knowledge distillation [23], and neural architecture search [47]. Later, Mistify [18] automated the cloud-to-device model porting process given the customized requirements of heterogeneous mobile devices, while some work designed more reasonable task splitting strategies rather than offloading the full inference task. For example, Neurosurgeon [29] was proposed to automatically partition DNN computation between a mobile device and the cloud at the granularity of DNN layers.

Besides inference, the popular cross-device federated learning (FL) framework [34] elegantly generalizes the conventional parameter server framework [30] and enables multiple mobile devices to collaboratively train a global model under the coordination of a cloud server. The tenet of FL is to keep user data on local devices, thereby protecting data security and privacy. The device-cloud collaboration in FL is purely through exchanging model and its update periodically. The task splitting strategy is that mobile devices conduct model training, and the cloud aggregates model updates. Google has experimentally deployed FL on its Android keyboard, called Gboard, to polish language models [5].

Finally, many application-specific solutions were proposed under the principle of device-cloud collaboration. FilterForward [6] and Reducto [31] considered how to effectively and efficiently do camera-side frame filtering with ML techniques to facilitate cloud-side video analytics. DDS [11] adopted an interactive workflow, where a camera first uploads a low-quality video stream and re-sends a few key regions with higher quality according to the cloud's feedback to improve inference accuracy. COLLA [32] studied the user behavior prediction task with RNN and leveraged knowledge distillation to mutually and continuously transfer the knowledge between the device-side small models and the cloud-side large model, thereby mitigating data heterogeneity and data drift over time. DDCL [44] and CoDA [17] focused on recommendation. DDCL relied on patch learning for on-device model personalization and adopted model distillation to integrate the patches from mobile devices into the cloud-side global model. CoDA, instead, was proposed to retrieve similar samples from the cloud's global pool to augment each mobile device's local dataset for training personalized recommendation models. Backed by Walle, CoDA was deployed in Mobile Taobao.

9 Conclusion

In this work, we have built the first end-to-end, general-purpose, and large-scale production system, called Walle, for device-cloud collaborative ML. Walle is oriented by the lifecycle of ML tasks and consists of a cross-platform, high-performance, and quickly iterative compute container; a more reasonable and efficient data pipeline; and a scalable, timely, and robust deployment platform. Evaluation of Walle in practical e-commerce scenarios and extensive micro-benchmarks have demonstrated the necessity of device-cloud collaboration and the superiority of each ingredient. Walle has been deployed in Alibaba for wide scale production use, serving billion-scale users with mobile devices every day.

Acknowledgments

We sincerely thank our shepherd, Wenjun Hu, for her insightful and thorough guidance. We thank the anonymous OSDI reviewers for their constructive feedback. We thank Kai Liu, Hansong Liu, Hao Jiang, Zhijie Cao, and Yan Chen from Alibaba for their great support. Abstract

This paper presents Unity, the first system that jointly optimizes algebraic transformations and parallelization in distributed DNN training. Unity represents both parallelization and algebraic transformations as substitutions on a unified *parallel computation graph* (PCG), which simultaneously expresses the computation, parallelization, and communication of a distributed DNN training procedure.

Optimizations, in the form of graph substitutions, are automatically generated given a list of operator specifications, and are formally verified correct using an automated theorem prover. Unity then uses a novel hierarchical search algorithm to jointly optimize algebraic transformations and parallelization while maintaining scalability. The combination of these techniques provides a generic and extensible approach to optimizing distributed DNN training, capable of integrating new DNN operators, parallelization strategies, and model architectures with minimal manual effort.

We evaluate Unity on seven real-world DNNs running on up to 192 GPUs on 32 nodes and show that Unity outperforms existing DNN training frameworks by up to 3.6× while keeping optimization times under 20 minutes. Unity is available to use as part of the open-source DNN training framework FlexFlow at https://github.com/flexflow/flexflow.

1 Introduction

Deep neural networks (DNNs) are becoming progressively larger and computationally more expensive to train, and as they have grown, so has interest in optimizing their execution to reduce training times and improve scalability. Two key classes of optimizations shown to yield significant performance improvements across diverse model architectures are algebraic transformations and parallelization.

Algebraic transformations exploit operator identities to perform the underlying computation in a more efficient way, but ignore parallelization and distribution of training. Common examples of algebraic transformations include operator fusion, which merges two operators into a single semantically-equivalent operator whose computation is more efficient, and operator reordering, where the associativity or commutativity of sets of operators allows them to be reordered into more efficient configurations or to expose further optimization opportunities. More explanation of algebraic transformations, along with examples, is provided in Section 2.2.

Parallelization, in contrast, distributes operators over multiple devices, but does not change the way in which the underlying computation is performed. DNN training exploits a class of parallelism named *partition-n-reduce* [59], in which every distributed subcomputation of an operator must perform the same computation, and may only differ in the input data it consumes. The tensor computations in DNN training are particularly well-suited to this form of parallelism, and many *parallelism dimensions* along which to divide distributed operators have been identified, such as data [6], model [13], spatial [27], reduction [50], and pipeline [39]. For a detailed overview of these various approaches, see Section 2.1.

When applied effectively, these two techniques can improve training times by more than an order of magnitude. However, effective application is nontrivial. Rewriting the computation graph for maximum speedup can require many transformations, some of which may harm performance except in the context of a longer sequence of transformations [26]. The optimal parallel execution strategy for a model often requires simultaneously exploiting multiple parallelization dimensions and using different parallelization schemes for each operator [24]. Early work relied on the programmer to manually determine the correct optimizations to apply [6]. While manual optimization allows fine-grained control over the model's performance, it requires many hours of tuning by experts to achieve good performance. As the pace of new developments in model design has increased, manual optimization has struggled to scale beyond the most commonly used models.

Recent work has focused on automating optimizations. MetaFlow [26], TASO [25], and PET [58] propose algorithms for automatically generating and applying algebraic transformations by posing optimization as a search problem.

♠ Contributed equally.

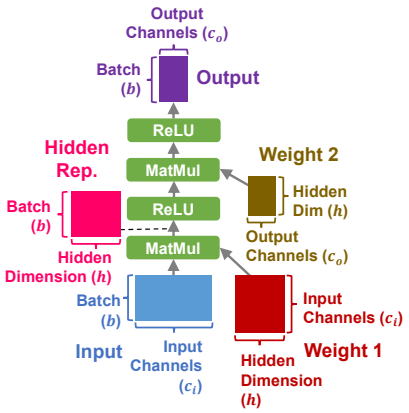

Figure 1: Computation graph for a 2-layer MLP.

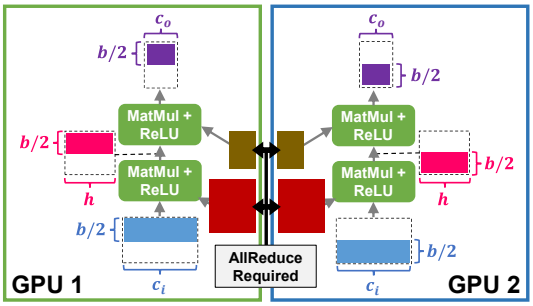
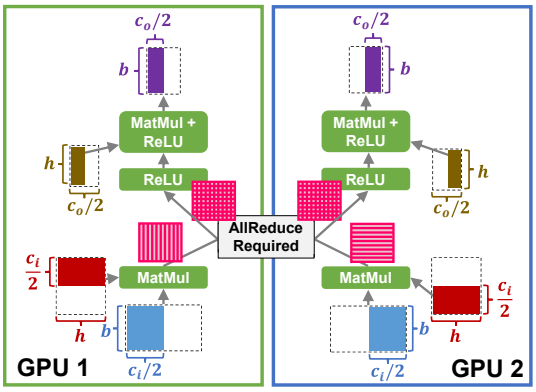
FlexFlow [27], automap [48], Tofu [59], and Whale [23] bring a similar approach to parallelism. These works present impressive benchmarks, yielding the impression that automating algebraic and parallelization optimization is a solved problem.

However, to reduce training time as much as possible, we want to apply both of these optimizations, but the most effective way to combine algebraic and parallelization optimizations is not obvious. The simplest solution is to apply them independently, in one of two orders: algebraic optimization followed by parallelization, or the reverse. The reverse order turns out to be problematic: since algebraic transformations can introduce new operations or replace existing ones, running algebraic optimization after parallelizations have been assigned can lead to the final solution having operations without assigned parallelizations (if the operation was created) or invalid parallelizations (if the operation was replaced). Workarounds can be used to fix invalid solutions by using default parallelization strategies or copying the strategies of nearby operators, but it is easy to find cases in which these workarounds lead to suboptimal solutions. As such, applying algebraic optimization before parallelization is the only option, but as we see in the next example, it can miss significant optimization opportunities.

Consider the computation graph shown in Figure 1, which represents a 2-layer multilayer perceptron (MLP). If we are optimizing independently (also referred to as "sequentially"), we start by applying algebraic transformations without considering parallelism. A typical algebraic optimizer will fuse the `MatMul` and `ReLU` operators to remove redundant memory loads and stores. The model is then parallelized (we consider only 2 GPUs for simplicity) resulting in Figure 2a: data parallelism is used for both operators and thus the weight gradients must be synchronized with an AllReduce. Since weight 1 has size $c_i h$ and weight 2 has size hc_o, the total communication is $2(c_i h + hc_o)$. Using a set of parameters for a basic image classification model for MNIST ($b = 64$, $h = 512$, $c_o = 10$, $c_i = 28 \times 28 = 784$) yields a total communication of $813,056d$ bytes, where d is the element size.



(a) Sequential optimization.



(b) Joint optimization.

Figure 2: Comparing joint and sequential optimizations.

Instead of independently applying algebraic transformations and parallelization, we can combine them and solve a single joint optimization problem that discovers the solution in Figure 2b. By not fusing the first `MatMul` and `ReLU`, more efficient reduction parallelism can be used. This requires synchronizing the activation and gradient of the first `MatMul`'s output, but not the weights: a total inter-GPU communication of $4bh$, or $131,072d$ bytes for our MNIST example. Joint optimization reduces communication by $6\times$, which far exceeds the cost of not fusing the first `ReLU`.

As this example shows, joint optimization is necessary to maximize performance. However, it also poses significant challenges. The first is representation: existing frameworks perform optimizations on a model's computation graph. As discussed above, algebraic transformations can leave operators in the computation graph with unassigned or invalid parallelizations. To prevent such invalid solutions from arising during search, we need a representation that allows algebraic transformations to consider the current parallelization before being applied. Further discussion of the representation challenges is in Section 3.4.

The second challenge is scalability: existing search-based approaches already struggle to scale up to large models and GPU counts. Improvements have been made for algebraic transformations alone [62], but the complexity of these solutions makes adding parallelization a daunting task. Simultane-

ously considering both optimization classes only exacerbates this problem by exponentially increasing the search space size. For joint optimization to be practical, search algorithms must improve on the scalability of past techniques.

1.1 Unity's Approach

The key idea behind Unity is to represent both algebraic transformations and parallelization as graph substitutions on a unified *parallel computation graph*, and then to use a hierarchical search algorithm to efficiently identify which combination of substitutions yields the best performance. Figure 3b shows an overview of Unity, which differs from existing frameworks in the following ways:

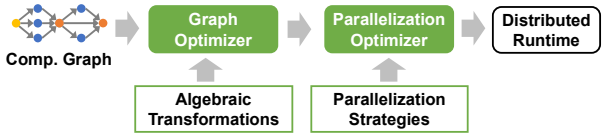
Unified graph representation. We introduce the *parallel computation graph* (PCG)[1] as a unified representation of distributed DNN training that simultaneously expresses computation, parallelism, and data movement. All parallelization strategies used in existing frameworks can be represented as specific PCGs, and parallelization and algebraic transformations as sequences of graph substitutions. pONNX [57] previously proposed merging computation and parallelism into a single graph, but certain design decisions prevent Unity-style joint optimization. For a detailed comparison, see Section 3.4.

Transformation generation and verification. Unity does not require users to explicitly define possible parallelization strategies for DNN training. Unlike prior work that automatically generates parallelization strategies [59] or algebraic transformations [25], by using the PCG Unity is able to generate both kinds of transformations with a single approach, as well as hybrid algebraic-parallelization optimizations absent in prior automated approaches. Automatically generating and verifying transformations greatly reduces the engineering effort required to support different parallelism dimensions and enables extensibility to new operators.

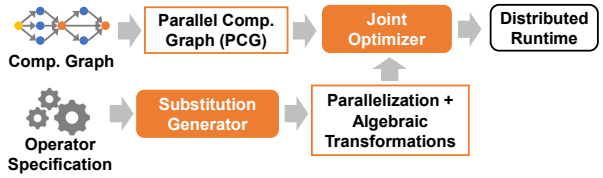
Joint optimization. Unity uses a hierarchical search algorithm to discover highly optimized PCG substitutions and device placements while maintaining scalability to models with hundreds of operators distributed over hundreds of GPUs. Unity's cost model includes both computation and communication time, and the search algorithm handles custom network topologies and heterogeneous compute devices. Despite the exponentially larger search space being considered, Unity outperforms existing search-based approaches (see Section 6).

The rest of this paper provides additional background (Section 2), discusses Unity's design and implementation (Sections 3, 4, and 5), and evaluates its performance on seven real-world DNNs (Section 6). For widely-used DNNs highly optimized by existing frameworks, such as BERT [14], Unity matches the performance of existing expert-designed strategies while being completely automated. For complex DNN architectures with a mixture of compute- and communication-intensive operators, such as DLRM [41] and CANDLE-Uno [1], Unity is up to 3.6× faster than existing frameworks.

[1]To prevent ambiguity, we use the term *computation graph* strictly to refer to the conventional computation graph used in prior work, and *parallel computation graph* or PCG to refer to Unity's new unified representation.



(a) Existing approach.



(b) Unity's approach.

Figure 3: Comparing existing DNN frameworks and Unity.

2 Background

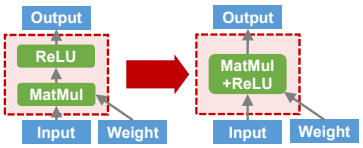
We first provide a brief overview of the two classes of optimizations that Unity exploits, parallelization (Section 2.1) and algebraic transformations (Section 2.2), as well as a discussion of how they are represented in existing systems (Section 2.3). For a discussion of how Unity interacts with other classes of optimizations, see Section 8.

2.1 Parallelization

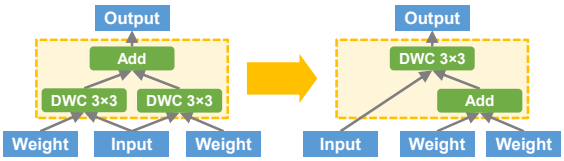
The massively parallel nature of tensor algebra creates many opportunities for parallelizing DNN training. We identify six primary forms of parallelism leveraged in DNN systems:

1. *Data parallelism* is the most common approach used in existing frameworks [6, 9, 42]. Data parallelism keeps a replica of the entire DNN model on every device and assigns each a subset of the training data.
2. *Model parallelism* divides a DNN model into disjoint sub-models and trains each sub-model on a dedicated device.
3. *Spatial parallelism*[2] divides the spatial dimensions of a tensor (e.g., the height and width of images) into multiple partitions, each of which is assigned to a specific device [27]. Spatial parallelism often requires synchronizing the shared elements (e.g., the shared pixels along the boundary of different sub-images) between devices.
4. *Reduction parallelism* exploits the linearity of tensor algebra operators. For a matrix multiplication $C = A \times B$, reduction parallelism splits A along its columns and B along its rows as follows: $A = [A_1, \ldots, A_n]$, $B = [B_1^T, \ldots, B_n^T]^T$ The matrix multiplication is distributed across n devices, with the i-th device computing $C_i = A_i \times B_i$. An extra reduction afterward recovers the original result: $C = \sum_i C_i$.

[2]Spatial parallelism was called *attribute parallelism* in [27].



(a) Basic operator fusion.



(b) A more complex algebraic transformation.

Figure 4: Example algebraic transformations. `DWC` stands for `DepthwiseConv` (i.e., depth-wise separable convolution).

5. *Pipeline parallelism* exploits the opportunity to parallelize across different training iterations [39].
6. *Operator-specific parallelism.* The introduction of new DNN operators provides operator-specific parallelization opportunities. For example, the following equation shows the batched matrix multiplication used in Transformer [54]: $output(s,h,o) = \sum_i input(s,h,i) \times weight(h,o,i)$. This differs from typical matrix multiplication in that it applies a different weight for each input sample. As a result, these batched matrix multiplications across attention heads can be run in parallel (i.e., the h dimension) without any tensor replication or synchronization.

Most parallelizations are not pure performance optimizations, but are instead trade-offs among different cost metrics. For example, applying data parallelism reduces per-device computation time at the cost of increased memory usage and data movement for storing and synchronizing model parameters. Thus, DNN operators typically require a combination of these forms of parallelism to achieve optimal performance.

2.2 Algebraic Transformations

Algebraic transformations are very diverse and are not as easily categorized as the forms of parallelism, so we instead provide examples. For a more comprehensive exploration of algebraic transformations, see [25].

The most basic algebraic transformation is operator fusion, shown in Figure 4a. Unfused, the device needs to load and store activations to and from memory twice, once before and after each operator. If the two operators are fused, however, the combined kernel can compute the `ReLU` operation as it stores the outputs of the `MatMul` back to memory.

For a more complex example, see Figure 4b. By exploiting `DepthwiseConv`'s linearity, a computation that previously required two `DepthwiseConv` operations now only requires one plus an additional `Add`, effectively halving the amount of computation needed.

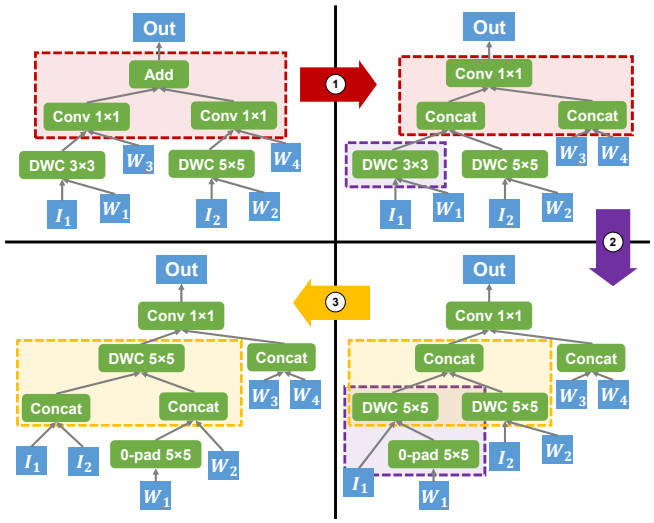


Figure 5: Compositions of small algebraic transformations can lead to significant changes.

Small algebraic transformations can be composed to create large changes. Consider the sequence of transformations shown in Figure 5: while each individual transformation is relatively small, the final output is radically different from the original computation graph. Also, notice that not all performance gains are realizable in a single transformation: for example, moving from graph 2 to graph 4 reduces the amount of computation by reducing the number of `DepthwiseConv` operations performed, but it is first necessary to pass through graph 3 which performs worse than either graph 2 or 4.

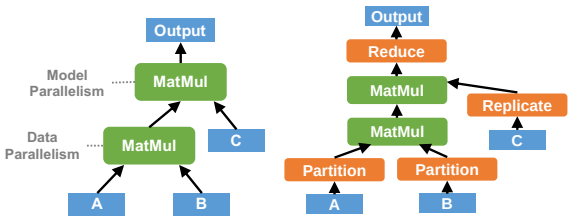
2.3 Intermediate Representations

Most existing optimizing frameworks represent a DNN architecture as a *computation graph*[3]: a node is a mathematical tensor operator (e.g., matrix multiplication, etc.), and an edge is a tensor (i.e., n-dimensional array) passed between operators. An example computation graph is shown in Figure 6a. Algebraic transformations are performed by iteratively applying graph substitutions, and the model is parallelized by assigning each node a set of parallelism annotations.

This representation has two limitations. First, while using distinct representations for algebraic transformations (i.e., graph substitutions) and parallelization (i.e., node annotations) is convenient, it hinders joint optimization. The key issue is that algebraic transformations can add or replace nodes in the graph, while parallelization views the computation graph as static and thus cannot handle these newly-created, unannotated nodes. This prevents interleaving the two search algorithms, since at any time a substitution can transform a valid parallelization into an invalid one.

Second, a computation graph does not explicitly capture

[3] Alternative representations are discussed in Section 3.4 and Section 7.



(a) Computation graph. (b) Parallel computation graph.

Figure 6: Comparing computation graph and PCG. Both graphs describe the same parallelization of two consecutive matrix multiplications $(A \times B) \times C$ (a simplified form of attention). The green and orange boxes denote regular DNN operators and Unity's new parallelization operators (see Section 3.3) respectively.

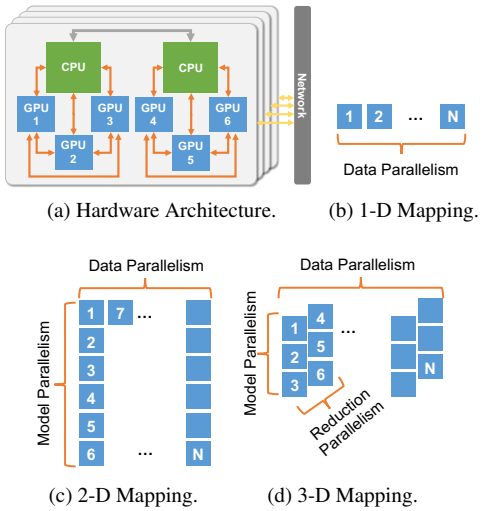
the communication costs associated with parallelism. This absence makes it difficult for algebraic transformations to reason about the impact on the performance of the final model.

3 Parallel Computation Graph

To solve the shortcomings of the existing model representations described in Section 2.3, we introduce the *parallel computation graph* (PCG) as a unified representation of distributed DNN training that is capable of simultaneously expressing computation, parallelism, and communication. The PCG allows Unity to consider both algebraic transformations and parallelization as graph substitutions on a common graph. While the PCG is not the first to merge computation and parallelization into a single graph, the PCG is tailored for optimization and as such differs from prior unified graph representations in key aspects, which we discuss in Section 3.4.

PCGs extend the existing computation graph representation by allowing nodes to represent changes in parallelization in addition to mathematical tensor operations, and edges to represent distributed movement of tensor data in addition to data dependence. A set of *parallelization operators* are added that allow PCGs to express all existing parallelization strategies and provide an explicit representation of data movement and its associated costs during training. Additionally, each operator in a PCG is associated with a *machine mapping*, denoting how the execution of the operator is mapped to individual processors in a parallel machine. Figure 6b shows an example of a PCG.

Sections 3.1, 3.2, and 3.3 provide a brief description of the tensor representation, machine mappings, and parallelization operators, respectively. Finally, Section 3.4 discusses the design decisions that make the PCG uniquely suited for joint optimization, and how it differs from alternative unified graph representations.



(a) Hardware Architecture. (b) 1-D Mapping.

(c) 2-D Mapping. (d) 3-D Mapping.

Figure 7: Example machine mapping for a compute node in our evaluation. (a) shows the node's hardware architecture, where and orange and grey arrows denote NVLink and X-Bus. Numbers in mapping examples denote GPU ids.

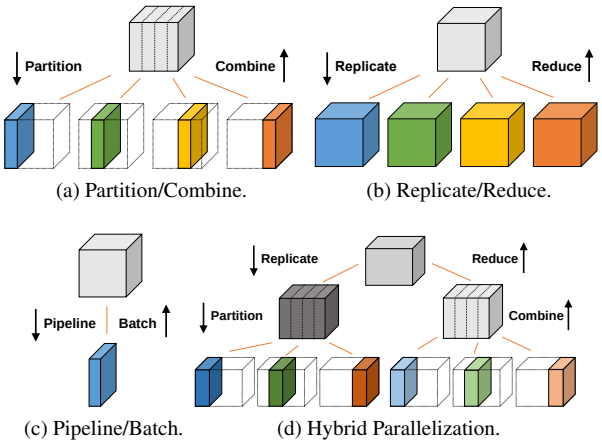
3.1 Tensor Representation

Unity models tensors as a set of data dimensions, each of which has two fields: a size and a degree. The degree field specifies the number of partitions the tensor has been divided into along that dimension. Every tensor also includes a special *replica dimension*, which represents the number of replicas of that tensor's data.

3.2 Machine Mappings

Each operator in a PCG is associated with a *machine mapping*, an n-dimensional array of devices/processors that specifies on which device to run each piece of the operator's computation. More formally, given an operator and a set of n applicable parallel dimensions with degrees $d_1, \ldots, d_n$, Unity divides the operator into $d_1 \times d_2 \times \ldots \times d_n$ parallel tasks, which we reference with tuple indices of the form $(i_1, \ldots, i_n)$ where $0 \leq i_k < d_k$. A machine mapping is a map from task indices $(i_1, \ldots, i_n)$ to individual GPUs that will be used to run that parallel task. For convenience, we also define the machine mapping of an entire PCG to be the set of machine mappings of each of its constituent operators.

Figure 7 shows some example machine mappings for the Summit compute nodes [55] used in our evaluation. The hardware architecture is depicted in Figure 7a. Figure 7b shows a basic 1-D machine mapping for data parallelism, while Figure 7c shows a 2-D machine mapping of a hybrid parallelization strategy combining data and model parallelism, where model parallelism is applied across GPUs within the same compute node and data parallelism across distinct compute nodes. Figure 7d shows a 3-D machine mapping where we apply model parallelism across GPUs attached to the same



(a) Partition/Combine. (b) Replicate/Reduce.

(c) Pipeline/Batch. (d) Hybrid Parallelization.

Figure 8: Parallelization operators in Unity.

CPU, reduction parallelism across GPUs attached to different CPUs but on the same compute node, and data parallelism across different compute nodes.

Unity includes a comprehensive set of machine mappings that capture effective usages of a parallel machine. In addition, developers can register custom machine mappings tailored to specific hardware architectures. For example, when node pairs in a cluster have different network bandwidths and latencies, an extra dimension can be added to the existing machine mappings to represent node-level locality.

Machine mappings provide two key desirable properties: *expressiveness* and *scalability*. All effective distributions of parallel tasks in a PCG can be captured in just a few machine mappings, and complex features of a machine's hardware architecture can be easily leveraged through adding additional machine mappings. Machine mappings also allow Unity to capture all effective device assignments while remaining linear in the number of devices and aid Unity's search algorithm by removing inefficient assignments from consideration.

3.3 Parallelization Operators

Unity uses six parallelization operators to capture the computation and communication costs associated with different parallelization strategies. These six are further divided into three pairs, where one operator is the "back propagation" of the other (e.g., when back propagation is done on `Partition` it becomes semantically equivalent to `Combine`, and the same in reverse). The three pairs are:

1. *Partition and Combine*: `Partition` and `Combine` change a tensor's degree of parallelism. More specifically, `Partition` increases the parallelism degree of a tensor dimension by splitting the dimension into multiple equal-sized partitions, as shown in Figure 8a. `Combine` performs the reverse: reducing a tensor's degree of parallelism by concatenating multiple partitions into one.
2. *Replicate and Reduce*: `Replicate` and `Reduce` control the parallelism degree of the replica dimension by copying and summing tensors, as shown in Figure 8b. Parameter synchronization is naturally captured as the back propagation of `Replicate` operations applied to weight tensors.
3. *Pipeline and Batch*: `Pipeline` splits a tensor dimension into equal size partitions and processes one partition at a time, while `Batch` aggregates tensors across iterations (see Figure 8c). Note that `Pipeline` does not modify the parallelism degree of a tensor dimension, but instead reduce its size.

As a basic demonstration of the PCG's expressiveness, Figure 9 illustrates how Unity's six parallelization operators can represent some example parallelization strategies from Section 2.1. These parallelization operators can also be composed to create hybrid parallelism. Figure 8d shows an example that applies `Replicate` and `Partition` on the same tensor dimension, replicating the tensor and partitioning each replica. To improve efficiency, Unity replaces particular sequences of parallelization operators with fused versions at run time (e.g., a `Reduce` followed by a `Replicate` can be implemented as an AllReduce).

3.4 Discussion and Comparison

Unity's decision to use the PCG instead of an annotated computation graph is driven by how easily the representations lend themselves to joint search and not a fundamental limitation of annotated computation graphs. Theoretically, there exist annotation languages isomorphic to the PCG, but attempts to design such a language quickly lead to a number of difficulties.

First, because each operator can use different forms of parallelism, including operator-specific forms of parallelism, the number of annotations quickly grows prohibitively large. Which annotations are supported by which operators, along with their semantics and composition, must then be baked into the representation itself. By comparison, Unity's PCG moves this knowledge into the PCG substitutions, which are generated automatically. This separation of concerns makes the core of Unity simpler and easier to maintain.

Second, not explicitly representing communication forces communication patterns along dataflow edges to be reconstructed from their source and destination node annotations, which is difficult due to the expressive forms of parallelism Unity considers. Specifically, supporting n parallelism dimensions requires considering up to 2^n different subsets of these dimensions and thus $2^n \times 2^n = 4^n$ potential communication patterns between operators. Unity explicitly represents communication patterns throughout search, obviating the need for a complex analysis to reconstruct them. Representing these patterns via a small set of parallelization operators also allows Unity to easily recognize and optimize common communication patterns, such as executing a pair of `Reduce-Replicate`

operators as an AllReduce. In an annotated computation graph, these optimizations become entangled with the code for reconstructing the communication patterns themselves, adding significant complexity and implementation effort.

Finally, jointly optimizing an annotated computation graph is challenging, as algebraic transformations can introduce new operators which, since they have not yet been parallelized, lack annotations. As such, the internal representation becomes underspecified and the cost becomes undefined. It is possible to add an additional mechanism to "fill in" these missing annotations such as inserting a random annotation, a fixed value, a value from a neighboring node (though this becomes challenging when neighboring nodes have differing parallelizations), or evaluating the valid parallelizations and choosing the best one. However, Unity's PCG avoids this additional complexity by representing each parallelization strategy for the new operator as one or multiple PCG substitutions, offering an efficient and uniform approach to joint optimization.

pONNX. Unity is not the first to integrate computation and parallelism into a single graph: pONNX [57] proposed doing so using `Split`, `Concat`, and custom operators `Send` and `Recv`. However, Unity focuses on optimization while pONNX is designed as a serialization format, leading to critical differences.

First, an operator in pONNX with a parallelism degree of n is duplicated n times, requiring an optimizer to reconstruct the operator from multiple nodes. Unity simply adds a parallelism operator so the operator remains a single node in a PCG.

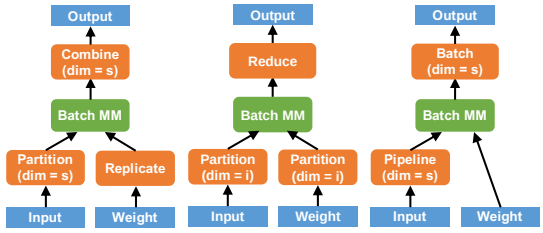
Second, pONNX assigns every communication its own `Send`/`Recv` node, which dramatically increases the size of the graph. Since communication patterns in DNN training are highly regular, Unity eschews materializing every communication in favor of optimizing communication patterns (e.g., `Reduce`, `Replicate`, etc.), which allows Unity to represent communication costs without reasoning about individual communications.

Finally, pONNX makes device placement part of the operator, while Unity represents it separately as a machine mapping. This allows Unity's search to optimize device assignments separately and to ignore the symmetries created by a large number of compute devices with identical capabilities.

Additional unified representations have been proposed [47, 48], which are discussed in Section 7.

4 Graph Substitutions

Since Unity represents both algebraic transformations and parallelization as graph substitutions, the effectiveness of joint optimization relies on having an appropriate set of graph substitutions. The number of potential substitutions increases exponentially with size, so Unity represents large and complex algebraic transformations and parallelization strategies as compositions of small PCG substitutions. For example, Figure 10 shows the sequence of substitutions for the hand-tuned parallelization strategy used in Megatron-LM [50].



(a) Data/Sample. (b) Reduction. (c) Pipeline.

Figure 9: Representing different parallelization strategies for batched matrix multiplication with a PCG. s, i, o, and h indicate the sample, input channel, output channel, and attention head dimensions, respectively.

Substitution generation. To reduce the engineering effort to support new parallelization strategies, Unity automatically generates and formally verifies all valid PCG substitutions up to a fixed size to serve as a "basis set" from which the search algorithm can construct sophisticated optimizations. This also allows Unity to not only automatically discover algebraic transformations and parallelization strategies, but also to find novel hybrids of the two missed by prior approaches. To do so, Unity adopts TASO's super-optimization approach [25].

As in TASO, Unity discovers substitutions in two steps: first it uses a fast heuristic to identify candidate substitutions, and then it uses a more expensive formal verification to ensure correctness. To find candidate substitutions, Unity enumerates all possible PCGs up to a fixed size. Note that this fixed size does not limit the size of the transformations Unity can apply, as many larger substitutions are compositions of smaller ones.

For each generated PCG, Unity computes a *fingerprint*: a hash of the PCG's output tensors generated by evaluating the PCG on some fixed input tensors. To allow Unity to account for parallelization, we extend the fingerprint function in TASO [25] to include the parallelism degree of each tensor dimension. A pair of PCGs is considered a candidate substitution if both PCGs have an identical fingerprint. The addition of parallelism causes Unity to discover 651 new candidate substitutions beyond the 743 previously identified by TASO.

Substitution verification. Similar to TASO, Unity formally verifies the new substitutions using an automated theorem prover (Z3 [12] in our implementation). Operator specifications are provided in first-order logic, where an operator is represented as a function of its inputs and configuration parameters. For example, $\texttt{Reduce}(d,x)$ defines a `Reduce` operator with input x and parallelism degree d. The fact that `Reduce` commutes with matrix multiplication is captured by the following operator property (where $\texttt{Replicate}(d,y)$ represents a `Replicate` with input y and parallelism degree d):

$$\forall d,x,y.\ \texttt{Matmul}(\texttt{Reduce}(d,x),y) = \texttt{Reduce}(d,\texttt{Matmul}(x,\texttt{Replicate}(d,y)))$$

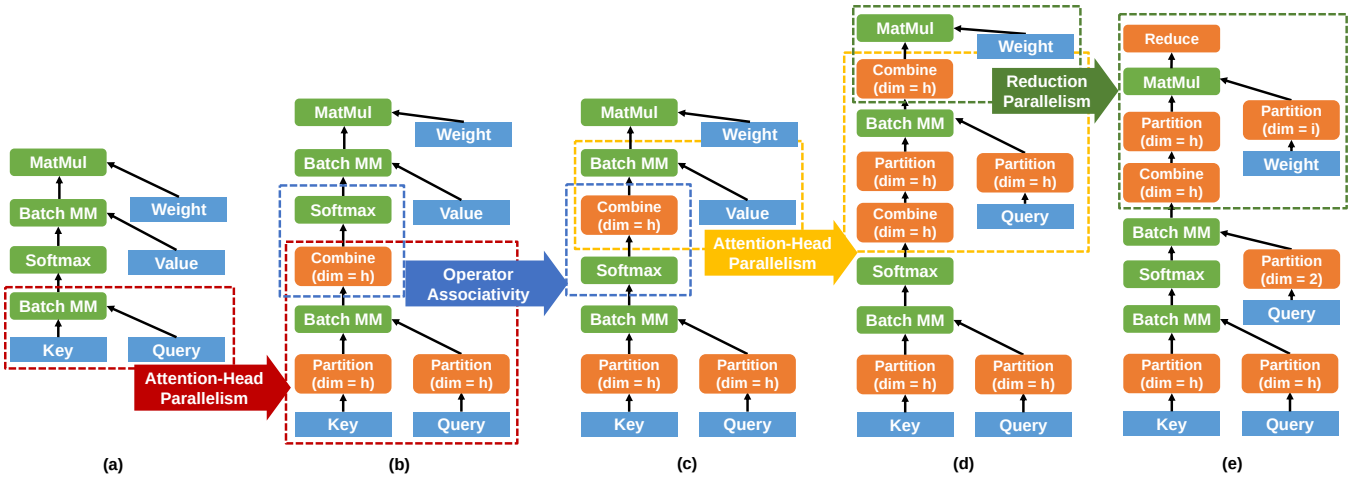


Figure 10: Representing the hand-tuned parallelization strategies used in Megatron-LM [50] as a sequence of basic graph substitutions in Unity. `BatchMM` and `MatMul` are batched and regular matrix multiplications, respectively. Each arrow denotes a graph substitution, where the dotted subgraphs in the same color are the source and target graph of the substitution. For `Partition` and `Combine`, the parentheses indicate the data dimension for which they are performed.

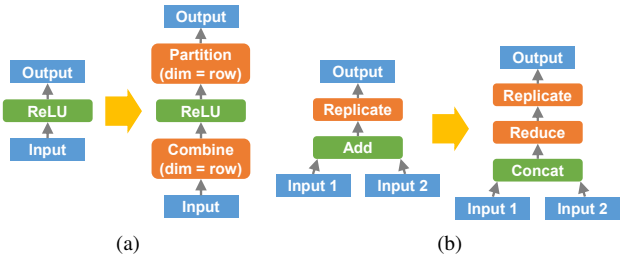

Figure 11: Substitution (a) shows that spatial parallelism is valid for `ReLU`. Substitution (b) demonstrates a hybrid algebraic-parallel transformation: transforming an `Add` into a `Concat` followed by a `Reduce` allows Unity to use the more efficient AllReduce communication pattern.

We follow TASO's methodology for developing operators' parallelization properties: we attempt to formally verify all candidate substitutions using Z3, and when a substitution cannot be verified but is correct, we add the missing operator properties. This procedure was repeated until all 651 new substitutions discovered by Unity were verified. Overall, we introduced 33 operator properties in addition to the 43 properties from TASO [25, Table 2] to verify all PCG substitutions.

Combined, the substitution generation and verification process takes a total of 30 minutes. Since the available substitutions only change on the addition of new operators or forms of parallelism, this process can be run entirely offline so as not to impact the execution time of Unity's joint search algorithm.

Example Substitutions. Most new substitutions generated by Unity simply state the parallelism valid for an operator. For instance, the substitution in Figure 11a indicates that `ReLU` supports spatial parallelism in the row dimension. However, combining algebraic transformations and parallelization also yields novel hybrids, such as the example shown in Figure 11b, where Unity identifies that an `Add` operator is equivalent to a `Concat` followed by a `Reduce`. In the left PCG, when `Input 1` and `Input 2` are located on separate devices and `Output` is required to be replicated across those same devices, `Input 1` and `Input 2` would have to be sent to and from a single device to be added. By applying this transformation, Unity is able to merge the input tensors into a single distributed tensor through a `Concat` (which moves no data) and replace the communication with a `Reduce` followed by a `Replicate` (which is implemented as an AllReduce).

5 Joint Optimization

This section describes Unity's search algorithm for jointly optimizing algebraic transformations and parallelization. The core problem is as follows: given a PCG (Section 3), a set of operator-level machine mappings (Section 3.2), and a set of PCG substitutions (Section 4), find (1) a sequence of PCG substitutions and (2) a machine mapping for the resulting PCG that minimize the per-iteration training time. A key challenge is the exponentially larger search space created by unifying algebraic transformations and parallelization. The search must also scale to both complex DNNs (i.e., a large input PCG) and large numbers of compute devices (i.e., a large set of operator-level machine mappings).

Unity uses a three-level hierarchical search algorithm, depicted in Figure 12. In simplified form, Unity breaks an input PCG into subgraphs, determines an optimized sequence of substitutions for each subgraph (which requires determining the optimized machine mapping for each candidate), and then

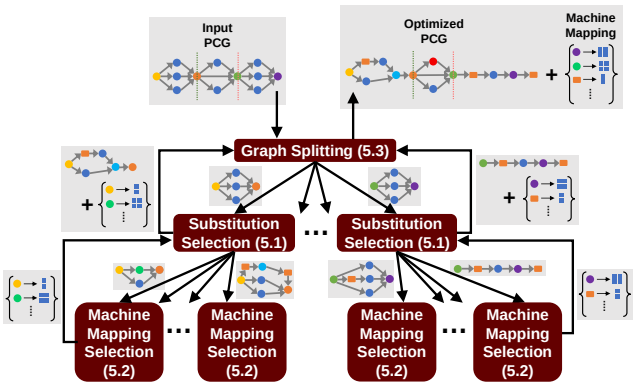

Figure 12: High-level depiction of Unity's hierarchical search.

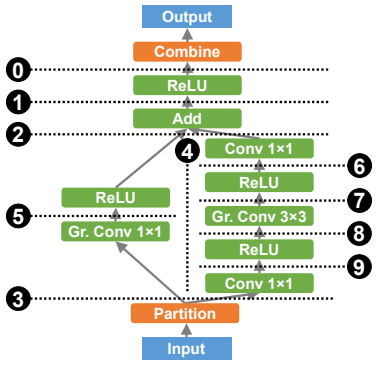

Figure 13: Applying sequence and parallel graph splits on a data-parallel ResNeXt module. Horizontal and vertical dotted lines refer to sequence and parallel splits, respectively, and numbers indicate the order they are applied.

combines these sub-solutions to produce the final output. This allows Unity to scale to DNNs with over 300 operators and machines with 192 GPUs while keeping search times below 20 minutes, which is negligible compared to the hours or days needed to train modern DNNs.

In the following section, we provide a more detailed description of Unity's search algorithm. Sections 5.1, 5.2, and 5.3 describe the three levels of Unity's search algorithm, starting from the middle layer (*substitution selection*), then the lowest (*machine mapping selection*), and finally introducing the highest level (*graph splitting*) as an optimization to help Unity scale to large DNNs. Afterward, we briefly address Unity's cost estimation and how the search algorithm can be tweaked to integrate pipeline parallelism.

5.1 Substitution Selection

Unity uses the cost-based backtracking search algorithm from TASO [25] to identify a sequence of substitutions that minimizes the execution time of an input PCG. Unity maintains a queue of candidate PCGs sorted by their execution times, and until the queue is emptied or a fixed budget is exceeded, Unity iteratively removes the best candidate from the queue and uses it to generate new candidates by applying every available substitution at every location in the PCG whenever applicable. Candidate PCGs with execution times that are a threshold factor times worse than the best candidate PCG seen so far are pruned, while the rest are inserted into the queue. The threshold factor allows the user to balance the search time and amount of exploration. In our experiments, we use a threshold factor of 1.05.[4]

This algorithm allows Unity to explore arbitrary sequences of substitutions, but requires an accurate cost estimator to evaluate the execution time of each candidate PCG. Since a PCG contains only the parallelization of each operator but not the devices to which it is assigned (i.e., the machine mapping), this cost estimator must first determine an optimized machine mapping. An efficient algorithm must be used to identify this mapping, as the cost estimator is called for every candidate PCG. Section 5.2 introduces our algorithm to find optimized machine mappings.

[4]This specific value was chosen to match [25].

5.2 Finding Optimized Machine Mappings

The lowest level of Unity's search algorithm identifies the optimized machine mapping for a candidate PCG. The key observation behind this level is that most modern DNN architectures consist of linear chains of independent strands of parallel computation. For example, ResNeXt [19] is built around two parallel strands of convolutions (see Figure 13), which are repeated to form the final model. Unity leverages this structure by recursively decomposing these linear chains and parallel strands into independent subgraphs through *sequence* and *parallel graph splits* respectively. Figure 13 demonstrates how sequence and parallel graph splits can be iteratively applied to decompose a ResNeXt module into recursive sub-problems which can be solved via dynamic programming.

A *sequence graph split* partitions an input PCG $\mathcal{G}$ by finding a postdominator node n, such that all paths from the inputs to the outputs of $\mathcal{G}$ go through n. This post-dominator node splits $\mathcal{G}$ into two disjoint subgraphs $\mathcal{G}_1$ and $\mathcal{G}_2$. Since all of $\mathcal{G}_2$ depends on n, and n depends on all of $\mathcal{G}_1$, every operator in $\mathcal{G}_1$ must complete before any in $\mathcal{G}_2$ can start. This reduces the task of finding an optimized machine mapping for $\mathcal{G}$ to optimizing machine mappings for $\mathcal{G}_1$, $\mathcal{G}_2$, and n. For example, for split ❶ in Figure 13, assuming no other splits (such as ❼) had already been applied, n would be the `Add` node, $\mathcal{G}_1$ would be all the nodes from `Input` up to but not including `Add`, and $\mathcal{G}_2$ would be all the nodes after the `Add` until `Output`.

A *parallel graph split* partitions a PCG $\mathcal{G}$ into independent subgraphs whose computations can be performed in parallel. In this case, Unity considers two potential ways of running the sides $\mathcal{G}_1$ and $\mathcal{G}_2$: in sequence (with access to the full machine resources) or in parallel (with each side given a disjoint share of the available resources) and chooses the faster one. Unity

does not allow combinations of serial and parallel execution, in which branches are run partially in parallel and partially in serial. While this eliminates certain strategies, considering them would significantly reduce Unity's scalability as it requires analyzing exponentially many interleavings of operators, and as evidenced by the results in Section 6, these strategies are not necessary to achieve good performance. To determine how to partition the available resources when running in parallel, Unity iterates over all possible resource quantities that can be assigned to each side. By considering resource quantities, Unity ignores redundant divisions that differ only in which GPUs are assigned and not in the number and location of these GPUs, replacing an exponential search over all subsets of devices with a quadratic search over resource quantities.

As an additional optimization, Unity maintains a cache of the selected machine mappings for all subgraphs. Since substitution selection generates a new candidate for each substitution, and each substitution modifies only a small part of a PCG, many candidate PCGs have most of their subgraphs in common with other candidates. This allows Unity to skip computing the cost and machine mapping of all but the part of the PCG modified by the substitution under consideration.

5.3 Scaling to Large Graphs

Even with the dynamic programming algorithm and cross-invocation caching, the search algorithm described so far fails to scale to large models. To understand why, we examine how the number of candidate PCGs in substitution selection scales with the size of the input PCG.

As described in Section 5.1, at each iteration Unity generates a candidate PCG for every possible application of each substitution. In the worst case this would require examining $O(2^{gs})$ candidates, where g is the number of nodes in the PCG and s is the number of substitutions Unity considers. In practice s has limited impact on search time as only a small fraction of the substitutions Unity considers can be applied to any one model, but for large models the exponential behavior of g becomes problematic.

To solve this, we borrow from Section 5.1 and decompose the PCG into independent sequential subgraphs. However, this approach prevents applying substitutions across these splits, which is problematic since Unity uses substitutions to represent parallelization. Thus, naive graph splitting would reduce the parallelism degree across all splits to 1, eliminating many common and important parallelization strategies, such as using data parallelism across the entire model.

Unity addresses this issue by explicitly searching for the optimal parallelization across every split location. More specifically, for every possible partitioning of the tensor communicated across the split, Unity optimizes the resulting two subgraphs under the condition that the first subgraph's output and the second subgraph's input must both match the partitioning under consideration. When either subgraph does not meet this condition, parallelization operators are inserted to ensure any communication cost arising from a change in partitioning is accounted for.

This method works for `Partition` and `Combine` but encounters a problem with `Replicate` and `Reduce`. For example, consider the case of the tensor crossing the split location having its replica degree fixed to 2 by the search algorithm. To coerce the first subgraph to output a tensor in this format, the search algorithm could insert a `Replicate` as its final operation, and the algorithm similarly could insert a `Reduce` as the first operation of the second subgraph. However, this will incorrectly scale the tensor by a factor of 2! The core issue is that unlike `Partition` and `Combine`, `Replicate` and `Reduce` are not inverses of each other. Fortunately, since reduction parallelism that spans many nodes of a computation graph is rarely useful in practice, we limit the partitionings across splits to only those with a replica degree of 1.

To reduce the number of algebraic transformations these splits prevent, Unity follows MetaFlow [26] and chooses split locations that disrupt the fewest substitutions while maintaining a minimum subgraph size k.[5] Thus graph splitting reduces the worst-case number of candidate PCGs from exponential in g to linear in g, specifically from $O(2^{gs})$ to $O\left(\frac{gp}{k} \times 2^{ks}\right)$ where p is the number of valid tensor partitionings.

Cost estimation. To estimate operator run times and communication costs we use similar methods as prior work [24, 27]. More accurate cost models are possible [47], but we have not noticed any issues caused by inaccuracies in our model.

Pipeline parallelism. When considering pipeline parallelism, Unity adopts the 1F1B schedule (i.e., interleaving forward and backward micro-batches on each device) and the weight update semantics from PipeDream-2BW [40], which achieves both high training throughput and low memory footprint. To reduce the search space, Unity only considers strategies where pipeline parallelism is applied to *all* operators in a PCG, since a non pipeline-parallel operator in the PCG would disable the benefits of pipeline parallelism. In addition, similar to prior work [20, 39, 65], Unity only considers sequential pipeline parallelism where each stage only communicates with a single next stage in the pipeline (except for the last stage, which directly performs back propagation after forward processing). Unity also follows prior work [16, 20, 53] in assuming that the number of micro-batches in a mini-batch is much larger then the number of pipeline stages so the additional latency introduced by pipeline initialization can be ignored. These constraints allow Unity to explore a comprehensive search space that includes existing pipeline parallelism strategies while maintaining reasonable search time. The search algorithm is also slightly modified: instead of using per-iteration run time as a proxy for throughput, we

[5] Our experiments use $k = 10$ as it strikes a balance between keeping subgraph sizes small enough for good scalability while blocking relatively few substitutions.

maximize the throughput directly.

6 Evaluation

6.1 Implementation and Experimental Setup

Unity is implemented on top of FlexFlow [27], a distributed multi-GPU runtime for DNN training. We modified FlexFlow to represent models with PCGs, added support for Unity's additional forms of parallelism, and replaced FlexFlow's randomized search with the algorithm described in Section 5. The substitution generator (Section 4) is implemented on top of TASO [25], and extends its fingerprint function to consider parallelization. We also add 33 parallelization-specific properties that are used by the substitution verifier as axioms capturing the semantics of the parallelization operators.

All experiments were performed on the Summit supercomputer [2, 56]. Each compute node is equipped with two IBM POWER9 CPUs, 512 GB main memory, and six NVIDIA Volta V100 GPUs. Three of the GPUs within a node are connected to the same CPU and interconnected via NVLink. Nodes are connected with Mellanox EDR 100Gb InfiniBand.

DNNs. Table 1 summarizes the seven DNN models used in our evaluation. ResNeXt-50 [60] and Inception-v3 are commonly used DNNs for image classification. BERT [14] is a language model with state-of-the-art accuracy on a spectrum of language tasks. DLRM [41] and XDL [28] are deep learning recommendation models for personalization and ads recommendation. CANDLE-Uno [3] is a DNN architecture for precision medicine. Multi-layer perceptron [17] (MLP) is a widely used architecture for a variety of regression tasks and a core component in many DNNs.

We follow prior work in setting hyperparameters for training (e.g., batch sizes, learning rates) [3, 14, 38, 41, 60]. We report per-GPU minibatch size B: for runs with n GPUs, the global minibatch size is $n \times B$. The global minibatch sizes are consistent with those reported in the literature. We use a per-GPU minibatch size of 64 for ResNeXt-50 and Inception-v3, 4 for BERT-Large, 1024 for DLRM and XDL, and 256 for CANDLE-Uno and MLP. The MLP model includes 16 dense layers, each of which has a hidden dimension of 8192. We use Adam [29] with a learning rate of 0.0001 for BERT-Large, and SGD [18] with a learning rate of 0.01 for the other DNNs.

Unless stated, pipeline parallelism is disabled when comparing against frameworks that do not support this feature. We evaluate the impact of pipeline parallelism in Figure 15a.

Search Time. For all DNNs except Inception-v3, Unity's search times are under 10 minutes even for the largest GPU count (i.e., 192). Even for Inception-v3, the most complex architecture in our evaluation with 323 operators, search terminates within 20 minutes. These times are negligible compared to the hours or days needed to train these DNNs.

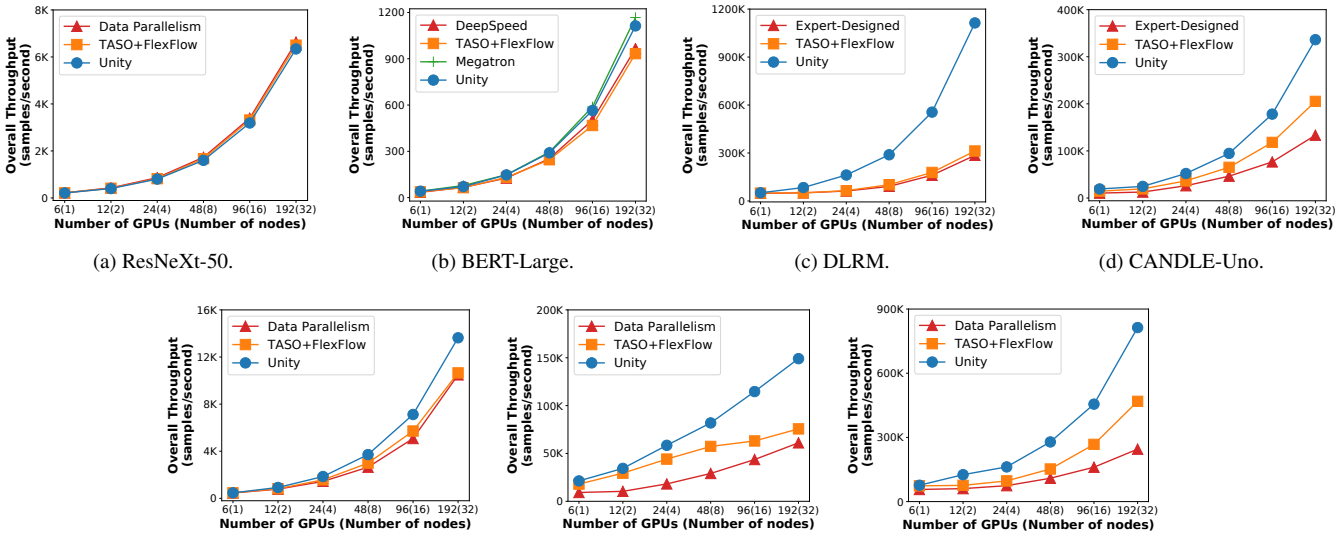
6.2 End-to-end Evaluation

We compare the end-to-end training performance of Unity and existing frameworks such as Megatron [50] and DeepSpeed [43]. We also compare against using TASO [25] and FlexFlow [27] to perform sequential optimization (i.e., TASO first and FlexFlow second). Since Megatron [50] and DeepSpeed [43] require the user to manually optimize each model, these baselines are only present for a subset of the models, while the automated approaches of FlexFlow and Unity can be used across all seven. Figure 14 shows the results.

BERT-Large has been highly optimized by existing frameworks such as Megatron and DeepSpeed which use expert-designed strategies combining multiple forms of parallelism. As such, Unity is not expected to outperform these strategies. Instead, the primary purpose of this evaluation is to determine if Unity can re-discover these hand-tuned strategies within a few minutes of automated search. Note that since Megatron and DeepSpeed require users to manually specify all parallelism degrees for data, tensor-model, and pipeline parallelism, we explore different combinations of the supported parallelism degrees and report the best performance.

Unity achieves on-par performance with Megatron and outperforms both DeepSpeed and FlexFlow. We find that the best strategy discovered by Unity is almost the same as the expert-designed strategy in Megatron: the only difference is that for some matrix multiplications Megatron uses reduction parallelism while Unity uses data parallelism, which has a negligible impact on overall training performance. This shows that even on highly-optimized models Unity is able to automatically generate parallelization optimizations that match those manually designed by domain experts. Megatron is customized for Transformer-based language models and does not support the other DNNs in our evaluation. The fact that the parallelization strategy discovered by Unity matches the expert-designed strategy in Megatron is, in our view, a positive outcome of Unity.

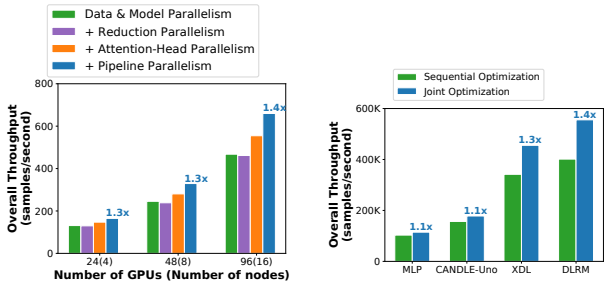
DLRM and CANDLE-Uno both exceed the memory capacity of a single GPU, preventing data parallel training. For both models we use the expert-designed strategy proposed in [38] as a baseline, which parallelizes communication-intensive operators (e.g., embedding tables) in model parallelism and compute-intensive operators (e.g., matrix multiplications) in data parallelism. Unity outperforms both expert-designed strategies and TASO+FlexFlow by up to 3.6× on DLRM and 1.6× on CANDLE-Uno. For all other models, we compare Unity against data parallelism and TASO+FlexFlow.



(a) ResNeXt-50. (b) BERT-Large. (c) DLRM. (d) CANDLE-Uno.

(e) Inception-v3. (f) MLP. (g) XDL.

Figure 14: Training throughput comparison among existing frameworks and Unity. The experiments were performed on the Summit supercomputer [2] with 6 GPUs per node. All numbers were measured by averaging 1,000 training iterations.



(a) (b)

Figure 15: (a) End to end performance of BERT-Large integrating different parallelization dimensions. Speedups relative to data+model parallelism. (b) Speedups solely attributable to joint vs sequential optimization on 96 V100 GPUs (16 nodes). Search space and algorithm are fixed to remove effects from Unity's larger search space and improved search scalability.

Unity outperforms the best existing approaches by 1.0× on ResNeXt-50, 1.3× on Inception-v3, 2.0× on MLP, and 1.9× on XDL. The lack of improvement on ResNeXt-50 is expected as the model's optimal strategy (data parallelism) is already the default used by most frameworks.

We observe that the performance improvement is achieved by (1) supporting operator-specific parallelism and (2) jointly optimizing algebraic transformations and parallelization. We further analyze these details in the following experiments.

6.3 Parallelism Dimensions

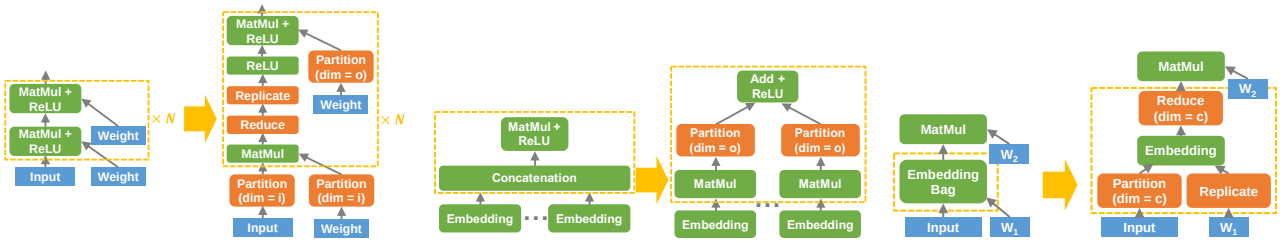
To evaluate how different parallelism dimensions improve training performance, we perform an ablation study of Unity on BERT-Large by iteratively adding new dimensions to Unity and measuring the training throughput. Figure 15a shows the results. Compared to data and model parallelism, adding reduction parallelism does not improve training performance, but combining reduction and attention-head parallelism increases performance by up to 1.2× because optimizing the attention operators in BERT-Large requires both reduction and attention-head parallelism, as shown in Figure 10. Enabling pipeline parallelism achieves an overall speedup of 1.4×. This result shows that hybrid strategies and operator-specific dimensions are critical for DNN training performance.

6.4 Joint Optimization

To evaluate Unity's joint optimization, we compare against sequential optimization of algebraic transformations and parallelization. Results are shown in Figure 15b. Unlike the TASO+FlexFlow baseline in Figure 14, in Figure 15b we include Unity's additional parallelism dimensions and improved scalability to isolate the effects of joint optimization. As a result, the performance improvement (up to 1.4× speedup) comes solely from the ability to optimize jointly rather than sequentially. We study three examples in detail.

The first (Figure 16a) is a slight generalization of the example introduced in Figure 2. By not fusing the first `MatMul` and `ReLU`, which would be done in sequential optimization as the algebraic optimizer would ignore parallelism, Unity is able to significantly reduce the amount of communication by using reduction parallelism and a more efficient AllReduce (represented by the `Reduce` followed by `Replicate`).

The second is shown in Figure 16b. `Concatenation` is the main performance bottleneck in DLRM and XDL, since it can-



(a) Multi-layer perceptron. (b) `Concatenation`. (c) `EmbeddingBag`.

Figure 16: Example joint optimizations of computation graph and parallelization discovered by Unity. For `Partition`, *i* and *o* indicate the input and output channel dimensions of a matrix multiplication.

Table 2: Search algorithm ablation study. "Scaled" numbers are relative to the 2 GPU time with all optimizations enabled.

	All		w/o Split		w/o Cache+Split	
	Time	Scaled	Time	Scaled	Time	Scaled
6 GPUs (1 nodes)	57s	1×	4m 01s	4.3×	37m 01s	38.5×
12 GPUs (2 nodes)	1m 47s	1.9×	11m 15s	16.8×	> 1h	n/a
24 GPUs (4 nodes)	3m 00s	3.1×	> 1h	n/a	> 1h	n/a
48 GPUs (8 nodes)	5m 55s	6.1×	> 1h	n/a	> 1h	n/a

not be parallelized in the same dimension as the `Embedding` operators and requires an all-to-all synchronization. The optimization eliminates the `Concatenation` by replacing the subsequent `MatMul` with independent `MatMul`s executed using the same model parallel strategy as the `Embedding` operators, which reduces communication costs as the `Embedding` operators' outputs are only used locally.

The third optimization is shown in Figure 16c. An `EmbeddingBag` [15] operator computes the sum of a bag of embeddings for each training sample. Unity discovers a joint optimization that transforms an `EmbeddingBag` to a normal `Embedding` to enable additional parallelization opportunities.

6.5 Search Algorithm

To evaluate the impact of the three search optimizations (graph splitting, cross-invocation cache, and dynamic programming) presented in Section 5, we perform an ablation study of the search time for ResNeXt-50. With all three techniques enabled (the "All" column), we see roughly linear scaling as we move from 6 to 48 GPUs. This, along with Figure 14, demonstrates that Unity's search algorithm scales to nontrivial node counts.

Disabling graph splitting increases search times by 4.3-8.8× and causes them to scale nonlinearly, while disabling the cross-invocation cache adds an additional 8.9×. Disabling the dynamic programming algorithm causes even the smallest cases to time out. These results indicate that the three proposed techniques are necessary for adequate performance.

7 Related Work

Manually-designed parallelization strategies. Manually-designed parallelization strategies are used in most existing DNN frameworks to optimize distributed DNN training [5, 6, 42, 43, 49]. For example, Neo [38] optimizes DLRM by using data parallelism for compute-intensive operators and model parallelism for communication-intensive operators. Megatron-LM [50] proposes a model-specific customized strategy that combines data, reduction, and attention-head parallelism for training large language models. These strategies only work for specific DNN models and do not generalize. We use these expert-designed strategies as baselines in our evaluation and show that Unity can automatically discover strategies with improved performance.

Automated DNN parallelization. Recent work has proposed automated approaches to optimizing distributed DNN training. For example, ColocRL [36, 37] and Placeto [7] use reinforcement learning to find efficient device placement for model parallelism. Baechi [22] achieves fast device placement for model parallelism using two memory-constrained algorithms. FlexFlow [27] uses randomized search to optimize data, model, and spatial parallelism. GSPMD [61], a generalization of GShard [34], finds parallelization strategies based on user-provided hints. PipeDream [39] uses dynamic programming to find optimized strategies combining pipeline and data parallelism. Tofu [59] uses recursive search to minimize communication time and automatically discovers parallelization dimensions via interval analysis. Tarnawski et al. [52, 53] propose a two-level dynamic programming algorithm to partition a DNN computation graph across devices by combining data, pipeline, and tensor model parallelism. Alpa [65] automates inter-operator (i.e., pipeline) parallelism using dynamic programming and intra-operator (i.e., data and tensor model) parallelism using integer linear programming. Whale [23] uses computation-balanced partitioning to accomodate heterogenous compute devices and allows specifying parallelization strategies through small parallelization primitives. TensorOpt [8] introduces the *cost frontier* to simultaneously reason about multiple objectives (e.g., execution time and cloud resource cost) in automatic parallelization. Finally,

AutoSync [63] learns to optimize synchronization strategies for data-parallel training from a few thousand samples. However, existing approaches (except Tofu) only support limited parallelism dimensions and none jointly optimizes algebraic transformations and parallelization. Unity supports all existing parallelism dimensions, is extensible to new operators and forms of parallelism, and jointly optimizes algebraic transformations and parallelization.

Automated algebraic transformations. TASO [25] automatically discovers algebraic transformations for DNNs but does not support parallelization. Unity adopts the superoptimization idea from TASO to generate and verify PCG substitutions. However, unlike the algebraic transformation task considered by TASO, Unity deals with a significantly larger search space and considers additional tasks, such as device assignments. We observe that TASO's search algorithm alone is incapable of exploring the larger search space. To address this challenge, Unity introduces three novel elements of the search technique: the dynamic programming algorithm for finding optimized machine mappings, the subgraph cache for exploiting the locality of graph substitutions, and the additional parallelism-compatible divide-and-conquer approach to enabling scalability to complex models.

Automated DNN code generation. Recent work has proposed approaches for generating hardware-specific code for DNN operators. TVM [10, 11] uses a learning-based algorithm to generate optimized code for a diverse set of hardware backends. Ansor [64] extends TVM by utilizing a hierarchical search algorithm to explore a much larger search space of program candidates. Unity optimizes DNN computation at a higher level than these approaches. Therefore, Unity's optimizations are orthogonal and can be combined with existing code generation techniques. We leave integrating code generation into Unity as future work.

Intermediate representations for DNN parallelization. TensorFlow [**?**], MLIR [31, 32], Relay [45], and ONNX [33] represent DNN computation with graph-based intermediate representations (IRs). Distributed training of a model is represented by annotating each operator with a parallelization strategy describing how the operator is parallelized across devices. These approaches represent algebraic transformations and parallelization separately and optimize them sequentially, missing joint optimizations. pONNX [57], automap [48], and DistIR [47] propose IRs that express both computation and communication, but are too low-level to be used for Unity-style joint optimization (see Section 3.4 for details). Unity uses a higher-level representation better suited to optimization, the PCG, and represents both parallelization and algebraic transformations as graph substitutions on PCGs.

8 Limitations and Future Work

To scale to large DNNs and machines, Unity's search algorithm exploits the sequential and parallel structure of modern DNNs (see Section 5.2). However, there exist DNN architectures (e.g., NASNet [66]) that violate this structure. Extending Unity to include these DNNs would improve generality, but potentially at the cost of decreased scalability.

While Unity successfully optimizes two of the most prominent classes of optimizations (i.e., algebraic transformations and parallelization), there are a variety of additional optimizations currently not considered, such as tensor offloading and rematerialization [21, 30, 44]. The PCG can be extended to represent these optimizations, but the search algorithm as presented in Section 5 does not reason about memory usage and therefore may generate parallelization strategies that violate memory constraints. While these invalid strategies can be made valid by applying the necessary tensor offloading and rematerialization afterward, not including these optimizations in Unity's joint search potentially leads to suboptimal performance. Thus, integrating memory optimizations into Unity's search algorithm is a promising area for future research.

Another limitation of Unity is its support for pipeline parallelism. While PCGs are capable of representing parallelization strategies that interleave pipeline-parallel and non-pipeline-parallel operators in a PCG, our search algorithm excludes these cases to reduce the search space. In addition, Unity's search algorithm does not consider non-sequential pipeline parallelism strategies, where a stage can have multiple predecessor/successor stages.

9 Conclusion

This paper presents Unity, the first system that jointly optimizes algebraic transformations and parallelization in distributed DNN training. Unity represents both parallelization and algebraic transformations as substitutions on a unified graph representation, uses a novel hierarchical search algorithm to identify an optimized sequence of substitutions, and scales to large numbers of GPUs and complex DNNs.

Our evaluation with seven real-world DNN benchmarks on up to 192 GPUs show that Unity outperforms state-of-the-art parallelization approaches by up to 3.6× while keeping optimization times under 20 minutes. As nearly half of this speedup is attributable solely to the use of joint optimization over sequential optimization, Unity demonstrates that joint optimization is practical and that future systems will need to include it or else miss significant performance gains.

Trinity: High-Performance Mobile Emulation through Graphics Projection

Di Gao[†*], Hao Lin[†*], Zhenhua Li[†], Chengen Huang[†], Yunhao Liu[†]
Feng Qian[§], Liangyi Gong[‡], Tianyin Xu[¶]

Abstract

Mobile emulation, which creates full-fledged software mobile devices on a physical PC/server, is pivotal to the mobile ecosystem, especially for PC-based mobile gaming, app debugging, and malware detection. Unfortunately, existing mobile emulators perform poorly on graphics-intensive apps in terms of either efficiency or compatibility or both. To address this, we introduce *graphics projection*, a novel graphics virtualization mechanism that adds a small-size *projection space* inside the guest memory of a virtual mobile device. The projection space processes graphics operations involving control contexts and resource handles without host interactions. Novel flow control and data teleporting mechanisms are devised to match the decoupled graphics processing rates of the virtual device and the host GPU to maximize performance. The resulting new Android emulator, dubbed Trinity, exhibits an average of 93.3% native hardware performance and 97.2% app support, in some cases outperforming other emulators by more than an order of magnitude. It has been adopted by Huawei DevEco Studio, a major Android IDE with millions of developers.

1 Introduction

Mobile emulation has been a keystone of the mobile ecosystem. Developers today typically debug their apps on generic mobile emulators (*e.g.,* Google's Android Emulator, or GAE for short) rather than on heterogeneous real devices. Also, various dedicated mobile emulators (*e.g.,* Bluestacks [14] and DAOW [55]) are used to detect malware in app markets [21, 44, 54], to enable mobile gaming on PCs [14, 55], and to empower the emerging notion of cloud gaming [36].

1.1 Motivation

To create full-fledged software mobile devices on a physical PC/server, mobile emulators usually adopt the classic virtualization framework [33, 40, 45, 46] where a mobile OS runs in a virtual machine (VM), referred to as the guest, hosted on a PC/server, referred to as the host. However, traditional virtualization techniques are initially designed to work on headless servers or common PCs without requiring strong UI interactions within the VM, while real-world mobile apps are highly interactive [37] and thus expecting mobile emulators to have powerful graphics processing capabilities (as provided by real mobile phones) [55]. This *capability gap* is further aggravated by the substantial architectural differences between the graphics stacks of desktop and mobile OSes [15].

Over the years, several approaches have been proposed to fill the gap. Perhaps the most intuitive is solely relying on a CPU to carry out a GPU's functions. For example, as a user-space library residing in mobile OSes (*e.g.,* Android), SwiftShader [26] helps a CPU mimic the processing routines of a GPU. This achieves the best compatibility since any mobile app can thus seamlessly run under a wide variety of environments even without actual graphics hardware, but at the cost of poor efficiency since a CPU is never suited to handling the highly parallel (graphics) rendering tasks.

To improve the emulation efficiency, a natural approach is multiplexing the host GPU within a PC/server through API remoting [18, 50], which intercepts high-level graphics API calls at the guest and then executes them on the host GPU with dedicated RPC protocols and guest-host I/O pipes. Unfortunately, the resulting products (*e.g.,* GAE) cannot smoothly run many common apps, let alone "heavy" (*i.e.,* graphics-intensive) apps for AR/VR viewing and 3D gaming. This shortcoming stems from frequent VM Exits to the host to execute API calls, introducing a considerable "tromboning" effect [19] on the control and data flows. This results in additional idle waiting at the guest, as it must wait not only for the API call to complete, but also for the added process of exiting to the host and returning back to the guest.

To mitigate the issue, *device emulation* [17] moves the virtualization boundary from the API level to the driver level. It forwards guest-side graphics driver commands to the host with a shared memory region inside the guest kernel to realize their effects with the host GPU. Compared to high-level APIs, driver commands are much fewer, more capable, and mostly asynchronous [17], so device emulation effectively reduces guest-host control/data exchanges and idle waiting. However, the translation from API calls to driver commands degrades critical high-level abstractions such as windows and threads to low-level memory addresses and register values. Due to the loss of high-level information, driver commands must be sequentially executed at the host, degrading guest-side multi-threaded rendering to host-side single-threaded rendering. Hence, the resulting emulators (*e.g.,* QEMU-KVM) can smoothly run regular apps but not heavy ones.

[*] Co-primary authors. Zhenhua Li is the corresponding author.

Another approach is to break guest-host isolation by removing the virtualization layer so apps can directly use the GPU, as embodied in DAOW [55]. This requires manually translating Linux system calls used by Android to Windows ones. Unfortunately, many apps cannot run on DAOW because many (∼46%) system calls are not translated due to the huge engineering efforts required for full system calls' translation. Also, the supported apps must run under the protection of additional sophisticated security defenses to compensate for the lack of guest-host isolation.

1.2 Contribution

We present Trinity, a novel mobile emulator that simultaneously achieves high efficiency and compatibility. Our guiding principle is to decouple the guest-host control and data exchanges and make them as asynchronous as possible when multiplexing the host GPU under the virtualization framework, so that frequent VM Exits for synchronous host-side execution of API calls can be largely reduced. For this purpose, we propose to add a *projection space* inside the guest memory, where we selectively maintain a "projected" subset of control contexts (termed *shadow contexts*) and resource handles. Such contexts and handles are derived but different from the real ones required by a physical GPU to perform rendering, so as to reflect and reproduce the effects of guest-side graphics operations (*i.e.,* API calls). Thus, the vast majority (99.93%) of graphics API calls do not need synchronous execution at the host, while consuming less than 1 MB memory for even a heavy 3D app.

Concretely, when an Android app wants to draw a triangle on a physical phone, it sequentially issues three types of graphics API calls: context setting (Type-1), resource management (Type-2), and drawing (Type-3). Type-1 prepare the canvas and bind resource handles; Type-2 populate the handles' underlying resources with the triangle's vertex coordinates, filling colors/patterns, *etc.*; Type-3 instruct the GPU to render and display the triangle. In contrast, as shown in Figure 1, when the app runs in Trinity, Type-1 and Type-2 calls are first executed only in the projection space, *i.e.,* their effects are temporarily reflected on the shadow contexts and resource handles. Later upon drawing calls (Type-3), their effects are delivered to the host to realize actual rendering.

Combined with graphics projection, an elastic flow control algorithm is devised in Trinity to orchestrate the execution speeds of control flows at both the guest and host sides. Regarding the guest-host data flows, we find that the major challenge of rapidly delivering them lies in the high dynamics of system status and data volume (*e.g.,* bursty data flows are common in graphics operations). To this end, we find that the dynamic situations in fact follow only a few patterns, each of which requires specific data aggregation, persistence, and arrival notification strategies. Therefore, we implement all the required strategies, and utilize *static timing analysis* [12]

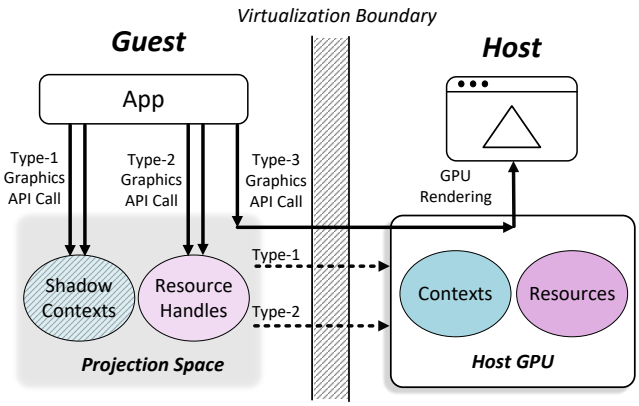

Figure 1: Basic workflow of Trinity.

to estimate which strategy is best suited to a data flow. With these efforts, we achieve high emulation efficiency for Trinity.

Similar to GAE, Trinity is also implemented atop QEMU (for general device extensibility) and hosts the Android OS, with 118K lines of C/C++ code. We evaluate its performance using standard graphics benchmarks, the top-100 3D apps from Google Play, and 10K apps randomly selected from Google Play. We also compare the results with six mainstream emulators: GAE, QEMU-KVM, Windows Subsystem for Android, VMware Workstation, Bluestacks, and DAOW. The evaluation shows that Trinity can achieve 80%∼110% (averaging at 93.3%) native hardware performance, outperforming the other emulators by 1.4× to 20×. For compatibility, Trinity can run the top-100 3D apps and 97.2% of the 10K randomly selected apps. To our knowledge, Trinity is the first and the only Android emulator that can smoothly run heavy 3D apps without losing compatibility (or security).

Software/Code/Data Availability. Trinity has recently been adopted by Huawei DevEco Studio [28], a major Android IDE (integrated development environment) with millions of developers. Currently, it is going through the beta test run for minor functional adjustments and bug fixes. The binary, code, and measurement data involved in this work are released at `https://TrinityEmulator.github.io/`.

2 Understanding Mobile Graphics APIs

We first delve into the three types of APIs in OpenGL ES, the de facto graphics framework of Android (§2.1), and then measure real-world 3D apps to obtain an in-depth understanding of their graphics workloads (§2.2).

2.1 Background

Figure 2 shows a basic OpenGL ES program for drawing a triangle. The program creates a graphics buffer in a GPU's graphics memory using a Type-2 API—`glGenBuffers`, populates the buffer with the coordinate data of the triangle's

```
float vertices[9] = {  0.0f,  0.5f,  0.0f, // First vertex
                      -0.5f, -0.5f,  0.0f, // Second vertex
                       0.5f, -0.5f,  0.0f  // Third vertex
};  // Triangle vertices' (x, y, z) coordinates

float *vtx_mapped_buf; // Address of the mapped buffer

void populate_buffer() {
    glBufferData(GL_ARRAY_BUFFER, sizeof(vertices),
                                0, GL_DYNAMIC_DRAW);
    ...
    // Type-2: query the buffer size
    int buf_size;
    glGetBufferParameteriv(GL_ARRAY_BUFFER,
                GL_BUFFER_SIZE, &buf_size);
    // Type-2: map the buffer to main memory space
    vtx_mapped_buf = glMapBufferRange(GL_ARRAY_BUFFER,
                      0, buf_size, GL_MAP_WRITE_BIT);

    memcpy(vtx_mapped_buf, vertices, buf_size);
    // Type-2: unmap the buffer
    glUnmapBuffer(GL_ARRAY_BUFFER);
}
```

(a) Populate the bound graphics buffer by latent mapping.

```
uint vertex_buffer_handle; // Graphics buffer handle

void draw() {
    ...
    // Type-2: allocate a buffer and generate its handle
    glGenBuffers(1, &vertex_buffer_handle);

                1. The buffer's handle is bound to the context
    // Type-1: bind the buffer to context
    glBindBuffer(GL_ARRAY_BUFFER, vertex_buffer_handle);

    populate_buffer();
    ...
    // Type-3: draw the triangle
    glDrawArrays(GL_TRIANGLES, 0, 3);
    ...
}
```

2. All subsequent operations do not need to specify the handle again

(b) Draw the triangle.

Figure 2: OpenGL ES code snippet for drawing a triangle.

vertices through a Type-1 API—`glBindBuffer` and a Type-2 API—`glMapBufferRange`, and then instructs the GPU to draw the triangle using a Type-3 API—`glDrawArrays`.

Type-1: Context Setting. To manipulate or use the allocated graphics buffer, instead of passing the buffer's handle to every API call, the program first calls `glBindBuffer`, which binds the handle to a thread-local *context*, *i.e.,* the transparent, global state of the thread. Then, all the subsequent buffer-related API calls (*e.g.,* the buffer population call `glBufferData` and the drawing call `glDrawArrays` that uses the buffer data to draw) will be directly applied to the bound buffer, without needing to specify the buffer handle in their call parameters.

The above process is called *context setting*, which configures critical information of the current thread's context. This programming paradigm avoids repeatedly transferring context information from the main memory to the GPU, particularly when the information is rarely modified. In general, the context information that requires setup includes the current *operation target*, *render configurations*, and *resource attributes*. The operation target identifies the object that subsequent API calls will affect, *e.g.,* in Figure 2 the buffer handle becomes the operation target of subsequent API calls after it is bound to the context. Render configurations define certain rendering behaviors, *e.g.,* whether to perform validation of pixel values after a frame is rendered. Resource attributes correspond to resources' internal information, *e.g.,* formats of images and data alignment specifications.

Type-2: Resource Management. Resources involved in graphics rendering include *graphics buffers* that store vertice and texture data (*"what to draw"*), *shader programs* that produce special graphics effects such as geometrical transformation (*"how to draw"*), and *sync objects* that set time-wise sync points (*"when to draw"*). Graphics buffers hold most of the graphics data and thus require careful management. To populate a buffer with graphics data, there are mainly two approaches—*immediate copy* and *latent mapping*.

With regard to immediate copy, data are passed into the `glBufferData` API's third call parameter and copied from the main memory to the bound graphics buffer, *i.e.,* the buffer underlying `vertex_buffer_handle`. This approach is easy to implement but involves synchronous, time-consuming memory copies. In contrast, Figure 2 shows the latent mapping approach, where `glBufferData` is called but no data are passed to it; `glMapBufferRange` instead maps the graphics buffer to a main memory address, *i.e.,* `vtx_mapped_buf`. The data can then be directly stored in the mapped main memory space, without needing to synchronously trigger memory-to-GPU copies. The data are latently copied to the graphics buffer by the GPU's hardware *copy engine* (a DMA device) usually when `glUnmapBuffer` is called to release the address mapping, thus being more flexible and efficient.

Type-3: Drawing. After the contexts and resources are prepared, the drawing phase is usually realized with just a few API calls, *e.g.,* `glDrawArrays` as shown in Figure 2. Such APIs are all designed to be asynchronous in the first place, so that the graphics processing throughput of a hardware GPU can be maximized. When a drawing call is issued, the call is simply pushed into the GPU's command queue rather than being executed synchronously.

Apart from the above operations for rendering a single frame, graphics apps often need to render continuous frames (*i.e.,* animations) in practice. To this end, a modern graphics app usually follows the *delta timing* principle [16] of graphics programming, where the app measures the rendering time of the current frame (referred to as the frame's delta time) to decide which scene should be rendered next. For example, when a game app renders the movement of a game character, the app would measure the delta time of the current frame to compute how far the character should move (*i.e.,* the character's coordinate change) in the next frame based on the delta time and the character's moving speed.

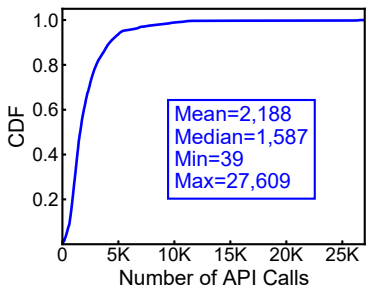

Figure 3: Number of API calls issued for rendering a single frame.

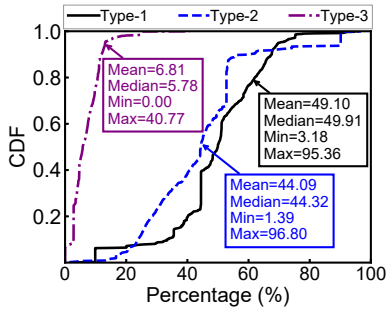

Figure 4: Percentages of specific types of API calls for the top-100 3D apps.

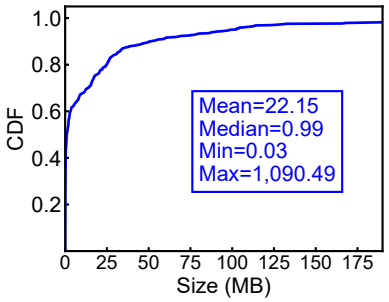

Figure 5: Graphics data amount generated per second by top-100 3D apps.

Graphics APIs beyond OpenGL. While the above descriptions focus on OpenGL (ES), we find that the API semantics of other existing graphics frameworks (such as Vulkan) have similar characteristics. Their APIs can also be categorized into the aforementioned three types. For example, in Vulkan `VKInstance` is used for managing context information, `vkCreateBuffer` is called for allocating buffer resources, and `vkCmdDraw` issues drawing commands.

This is not surprising, but stems from a common GPU's internal design. Like a CPU, a GPU usually leverages dedicated *state registers* for determining the current operation targets and parameters (*i.e.,* contexts), based on which an array of *computation cores* perform rendering and computing tasks in parallel. Special high-bandwidth *graphics memory* is often embedded in a GPU for holding a large amount of graphics resources (*e.g.,* vertex and texture), therefore mitigating the *memory wall* issue observed in a CPU [53], *i.e.,* the speed disparity between memory accesses and computations. Correspondingly, the three types of graphics API calls are then used for manipulating these essential hardware components throughout a rendering thread's lifecycle.

2.2 Real-World Graphics Workloads

To obtain a deeper understanding of modern graphics workloads in terms of both control flow and data flow, we measure the top-100 3D apps (which are all game apps) from Google Play as of 11/20/2021 [51] by examining the distributions of their API calls and the sizes of their generated graphics data. We instrument vanilla Android 11's system graphics library to log the API calls and count the graphics data of a test app during its run time. For each game app, we play a full game set (whose specific operations depend on the app's content) to record the runtime API invocation data. The experiments are conducted on a (middle-end) Google Pixel 5a device, which is equipped with a Qualcomm Snapdragon 765G SoC, 6 GB memory, 128 GB storage, and 1080p display.

Figure 3 shows that an average of 2,187 API calls are issued for rendering a single frame. For most (88%) of the frames, the number of API calls is larger than 1,000. Figure 4 depicts the percentages of specific types of API calls. As shown, the distribution is quite skewed—Type-1 and Type-2 occupy the vast majority (around 94% on average), while Type-3 take up merely 6% on average. Additionally, we find that despite being the majority, most Type-1 and Type-2 calls do not have immediate effects on the final rendering results until Type-3 calls are issued. For example, graphics data stored in a graphics buffer are usually not used by the GPU before certain drawing calls are issued.

With respect to data flow, there also exists considerable disparity in the graphics data amount generated per second, as indicated in Figure 5. While 90% of the graphics data generated per second are less than 60 MB in size, the peak data rate can be as high as 1.06 GB/second, revealing significant data rate dynamics in real-world graphics workloads.

2.3 Implications for Mobile Emulation

Type-1 and Type-2 calls are relatively cheap when executed natively, but this may not be the case in a virtualized environment. If a Type-1 or Type-2 call is synchronously executed on the host GPU, it can be expensive to first exit the guest, then wait for the host to execute the call, and then return back to the guest. This "tromboning" process adds substantial latency to what might otherwise be an inexpensive call, especially when Type-1 and Type-2 calls are very frequent.

To mitigate the problem, an intuitive approach is using a buffer to batch void API calls, *i.e.,* calls that do not return any values, so that not only the void Type-1 and Type-2 calls are delayed, but the asynchronous nature of Type-3 calls (which are all void calls) can also be exploited. However, the resulting efficiency improvement is limited by the proportion of void API calls, *i.e.,* only 41.4% according to our measurement. Thus, it is no wonder that GAE, which takes this approach to improve efficiency, cannot smoothly run many common apps.

In hopes of fundamentally addressing the problem, we make the following key observation—resource-related operations (involving all Type-2 and most Type-1 operations) are fully *handle-based*. That is to say, these operations only interact with indirect, lightweight resource handles in the main

memory, rather than the actual resources lying in the GPU's graphics memory. As demonstrated in Figure 2, a resource handle is merely an unsigned integer. In hardware GPU environments, this greatly facilitates the manipulation of graphics resources (without actually holding them in the main memory), thus avoiding frequently exchanging a large volume of graphics data between the main memory and the graphics memory. Note that the two memories are isolated hardware components connected via a relatively slow PCI bus.

We can exploit this key insight to accelerate mobile emulation, given that guest and host are also isolated by virtualization. We "project" a selective subset of contexts and resource handles, which are necessary for realizing actual rendering at the host GPU, onto the address spaces of guest processes; the resulting contexts after projection are termed *shadow contexts*. With the help of shadow contexts and resource handles, most (void and non-void) APIs can be asynchronously executed at the host. Moreover, certain Type-1 and Type-2 API calls (mostly used for querying context and resource information) can be directly accomplished within the projection space, *completely* eliminating their execution at the host.

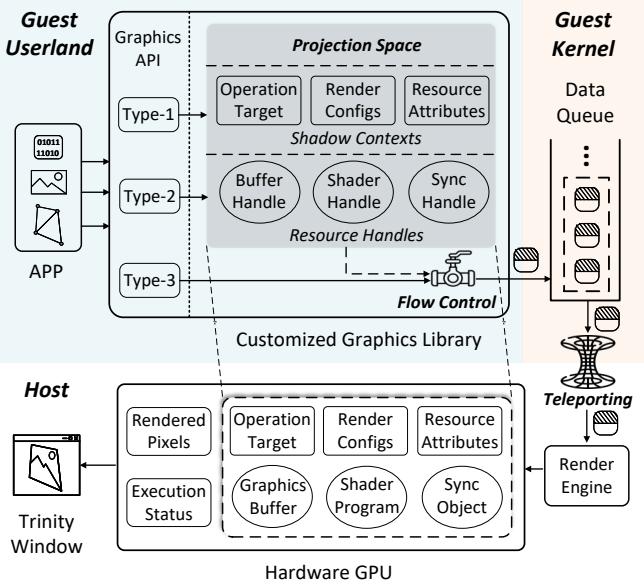

Figure 6: Architectural overview of Trinity.

3 System Overview

Figure 6 depicts Trinity's system architecture. It uses virtualization to isolate guest and host execution environments to retain strong compatibility and security. At the heart of Trinity lies a small-size *graphics projection space*, which is allocated inside the memory of a guest app/system process. Within the space, we maintain a special set of shadow contexts and resource handles which correspond to a subset of control contexts and resources inside a hardware GPU (*cf.* §4).

Once Type-1 or Type-2 API calls issued from a guest process are executed in the projection space, the shadow contexts and resource handles will reflect and preserve their effects. Control flow then returns to the guest process for executing its next program logic without synchronously waiting for host-side execution of the API calls (as conducted by API remoting). Meanwhile, the host contexts are asynchronously aligned with the shadow contexts; mappings are asynchronously established between resource handles and host resources.

Since synchronous host-side API execution is avoided, rather than exiting to the host to deliver data, the host can choose to asynchronously fetch the guest data required for API execution from the guest memory space through polling (*cf.* §6.1), thus reducing frequent VM Exits. Later when the guest process issues Type-3 API calls, they are also asynchronously executed at the host as they are designed to be asynchronous. In this manner, the originally time-consuming guest-host interactions can be effectively decomposed into interleaved and mostly asynchronous guest-projection interactions and projection-host interactions.

For example, when running the program in Figure 2, Trinity directly generates a buffer handle upon the Type-2 API call `glGenBuffers`, which is then sent to the host. When the program finishes sending the handle, its control flow continues; meanwhile, the host asynchronously allocates a buffer and its handle by also calling `glGenBuffers` in a dedicated host rendering thread using the host-side desktop OpenGL library, whose APIs are a superset of OpenGL ES APIs.

The relation between the host handle and the guest one is recorded in a hash table at the host. When `glBindBuffer` (Type-1) is called with the guest handle, Trinity adjusts the shadow context information of the currently bound buffer handle, and then sends the bound guest handle to the host. When the guest finishes sending the handle, the host asynchronously looks up the corresponding host handle in the hash table, and then calls `glBindBuffer` at the host to bind the host buffer (handle) in the rendering thread.

When `glMapBufferRange` (Type-2) is called, Trinity allocates a guest memory space and returns it to the guest program. When `glUnmapBuffer` (Type-2) is called, Trinity transfers the data in the guest memory space to the host, as no further modifications can be made to the data then. At the host side, the real buffer is then asynchronously populated with the data also through `glMapBufferRange`. Finally, upon `glDrawArrays` (Type-3), Trinity asynchronously executes it at the host rendering thread, so as to instruct the host GPU to realize actual rendering with the graphics buffer's data.

To sum up, Trinity's projection space provides two key advantages. First, it helps to avoid synchronous host-side execution of APIs (as in API remoting), even for non-void calls (such as `glGenBuffers`) that need to be processed immediately, so that expensive VM Exits can also be reduced. Second, it can resolve the API calls for querying context and resource information, such as `glGetBufferParameteriv`

in Figure 2, without sending them to the host. Quantitatively, 99.93% calls do not need synchronous host-side API execution, among which 26% are directly resolved at the guest (*cf.* §8.3). Although the projection space can involve processing certain calls twice—once at the guest and once at the host, this is done with relatively cheap operations whose extra costs are more than outweighed by the savings from reduced synchronous host-side execution of the APIs and the accompanied VM Exits.

To maximize Trinity's graphics processing throughput, all the above guest-side and host-side operations are coordinated by an elastic flow control algorithm (§5). Furthermore, the projection-host interactions are accomplished via a data teleporting method (§6) that attempts to maximize the data delivery throughput under high data and system dynamics.

4 Graphics Projection

We present the construction and maintenance of shadow contexts (§4.1) and resource handles (§4.2), *i.e.,* the key data structures that format the projection space.

4.1 Shadow Context

In §2.1, we have introduced that Type-1 APIs are usually used to manipulate three types of context information: 1) operation target, 2) render configurations, and 3) resource attributes. Apart from the above, as shown in Figure 6, context information in a real GPU environment also includes 4) rendered pixels and 5) execution status. Here rendered pixels refer to the rendered pixels stored in graphics memory, and execution status is the current status of the GPU's command queues.

For a shadow context, we carefully select to maintain the following three types of context information: 1) operation target, 2) render configurations, and 3) resource attributes. Consequently, with the above information, subsequent reads of context information can be directly fulfilled with the shadow contexts without resorting to the host. The shadow context is maintained based on Type-1 calls issued by a guest process. For example, when the process calls `glBindBuffer` (as shown in Figure 2) to bind a buffer handle (`vertex_buffer_handle`) as the current operation target, the operation target maintained in the shadow context (usually an integer) will be modified to the buffer handle.

The other two pieces of context information we choose not to maintain, *i.e.,* rendered pixels and execution status, are related to a hardware GPU's internal states. Managing such information requires frequent interactions with the host GPU, thus incurring prohibitively high overhead. If such information is actually required, it will be retrieved from the host synchronously. Fortunately, such cases occur with a pretty low (0.07% on average) probability during an app's rendering (according to our measurement in §2.2). Even when such cases occur, we make considerable efforts to minimize the incurred time overhead by carefully designing the data teleporting method, which will be detailed in §6.

Similar to a CPU context, a rendering context is tightly coupled with the thread model of an OS. At any given point of time, a thread is bound to a single rendering context, while a rendering context can be shared among multiple rendering threads of a process to realize cooperative rendering. Thus, in the graphics projection space of a process, we maintained shadow contexts on a per-thread basis, while keeping a reference to the possible shared contexts.

4.2 Resource Handle

As introduced in §2.1, resources involved in graphics rendering include *graphics buffers*, *shader programs* and *sync objects*. Compared to contexts, the allocation of resource handles and management of actual resources often require more judicious data structure and algorithm design, as well as guest-host cooperation, since they can easily induce inefficient memory usage and implicit synchronization, thus impairing system performance.

Handle Allocation. As mentioned before, all the graphics resources are managed through resource *handles* by modern GPUs. Guided by this, when a guest process requests for a resource allocation, we directly return a handle generated by us, which is not backed with a real host GPU resource upon handle generation. Then, after the control flow is returned to the guest process, the host will perform actual resource allocation in a transparent and asynchronous manner, and record the mapping between the guest handle and the host one in a host-side hash table. To make the guest-side handle allocation efficient, we adopt a bitmap for managing each type of resource handle, with which all the resource creation and deletion can be done in $O(1)$ time complexity, and we can maintain good memory density through handle recycling.

Resource Management. After allocating resource handles for a guest process, we also need to properly manage the actual resources underlying the allocated handles. In particular, the management of buffer resources is critical to system performance as they hold most of the graphics data. As discussed in §2.1, there are two approaches to populating a graphics buffer with data, *i.e.,* immediate copy and latent mapping.

For the former, developers would call `glBufferData` and pass the data's memory address to the API to initiate copying the data from the main memory to the graphics buffer. In this case, we need to immediately transfer the data (upon the API call) to the host as required by the API. For the latter, as discussed in §3, the data transfer is conducted when the guest memory space is unmapped (*i.e.,* `glUnmapBuffer` is called) by the guest process. When the data are transferred to the host, we need to populate the actual host-side graphics buffer with the data. To this end, we first ensure that the host context is aligned with the shadow context so that the correct

buffer is bound and populated. Then, to efficiently populate the buffer, we copy the data to a graphics memory pool we maintain at the host, which maps a pre-allocated graphics memory space to a host main memory address also using latent mapping. In this way, modern GPUs' DMA copy engine can still be fully utilized to conduct asynchronous graphics buffer population without incurring implicit synchronization (*cf.* §2.1). After this, the allocated guest memory space will be released, avoiding redundant memory usages.

5 Flow Control

With the guest and host control flows becoming mostly decoupled with the help of the projection space, their execution speeds also become highly uncoordinated. This is because a guest process' operations at the projection space usually only involve lightweight adjustments to the shadow contexts and resource handles, thus being much faster than host-side operations (*i.e.,* actual rendering using the hardware GPU).

At first glance, this should not raise any problems since guest API calls that require (synchronous or asynchronous) host-side executions can simply queue up at a guest blocking queue—if the queue is filled up, the guest process would block until the host render engine finishes prior operations. However, we find that in practice this could easily lead to *control flow oscillation*. From the guest process' perspective, a large amount of API calls are first quickly handled by the projection space when the data queue is not full. Soon, when the queue is filled up, a subsequent call would suddenly take a significantly longer time to complete as the queue is waiting for the (slower) host-side actual rendering. The long processing time further leads to a long delta time of the current frame as discussed in §2.1. As a result, the guest process may generate abnormal animations following the delta timing principle, *e.g.,* a game character could move an abnormally long distance in just one frame due to the long delta time, leading to poor user-perceived smoothness.

To resolve this problem, instead of solely relying on a blocking queue, we orchestrate the execution speeds of control flows at both the guest and host sides. Our objective is the *fast reconciliation* of the guest-side and host-side control flows, so that the overall performance of Trinity can be staying at a high level. To this end, we design an elastic flow control algorithm based on the classic MIMD (multiplicative-increase/multiplicative-decrease) algorithm [31] in the computer networking area, which promises fast reconciliation of two network flows. To adapt MIMD to our graphics rendering scenario, we regulate control flows' execution speeds at the fine granularity of each rendered frame.

In detail, when a guest rendering thread finishes all the graphics operations related to a frame's rendering, we let it sleep for T_s milliseconds and wait for the host GPU to finish the actual rendering. T_s is then calculated as $T_s = \frac{N'}{N} \times (\overline{T_h} - \overline{T_g})$, where N' is the current difference in the number of rendered frames between the guest's and host's rendering threads, N is the desirable maximum difference set by us (N is currently set to 3 in Trinity as we use the widely-adopted *triple buffering* mechanism for smooth rendering at the host), $\overline{T_h}$ is the host's average frame time (for executing all the graphics operations related to a frame) for the nearest N frames, and $\overline{T_g}$ is the guest's average frame time also for the nearest N frames. $\overline{T_h}$ and $\overline{T_g}$ are calculated by counting each frame's rendering time at the host and the guest sides.

Specifically, if $N' > N$ (*i.e.,* the guest is too fast), T_s will be multiplicatively increased to a longer time to approximate the host's rendering speed. Otherwise, T_s will be multiplicatively decreased, striving to maintain the current frame number difference at the desirable value. Typically, T_s lies between several milliseconds and tens of milliseconds depending on the guest-host rendering speed gap. In this way, Trinity can quickly reconcile the guest-side and host-side control flows.

6 Data Teleporting

Fast guest-host data delivery is critical for keeping projection-host interactions efficient. To realize this, we first analyze system and data dynamics (§6.1) that constitute a major obstacle to the goal, and then describe the workflow of our data teleporting method (§6.2), which leverages static timing analysis to accommodate the dynamic situations.

6.1 System and Data Dynamics

When control flows are synchronously accompanied by data flows, the guest-host data delivery mechanism can be very simple. For example, in API remoting, VM Exits/Enters are leveraged to achieve control handover and data exchange at the same time. In Trinity, however, data flows are decoupled from control flows (thanks to the graphics projection space), so we are confronted with complicated situations as well as design choices. Among these data flows, projection-host data exchanges are the most likely to become a performance bottleneck due to their crossing the virtualization boundary.

By carefully analyzing the projection-host data exchanges when running top-100 3D apps, we find that the major challenge of rapidly delivering them lies in the high dynamics of system status and data volume (abbreviated as *system dynamics* and *data dynamics* respectively). With regard to system dynamics, the major impact factors are the available memory bandwidth and current CPU utilizations, which are not hard to understand. As to data dynamics, call data of APIs that require synchronous host execution are sensitive to end-to-end latency (*i.e.,* the delay until host-side executions of the calls), while asynchronous ones require high processing throughput. Further, we pay special attention to distinct data sizes and bursty data exchanges (*i.e.,* bulk data exchange during a short period of time) which are common in modern graphics workloads as

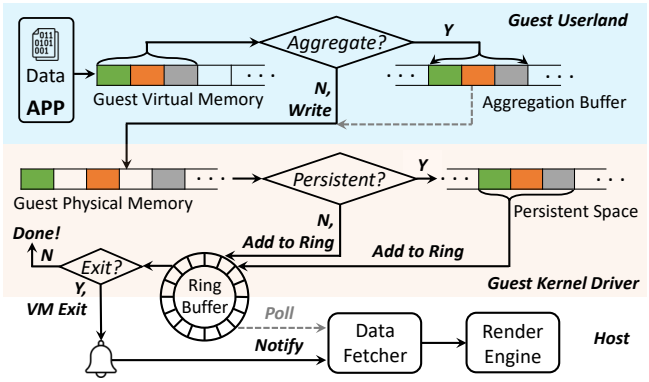

Figure 7: Workflow of data teleporting.

shown in Figure 5. In general, we can classify the dynamic situations into ∼16 patterns, roughly corresponding to the combinations of 1) high/low CPU utilization, 2) high/low available memory bandwidth, 3) synchronous/asynchronous API call data, and 4) large/small data sizes.

To accommodate the dynamic situations, our key observation is that the guest-host data delivery process can be decomposed into three stages, *i.e., data aggregation*, *data persistence* and *arrival notification*, as the data travel through the guest user space, the guest kernel space and the host. Moreover, in each of the stages, we find that there are mainly two different data delivery strategies, which make opposing tradeoffs under different dynamic situations as discussed below.

- Data Aggregation. As exercised in GAE, aggregating non-void API calls with a user-space buffer can usually reduce the frequency of user/kernel switches. This is also the case for Trinity since host-side execution of API calls is mostly asynchronous. However, if the data to be transferred are particularly large (*e.g.,* in bursty data exchanges), memory copies during data aggregation could bring larger time overhead compared to user/kernel switches; hence, the data should be delivered to the kernel as early as possible without any aggregation.
- Data Persistence. For the data of a guest rendering thread, we need to ensure their persistence until they are fetched by the host. To this end, a simple strategy is blocking the thread's control flow until the data delivery is done (as adopted by GAE). In Trinity, we realize that there is an alternative strategy by using a special persistent space (*e.g.,* in the guest kernel) to maintain the guest thread's data, so that there is no need to block the thread's control flow. Intuitively, this strategy is most suited to small data delivery, which does not incur long-time memory copies.
- Arrival Notification. To notify the host to fetch the data that have arrived, we can simply leverage the VM Exit-based strategy (adopted by GAE), whose incurred delays can be as low as tens of microseconds. This, however, can lead to the guest core's being completely stopped. Alternatively, for asynchronous data fetching, we can utilize a data polling-based strategy at the host, which does not incur the guest world's stopping but would introduce millisecond-level delay due to the thread sleeping and CPU scheduling delays of a common time-sharing host OS.

6.2 Workflow

Given that there is no single strategy that can accommodate every dynamic situation, we implement in Trinity all the combinations of strategies. Almost all of them are implemented at the guest side, except that data polling is realized by the host.

To decide the proper strategy during each stage of data delivery, we adopt the *static timing analysis* [12] method, which calculates the expected delay of each *timing step* (*i.e.,* stage) incurred by different data delivery strategies. As mentioned before, the stages include data aggregation, data persistence, and arrival notification. Suppose a guest app wishes to deliver a data chunk of size S_{data}, the current copy speed of the guest memory is V_{guest}, the current copy speed of the host memory is V_{host}. Below we elaborate on the workflow of data teleporting which selects the suitable strategy in each data delivery stage based on static timing analysis.

Data Aggregation. As shown in Figure 7, if the data to be delivered are asynchronous API call data (*i.e.,* call data of APIs that do not need synchronous host-side execution), we can aggregate them in a user-space buffer to reduce projection-host interactions. However, aggregating the data in the buffer incurs a memory copy, resulting in a delay of $\frac{S_{data}}{V_{guest}}$. Otherwise, an individual `write` system call will be invoked to write the data to our kernel character device driver (*cf.* §7), whose time overhead is T_{write}. Obviously, if $\frac{S_{data}}{V_{guest}} < T_{write}$, we choose to aggregate the data; else, we choose not to.

In contrast, for synchronous API call data we should always avoid data aggregation since synchronous calls should be immediately delivered to the host for executions. Then, along with these non-aggregation data, the aggregation buffer will also be written to our kernel driver and then cleared. We next enter the data persistence stage.

Data Persistence. In this stage, our kernel driver will decide whether to block the guest app's control flow, or utilize an additional persistent space for ensuring the persistence of a guest thread's data until the data are fetched by the host. Unlike the user-space data aggregation buffer that serves to reduce the frequency of entering the kernel and interacting with the host, the kernel persistent space allows the app's control flow to quickly return to the user space for executing its next logic. In practice, if we resort to the control flow blocking strategy, the blocking time will consist of four parts: 1) the delay of adding the data to a ring buffer shared by the guest and the host for realizing data delivery—T_{ring}, 2) the delay of host notification—T_{hn}, 3) the time for a host-side memory copy to fetch data (detailed later in Data Fetching)—$\frac{S_{data}}{V_{host}}$, and 4) the

delay of host-to-guest notification through interrupt injection for returning the control flow to the guest app—T_{gn}. Here the ring buffer does not directly store the data; instead, to transfer a large volume of data, it holds a number of (currently 1024) pointers, each of which points to another ring buffer of the same size, whose buffer item stores the data's physical addresses. Therefore, the blocking strategy's time overhead $T_{blocking}$ is the sum of them: $T_{blocking} = T_{ring} + T_{hn} + \frac{S_{data}}{V_{host}} + T_{gn}$ Here we encounter a challenge: T_{hn} is dependent on the arrival notification strategy which we have not decided yet. Fortunately, we find that when the control flow blocking strategy is adopted, the app thread's execution flow has already stopped. Thus, a VM Exit's side effect no longer matters in this case, but its advantage of short delay makes it an appropriate choice. We then naturally take the VM Exit-based arrival notification strategy, so T_{hn} generally equals the delay of a VM Exit.

On the other hand, if we choose to leverage a kernel persistent space for data persistence, the time overhead comes from 1) a memory copy to the persistent space and 2) adding the data to the ring buffer, *i.e.,* $T_{persistent} = \frac{S_{data}}{V_{guest}} + T_{ring}$. After the above are finished, the guest app's control flow is immediately returned to its user space for executing its next program logic, while the host asynchronously polls for data arrival and fetches data (as to be detailed later).

Based on the calculated $T_{blocking}$ and $T_{persistent}$, we can then choose the data persistence strategy with a smaller delay. Also, for synchronous API call data, we directly choose the blocking strategy because during synchronous calls the control flow is naturally blocked until host-side executions. With respect to the parameters used in the above analysis, they can be either directly obtained (*e.g.,* S_{data}) or statistically estimated by monitoring their recent values and calculating the average (*e.g.,* V_{guest} and V_{host}).

Arrival Notification. After the data are added to the ring buffer, we then need to choose a proper strategy for notifying the host of data arrival. In practice, we find that the arrival notification strategy is closely related to the data persistence strategy. Specifically, control flow blocking is particularly sensitive to the arrival notification delay, and thus should be coupled with VM Exits. On the contrary, the persistent space-based strategy allows arrival notification and data fetching to be asynchronous, and thus the polling-based strategy should be selected; the polling is performed by a host-side data fetching thread (referred to as Data Fetcher) every millisecond.

Data Fetching. When Data Fetcher is notified of data arrival, it would read the ring buffer to acquire the data. If the data are contiguous in the guest physical memory (and thus contiguous in the host virtual memory), the data can be directly accessed without further memory copy; otherwise, they should be copied to a contiguous host buffer. The fetched data are then distributed to the host render engine's rendering threads for realizing actual rendering.

7 Implementation

To realize Trinity, we make multiple modifications to the guest Android system and QEMU. First, we find that Android (as well as many UI-centric systems) clearly separates its versatile user-level graphics frameworks/libraries [6, 49] from the underlying system graphics library that realizes actual rendering. This enables us to effectively delegate every graphics API call by customizing only the system graphics library. At the guest user space, we replace the original system graphics library (*i.e.,* `libGLES`) with our customized one, which maintains the projection space and conducts flow control. The library exposes the standard OpenGL ES interfaces to apps, allowing them to seamlessly run without modifications.

To execute the delegated Type-1 and Type-2 APIs in the projection space, we implement all of them in the system graphics library, involving a total of 220 Type-1 APIs, 128 Type-2 APIs and 10 Type-3 APIs, which fully cover the standard OpenGL ES APIs from OpenGL ES 2.0 to the latest OpenGL ES 3.2. Additionally, we implement all the 54 Android Native Platform Graphics Interface (EGL) [5] functions to interface with the Android native window system. In practice, many APIs have similar functions, simplifying their implementations, *e.g.,* `glUniform` has 33 variants used for data arrays of different sizes and data types, such as `glUniform2f` for two floats and `glUniform3i` for three integers.

At the guest's kernel space and the host, we realize data teleporting via a QEMU virtual PCI device and a guest kernel driver. As a typical character device driver, our kernel driver mounts a device file in the guest filesystem, where the user-space processes can read from and write to so as to achieve generic data transferring. With this, API calls that require host-side executions are compacted in a data packet and distributed to our host-side render engine. The render engine then leverages the desktop OpenGL library to perform actual rendering using the host GPU.

Trinity is implemented on top of QEMU 5.0 in 118K lines of (C/C++) code (LoC). In total, the projection space, flow control and data teleporting involve 113K LoC, 220 LoC and 5K LoC, respectively. Among all the code, only around 2K LoC are OS-specific, involving kernel drivers and native window system interactions.

Trinity hosts the Android-x86 system (version 9.0). Since our modifications to QEMU and Android-x86 are dynamic libraries and additional virtual devices, they can be easily applied to higher-version QEMU and Android. Trinity can run on most of the mainstream OSes (*e.g.,* Windows 10/11 and macOS 10/11/12) with both Intel and AMD x86 CPUs. It utilizes hardware-assisted technologies (*e.g.,* Intel VT and AMD-V) for CPU/memory virtualization. For the compatibility with ARM-based apps, Trinity incorporates Intel Houdini [29] into the guest system for dynamic binary translation.

8 Evaluation

We evaluate Trinity with regard to our goal of simultaneously maintaining high efficiency and compatibility. First, we describe our experiment setup in §8.1. Next, we present the evaluation results in §8.2, including 1) Trinity's efficiency measurement with standard 3D graphics benchmarks, 2) Trinity's smoothness situation with the top-100 3D apps from Google Play, and 3) Trinity's compatibility with 10K apps randomly selected from Google Play. Finally, we present the performance breakdown in §8.3 by removing each of the three major system mechanisms—projection space, flow control and data teleporting.

8.1 Experiment Setup

To understand the performance of Trinity in a comprehensive manner, we compare it with six mainstream emulators, including GAE, QEMU-KVM, VMware Workstation, Bluestacks, and DAOW, as well as Windows Subsystem for Android (WSA)—a Hyper-V-based emulator released in Windows 11. Their architectures and graphics stacks are shown in Table 1. We use their latest versions as of Dec. 2021.

Software and Hardware Configurations. Regarding the configurations of these emulators, we set up all their instances with a 4-core CPU, 4 GB RAM, 64 GB storage, and 1080p display (*i.e.,* the display width and height are 1920 pixels and 1080 pixels, respectively) with 60 Hz refresh rate. However, since WSA does not allow customizing configurations, we use its default settings which utilize the host system's resources to the full extent. For other options (*e.g.,* network) in the emulators, we also leave them as default.

Our evaluation is conducted on a high-end PC and a middle-end PC. The former has a 6-core Intel i7-8750H CPU @2.2 GHz, 16 GB RAM (DDR4 2666 MHz), and a NVIDIA GTX 1070 MAX-Q dedicated GPU. The latter has a 4-core Intel i5-9300H CPU @2.4 GHz, 8GB RAM (DDR4 2666 MHz), and an Intel UHD Graphics 630 integrated GPU. Their storage devices are both 512 GB NVME SSD. Regarding the host OS, we run most of the abovementioned emulators on Windows 11 (latest stable version) given that WSA, Bluestacks, and DAOW are Windows-specific. However, since QEMU-KVM is Linux-specific, we run it on Ubuntu 20.04 LTS which is also the latest stable version as of Dec. 2021.

Workloads and Methodology. We use three different workloads to drive the experiments, in order to dig out the multi-aspect performance of Trinity. First, we use representative 3D graphics benchmark applications: 3DMark [34] and GFXBench [32], both of which are widely used for evaluating mobile devices' GPU performance. Together they provide three specific benchmarks, which are referred to as Slingshot Unlimited Test 1 (3DMark), Slingshot Unlimited Test 2 (3DMark) and Manhattan Offscreen 1080p (GFXBench).

Table 1: Comparison of the evaluated emulators.

Mobile Emulator	System Architecture	Graphics Stack
GAE [23]	x86 Android on customized QEMU	API remoting
WSA [41]	x86 Android on Windows Hyper-V	API remoting
QEMU-KVM [46]	Android-x86 on QEMU	Device emulation
VMware Workstation [52]	Android-x86 on VMware Workstation	Device emulation
Bluestacks [14]	Android-x86 on VirtualBox	Proprietary
DAOW [55]	Direct Android emulation on Windows	API translation with ANGLE [22]

These benchmarks generate complex 3D scenes in an *off-screen* manner, *i.e.,* the rendering results are not displayed on the screen and thus is not limited by the screen's refresh rate, so the graphics system's full potential can be tested. In detail, we run each benchmark on every emulator and hardware environment for five times, and then calculate the average results together with the error bars. Also, since the benchmarks come with Windows versions as well, we further run them directly on Windows to figure out the native hardware performance.

Second, to understand Trinity's performance on real apps, we run the top-100 3D (game) apps from Google Play as of 11/20/2021 [51], which are the same 100 apps discussed in §2.2. Concretely, for each of the apps, one of the authors manually runs a (same) full game set on every emulator, and repeats the experiment five times. During an app's running, we log the FPS (Frames Per Second) values of the app, which is a common indicator of a mobile system's running smoothness. We then use the average FPS value of the five experiments as the final FPS value of the app. Generally, we find that for all the studied apps, the standard deviations of the five experiments are all less than 4 FPS, indicating that the workloads are mostly consistent among different experiments. Since all the apps adopt the V-Sync mechanism to align their framerates with the screen's refresh rate (which is 60 Hz), their FPS values are always smaller than 60.

Third, to further evaluate Trinity's compatibility, we randomly select 10K apps from Google Play in Trinity. We use the *Monkey* UI exerciser [24] to generate random input events for each app for one minute, and monitor possible app crashes.

8.2 Evaluation Results

Graphics Benchmark. Figure 8 and Figure 9 illustrate the graphics benchmarks' results obtained on the high-end PC and the middle-end PC, respectively. Results of DAOW and WSA are not complete because they cannot successfully run all the benchmarks due to missing graphics APIs or abnormal API behaviors as complained by the benchmark apps. As shown, compared to the other emulators, Trinity can achieve the best efficiency on all the three benchmarks with both PCs.

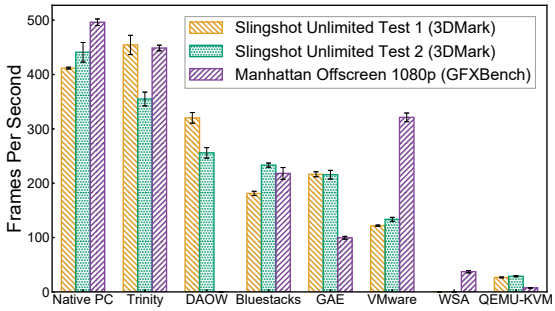

Figure 8: Benchmark results on the high-end PC.

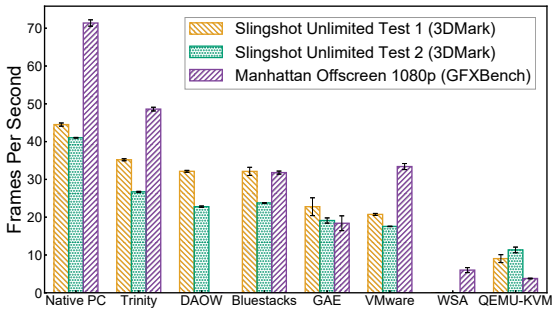

Figure 9: Benchmark results on the middle-end PC.

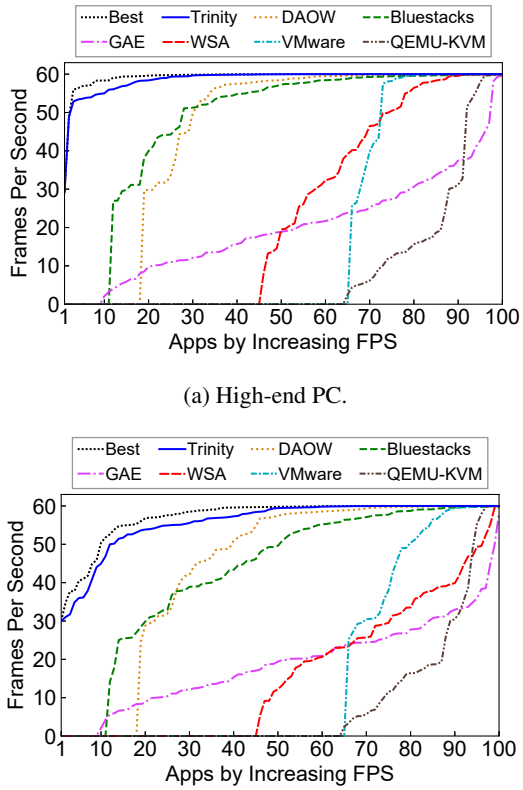

(a) High-end PC.

(b) Middle-end PC.

Figure 10: Average FPS of the top-100 3D apps across different emulators on the high-end and middle-end PCs. The "Best" line represents the highest FPS among the evaluated emulators of each app. If an app cannot run normally on an emulator, its corresponding FPS value is taken as zero.

Specifically, on the high-end PC that is equipped with a dedicated GPU, Trinity can outperform DAOW by an average of 40.5%, and reach 93.3% of the high-end PC's native hardware performance. In particular, for Slingshot Unlimited Test 1 we can achieve 110% native performance. This is attributed to the graphics memory pool (§4.2) maintained by Trinity at the host which can fully exploit the host GPU's DMA capability. Instead, the native version of the benchmark leverages synchronous data delivery into the GPU rather than a DMA-based approach, causing suboptimal performance. Further on the middle-end PC, we observe that Trinity can outperform the other emulators by at least 12.7%, indicating that Trinity can still maintain decent efficiency even on an integrated GPU with much poorer performance.

Top-100 3D Apps. Figure 10 depicts the average FPS of the top-100 3D apps from Google Play on different emulator platforms, when the apps are ranked by their FPS values on the corresponding emulator. Particularly, if an app cannot be successfully executed on (*i.e.,* is incompatible with) an emulator, its FPS value is taken as zero. Thus, the FPS values can reflect both the compatibility and efficiency of different emulators. In this regard, Trinity outperforms the other emulators by an average of 22.4%∼538% on the evaluated PCs. We next look into the compatibility and efficiency aspects of the evaluated emulators, respectively.

For compatibility, the numbers of compatible apps of Trinity, DAOW, Bluestacks, GAE, WSA, VMware, and QEMU-KVM are 100, 82, 89, 91, 55, 35 and 36, respectively. Delving deeper, we find that the root causes of other emulators' worse performance vary significantly. In detail, VMware and QEMU-KVM show the worst compatibility, mostly because their guest-side graphics stacks are both built atop the open-source desktop Linux graphics library Mesa [39], whose API behaviors sometimes differ from that of a typical Android graphics library. For GAE, its incompatibility with apps in fact roots in its poor efficiency—many incompatible apps become unresponsive for a long time during a game set, thus leading to Application Not Responding (ANR) [4]. For WSA, the problem is generally the same as GAE, as we find that WSA reuses most of the GAE's host-side and guest-side system components. Differently, its lack of Google Play Service (essential for many apps' running) in the guest system introduces more compatibility issues. For Bluestacks, its stable version runs an outdated Android 7.0 guest system, and thus cannot run some recent apps. Notably, despite the selective translation of system calls (*cf.* §1.1) that compromises compatibility, DAOW's compatibility with the 100 game apps is

only slightly worse than GAE, because it focuses on translating system calls frequently used by games [55].

For efficiency, we conduct a pairwise comparison between Trinity and each of the emulators in terms of the FPS of the apps that Trinity and the compared emulator can both successfully execute. On the high-end PC, Trinity outperforms DAOW, Bluestacks, GAE, WSA, VMware and QEMU-KVM in terms of the compatible apps by an average of 6.1%, 9.8%, 164.8%, 34.1%, 8.6%, and 132.2%, respectively. We observe a significant visual difference between Trinity and GAE, WSA, and QEMU-KVM across all apps. We observe less visual difference between Trinity and DAOW, Bluestacks, and VMware for many apps. However, the visual difference is very noticeable especially on apps where Trinity performs more than 15 FPS better, for which there were 9, 12, and 5 apps for DAOW, Bluestacks, and VMware, respectively. Regarding the average FPS values of individual apps, we find that Trinity shows the best efficiency on 76 of the apps. For the 24 apps that Trinity shows worse efficiency, we find that the differences in the apps' average FPS values are all less than 6 FPS, with 12 of them are in fact less than 1 FPS. On these apps, we find that there is not any notable smoothness difference between Trinity and the emulators that yield the best FPS.

Similar situations can also be observed on the middle-end PC (as demonstrated in Figure 10b). Trinity outperforms DAOW, Bluestacks, GAE, WSA, VMware and QEMU-KVM on the middle-end PC in terms of the compatible apps by an average of 4.9%, 16.1%, 168.7%, 84.6%, 17%, and 137.7%, respectively. Also, although there are more (42) apps where Trinity does not yield the best efficiency, the FPS differences are still mostly insignificant, with 36 of them being less than 5 FPS. For the remaining 6 apps, DAOW has the best FPS and outperforms Trinity by 6 to 9 FPS, though we could not perceive any visual difference between the two. Careful examination of the apps' runtime situations shows that they tend to heavily stress the CPU as its graphics scenes involve many physics effects such as collisions and reflections, which require the CPU to perform heavy computations such as matrix transformations. Thus, DAOW's directly interfacing with the hardware CPU without the virtualization layer allows it to perform better than Trinity (as well as the other emulators), particularly given the middle-end PC's rather weak CPU. In comparison, Trinity performs better than DAOW for all the 6 apps on the high-end PC.

Compatibility with Random 10K Apps. For the apps randomly selected from Google Play, we can successfully install all of them and run 97.2% of them without incurring app crashes. For the apps we cannot run, we find that some (2.3%) of them have also exhibited crashes on real devices; In addition, 0.43% require special hardware that Trinity currently has not implemented, *e.g.,* GPS, NFC and various sensors, which is not hard to fix given the general device extensibility of QEMU that Trinity is built on. Finally, the remaining 0.07% seem to actively avoid being run in an emulator by closing themselves when they notice that certain hardware configurations (*e.g.,* the CPU specification listed in `/proc/cpuinfo`) are that of an emulator as complained in their runtime logs.

8.3 Performance Breakdown

To quantitatively understand the contributions of the proposed mechanisms to Trinity's efficiency, we respectively remove each of the three major mechanisms of Trinity (*i.e.,* projection space, flow control and data teleporting), and measure the resulting efficiency degradations when running the top-100 3D apps on the high-end PC. In detail, removing projection space degrades Trinity to API remoting, whose guest-host control and data exchanges are still backed by our data teleporting mechanism. Removing data teleporting disables all the static timing analysis logics apart from data aggregation, which allows us to retain at least the data transferring performance of GAE since it also adopts a moderate buffer to batch void API calls. For data persistence and arrival notification, we adopt control flow blocking and VM Exit following GAE's design.

Further, to fully demonstrate the efficiency impacts of the three mechanisms, we also measure the performance breakdown when the maximum framerate restriction (which is 60 FPS) of the apps is removed. Note that we do not remove this restriction when evaluating the top-100 3D apps in §8.2 since this requires source code modifications to the emulators, while many of the emulators are proprietary (*e.g.,* DAOW and Bluestacks). Figure 11 depicts the average FPS values of the top-100 3D apps in the breakdown experiments with the 60-FPS framerate restriction, while Figure 12 shows the results without the framerate restriction.

Projection Space. After the projection space is removed, the average FPS drops by 6.1× (8.6×) with (without) the framerate restriction, providing the most significant efficiency benefits. This is not surprising as our in-depth analysis of the API call characteristics (by instrumenting our system graphics library as discussed in §2.2 during the breakdown experiments) shows that with the projection space, 99.93% of graphics API calls do not require synchronous host-side executions. The remaining 0.07% API calls are Type-1 calls related to the context information we do not maintain in shadow contexts, including the rendered pixels and execution status of a GPU as discussed in §4.1.

Among these asynchronously-executed calls, 26% are directly resolved at the projection space (with our maintained context and resource information), fundamentally avoiding their needs for any host-side executions. Such calls are mostly related to context manipulation and context/resource information querying. For the remainder (74%), they involve APIs for resource allocations and populations, as well as drawing calls. We also measure the memory consumption of the added projection space when running the top-100 3D apps by monitoring the maximum memory consumed by our provided

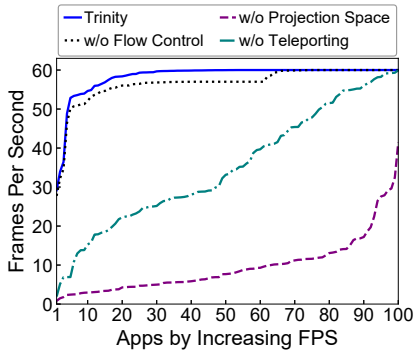

Figure 11: Performance breakdown with regard to the top-100 3D apps with framerate restriction.

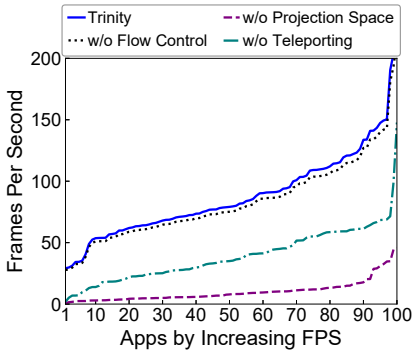

Figure 12: Performance breakdown with regard to the top-100 3D apps without framerate restriction.

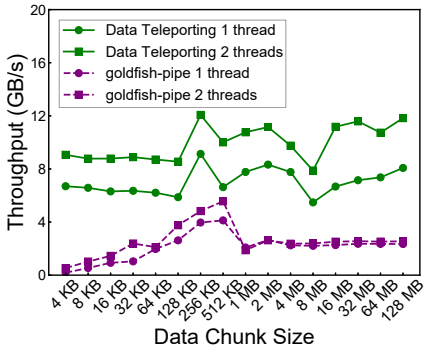

Figure 13: Throughput of data teleporting and `goldfish-pipe`, with one and two threads.

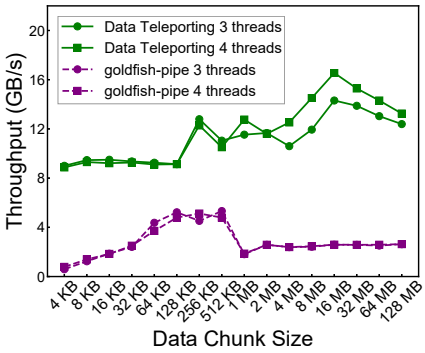

Figure 14: Throughput of data teleporting and `goldfish-pipe`, with three and four threads.

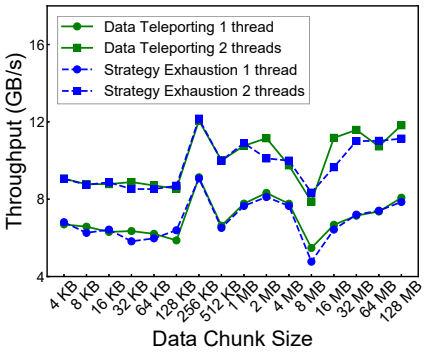

Figure 15: Throughput of data teleporting using strategy exhaustion and static timing analysis, with one and two threads.

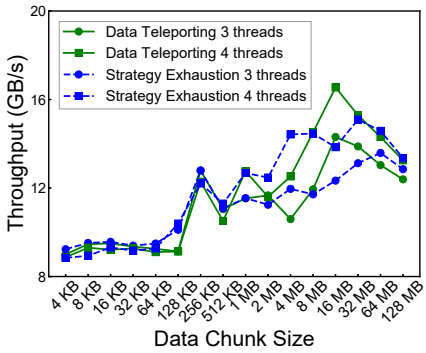

Figure 16: Throughput of data teleporting using strategy exhaustion and static timing analysis, with three and four threads.

system graphics library at the guest side. We find that the projection space only takes an average of 466 KB (at most 1021 KB) memory for an app. The memory consumption is small because the shadow contexts and resource handles are mostly small integers, and our careful resource management has prevented redundant memory usages.

Flow Control. On the other hand, flow control contributes 2.7% (5%) FPS improvement on average with (without) the framerate restriction. This is because flow control mainly serves to mitigate the control flow oscillation problem (*cf.* §5), thus contributing less to the running smoothness *as measured by FPS*. To quantify the actual effects of flow control, we further measure the occurrences of control flow oscillations during the apps' running. As a result, without flow control, control flow oscillation occurs 20× more frequently on average. When that happens, as discussed in §5, the apps' animations will look extremely unsmooth *from users' perspective* since many essential frames of the animations are skipped (*i.e.,* not rendered) by the apps as dictated by the delta timing principle, while the total number of frames rendered per second (*i.e.,* FPS) remains mostly unchanged.

Data Teleporting. Finally, when data teleporting is disabled, the fixed data delivery strategy cannot well adapt to system and data dynamics, leading to 1.7× (2.2×) FPS degradation with (without) the framerate restriction. To demystify the efficiency gains brought by data teleporting, we further examine its throughput under diverse system and data dynamics on the high-end PC. Specifically, we develop a benchmark app that synthesizes data chunks ranging from 4 KB (a continuous memory page space) to 128 MB, and doubles the size for each successive experiment. In each experiment, the app writes the data chunk to our kernel character device file (*cf.* §7) to transfer it to the host 1,000 times with one, two, three, or four threads; here the number of threads varies from one to four (the number of the emulator's CPU cores) to mimic different system dynamics. By measuring the time consumed for data transfer, we can calculate the final throughput result.

In comparison, we conduct the same experiments on GAE's guest-host I/O pipe called `goldfish-pipe`, which is GAE's core infrastructure for sending API call data from the guest to the host and realizing API remoting. To this end, we customize GAE to include a dedicated graphics API for throughput

measurement, which our benchmark app can call to transfer guest data to the host as described above. This API is made to be a void API so that GAE's buffer for batching void APIs can take effect. Consequently, as shown in Figure 13 and Figure 14, data teleporting's throughput clearly exceeds that of `goldfish-pipe` under all the data and thread settings. On average, data teleporting's throughput is 5.3 times larger than that of `goldfish-pipe`.

Furthermore, we wish to know the effectiveness of static timing analysis. For this purpose, we measure the performance of the data teleporting mechanism using the above experiments when we adopt every possible strategy. Then, we compare the highest throughput produced by the above strategy exhaustion with that produced by the static timing analysis. As shown in Figure 15 and Figure 16, the throughput values produced by strategy exhaustion and static timing analysis are very close (4% average deviation). More in detail, static timing analysis can make the most suitable strategy choice in 95.4% of the data delivery tasks.

9 Related Work

Commercial Mobile Emulators. A plethora of commercial mobile emulators have similar architectures to the ones we evaluate in §8. For instance, Anbox [3], which directly runs Android's Framework layer on a Linux PC, leverages the container technique to achieve lightweight guest-host isolation, and reuses GAE's graphics stack—all the guest-side graphics operations are sent to a host-side daemon for execution, thus requiring synchronous inter-process communications. Accordingly, its efficiency is similar to that of GAE.

LDPlayer [35], MEmu [38], NoxPlayer [42] and Genymotion [20] all adopt the AOVB (Android-x86 on VirtualBox) architecture (as in Bluestacks). To realize graphics rendering, they also reuse some of the graphics libraries of GAE, *e.g.,* `libGLESv2_enc` at the guest that encodes OpenGL ES API calls into a data packet, and ANGLE [22] at the host that translates guest-side OpenGL ES calls to desktop OpenGL or Direct3D calls. Prior measurements [13, 55] show that the performance of such AOVB-based emulators is close to that of Bluestacks, probably due to their similar architectures.

GPU Virtualization. In PC/server virtualization, GPU multiplexing is typically achieved through hardware-assisted GPU passthrough [1, 2] or mediated passthrough [27, 30, 43], which allow a virtual machine (VM) to directly access the host GPU by remapping its DMA channels and interrupts to the guest. Differently, GPU passthrough monopolizes the host GPU, while the mediated approach allows sharing the GPU among multiple VMs through GPU context isolation.

However, the substantial differences between the graphics stacks of desktop OSes and mobile OSes significantly hinder their adoption by mobile emulators, as host GPUs' drivers are missing in mobile systems and developing them for mobile environments is extremely complicated (since mainstream desktop GPUs' specifications are often proprietary). Hence, we take a completely different approach of graphics projection to address the problem of multiplexing the host GPU, which is agnostic to the underlying hardware specifications and thus should also be beneficial to PC/server GPU virtualization.

Cross-OS and Cross-Device Graphics Stacks. Trinity focuses on Android emulation on a PC, while several researches have explored running iOS apps on Android graphics stacks based on their similarities in OpenGL ES libraries [7, 8]. This suggests that Trinity's graphics projection mechanism might also be applicable to the emulation of iOS apps on a PC. Also, various approaches remote graphics processing from one device to another over a network [9–11, 25, 47, 48]. For them, data exchanges over network often constitute a major bottleneck, which is similar to the bottleneck of frequent cross-boundary control/data exchanges in the virtualization setting. Thus, our idea of decoupling guest/host control and data flows via graphics projection should also be useful to relevant studies and applications, *e.g.,* cloud/edge gaming.

10 Conclusion

In this paper we present the design, implementation, performance, and preliminary deployment of the Trinity mobile emulator. It substantially boosts the efficiency of mobile emulation while retaining high compatibility and security through graphics projection, a novel approach that minimizes the coupling between the guest-side and host-side graphics processing. This unique design, together with strategic flow control and data teleporting, make Trinity a first-of-its-kind emulator that can smoothly run heavy 3D mobile games (achieving near-native hardware performance) and meanwhile retain comprehensive app support and solid guest-host isolation.

As part of a major commercial Android IDE, Trinity is expected to be used by millions of Android developers in the near future, contributing vibrantly to the ecosystem. We believe that many lessons and experiences gained from this work could also be applied to (graphics-heavy) PC emulation and cloud/edge gaming, as to be explored in our future work.

Acknowledgements

We would like to express our deepest appreciation to our shepherd, Jason Nieh, who was very responsive during our interactions with him and provided us with valuable suggestions, which have significantly improved our paper. We also thank the anonymous reviewers for their constructive suggestions. We thank Wei Liu and Xinlei Yang for their help in data collection and analysis. A Artifact Appendix

Abstract

Trinity's artifact is publicly available at GitHub. To facilitate developing and using Trinity, we provide step-by-step instructions in the form of both documentations and videos. Please refer to our README file at https://github.com/TrinityEmulator/TrinityEmulator for details.

Scope

The artifact can be used to reproduce all the major results, including those of the graphics benchmarks and 3D apps.

Contents

Trinity's artifact includes code of the host emulator, binary of the guest Android system, and our evaluation scripts/data.

Hosting

We host the code/binary and data in two repositories (both in the `main` branch). We also provide a DOI for the artifact.

- **Trinity Code and Binary.**

  Link: https://github.com/TrinityEmulator/TrinityEmulator.

- **Evaluation Data and Figure Plotting Script.**

  Link: https://github.com/TrinityEmulator/EvaluationScript.

- **DOI for the Artifact.**

  DOI: 10.5281/zenodo.6586575

Abstract

Serverless applications represented as DAGs have been growing in popularity. For many of these applications, it would be useful to estimate the end-to-end (E2E) latency and to allocate resources to individual functions so as to meet probabilistic guarantees for the E2E latency. This goal has not been met till now due to three fundamental challenges. The first is the high variability and correlation in the execution time of individual functions, the second is the skew in execution times of the parallel invocations, and the third is the incidence of cold starts. In this paper, we introduce ORION to achieve this goal. We first analyze traces from a production FaaS infrastructure to identify three characteristics of serverless DAGs. We use these to motivate and design three features. The first is a performance model that accounts for runtime variabilities and dependencies among functions in a DAG. The second is a method for co-locating multiple parallel invocations within a single VM thus mitigating content-based skew among these invocations. The third is a method for pre-warming VMs for subsequent functions in a DAG with the right look-ahead time. We integrate these three innovations and evaluate ORION on AWS Lambda with three serverless DAG applications. Our evaluation shows that compared to three competing approaches, ORION achieves up to 90% lower P95 latency without increasing $ cost, or up to 53% lower $ cost without increasing P95 latency.

1 Introduction

Serverless computing (*a.k.a.*, FaaS) has emerged as an attractive model for running cloud software for both providers and tenants. Recently, serverless environments are becoming increasingly popular for video processing [12, 58], machine learning [18, 55], and linear algebra applications [32, 48]. The requirements of these applications can vary from latency-strict (*e.g.*, Video Analytics for Amber Alert responders [61]) to latency-tolerant but cost-sensitive (*e.g.*, Training ML models [28]). Accurate latency estimation is essential to meet the requirements for both, as the cost in FaaS platforms is based on resource usage and runtime. The workflow of these serverless pipelines is usually represented as a directed acyclic graph (DAG) in which nodes represent serverless functions and edges represent data flow dependencies between them.

Serverless platforms experience high performance variability [4, 27, 35, 40, 42, 56] due to three primary reasons: First, some function invocations have cold starts. Second, there is skew in the execution time of various functions because of different content characteristics that the functions operate on. Third, there exists skew in the execution time due to variability in infrastructure resources (*e.g.*, network bandwidth for an allocated VM). Because of this variance in performance, predicting the mean (or median) execution time of individual functions is not sufficient to meet percentile-specific latency requirements (*e.g.*, P95) for serverless DAGs. Rather, a distribution-aware modeling technique is essential to capture this variability and provide accurate latency SLOs.

Key Idea. We propose ORION, a novel technique for performance modeling of serverless DAGs to estimate the end-to-end (E2E) execution time (synonymously, E2E latency). We leverage this model to enable system optimizations such as allocating resources to each function to reduce E2E latency while keeping $ costs low and utilization high. The different components of ORION are shown in Figure 1. We derive insights about serverless DAGs from analysis of production traces at *Azure Durable Functions* [13]. This analysis drives our performance model and the design features.

First, we observe the inherent performance variability in serverless DAGs and therefore represent the latency of a single function, as well as that of the entire DAG, as a distribution rather than a single value. For example, Figure 5 shows the variance in execution times for the top-5 most frequently invoked DAG-based applications. The execution times of invocations of the *same* DAG vary significantly, and the P95 latency is 80X of the P25 latency, averaged over the 5 applications. Thus, our performance model profiles the latency distribution for each function in the DAG and builds a performance model to capture the impact of varying the resource allocation to that function on its latency distribution. Afterward, we estimate the DAG E2E latency distribution by applying a se-

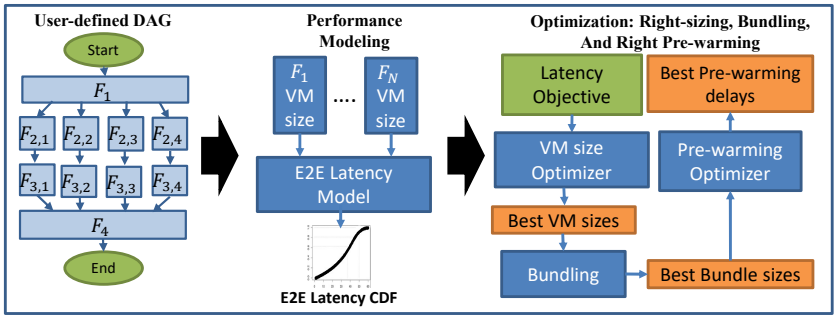

Figure 1: ORION *Overview.* ORION *profiles the DAG, estimates E2E latency CDF using CONV and MAX, and performs three system optimizations — right-sizing, bundling, and right pre-warming.*

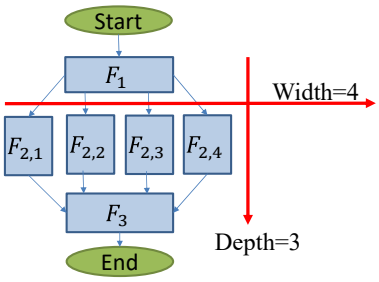

Figure 2: Illustration of DAG Depth **(i.e.,** *number of in-series stages) and Width* **(i.e.,** *Maximum fanout degree).*

ries of two statistical combination operations, `convolution` and `max`, for in-series and in-parallel functions, respectively. Moreover, we observe it is essential to consider the correlation between the workers across stages and within the same stage to accurately estimate the joint distributions. Our performance model does not require expensive profiling, as is needed for the leading technique, Bayesian Optimization [3, 5, 15].

We then use our performance model to design three optimizations for serverless DAGs. (1) **Right-sizing**: Finding the best resource configurations for each function to meet an E2E latency objective (*e.g.*, 95-th percentile latency < X sec) with the minimum cost. (2) **Bundling**: Identifying stages where co-locating multiple parallel instances of a function together to be executed on a single VM will be beneficial. The benefit arises when there is computation skew among the parallel workers caused by different content inputs. (3) **Right pre-warming**: The VMs to execute the functions in the DAG are pre-warmed just right, ahead of time, so that cold starts can be avoided while keeping provider-side utilization of resources high. With these three optimizations, ORION accurately meets latency SLOs while reducing execution cost (Figure 3).

ORION can be deployed by either the cloud service provider or by the end consumer. For the former, the use case is to provision its resources better to meet client SLOs. For the latter, the driving force is the appropriate resource provisioning to minimize E2E latency while minimizing execution cost.

Evaluation and Insights. We evaluate ORION on three serverless applications on AWS Lambda: two variants of Video Analytics [35], an ML Pipeline [17], and an NLP Chatbot [44] application. Our evaluation, comparing to three approaches: Best-Memory [2, 59], Speculative-Execution [30], and CherryPick [5], shows that the benefits of ORION persist across the different applications with different DAG structures, skews in execution times, and invocation frequencies. Our evaluation brings out the following insights:

(1) Latency correlation across stages *and* within a stage is important (Tables 1 and 2). Even when correlations are weak, not taking them into account can introduce significant error in the latency estimations. Further, to make the solution scalable, we have to compute the E2E latency estimation using just the right degree of correlation.

(2) Selecting the best VM sizes for serverless functions in a DAG is challenging (Table 3). This is because different resources in a VM scale up differently with their size. For example, for AWS-λ, CPU cores go from fractional to a maximum of six, network bandwidth only increases till a level, and disk capacity stays constant.

(3) Bundling multiple parallel instances of a function within a single VM helps when there is content skew and the functions are scalable, *i.e.*, they can make use of additional resources (Figure 16). Here also, the degree of bundling has to be carefully determined so as not to cause resource contention.

(4) Using the DAG structure and the function latency model, we can estimate the right time to pre-warm VMs and thus mitigate cold starts (Figure 15). With pre-warming, lower P95 latency is achieved with higher resource utilization.

In summary, the main contributions of ORION are the following: (1) Workload characterization for serverless DAGs seen by *Azure Durable Functions*. (2) A performance model for E2E latency of serverless DAGs; (3) A method for assigning the right resources for serverless DAGs to meet the E2E latency requirements within a reduced $ cost; (4) An application-independent way to bundle multiple function invocations to mitigate skews. (5) A method for deciding when to start pre-warming VMs for functions in a serverless DAG to minimize initialization latency while providing acceptable resource utilization.

ORION is open sourced and we release its code, the workload characterization data, and the evaluation applications at: https://github.com/icanforce/Orion-OSDI22

2 Motivation

2.1 Workload Characterization

Definitions. A DAG is a chain of two or more serverless function stages that execute in-series. A stage consists of one or more parallel invocations (a.k.a. instances) of the same serverless function. DAG *depth* is the number of stages in the DAG. DAG *width* is the max number of parallel worker functions (a.k.a. fanout degree) across all stages in the DAG.

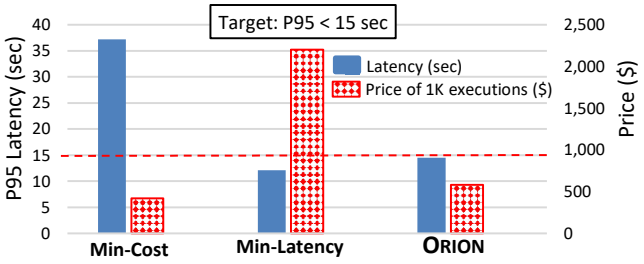

Figure 3: ORION ***improves both latency and cost of Video Analytics DAG. Executions with min VM size (i.e., Min-Cost) and max VM size (i.e., Min-Latency) are for reference, and all latencies are for warm executions.***

A DAG with $width = 1$ means it is a chain of sequential function invocations, whereas a DAG with $width > 1$ means it has at least one parallel stage. We show an illustration of DAG depth and width in Figure 2. Finally, we define skew in a parallel stage as the ratio of the execution times of the slowest to the fastest worker function.

Analysis. In this section, we characterize the workload of serverless DAGs from *Azure Durable Functions*. We collect a subset of the logs of DAG executions from six datacenters — three located in the US, two in Europe, and one in Asia from 10/19/21 to 10/25/21 (1 week). The workload we analyze includes 20M-30M DAG executions/day. From our characterization, we draw the following conclusions, which in turn motivate various design decisions of ORION.

(1) DAG Structure and Execution Time. We study the depth and width of serverless DAGs and their distributions in Figure 4. We account for the DAG invocation frequencies — if a DAG is invoked N times, its width and depth are included N times in the CDFs. First, we notice that DAG depth is low, with a median of 3 stages and a P95 of 8 stages. Second, although 65% of the DAGs are linear chains (no fanout), the width can grow to as high as 37 in the 95th percentile. We also study the execution time of DAGs and find that they can range from 10 ms to 112 min, with a median of 3.7 sec and a mean (weighted by invocation frequencies) of 48 sec. This motivates the need for considering DAG structure while minimizing the E2E latency.

(2) DAG Invocation Frequency and Relation to Cold Starts. Figure 7 shows the frequency of invocations/day for each DAG and the corresponding percentages of cold starts. We notice that the frequency of invocations is heavily skewed, with the top-5 most frequent DAGs accounting for 46% of all invocations. Thus, the optimized executions of these frequently invoked DAGs result in higher cost savings. We also notice that the percentage of cold starts decreases with higher invocation frequency. For example, DAGs invoked ≥ 100 times/day have very low percentages of cold start with a median of 0.35%. However, most of the DAGs are rarely invoked: 80% of the DAGs have an invocation frequency of < 100 times/day, and these experience a high percentage of cold starts with a median of 50%. This shows an increase in the proportion of infrequent serverless applications (DAG-based in our case) compared to a prior study [47], which showed that 55% of the serverless applications are invoked less than 100 times/day.

Hence, using keep-alive policies (as done by most major FaaS platforms) for those DAGs will not be sufficient and pre-warming becomes essential to mitigate cold starts. Even for the DAGs that are not the most frequently invoked, keeping E2E latency low is a desirable feature.

(3) Variance in DAG Execution Time. Figure 5 shows a boxplot for the execution time of the top-5 most frequently invoked DAGs (which contribute 46% of all invocations). We notice that the variance in execution times across different invocations of the same DAG is high. For example, the P95 latency is 80X the P25 latency, averaged over the five DAGs. We also notice that the *distribution of execution times can be heavily skewed.* For example, P50 is not centered between MIN and MAX, or between P25 and P75. Hence, it is essential to represent E2E latency of serverless DAGs as a distribution when modeling their performance to capture this variability.

(4) Degree of Skew. Figure 6 shows the skew distribution for parallel stages for different ranges of DAG widths. We notice that skew among parallel worker functions is at least 2× for 98.2% of the DAGs and increases as the width increases. This motivates the need for a mechanism to mitigate latency skew of parallel worker functions to reduce the E2E latency.

2.2 Performance Modeling

Modeling Latency as a Distribution rather than a Single Statistic. To estimate the E2E latency and cost of a serverless DAG, it is essential to model the latency of each component as a distribution. For example, the latency of the image classification function (`Classify-Frame`) in the Video Analytics DAG can vary by up to 2× when processing different frames, even when keeping the VM-size fixed to 1 GB. Although similar performance variability can be observed in server-centric platforms, our model is geared to serverless platforms due to their ability to scale resources according to demand virtually unboundedly and hence showing negligible queuing times [56]. Now consider a simple stage of two `Classify-Frame` functions running in parallel. Let X and Y be random variables representing the latency of each. The E2E latency of the two workers combined is given as $P(Z \leq z) = P(X \leq z, Y \leq z)$, which depends on the slowest of the two and hence knowing their median or even their P99 latencies is not sufficient to estimate their combined CDF. In fact, we need the *entire* distribution of *both* components to estimate the E2E latency distribution. Moreover, simply using statistical tail bounds is not suitable for our purpose. For example, Chebyshev's inequality uses the mean and variance to establish a loose tail bound and it is not known how to combine tail bounds for in-series and in-parallel functions with their correlations.

Modeling Correlation. To accurately estimate the combined latency distribution for in-series or in-parallel functions, we need to capture the correlation between their execution times.

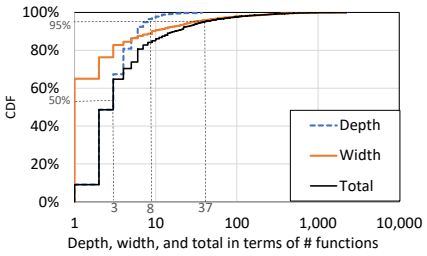

Figure 4: Characterization of depth (number of stages), width (degree of parallelism), and total number of nodes. Depth is low (P50 = 3; P95 = 8). 65% of DAGs are linear chains (no fanout) and width reaches 37 at the 95th percentile.

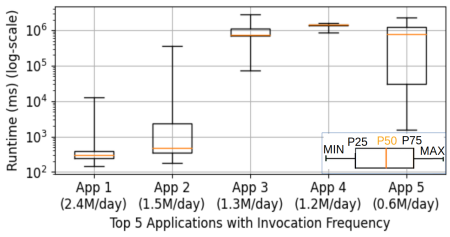

Figure 5: Latency distributions for the top-5 most frequent applications executed by **Azure Durable Functions** *over a period of 1 week. We notice that the execution time varies significantly across different invocations of the same application.*

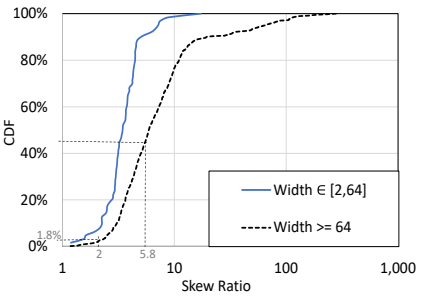

Figure 6: Skew CDF for stages with different width ranges. 98.2% of the DAGs have a skew ≥ 2X, and skew increases for wider DAGs.

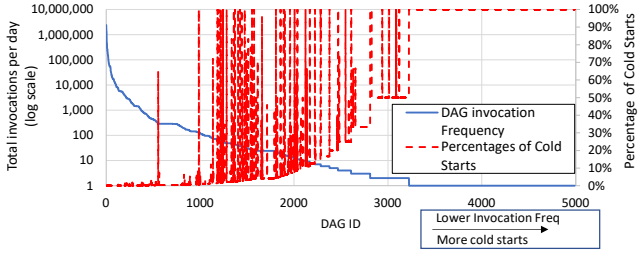

Figure 7: DAG invocation frequency (Blue solid) and its impact on the percentage of cold starts (Red dashed). DAGs with low invocation rate (e.g., once per day) always experience a cold start, whereas very frequent DAGs (e.g., ≥ 500 invocations per day) have very rare cold starts.

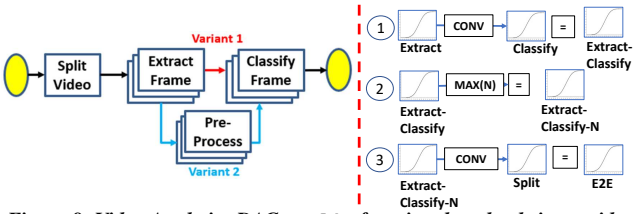

Figure 8: Video Analytics DAG. `Split` *function downloads input video and splits it into chunks. Each chunk is passed to an instance of* `Extract` *function — extracting a representative frame, sent either to* `Classify` *function (Variant #1), or sent to Pre-process function and then* `Classify` *(Variant #2). The steps of estimating E2E latency distribution for Variant #1 are on the right.*

Ignoring correlation by assuming statistical independence leads to over-estimating the combined distribution for in-parallel functions, while it leads to under-estimation for in-series functions. In our evaluation, we give quantitative evidence of these effects (§ 5.4.2) and show that a performance model that is distribution-agnostic (*e.g.*, SONIC [40]), or correlation-agnostic (*e.g.*, [26]), fails to provide accurate E2E latency estimates.

3 Design

We first describe the performance model and E2E latency estimation. Then, we describe how we use the performance model to perform our three optimizations.

3.1 Modeling E2E Latency Distribution

Modeling Functions Runtimes. We represent the runtime of a function as the sum of its initialization and execution times. Since both phases have a high variance, we represent them as separate distributions. This separation allows us to estimate the gains from each optimization. Allocating the right resources and bundling mainly impacts the execution times, whereas pre-warming reduces initialization times.

Combining Latency Distributions. Given a latency distribution for every function, ORION applies a series of statistical operations to estimate the DAG E2E latency distribution.

For two in-series functions with latency distributions represented as random variables X and Y, we use `Convolution` to estimate their combined distribution as: $P(Z=z) = \sum_{\forall k} P(X=k, Y=z-k)$.
If X and Y are independent, we simplify the computation: $P(Z=z) = \sum_{\forall k} P(X=k) \cdot P(Y=z-k)$.

The latter is simpler to estimate since it only requires the marginal distributions of the two components, which can be profiled *separately*, rather than *jointly*.

On the other hand, if the two functions execute in parallel, then their combined latency distribution will be defined by the max of the two. Therefore, we use the `Max` operation to combine their CDFs as follows: $P(Z \le z) = P(X \le z, Y \le z)$. Similar to the `Convolution` operation, a simpler form can be used when X and Y are independent: $P(Z \le z) = P(X \le z) \cdot P(Y \le z)$, which uses the marginal CDFs of the two functions, rather than their joint CDF.

Handling Correlation Among Functions.

We consider two types of statistical correlation in the DAG: in-series and in-parallel correlation. For example, our Video Analytics application (Figure 8) has high correlation between *Pre-process* and *Classify* stages, and also high correlation between parallel *Extract* invocations or parallel *Classify* invocations. (Table 1). By analyzing the correlation between the stages as well as the correlation between the parallel invocations in the same stage, ORION identifies both types of correlation. We consider a Pearson correlation coefficient value > experimental parameter θ, as an indication of correlation. This then determines whether to apply the independent

or dependent formulation for the CONV or the MAX operation. In our experiments, we find that the performance of ORION is relatively insensitive for $\theta \in (0.2, 0.5)$ and we run all the experiments with $\theta = 0.4$.

To determine the length of correlation chains (pairwise, etc.), ORION uses conditional entropy measurements of the execution time and compares the reduction in entropy by including additional terms. Thus, if marginal entropy of stage Y is $H(Y) \gg H(Y|X_i) \approx H(Y|X_i, X_j) \approx H(Y|X_i, X_j, ..., X_s)$, where X_i denotes the random variable of invocation i's execution time, then ORION infers that correlations across stages are at most pairwise. We find that correlations in all our application DAGs *across* stages are at-most pairwise. Our formulation, however, can handle any degree of correlation, not just pairwise. Only the amount of profiling data needed will increase with higher degrees of correlation.

In case of high correlation between N parallel invocations in the same stage, the max operation can be expanded by the chain rule: $P(Z \leq z) = P(X_1 \leq z).P(X_2 \leq z|X_1 \leq z).....P(X_N \leq z|X_1 \leq z, X_2 \leq z, \ldots, X_{N-1} \leq z)$, which is further simplified in case of pairwise correlations by only conditioning on one invocation, hence all conditional terms reduce to: $P(X_i \leq z|X_{i-1} \leq z)$.

Since all components within a stage are identical, we estimate the above equation as follows:

$$P(Z \leq z) = P(X_i \leq z).[P(X_k \leq z|X_i \leq z)]^{n-1} \quad , k \neq i \tag{1}$$

Therefore, we use two distributions to model the max for *any* number of parallel components — the marginal distribution and the conditional distribution.

In practice, all individual components are used to estimate the marginal distribution and all pairs of components are used to estimate the conditional distribution, as all marginal distributions are identical and so are all conditional distributions.

Using this performance model, ORION designs three optimizations for serverless DAGs, which we describe next — ***Right-sizing*** in § 3.2, ***Bundling*** in § 3.3, and ***Right pre-warming*** in § 3.4.

3.2 Allocating the Right Resources

The target of this optimization is to assign the right resources for each function in the DAG so that the entire DAG meets a latency objective with minimum cost. Normally, the user picks the VM-size for each function, and the VM-size controls the amount of allocated CPU, memory, and network bandwidth capacities. What makes this problem challenging is twofold — the scaling of multiple orthogonal resources is coupled together and the scaling of different resources is not linear. As an example, the Classify-Frame function in the Video Analytics DAG has a small memory footprint (540 MB). However, increasing its VM-size above 1,792 MB (as that size comes with a full vCPU [7]) reduces latency. This is because larger sizes come with a fraction of a second core up to six cores, which this function utilizes. The first step in this optimization is to map a given configuration candidate (*i.e.*, a vector of VM-sizes, with one entry per stage) to the corresponding latency distribution. To achieve this, we build a per-function performance model that maps VM-sizes to latency distributions. Next, we combine these distributions to estimate the E2E latency distribution.

Per-function Performance Model. For each function in the DAG, we collect the latency distributions for the following VM sizes: *min* (the minimum VM size needed for this function to execute), 1,024 MB, 1,792 MB, and *max*. We pick 1,024 MB as it is the point of network-bandwidth saturation (increasing VM-size beyond it does not provide more bandwidth), and 1,792 MB as it comes with one full CPU core. Hence, this initial profiling divides the configuration space into 3 regions: [Min, 1024), [1024, 1792), and [1792, Max].

In order to estimate latency distribution for intermediate VM-sizes, we use percentile-wise linear interpolation. For example, the P50 for 1408 MB is interpolated as the average between the P50 for 1,024 MB, and the P50 for 1,792 MB settings. This generates a *prior* distribution for these intermediate VM-size settings. To verify the estimation accuracy in a region, ORION collects a few test points using the midpoint VM-size in that region to measure its actual CDF (*i.e.*, the *posterior* distribution) and compares it with the *prior* distribution. If the error between the *prior* and *posterior* CDFs is high, ORION collects more data for the region midpoint and adds it to its profiling data. In summary, this approach divides the space of a potentially non-linear function into a set of approximately linear functions, and hence, more complex functions get divided into more regions, with a profiling cost overhead. In practice, we find that 5 to 6 regions accurately model the latency distributions for all functions in our applications.

Optimizing Resources for a Latency Objective. Since the performance model estimates the E2E latency distribution of the DAG, we can use it to choose a configuration (*i.e.*, the set of VM sizes) to execute a DAG in order to meet a user-specified latency objective while reducing $ cost. We search for the configurations using a heuristic based on Best-First Search (BFS) [57]. The pseudo-code is shown in Algorithm 1.

The algorithm starts by creating a priority queue, in which all the new states are added. A state here represents a vector of VM sizes, one for each stage. Each new state expands the current state in one dimension (with a step-size of 64 MB) and the start state S_0 has the minimum VM size for every function. The priority is set to be the difference between the target latency and each state's estimated latency multiplied by the $ cost of the new state (lower value means higher priority). Our chosen heuristic is suitable for our problem because latency is a monotonically non-increasing function of resources allocated to a function. The worst-case complexity of BFS is $O(n * log(n))$, where n is the number of states.

3.3 Bundling Parallel Invocations

Stragglers can dominate an application's E2E latency [11, 16, 36, 53]. Here we show how to bundle multiple parallel invocations in one stage within a larger VM, rather than the

Algorithm 1 Best-First algorithm to identify the best VM sizes for functions in a DAG given a user-defined latency objective.

Input: Latency-Percentile=P, Latency-Objective: T_O
Output: Best VM sizes=S_{best}

```
1: ## Initialize priority queue pq, performance model GetLatency, cost
   model GetCost, StepSize = 64 MB
2: ##Set start state S_0 to minimum VM size for every function in DAG
3: pq.insert(s_0)

```

current state-of-practice of executing each in a separate VM. This promotes better resource sharing, thus mitigating skew.

To understand how bundling works, consider the example shown in Figure 9 for a stage of 4 parallel worker functions experiencing load imbalance. Specifically, the load for workers #2 and #4 is low and both require only one time step of execution. In contrast, the load for workers #1 and #3 is higher and requires 7 and 3 time steps of execution, respectively. Also, assume that the workers are scalable and can actually make use of additional resources made available. If we execute each worker function on a separate VM, say with 1 core each, the E2E latency is dominated by the slowest worker and the entire stage will take 7 time steps. However, if we bundle the workers together in a single VM with 4 cores, the E2E latency reduces to 3 time steps only. This is because the straggler workers get access to more resources when the lightly loaded workers finish their execution. Notice that the cost remains the same in both cases because they consume 1 core $\times$ 12 time steps or 4 cores $\times$ 3 time steps for the entire stage.

We make a few observations about the applicability of bundling. *First*, bundling is useful in reducing the latency if the execution skew is due to *load imbalance*, which arises from processing bigger partitions of data, or inputs that require more computation. We detect load imbalances due to content by subtracting latency CDF #1 from #2: (#1) When the function is executed multiple times with the same input. (#2) When the function is executed multiple times with different inputs. Moreover, the higher the correlation between workers, the lower the gap between their execution times, and hence, the lower is the benefit from bundling.

Second, for bundling to be useful, the function has to be *scalable* to benefit from the additional resources. We identify a function's scalability using our performance model to estimate the impact on the function's latency CDF when given more resources (§ 3.2). We benefit from the fact that the community has developed many highly scalable libraries, *e.g.*, [10], which are widely used in serverless applications.

Third, our example in Figure 9 assumes there will be *no contention* between bundled workers. However, in practice, we find that this contention can be high, especially for network-bound or IO-bound functions, as these resources do not scale linearly with the VM size. For example, all VM sizes in AWS Lambda get the same disk space of 512 MB and network bandwidth scales only for VM sizes until 1,024 MB.

Based on these three requirements, ORION identifies the best bundle size in two steps. First, ORION identifies functions that experience execution skew and are scalable using the performance model. Second, ORION searches the space of bundle sizes through multiplicative increase (*i.e.*, bundle sizes of 1, 2, 4, etc.). At each step, ORION collects very few profiling runs (we use 10) to capture contention. The search terminates when bundling more workers causes contention and hence increases the E2E latency. ORION strives to spread stragglers across different VMs, by performing a "redistribute" operation if needed, so that each straggler has excess resources to speed up its execution. Since skew often shows up with temporal locality, we spread the parallel functions among the available bundles in a round-robin manner. For example, for the Video Analytics application, load typically varies gradually across consecutive frames.

ORION's security considerations: ORION does not currently bundle functions in different stages for security purposes. Moreover, all the invocations to be bundled together belong to the same user and the same DAG invocation. Additionally, in cases when the stages have very different resource requirements, it becomes counter-productive to come up with one VM size that fits multiple stages. We defer the possibility of bundling invocations across different functions as future work.

3.4 Pre-warming to Mitigate Cold Starts

We describe our approach to mitigating cold starts, leveraging the DAG structure of the application. We describe how to identify when to start pre-warming the VMs for each stage in the DAG, in order to balance the E2E latency and the utilization of the computing resources. This step is performed after we perform the previous two optimizations: Right-sizing and Bundling. Figure 10 shows conceptually the impact of different pre-warming delays on E2E latency and utilization. At the extreme, a delay of zero for every stage minimizes the E2E latency but also minimizes the utilization. The other extreme is no pre-warming at all, which is the state-of-practice. First, we define `pre-warming delay` for a stage S as the time elapsed between the start of the DAG execution and the beginning of initialization of the VMs for that stage. For a given DAG of

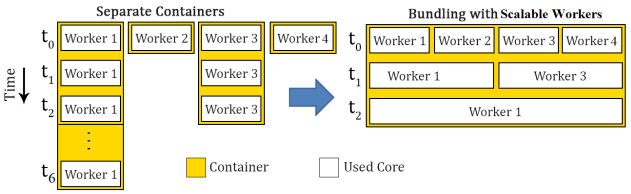

Figure 9: (Left) Separate VMs: workers #2 & #4 finish early, while workers #1 & #3 take longer. (Right) Bundling: after workers #2 & #4 finish, workers #3 & #4 get more resources reducing stage latency.

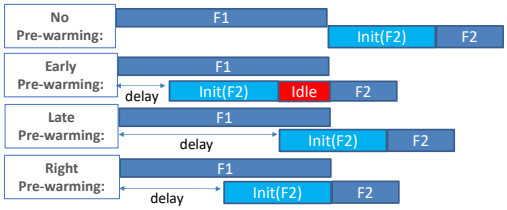

Figure 10: Impact of different pre-warming decisions on the E2E latency and utilization for a chain of two in-series functions. Without pre-warming, the E2E latency increases due to added initialization time of function F2. Both early and late pre-warming are not desirable.

N stages, we want to select a vector $\vec{d} = [d_1, d_2, ...d_N]$ representing the pre-warming delays for each stage in the DAG. For the first stage in the DAG, we have the degenerate case and set its delay (d_1) to zero. This is because pre-warming requires predicting when the DAG will be invoked, which is challenging in the general case. The optimal delay vector, given a performance model $\mathcal{P}$, is defined as follows:

$$\vec{d}^* = \arg\min_{\vec{d}} \; E2E\text{-}Latency(\mathcal{P}, \vec{d}) \quad \text{subject to} \quad Util(\mathcal{P}, \vec{d}) \geq \text{Target Utilization} \tag{2}$$

The selected vector is the one that minimizes the DAG E2E latency while achieving the target resource utilization as set (and dynamically adjusted) by the provider. Both the utilization and the E2E latency are estimated by our performance model $\mathcal{P}$. The metric $Util(\mathcal{P}, \vec{d})$ measures the utilization for a given delay vector using the performance model, and is estimated as $\frac{BusyTime(VM)}{BusyTime(VM)+IdleTime(VM)}$. $BusyTime(VM)$ includes both initialization and execution times, while $IdleTime(VM)$ is the time between when the initialization completes to when the function starts executing. We again use Best-First Search (BFS) to select vector $\vec{d}^*$ as follows. We start by setting all values of $d_i = 0$. In each iteration, we add a delta (100 ms) to the delay factor d_i that yields the best improvement in utilization over the current state without increasing the E2E latency. The algorithm terminates when adding delta to any delay factor does not improve utilization but increases E2E latency.

3.5 Further Design Considerations

Deployment. ORION is designed to serve as a DAG optimization layer. Although the primary use case is to be deployed by the provider, ORION can also be deployed by end-users. In the latter, users are able to select the VM sizes for their functions. For this, the end-user will need to profile her code and also send pre-warming requests to the provider at the right times, as identified by ORION. However, users do not need to change their function code for Bundling. Instead, ORION identifies the bundle size for each parallel stage in the DAG and executes multiple invocations together. The cloud provider still decides the mapping of specific VMs to function bundles.

Naturally, ORION's performance model is trained faster for functions with higher invocation frequency as they provide natural training data points. As discussed in 2.1, frequently invoked DAGs dominate the total set of DAG invocations. For example, the 5%-most frequent DAGs have an invocation rate of 2.3K per day. Hence, it will take us less than 3.5 hours to gather 300 training samples per function. We can accelerate this, and also handle less frequently invoked DAGs, by inserting synthetic but realistic DAG invocations to generate training data points. It is also possible that we will have to re-train our models from time to time when the workload characteristics have changed significantly, or less commonly, the application DAG or the infrastructure characteristics has changed significantly. This incremental training is *not* a computationally heavy task as it involves updating only *parts* of the distribution curves. Maintaining the latency data for performing such updating is also *not* a memory-heavy task.

4 Implementation

We implement ORION in C# and Python 3.8 with 2,100 LOC. We execute the serverless DAG applications in AWS Lambda and use Amazon S3 for data passing between the functions. We use AWS Step Functions [6] to orchestrate the DAG. Function bundling is implemented without any code change by using a wrapper around the (developer-provided) entry point to each function. We use the Python multiprocessing library [9] to execute bundled invocations together.

Runtime Overhead. In theory, the worst-case runtime of Algorithm 1 increases exponentially with the number of stages in the DAG. However, we find that ORION's BFS algorithm has a very low overhead in practice: Each iteration in Algorithm 1 takes [3,7.5] msec, and the best solution takes between 6 and 88 iterations while exploring < 1% of all possible states. The number of iterations depends on the latency target, the steepness of the latency-VM size relation, and the step size (we use 64 MB). For finding the best pre-warming delays, BFS takes between [0.4,3] seconds across all applications.

Scalability. We evaluate the scalability of ORION in Figure 18 with respect to increasing the number of stages. We synthetically replicate the last (and most time consuming) stage of the Video Analytics application to create a DAG of up to 8 stages. The overhead is defined as the inference time divided by the application lifetime, and it ranges between 0.12% for 3 stages to 0.07% for 8 stages. Also, increasing the number of stages, the prediction error increases, but slowly. Specifically, with up to 8 stages, P50 error is stable, and P90 and P95 increase

slowly but never reach 15%. With wider DAGs, our inference time remains unchanged as the fanout degree is used as a parameter in our estimation of MAX (Eq. 1).

Pre-warming. Ideally, implementing pre-warming in AWS Lambda requires our control over assigning invocations to warm containers or VMs. Since we do not have such control, we rely on AWS Lambda's container reuse to implement pre-warming. Specifically, we perform pre-warming by sending a dummy call to a function, then send the actual call right after the response from the dummy call is received.

5 Experimental Evaluation

We evaluate ORION running on AWS Lambda. First, we describe the three serverless DAG applications used in our evaluation. Then, we show an E2E evaluation compared to three alternatives. Next, we show a set of microbenchmarks to evaluate each component of ORION. Finally, we provide a unit experiment on Azure Functions, a platform that allows less configurability for an external mechanism like ORION.

5.1 Serverless DAG Applications

Video Analytics. This application, adopted from Pocket [35], analyzes an input video by extracting representative frames from the video and classifying each frame. The application stages are shown in Figure 8. The first variant of this application directly calls a third function, *Classify-Frame*, which uses a YOLO [45] pre-trained DNN model to classify object(s) in the frame into 1,000 classes. The second variant calls an intermediate pre-processing function, *Pre-process*, which applies a sharpening filter to improve image quality before classification. We refer to this variant as "Video Analytics w/ Preprocess" (VA-Pre, for short). Finally, all classification results are uploaded to remote storage. For VA-Pre, there is a high correlation between the times of the *Pre-process* and the *Classify* functions. We use 600 YouTube videos (300 for profiling, 300 for testing), each of length 1 min, belonging to the "Nature" and "News" categories.

ML Pipeline. This application is a machine learning pipeline (adopted from Cirrus [18]).It consists of three stages: dimensionality reduction (PCA), model training, and testing (*Combine*). The second function, *Train-Model*, runs in parallel and each instance trains a decision tree model using the *LightGBM* Python library [37]. In this stage, a user-specified number of functions is triggered (we use 64 trees in our evaluation), and every function trains a different decision tree. The third function, *Combine*, combines the trained models into a random forest and evaluates its joint accuracy on a held-out test dataset. We use the MNIST [23] database of handwritten digits that has a total of 60K images. We execute the application with 600 runs (300 profiling, 300 test), and in each run, we use 5K images to train the ML model, and 15K for testing.

Chatbot. This application trains a domain-specific Natural Language Understanding (NLU) model, whose task is to identify the accurate "intent" of a user-spoken utterance. We use the Chatbots Intent Recognition Dataset, available on Kaggle [44], which consists of 22 intents and 455 utterances. As before, we evaluate with 300 profiling and 300 test runs. The first lambda in this application parses the dataset and constructs bag-of-words representation for all utterances. Next, a stage of parallel lambdas trains One-vs-Rest classifiers with one lambda per intent. The models are then uploaded to remote storage for real-time intent detection.

The three applications cover important characteristics of serverless DAGs. Specifically, Video Analytics and Chatbot have scatter communication pattern, whereas ML Pipeline has a broadcast pattern. They also cover different fanout degrees (22 for Chatbot, 32 for Video Analytics, 64 for ML Pipeline) and their execution times resemble the average latency of DAGs in our workload characterization (§ 2.1). Moreover, Video Analytics and ML Pipeline are both compute bound, whereas Chatbot is network bound.

5.2 ORION and Competing Approaches

We compare our E2E latency and cost to multiple resource allocation, skew mitigation, and pre-warming approaches:

(1) **Best-Memory:** This is a resource allocation approach that uses our performance model and progressively increases the VM size for every function in the DAG till the latency objective is met. This mimics the standard VM autoscaling that is employed in many cloud scheduling solutions [2, 59]. All invocations run in separate VMs of the same size.

(2) **CherryPick [5]:** CherryPick uses Bayesian-Optimization (BO) to find latency-optimized memory configurations. BO relies on an *acquisition* function to propose new points to sample next. This makes BO a distribution-agnostic baseline as each VM size is profiled once, then a new size is selected by the acquisition function. We set the loss function in BO to be the difference between the achieved latency and the user-specified latency target. Since CherryPick is distribution agnostic, it cannot detect execution time skew and hence performs no bundling. We choose CherryPick as it (BO with Gaussian processes) was recently demonstrated as the most competitive approach in the category [15] and recent approaches have used it for configuring serverless functions [3].

(3) **Speculative-Execution:** This is a skew mitigation approach that identifies stragglers at runtime and executes a duplicate invocation on a different VM. Speculative execution is widely used in MapReduce, Hadoop, and Spark systems for skew mitigation to reduce tail latency [11, 19, 31, 51]. We adapt this baseline from Spock [30] (specifically the technique called "conservative autoscaling in predictive mode"). Since the skew is caused by the input's content, the new invocation will likely take as long as the first one unless it is assigned more resources. Accordingly, we modify the technique by assigning the "Max" resources (10 GB) for the new invocation.

(4) ORION **Right-Sizing:** This variant of ORION performs Right-Sizing only, and not the other two optimizations.

(5) ORION **Full:** This is our complete solution, which includes

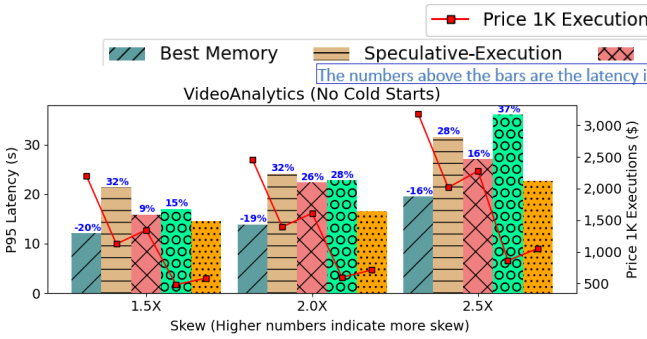

Figure 11: Skew is varied by changing the detection probability threshold as: 2%, 10%, and 15%, with lower values resulting in more detected objects and higher skews [22].

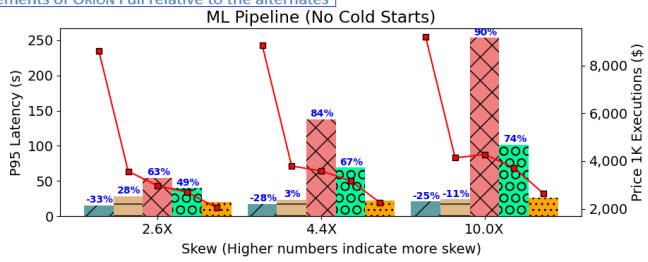

Figure 12: Skew is varied by changing the maximum value for each hyper-parameter, e.g., we vary the max number of trees as: 50, 100, and 200, and these map to 2.6×, 4.4×, and 10× skews.

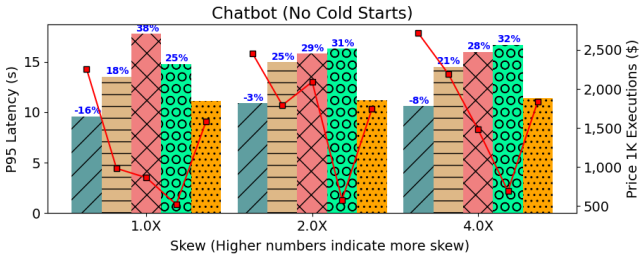

Figure 13: Skew is altered to 1×, 2×, and 4× by changing the number of training epochs as: 100, 500, and 200.

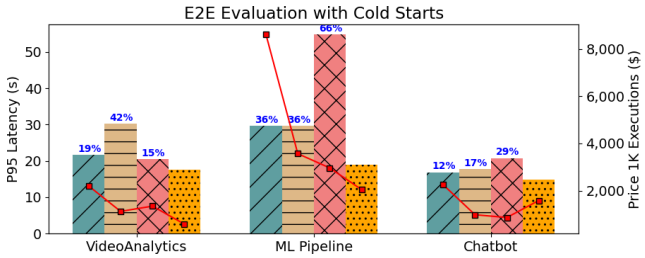

Figure 14: E2E evaluation with cold starts. ORION *achieves the lowest latency and cost compared to all baselines.*

Right-Sizing, Bundling, and Pre-Warming.

5.3 End-to-End Evaluation

We show the P95 latency (primary Y-axis, shown using bars) and cost (secondary Y-axis, shown using lines) of each approach in Figures 11, 12, and 13 for the three applications. The numbers above the bars are the latency improvements of ORION Full relative to the alternates. First, we set the latency objective to the minimum achievable latency, which is identified by executing all functions with *max* VM size, while computation skew is minimized. For each application, we vary the skew in a controlled manner through application-specific parameters. For each solution and for each experimental point, we execute each application 300 times and highlight the gains of ORION's right sizing and bundling. In this part, we take care to eliminate all cold starts for the experimental data points. Later, we show the impact of cold starts and the additional gain due to ORION's pre-warming design in Figure 14. Compared to Best-Memory, ORION has a slightly higher latency since Best-Memory assigns high resources to all workers, including stragglers. However, this baseline increases the cost significantly by assigning identical resources for each stage and parallel running workers in separate VMs, which over-provisions the resources to meet the latency objective. ORION provides [33%,71%] lower cost by assigning the right resources for each function and bundling parallel workers. Compared to Speculative-Execution, we notice that ORION has consistently lower latency and cost across all skews. For example, with the lowest skew, ORION shows [18%, 32%] lower latency and [46%, 57%] lower cost for the three applications. This is because Speculative-Execution detects straggling workers (using a user-specified threshold) and re-executes them on new VMs with the max size. This causes an additional delay due to the wasted execution time. It also increases cost as it sometimes mistakenly re-executes workers that would finish shortly after the threshold. ORION's bundling does not require any user-specified threshold to detect straggling workers, assigning them more resources once co-located workers finish and release their resources.

For CherryPick, since it is distribution-agnostic, we modify the BO algorithm so that 100 points are profiled for each point selected by BO's acquisition function to measure the latency percentiles. We run CherryPick for 100 iterations total (a generously high number compared to the original work and follow-on works), resulting in 10K profiles for each application. Notice that ORION requires only 300 profiling runs to model the E2E latency distribution, reducing the profiling burden of CherryPick by 97%. Compared to CherryPick, we notice that ORION Full consistently provides lower latency and cost, except for Chatbot where CherryPick has higher latency but lower cost. Specifically, with the highest skew, ORION Full shows [16%, 90%] lower latency and [38%, 53%] lower cost for Video Analytics and ML Pipeline. For Chatbot, this application has a lower bundle size than the others, reducing the gain from ORION's bundling mechanism. Compared to ORION Right-Sizing, adding bundling significantly reduces the latency across the three applications. However, bundling causes a slight increase in the cost for Video Analytics by

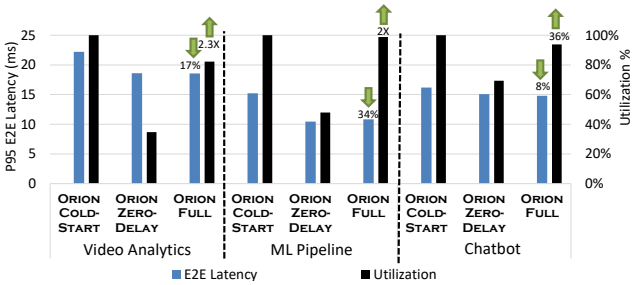

Figure 15: Impact of pre-warming on latency and utilization. We use VM and bundle sizes selected by* ORION *and compare different execution strategies w.r.t. cold starts. Percentages over the bars of* ORION *show the improvements in P95 Latency (over* ORION *Cold-Start) and Utilization (over* ORION *Zero-Delay pre-warming).

22% (relative to No-Bundling), while it causes a decrease in cost for ML Pipeline by 30%. The reason is that the ML Pipeline experiences higher skews (up to 10X), and for higher skew, Bundling is more beneficial. We also notice that the reduction in latency increases with higher skews. For Chatbot also, bundling reduces the latency compared to no bundling, but increases the cost by 163%. This is because the Chatbot application is more network bound and not compute bound than the other two, and hence the best bundle size is only 2, vs [6,8] for the other applications. However, cost with bundling is still 33% lower than Best-Memory, which is the closest to us in latency among all baselines.

Mitigating Cold Starts with Pre-warming. So far, we have compared ORION to the baselines with only warm executions. Now we show the gain of our pre-warming technique and how useful it is in reducing cold starts. Figure 14 shows ORION's latency and cost vs other baselines in the case of cold start for every function in the DAG. We notice that all baselines are impacted by cold starts and their latencies increase, whereas ORION's pre-warming technique is able to mitigate the impact of cold starts. For example, Best-Memory shows an increase of E2E latency over ORION by 19%, 36%, and 12% for Video Analytics, ML Pipeline, and Chatbot, respectively. Similarly, Speculative-Execution suffers from cold starts twice, once for the first execution with the small VM, and once more for the second execution with the max VM size. Hence, ORION's improvements in latency over Speculative-Execution increase to 42%, 36%, and 17% for the three applications. To summarize, ORION's three optimizations of Right-sizing, Bundling, and Right pre-warming provide lower E2E latency and cost over all competing approaches. In the next section, we show a set of microbenchmarks to separately evaluate the performance of each component of ORION.

5.4 Microbenchmarks

5.4.1 Impact of Pre-warming on Utilization & Latency

Figure 15 shows the latency and utilization achieved by ORION versus its two variants. The first, called ORION Cold-Start, does not perform any pre-warming and hence suffers from increased latency, yet has very high utilization as it causes no idle times. The second, called ORION Zero-Delay, initializes all the containers with zero delay for all stages, *i.e.*, at the beginning of the DAG execution. Hence it ensures the lowest latency that can be achieved, but incurs increased idle times due to early pre-warming and hence suffers from low utilization. On the other hand, ORION Full uses the right delay times identified by BFS (§ 3.4). As shown in Figure 15, ORION Full consistently achieves lower latency than ORION Cold-Start, and consistently higher utilization over ORION Zero-Delay for all three applications. We also notice that the latency gains are higher for ML Pipeline and Video Analytics than for Chatbot, which is due to the higher initialization times observed in these two applications when downloading the heavy ML packages and the large pre-trained object detection models. Therefore, estimating the right values of the delays for each stage, as done by ORION, is essential to mitigate cold starts without significantly reducing utilization.

5.4.2 Evaluation of Performance Model

Capturing Correlation between Functions.

Here we evaluate how much correlation exists in our target applications. We calculate the Pearson's correlation coefficient between in-series functions (*e.g.*, between *Split-Video* and *Extract-Frame*), and between in-parallel functions (*e.g.*, between multiple instances of *Extract-Frame*). We show the correlation scores in Table 1 for Video Analytics.

Table 1: **Correlation between execution times of functions in the Video Analytics DAG. In-series correlation is low but in-parallel correlation is high.**

VM-Sizes (in MB)	In-series Correlation			In-parallel Correlation	
Split, Extract, Classify	Split ⇕ Extract	Extract ⇕ Classify	Preprocess ⇕ Classify (VA-Pre)	Extract	Classify
192, 192, 576	0.09	0.04	0.45	0.05	0.43
1024, 1024, 1024	0.07	0.02	0.61	0.34	0.44
1792, 1792, 1792	-0.07	-0.04	0.69	0.48	0.58
3008, 3008, 3008	0.05	-0.01	0.88	0.65	0.51

The correlation scores between in-series components are close to zero (0.036 on average for Video Analytics, 0.06 for ML Pipeline, and 0.04 for Chatbot), while the correlation scores between functions in the same stage are high for Video Analytics (0.55), while low for ML Pipeline (0.052) and for Chatbot (0.03). For Video Analytics w/ Preprocess, `Pre-process` has a high correlation with in-series `Classify` functions (0.65). Therefore, we apply the dependent `conv` operation between `Pre-process` and `Classify`, while we use the independent `conv` operation for all other in-series functions for all applications. Additionally, we incorporate correlation when performing `max` operation (if correlation is detected) by using the conditional distribution.

Estimating E2E Latency Distribution. Here we evaluate the accuracy of ORION in predicting the E2E latency

Table 2: **Video Analytics: Error rates for ORION's E2E latency estimation. Abbreviations: S→Split, E→ Extract, and C→Classify**

Video Analytics						
VM Sizes (MB)	ORION		Distribution Agnostic		Correlation Agnostic [26]	
S, E, C	**P50**	**P95**	**P50**	**P95**	**P50**	**P95**
512 , 1280 , 1536	14.0%	13.0%	40.0%	15.6%	78.7%	47.5%
768 , 1280 , 2240	14.0%	12.0%	35.4%	11.6%	67.7%	38.3%
1536 , 512 , 1536	13.0%	11.0%	39.7%	16.7%	79.4%	49.9%
1792 , 1792 , 576	6.4%	11.8%	11.6%	-39.0%	49.7%	-18.2%
6000, 6000, 6000	14.5%	10.7%	24.2%	3.3%	56.9%	30.5%
MAPE	**13.0%**	**12.0%**	**32.0%**	**21.0%**	**68.0%**	**39.0%**

distribution for the entire DAG. We compare to two baselines — distribution-agnostic (as mentioned earlier, any BO-based technique like CherryPick falls in this category) and correlation-agnostic (*e.g.*, [26]). The results are shown in Table 2 for Video Analytics.

ORION estimates the E2E latency distribution for the applications with low error rate (<15%), much lower than those of both baselines. We find through drill down of our estimation error that: (i) our estimated length of correlation chains as pairwise (§ 3.1) is accurate and hence does not lead to much error (ii) the dominant source of error lies in the interpolation of the CDFs for each function for the *unseen* memory configurations. This is despite our design, where if the interpolation causes too much error, the memory region is split into two and further data points are collected (§ 3.2). These observations hold across all three applications. Error rates are higher in Video Analytics relative to ML Pipeline because the execution time is content sensitive for the former. Our technique does *not* create content-specific models since we (and any provider-side tool) cannot have visibility into user data due to privacy concerns. The ***Distribution-Agnostic*** baseline uses the median execution times and predicts the median execution times for unseen configurations by interpolation. This baseline has a high error rate in the range of [-39%, 40%] for Video Analytics, [-5%,108%] for ML Pipeline, and [-6%, 66%] for Chatbot. The ***Correlation-Agnostic*** baseline from [26] also has a higher error rate in the range of [-18%, 79%] for Video Analytics, [-5.4%,103%] for ML Pipeline, and [80%, 111%] for Chatbot. Note that the majority of the errors for the ***Correlation-Agnostic*** baseline are over-estimation, which is caused by ignoring the correlation between parallel workers. In conclusion, it is important to take into account the latency distributions and not simply a point estimate and to account for the correlation across stages and across workers within a stage, even when the correlations are quite weak (Table 1).

5.4.3 Optimizing Resources for a Target E2E Latency

We profile the applications to build the E2E performance model in ORION for all three applications as mentioned in § 5.4.2, then set 6 latency targets per application. ORION proposes the DAG configuration (*i.e.*, VM size for each function in the DAG) to meet each latency target at while reducing cost. We validate ORION's accuracy by executing the application with the proposed configuration and comparing the achieved latency to the user requirement.We notice that ORION's proposed configurations are very close to the latency requirement in all applications, with error rate of [-2.75%, 4.93%] for Video Analytics, [-1.37%, 2.6%] for ML Pipeline, and [-3.5%, 3.7%] for Chatbot. Table 3 lists detailed configurations for Video Analytics. We notice that expectedly, ORION tends to assign more resources as the latency percentile increases (*i.e.*, P50 → P95) or as the latency requirement decreases (50 sec → 30 sec). Also ORION decides to increase the allocated resources for a subset of functions and by different amounts, based on the latency requirement. For example, for ML Pipeline, ORION increases the VM-size of PCA from 768 MB to 832 MB to achieve a latency requirement of (P90 $\leq$ 50 sec). However, ORION decides to increase the VM-size of Combine from 1,408 MB to 1,472 MB to achieve a latency requirement of (P90 $\leq$ 40 sec). This shows ORION's BFS adjusts the *Best* function to increase its resources according to the estimated latency of the current state.

5.4.4 Impact of Varying Bundle Size

We evaluate the impact of varying bundle sizes on the E2E latency CDF and cost (Figure 16). First, we run our Video Analytics application with the best VM size selected by BFS but without bundling. This is an application that is both CPU bound and scalable, and thus a good candidate for demonstrating the effect of bundling. Next, we progressively increase the bundle size and the VM size proportionally. For example, if the best VM size selected by BFS is 1,792 MB (1 core), we use a VM of size 1,792 $\times$ 2 when we bundle pairs together, and so on. We notice that increasing the bundle size from 2 to 6 workers reduces the latency; however, increasing the bundle size beyond that (to 10 and 30) causes an increase in the latency. This is because the maximum number of cores available in AWS Lambda is 6 and hence, at the higher bundle sizes (10 or 30), each worker is getting less than its required resource.

Thus, the design of ORION to choose the best bundle size is essential to optimize latency by avoiding contention.

5.5 Generalizability to Microsoft Azure

To test if ORION generalizes to other FaaS providers, we evaluate our model using Azure Functions as the serverless environment. Azure Functions supports a few plans, but the most popular one is the *Consumption Plan*. In this plan, users are charged for the exact amount of resources consumed by their functions at runtime, whereas all other plans have a flat rate pricing model. Although we have no control over the resources assigned to individual functions when selecting the *Consumption Plan*, we wanted to measure the accuracy of ORION's E2E latency estimates compared to the actual la-

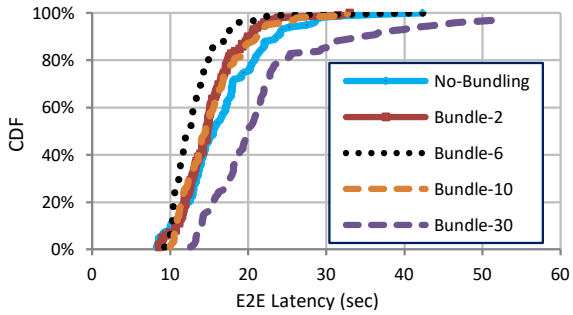

Figure 16: Video Analytics: Impact of varying bundle sizes. No-bunling has high latency due to computation skew. The optimal bundle size here is 6, and using a bundle size of $\geq$ 10 causes contention and the latency increases.

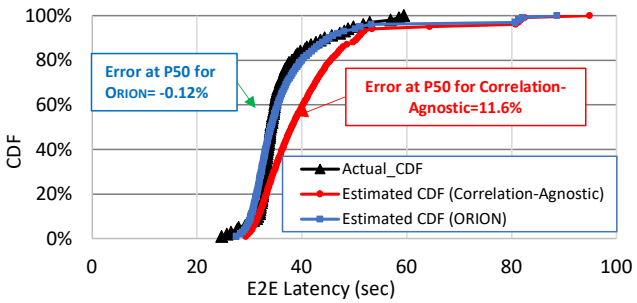

Figure 17: ORION's estimated latency CDF vs Actual CDF for Video Analytics application deployed in Azure Functions. Ignoring in-parallel correlation leads to higher errors for the Correlation-Agnostic baseline.

Table 3: **ORION's E2E latency-optimized VM sizes. ORION meets the latency objective with a low error rate in the range of [-2.75%, 4.93%]**

Video Analytics			
User Requirement	ORION's configs (MB) Split,Extract,Classify	Achieved Latency	Error Rate
P50 $\leq$18 s	192, 192, 640	18.3 s	1.5%
P95 $\leq$18 s	384, 192, 768	17.5 s	-2.8%
P50 $\leq$17.5 s	192, 192, 704	18.4 s	4.9%
P95 $\leq$17.5 s	640, 192, 768	17.4 s	-0.5%
P50 $\leq$17 s	256, 192, 768	17.8 s	4.4%
P95 $\leq$17 s	832, 256, 1024	17.3 s	2.0%

tency observed with this plan. We show ORION's estimated CDF and actual CDF in Figure 17. We use our Video Analytics application with the earlier-mentioned 600 YouTube videos.

We use our E2E performance model to estimate the CDF for the entire DAG. For fair comparison to AWS-Lambda, we also rely on remote-storage (*i.e.*, Azure Blob Storage) for data-passing between the functions. We also show the estimated CDF when correlations among functions are ignored — this corresponds to the "Correlation-Agnostic" baseline from our earlier experiment (§ 5.4.2). We notice that ORION predicts the E2E latency with very low error rates (-0.12% for P50, 1.9% for P90, and 2.5% for P95 latencies). The Correlation-Agnostic baseline has significantly higher errors (11.6% for P50, 14.4% for P90, and 29.2% for P95). Thus, the baseline suffers more for higher percentiles.

6 Pre-warming Policy Simulator

To better understand different pre-warming policies without being constrained by privileges granted by the cloud provider, we build a policy simulator, implemented in Python 3.8 with 1,058 LOC. The simulator takes as input the latency CDFs for stages in the DAG. Policies are implemented through a state machine with different actions being taken in each state (such as FUNC_START, FUNC_END, FUNC_PREWARM, etc.). The output of the simulator are the E2E latency CDF of the DAG and the overall resource utilization. We open source the simulator for future exploration of serverless DAGs [1].

Simulation Results. Figure 19 shows the utilization achieved by a policy with optimal pre-warming using an Oracle that knows the exact runtimes of each function invocation. The input DAG has 2 stages with width of 10 for each stage. The X-axis denotes the skew on the runtime of the first stage. The Y-axis denotes the percentage of variance on the delay chosen by the Oracle for pre-warming functions of the second stage — so if the value is $X\%$ and ORION calculated deterministic delay is Y, then the Oracle can pick a delay in the range $[Y - X\%$ of $Y, Y + X\%$ of $Y]$. Thus, the range of values the Oracle can choose from is capped even if the Oracle determines the optimal pre-warming time for a specific function invocation lies outside of the range. The lowest point on the Y-axis is the optimal deterministic delay determined by ORION for all function invocations in the second stage. We find that the E2E latency is unaffected (not shown) by increasing the size of the range on higher skews, but utilization increases. This is because the policy is able to pre-warm with the ideal delay and hence does not incur any idle time. This shows the theoretical best achievable utilization since we use an Oracle. However, implementing this Oracle has two challenges: (1) Predicting per-function *exact* latency is impractical. (2) Selecting a delay factor for each function invocation rather than each stage increases search space exponentially with DAG width.

7 Related Work

Minimizing cost and/or execution time for serverless chains is the target of a few recent studies. For example, Sequoia [52] makes the observation that current serverless platforms treat functions within a DAG separately, without making use of the DAG structure. SONIC [40] reduces the communication latency between in-series serverless functions by optimizing the data passing strategy. SONIC selects from among the data passing strategies: direct passing, remote storage, and local VM-storage, where only the latter two can be implemented directly in AWS Lambda. Caerus [60] stresses the importance of optimizing latency and cost jointly for serverless DAGs, and achieves this by identifying pipeline-amenable data de-

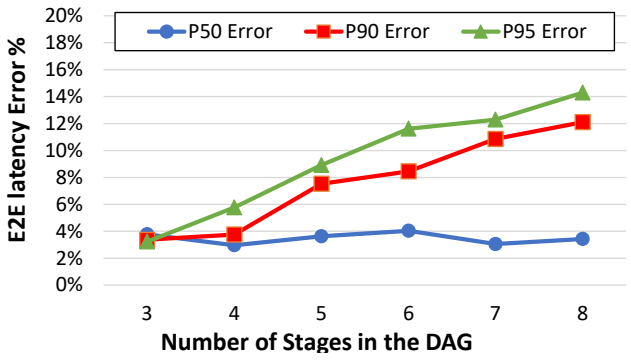

Figure 18: ORION*'s error with varying number of stages. More stages increase the error for the tail, while the median stays stable.*

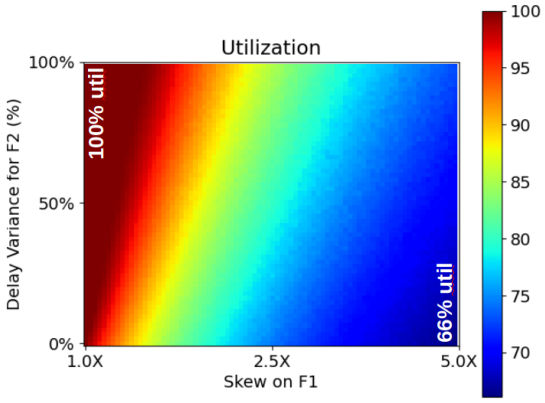

Figure 19: Simulation of an Oracle pre-warming policy where utilization improves with the width of distribution from which the pre-warming delays are chosen. ORION*'s strategy corresponds to the 0% variability,* **i.e.,** *deterministic delay.*

pendencies between stages to find ideal task launch times. Xanadu [21] and Kraken [14] tackle the problem of cascading cold starts in a dynamic DAG. Neither can determine the optimal pre-warming time to mitigate cold starts.

Overall, no prior work in this category considers execution time variance and its impact on cost or utilization.

Latency and Cost Prediction for Serverless Functions. A few prior studies have targeted predicting the execution time and cost for serverless functions. For example, [25] predicts (a point estimate) and optimizes resources for a *single* serverless function by building regression models from a host of synthetic functions. The authors in [26] also observe a variance in execution time in serverless environments, and hence, apply mixture density networks to predict the distribution of the function cost. However, their Monte-Carlo simulation mechanism is very sample inefficient.

ORION uses a more direct method by applying statistical operations to combine the distributions of individual functions and thus, to infer the E2E latency distribution. A number of prior works target reducing the cost of serverless DAGs by optimizing the intermediate data transfer between functions, such as, Costless [27], SONIC [40], Locus [43], and Pocket [35]. They solve an orthogonal problem to ours, namely, reducing the cost of intermediate data transfer. ORION does *not* introduce a new mechanism for intermediate data transfer, nor does it limit or specify the method for state transfer between functions. We use state-of-practice remote storages, such as AWS S3 and Azure Blob Storage. However, ORION would integrate seamlessly with the mentioned systems as the read/write times are included in the latency profiles used in ORION 's model.

Scheduling in Serverless Computing. Photon [24] optimizes *single-stage* serverless functions by doing the equivalent of bundling in ORION, but not for skew mitigation. Its main motivation is to reduce the memory footprint of parallel invocations of a function, while its design sophistication is meant to address security concerns of bundling (out of scope for ORION). One work that targets meeting latency SLAs for serverless DAGs is Atoll [50].

It takes a complementary approach to ours—partitioning a cluster to lower scheduling overheads, and proactively starting up containers and then routing function requests to the appropriate containers.

Resource Optimization in the Cloud. Black-box configuration tuning systems such as CherryPick [5], Selecta [34], OptimusCloud [39], and Ernest [54] target optimizing the cloud resources for a wide range of applications by selecting the right VM type and size, which vary in the amount of allocated resources. However, these systems treat the application as a single component, and thus, do not take the DAG workflow information into account. Further, they are not directly applicable to serverless applications.

Cold Starts Mitigation. Many prior works identified cold starts as a major performance bottleneck in FaaS platforms. Accordingly, several solutions have been proposed such as keeping containers alive [29], leveraging checkpoint/restore operations [49], or using *Pause* containers [41]. Although these solutions reduce the initialization time significantly, there is still a significant user-observable initialization time. ORION hides this initialization time through pre-warming and decides the right time to start pre-warming to minimize idle time, hence keeps resource utilization high.

8 Discussion

Profiling and Modeling Overheads. ORION requires monitoring the execution of the application for a number of runs to accurately capture the latency distribution for each function in the DAG. In our evaluation, for all the applications, a total of 300 profiling runs was found sufficient for accurate 95-percentile latency estimates. Initially, and before convergence is reached, the data collection is performed as a background

process while the DAG executes with user-provided configurations. An important design consideration for ORION is that this data collection does not have to happen purely offline and in batch mode. Rather, that is complemented with online data collection and incremental model refinement, which is a lightweight task. When predicted and observed latencies differ significantly (as can happen if the workload or the application changes), we restart the data collection phase to capture the changes in the latency distributions.

Bundling and Performance Model Interaction. Bundling changes the DAG structure (by reducing the fanout degree), and hence, the performance prediction model needs to be updated. Therefore, this becomes an iterative process, with each iteration being *Performance model building* $\Rightarrow$ *Resource optimization* $\Rightarrow$ *Bundling*. In practice, we find that a single iteration, or at most two iterations, leads to convergence.

Impact of The Three Optimization. The three optimizations of ORION can have a negative impact on performance, resource utilization, or $ cost if not performed carefully. First, over-provisioning the VM size for all workers to mitigate execution skew (as done by the Best Memory baseline in our evaluation) unnecessarily increases the $ cost (Figures 11, 12,& 13). Second, excessive Bundling (bundle size > right bundle size) can lead to resource contention and increase of the latency (Figure 16). Third, early pre-warming (delay < right delay) decreases resource utilization, whereas late pre-warming increases latency (Figure 15). This motivates the need for an accurate performance model to accurately perform these three optimizations. In terms of cost, we notice that users do not pay for initialization times, hence pre-warming does not impact cost. However, the provider should treat a pre-warming request as a hint since a true invocation is always more important.

Applicability of Performance Model.

ORION is tailored to model the performance for serverless DAGs. In general, the response time of a job includes queuing and execution times. Cloud providers operate large serverless platforms, providing virtually infinite capacity, reducing queuing delays to primarily cold-start latencies [38]. Further, serverless platforms typically limit the execution time of each invocation [8] favoring modular reusable functions. The combination of short queuing and execution times enables ORION to model E2E latency, without the need to predict variable (and long), heavy-tailed queuing times that appear in other environments [20, 33, 46].

Mitigating Infrastructure-caused Delays. In serverless platforms, two types of stragglers can be observed: (1) Stragglers that experience longer execution times due to their input content (e.g., larger data portions or more complex inputs such as video frames with many objects). (2) Stragglers that appear due to infrastructure causes (e.g., network fluctuations). Bundling mitigates the first type of stragglers. The second type is well studied in the literature, and solutions such as *Speculative Execution* [11] work well in practice. Nevertheless, Bundling has a positive side effect of using fewer VMs/containers, reducing the likelihood of occurrence for infrastructure stragglers.

Supporting Dynamic DAGs. In a dynamic DAG, the execution flow is identified at runtime, say based on input data. Such DAGs appear in microservice-based applications [14], among others. ORION, as well as other provider-side tools, cannot have visibility into user data due to privacy concerns. Hence, ORION cannot support dynamic DAGs where the path is determined based on request content.

Future Work. Our bundling approach increases VM size proportionally with the bundle size. For example, assuming a single function invocation use a VM of size VM_{single}, we bundle N invocations in a VM with a size of $N \times VM_{single}$. There is, however, room to explore choosing other VM sizes beyond linear scaling. Furthermore, combining two or more in-series functions together to execute in a single VM can improve performance compared to invoking those function in separate VMs (e.g. due to avoiding remote storage communication). We plan to explore the performance benefits of these ideas.

9 Conclusion

We proposed ORION as a novel optimization technique for serverless DAGs. It presents four design innovations: a distribution and correlation-aware performance model for E2E latency, a resource optimization strategy, a design for bundling multiple invocations of a function within a stage to mitigate execution time skews, and a pre-warming strategy to mitigate cold starts. We evaluate ORION on AWS Lambda on three serverless applications with different DAG structures, skews in execution time, and communication patterns. We compare ORION to three competing approaches and show significant improvements in E2E latency, $ cost, or both. We highlight the following insights: (1) It is challenging to decide on the right resource configurations that accurately meet latency SLOs for serverless DAGs. (2) It is important to bundle parallel workers together to mitigate skew, yet it is challenging to pick the right bundle size that avoids resource contention. (3) We can leverage the DAG structure information along with latency CDF estimates to find efficient pre-warming delays that minimize E2E latency without degrading utilization.

A Artifact Appendix

Abstract

This artifact appendix includes all the necessary information to reproduce the main evaluation results of the OSDI' 22 paper: ORION and the Three Rights: Sizing, Bundling, and Prewarming for Serverless DAGs.

Scope and Usage

ORION is a serverless DAG optimization layer implemented in C# and Python 3.8. ORION accepts a DAG as an input and profiles the execution time for each function in the DAG as well as the entire DAG. The execution times are represented as distributions (CDFs) to capture the variability in runtimes. Afterward, users provide ORION with requirements such as a latency target (*e.g.*, P95 $\leq$ 20 seconds) and/or an upper limit on the budget (*e.g.*, cost of 1K executions $\leq$ $1000). Next, ORION performs three optimizations to achieve user-provided requirements. The three optimizations are: (1) **Right-sizing**: Finding the best resource configurations for each function to meet the E2E latency objective with the minimum cost. (2) **Bundling**: Identifying stages where co-locating multiple parallel instances of a function together to be executed on one VM will be beneficial. The benefit arises when there is computation skew among the parallel workers caused by different content inputs and functions are scalable. (3) **Right pre-warming**: The VMs to execute the functions in the DAG are pre-warmed just right, ahead of time, so that cold starts can be avoided while keeping provider-side utilization of resources high. With these three optimizations, ORION accurately meets latency service level objectives (SLOs) while reducing execution cost. The output of ORION is a transformed DAG that has the same semantics as the user-provided DAG, but with higher performance (*i.e.*, lower latency) and lower execution cost.

Contents

1. **Benchmarks-AWS-Lambda:** This folder contains the code for the three evaluation applications (Video-Analytics, ML-Pipeline, and NLP-ChatBot). By running `deploy_application.sh` in each application directory, a DAG serverless workflow can be deployed on AWS Lambda using AWS Step Functions.

2. **DAG_Profile:** This folder contains the code for our DAG profiler. The code is generic enough to profile any application defined as a standard state machine on AWS Step Functions.

3. **DAG_Modeler:** This folder contains the code used to build the E2E performance model of the DAG. This module also contains the `VM_Size_Optimizer` to select the best VM size for each function in the DAG.

4. **Bundling_Manager:** This folder contains the code of ORION's Bundling optimization. This component of ORION profiles the DAG with varying bundle sizes and shows the P50 Latency, P95 Latency, and $ cost for each bundle size.

5. **Prewarming_Optimizer:** This folder contains the code to select the best pre-warming delays for each stage in the DAG.

6. **Comparison_to_Baselines:** This folder contains the code that compares ORION to two baselines: Best memory and CherryPick. The script produces the tail latency and cost (in $) for ORION as well as the two baselines.

7. **Policy_simulator:** This folder contains the code for our pre-warming policy simulator. This component compares different pre-warming policies without being constrained by what is possible in commercial public cloud.

Hosting

ORION is open sourced and we release its code, the workload characterization data, and the evaluation applications. All these components can be obtained at: https://github.com/icanforce/Orion-OSDI22

Requirements

The artifact uses AWS Lambda to host serverless functions, and AWS Step Functions to orchestrate the functions and organize them in a DAG. Some functions have large dependencies and hence are deployed as images on AWS ECR (Amazon Elastic Container Registry). Accordingly, users need to install the following dependencies:

1. **Amazon AWS CLI:** Can be obtained at: https://aws.amazon.com/cli/

2. **Docker:** Can be obtained at: https://www.docker.com/

Environment Setup

1. First, deploy one of the evaluation applications from `Benchmarks-AWS-Lambda` directory in AWS StepFunctions.

2. Then, use the `DAG_Profiler` to profile and generate the latency distributions for each function in the DAG.

3. Use `DAG_Modeler` to build the E2E performance model of the DAG, this module also contains the `VM_Size_Optimizer` to select the best VM size for each function in the DAG.

4. Use `Bundling_Manager` to select the best bundle size.

5. Use `Prewarming_Optimizer` to select the best pre-warming delays for the stages in the DAG.

6. Use `Comparison_to_Baselines` to compare Orion with CherryPick and Best Memory baselines.

Occualizer: Optimistic Concurrent Search Trees From Sequential Code

Tomer Shanny
Tel Aviv University

Adam Morrison
Tel Aviv University

Abstract

This paper presents Occualizer, a mechanical source code transformation for adding scalable optimistic synchronization to a sequential search tree implementation. Occualizer injects synchronization only to the update steps of tree operations, leaving traversal steps to execute unsynchronized, thereby maximizing parallelism.

We use Occualizer to create concurrent versions of a sequential B+tree, trie, and red-black tree. Evaluation on a 28-core machine shows that Occualizer's trees significantly outperform prior mechanically-crafted trees on non-read-only workloads and are comparable (within 4%) on read-only workloads. Overall, Occualizer shrinks the performance gap between mechanically- and hand-crafted trees by up to 13×. When using Occualizer's B+tree as the index in the STO main-memory database, the system's throughput degrades by less than 30% compared to the default Masstree index, and it scales better.

1 Introduction

In-memory tree data structures, or *search trees*, lie at the foundation of many systems, from databases [30, 58–60, 80] through operating systems [19–21] to storage engines [46, 68, 71]. Performance in such multicore systems depends not only on the sequential (single-threaded) speed of searching the tree, but also—often, mostly—on the scalability of the tree's *synchronization protocol*, which ensures correctness of concurrent tree operations [29, 47].

Scalable synchronization protocols typically apply *optimistic concurrency control* (OCC). In an optimistic protocol, traversals of tree paths are read-only and do not perform synchronization such as acquiring locks or executing atomic read-modify-write (RMW) instructions [11, 16, 29, 71]. Synchronization occurs only if and when an operation starts updating the tree. The optimistic approach thus limits serialization of tree operations (due to locking and/or cache coherence contention) mostly to the step that physically mutates the tree, allowing other steps to execute completely in parallel. The result is scalable performance that improves as the amount of hardware parallelism grows (unless the workload is contended at the semantic level, e.g., operations updating the same key).

Deploying an optimistic concurrent search tree in a system can be a hard problem, however. Systems often cannot deploy "off the shelf" trees, as their target use cases and workloads call for new, customized data structures [6, 17, 65, 67, 71, 80]. But designing a scalable synchronization protocol for a custom data structure—particularly an optimistic protocol—is notoriously challenging, because it involves *concurrent reasoning* to verify the algorithm's correctness under any possible thread interleaving allowed by the protocol [55, 64]. This effort also needs to be repeated whenever the data structure's algorithm changes, e.g., due to new optimizations or features.

To solve the problem of manually adding synchronization to a data structure, concurrency research has proposed *automatic transformations* such as universal constructions [2, 3, 18, 26, 35, 40, 51, 52] and transactional memory [54, 77]. These transformations receive a sequential data structure implementation (code) and produce a correctly synchronized version.

When applied to search trees, however, the automatic transformations do not produce efficient, scalable data structures. Some transformations inject pessimistic synchronization, which fully serializes all operations [18, 40, 51, 52] or all non-read-only operations [5, 26, 35]. Transactional memory-style transformations [2, 3, 31, 35, 41, 77] use optimistic synchronization, but block or restart operations whose path crosses nodes modified by a concurrent update operation, which degrades scalability. Overall, current automatic transformations produce trees whose throughput flatlines beyond 12 cores if even 3% of the workload's operations are not lookups (§ 7), as typically happens in dynamic workloads [4, 20, 58, 71].

Solution: Occualizer. This paper proposes *Occualizer*, a mechanical transformation for augmenting common sequential search tree implementations with scalable optimistic synchronization,[1] producing linearizable [56] concurrent trees. Occualizer's transformation requires the input tree to satisfy certain natural prerequisites, which most algorithms we are aware of meet, and our current prototype requires some manual effort to transform the input code. Occualizer injects synchronization only to the update steps of an operation (if any), leaving traversal steps to execute unsynchronized, unchanged from their baseline sequential code. Our key idea is to design Occualizer's injected synchronization so that it satisfies the "forepassed" condition of Feldman et al. [44]—which they prove implies the correctness of unsynchronized traversals in the presence of concurrent updates. We thus *design synchronization to satisfy a proof* instead of endeavoring to find a proof for our synchronization.

[1] Occualizer: one that adds OCC (optimistic concurrency control).

Informally, the "forepassed" condition requires that if a memory write w in the concurrent tree changes the search path for a key k, then any node v removed from the path must become immutable [44].[2] To obtain this property, Occualizer uses *localized copy-on-write* (LCOW), wherein all of an operation's writes are performed by atomically replacing the written-to nodes with new, updated copies, and making the old copies immutable. Crucially, LCOW does not require copying the entire path from the root to the updated nodes and thereby avoids synchronization bottlenecks at the top of the tree—a fundamental difference from prior COW techniques [5, 19].

We use Occualizer to produce concurrent versions of the sequential `tlx` B+tree [8], a radix tree (trie), and a red-black tree, and evaluate them on a dual-socket 28-core machine. Compared to prior transformations, Occualizer's search trees are far faster and more scalable in dynamic (non-read-only) workloads, outperforming trees using GCC's transactional memory by up to 17× and the CX universal construction [26] by orders of magnitude. On read-only workloads, Occualizer's trees are comparable to prior constructions' (within 4%). Due to instrumentation overheads, however, Occualizer's trees do not match the performance of hand-crafted concurrent algorithms. For instance, when used as an index in the STOv2 main-memory database system [58], Occualizer's B+tree has better scalability but is 25%–30% slower than the default index, Masstree [71], a hand-crafted concurrent trie/B+tree hybrid.

Overall, Occualizer significantly changes the cost/benefit analysis of hand-crafting a concurrent search tree. By shrinking the performance gap between mechanically- and hand-crafted trees by up to 13×, Occualizer makes mechanically-crafted trees applicable in many more contexts and performance targets, freeing up time and costs that would otherwise be spent on designing, implementing, and testing a hand-crafted implementation.

Contributions. We make the following contributions:

- **Transformation.** We describe Occualizer, a mechanical transformation for augmenting common sequential search tree implementations with optimistic synchronization.
- **Implementation.** We implement Occualizer and use it to produce concurrent versions of the sequential `tlx` B+tree, a radix tree (trie), and a red-black tree. Occualizer's code is available at `https://github.com/tomershanny/Occualizer`.
- **Evaluation.** We show that Occualizer's trees outperform trees using GCC's transactional memory by up to 17× and the CX universal construction by orders of magnitude, but are slower than hand-crafted concurrent trees.

[2] Intuitively, this condition guarantees that any operation whose search for k is currently located at v will either rejoin the new path or will end at an immutable node from which it cannot "damage" the tree.

2 Background, motivation, and related work

Designing efficient fine-grained synchronization for data structures is notoriously hard, because verifying synchronization correctness requires reasoning about every possible thread interleaving allowed [55, 64], while scalability requires the protocol to allow more possible interleavings. Optimistic search tree design exemplifies this challenge. On one hand, to maximize scalability, the synchronization protocol should not block or restart a traversal that encounters concurrent updates of its search path [11]. On the other hand, a traversal encountering such updates can observe *inconsistent* tree states, which cannot occur in a sequential execution but must be reasoned about to verify the protocol's correctness [43, 44, 61, 62, 66, 73, 81, 82].

The difficulty of designing a highly-scalable and correct optimistic tree lead some systems to deploy search trees with relaxed correctness guarantees. Linux's red-black tree, for instance, guarantees only that searches do not crash in the face of concurrent updates—but not search correctness [69]. Researchers have identified principles for designing optimistic synchronization protocols [11] as well as compiler support to simplify their implementation [84], but such research does not address the fundamental verification difficulty of a scalable, human-designed synchronization protocol.

Our motivation is therefore to automate the task of adding optimistic synchronization to a custom-designed sequential search tree. Concurrency research has proposed approaches for automatically transforming a sequential data structure into a concurrent one: universal constructions (§ 2.1) and transactional memory (§ 2.2). But these approaches do not produce scalable concurrent data structures when applied to search trees, as we discuss next.

2.1 Universal constructions

A *universal construction* (UC) [51] takes a sequential implementation of a data structure and outputs a linearizable concurrent version of it, without modifying the sequential code—i.e., by "wrapping" it in synchronization in some fashion. UCs can apply *nonblocking* or *blocking* synchronization.

Nonblocking universal constructions create concurrent data structures with nonblocking progress properties: either *wait-free*, which means every operation can complete in a finite number of its own steps, or *lock-free*, which means that some operation always completes after a finite number of execution steps [51]. Achieving these progress guarantees typically requires operations to coordinate and *help* each other make progress, which adds overhead [55].

Blocking universal constructions are based on the *delegation* technique [10, 15, 39, 50, 70, 74], which delegates the execution of the data structure operations threads to one thread. This "server" thread executes operations on behalf of the other, "client" threads. Delegation schemes differ in the types of operations delegated (e.g., all operations [39, 50, 70], up-

date operations [15], or read-only operations [10]) and/or their inter-thread communication techniques [14, 75].

The flip side of UCs' treatment of the input code as a black box is that the synchronization they add is coarse-grained, pessimistic, and slow. Early nonblocking UCs [18, 38, 40, 51, 52] work by having each operation execute on a local copy of the entire data structure which it then tries to install as the new version. This approach fully serializes all operations and is prohibitively slow on real-world-sized data structures. Early delegation UCs [39, 50, 70] also fully serialize all operations, as they delegate every operation to the "server" thread. Modern nonblocking UCs [5, 26, 35] improve on the full serialization aspect by optimizing read-only operations, allowing them to execute in parallel, but non-read-only operations are still serialized. Likewise, modern delegation UCs allow certain types of operations to execute in parallel (updates [10] or read-only operations [15]), but all other operations remain serialized by delegation.

COW UC. A nonblocking UC technique that reduces copying overhead (and is closely related to Occualizer) is copy-on-write (COW), used in the transactional system of Ben-David et al. [5]. The core idea is for a writing operation to create its updated version without copying the entire data structure, by having it share as much as possible with the previous version. For trees, this technique updates a node by creating an updated version of the node and the path that leads to it, and atomically swapping the updated root with the new one (Figure 1). The COW approach allows read-only operations to proceed without synchronization, since the version they observe is immutable. Writing operations, however, remain serialized.

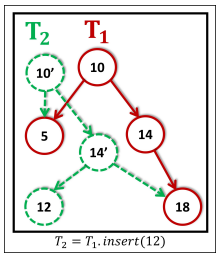

Figure 1: COW: Adding 12 as a child of 14 in T_1 yields T_2.

2.2 Transactional memory

Transactional memory (TM) [54, 77] executes sequential code segments as isolated atomic transactions. With hardware TM (HTM), serializability of the transactions is enforced by the hardware [54]. HTM can thus be viewed as a UC. Real-world HTM extensions, however, have several limitations [33, 33, 34] and are currently disabled on many processors due to hardware errata [63]. We therefore focus on software TM (STM). STMs differ from UCs in that they require *code instrumentation*, so that the STM runtime can mediate reads/write to memory and (in some cases) memory allocation/deallocation.

Modern STMs have converged on designs using optimistic-style lock-based synchronization [36, 48]. In these designs, the STM algorithm performs transactional reads without writing to memory (e.g., to acquire a lock); writes either acquire locks ("eager" locking) or are buffered in a write set ("lazy" locking). When the transaction ends, the STM checks whether there is a point in time in which all of the transaction's reads and writes can appear to take place atomically. If so, the transaction *commits* and its writes are made visible to other transactions (e.g., locks are released). Otherwise, the transaction *aborts* and must restart.

Unfortunately, since the STM does not understand the semantics of the underlying code, its validation conservatively depends on every value read by the transaction [31, 41]. Therefore, if any memory location read by a transaction is written to before the transaction commits, the transaction will abort. This effect severely limits scalability of STM-based trees, because any concurrent write to an operation's search path causes the operation to abort—even if the operation would have reached the same location in the tree had it executed on the new path (a fact the STM cannot know). In our experiments, TM performance can flatline at low core counts even if as few as 3% of the tree operations are updates (§ 7).

TM research has proposed several approaches to address the above problem. First, an STM can determine the serial order of transactions (*conflict detection*) more intelligently [76, 85]. But this typically requires transactional reads to write to memory, which can lead to undesirable serialization of readers. Second, transactions can be built over higher level objects instead of low-level memory reads/writes [49, 53, 57]. But this requires designing the underlying thread-safe objects, which was our original problem. Finally, transactional semantics can be relaxed [42] to avoid aborting a transaction in cases such as search path changes. But then one has to prove the resulting relaxed transactions correct, which requires the concurrent reasoning about thread interleaving that we wish to avoid.

2.3 Summary and goals

In summary, there is still no mechanic way to transform the source code of a sequential tree implementation into an optimistic, fast, and scalable concurrent tree—without needing to perform concurrent reasoning to verify the correctness of the produced concurrent code. This is our goal.

Occualizer sits in the middle between UCs and TM. Compared to universal constructions, Occualizer takes a pragmatic approach. Instead of accepting arbitrary sequential code as input, Occualizer requires the input to have certain natural prerequisites, and also transforms/instruments the sequential code. Compared to transactional memory, Occualizer is specialized to search trees, which enables us to design an optimistic synchronization protocol that does not restart operations whose search path is modified by concurrent operations.

3 Occualizer Overview

Occualizer receives source code of a sequential (single-threaded) search tree and transforms it into an optimistic concurrent implementation by adding calls to Occualizer's synchronization library into the input source code. This section gives an overview of the Occualizer transformation.

We first define the family of sequential tree implementations to which Occualizer is applicable (§ 3.1). (We discuss verifying that a sequential tree meets Occualizer's requirements in § 3.5.) We then give an overview of Occualizer's source code changes (§ 3.2) and the run-time synchronization protocol they inject, called localized copy-on-write (§ 3.3). The details are described in §§ 4–5. Finally, we outline the correctness proof of the produced concurrent tree (§ 3.4), which appears in § 6.

3.1 Scope

We consider correct sequential implementations of a dictionary datatype, namely, that provide lookup, insert, and delete operations on key-value pairs. The implementation may also (optionally) support ordered iteration over the stored keys, provided via key predecessor/successor operations. We assume a programming language with manual memory management. (Our prototype targets C++.)

Occualizer requires the sequential input algorithm to meet certain prerequisites (PRs), detailed below. At a high level, the prerequisites are that (1) tree operations are composed of a read-only traversal followed by reads and writes which are determined only by what the operation observes after the traversal; (2) each step in the traversal depends only on the target key and the current node; and (3) any operation that moves a node v off some search path(s) must also access v.

The user is responsible for verifying that the input meets Occualizer's prerequisites, and the concurrent tree produced by Occualizer is not guaranteed to be correct if they are not met. The human effort required for this verification (and the possibility of errors there) are limitations of Occualizer compared to general universal constructions that accept arbitrary code. While our experience has been that the prerequisites are met by many algorithms and that verifying them requires reasonable effort (see § 3.5), our vision is to develop automated verification of the prerequisites to fully automate Occualizer.

Prerequisites. We define the prerequisites in terms of an algorithm maintaining a directed graph G of nodes, whose edges represent pointers between nodes.

PR1 Maintain a rooted tree: At the end of any sequence of operations, the graph G is a rooted tree.

Crucially, PR1 does not care about intermediate states that occur while a tree operation executes, only about the graph's structure upon its completion. PR1 is conservative, as Occualizer can support structures with auxiliary edges linking nodes to their successor/predecessor, which create multiple paths from the root to nodes and so are not formally trees. We defer these details to § 4.

PR2 Read-only traversals: Every operation $op(k)$ consists of a read-only traversal $traverse(k)$ that searches for k followed by read/write steps.

PR2 is not met by self-balancing trees that perform balancing during traversals, such as splay trees [78]. But PR2 is met by self-balancing trees such as red-black, AVL, or B-trees, which perform self-balancing after updating the tree (post-traversal).

PR3 Traversals are single-step: The next node visited by $traverse(k)$ depends only on k and on the current node.

PR3 is met by trees with comparison-based traversals, such as B+trees [22], Bw-Trees [67, 83], red-black and AVL trees, etc., where how $traverse(k)$ proceeds depends only on how k compares to the key(s) of the current visited node. PR3 can also be met by tries, provided that nodes encode the key offset they represent; otherwise, the next node visited becomes dependent on all the nodes visited so far, which violates PR3.

Our next prerequisite states that the reads and writes an operation performs after its traversal are not a function of observations made during the traversal:

PR4 Post-traversal actions depend only on subgraph accessed post-traversal: Consider an operation $op(k)$ that executes on tree T, whose $traverse(k)$ finishes at node v. Let $RW^{op(k)}$ be the set of nodes read/written to by $op(k)$ after finishing its traversal. Let $T_{RW^{op(k)}} \subseteq T$ be the smallest subgraph of T containing $RW^{op(k)}$. Then for any sequence of operations that execute on T resulting in tree T', if $T_{RW^{op(k)}} \subseteq T'$ and $traverse(k)$ executed on T' finishes at the same node v as in T, it holds that running $op(k)$ over T' results in exactly the same reads and writes as in op's execution over T.

PR4 does not preclude an algorithm from reading or writing parts of its search path after completing the traversal—as in, e.g., rebalancing of red-black, AVL, and B-trees—because any node on the path that an operation $op(k)$ reads or writes post-traversal becomes part of $RW^{op(k)}$. PR4 is thus met by classic tree algorithms that perform post-traversal rebalancing.

PR5 Moving off a search path implies a post-traversal access: For any operation op and any key k, consider the paths P and P' that would be taken by $traverse(k)$ before and after op executes. Then if $v \in P$ but $v \notin P'$, op must read, write, or destroy v after its traversal.

For an implementation that does not expose nodes to its client, PR5 is met by every tree algorithm we are aware of. In these algorithms, a node moves off a search path due to either (1) a structural modification that changes the node's position in the tree, in which case the node is written and/or read; or (2) being removed from the tree, in which case the implementation destroys and frees the node, as it has no other references.

Occualizer for managed languages. Occualizer's design and its prerequisites are programming language agnostic. Most tree implementations, however, fail to meet PR5 when implemented in a managed language. The reason is that

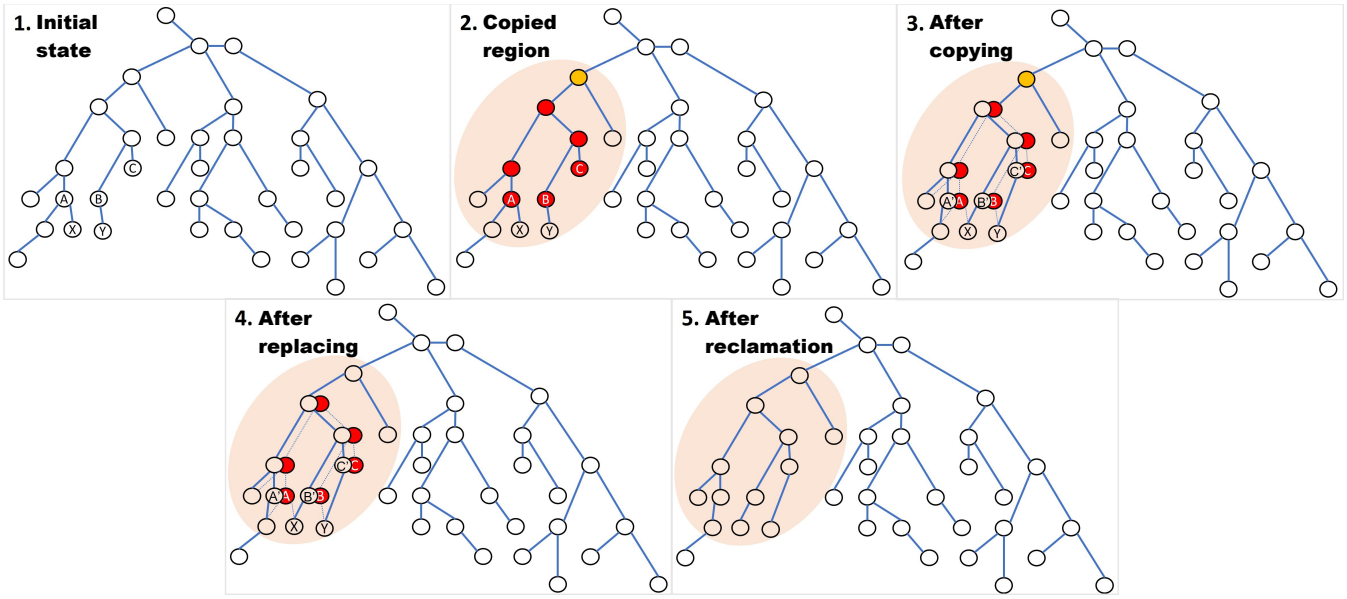

Figure 2: Illustration of LCOW on an operation that makes B and C the parents of X and Y, respectively.

node destruction in managed languages is performed asynchronously by the garbage collector and not explicitly by the program, so a managed tree implementation meets PR5 only if it writes to a node when removing it from the tree—which most algorithms do not do. This problem can be fixed (currently, manually) by adding no-op writes to removed nodes.

3.2 Code transformations

Occualizer transforms the sequential input code by adding calls to Occualizer's synchronization library. These calls are similar to object-level transactional memory instrumentation. They include calls to demarcate each operation's start and completion, and to access (read/write) node fields only through the library's interface. Field accesses are captured straightforwardly by requiring the sequential input code to access fields using only getter/setter methods, which the transformation then replaces. The transformation also adds locks and metadata fields to the node structure.

The code transformation is mechanic and our design is for it to be done automatically, with minimal user involvement. In our current prototype, however, we implement only the synchronization library and perform the code transformations of the evaluated trees manually (following the mechanical recipe given in § 4). Implementing the automatic code transformation is an ongoing effort.

3.3 LCOW synchronization library

Occualizer's code transformation leaves the logic of traversals unchanged. In particular, traversals do not block or retry mid-operation. The synchronization added to writing operations guarantees the correctness of both traversals and writing operations. To this end, the library uses a technique we call *localized copy-on-write* (LCOW). LCOW exposes all of an operation's writes atomically, using one atomic write. Unlike other COW techniques [5, 19], this write *does not* typically target the tree's root and thereby avoids creating a synchronization bottleneck.

LCOW works as follows. Once an operation *op* finishes its traversal, the library uses a combination of locking and validation checks to maintain an invariant that *op*'s further observations of the tree are consistent with some sequential execution. This invariant is needed to guarantee that *op*'s code behaves correctly. In particular, whenever *op* first writes to some node v, the library locks v and creates a copy of v, v'. (If a lock acquisition fails, *op* is restarted, releasing any locks it holds and freeing node copies it had made.) Subsequently, all of *op*'s accesses to v are redirected to v', ensuring *op* "sees its own writes." When *op* completes, the library identifies a minimal subgraph containing all written nodes, called the *copied region*. This subgraph is itself a tree rooted at some node n, but it may not be n's subtree (i.e., it may not include all of n's descendants). Next, the library locks and creates a copy of the copied region, updated to contain the nodes written to by *op*. Finally, the library exposes *op*'s writes atomically by linking u', the root of the copied region, instead of its original version u with one atomic write. Crucially, the old versions of the nodes remain locked, making them immutable.

The library reclaims the memory of the old copied region only once it is guaranteed that no concurrent operation may be accessing the old region, using a read-copy update (RCU) epoch-based memory reclamation scheme [45, 72].

Figure 2 illustrates LCOW on some abstract operation *op*. ① shows the initial tree state. Assume that executing *op*'s sequential code from start to finish in this state would make

B and C the parents of X and Y, respectively. ② shows the copied region: LCOW locks the orange and red nodes, thereby blocking concurrent modifications to every node in the pink circle. ③ LCOW copies the red nodes, creating a new version of the copied region in which *op*'s writes are made to the nodes A', B', and C'. Finally, ④ shows the memory state after atomically replacing the copied region with its new version, and ⑤ shows the memory state after the original copied region is reclaimed.

The upshot is that Occualizer guarantees that (1) executing operations run correctly, as they would in a sequential execution, and (2) the state of the tree in memory is always a state that can be produced by a sequential execution. Crucially, however, this is all achieved while still allowing the *traversal* part of an operation to observe an inconsistent state. E.g., a traversal can start in tree T_1 and then cross into tree T_2, walking a path that never actually existed in memory.

3.4 Linearizability argument

Trees produced by Occualizer are linearizable [56], i.e., operations appear to execute atomically. The main challenge of proving linearizability is that because traversals are unsynchronized and can observe inconsistent tree states, it is not clear that a traversal ultimately reaches the correct node.

The key idea of Occualizer is to design its synchronization to satisfy the precondition of an existing proof (from the concurrency literature) that an unsynchronized traversal is correct. Occualizer's trees satisfy the "forepassed" condition, which Feldman et al. [44] prove implies that if an unsynchronized traversal searching for key k reaches node v, then at some point during its execution, v was on the search path for k. (That is, the state of the tree was such that had the traversal executed from start to finish then, it would have reached v.)

The above immediately proves the linearizability of read-only lookups that consist only of traversals. To prove linearizability of writing operations, we show that when a writing operation atomically performs its writes using LCOW, then the state of the tree is such that had the operation's sequential code executed atomically now, it would have behaved exactly the same. In other words, the state of the tree in memory remains consistent with some sequential execution of the original sequential code. We show this by first proving an invariant that an operation locking node v implies that v is on the relevant search path at lock acquisition time ("now"). The proof then follows from PR4, since the copied region locked by an operation contains the subgraph it accessed post-traversal.

3.5 Discussion: Prerequisite verification

For our evaluation (§ 7), we use Occualizer on sequential implementations of classic tree algorithms, such as the B+tree. We draw on this experience to discuss the effort and reasoning needed to manually verify that an implementation meets Occualizer's prerequisites. In a nutshell, we find that the prerequisites are met by many algorithms (e.g., red-black and B-trees) and tree design techniques. We also find that checking the prerequisites requires reasonable effort, given basic understanding of the input tree's algorithmic properties. In particular, there is no need for concurrent reasoning, as the prerequisites are properties of sequential code.

Verifying PR1–PR3 involves straightforward code inspection. In particular, verifying that every tree operation begins with a read-only traversal (PR2) is easy for implementations with an explicit traversal method and for recursive implementations, where one only needs to check the recursive function.

Verifying PR4–PR5 requires reasoning about the principles driving the sequential input algorithm. To verify that post-traversal actions depend only on the subgraph accessed post-traversal (PR4), we need to check that the nodes and fields an operation chooses to access and the values it writes depend only on what it reads after its traversal. PR4 would be violated, for example, by an operation writing a node's depth (distance from the root) that was computed while searching for the node. On the other hand, PR4 is satisfied by an operation maintaining the height of a node (or the balance factor in an AVL tree) using a bottom-up computation after the traversal. PR4 holds trivially if traversals are performed as a subroutine call that returns only the target node, thereby making the search path opaque to the operation.

To verify that if a node stops being on the search path for some key k, then the node must be accessed or destroyed (PR5), we need to verify that a node removal destroys it, and to reason about how tree structure modifications affect the behavior of searches. We find that common tree algorithmic techniques meet PR5. For instance, consider a binary tree rotation [25] moving node y above its parent y (Figure 3). The only node that moves off a search path as a result of the rotation is y (which moves off the paths leading to subtree A) and y is indeed written by the rotation (its left child changes).[3] As another example, in a binary tree that deletes an internal node by replacing it with its successor [25] (the leftmost node of its right subtree), the nodes on the path to the successor move off the search path to the successor. These nodes are read by the removing operation as it searches for the successor, so PR5 is met.

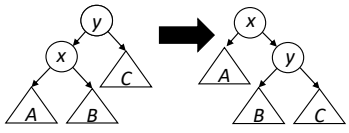

Figure 3: Rotation moving x above y.

4 Design

This section describes Occualizer's design. We first describe Occualizer's synchronization library interface and the mechanical rules for calling its methods from a sequential tree implementation (§ 4.1). We next describe how the library

[3] Crucially, PR5 depends only on the effect that a complete rotation has on future searches—not on the exact order of writes performing the rotation in the sequential code.

implements the LCOW synchronization protocol (§ 4.2) and then extend the design to support algorithms with auxiliary edges between nodes, which are typically used to optimize iteration over nodes (§ 4.3).

4.1 Library interface & code transformations

Interface. Occualizer augments the input with calls to its library. Table 1 describe the library's transactional memory-like interface, which consists of "macro" and "micro" methods.

The "macro" methods demarcate the points in which the operation starts/finishes and where its traversal ends. In particular, `occ_start` checkpoints the calling thread's register state (e.g., with `setjmp()`) and restores it if the library decides to abort the operation. When an abort happens, `occ_start` returns a failure indication.

The "micro" methods read and write node fields (or the root pointer) and notify the library of allocated or destroyed nodes. For simplicity, we show the read/write methods as taking the field name as an argument. An implementation either generates specific methods for each field or has a general method that takes the field's offset and size in the node.

Transformation. Transforming a sequential tree to an optimistically-synchronized one using Occualizer requires two types of transformations. Macro transformations add macro calls to demarcate each operation with `occ_start`, `occ_traverse_done`, and `occ_finish` calls, and restart it after an abort (Listing 1). Occualizer does not require modifying the input code to separate the traversal into its own method, only to call `occ_traverse_done` when it is done. This property allows the operation's subsequent code to reuse information learned during the traversal, e.g., to climb back up the path for tree maintenance.

Micro transformations replace calls to node setter/getter methods with the appropriate `occ_set`/`occ_get` calls, and add `occ_node_born`/`occ_node_dies` calls to the node constructor/destructor.

Method	Called when (and why)
`occ_start`	Operation starts (to initialize bookkeeping data)
`occ_traverse_done`	Traversal finishes (to start consistency checks)
`occ_finish`	Operation finishes (to atomically perform operation's writes)
`occ_restart`	Restarting an aborted operation (to free resources acquired during the failed execution)
`occ_set`(n, f, v)	Writing $n.f \leftarrow v$ (to lock and copy n)
`occ_get`(n, f)	Reading $n.f$ (to read from n's copy, if it exists)
`occ_node_born`(n)	Node is allocated
`occ_node_dies`(n)	Node is destroyed

Table 1: Occualizer synchronization library interface.

```
Function transformed<op>(args):
    while True do
        if occ_start() then
            result ⟵ op(args) ; ▷ occ_traverse_done was
              added inside op's code
            if occ_finish() then
                return result
            end
        end
        occ_restart() ; ▷ Op aborted
    end
```

Listing 1: Code of macro-transformed operation *op*.

Mechanizing the transformation. The transformation can be performed automatically by a source-to-source transformer tool, which we are in the process of implementing. The transformer requires the user to supply the tree's sequential source code, the names of methods to be macro-transformed and structure(s) implementing nodes, and to manually add the `occ_traverse_done` call. The transformer performs the following steps: ① Ensure that all node fields are accessed via setter/getter methods, by replacing every direct field access with an appropriate setter/getter call and generating getter/setter methods if they do not exist in the input code. ② Perform the micro-transformations by modifying methods in the node structure. ③ Generate the macro-transformed operations.

4.2 LCOW synchronization library

Occualizer's synchronization library has two high level tasks. First, it tracks the tree as observed by the operation, so that once the operation's traversal finishes, Occualizer can guarantee that the tree is in a consistent state from the operation's perspective. Second, the library buffers the operation's writes and exposes them atomically when the operation completes. We now walk through the library's flow.

Initialization (occ_start). This method checkpoints the thread's local state, so that execution can restart if the operation subsequently aborts. It then initializes the library's thread-local bookkeeping variables (Table 2), which track edges observed by the operation, nodes allocated, destroyed, locked, and copied, and other flags, such as whether the operation is in the midst of its traversal. We treat these variables as abstract datatypes for now (in particular, without considering implementation efficiency); § 5 describes our implementation.

Node reads (occ_get). We first focus on the case of reading a node pointer (child), i.e., reading an edge. As long as an operation is traversing the tree, its reads are handled with minimal overhead. The library only stores traversed edges in the `edgeSet`, to verify their consistency in case the operation rereads them in its post-traversal steps. Once the traversal

Name	Type	Content
`edgeSet`	Set of edges	Edges observed during operation
`lockedSet`	Set of nodes	Nodes locked by operation
`copySet`	Set of node pairs	Copied nodes and their copies
`bornSet`	Set of nodes	Nodes allocated by operation
`destroyedSet`	Set of nodes	Nodes destroyed by operation
`traversing`	Boolean	Initially *True*; *False* after `occ_traverse_done` called

Table 2: Thread-local bookkeeping structures. The term "node" refers to a pointer to the relevant object in memory.

completes, the library switches to a mode that guarantees consistency of the observed tree. This is accomplished by locking any node accessed post-traversal, while verifying that the locked node belongs to the most updated tree in memory. If this verification fails, the operation is aborted (releasing any locks it acquired and nodes it allocated) and restarted.

Listing 2 shows the pseudo code of `occ_get`. Suppose operation *op* is trying to read the c-th child of node n. (For generality, we assume child pointers are stored in a `children` vector in the node.) If *op* previously created a copy of n, the read is satisfied from the copy n' without further checks. Otherwise, n's c-th child, u, is read from n. If *op* is traversing, the method *trackEdge* only remembers the edge (n,c,u) in `edgeSet`. Otherwise, *trackEdge* locks n by calling *lockNode*.

The *lockNode* method locks n while checking its consistency with *op*'s observations of the tree. If n is not present in *op*'s `lockedSet`, *op* tries to acquire n's lock. If n is locked, *op* aborts, to avoid deadlocks. Then *op* checks that any edge into or out of n that *op* previously observed still exists. If so, n is added to *op*'s set of locked nodes. Otherwise, *op* aborts.

Reads of non-pointer fields are handled identically (locking the node, etc.) except that the read values are not tracked.

Node writes (occ_set). On any write to a node n, the library locks n and creates a copy of it, n'. If the operation completes successfully, n' will take the place of n in the tree and n will remain locked and hence immutable until its memory is reclaimed. Listing 3 shows the pseudo code of `occ_set`, again focusing on the case of writing a child pointer. If *op* has made a copy, v', of the pointed-to node v, the value to be written is changed to v'. Next, *op* checks if the written node n is part of the tree, i.e., it was not allocated by *op* itself and is not a copy. If so, *op* creates a copy of n by calling *occ_create_copy*. Finally, the write is performed.

To copy n, the *occ_create_copy* methods locks n using the *lockNode* method described above. It then copies the (now locked) n into a new node, n', records that n has a copy n' in *op*'s `copySet`, and finally adjusts the links between the existing copied nodes to reflect the new copy. For every $(x,x') \in$ `copySet`, the *fixLinks* method changes any edge

```
Function occ_get_child(n, c):
    if (n,n') ∈ copySet then
        return n'.children[c]
    else
        u ← n.children[c]
        trackEdge(n, c, u)
        return u
    end

Function lockNode(n):
    if n ∈ lockedSet then
        return
    if tryLock(n.lock) fails then
        abort operation
    ▷ Validate
    foreach (x,c,y) ∈ edgeSet, s.t. x = n or y = n do
        if x.children[c] ≠ y then
            abort operation
    end
    lockedSet.add(n)
```

Listing 2: Code of reading a node child..

```
Function occ_set_child(n, c, v):
    if (v,v') ∈ copySet then
        v ← v'
    end
    if n ∉ bornSet and (n,_) ∉ copySet then
        n ← occ_create_copy(n)
    end
    n.children[c] ← v

Function occ_create_copy(n):
    lockNode(n)
    n' ← copy of n
    copySet.add(n,n')
    fixLinks(n,n',copySet,bornSet)
    return copy
```

Listing 3: Code of writing a node child.

pointing from x' to n to point to n' instead, and changes any edge from n' pointing to x to point to x' instead. It similarly fixes any edge pointing to n from nodes allocated by *op*.

Writes of non-pointer fields are handled identically, except that value written is not "translated" as it is not a node pointer.

Traversal completion (occ_traverse_done). On traversal completion, the library switches to its post-traversal mode, in which any accessed nodes is locked. In addition, the last node read by the traversal is locked using the *lockNode* method. This locking is needed to guarantee that concurrent tree modifications do not "invalidate" the node's traversal (see § 6).

Node allocation/deallocation. On node allocation, the new node n is added to `bornSet`. On node destruction, the destroyed node n is locked (using *lockNode*) and added to `destroyedSet`. This is done so that n can be left immutable when the operation completes.

Operation commit (occ_finish). This method *commits* an operation by atomically applying its writes to the tree. Consider first the simple case in which the operation *op* finishes its traversal at node n and subsequently accesses nodes only down the tree. In this case, the paths to nodes written by *op* form a tree T_n rooted at n, and all nodes in T_n are locked by *op*. Occualizer can thus atomically apply *op*'s writes by creating a copy of T_n, T_n', which contains the updated versions of the nodes *op* wrote to and then swinging the pointer to n from its parent, p, to point to n', the root of T_n'. (Figure 2, with p being the orange node.) We thus call T_n the *copied region*.

To ensure atomicity, *op* must verify that p is still in the tree and that the edge (p,c,n) that it swings has not changed since *op* originally crossed p during the traversal. If n is a non-root node, this is done by locking p and validating that $p.children[c] = n$ before overwriting it. If n is the root, this is done by locking a global root lock and validating the root's value (which also gets saved in `edgeSet`). Although we describe this parent validation step last, it chronologically occurs before copying any yet uncopied nodes from T_n, to avoid wasting CPU cycles in case *op* is doomed to abort.

Finally, nodes locked by *op* that are not in T_n are released. The nodes of T_n are *retired*, which means that their memory is freed/reclaimed once no concurrent operation can observe them. (Occualizer relies on an RCU-like epoch-based safe memory reclamation (SMR) management library [45, 72] to provide this functionality.) Until reclamation, these nodes remain locked and thus immutable.

In the general case, *op* may have proceeded up the tree, by accessing nodes it observed while traversing. The above discussion still holds, except that instead of taking n as the copied region's root, *occ_finish* needs to find the lowest common ancestor (LCA) of all written nodes and lock every path from that LCA to each written node. This is straightforward to do, because the LCA and all relevant edges have been read during *op*'s run (possibly only in the traversal step).

4.3 Optimizing range scans

An important feature of search trees is that they support *range scans*, the ability to iterate over the stored keys in order by using successor/predecessor calls. Specifically, we assume the tree implements a C++ standard library (STL)-like `iterator` object. The iterator maintains a key k', which is initially the predecessor or successor of its constructor argument. The iterator provides next/prev calls, each of which updates k' to its successor/predecessor, respectively. As with other concurrent search trees [9, 71], our goal is for the individual next/prev calls to be atomic (linearizable)—not for an entire range iteration performed by a sequence of such calls to be atomic with respect to insertions/deletions.

In sequential trees, a common method of implementing an iterator is to add *auxiliary* next/prev pointers to node fields, so that advancing an iterator does not require walking paths in the tree. Occualizer supports trees with such auxiliary edges, provided that they are symmetric (i.e., v points to u via an auxiliary link if and only if u points to v), as is the case of next/prev pointers. In addition, the user is required to specify the field names of auxiliary links in the node structure. Occualizer then leaves iterator movement over auxiliary edges as a read-only operation.

Extended commit protocol. We extend Occualizer's commit protocol to support auxiliary edges as follows. When an operation *op* is ready to commit, after having locked and validated p, the parent of r, the copied region's root, *op* checks each auxiliary edge (v,u) pointing to the copied region (i.e., such that u is in the copied region and v is not) and attempts to lock v (aborting if it fails).[4] Once all these "border" nodes are locked, *op* updates p to point from r to its new version r' with one atomic write, and then iterates over each locked border node v, updating its relevant auxiliary edges to point to the new version of the neighbor u (from (v,u) to (v,u')), and releasing v's lock afterwards. This protocol may seem heavyweight, but in practice copied regions tend to be small, so the extra cost of handling auxiliary edges is not substantial.

Unfortunately, the extended commit protocol breaks Occualizer's LCOW technique of replacing a copied region with one atomic memory write. The problem is that a sequential tree with auxiliary edges does not meet our PR1, because the auxiliary edges create more than one path to a node, and the commit protocol needs to update these paths when replacing a copied region. For example, in an external binary tree whose leaves are connected with next/prev links, Occualizer needs three writes to replace a copied region—to the parent of the region's root and to the predecessor and successor nodes of the region's leftmost and rightmost leaves, respectively.

Because Occualizer cannot *physically* atomically update all edges crossing the border between a copied region and the rest of the tree, our solution is to make the update *logically* atomic, as detailed below.

Logically atomic updates. To make iterators observe updates atomically, we ensure that an iterator only moves across auxiliary edges that exist in the latest version of the tree—i.e., edges that are not part of, or cross into, a copied region which is being replaced. To achieve this, Occualizer prevents iterators from moving to a locked node, relying on the fact that every node in a copied region is locked. When an iterator positioned at node v attempts to move to v's neighbor u and finds either v or u locked, the iterator instead "resynchronizes" its position using the latest version of the tree. Specifically, the iterator searches from the root for v's predecssor or successor x (as during iterator construction), according to where the iterator was trying to move. The iterator then positions itself at x and returns x's key.

This protocol guarantees that after an updating operation *op* exposes its writes (by updating some child pointer to link

[4] Our requirement that auxiliary edges are symmetric guarantees that *op* finds every node with an auxiliary edge to the copied region.

the new version of *op*'s copied region into the tree), no iterator can move into the copied region (whether the iterator is positioned inside or outside the copied region). Attempting such a move causes the iterator to "resynchronize" itself in the updated tree, which no longer contains the copied region. The protocol is conservative, however, in that while *op* holds the copied region locked but has not yet exposed its writes, an iterator moving across an auxiliary edge (v,u) to such a locked node u will "resynchronize" superfluously, ending up at u again, as it remains reachable from the root. Such a superfluous "resynchronization" does not violate the iteration's correctness; it can be thought of as reaffirming the iterator's position in the tree, with the iterator's move being linearized before *op*'s updates.

5 Implementation

In our Occualizer prototype, we perform the input code transformations manually (following the recipe of § 4.1) and implement the synchronization library in C++ using `pthread` spinlocks. This section describes the library's implementation.

Thread-local structures. We implement the various sets using thread-local dictionary (unordered map) objects, for efficient access. The `copySet` is implemented as a pair of maps, from nodes to their copies and vice versa. The `edgeSet` is implemented as a pair of maps, an *incoming* map that maps a node to its parent and child index there, and an *outgoing* map that maps a node to a list of its children indices read. The `lockedSet` is implemented as a map from locked nodes to a boolean indicating if the lock should be released on commit. The other sets are implemented as C++ STL vectors.

Efficient `copySet` searches. We further optimize `copySet` searches by adding a flag into the node structure which is set when a node is copied. The `occ_get` method uses this flag to avoid superfluous `copySet` searches. When an operation aborts, it clears this flag from all the nodes it copied.

Optimized dictionaries. Our initial implementation used C++ STL hash tables (`unordered_map`), but we observed that they impose considerable overhead. We therefore replace them with an optimized design, which initially inserts items into a small STL vector, and if the vector becomes full, stores overflowing items in an `unordered_map`. The observation underlying this optimization is that in most tree algorithms, the thread-local data structures Occualizer maintains will be small. But for correctness, we must support worst-case behavior in which these structures may contain every node in the tree. Overall, this optimization improved the throughput of an Occualizer B+tree by a factor of two.

Correctness testing. We use a couple of testing techniques to gain confidence in the correctness of the Occualizer prototype. First, we use the linearizability checking option of the SetBench [13] benchmarking harness (§ 7.1). With this option, SetBench verifies that every successful insert/delete operation during the execution is correctly reflected in the final state of the tree—so that, for example, inserted items were not lost or inserted more than once. We test different tree sizes, to test executions with varying contention levels and thread interleavings. Second, we check that tree-structural invariants of the sequential implementations we transform (e.g., the red-black property of a red-black tree) hold, both at random times during the execution and after it completes.

6 Correctness

This section sketches the proof that trees produced by Occualizer are linearizable [56], i.e., tree operations appear to execute atomically. We consider the shared-memory system running the tree. A *state* of the system consists of the memory state (contents of each address) and the local states of each thread. In each *step* of the execution, some thread accesses memory, and as a result, its internal state and/or memory change.

Our proof works as follows. We first show that traversals are correct. That is, if $traverse(k)$ stops at node v in the concurrent execution, then at some point during its run, the memory state σ was such that had $traverse(k)$ executed atomically (from start to finish) on σ, it would also reach v. We denote this property of a state σ by $\sigma : \overset{k}{\rightsquigarrow} v$. We then use traversal correctness and Occualizer's synchronization protocol to show that if an operation *op* commits in memory state σ, then had *op* run from start to finish on σ, it would have executed exactly the same. Hence, *op* appears to execute atomically at σ.

Showing traversal correctness is hard, because traversals are unsynchronized and can observe inconsistent tree states. We solve this problem by applying the theorem of Feldman et al. [44], which says that in a concurrent tree satisfying a "forepassed" condition, unsynchronized traversals are correct. The "forepassed" condition requires (1) traversals to be single-step, which we satisfy by PR3; and (2) that if the concurrent algorithm performs a write w moving the system from state σ to σ', such that $\sigma : \overset{k}{\rightsquigarrow} v$ but $\sigma' : \overset{k}{\not\rightsquigarrow} v$ for some k and v, then v is never modified later.

Requirement (2) above follows from PR5 and the fact that Occualizer leaves written/destroyed nodes immutable (locked). There is a subtle issue, however, which is that the prerequisites are met by the sequential code, so unless we know operations in the Occualizer tree behave correctly, we cannot rely on the prerequisites. But we need traversal correctness to prove this fact, creating a "chicken and egg" problem.

We address this problem using a proof technique suggested by Feldman et al. for proving "forepassed" is satisfied [44, §7]. The technique is to prove both that "forepassed" is satisfied and that the concurrent tree is correct in tandem, inductively (on steps of the execution), so that each proof can rely on the other property holding on the execution thus far.

Accordingly, we prove correctness of an Occualizer tree assuming traversal correctness. The proof is inductive: we need to show that in every state σ, if $op(k)$ runs sequentially on σ, its post-traversal memory accesses are identical to its post-traversal memory accesses so far.

In the base case, σ is when *op*'s traversal's stops at node *v*. Traversal correctness implies that for some σ' during *op*'s execution, $\sigma' :\overset{k}{\rightsquigarrow} v$. Now, Occualizer locks *v*. Based on the induction hypothesis, a lock acquisition implies that $\sigma :\overset{k}{\rightsquigarrow} v$—i.e., *v* is on the search path for *k* "now"—as otherwise, *v* would have been locked and copied between σ' and σ and *op*'s lock acquisition would have failed. Thus, if *op* runs sequentially at σ, its traversal would reach *v*. But the lock acquisition then implies that the traversal would also *stop* at *v*, since only pointer fields in *v* could have changed, but *op* verifies that any pointer it read did not change after locking *v*.

The inductive step is similar. We are in state σ with *op* successfully locking some node *u*. Inductively, we know that (1) in some σ' in the past, the state of the tree was such that *op*'s execution on it would have lead it to its current local state, and (2) any modifications made to the tree since σ' have only moved it through consistent states. Moreover, due to *op*'s locking, these changes in tree state do not change the nodes and edges *op* has observed post-traversal. It follows from PR4 that if we run *op* in state σ, it will behave exactly the same. This concludes the overall proof, when σ is the state in which *op* commits its writes.

7 Evaluation

We compare Occualizer trees to mechanically-crafted trees (§ 2) and to hand-crafted trees, with respect to scalability, throughput, and memory use. We first evaluate the trees on workloads with different amounts of writing operations (§ 7.1). We then focus on an Occualizer B+tree: we compare it as an index in the STOv2 main-memory database to the default Masstree index (§ 7.2), and analyze its overhead (§ 7.3).

Transformed trees. We use Occualizer to create concurrent versions of the following sequential trees:

- **B+tree**: An improved version of the optimized STX in-memory B+tree [7] taken from the `tlx` library [8].
- **Radix**: An implementation of a radix tree (trie) [79]. The code follows the description of Linux's radix tree [24].
- **RB**: A red-black tree [32]. The code is the sequential implementation used in Synchrobench [47].

We refer to a transformed tree implementation *T* as *occ[T]*.

Experimental platform. We use a dual-node NUMA server. Each node has a 14-core Intel Xeon Gold 6132 (Skylake) processor and 96 GB of DDR4-2666 DRAM. Hyper-Threading and Turbo-Boost are disabled. Threads are split between the nodes and memory allocation is interleaved across the nodes. Code is compiled using GCC 8.3.0 and linked with the `jemalloc` [37] multi-threaded memory allocator. Reported numbers are averages of 10 runs; all measurements are within $\pm 5\%$ of the average.

7.1 Contention benchmarks

We compare Occualizer's trees to mechanically- and hand-crafted trees on workloads with increasing amounts of writing operations.

Trees. We compare to the following trees, which unless noted otherwise are mechanically-crafted from the same sequential code used for Occualizer:

- **Global-Lock**: Created by serializing operations with a global lock.
- **GCC-TM** [1]: Created by wrapping operations in transactions using GCC's transactional memory (TM) support. The underlying TM algorithm uses optimistic concurrency control with eager locking and tracks conflicts at word granularity.
- **CX** [26]: Created with the CX universal construction, which produces wait-free operations and does not serialize read-only operations. It is the fastest wait-free universal construction we are aware of, although it still copies the entire data structure. We use the original authors' implementation [27].
- **COW** [5]: Created with a COW-based approach inspired by Ben-David et al., which produces lock-free writing operations and wait-free read-only operations, without serializing read-only operations. We implement COW ourselves.
- **Hand-Crafted:** We use hand-crafted designs of comparable algorithms, as we are not aware of concurrent implementations of exactly the same trees. We compare occ[RB] to SnapTree, a concurrent AVL tree with optimistic (lock-based) synchronization [11]. We compare occ[Radix] to a lock-free version from the same repository [79]. We compare occ[B+tree] to Brown's lock-free B-slack tree [12] (a B-tree variant). We use the original authors' implementations.

Our tree selection covers a spectrum of mechanically- and hand-crafted synchronization techniques. While some of these techniques do not form an "apples to apples" comparison with Occualizer's optimistic lock-based synchronization (e.g., due to being lock- or wait-free), the point is that they represent the space of currently available mechanical techniques.

Workloads. We populate the tree with 64 M uniformly random 8-byte keys and then run a workload for 3 seconds. Each workload has a different mix of operation types (Table 3). Our workloads are inspired by the standard Yahoo! Cloud Serving Benchmark (YCSB) [23] workloads, which are designed to simulate real-world application workloads, but differ in that (1) we replace updates with insertions and do not test range

Workload	Description
R-100	100% lookups (YCSB-C)
R-97	97% lookups, 3% insertions (≈ YCSB-B)
R-75	75% lookups, 25% insertions
R-50	50% lookups, 50% insertions (≈ YCSB-A)

Table 3: Contention workloads.

queries, as not all implementations support these operations; and (2) we use more levels of writing operations, for more fine-grained insight. Experiments run under SetBench [13], a benchmarking harness for concurrent C++ dictionaries that provides epoch-based memory reclamation.

Throughput. Figures 4–6 show the aggregate throughput for each workload with varying numbers of threads for the B+tree, radix, and red-black tree variants, respectively. All variants except Global-Lock scale on the read-only workload (R-100), although GCC-TM's throughput drops for RB at 24–28 cores. But for workloads with any level of writing operations, only Occualizer and the hand-crafted trees scale, with throughput of mechanically-crafted trees typically flatlining at low core counts.[5]

The mechanically-crafted trees do not scale due to suboptimal synchronization. In CX and COW, all writing operations are serialized, although serialization in COW, which is done with a CAS to the tree root, is significantly faster than in CX, where writing operation participate in a helping scheme and may copy the entire data structure. In GCC-TM, the problem is its conservative version of optimistic synchronization, which retries any transaction if any node it reads is updated before the transaction commits. Thus, for example, GCC-TM breaks down on RB—where tree rebalancing writes to the top of the tree—much earlier than on Radix.

Compared to the hand-crafted trees, Occualizer achieves comparable or better throughput when the level of mutation is low (R100-R97). The cases in which Occualizer is faster are due to differences in the underlying algorithms, which manifest when synchronization overhead is low. This effect demonstrates the power of Occualizer's approach, which removes the difficulty of adding synchronization to a tree from consideration, and thereby allows focusing on the (sequential) "quality" of the tree, i.e., how fast it is to search.

As mutations increase (R75-R50), however, synchronization becomes the dominating factor and Occualizer significantly underperforms the hand-crafted trees. The reason is that Occualizer writing operations are slower than in the hand-crafted trees, due to bookkeeping and copying overhead (see § 7.3), and so as the proportion of mutations grows, overall throughput degrades.

[5]The only exception is GCC-TM on Radix. In Radix, the tree only grows downwards, so any non-null pointer read during a traversal is immutable. GCC-TM thus rarely aborts transactions even with moderate mutation levels, and so achieves high throughput.

Tree	Throughput relative to hand-crafted	R-100	R-97	R-75	R-50
B+tree	Occualizer	0.79	0.77	0.64	0.72
	Best mech-crafted	0.82	0.38	0.05	0.05
	Gap shrink	**—**	**2.01**	**12.28**	**13.54**
Radix	Occualizer	1.08	0.84	0.73	0.50
	Best mech-crafted	1.15	0.90	0.74	0.36
	Gap shrink	**—**	**0.93**	**0.99**	**1.38**
RB	Occualizer	1.01	0.90	0.31	0.19
	Best mech-crafted	1.02	0.24	0.04	0.03
	Gap shrink	**—**	**3.78**	**8.64**	**6.08**

Table 4: Throughput difference between Occualizer and the best result of the mechanically-crafted trees at 28 cores, for each workload.

Tree	B+tree	Radix	RB
occ[·]	2.14 GB	2.10 GB	3.12 GB
Global-Lock	0.91×	0.93×	0.93×
GCC-TM	0.91×	0.96×	0.95×
CX	13.5×	13.18×	13.03×
COW	1.02×	1.18×	1.04×
Hand-Crafted	1.12×	0.97×	1.01×

Table 5: Memory use at 28 cores (R-50), normalized to Occualizer's.

The takeaway is that Occualizer significantly shrinks the performance gap between mechanically- and hand-crafted trees in workloads with mutations. Table 4 reports this gap, and by how much Occualizer shrinks it. Overall, Occualizer shrinks the gap by up to 13.54×, 1.38×, and 8.64× for B+tree, Radix, and RB, respectively.

Memory use. Node copies made by an Occualizer tree may increase memory use compared to its sequential version, as a function of how quickly old nodes are reclaimed. To quantify this effect, Table 5 shows peak memory use for each tree in the R-50 workload (results for other workloads are similar). Both Occualizer and COW indeed use more memory than the sequential baseline (captured by Global-Lock), but Occualizer's LCOW increases memory use by 7%–9% whereas COW, which copies entire paths, adds an overhead of 11%–26%. In contrast, CX uses about 14× the memory of Global-Lock. The reason is that CX maintains multiple replicas of the data structure, so that read-only operations can read from a replica and avoid being serialized. Results of the hand-crafted algorithms are shown only for completeness, as they are not implementations of the same algorithm.

7.2 Full-system benchmark

We add occ[B+tree] as the index data structure in the STOv2 main-memory database system [58], and compare the result to the default index, Masstree [71], a hand-crafted concurrent

Figure 6: Throughput of RB (red-black tree) variants for workloads with increasing amounts of mutation.

tree combining aspects of B+trees and tries.[6]

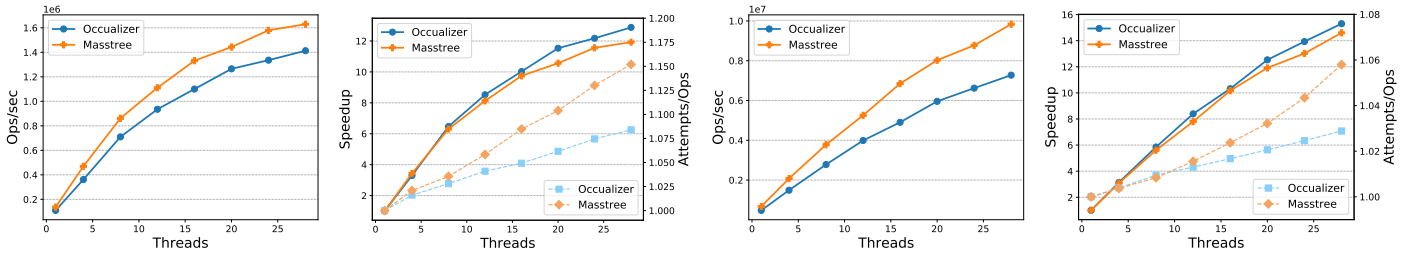
STO provides serializable transactions. Transactions are specified via C++ programs accessing STO's transactional interface. STO's transaction concurrency control is tightly coupled with Masstree, as it relies on Masstree node version numbers to detect and block certain anomalies. To integrate occ[B+tree] into STO, we therefore implement an equivalent versioning scheme in the `tlx` B+tree.

Workloads. We evaluate two transactional workloads, TPC-C and Voter. TPC-C is the industry standard benchmark for evaluating the performance of online transaction processing (OLTP) systems [28], by simulating an order processing application. We use a database with one warehouse, 100,000 items, and run the full mix of all TPC-C transactions. This workload performs index range queries. Voter is a benchmark that simulates a phone-based voting application. It consists of many short transactions and does not perform range queries.

Results. Figure 7 shows the throughput (committed transactions per second) and scalability of the system for both workloads, measured over a 10-second run. Scalability is measured by normalizing the throughput obtained with each index to the single-threaded throughput obtained with that index. On both workloads, occ[B+tree] is slower than Masstree, but has better scalability. As a result, the performance gaps between them shrinks as more threads are added: from a single-threaded difference of 22% and 29% for TPC-C and Voter, respectively, to a difference of 12% and 26% at 28 threads.

The reason behind occ[B+tree]'s better scalability is that Occualizer's optimistic synchronization protocol causes fewer operations to abort and retry than Masstree's protocol (which is also optimistic). Masstree uses per-node version counters to guarantee that searches observe only consistent node states. In Masstree's protocol, any operation—including a lookup—might abort and retry if its version checking indicates it may

[6] We use a B+tree here because it is closest algorithmically to Masstree, which is a B+tree variant. Comparing to, say, a red-black tree would not be meaningful, because Masstree outperforms a red-black tree for reasons unrelated to concurrency control (e.g., its much "shallower" tree structure).



(a) TPCC throughput. (b) TPCC speedup. (c) Voter throughput. (d) Voter speedup.

Figure 7: Throughput and speedup (throughput normalized to single-threaded throughput) of occ[B+tree] vs. Masstree in STOv2. Speedup plots also show the average number of attempts required to complete an operation (right Y axis).

Enabled methods	Relative throughput
None (call overhead)	93%
`occ_start`	87%
+ `occ_finish`	81%
+ `occ_get`	53%
+ `occ_set` = occ[B+tree]	40%

Table 6: Single-threaded throughput of occ[B+tree] relative to sequential B+tree (R-50 workload) as Occualizer's synchronization functionality is gradually enabled.

have observed an inconsistent node state. In contrast, Occualizer relies on LCOW to guarantee that observed nodes are consistent, and on the "forepassed" condition [44] to guarantee correctness of searches that traverse inconsistent tree states. In Occualizer's protocol, read-only lookups never abort and retry—only update operations do. As a result, as Figures 7b and 7d show (on the right Y axis), the average number of attempts required to complete an operation is larger in Masstree than in occ[B+tree]—and the difference grows with the number of threads.

7.3 Overhead analysis

To break down the sources of Occualizer's performance overhead, we evaluate the throughput impact of making the transformation but using a no-op implementation of each library method, then gradually adding in each method's actual implementation. We use single-threaded execution for this evaluation, because an Occualizer tree does not run correctly when any of the methods are disabled.

Table 6 shows the results, comparing occ[B+tree] to the original sequential B+tree, on the R-50 workload. The lion's share of overhead is due to `occ_get` and `occ_set`, which interpose on node field accesses. The impact of `occ_get` is $\approx 2\times$ that of `occ_get`, as reading fields is more frequent. Invoking the methods, `occ_start`, and `occ_finish` each degrade throughput by 6–7% points.

8 Conclusion

This paper presented Occualizer, a mechanical transformation for adding scalable optimistic synchronization to a sequential search tree implementation. Occualizer's specialization to trees enables designing a synchronization protocol that does not suffer from the limitations of transactional memory and universal constructions. Overall, Occualizer trees shrink the performance gap between these automatic transformations and hand-crafted trees by up to 13×.

Occualizer is limited, however, in that it applies only to sequential search trees that satisfy its prerequisites. Relaxing the prerequisites and automating the verification that an input tree satisfies them are interesting future directions, as is reducing the overhead of Occualizer's synchronization library. Our current Occualizer prototype also requires some manual steps to transform the input tree; automating these steps is an ongoing effort.

Occualizer's code is available at https://github.com/tomershanny/Occualizer.

Immortal Threads: Multithreaded Event-driven Intermittent Computing on Ultra-Low-Power Microcontrollers

Eren Yıldız

Kasım Sinan Yıldırım
University of Trento, Italy

Abstract

We introduce Immortal Threads, a novel programming model that brings pseudo-stackful multithreaded processing to intermittent computing. Programmers using Immortal Threads are oblivious to intermittent execution and write their applications in a multithreaded fashion using common event-driven multithreading primitives. Our compiler fronted transforms the stackful threads into stackless threads that waste a minimum amount of computational progress upon power failures. Our runtime implements fair scheduling to switch between threads efficiently. We evaluated Immortal Threads on real hardware by comparing it against the state-of-the-art intermittent runtimes. Our comparison showed that the price paid for the Immortal Threads is a runtime overhead comparable to existing intermittent computing runtimes.

1 Introduction

Advancements in low-power electronics and energy harvesters exploiting ambient sources (e.g., solar [20], indoor light [21], and radiofrequency [27]) paved the way for sustainable systems that can work without batteries. Recent studies have demonstrated promising examples of these systems, such as body implants [23] and long-lived wearables [51], where continuous power is not available and changing batteries is difficult. There are several microcontroller-based batteryless computing platforms (e.g., WISP [46], Flicker [24], Camaroptera [42] and Engage [16]) developed by the researchers. Instead of a battery, these platforms comprise a capacitor that powers all hardware components, including the ultra-low-power microcontroller (MCU), sensors, communication circuitry, and other peripherals. When a batteryless platform consumes the energy stored in its capacitor, it turns off due to a power failure. The platform charges its capacitor until the stored energy exceeds an operating threshold, which turns on the platform again. Therefore, the software on batteryless platforms runs *intermittently* due to frequent power failures and charge-discharge cycles.

Each power failure clears the CPU registers and the volatile memory during an intermittent execution. Hence, the computation might not progress forward since the control returns to the application's entry point [11]. Moreover, power failures may cause data stored in non-volatile memory to be partially updated, leading to memory inconsistency [43]. The prior art proposed mainly two approaches to overcome these issues. The first one is to place checkpoints in program source [6, 8, 26, 28, 30, 31, 33, 36, 44, 53], which store their continuation (i.e., the control state including the registers, stack and global data) in non-volatile memory. After a power failure, control resumes from the latest successful checkpoint location. Another approach is to employ a task-based programming model [10, 19, 25, 34, 37, 38, 45, 54], which requires programmers to implement their programs as a collection of tasks and transitions between them. This model eliminates the cost of checkpoints, since the all-or-nothing semantic of tasks, defined by the programming model, means that a function pointer to the current task is enough to represent the continuation of the program, which makes saving and restoring it from non-volatile memory extremely cheap [10].

Despite efficiency, the task-based model poses significant problems in developing *event-driven* applications [17, 32]. This situation prevents the widespread adoption of intermittent systems since most sensing applications are event-driven.

P1-Event Handling Complexity: Event handling, in general, is implemented in the form of state machines that require explicit management of states and transitions [18]. Implementing event-driven applications using the task-based model requires programmers to manage (i) task partitioning, (ii) task-based control flow, (iii) event states, and (iv) state transitions simultaneously. This situation creates an excessive cognitive burden concerning event-driven intermittent computing.

P2-Limited Concurrency: Existing event-driven task-based systems (e.g., [45, 54]) cannot fully support preemptive threads. Since tasks execute atomically, they voluntarily yield the control, and other tasks cannot preempt them. Moreover, tasks cannot block on events, trigger new threads of execution, and notify the completion of event processing. Therefore, pro-

grammers need to partition long-running computation (e.g., compression [29]) into a set of tasks to avoid missing events.

P3-Wasted Progress: Partial execution of tasks (due to power failures) leads to loss of computational progress within tasks since tasks have all-or-nothing semantics. This issue increases event response time, which is critical for event-driven systems. Recent work proposed loop continuation to preserve computational progress after each loop iteration by selectively *violating* the task-based model [22] (see Sections 1 and 6).

Problem Statement. Considering the mentioned problems, we seek a programming model that:

(Req.-1) removes the cognitive load of the task-based model while retaining its lightweight characteristics;

(Req.-2) brings the flexibility of preemptive multithreaded programming to intermittent systems;

(Req.-3) enables progress from the point where a thread has been interrupted due to a power failure.

Challenges. Fulfilling these requirements is not trivial. To satisfy (Req.-1), Kortbeek et al. [31] proposed giving up the task-based model and using lightweight and sparse checkpoints that save all registers and only the memory segments modified by the program. However, to fulfill (Req.3), checkpoints need to be placed almost at each line in the code. This situation creates an unmanageable overhead even with these lightweight checkpoints. Finally, concerning (Req.-2), we note that it is not enough to use a checkpoint runtime on top of an existing multithreaded OS, since OS primitives such as mutexes, semaphores, as well as interrupt handling, must be implemented taking the intermittence into account, to avoid memory consistency issues due to partial updates.

Contributions. In this paper, we introduce Immortal Threads that brings *pseudo-stackful* preemptive multithreaded programming model to event-driven intermittent computing. Programmers using Immortal Threads are oblivious to intermittent execution and write their applications in a multithreaded fashion using plain C without tasks (see Figure 1). Immortal Threads compiler fronted transforms stackful threads into stackless threads, inserts ultra-lightweight checkpointing mechanisms under the hood to minimize wasted progress, and maintains the memory consistency. The Immortal Threads library implements a preemptive scheduler to switch between threads and provides common event-driven primitives such as semaphores and blocking event wait operations. Our real-world experiments showed that Immortal Threads has runtime overhead comparable to the prior art intermittent runtimes InK [54], Alpaca [34] and TICS [31]. Moreover, during frequent power failures, Immortal Threads reduced execution time and wasted work by up to 40% and 90%, respectively.

In summary, Immortal Threads introduces the following contributions:

(1) Preemptive Multithreading: For the first time, we enable preemptive multithreading for event-driven intermittent systems, which provides programming flexibility and eliminates the cognitive burden of task-based programming.

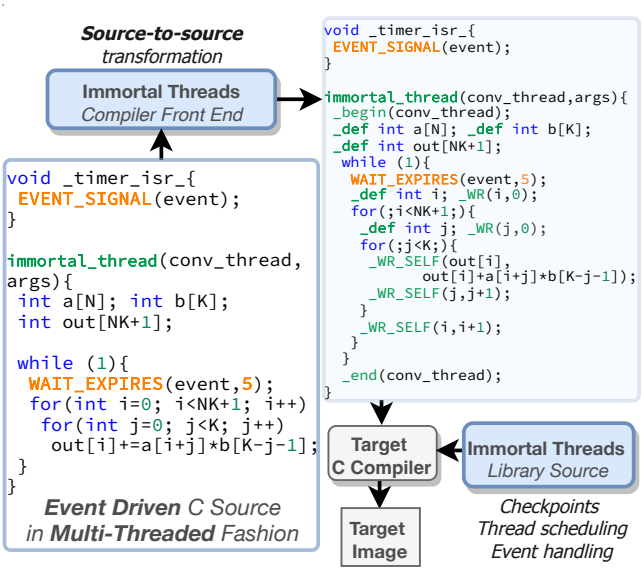

Figure 1: With Immortal Threads, programmers write applications in a multithreaded fashion without concerning intermittent execution, and focus **only** on *event-driven* aspects.

(2) Almost-Free Checkpoints: We propose a novel checkpointing technique, inspired by Dunkels et al. [18], that saves *only* the program counter rather than all registers and memory.

(3) Just-in-time Privatization: We propose a novel technique that eliminates the need for creating static versions of non-volatile program variables to keep memory consistent.

(4) Micro Continuation: Thanks to almost free checkpoints and just-in-time privatization, threads always progress from their latest memory update, and they do not waste computational progress upon power failures.

(5) Open-source Release: We release Immortal Threads as a C library with compiler support (via [55]) for the widespread adoption of intermittent computing.

2 Background and Related Work

Batteryless computing platforms comprise ultra-low-power MCUs with embedded non-volatile memory. For instance, MSP430FR5969 [48], one of the mainstream MCUs used in batteryless platforms, has 64kB of FRAM [50] and 2kB of SRAM memory. FRAM stores data that will persist upon power failures. The key challenges of intermittent computing are the loss of computational progress after power failures and memory inconsistency issues. Power failures reset the MCU, and the control returns to the application's entry point. Moreover, power failures might keep persistent variables (i.e., variables maintained in non-volatile memory) partially updated and in an inconsistent state. Code blocks with WAR

(Write-After-Read) dependencies on persistent variables are not idempotent, since they might produce different results when the MCU re-executes them after a power failure [43]. For example, assume that `x` is a persistent variable and the program executes `{x++; vector[x]=v;}`. A power failure after `x++` re-executes `x++` and leads `x` to be increased twice.

2.1 Intermittent Computing Approaches

The prior art focused on the forward progress and memory consistency aspects of intermittent execution but also considered the timeliness of data processing and event-driven concurrency.

Checkpoints. In energy-guided checkpointing, the device continuously monitors the capacitor to perform a checkpoint on imminent power failure, for example, as in Hibernus [6]. However, voltage monitoring is quite expensive in terms of energy consumption [52]. In software-only checkpointing (e.g., DINO [33], Chinchilla [36] and TICS [31]), the program source is instrumented with checkpoints, either by a programmer or a compiler. The checkpoints are double-buffered in non-volatile memory to prevent the latest consistent checkpoint from being superseded immediately by an inconsistent (i.e., partially updated) checkpoint. Moreover, a compiler analysis is required to determine the modified persistent variables between two checkpoints and create their versions to prevent violations of idempotency upon resumption [33]. After a power failure, the checkpointing runtime restores the versions that isolate the code from partially updated versions, and the control resumes from the latest successful checkpoint location. There are several other works that aim to reduce the overhead of checkpoints [3, 4].

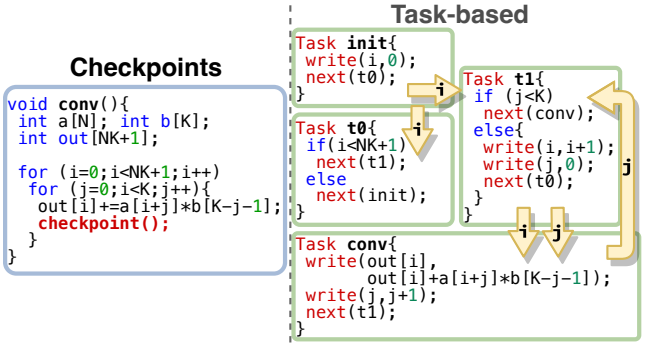

Figure 2: The task-based and checkpoint-instrumented versions of a 1-D convolution code. Arrows among the tasks denote channels that hold versions of task-shared variables.

Task-based Model. This model eliminates the overhead of checkpoints by proposing tasks that do not have a restoration cost. Tasks have read-only inputs and write-only outputs (called channels [10]), which are maintained in non-volatile memory separately. Tasks are inherently idempotent since separate channels avoid WAR dependencies in the task body. Runtimes execute tasks atomically with all-or-nothing semantics. The task-based model employs static multi-versioning by creating multiple copies of the data distributed over the inputs and outputs of the tasks (see Figure 2). Alpaca [34] avoided multi-versioning by proposing *privatization* that creates local copies of the task-shared persistent variables. Each task loads its local copies with the original values, manipulates local copies, and commits them to the original locations upon completion.

Timely Execution. Data (processing) might expire due to charging times during intermittent execution. Mayfly [25], InK [54] and CatNap [37] proposed extensions to the task-based programming model to express timely data constraints and time-critical code. TICS [31] added extensions to checkpointing systems to enable timely data processing.

Event-driven Intermittent Computing. InK [54] proposed task threads, which are triggered by events to execute a sequence of tasks. Coati [45] handles the event-driven concurrency issues by serializing concurrent interrupts with the tasks to keep the shared persistent state consistent. CatNap [37] isolated energy for reliable intermittent execution of periodic events, which are time-critical tasks in a task-based model. TICS [31] does not support event-driven constructs, but it can checkpoint event-driven legacy code—though these checkpoints do not guarantee the semantically correct operation [31] (see Section 5.1).

2.2 Embedded Concurrency Models

Several studies proposed different concurrency models for embedded systems [2, 7, 29, 32, 32, 40, 41]. We classify the main differences in these models into two spheres: whether the concurrency is cooperative or preemptive, and whether the concurrency units (i.e., "threads") are stackful or stackless.

Concurrency Approaches. Stackful concurrency has programming expressiveness, since continuations can be set anywhere in the thread's call stack by preserving the local variables [29]. It is costly since each thread requires its own stack, and thread preemption requires storing all registers into the continuation. In stackless concurrency, threads share the same stack, and local variables are not maintained when a thread blocks. As an example, Protothreads [18] implements a stackless cooperative concurrency model. Consequently, a protothread can yield control only within its main body, not within the body of a function it calls.

Concurrency and Checkpoints. The former sets continuations (a.k.a. execution context) to switch context among threads, while the latter sets them to restore the program state after reboot. Therefore, from the perspective of concurrency, software-only checkpointing systems are non-preemptive, in the same way stackful threads voluntarily set a continuation and yield control. Besides, energy-guided checkpointing systems are preemptive since they stop thread execution and set a

Intermittent Runtimes	Main Features							Timely, Event-Driven Intermittent Program Development

Table 1: A comparison of the main features of Immortal Threads with the relevant intermittent computing approaches.

continuation upon an imminent power failure. Intuitively, the task-based model is a form of static non-preemptive stackless checkpointing system. Static and non-preemptive because task decomposition is done at programming time and checkpoints are taken only at task boundary, and stackless because only the active task's function pointer is checkpointed. Similar to stackless threads, the low-overhead of the task-based model comes at the cost of imposing a programming model with a high cognitive load.

2.3 Drawbacks of Prior Works

Table 1 presents a comparison of the main characteristics of this work and the existing intermittent computing approaches.

1- Event-handling Complexity with Tasks. The task-based implementation of a small deep neural network (DNN) inference in Gobieski et al. [22] has 18 tasks and 61 control flow declarations. Implementing an event-triggered state machine using tasks is even more complex. For example, a low-level radio driver depicted in Dunkels et al. [18, Table 1] has 26 explicit states and 32 state transitions. Implementing this driver using existing task-based event-driven intermittent runtimes [37, 45, 54] requires handling task partitioning and control flow, states, and transitions simultaneously, which is an unmanageable cognitive load.

2- Programming Model Violations. Power failures lead to the waste of computational progress (and energy) when they prevent the execution from reaching the successive checkpoint or the end of the current task. For example, a power failure in the middle of the convolution task while performing the DNN inference in Gobieski et al. [22] might lead to the loss of almost 150000 multiplications. Prior work proposed loop continuation [22] that avoids wasted work by allowing tasks to directly modify non-volatile memory in a loop nest, which is a violation of the task-based model.

3- Limited Concurrency. None of the existing intermittent systems supports the stackful preemptive concurrency model. As Yildirim et al. [54] comments, checkpointing an existing preemptive multi-threading operating system is not practicable due to the inefficiency issues and the memory inconsistencies caused by intermittence-unaware interrupt handling. Similar concerns hold for existing works (e.g., [41]) that can transform stackful threads into stackless continuations for continuously powered systems. For the sake of efficiency, many existing work on intermittent computing utilizes a lightweight stackless cooperative concurrency approach via tasks [37, 45, 54].

3 Immortal Threads: Overview

Immortal Threads consists of a programming interface, a compiler frontend, and a small run-time library, which bring *pseudo-stackful* preemptive multithreading model into intermittent computing. Programmers using Immortal Threads are oblivious to intermittent execution, and they develop their programs in a multithreaded fashion as they are programming a continuously powered system. The compiler frontend transforms the source code into stackless continuations that handle intermittency without programmer intervention.

As depicted in Figure 1, the main building block of an intermittent event-driven application is the thread of execution that continues running from where it left upon power failures, which we call *immortal thread*. Unlike the task-based model (which requires explicit idempotent code generation via task splitting), the unnecessary details of the intermittent execution are not visible to the programmers. The duties of the programmers are to (i) identify the events in their system, (ii) design their systems as a set of threads that are the handlers of these events, (iii) manage the necessary state management and state transitions, and (iv) consider timing aspects during event-driven intermittent execution. It is worth mentioning that duties (i)–(iii) are identical to the steps followed to develop event-driven applications in continuously powered systems [17, 32]. Differently, in (iv), programmers embed (if required) the necessary program logic to check event expiration due to the delays stemming from the charge/discharge cycles during the intermittent execution.

Language Construct	Explanation
`_SEM_WAIT(sem)/_SEM_POST(sem)`	wait on/post semaphore **sem**
`_SEM_POST_ISR(sem)`	post semaphore **sem** in an ISR
`_EVENT_SET_TIMESTAMP(e, t)`	sets the timestamp of **e** as **t**.
`_EVENT_GET_BUFFER(e)`	returns a pointer to the data buffer of **e**
`_EVENT_GET_TIMESTAMP(e)`	returns the timestamp of **e**
`_EVENT_WAIT(e,buf)`	blocking wait on **e** w/o expiration time, returns the event data via **buf**
`_EVENT_WAIT_EXP(e, buf, t)`	blocking wait on **e** w/ expiration time **t**, returns the event data via **buf**
`_EVENT_SIGNAL(e)`	signals the event and unlocks the thread waiting on the event

Table 2: Immortal Threads core language constructs.

Language Construct	Explanation
`_begin(name)/_end(name)`	immortal body start/end
`_def/_gdef`	pseudo local variables and persistent global variables
`_WR(arg,val)`	**arg** = **val** (variable assignment operations w/o W-A-R, e.g., `x=5`)
`_WR_SELF(type,arg,val)`	**arg** = **(type) val** (variable assignment operations w/ W-A-R, e.g., `x++`)
`_call(name,...)`	call immortal function **name** with appropriate arguments

Table 3: Main interfaces used by the compiler frontend.

3.1 Programming Model

Immortal Threads supports the common multithreaded event-driven language constructs, as presented in Table 2.

Timely Events and Blocking Wait. Immortal Threads provides an event primitive that builds a bridge between threads and ISRs (interrupt service routines). Threads can block (i.e., wait) on events using `_EVENT_WAIT` and `_EVENT_WAIT_EXP` interfaces, which suspend threads until the relevant event occurs. Signaling an event via the `_EVENT_SIGNAL` interface unblocks the waiting thread to continue its execution. Immortal Threads cannot guarantee event handling deadlines, but programmers can provide an expiration time to catch outdated events and prevent unnecessary event processing. To detect event expiration, programmers can use `_EVENT_WAIT_EXP`, which subtracts the current time from the timestamp of the event. This interface unblocks the corresponding thread if the result of the subtraction is less than the expiration time provided by the programmer. Blocking wait interfaces also pass a pointer to the event data to let the waiting thread copy these data into its thread-local buffer.

Wait and Post Semaphores. Immortal Threads provides a binary semaphore implementation for inter-thread signaling. A thread can block (wait) on a semaphore using the `_SEM_WAIT` interface. Another thread can post this semaphore using `_SEM_POST` interface to unblock that thread. ISRs can also post semaphores using a separate interface `_SEM_POST_ISR`.

ISRs and Event Signaling. In Immortal Threads model, interrupts have *all-or-nothing* semantics. ISRs interface with the hardware, obtain the data, and deliver it to threads. Each ISR has an associated `event` structure. When an interrupt (i.e., an event) occurs, the ISR obtains a pointer to the event data buffer via the `_EVENT_GET_BUFFER` interface. ISRs store the event data (e.g., the sensor reading) into this buffer and set the event timestamp via `_EVENT_SET_TIMESTAMP`. ISR commits these changes atomically and notifies the waiting thread via the `_EVENT_SIGNAL` interface. A power failure up to this point might lead to an event loss. Otherwise, the notified thread will obtain the event data and perform the necessary processing.

```
_immortal_thread(thread1){
 /* the main thread body */
 _begin
 /* variable declerations */
 _def uint8_t cnt;
 ...
  while(1){
   _EVENT_WAIT(event);
   /* necessary actions */
   _WR_SELF(uint8_t,cnt,cnt+1);
   ...
   /* notify thread 2 */
   _SEM_POST(sem);
   ...
  }
 _end
}
```

```
void _timer_isr_{
 /* notify event */
 _EVENT_SIGNAL(event);
}
```

```
_immortal_thread(thread2){
 /* the main thread body */
 _begin
 ...
  while(1){
   _SEM_WAIT(sem);
   /* necessary actions */
   _call(other_function);
   ...
  }
 _end
}
```

Figure 3: Output of the compiler frontend. Initially `thread1` and `thread2` are blocked. The timer ISR signals the event and unblocks `thread1` that unblocks `thread2`.

3.2 Execution Model and Multi-threading

Immortal Threads employs a multithreaded preemptive execution model by implementing a simple but efficient Round-Robin scheduling mechanism. Threads are initially blocked on events, waiting for ISRs to signal them. When an interrupt is triggered, the corresponding ISR signals an event, and the event handler thread wakes up and performs the computation. Therefore, there might be several threads running simultaneously during the execution of programs. Thanks to the compiler frontend, Immortal Threads manages the forward progress and memory consistency without programmer intervention.

3.3 Pseudo-Stackful Threads

The Immortal Threads compiler frontend performs a source-to-source transformation to convert the stackful threads into stackless continuations by employing almost-free checkpoints and just-in-time privatization. To do so, it uses the interfaces in Immortal Threads library (see Table 3). After the compiler pass, the transformed source code is linked with the Immortal Threads library. Figure 3 presents the output of the compiler frontend for a multithreaded event-handling example.

The compiler frontend instruments all programmer-defined functions, including thread entry points, to create immortal

functions. More specifically, an immortal thread is a concurrency unit whose entry point is an immortal function.

Instrumentation of an Immortal Function. The compiler frontend instruments all local variables by using `_def` followed by the data type and name (i.e., the ordinary way of variable declaration in C language). This operation converts programmer-defined local variables to persistent static variables with local scope. Compiler frontend instruments variable manipulations using `_WR` and `_WR_SELF` interfaces to ensure memory consistency. These interfaces manage WAR dependencies, perform checkpoints, and keep functions idempotent. `_WR` manipulates variables when the update operation does not include any WAR dependency. `_WR_SELF` manipulates variables when there is a WAR dependency during the update operation. For example, the Immortal Threads library implements the assignment `{x=0}` using `_WR(x,0)` since there is no WAR dependency during this update. For `{x=x+5}`, the necessary operation becomes `_WR_SELF(uint32_t,x,x+5)` since the variable `x` is read first and then written. Immortal Threads provides different interfaces for variable manipulations with WAR dependencies to implement *just-in-time privatization*, which we will explain in Section 4. Additionally, calls to other immortal functions in an immortal function body are instrumented with the `_call` interface, which makes setting micro-continuations inside called immortal functions possible. Finally, the compiler frontend also instruments the function body by wrapping it using `_begin/_end` block. When a thread starts running for the first time, the first instruction in its entry immortal function is executed. If a power failure interrupts thread execution, the thread continues from the last checkpoint performed by the underlying Immortal Threads runtime, which can also be deep down in the call stack.

Thread Preemption. Unlike common preemptive models, where the continuation is saved on preemption, Immortal Threads saves the continuation (i.e., checkpoint) on each memory update. This guarantees the idempotence of the execution until the next checkpoint. Therefore, the scheduler can simply interrupt the execution of a thread and switch to the other one.

4 Implementation of Immortal Threads

We implemented Immortal Threads library mainly using standard C macros and preprocessor directives. The library also includes functions for system initialization and scheduling operations. We implemented the source-to-source transformation using the LLVM & Clang LibTooling library [1].

Target Hardware. The current implementation of Immortal Threads library targets MSP430FR5994 [48] microcontroller from Texas Instruments that is equipped with 256KB FRAM and 8KB SRAM memory. Immortal Threads library uses a persistent time circuitry (which keeps track of time across power failures [14, 15]) to handle events and data expiration. It is worth mentioning that a persistent timekeeper is not a mandatory requirement for Immortal Threads runtime since it will work even without checking event time constraints. On the other hand, de facto intermittent computing platforms, e.g., Flicker [24], already include a persistent timekeeper circuit.

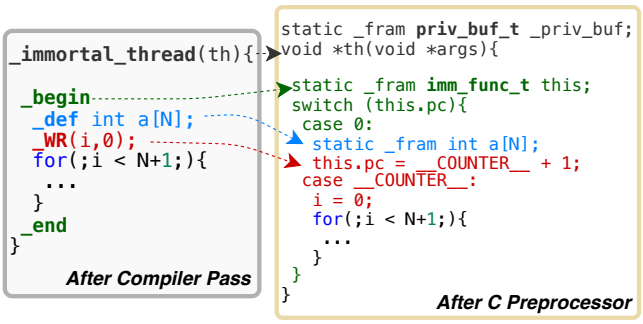

Figure 4: The structure of a source file after C preprocessor.

4.1 Immortal Function and Threads

Each immortal function (which can also be the entry point of a thread) maintains `imm_fn_t` structure that comprises a program counter (`pc`) to enable *micro continuations*, and a pointer to the same structure (`callee`) for calling other functions (via `_call`). For the *just-in-time privatization* operations, a privatization buffer (represented by `priv_buf_t`) is also maintained. All local variables are allocated in non-volatile memory as variables with static storage duration, which makes immortal threads (based on immortal functions) stackless. Figure 4 presents a sample output of the C preprocessor, which depicts how the privatization buffer (`__priv_buf`) and the function structure (`this`) are allocated in non-volatile memory.

4.2 Enabling Micro Continuations

Threads can be interrupted at any time by power failures, and their execution continues from the latest checkpoints. Immortal Threads library performs an almost-free checkpoint at each memory update via the `_WR` and `_WR_SELF` interfaces. Memory updates that lead to WAR dependencies (i.e., `_WR_SELF`) require *just-in-time privatization* to keep memory consistent.

Almost Free Checkpoints. Figure 4 presents how `_begin/_end` blocks (which are just C macros) are transformed into `_switch/_case` structures in C. Since the `imm_fn_t` structure for each immortal function is statically allocated, the `pc` field of is initialized with zero. Therefore, a function initially starts by executing its first case block `case 0:`. The almost-free checkpoint is just adding a new case statement at compile-time and modifying `pc` of the function. We implemented almost-free checkpoints using the standard GNU C preprocessor macro `__COUNTER__`, whose value increments each time the preprocessor encounters it. We implemented the core checkpoint code as follows:

```
#define _CP() \
    this.pc = __COUNTER__ + 1; case __COUNTER__:
```

If the thread (in which the function is running) restarts, the execution will continue from the `case` statement of the last checkpoint. However, only checkpoints are not sufficient to keep memory consistent. As indicated previously, `_WR` performs single-memory updates that do not lead to WAR dependencies. However, a sequence of operations `_WR(x,y);` `_WR(y,z);` form a WAR dependency. Therefore, we need to take a checkpoint before each memory update operation using `_WR`. We implemented this macro as follows:

```
#define _WR(arg,val) _CP(); arg=val;
```

Just-in-Time Privatization. Single memory updates that include WAR dependencies, e.g., `x++`, require a *two-phase commit* operation to keep memory consistent. In the first phase, Immortal Threads library creates a *private* version of the variable in the privatization buffer (`__priv_buf`) and updates the private version. Then a checkpoint is taken. In the second phase, Immortal Threads library commits the private version to the original variable. We present the implementation of the `_WR_SELF` macro that captures these steps below:

```
#define _WR_SELF(type,arg,val) \
    _CP(); *((type*)&__priv_buf.buffer)=val;\
    _CP(); arg=*((type*)&__priv_buf.buffer);
```

Thanks to just-in-time privatization, Immortal Threads does not require a compiler analysis to detect idempotent code blocks, as in Woude et al. [53]. Furthermore, there is no need for *static versioning*, as in Colin et al. [10]. Immortal Threads library forms a continuous sequence of idempotent code blocks by connecting them using almost-free checkpoints on the fly.

Calling other functions. When there is a power failure while a callee executes, the control should resume from the last memory update in the callee body. To call an immortal function, Immortal Threads library first checkpoints, saves the pointer to the callee in the caller's `_imm_fn_t` structure, and then makes the call as shown in the following pseudo-code:

```
#define _call(name,args) \
  _CP(); this.callee=name(args); \
  _CP(); this.callee->pc = 0; _CP();
```

If the callee successfully returns, the caller sets the program counter (`pc`) of the callee to zero and checkpoints. Consequently, the function will be able to be called again. If there is a power failure before the callee returns, the thread execution will restart from the entry immortal function, which will perform a set of nested function calls to reach the callee that has not finished yet. Therefore, the execution resumes from the last memory update in the leaf callee's body.

```
__asm__ volatile (
 "MOVA SP, %0" /* save SP on __sp variable */
 : "=m" (__sp) /* output */);

while (1) {
 functions[__th](0); /* call thread */
 __asm__ volatile (
  "ISR_return: \n" /* _schedISR will jump here */
  "MOVA %1, SP \n" /* restore old stack */
  "INC.B %0 \n"    /* __th++ */
  "CMP.B %2,%3 \n" /* if (__th == size) */
  "JNZ cont \n"
  "CLR.B %2 \n"    /* __th = 0 */
  "cont: \n"
  : "=m" (__th)    /* output */
  : "m" (__sp), "m" (__th), "m" (size)/* input */);
}

void __interrupt(TIMER0_A0_VECTOR) _schedISR(void){
 /* write return address ISR_return */
 __asm__ volatile ("MOV.W #ISR_return, 2(SP)");
}
```

Figure 5: The Round-Robin scheduler, which is the only platform-specific code in Immortal Threads library.

4.3 Thread Scheduling Implementation

The Immortal Threads scheduler includes platform-specific assembly code that switches the execution from the current thread to the next one. Figure 5 presents a part of our scheduler implementation. When the system restarts, the value of the stack pointer is saved in the variable `__sp`. The array `functions` contains pointers to the thread entries that are ready to run. The while loop indexes the threads with the persistent variable `__th` and calls them in order.

When the periodic timer of the scheduler fires, it interrupts the current thread, and the execution jumps to the `_schedISR` ISR routine. This ISR modifies the stack to replace the interrupt return address with the address of the label `ISR_return` in the scheduler loop. Upon interrupt return instruction (ISR routines execute `iret` upon return), the execution jumps to `ISR_return` label. At this point, the stack pointer is restored (using the old stack pointer in `__sp`) to continue the execution of the scheduler loop using its stack frame. Then, the value of the index `__th` is incremented, and the corresponding thread function is called. It is worth mentioning that thanks to micro continuation, the interrupted thread will not be in an inconsistent state. When the scheduler loop starts running again, it will continue execution from its latest checkpoint. Indeed, the ISR interruption acts as an artificial power failure.

Semaphores, Events and Data Races. Power failures might break the atomicity of operations on semaphores and events (e.g., post and wait) and might lead to data races. For example, if a thread modifies the semaphore but does not checkpoint due to a power failure, it will post the semaphore again after recovery. This situation leads to incrementing the semaphore twice. To prevent such issues, Immortal Threads library im-

plements event and semaphore operations by employing two-phase commit and double buffering, which are the main techniques proposed in the prior art to keep memory consistent despite power failures [31,34,54]. These operations firstly update the temporary values dedicated to events and semaphores. Then, the temporary values are atomically committed to their original locations. Upon system reboot, the scheduler checks if there is an uncommitted semaphore or event operation. If this is the case, it commits this operation. Then, it enables the interrupts and starts executing the threads. Immortal Threads library manages the data races between ISRs and threads by employing the same approach. Each event has a double-buffered event data buffer. An ISR does not modify the original buffer and immediately overwrites the event data. It uses the temporary buffer and then atomically commits it using a two-phase commit operation. These operations prevent the data races and inconsistency issues.

4.4 Compiler Frontend Implementation

We implemented Immortal Threads compiler frontend using the LLVM & Clang LibTooling framework. The AST produced by Clang is generally immutable, and source code rewriting cannot be directly reflected on the AST and its associated metadata. Therefore, it is necessary to keep track and manage the position offsets introduced by the transformations and solve conflicts when these transformations overlap. This limitation of Clang libraries, combined with the relative complexity of the entire source transformation for Immortal Threads, led us to adopt a multi-pass architecture inspired by the LLVM IR Pass framework. Each pass matches some parts of the AST and performs the appropriate source code rewriting. The rewritten source code is used to generate a new AST, on which the next pass operates.

Syntax Decomposition. One of the main challenges for source-to-source transformation is the `switch` constructs used in Immortal Threads lightweight checkpoints, which allow checkpoints only with a statement granularity. However, C programs might include expressions with WAR dependencies inside them, so it must be possible to perform checkpoints inside expressions. To this end, we decomposed these syntax constructs into separate statements so that it is possible to perform Immortal Threads lightweight checkpoints. In doing so, we paid special attention to aspects such as operator precedence and short-circuit evaluation.

Pessimistic Privatization due to Aliasing. The `_WR_SELF` interface, which performs JIT privatization, must be used for assignments where the left-hand side operand aliases with the right-hand side operand. In general, it is not possible to deduce all such aliases at compile time, e.g., when pointers are involved. Our current implementation pessimistically uses `_WR_SELF` instead of `_WR` when at least one operand contains a pointer dereference. We left integrating more advanced aliasing analysis as future work.

Shim API replacement. While a significant portion of the Immortal Threads operations is hidden from the programmer by the compiler frontend, primitives such as semaphores, mutexes, etc. (see Table 2) are visible to the programmer. These primitives have C macro-based implementations that generate `_case` statements for `_switch` blocks, which are inserted by the compiler frontend via `_begin` and `_end` statements later. Therefore, Clang fails to generate the initial AST that sets off the transformation pipeline. We solved this issue by providing these primitives as shim functions, and the compiler frontend replaces them with their actual macro-based implementations.

Pass Grouping Optimization. While the compilation time of the C language by modern compilers such as Clang is generally fast enough, having to re-parse the translation unit after each transformation is still a noticeable overhead when long source files are involved. Some of the presented passes depend on others. For example, instrumenting assignments with `_WR` and `_WR_SELF` is easily performed once syntax decomposition is done. On the other hand, some passes operate on orthogonal elements of the AST, for which we don't need to worry about source rewriting conflicts. We grouped these passes and executed them using the same AST.

Compiler Directives and Code Optimization. In exceptional cases, the programmer can modify the behavior of the Immortal Threads compiler using custom attribute directives (`__attribute__`). For example, we allow the programmer to mark idempotent functions so that they are not instrumented for the sake of some manual optimizations. This feature reduces the overhead of frequent checkpoints but creates a risk of wasted work. In Section 6 we discuss ways to improve this aspect. Furthermore, we also implemented a specific compiler optimization to coalesce successive `WR` and `WR_SELF` macros in the code to eliminate frequent checkpoints that might degrade the execution time of time-sensitive computational loads. The programmer can enable this optimization by passing a flag to the compiler frontend. In this case, the compiler puts the best effort to reduce the number of checkpoints in basic blocks. In summary, Immortal Threads compiler frontend enables the developers to select the trade-off between the checkpointing overhead and wasted work based on the specific requirements of their applications.

Switch Statements. We allow programmers to use a subset of the `switch` statement in their code (unlike Protothreads, which does not permit programmers to use switch statements). Specifically, we support switch statements in which all the statements associated with case labels either finish with a `break` statement or are empty, i.e., the case directly falls through to the next case. Given the constraint we put, it is straightforward to transform such use of the switch into an equivalent if/else based code. The compiler frontend terminates with an error message if it encounters an unsupported usage of the switch statement.

Function Reuse. Immortal Threads needs to create different instances of thread-shared immortal functions to prevent data

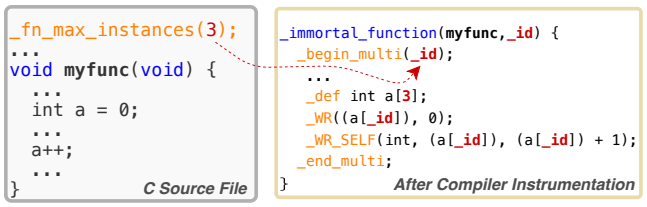

Figure 6: The compiler instrumented version of a sample function `myfunc` that is shared among multiple immortal threads.

races and memory inconsistencies. We implemented function reuse through a combination of compiler and Immortal Threads library support. Figure 6 presents a sample function that is shared among several immortal threads, and its instrumented version. The programmer uses a compiler directive (`_fn_max_instances` as indicated in the figure) to declare the maximum number of concurrent callers for the shared functions in the application. If the number of instances is not provided, the compiler can also use a default number to avoid programmer intervention. Our compiler modifies the signature of each shared immortal function by prepending an id parameter. Moreover, the compiler also transforms all local variables into arrays whose lengths correspond to the number of instances. Thus, each access to any local variables becomes an array access, where the index is the id. Alternatively, to avoid the overhead of accessing the array, the Immortal Threads compiler can also create copies of the same immortal function at the source code level. Therefore, it can replace the original immortal function's body with a call table that calls the appropriate function copy depending on the id parameter. This support lets the developer trade executable size for runtime efficiency. Besides, for each shared immortal function, the compiler allocates an associated metadata data structure containing a bitmap to represent unused instances, where each bit that is one represents a free instance. We present the pseudo-code of the macro that is used for calling shared functions as follows:

```
#define _call_multi(name,args) \
  _CP(); get_instance_id(&this->callee_id); \
   this.callee=name(this->callee_id, args); \
  _CP(); release_instance_id(&this->callee_id); \
   this.callee->pc = 0; _CP();
```

The caller of an immortal function must first get a free instance, that is, access the bitmap and clear a bit that is set (using `get_instance_id`). It is worth mentioning that not getting a free instance should not happen by design. The programmer must ensure to provide the correct `_fn_max_instances` number configuration. If no free instance is available at runtime, it's an assertion failure. Once the immortal function returns, the caller must release the called immortal function instance by setting the previously cleared bit (using `release_instance_id`). As a side note, recursive functions are not supported in the current implementation of Immortal Threads. We argue that this is not a significant limitation, as recursion is generally avoided in embedded systems.

5 Evaluation

We proceed with the evaluation of Immortal Threads by presenting a performance comparison against three state-of-the-art runtimes Alpaca [34], InK [54], and TICS [31].

Benchmarks. We selected Bitcount (BC), Cuckoo Filter (CF), and Activity Recognition (AR) as the main benchmarks since they are widely used in previous works [31, 34, 54]. We also considered the DNN inference presented in Gobieski et al. [22] as a benchmark since the inference operations are computationally intense (e.g., the first convolution layer requires 150080 multiplications) and access non-volatile memory excessively (FRAM is more expensive compared to SRAM access). We used the BC, CF, and AR implementations in publicly available code repositories of Alpaca, InK, and TICS during our evaluations. We also considered the publicly available plain C versions of these benchmarks, which we call *Plain-Ram*, where all variables are in SRAM (no FRAM access). Therefore, they do not have overheads regarding non-volatile memory access, checkpoints, privatization, etc. Moreover, we created the *Plain-Fram* versions of these benchmarks where all variables are maintained in FRAM. Therefore, they have an additional FRAM access overhead compared to Plain-Ram versions. Note that the Plain-Ram and Plain-Fram implementations do not guarantee forward progress and memory consistency.

Compiler Directives. In the task-based implementations of the benchmarks (in Alpaca and InK), we observed that some functions are not declared as tasks to reduce task transition overheads and employ a *manual* compile-time optimization for these task-based systems. These functions are idempotent since they do not modify their inputs or global variables. Moreover, they are mostly small in size and frequently called at runtime. Similarly, in Immortal Threads implementations of these benchmarks, we annotated these idempotent functions (using the compiler directives mentioned in Section 4.4) to bypass unnecessary compiler instrumentation and reduce the number of checkpoints and the execution time overhead of Immortal Threads. Using annotations, we marked eight functions in BC, six functions in CF, three functions in AR, and seven functions in DNN, respectively. Furthermore, for the DNN benchmark, we enabled the checkpoint coalescing feature of our compiler frontend to reduce the memory access overhead of the data-intensive computations. These features of Immortal Threads compiler frontend allowed us compile-time optimizations *without programmer involvement* (excluding the annotation of idempotent functions).

Target Platform and Tools. We used the MSP-EXPFR5994 evaluation board [48], which includes 256kB FRAM and 4kB SRAM memory and can operate at up to 16MHz. We

used the 1 MHz frequency during the experiments on performance comparison (to be compatible with existing studies [31, 34, 54]. We used the GNU GCC v9.2.0.50 to compile our applications. To measure the time overhead and energy consumption, we used a logic analyzer and TI EnergyTrace software [49], respectively. We used the Powercast TX91501-3W [12] RF transmitter operating at 915 MHz center frequency to power wirelessly our evaluation board connected to the P2110-EVB [13] RF receiver. We used the 1mF and 50mF capacitors on P2110-EVB as energy storage to observe different power failure patterns. We also emulated power failures for the repeatability and replicability of comparative measurements. We generated a random soft reset triggered by an MCU timer with a uniformly distributed firing period in the interval of [5ms, 20ms] (as in Yildirim et al. [54]).

Evaluation Metrics. We considered *execution time* and *energy consumption* as the main metrics to evaluate the benchmarks. We also measured *wasted work* (which denotes computational progress lost due to power failures), *runtime overhead* introduced to progress the computation and keep memory consistent, and the memory requirements and code sizes of the benchmark implementations.

5.1 Evaluation Using BC, CF and AR

The InK and Alpaca implementations of the benchmarks have identical task boundaries. We placed TICS checkpoints aligned with task boundaries in the InK and Alpaca implementations for the sake of a fair comparison.

Continuous Power. Table 4 presents the continuously-powered execution time and energy consumption of the benchmarks. These benchmarks have different characteristics; for example, BC accesses memory more frequently to manipulate variables, and CF is more computationally dense. The differences in the time and energy overheads of the plain-Ram and plain-Fram versions show that intermittent computing, which requires frequent FRAM access, comes with significant overheads. Immortal Threads, InK, Alpaca, and TICS introduce additional overhead to Plain-Fram versions of the benchmarks to ensure forward progress and memory consistent. We observed that the performance of Immortal Threads is quite comparable to that of InK, TICS, and Alpaca during the continuous execution of the benchmarks. The reason is that InK and Alpaca need to perform bulk copy operations to commit the temporary buffers atomically during task transitions. Similarly, TICS needs to copy the stack and registers upon each checkpoint. Even though Immortal Threads maintains all variables in FRAM (which increases the time and energy overhead), almost-free checkpoints reduce the checkpointing cost, and just-in-time privatization eliminates block FRAM copy operations. Table 5 summarizes the average execution time of a task and the overhead of task transitions and checkpoints.

Intermittent Power. Figure 7 presents the wasted computational progress due to power failures and runtime overheads during intermittent execution with randomly generated power failures. The runtime overhead in InK and Alpaca is mainly due to the undo and redo logging operations performed by the tasks to recover computation upon power failures. Alpaca has a lower task transition overhead since it only double-buffers the task-shared variables with WAR dependencies and commits them upon task completion. Similarly, the overhead of TICS is due to the checkpoints and their restoration. TICS has more commit overhead since it checkpoints at the end of each task boundary, which requires a large bulk memory copy operation compared to task transitions in InK and Alpaca (see Table 5). During our experiments, Alpaca implementations of the benchmarks led to shorter task execution times and reduced wasted work since Alpaca introduced a lower runtime overhead compared to InK and TICS. In Immortal Threads, the runtime overhead is the total overhead of almost-free checkpoints, just-in-time privatization, and restoring compu-

tation. Conceptually, idempotent code blocks between two successive memory updates in Immortal Threads can be considered as a tiny task. These micro-continuations reduced wasted work and the total execution time significantly compared to existing runtimes.

5.2 Evaluation Using DNN Inference

Immortal Threads showed promising performance with relatively small benchmarks. To evaluate it under excessive memory access and computational load, we used the deep neural network (DNN) inference presented in [22]. This DNN model requires approximately 180kB FRAM to maintain the DNN weights and input matrix. The Alpaca DNN implementation in [22] employs *loop continuation* and has 18 tasks (2 tasks are for specific initialization operations). It is again worth mentioning that loop continuation relies on manually eliminated WAR dependencies and **violates** the task-based model. The implementation of TICS (from its public repository) could not support DNN inference, since its checkpoints lead to memory inconsistencies when the application accesses the higher regions of FRAM.InK requires DNN weights and the input matrix to be allocated in task-shared memory regions. However, InK double buffers all task-shared variables and commits them non-selectively at each task completion. Therefore, the implementation of DNN in InK is not feasible since it needs to commit a large amount of task-shared data at each task transition. However, by **violating** the InK model, we provided loop continuation support, allowed tasks to manipulate FRAM directly, and managed to implement DNN, which has 16 tasks (2 tasks specific to Alpaca are not required). Since our platform has only 4kB SRAM, we could not implement the Plain-RAM version of DNN.

Continuous Power. Due to the increased number of memory write operations, the overhead of Immortal Threads is more visible in this case (see Figure 8a). Immortal Threads introduced almost twice more overhead compared to Plain-Fram DNN (see Table 4). The main reason for performance degradation is committing each memory update atomically via the JIT privatization. INK and Alpaca performed better since they eliminated memory commit overheads by **violating** the task-based model via loop continuation. This violation allowed for larger tasks, which reduced the number of task transitions.

RF Powered. We used 1mF and 50mF capacitors as energy storage and three different distances from the RF power transmitter to observe different power failure patterns. The charging time of the capacitor increases with the distance between the receiver and the power transmitter. The charging time of the 50mF capacitor is longer than that of the 1mF capacitor. On the other hand, the 50mF capacitor provides a longer operation time. We observed significantly higher power failure rates with the 1mF capacitor. We conclude from Figure 8b and Figure 8c that Immortal Threads's performance becomes superior to the other runtimes as the power failure rate increases—it wastes less computational progress thanks to the micro-continuations.

Unviolated Task Model. We implemented DNN in Alpaca **without** the loop continuation to answer the question of what the DNN performance is without violating the task-based model. Our implementation, which we call the original Alpaca (*Alpaca (Org.)*), introduced an additional 11 tasks to the DNN implementation with loop continuation. Figure 9 presents execution time, runtime overhead, and wasted work during controlled power failures. We observed that Immortal Threads outperformed the original Alpaca significantly, i.e., led to a twice shorter execution time. Furthermore, even though

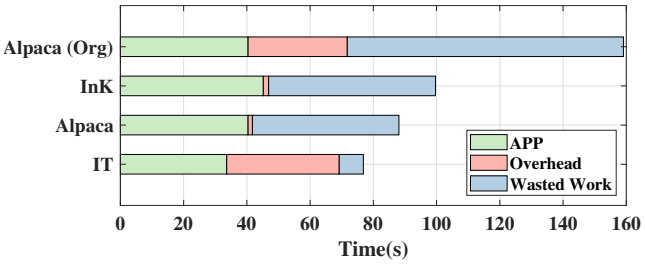

Figure 9: DNN execution time, runtime overhead and wasted work with **controlled power failures**.

Immortal Threads has more overhead compared to the InK and Alpaca implementations, it wasted significantly less work.

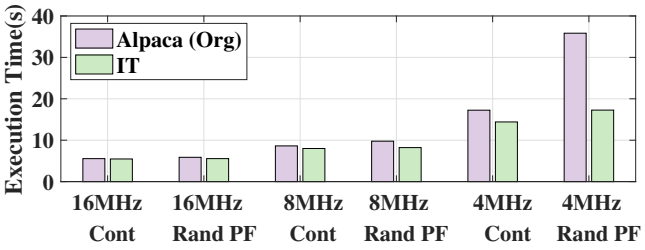

Figure 10: Performance of DNN at different frequencies.

Fram-CPU Bottleneck. As CPU speed increases, the FRAM access latency becomes more dominant in system performance. The FRAM in our platform can operate at a maximum speed of 8 MHz. We evaluated the original Alpaca and Immortal Threads DNN inference performances using clock frequencies of 4MHz, 8MHz and 16MHz with controlled power failures, as presented in Figure 10. We observed that as the clock frequency increases, the performances of both systems come closer to each other due to the latency of FRAM access, but Immortal Threads still performs better.

	Alpaca			InK			TICS		Immortal Th.

Table 6: Num. lines of code, num. of tasks and transitions (Alpaca and InK), num. of checkpoints (TICS and InK).

5.3 Cognitive Load, Code Size, and Memory Requirements

We define the *cognitive burden* of intermittent computing as the effort put to split code into idempotent sections, i.e., implementing tasks and task-based control flow in task-based systems and inserting checkpoints for checkpointing systems.

	Alpaca			InK			TICS			Immortal Th.		
	.text	*Ram*	*Fram*	*.text*	*Ram*	*Fram*	*.text*	*Ram*	*Fram*	*.text*	*Ram*	*Fram*
BC	2254	2	856	3356	0	4712	7160	4446	5572	10175	345	478
CF	3148	348	1070	4242	318	3000	11160	4655	6322	9831	370	498
AR	2258	0	784	3576	0	4474	11416	759	5430	11885	346	542
DNN	13898	224	192K	843	0	168K	✗	✗	✗	19394	356	149.5K

Table 7: Memory and Code Size requirements (in B).

We used the number of tasks (and checkpoints) and task-based control-flow declarations (in addition to the number of lines of code) shown in Table 6 as a metric to measure the burden. Thanks to the Immortal Threads compiler frontend, programmers write their programs without focusing on the details of the intermittent execution. The compiler frontend automatically wraps variable manipulations using the macros shown in 3, inserts checkpoints and creates idempotent code sections on the fly. Programmers use only the interfaces in Table 2, which are almost *identical* to the interfaces found in continuously powered event-driven systems [17, 32]. It is worth mentioning that Table 6 presents the number of lines after the Immortal Threads compiler pass (which has additional code inserted by the compiler). Even in this case, the number of lines in the implementations with Immortal Threads is almost half of that in the implementations with task-based models. As shown in Table 7, the code size of the application implemented in Immortal Threads library is larger than others. The main reason is that Immortal Threads library is implemented using C macros. It is worth mentioning that just-in-time privatization eliminates data versioning, reflected as considerably reduced data section requirements.

5.4 Summary of Evaluation Results

Our results showed that Immortal Threads has comparable runtime overhead to the existing runtimes. The runtime overhead and benefits of Immortal Threads depend on the application's memory access patterns and the frequency of the power failures. Compared to Immortal Threads, InK (violated task-based model) had approximately ten times more wasted computation and 1.5 times more execution time DNN inference under power failures. Besides, the original Alpaca (the unviolated task-based model) had approximately 17 times more wasted computational progress and 2.4 times more execution time. Therefore, we observed that during frequent power failures Immortal Threads reduced execution time and wasted work by up to 40% and 90%, respectively. We conclude that Immortal Threads brings pseudo-stackful multithreaded programming with acceptable overhead and no cognitive burden.

5.5 Greenhouse Monitoring Application

We proceed with greenhouse monitoring, which is a common application shown in intermittent computing studies (e.g., [31]), to demonstrate a time-constrained event-driven

scenario. To this end, we used a temperature sensor on the MSP430FR5994 MCU, a solar panel for energy harvesting, and an eZ430-RF2500 [47] board equipped with a CC2500 transceiver to transmit and receive data. MCU used a UART connection to send commands to eZ430-RF2500 for data transmission. We used the DS1302 [39] Real-Time Clock for time tracking despite power failures. As energy storage, we used the 50 mF supercapacitor of the P2110-EVB since it has a voltage regulator.Figure 11 shows our experimental setup.

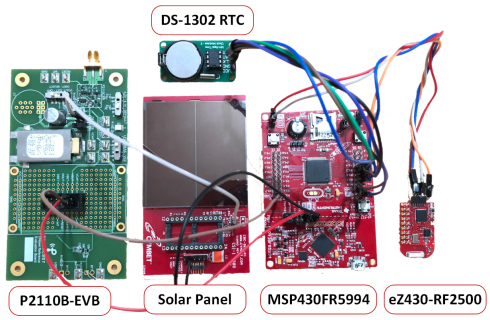

Figure 11: Greenhouse monitoring experimental setup.

GHM Implementation. A timer thread checks the RTC to signal timer events every 6 seconds. The sense thread blocks on the timer event to sense the temperature and store it in a buffer with a timestamp. When the number of samples reaches 10, the sense thread calculates the average and signals the send event. The send thread unblocks, checks the event timestamp (via `_EVENT_WAIT_EXP`), and sends data to eZ430-RF2500 if the event has not expired. Otherwise, it ignores the event.

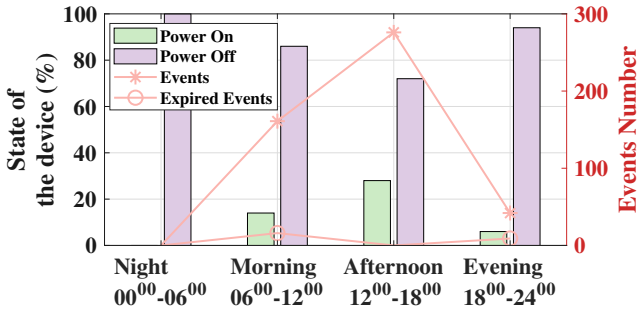

Figure 12: The number of expired events and the on/off time percentage of the device during different parts of the day.

Results. We placed our setup in an outdoor location on our campus for 24 hours. Figure 12 shows the results according to the parts of the day. To expose the effects of energy availability, we split the results into 6-hour timeframes. Since there was not enough energy at night, no events occurred. Due to power failures and charging times, 16 out of 177 events expired in the morning. The available environmental energy was high during the afternoon, and none of the 276 events expired since there were no power failures. Similarly, 9 out of 42 events have expired in the evening. We conclude that Immortal Threads successfully caught these expirations and stopped data processing to save precious harvested energy.

6 Discussion and Future Work

Programming models. Protothreads [18] is an abstraction designed for continuously-powered sensors. Its local continuation concept enables blocking threads, but such continuations can be saved only in the thread's entry function. InK task-threads provide a solution for intermittent event-driven applications, but they have mentioned drawbacks in this paper, e.g., the cognitive load of the task-based systems. Immortal Threads is an abstraction that provides micro continuation in intermittently powered systems, which is as lightweight as Protothreads's local continuation. In addition, they can be saved anywhere in the call stack of a thread, not only in the entry function. However, the current implementation of micro continuations achieves pseudo-stackfulness by employing `switch`-based constructs. An essential question for our future work is whether it is possible to control the compiler's usage of registers so that continuations can be composed of only the program counter and stack pointer while maintaining the remaining state in the (non-volatile) memory. Checkpointing at the statement boundary, combined with declaring variables as `volatile` or compiler fences, may provide a possible direction.

Peripheral operations support As previous works (e.g., [35]) point out, peripheral interaction should be atomic,which means no power failure can be allowed in between. In order to enable atomic execution of I/O handling operations, Immortal Threads compiler frontend can be extended to support a new compiler directive to mark atomic I/O functions, i.e., functions that should not contain checkpoints. The compiler frontend can add the necessary code that performs privatization of the parameters passed by address to such functions.

Checkpoint Optimization. Immortal Threads performs frequent checkpoints. Compiler analysis can be performed to merge and reduce unnecessary checkpoints. However, this may lead to more wasted work. In general, there is always a trade-off between checkpoint frequency (and the associated overhead) and the amount of waste work. Maeng et al. [36] proposes an adaptive approach: checkpoints are disabled at runtime when the system has still enough energy. However, this approach is effective only when *determining whether to checkpoint* has much less cost than *taking the checkpoint*, which does not apply to Immortal Threads, where checkpointing is merely an atomic write. One possible way to introduce adaptive checkpointing is to have multiple versions for each immortal function with a different checkpoint density. The runtime can then determine which version to call based on the energy availability. We leave this issue for future work.

7 Conclusions

Immortal Threads is the first intermittent computing runtime that enables pseudo-stackful multithreaded programming. Using Immortal Threads, programmers focus only on their multithreaded program logic that handles events instead of focusing on managing intermittent execution. Immortal Threads brings the missing event-driven primitives to intermittent computing, e.g., semaphores and event expiration handling. All these features come with an overhead comparable to the overhead of existing intermittent computing runtimes. We observed that, depending on the application and power failure frequency, Immortal Threads can even reduce execution time and wasted work by up to 40% and 90%, respectively.

Acknowledgments

We thank the anonymous reviewers of OSDI 2021, SOSP 2021, ASPLOS 2021 and OSDI 2022 for their valuable comments and feedback. We would like to thank Przemysław Pawełczak (TU Delft, The Netherlands) for encouraging us to send this work to OSDI 2022. We are also grateful to Rodrigo Bruno for shepherding our final draft.

Availability

We release Immortal Threads as an open source project for the community, whose artifacts can be downloaded from https://tinysystems.github.io/ImmortalThreads.

Abstract

Debugging is time-consuming, accounting for roughly 50% of a developer's time. To identify the cause of a failure, a developer usually tracks the state of their program as it executes on a failing input. Unfortunately, most debugging tools make it difficult for a developer to specify the program state that they wish to observe and computationally expensive to observe execution state. Moreover, existing work to improve our debugging tools often restrict the state that a developer can track by either exposing incomplete execution state or requiring manual instrumentation.

In this paper, we propose an `OmniTable`, an abstraction that captures all execution state as a large queryable data table. We build a query model around an `OmniTable` that supports SQL to simplify debugging without restricting the state that a developer can observe: we find that `OmniTable` debugging queries are more succinct than equivalent logic specified using existing tools. An `OmniTable` decouples debugging logic from the original execution, which SteamDrill, our prototype, uses to reduce the performance overhead of debugging. The system employs *lazy materialization*: it uses deterministic record/replay to store the execution associated with each `OmniTable` and resolves queries by inspecting replay executions. It employs a novel multi-replay strategy that partitions query resolution across multiple replays and a parallel resolution strategy that simultaneously observes state at multiple points-in-time. We find that SteamDrill queries are an order-of-magnitude faster than existing debugging tools.

1 Introduction

Developers spend the majority of their time debugging their software [26]. Usually, a developer debugs by iteratively executing their program and using debugging tools to observe its state during the failing execution.

A developer can often identify the root cause of a simple bug by making a few observations about their program's execution state. However, to identify the root cause of a complex bug, such as a atomicity violation or performance degradation, the developer will need to make sophisticated observations. Conceptually, we can model the logic for such sophisticated observations as a *debugging program*, designed to make sense of the failing program. For example, when debugging, a developer may observe all of the values to which a variable is assigned during an execution. Their debugging program consists of a set data structure to store the values, logic after each assignment in the failing execution that adds the assigned value to the set, and a print statement to print the set when the execution terminates.

Unfortunately, many debugging tools, such as `gdb`, "printf"-debugging, and binary instrumentation, support debugging programs that have both high programming complexity and high performance overhead. Such tools support procedural debugging programs that observe state as a failing program executes. Procedural debugging programs have considerable programming complexity, especially for sophisticated tasks that track execution state over time (§6.2). High complexity can lead to bugs [15, 44] that prevent a developer from understanding the failing program. Additionally, such debugging programs impose high performance overhead since sophisticated debugging programs observe *a lot* of execution state which existing tools extract within the same execution context as the failing program. Consequently, procedural debugging programs can slow execution by between a factor of 2–1000 (§6.3), which can preclude the use of sophisticated debugging programs [11].

Alas, prior debugging work retains, or even exacerbates, high programming complexity or high performance overhead to improve the other. Some proposals lower the performance overhead of debugging by employing parallelism (e.g., Speck [30], SledgeHammer [35]) or low-level optimizations (e.g., optimistic hybrid analysis [9], efficient path profiling [3]). At best, such techniques require redesigning debugging programs, at worst, they require novel research contributions to accelerate even a single task (e.g., taint tracking [4]).

High-level debugging tools decrease programming complexity by allowing a developer to observe and summarize execution state using a high-level programming model (e.g.,

Fay [12], G2 [17], EndoScope [7]). However, such tools retain high performance overhead since they perform a debugging program's observations while executing the original failing program. To curtail the effect of high performance overhead, high-level debugging tools restrict the execution state that a developer can observe, either explicitly (e.g., by minimizing the times when a debugging program can observe state [12, 14, 25]) or implicitly (e.g., by requiring extensive manual instrumentation to specify observable execution state [17, 24, 40]). Such systems are well suited for tasks that only need to observe partial execution state, such as distributed tracing [24] or identifying specific classes of bugs [25], but are less suited for debugging complex issues.

This paper proposes the `OmniTable` query model, a new debugging paradigm that reduces the programming complexity and performance overhead of debugging without restricting the execution state that a developer can observe. The new `OmniTable` abstraction empowers the model. An `OmniTable` reduces programming complexity by presenting all of an execution's state as a large queryable data object. An `OmniTable` reduces performance overhead by decoupling a debugging program's observations from the original programs' execution to enable automated optimizations of debugging programs.

The `OmniTable` query model enables debugging programs that can observe any execution state with low programming complexity by turning to relational logic. Concretely, an `OmniTable` is a database table representation of an execution that contains all architectural state (i.e., the value of all bytes of memory and all registers) before every instruction executed by the program. From a developer's perspective, an `OmniTable` is extracted as a program executes and can later be queried using an extended SQL language to observe the execution's state. The model bridges the gap between the architectural state in an `OmniTable` and common debugging abstractions (e.g., the functions executed, variables assigned, etc.) by re-purposing existing database primitives (e.g., high-level views) and creating new query operators (e.g., traversal functions).

Unfortunately, naively materializing an `OmniTable` would lead to considerable performance overhead, since it would require performing a core-dump before every instruction. Instead, our prototype, SteamDrill, employs *lazy materialization*. Lazy materialization defers the calculation of an `OmniTable`'s state until a developer queries it. Rather than extract an `OmniTable` in its entirety during execution, SteamDrill uses deterministic record and replay to store the execution associated with the `OmniTable`. Deterministic record and replay enables SteamDrill to compress and store years worth of `OmniTables` on a commodity hard drive [10]. When a developer issues a query over an `OmniTable`, SteamDrill generates instrumentation which it injects into a new replay of the execution associated with the `OmniTable` to produce the execution state needed for the query.

SteamDrill reduces performance overhead by decoupling a debugging query's execution from the original program execution. SteamDrill uses a query planning approach that decomposes a debugging query into independent stages. SteamDrill implements a novel multi-replay query resolution strategy that executes each stage in a separate replay so that it can use data that is computationally inexpensive to observe (e.g., data about functions in an `OmniTable`) to reduce the compute cost of observing data that is computationally expensive to observe (e.g., data about each instruction in an `OmniTable`). In essence, multi-replay resolution uses the decoupling between an `OmniTable` query and the original execution to repeatedly observe `OmniTable` state at increasing detail. SteamDrill also uses decoupling to observe execution state from multiple points-in-time in parallel using thousands of machines [35, 47].

We built a SteamDrill prototype on top of Spark [47] and Arnold [10]. We evaluate the prototype using 5 detailed case studies of bugs reported in popular open-source applications (Memcached, redis, Apache, and SQLite). We identified 14 debugging programs that a developer would use to identify the root cause of each bug, including ad-hoc programs (e.g., "How many control-flow instructions did my function issue?") and standard dynamic analyses (e.g., a memory leak detector). We implemented the debugging programs using `OmniTable` queries and `gdb`'s python bindings, which provide a high-level language over `gdb` features. We found that `OmniTable` queries require up to 11.67 times fewer lines (with a geometric mean of 3.74 times fewer lines), up to 5.73 times fewer terms (with a geometric mean of 1.70 times fewer terms), and up to 23.49 times less estimated development time (with a geometric mean of 2.75 times less estimated development time) than `gdb` scripts. We evaluated the performance of SteamDrill on 3 representative debugging queries and find that it is faster than `gdb` by a factor of 99 based upon geometric mean.

We make the following contributions:

- The `OmniTable` query model, which decouples a debugging program from a failing execution to reduce the programming complexity and performance overhead of debugging.
- SteamDrill, which optimizes `OmniTable` queries using query planning, cluster-scale parallelization, and a novel multi-replay query resolution approach.
- An evaluation of 5 case studies and 14 queries that shows that `OmniTable` queries are more succinct and SteamDrill has lower latency than state-of-the-art tools.

2 Motivation

In this section, we describe a motivational case study showing how the `OmniTable` query model simplifies debugging. In the case study, a developer uses an `OmniTable` to diagnose a performance problem in redis [36]. In the study, a developer deploys redis as an in-memory key-value LRU cache for a

Vars(ot)	
Column `Name`: Type	Description
`time`: Long	Time of instruction
`thread`: Long	Thread that executed instruction
`eip`: Long	Program counter of instruction
`name`: String	Variable name
`value`: Any	Assigned value

Funcs(ot)	
Column `Name`: Type	Description
`enterTime`: Long	Time of function entry
`exitTime`: Long	Time of function exit (or null)
`name`: String	Function name
`thread`: Long	Thread that executed function
`callStack`: String	Call stack of function
`args`: Map[String->Any]	Argument values
`rVal`: Any	Return value of function execution

Figure 1: The schema of the `Funcs(ot)` and `Vars(ot)` views. Each line in each table describes a column in the view.

slow back-end service. Over time, the average end-to-end latency of their deployment creeps upwards; the developer notices that the increase correlates with the back-end service processing a higher percentage of requests.

The bug is challenging to diagnose since the developer only starts with a high-level symptom and is unaware of which parts of the program are related to the error. To determine the root cause of the bug, the developer summarizes an execution's behavior over time. The `OmniTable` allows the developer to observe all of the execution state of the program without requiring instrumentation; the query model's support for SQL aggregations allows the developer to succinctly summarize large amounts of execution state. Moreover, the `OmniTable` enables repeated queries over the same buggy execution, instead of requiring the bug be reproduced for each query.

In contrast, summarizing execution state over time is challenging with existing tools (§7). To use a procedural debugging tool (e.g., `gdb`), the developer must identify numerous instrumentation points, track execution state over time in complex data-structures, and implement algorithms to group data and calculate statistics. Other debugging tools simplify execution summarization, but provide incomplete interfaces in that they do not expose the execution state (e.g., PTQL [25], Fay [12]) or do not support the operators (e.g., Pivot Tracing [24], Execution Mining [20]) required for this case study. Finally, instrumentation-based tools (e.g., G2 [17], Pivot Tracing [24]) require extensive manual instrumentation to perform the necessary observations.

The developer uses 5 `OmniTable` queries to identify the root cause of the performance degradation. Rather than query an `OmniTable` directly, the developer uses *derived views* to simplify their queries. A derived view labels execution state according to an abstraction of execution behavior, such as the functions, in-scope variables, or memory read by each instruction in an `OmniTable`. Below, we describe the derived views

time	eip	name	value
100	0x1000	"used"	1000
100	0x1004	"entry"	NULL
102	0x1004	"used"	1000

Figure 2: Example data from `Vars(ot)` .

enterTime	exitTime	name	args	rVal
100	200	"lookupKey"	{"key":"k1"}	100
100	200	"lookupKey"	{"key":"k2"}	100
100	200	"incrRefCount"	{"key":"k1"}	NULL

Figure 3: Example data from `Funcs(ot)` (omitting the `callStack` and `thread` columns). .

that the developer uses. Then, we describe the `OmniTable` queries that the developer uses and compare them to debugging programs expressed using existing debugging tools.

2.1 Views

The developer uses two derived views, `Vars(ot)` and `Funcs(ot)`, which can be calculated over an `OmniTable`: `ot`. Figure 1 shows their schemas.

Vars(ot). The `Vars` view contains the value of all in-scope variables at each instruction in an `OmniTable`. Each row identifies the value of a single in-scope variable at a single instruction, regardless of whether that instruction accesses the variable. Figure 2 shows a few rows of the `Vars(ot)` view for the `OmniTable` for the buggy execution of redis used during this case study. A developer references the `Vars` view of an `OmniTable`, `ot`, by specifying `Vars(ot)` in their query.

Funcs(ot). The `Funcs(ot)` view contains information about the functions executed in an `OmniTable`—each row contains state from either the entry to or exit from a function execution contained in the `OmniTable`, `ot`. For example, Figure 3 contains a few rows of the `Funcs(ot)` view for the `OmniTable` for the buggy execution of redis used during this case study. The `enterTime`, `callStack`, and `args` columns are extracted upon function entry; the `exitTime` and `rVal` columns are extracted upon function exit (and are `NULL` for functions that never return); and the `name` and `thread` are extracted at both entry and exit and joined to match the entry and exit of each function. The `rVal` and `args` columns use the polymorphic type, Any, to encode different function signatures. For example, a developer specifies `args["i"]` to get the value of the argument `i` passed to a function.

The `time`, `enterTime` and `exitTime` columns from `Vars(ot)` and `Funcs(ot)` expose an ordering of events contained in the views and provide a primary key that uniquely identifies each row in the views. Moreover, a developer can use the the `time`, `enterTime`, and `exitTime` columns to correlated data across the `Funcs(ot)` and `Vars(ot)` views for the `OmniTable`. For example, a developer can determine the value of each in-scope variable at the entry to each function by joining `Funcs(ot)` and `Vars(ot)` on `enterTime = time`; the second query uses this feature (§2.2.2).

```
1 Select enterTime, count(distinct args["key"]) Over(
2   Order By enterTime
3   Rows Between 10000 Preceding and Current Row)
4 From Functs(ot)
5 Where f.name="lookupKey"
```

Listing 1: The developer's first query.

2.2 Queries

Next, we describe how the developer diagnoses the cause of the performance bug. First, they use deterministic record and replay to capture the `OmniTable` for an execution of redis during which the issue occurs. Then, they construct and execute the following five `OmniTable` queries.

2.2.1 First Query

The developer's first query (Listing 1) uses a windowed aggregation to approximate the number of items that the deployment caches in redis (i.e., the working set size) during the performance degradation. The developer suspects that the working set size increases over time, which would lead to additional cache misses in redis. Each cache miss sends a request to the back-end service, so this hypothesis would explain the creeping latency of the deployment.

The developer begins by inspecting redis's source code to identify the function, `lookupKey`, that finds an item in the cache. For each `lookupKey` execution, the developer creates a window containing the preceding 10,000 executions of `lookupKey` and counts the number of distinct keys passed to each function call in each window. The `OmniTable` query model succinctly represents this logic using *SQL aggregates*. SQL aggregates calculate a mathematical operation (e.g., **`count`**, **`sum`**) over a group of rows. An aggregate can operate over a window of requests, in which each group is an ordered list of rows that match an **`Over`** clause, as is the case in this query. Alternatively, an aggregate can operate over a group of rows that match a **`Group By`** clause, as is the case in the developer's third query (§2.2.3).

In detail, the query uses the **`Over`** operator to create sliding windows, each of which contains 10,000 consecutive calls to `lookupKey`, by ordering `Funcs(ot)` by `enterTime` (Lines 2–3). The query filters non-`lookupKey` windows (Line 5). It counts the number of distinct keys passed to each function call in each window using the `key` argument (`args["key"]`) and the **`count`** and **`distinct`** operators.

Existing debugging tools either cannot support the query, impose high programming complexity, or impose high performance overhead. EndoScope [7] and Fay [12] could support the developer's query, but imposes a high overhead since they tightly couple debugging logic's execution with the original program execution. Most high-level debugging tools do not support windowed-aggregations and are either unable to compute the query (e.g., Pivot Tracing [24], Execution Mining [20]) or require a developer to write a custom operator to compute the query (e.g., G2 [17] requires expressing the window clause in terms of a vertex-based graph-traversal). Instrumentation-based debugging tools (e.g., Pivot Tracing [24]) would require the developer manually instrument the `lookupKey` function to produce the value of `key`.

```
1  from gdb import Breakpoint, parse_and_eval
2  from collections import deque, defaultdict
3  class bp(Breakpoint):
4      keys=deque()
5      indexed=defaultdict(int)
6      def stop(self):
7          keys.append(parse_and_eval("key"))
8          indexed[keys[-1]] += 1
9          if len(keys) > 10000:
10             indexed[keys[0]] -= 1
11             if indexed[keys[0]] == 0:
12                 del indexed[keys[0]]
13             keys.popleft()
14         print (len(indexed))
15         return False
16 bp("lookupKey")
```

Listing 2: The developer's first query written for gdb's Python bindings.

An equivalent procedural debugging program is complex. The debugging program must navigate the performance-complexity tradeoff—creating a program with high overhead is straightforward, but creating one with low overhead requires complex logic to ensure consistency of two data structures. A mistake can lead to a misdiagnosis of the bug—our first version of the debugging program included such a mistake.

Listing 2 shows an implementation for `gdb`'s Python bindings, which provide a Python interface for `gdb` features such as breakpoints and backtraces. The developer creates a custom `Breakpoint` class, `bp` (Lines 6–15); by creating a `bp` with the argument `"lookupKey"` (Line16), the developer instructs the `gdb` framework to call the developer-supplied `stop` function at each call to `lookupKey`. The developer tracks the sliding window of 10,000 requests by storing the value of the `key` argument into `keys`, a `queue`, and removing the first element if there are more than 10,000 elements in `keys` (Lines 7, 9, and 13). The developer could recompute the unique values in `keys` in `stop`, but that would add significant performance overhead since `lookupKey` is executed frequently. Instead, the developer uses a dictionary object, `indexed`, to track the number of times each `key` value appears in the `keys` window (Lines 5, 8, and 10–12). This logic is subtle and challenging to get right—for example, we initially used a `set` to track the unique elements in `keys` instead of using a dictionary to track the number of times each element appears in `keys`. Our buggy implementation erroneously removes elements from `indexed` and produces misleading results.

```
1  Select v.time, v.value
2    From Vars(ot) as v Join Funcs(ot) as f
3   Where v.name = "used" And f.name = "lookupKey"
4     And f.enterTime = v.time
```

Listing 3: The developer's second query.

```
1  Define DefinedMemory(ot) as:
2  Select m.rVal as pointer, m.exitTime as start,
3         m.callStack as allocSite, f.enterTime as end
4         m.arg["size"] as size
5  From Funcs(ot) as m Left NextJoin Functs(ot) as f
6    On m.exitTime, f.enterTime,
7    m.name="malloc" And m.exitTime<=f.enterTime
8   And f.name="free" And m.rVal=f.arg["ptr"]
9
10 Select start, allocSite, sum(size)
11   Over(Partition By allocSite Order By start)
12 From DefinedMemory(ot)
13 Where end=NULL
```

Listing 4: The definition of the `DefinedMemory(ot)` view (Lines 1–8) and the developer's third query (Lines 10–13).

2.2.2 Second Query

Surprisingly, the working set size of the cache is fairly constant throughout the execution. Consequently, poor cache performance may arise from poor eviction decisions for the workload or from a decrease in the number of items in the cache over time. The developer's second query determines the number of items in the cache over time by checking the number of items in the cache before each execution of the `lookupKey` function (Listing 3). redis stores the size of the cache in a global variable, `used`; the query uses the `Vars(ot)` view to access the value of the variable (Lines 2–3). It prevents the query from producing extremely large amounts of data by using a `Join` to limit the rows to only those when the execution enters `lookupKey` (Lines 2–4).

Unlike the `OmniTable` query model, many debugging tools do not expose the value of variables at arbitrary points-in-time and cannot support the developer's second query (e.g., Fay [12], PTQL [14]). Endoscope [7] could support the query, but only exposes variable values when they are assigned and requires the query identify the most recent preceding assignment of `used` for each call to `lookupKey`. Instrumentation-based tools (e.g., Pivot Tracing [24], G2 [17]) and procedural tools (e.g., `gdb`) require instrumenting the `lookupKey` function to produce the value of `used`.

2.2.3 Third Query

The second query's output shows that the number of items in the cache decreases throughout the execution. Since the redis configuration specifies a total memory size for the cache and the deployment uses constant sized items, a declining number of items in the cache implies that there is a memory leak. Unfortunately, redis does not clean up memory on shutdown, so existing leak detection tools (e.g., memcheck [29] and AddressSanitizer [39]) report nearly all memory allocations as leaks.

```
1  Select dm.pointer, Count(*)
2  From Funcs(ot) as r Join DefinedMemory(ot) as dm
3  Where dm.allocSite=leakSite And dm.exit=NULL
4    And r.name="decrRefCount" Or r.name="incrRefCount"
5    And dm.pointer=r.arg["obj"]
6  Group By dm.pointer, r.name
```

Listing 5: The developer's fourth query.

The developer's third query uses an alternative approach: it tracks the number of leaked bytes by each allocation site (defined as the call stack of the allocation) over time. Allocation sites that produce bug-inducing leaks will have a gradual increase of leaked bytes throughout the execution. The developer's query observes three separate types of execution events with different happens-before relationships, which is greatly simplified by the `OmniTable` query model.

The developer first creates a view, `DefinedMemory(ot)` that contains the window of time during which each memory object is defined, i.e., allocated and not freed (Listing 4). The view joins each call to malloc with the subsequent call to free whose pointer argument, `ptr`, is equal to the return value from malloc (Lines 5–8). Since a pointer could be reallocated by malloc after being freed, the query only matches calls to free that occur after the call to malloc (`m.exitTime<f.enterTime` at Line 7). Additionally, it only matches each malloc with the next matching call to free, as ordered by `exitTime` and `enterTime`, respectively, by using **`NextJoin`**, a new operator provided by the `OmniTable` query model (Lines 5–6). The developer uses **`Left NextJoin`**, which produces output from the left relation even if there is no matching row in the right relation, so that memory which is never freed (i.e., leaked) has a `NULL` value for the `end` column.

The third query tracks the amount of data leaked by each allocation site over time. For each leaking allocation (Lines 12–13), the developer constructs a window containing all preceding leaking allocations from the same allocation site by using the **`Over`** operator (Line 11). They sum the number of bytes leaked within each window (Line 10).

Like with the previous queries, existing debugging tools either cannot support the third query, impose high programming complexity, or impose high performance overhead.

2.2.4 Fourth Query

The output of the third query identifies a single leaking allocation site, `leakSite`. redis uses reference counters to manage allocations from `leakSite`. Each counter tracks the number of live references to each object; redis should garbage collect the object when the count reaches 0. So, the developer suspects a problem in the reference counting and writes a query to count the updates to the reference counters of leak-

ing objects (Listing 5). They identify leaked objects that were allocated at `leakSite` (Lines 2–3) and match each leaked object with corresponding executions of `decrRefCount` and `incrRefCount`, the functions that modify reference counts (Lines 2, 4, and 5). The developer groups the rows by object and function name (Line 6) and determines the number of calls to increment and decrement the counter (Line 1).

Like the previous queries, existing debugging tools either cannot support the developer's fourth query, impose high programming complexity, or impose high performance overhead.

2.2.5 Fifth Query

The fourth query's output shows that the execution calls `incrRefCount` and `derRefCount` the same number of times on the leaked objects, indicating a problem in the implementation of `incrRefCount` or `decrRefCount`. The developer chooses a few candidate objects and determines the call stack of the calls to `incrRefCount` and `decrRefCount` for these objects. The final query[1] shows that the leaked object's reference counts are decremented by a lazy deallocation thread and by a logging thread and points to the root cause of the bug, a race condition in `decrRefCount`. In the fix for the original bug report, the developer redesigning the logging thread to copy objects instead of sharing them.

3 The `OmniTable` Query Model

We outline the features of the `OmniTable` query model that enable a developer to succinctly reason about the entire history of execution state. The central abstraction is an `OmniTable`, a database table containing all user-level architectural state of an execution immediately before every instruction in the execution. Concretely, an `OmniTable` contains a column for every byte of architectural state and a row immediately before each instruction. The model supports debugging queries over an `OmniTable` expressed using SQL-style **`Select`**...**`From`**...**`Where`** queries.

Alas, an `OmniTable` alone offers an inadequate debugging interface, since a developer would need to reference execution state in architectural terms. For example, a developer would need to determine the exact memory location of each variable whose value they wish to observe. So, the `OmniTable` model adopts and extends database concepts to enable debugging abstractions. It uses `Generators`, user-defined-table-functions that allow queries to reference non-execution state (e.g., debugging symbols). It adds new operators for debugging, such as traversal functions and new `Join` variants. Finally, the model uses derived views to label an `OmniTable`'s state according to familiar debugging abstractions such as the functions executed in an `OmniTable` or the variables in scope at each instruction in an `OmniTable`. A single row in a high-level view can expose execution state from multiple points-in-time during the execution (e.g., `Funcs(ot)`). Below, we elaborate on the model's components.

[1] Omitted for brevity, this query is a self-join of the `Funcs(ot)` view

3.1 Relations

The `OmniTable` query model supports two relational base tables, `OmniTables` and `Generators`. It supports columns with primitive types (e.g., Long, String), Structs, Maps, Arrays, and Any, a polymorphic type.

OmniTable. An `OmniTable` is a database table that includes all architectural execution state immediately before each instruction in the execution; Figure 4 shows an example. Before each instruction, the `OmniTable` contains the current `thread`, the value of all registers and memory addresses, and the top of the `stack` of the thread. To dereference an address, `addr`, a query specifies `Memory[addr]`. Additionally, each row includes a monotonically increasing logical `time`, which provides a total ordering of events in the `OmniTable` and uniquely identifies each row. In a multi-threaded program, the `time` field is a total ordering that is consistent with the partial ordering of the original execution. Together, the `thread` and `time` columns enable a developer to reason about concurrency.

Generators. `Generators` allow developers to bridge the semantic gap between traditional programming abstractions (e.g., functions, lines of code) and an `OmniTable`'s architectural state by referencing non-execution state (e.g., debugging symbols). For example, `Defs` identifies the functions defined in a binary; the following produces all such definitions for an executable, "a.out": **`Select`** `*` **`From`** `Defs("a.out")`. `Generator` input can depend on query data. For example, `Binaries` is useful for bootstrapping queries; it uses the deterministic record/replay log to identify the binaries mapped into the address space of an `OmniTable`. The following determines all functions defined in all binaries that are loaded in `ot`, an `OmniTable`, which we use to define the `FuncDefs` view: **`Select`** `*` **`From`** `Defs(`**`Select`** `*` **`From`** `Binaries(ot))`. Developers create `Generators` by writing a program that produces relational output; we have built a `Generator` that determines all variables defined in in all binaries mapped into an `OmniTable`, and one that creates stored procedures that produce the memory read and written by each instruction in an `OmniTable`.

3.2 Relational Operators

The model supports **`join`**, **`group by`**, **`order by`**, and **`pivot`**. It also introduces three `Join` variants for debugging.

StackJoin. SQL is unable to model a function stack, which would prevent the `OmniTable` query model from expressing critical debugging abstractions, such as `Funcs(ot)`, which is used in all of the queries in the redis case study (§2). Prior high-level debugging tools either remove support for such se-

Metadata				Registers				Memory

```

Listing 6: An Example StackJoin.

mantics (e.g., PTQL [14]) or require manual instrumentation (e.g., G2 [17]). Instead, the `OmniTable` model creates a new operator, **`StackJoin`**.

As an example, suppose that `fenter(ot)` is a view that contains a row for each function entry in `ot`, an `OmniTable`, with columns `name`, `thread`, and `time` for the name of the function, thread that entered the function, and time of entry; and that `freturn(ot)` is a view conatining a row for each function return in `ot`, an `OmniTable`, with columns `name`, `thread`, and `time` for the name of the function, thread that returned from the function, and time that the function returns. Listing 6 shows a **`StackJoin`** that matches each function entry with its function return. **`StackJoin`** partitions `fenter(ot)` and `freturn(ot)` into groups that match on `thread` and `name`. For each group, the operator orders the rows `fenter(ot)` by `time` and orders the rows from `freturn(ot)` by `time`. Repeatedly, the operator pushes all rows from `fenter(ot)` onto a stack until it finds a row that occurs after the next row in `freturn(ot)`; it then produces a row by joining the last row added to the stack and the next row in `freturn(ot)`.

OrderedJoins. When debugging, developers often reason about the next, or previous, event that satisfies some condition. For example, in the `DefinedMemory(ot)` view, the developer matched each call to `malloc` with the next call to `free` on the same pointer (§2.2.3). SQL requires inconvenient subqueries for this reasoning, so, the `OmniTable` query model adds two new ordered join operators. The `NextJoin` operator determines the next matching row across two relations and can be used to determine the next function executed by a thread or the next access to a shared variable: **`NextJoin on`** `ord1, ord2, equals` joins each row in the left relation, ordered by `ord1`, with the next row from the right relation, ordered by `ord2`, where `equals` is true. The `PrevJoin` operator does the opposite.

3.3 Column Operators

The `OmniTable` query model supports many column operators, including arithmetic and conditional operators, field expressions (`a.b`), subscript expressions (`a[b]`), traversal functions, stored procedures, and standard aggregations (e.g., **`Count`**, **`Max`**, **`Min`**, etc.) over groups and windows. The model also supports pointer dereferences by converting them into expressions over the `Memory` column (e.g., `a->b` becomes `Memory[a].b`). We elaborate on traversal functions and stored procedures.

Traversal Functions. SQL makes it difficult to traverse the elements in a data structure since it does not support unbounded traversals. So, the `OmniTable` query model builds new primitives for these operations. Given a pointer-typed `column` and a `field` within the pointed-to type, the `traverse(column, field)` expression produces a row of output for each element in the transitive closure of the structure by starting at `column` and following `field` pointers until the value is `NULL`. For example, `traverse(node, "next")` traverses the `next` pointer of all elements in a structure, starting at `node`.

Stored Procedures. Debugging logic often varies by execution context (e.g., the memory location of function arguments varies by function). Stored procedures [43] store relational logic in a table and allow a query to decide query logic during query resolution. Developers call stored procedures in their `OmniTable` queries with function syntax; for example, a developer could specify `Var_Loc(esp)` to use `Var_Loc`, a stored procedure that calculates the memory location of a variable given the value of the stack pointer.

3.4 Derived Views

The `OmniTable` query model allows developers to construct derived views for labeling execution state. The **Define** operator in Listing 4 shows how a developer constructs `DefinedMemory(ot)`. Our implementation provides three high-level views, `Funcs(ot)` (§2.1), `Vars(ot)` (§2.1), and `Insts(ot)`, a view that encodes information about each instruction in an `OmniTable`.

4 Design

In this section, we describe the design of SteamDrill, our system that supports the `OmniTable` query model. From a developer's perspective, SteamDrill computes queries over `OmniTables` that are extracted during execution and stored in a database. However, materializing an entire `OmniTable` is infeasible due to high storage and compute costs: an `OmniTable`'s size is equal to the addressable memory size

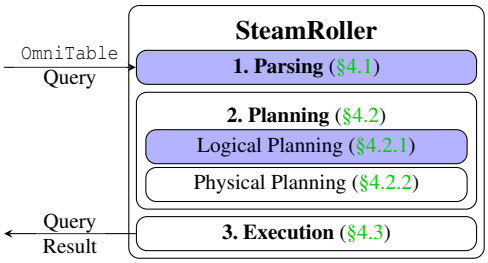

Figure 5: SteamDrill steps for query resolution. Blue steps re-use or customize existing approaches, and white steps are new designs.

```
1 Select eip, read, write
2 From Insts(ot) as i Left Join DefinedMemory(ot) as dm
3    On (i.read=dm.pointer Or i.write=dm.pointer)
4    And i.time>=dm.start And i.time<dm.end
5 Where dm.start=NULL
```

Listing 7: A simplified undefined use query.

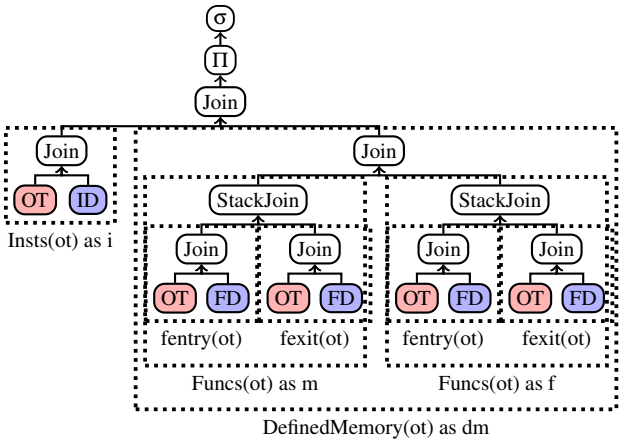

Figure 6: The relational tree for Listing 7. `OmniTables` are red ovals labeled with OT. `Generators` are blue ovals; `InstructionDefs` are ID nodes and `FuncDefs` are FD nodes. Relational operators are white rectangles; **`where`**, **`join`**, and **`select`** clauses are σ, Join, and Π nodes. The logic for each derived view is encapsulated in a dotted rectangle.

times the number of executed instructions and reaches petabytes, or even exabytes, for mere seconds of execution.

SteamDrill introduces lazy materialization as a solution. Rather than materializing an `OmniTable` during execution, SteamDrill uses deterministic record and replay [10] to capture a log of non-deterministic inputs to the execution. The system uses the log to generate `OmniTable` state on-demand by instrumenting and re-executing the original execution as necessary to resolve debugging queries. Delaying `OmniTable` materialization allows SteamDrill to filter `OmniTable` data *before* extracting state instead of afterwards.

In the rest of this section we describe how SteamDrill resolves debugging queries. Listing 7 presents a simplified use-after-free query as a running example. The query uses the `Insts(ot)` view to identify the memory read and written by each instruction in an `OmniTable`. It joins `Insts(ot)` with the `DefinedMemory(ot)` view from the third redis query, to match each memory access with the region of time during which its pointer was defined (Listing 4). The query uses a **`Left Join`** and identifies rows where `start` is `NULL` to identify the instructions that operate on undefined memory.

SteamDrill's design mirrors that of typical database management systems [2] (Figure 5). First, SteamDrill uses conventional SQL parsing to decompose a query into a tree of relational operators (internal nodes) over data tables (leaves) (§4.1). The tree contains a separate leaf node for each `OmniTable` referenced in the query. The relational operators that consume data from each `OmniTable` in the tree identify the execution state that the query needs from that `OmniTable`. During execution, SteamDrill uses these operators to limit the materialization of each `OmniTable` in the query by generating instrumentation that it injects into replay executions (§4.3).

The order of `OmniTable` materialization has a large impact on the amount of materialized data and the latency of query resolution. Delaying the materialization of an otherwise computationally expensive-to-materialize `OmniTable` often allows SteamDrill to filter the computationally expensive materialization using data from a less computationally expensive-to-materialize `OmniTable`. For example, to reduce the latency of the use-after-free query, the system first materializes the `OmniTable` state needed for the `DefinedMemory` view and uses the materialized data to filter the materialization of the `Insts(ot)` view.

Accordingly, SteamDrill uses multi-replay resolution—it splits `OmniTable` materialization across multiple replay executions. It uses query planning to determine the `OmniTable` materialization order and assigns `OmniTable` materialization to replay executions(§4.2). SteamDrill implements `OmniTable`-specific optimization strategies to decide the join order and join algorithm for each join in the tree (§4.2.1) which it uses to assign each operator to a stage. The system uses a single replay execution to materializes all `OmniTables` in the same stage. This approach minimizes the number of replay executions (since each replay execution adds additional overhead) and enables SteamDrill to limit `OmniTable` materialization.

4.1 Parsing

First, SteamDrill converts the query into a tree of relational operators over data tables using a standard SQL parser [2]; the tree encodes the logic required to resolve the query in terms of easy-to-optimize relational operations. The tree encodes each relational operator in the query as an internal node (i.e., a projection (Π), selection (σ), or join operator) and each `OmniTable` and each `Generator` in the query as a separate

leaf node. SteamDrill recursively decomposes each view into the relational logic that generates them until the tree is comprised entirely of relational logic and base tables (§3.1). A directed edge from node n_1 to node n_2 in the tree identifies that the operator n_2 consumes the output of n_1.

Figure 6 is the relational tree produced by SteamDrill for Listing 7. SteamDrill contains the internal logic of the `Insts(ot)` and `DefinedMemory(ot)` views (shown as dotted rectangles). The tree contains the logic of the `Insts(ot)` view: a **`Join`** between an `OmniTable` and `InstructionDefs`, a `Generator` containing metadata about the instructions defined in binaries used by an `OmniTable`.

The tree includes the internal logic of `DefinedMemory(ot)` and, recursively, all of the derived views comprising `DefinedMemory(ot)`. The tree contains the `DefinedMemory(ot)` logic (Listing 4): a **`Join`** between two `Funcs(ot)` views, one for executions of malloc (`Funcs(ot)` as m) and one for executions of free (`Funcs(ot)` as f). The tree contains the logic of each `Funcs(ot)` view (§3.2 and Listing 6): a **`StackJoin`** that combines `fentry(ot)` and `fexit(ot)`, relations over the entry and exit to each function in the `OmniTable`. Finally, the tree contains the logic for each `fentry(ot)` and `fexit(ot)`: a **`Join`** between an `OmniTable` and `FuncDefs`. Note, the tree includes the `fentry(ot)` of malloc and `fexit(ot)` of free even though the query does not use their output; during planning, SteamDrill determines that the query does not use the views and prunes them.

4.2 Planning

SteamDrill performs two tasks during planning. During logical planning, the system optimizes the relational tree using standard optimizations (e.g., predicate push-down) and determines the join order and join algorithm for each join in the tree using `OmniTable`-specific strategies (§4.2.1). The most crucial task in logical planning is determining the join order and algorithms for the query, since the join order and algorithms imply the partial order in which SteamDrill will materialize the `OmniTable` nodes contained in the query. SteamDrill supports two join algorithms: merge joins, which operate over two fully realized relations, and block-nested-loop joins (loop joins), which first calculate the left relation and use the left relation's output to limit right relation materialization.

During physical planning, SteamDrill produces a staged execution plan, which uses the join order and algorithms assigned during logical planning to assign each operator in the tree to a stage. In particular, physical planning assigns the children of merge joins to the same stage (so SteamDrill materializes them using the same replay) and assigns the right child of a loop join to the stage after the loop join's left child (so SteamDrill materializes them using different replays).

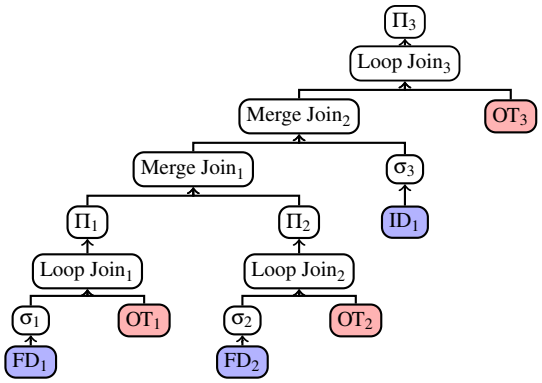

Figure 7: The relational tree for Figure 6 after logical planning.

4.2.1 Logical Planning

Traditional techniques for deciding join order and algorithms perform poorly on `OmniTable` queries for three reasons: First, similar subtrees in a relational tree have vastly different computational costs to materialize (e.g., the **`join`** subtree in the `Funcs(ot)` subtree is similar but much less computationally expensive than the **`join`** subtree in the `Insts(ot)` subtree). Second, the materialization cost of an `OmniTable` often depends on unpredictable properties of the underlying execution (e.g., it is difficult to predict the execution frequency of a particular function). Third, the enormous compute cost of materializing an `OmniTable` invalidates conventional rules.

Consequently, SteamDrill turns to a rule-based planner [1] that enables developers to encode semantic information that would be difficult or impossible for SteamDrill to deduce on its own. Each rule specifies regular-expression-like rules that pattern match subtrees of the relational tree and produce modified operators [1]. The join order and algorithm rules produce a left-deep join structure in which `OmniTable` nodes are isolated on the right-hand side of a join node (Figure 7), since these structures allow SteamDrill to perform as much filtering as possible when extracting data from an `OmniTable`. When queries join relations with different expected materialization compute costs, the rules place the less expensive relations on the left side, the more expensive relation on the right side and employ a loop join. When joining relations with the same expected materialization compute costs (e.g., two instances of `Funcs(ot)`), the rules use a merge join. Heuristically, SteamDrill expects that `Funcs(ot)` relations are less computationally expensive to materialize than `Vars(ot)` relations, which are less computationally expensive than `Insts(ot)` relations, which are less computationally expensive than `OmniTables`. Rules also encode traditional database optimizations.

Executing the relational tree in Figure 6 without logical planning would have high latency; SteamDrill would materialize the `OmniTable` five separate times! In contrast, SteamDrill's logical plan (Figure 7) uses multi-replay resolution to

observe only the exit from malloc, entry to free, and load/store instructions. Moreover, the plan reduces latency by only producing data for load/stores to undefined memory as they are observed, rather than producing data for all loads/stores and performing a join to determine undefined uses afterwards.

First, SteamDrill uses traditional database optimizations (e.g., operator push-down) to push operators towards leaf nodes to (1) produce `FuncDefs` data for only malloc and free (σ_1 and σ_2), (2) produce `InstructionDefs` data only for loads and stores (σ_3) and (3) eliminate the fentry(ot) for malloc and fexit(ot) for free. The system uses loop joins for Loop Join_1 and Loop Join_2, which materialize σ_1 and σ_2 before OT_1 and OT_1 to limit `OmniTable` state to the exit of malloc and entry to free in OT_1 and OT_2, respectively. The system joins them using a Merge Join (Merge Join_1) to limit the number of replay executions that it uses. OT_3, created for the `Insts(ot)` view, is computationally expensive to materialize, so SteamDrill defers its materialization. SteamDrill uses a Merge Join (Merge Join_2) to join σ_3 and Merge Join_1, which requires a Cartesian product and violates the traditional rule that such approaches be avoided. Materializing Merge Join_2 and using a loop join (Loop Join_3) to join it with OT_3 allows SteamDrill to identify only the loads/stores to undefined memory (i.e., loads/stores that read/write an address at a time when it is not contained in `DefinedMemory(ot)`) as they are performed by the execution rather than in an expensive join afterwards. In some queries, using a loop join like Loop Join_3 enables SteamDrill to elide inspection of some instructions altogether (e.g., Listing 8).

4.2.2 Physical Planning

Next, SteamDrill converts the optimized relational tree into a staged execution plan by assigning each operator from the tree into a *stage*. Each stage corresponds to a new replay execution (§4.3). SteamDrill assigns operators to stages that follow the partial order of `OmniTable` materialization that is implied by the join order and algorithm, but uses as few stages as possible, since each stage will require the additional latency and overhead of a replay execution.

SteamDrill performs a depth-first traversal of the tree starting at the root node and maintains an integer id for the current stage, starting at 1. The system assigns leaf nodes (`OmniTable`, `Generators`) to the current stage and unary nodes (i.e., all non-join operators) to their child's stage. The system assigns merge join operators to the largest stage among the join's children. For loop join operators, SteamDrill first assigns stages to operators in the left (inexpensive) child, adds one to the current stage, assigns the loop join to the new stage and traverses the right (expensive) child.

Figure 8 shows the staged execution plan for Listing 7. SteamDrill assigns FD_1, σ_1, FD_2, σ_2, ID_1, and σ_3 to the first stage. It assigns OT_1 and OT_2 to the second stage since Loop Join_1 and Loop Join_2 indicate that OT_1 and OT_2 should

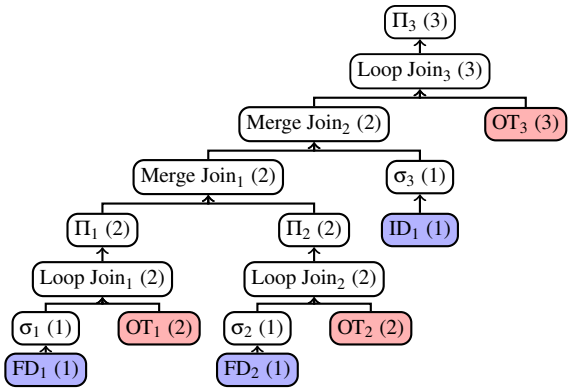

Figure 8: The staged execution plan for Figure 7. The stage of each node is shown in parentheses in the node.

be materialized after σ_1 and σ_2, respectively. SteamDrill also assigns Π_1, Π_2, Merge Join_1, and Merge Join_2 to the second stage since they inherit the largest stage of their children. The system assigns Loop Join_3, OT_3, and Π_3 to the third stage to follow the order required for Loop Join_3.

4.3 Execution

Finally, SteamDrill executes the staged execution plan. For each stage, the system generates instrumentation to materialize the state needed from each `OmniTable`, materializes each `OmniTable`, and calculates each operator in the stage.

4.3.1 Instrumentation Generation

SteamDrill generates instrumentation that it will inject into a replay execution for the `OmniTables` in a stage by determining instrumentation operators for each `OmniTable` node in the stage. For each `OmniTable` node, the system gathers all stateless operators (e.g., projections (Π) and selections(σ)) that only consume data from (1) the `OmniTable` node, (2) nodes resolved in previous stages, or (3) other nodes satisfying (1) and (2). For example, the instrumentation operators for OT_1 in Figure 8 includes Π_1 and Loop Join_1. Selecting stateless operations ensures that the resulting instrumentation will be parallelizable during materialization.

Then, SteamDrill creates a cursor object for each `OmniTable` node that combines all of the node's instrumentation operations. Cursor objects contain a `filter` and an `output` clause; logically, a cursor inspects the execution instruction-by-instruction, producing the `output` whenever the `filter` is true. SteamDrill generates the filter clause of the cursor for each `OmniTable` in the stage by combining all selection (σ) and loop join instrumentation operators and generates the output clause using the output of the top-most projection (Π) instrumentation operator.

4.3.2 Materialization

Next, SteamDrill materializes `OmniTable` nodes by executing the cursor objects on top of a replay of the execution associated with the tables. It uses epoch parallelism [34, 35] to parallelize cursor evaluation. Epoch parallelism partitions a replay execution into time slices, called epochs. It assigns each epoch to a separate core in a compute cluster and uses checkpoints, generated during recording, so that each core executes each cursor over only its assigned epoch.

However, naive cursor evaluation (i.e., instrumenting every instruction) imposes a many orders of magnitude slowdown. So, SteamDrill analyzes the filter clause of each cursor to identify instructions at which the system can elide cursor evaluation to optimize performance. For example, SteamDrill identifies that the cursors in the second stage of Figure 8 only need to be evaluated at malloc and free and removes all other cursor evaluations. Our prototype identifies these optimizations by finding comparisons to the program counter.

Additionally, SteamDrill calculates operators in the stage that were not assigned as instrumentation operators for any `OmniTable` node (e.g., Merge Join_1 and Merge Join_2 in Figure 8). SteamDrill uses existing algorithms to calculate merge join and aggregation operators [1, 16]. Additionally, it executes the program associated with each `Generator` in the stage to calculate `Generator` operators.

5 Implementation

We implement our SteamDrill prototype on top of Spark [1] and Arnold [10]; below, we describe its key components.

Spark SQL. Our prototype introduces new relational operators and base tables for `OmniTables` and `Generators`. We added support for block-nested-loop joins, stored procedures, and polymorphic columns (§3) by serializing data to and from a JSON format. We added catalyst rules for our `OmniTable`-specific join order and algorithm preferences (§4.2.1). Each rule required 25 lines of code, so we expect that developers will be able to easily add custom rules as needed for their debugging workflows.

Instrumentation. Efficient cursor instrumentation plays a vital role in our prototype's performance. Debugging tools often use dynamic instrumentation frameworks (e.g., PIN [23]), which are a scalability bottleneck when SteamDrill parallelizes the replay execution across many cores [34]. Our prototype performs static binary instrumentation. It disassembles the application binaries and rewrites the basic blocks contained in the application to call cursors, as required for the breakpoints determined from each cursor. The system single-steps execution for cursors that do not produce breakpoints.

Time Column. The time column is a critical element of the `OmniTable` query model, but, deriving the column by counting all instructions or basic blocks would be too expensive. We observe that instructions progress from low to high, except in the case of a backwards control-flow (e.g., branch, call, or return instructions that jump to a program location at a lower address). Thus, our prototype uses the number of backwards control-flow operations as a the first element of the time column and breaks ties using the instruction pointer. Serendipitously, Intel provides deterministic performance counters for conditional branch and call instructions[2], which allow our prototype to compute the number of backwards control-flow operations by counting the number of unconditional backwards branches during execution and adding the value of these performance counters.

6 Evaluation

In this section, we evaluate the `OmniTable` query model and SteamDrill by answering the following questions: "Does the `OmniTable` query model improve upon existing debugging interfaces?", "Does SteamDrill accelerate debugging questions?", and "How do SteamDrill design decisions impact query performance?".

We perform 5 detailed case studies of how a developer could use an `OmniTable` and SteamDrill to solve real-world bugs from open-source servers (§6.1) from which we derive 14 debugging questions. We implement the debugging questions using `OmniTable` queries and `gdb`'s python bindings, which provide a python interface for traditional `gdb` features (e.g., breakpoints and backtraces). We compare the complexity of the 14 `OmniTable` queries and `gdb` scripts using metrics from the software engineering community (§6.2). We deploy SteamDrill on a CloudLab [37] cluster of 8 r320 machines (8-core Xeon E5-2450 2.1 GHz processor, 16 GB Ram, 10 Gbps NIC) to evaluate the performance for 3 representatives from the original 14 debugging questions (§6.3). We calculate the latency results below as the average over 10 trials and include 95% confidence intervals.

6.1 Case Studies

We performed 5 detailed case studies by identifying the debugging questions that a developer would ask when solving real-world bugs. We choose notoriously difficult bugs including livelock, intermittent performance problems, and atomicity violations (on average, the bugs in our study took 159 days from being opened to the commit that fixed the bug). We choose case studies from popular open-source applications: redis, Memcached, Apache, and Sqlite. The redis 4323 case study is described in §2; below, we describe case studies for debugging a livelock [28] and atomicity violation [27] in Memcached. We omit a description of a performance degradation in Apache [6] and a segmentation fault in Sqlite [41].

The case studies illustrate the benefits of the `OmniTable` query model along two key dimensions: first, the all-inclusive

[2] Note that most performance counters are not deterministic

```
1 Select f.Name, Count(*)

4 Pivot Count() in (True, False)
```

Listing 9: The second query for Memcached 127.

state exposed by the table offers a powerful window into an execution's behavior. Second, SQL aggregations provide a powerful tool for summarizing and comparing program state. These features are particularly powerful when used in tandem. For example, in Memcached 271, the developer identifies the function that contains a livelock by counting the number of instructions executed by the functions left on the call stack at the end of the execution. This logic cannot be expressed in existing high-level debugging tools and is very complex when expressed using procedural tools such as `gdb`.

Memcached 271. In this case study, a developer observes livelock in the Memcached key-value store [28]. Livelock is notoriously difficult to diagnose since a developer needs to identify the cause of a missing property: forward progress [33].

In contrast, the `OmniTable` model allows the developer to succinctly track millions of execution events and use aggregations to identify anomalous execution state. Their first query, shown in Listing 8, identifies which function contains the livelock by counting the number of instructions executed during each function on each thread's call stack at program termination. The query matches each executed instruction with the most recent function called on the same thread to determine which function contained the instruction (Lines 2 and 3). It counts how many instructions were executed (Line 1) by each function that did not return (Line 4).

The output identifies a single function with a high number of branches. The function traverses a linked-list, which the developer suspects is corrupted. The developer's second query counts how many times each function that updates the linked list is called with every possible function argument value and shows a single anomalous call to free a linked-list item in which the item is still resident in the linked-list. Memcached reference counts linked-list items, so the developer's third and final query tracks all reference count updates and identifies an overflow that leads to the erroneous free of the item.

Memcached 127. This case study involves an atomicity violation in Memcached. An integer stored in the cache has the wrong value after all updates, which is challenging to debug since the developer does not know which program state to track or when to track it. Atomicity violation tools [32] use heuristics and may misidentify the root cause of the bug.

Table 1: Lines, Nodes, and Halstead Complexity for debugging questions expressed using `OmniTable` queries (OT) and `gdb` python scripts (`gdb`).

The `OmniTable` model, particularly SQL aggregations, provide a powerful tool for comparing the state of their program at many points-in-time to identify anomalous program state. The developer first isolates the module that contains the error. In particular, they determine if the bug arises when initially parsing requests or when processing them by using a `count` aggregate to count the number of times the function at the boundary between parsing and processing is called with each possible set of arguments. The query shows that the problem arises when processing requests.

The processing code maintains a boolean variable, `valid`, that tracks the validity of a global pointer used by the code. The developer's second query, shown in Listing 9, identifies how often `valid` is set to `true` and `false` during each of the instruction within the processing logic. It uses a **`Pivot`** operator to produce a row for each instruction and show the number of times `valid` is set to `true` and `false` across all executions of the instruction. The second query identifies a few instructions at which status has an anomalous state. The anomalous instructions do not modify the status, so the developer concludes that another thread must modify the status and identifies a mistake in the processing logic's use of a mutex.

6.2 Complexity

We implemented the 14 debugging queries from our 5 case studies using `OmniTable` queries and implemented equivalent logic using `gdb` python scripts. Qualitatively, we observe that `OmniTable` queries are less complex due SQL aggregations, the all-inclusive nature of an `OmniTable`, and the structured approach provided by high-level views: `OmniTable` queries usually involve an aggregation after joining a few high level views, whereas imperative debugging scripts regularly use multi-dimensional data-structures to track state, nested control-flow to implement aggregations, and complex

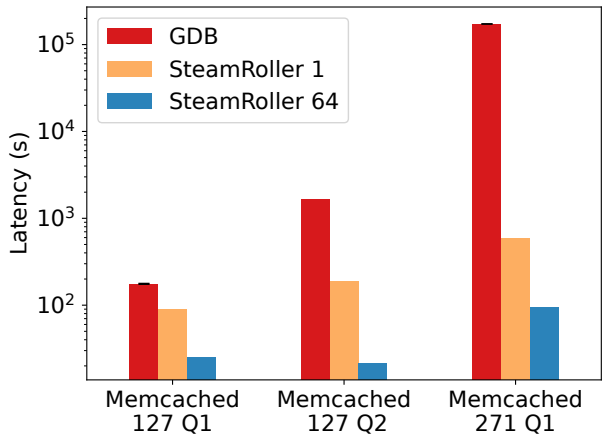

Figure 9: SteamDrill query latency on a single core and on 64 cores compared to `gdb` script latency (which is sequential). Y-axis is log-scale.

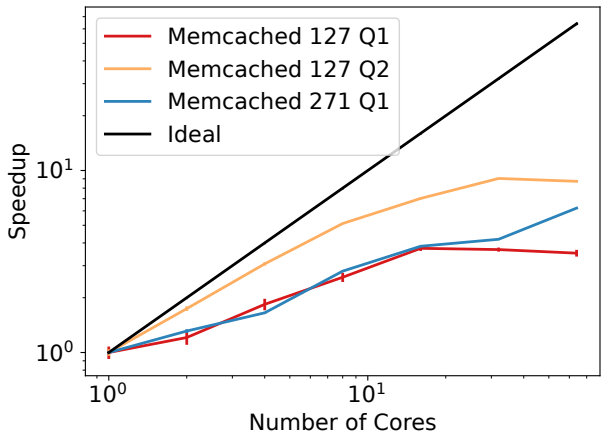

Figure 10: SteamDrill scalability. Shows number of cores on the x-axis vs. speedup on the y-axis; both axes are log-scale.

regular expressions to identify instrumentation points. We measure complexity of each `OmniTable` query and `gdb` script using three software engineering metrics: the number of lines of code, the number of terms in the abstract syntax tree (AST), and the Halstead complexity, which estimates the amount of time it would take to correctly produce the query or script using properties of the AST [18]. We included the definition of user-defined views (e.g., `DefinedMemory(ot)`) into the `OmniTable` queries that use them, so our results are an upper-bound on `OmniTable` query complexity.

Table 1 shows the results, indicating that `OmniTable` queries are less complex than `gdb` scripts. By geometric mean, `OmniTable` queries require 3.74 times fewer lines, 1.70 times fewer nodes, and 2.75 times less estimated time to develop than `gdb` scripts. There are only three queries that are more complex when expressed using the `OmniTable` model, the second and fifth redis 4323 queries, and the second Apache 60956 query. The two redis queries are small for both representations. The second Apache query suffers from the lack of kernel state in an `OmniTable`. The query identifies all blocking file descriptors, which requires substantial logic to track all function calls in the `OmniTable` model, but can be calculated in `gdb` using `fcntl`. Extending the `OmniTable` to include kernel state would reduce the complexity.

6.3 Query Latency

We evaluate the latency of `OmniTable` queries and `gdb` scripts for 3 representative queries from our case studies. We choose queries that use all of the high level views in our prototype (i.e., `Funcs(ot)`, `Vars(ot)`, and `Insts(ot)`) and offer a wide range of performance on current tools, from ~22 minutes to ~2 days. Figure 9 shows the latency of each debugging question evaluated using `gdb`, SteamDrill with a single core, and SteamDrill with 64 cores, with latency plotted on a log-scale. We executed Memcached 271 Q1 for 48 hours before killing the program and report its latency as 48 hours.

SteamDrill is significantly faster than `gdb`. SteamDrill query latency is between 2 and 290 times (with a geometric mean of 17) faster than `gdb` latency when using a single core, and between 6.9 and 1809 (with a geometric mean of 99) times faster than `gdb` latency when using 64 cores.

6.4 Optimizations

Next, we evaluate the impact of three optimizations on SteamDrill's latency: parallelization, multi-replay resolution, and performance-counters.

Scalability. We evaluate the query latency of SteamDrill queries when using 1–64 cores; Figure 10 shows the speedup on a log-log scale. SteamDrill queries are 10.5 times faster using 64 cores than when run sequentially. Importantly, whereas prior parallelization efforts require the developer to substantially redesign their debugging code [30, 34, 35, 38, 46], the parallelized and sequential `OmniTable` queries are identical. The current scalability bottlenecks are caused by high initialization and serialization cost in Spark and the high cost of compiling cursors.

Multi-Replay Resolution. We evaluate the impact of multi-replay query resolution on the Memcached 271 Q2 query. We calculate the query latency when using two rounds of replay (the approach chosen by the SteamDrill planner) and when using a single round of replay on 64 cores. SteamDrill is 3.6 times faster when using multi-replay resolution.

Performance Counters. We evaluate the impact of using performance counters to accelerate the calculation of the `time` column in an `OmniTable`. We executed the 3 queries with and

Tool	Model	Observations	Aggregates
Execution Mining [20]	Stream	All	No
Fay [12]	Stream	Partial	Partial
Pivot Tracing [24]	Relational	Log-Based	Partial
G2 [17]	Graph	Log-Based	Manual
PQL [25]	Stream	Partial	No
PTQL [14]	Relational	Partial	No
EndoScope [7]	Stream	Partial	Yes
EBBA [5]	Stream	Log-Based	No
TQuel [40]	Relational	Log-Based	Partial
`OmniTable`	Relational	Everything	Yes

Table 2: Feature comparison of high-level debugging tools .

without using performance counters (when disabled, SteamDrill instruments all `jump`, `call`, and `return` instructions) on 64 cores. The performance counter optimization accelerates query latency by a factor of 1.6.

7 Related Work

The `OmniTable` query model is the first debugging model that exposes all application state as a single entity and enables succinct observations via a high-level declarative language. Below we describe work related to high-level languages for debugging, using deterministic replay for debugging, and applying optimizations to accelerate debugging.

Existing systems support high-level debugging languages to reduce programming complexity; Table 2 illustrates the limitations of prior work compared to the `OmniTable` model. Execution Mining [20], PQL [25], EBBA [5] and EndoScope [7] expose a time-stream model of execution, which complicates debugging since it is difficult to summarize data over time (e.g., these tools cannot express the `Funcs(ot)` view since it contains execution data from multiple points-in-time). Other systems limit visibility of execution state: Fay [12], PQL [25], EBBA [5], EndoScope [7], and PTQL [14] expose partial program state consisting of only the function calls or global variables values in an execution. Pivot Tracing [24], G2 [17], EBBA [5], and TQuel [40] require manual instrumentation to enable observations, which essentially amounts to supporting queries over software logs. Finally, many tools provide no, or very few, aggregates [14, 20, 25]; G2 [17] supports aggregates but requires that they be expressed in terms of a graph processing language.

Many `OmniTable` queries compare correct execution behavior to incorrect execution behavior, similar to statistical debugging approaches [22]. There are two key differences (1) statistical bug isolation requires observing many correct and incorrect executions to come to a statistical verdict, whereas developers can often get a "sense" for correctness using an `OmniTable` query with fewer examples and (2) statistical debugging approaches hard code the values that they compare (e.g., function argument values), whereas developers can customize `OmniTable` queries to use program constructs best suited to their applications.

Many systems have noted that deterministic replay can be a great help when debugging software problems [8, 13, 19, 31, 42, 45]. Such systems enable a debugging program to explore an execution's time-sequence in reverse, but retain a procedural interface.

Recently, JetStream [34] and Sledgehammer [35] use deterministic replay as a vehicle for parallelizing debugging, which our prototype uses to accelerate `OmniTable` queries. However, these tools support procedural debugging models, similar to `gdb`, and consequently suffer from the programming complexity.

Existing tools do not decouple debugging logic's execution from the original execution to optimize query latency. PARTICLE [14], Fay [12], Pivot Tracing [24] and PMSS [21] reduce the debugging performance overhead using traditional SQL optimizations (e.g., predicate push-down). However, these tools add instrumentation to the program and re-execute it to recreate the bug, which tightly couples the execution of debugging and the original execution and increases performance overhead. Additionally, by inspecting new executions, these systems are cannot perform all SteamDrill performance optimizations, particularly multi-replay query resolution.

8 Conclusion

In this paper, we propose the `OmniTable` query model, a new debugging paradigm that reduces the programming complexity and performance overhead of debugging without restricting the execution state that a developer can observe. We show that the query model simplifies debugging questions compared to existing state-of-the-art tools by performing case studies of bugs reported in popular open-source software. Unfortunately, an `OmniTable`, the key abstraction in the model, cannot be stored or calculated due to its extreme size. So, our prototype, SteamDrill, implements *lazy materialization*: it delays an `OmniTable`'s calculation until a developer queries the table. It uses deterministic record and replay to store the execution associated with each `OmniTable` and then generates instrumentation and traces a new replay execution to resolve each developer query on-demand. The system uses declarative optimizations, debugging optimizations, and a novel multi-replay strategy to accelerate debugging queries by an order of magnitude compared to state-of-the-art tools.

XRP: In-Kernel Storage Functions with eBPF

Yuhong Zhong[1], Haoyu Li[1], Yu Jian Wu[1], Ioannis Zarkadas[1], Jeffrey Tao[1], Evan Mesterhazy[1], Michael Makris[1], Junfeng Yang[1], Amy Tai[2], Ryan Stutsman[3], and Asaf Cidon[1]

Abstract

With the emergence of microsecond-scale NVMe storage devices, the Linux kernel storage stack overhead has become significant, almost doubling access times. We present XRP, a framework that allows applications to execute user-defined storage functions, such as index lookups or aggregations, from an eBPF hook in the NVMe driver, safely bypassing most of the kernel's storage stack. To preserve file system semantics, XRP propagates a small amount of kernel state to its NVMe driver hook where the user-registered eBPF functions are called. We show how two key-value stores, BPF-KV, a simple B$^+$-tree key-value store, and WiredTiger, a popular log-structured merge tree storage engine, can leverage XRP to significantly improve throughput and latency.

1 Introduction

With the rise of new high performance memory technologies, such as 3D XPoint and low latency NAND, new NVMe storage devices can now achieve up to 7 GB/s bandwidth and latencies as low as 3 µs [11, 19, 24, 26]. At such high performance, the kernel storage stack becomes a major source of overhead impeding both application-observed latency and IOPS. For the latest 3D XPoint devices, the kernel's storage stack *doubles* the I/O latency, and it incurs an even greater overhead for throughput (§2.1). As storage devices become even faster, the kernel's relative overhead is poised to worsen.

Existing approaches to tackle this problem tend to be radical, requiring intrusive application-level changes or new hardware. Complete kernel bypass through libraries such as SPDK [82] allows applications to directly access underlying devices, but such libraries also force applications to implement their own file systems, to forgo isolation and safety, and to poll for I/O completion which wastes CPU cycles when I/O utilization is low. Others have shown that applications using SPDK suffer from high average and tail latencies and severely reduced throughput when the schedulable thread count exceeds the number of available cores [54]; we confirm this in §6, showing that in such cases applications indeed suffer a 3× throughput loss with SPDK.

In contrast to these approaches, we seek a readily-deployable mechanism that can provide fast access to emerging fast storage devices that requires no specialized hardware and no significant changes to the application while working with existing kernels and file systems. To this end, we rely on BPF (Berkeley Packet Filter [67, 68]) which lets applications offload simple functions to the Linux kernel [8]. Similar to kernel bypass, by embedding application-logic deep in the kernel stack, BPF can eliminate overheads associated with kernel-user crossings and the associated context switches. Unlike kernel bypass, BPF is an OS-supported mechanism that ensures isolation, does not lead to low utilization due to busy-waiting, and allows a large number of threads or processes to share the same core, leading to better overall utilization.

The support of BPF in the Linux kernel makes it an attractive interface for allowing applications to speed up storage I/O. However, using BPF to speed up storage introduces several unique challenges. Unlike existing packet filtering and tracing use cases, where each BPF function can operate in a self-contained manner on a particular packet or system trace — for example, network packet headers specify which flow they below to — a storage BPF function may need to synchronize with other concurrent application-level operations or require multiple function calls to traverse a large on-disk data structure, a workload pattern we call "resubmission" of I/Os (§2.3). Unfortunately the state required for resubmission such as access-control information or metadata on how individual storage blocks fit in the larger data structure they belong to is not available at lower layers.

To tackle these challenges, we design and implement XRP (eXpress Resubmission Path), a high-performance storage data path using Linux eBPF. XRP is inspired by XDP, the recent efficient Linux eBPF networking hook [28]. In order to maximize its performance benefit, XRP uses a hook in the NVMe driver's interrupt handler, thereby bypassing the kernel's block, file system and system call layers. This allows XRP to trigger BPF functions directly from the NVMe driver as each I/O completes, enabling quick resubmission of I/Os that traverse other blocks on the storage device.

The key challenge in XRP is that the low-level NVMe driver lacks the context that the higher levels provide. Those layers contain information such as who owns a block (file system layer), how to interpret the block's data, and how to traverse the on-disk data structure (application layer).

Our insight is that many storage-optimized data structures that power real-world databases [10, 12, 20, 27, 44, 66, 70, 80] – such as on-disk B-trees, log-structured merge trees, and log segments – are typically implemented on a small set of large files, and they are updated orders of magnitude less frequently than they are read; we validate this in §3. Hence, we exclusively focus XRP on operations contained within one file and on data structures that have a fixed layout on disk. Consequently, the NVMe driver only requires a minimal amount of the file system mapping state, which we term the *metadata digest*; this information is small enough that it can be passed from the file system to the NVMe driver so it can safely perform I/O resubmissions. This allows XRP to safely support some of the most popular on-disk data structures.

We present a design and implementation of XRP on Linux, with support for ext4, which can easily be extended to other file systems. XRP enables the NVMe interrupt handler to resubmit storage I/Os based on user-defined BPF functions.

We augment two key-value stores with XRP: BPF-KV, a B$^+$-tree based key-value store that is custom-designed for supporting BPF functions, and WiredTiger's log-structured merge tree, which is used as one of MongoDB's storage engines [27]. With random 512 B object reads on BPF-KV with multiple threads using a B$^+$-tree that has three index levels on disk, XRP has 47%–94% higher throughput and 20%–34% lower p99 latency than `read()`. XRP also enables more efficient sharing of cores among applications than kernel bypass: it is able to provide 56% better p99 latency than SPDK with two threads sharing the same core. In addition, XRP is able to consistently improve WiredTiger's performance by up to 24% under YCSB [41]. We open source XRP and our changes to BPF-KV and WiredTiger at `https://github.com/xrp-project/XRP`.

We make the following contributions.

1. **New Datapath**. XRP is the first datapath that enables the use of BPF to offload storage functions to the kernel.
2. **Performance**. XRP improves the throughput of a B-tree lookup by up to 2.5× compared to normal system calls.
3. **Utilization**. XRP provides latencies that approach kernel bypass, but unlike kernel bypass, it allows cores to be efficiently shared by the same threads and processes.
4. **Extensibility**. XRP supports different storage use cases, including different data structures and storage operations (e.g., index traversals, range queries, aggregations).

2 Background and Motivation

In this section we show why the Linux kernel is becoming a primary bottleneck with fast NVMe devices and provide a primer on BPF.

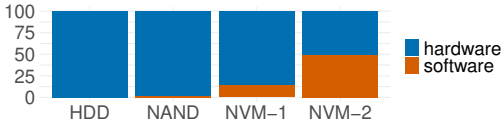

Figure 1: Kernel's latency overhead with 512 B random reads. HDD is Seagate Exos X16, NAND is Intel Optane 750 TLC NAND, NVM-1 is first generation Intel Optane SSD (900P), and NVM-2 is second generation Intel Optane SSD (P5800X).

kernel crossing	351 ns	5.6%
read syscall	199 ns	3.2%
ext4	2006 ns	32.0%
bio	379 ns	6.0%
NVMe driver	113 ns	1.8%
storage device	3224 ns	51.4%
total	6.27 µs	100.0%

Table 1: Average latency breakdown of a 512 B random `read()` syscall using Intel Optane P5800X.

2.1 Software is Now the Storage Bottleneck

New media like 3D Xpoint [1] and low-latency NAND [26], have led to new NVMe storage devices that exhibit single-digit µs latencies and millions of IOPS [11, 19, 24, 26]. The kernel storage stack is becoming a major performance bottleneck when accessing these devices. Figure 1 shows the percentage of time spent in the Linux stack when issuing a 512 B random read I/O on different storage devices. While the software overhead for the first generation of fast NVMe devices (first generation Intel Optane or Z-NAND) was non-negligible (~15%), with the latest generation of devices (Intel Optane SSD P5800X) the software overhead accounts for about half of the latency of each read request. The kernel's relative overhead will only get worse as storage devices become even faster.

Where is the time going? Table 1 shows the time spent in the different storage layers when issuing a random 512 B read with O_DIRECT on Optane P5800X. The experimental setup, which is used throughout this section, is a server with 6-core i5-8500 3 GHz with 16 GB of memory, using Ubuntu 20.04, and Linux 5.8.0. We also disable processor C-states and turbo boost, use the maximum performance governor, and disable KPTI [30]. The experiment shows that the most expensive layer is the file system (ext4), followed by the block layer (bio) and the kernel crossing, and that the total software overhead accounts for 48.6% of the average latency.

Why not just bypass the kernel? One approach to eliminate kernel overhead is to bypass it altogether [7, 65, 82, 83], leaving just the cost to post a request to the NVMe driver and the device's latency. However, kernel bypass is no panacea: each user is entrusted with full access to the device; they must also construct their own user space file systems [73, 74]. This means that there is no mechanism to enforce fine-grained

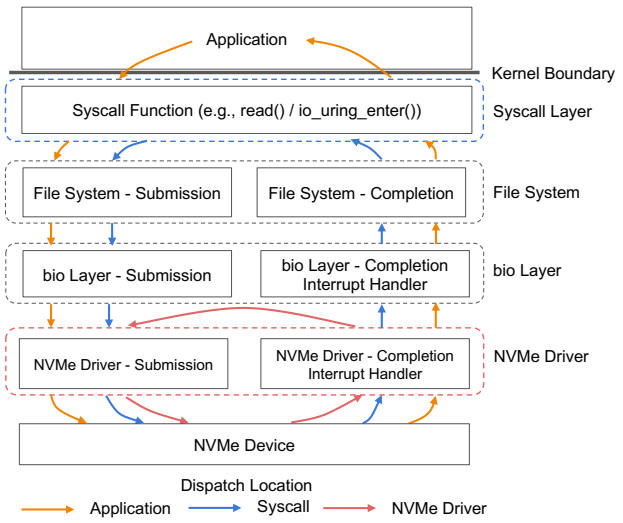

Figure 2: Dispatch paths for the application and two kernel hooks.

isolation or to share capacity among different applications accessing the same device. In addition, there is no efficient way for user space applications to receive interrupts on I/O completions, so applications must directly poll on device completion queues to obtain high performance. Consequently, when I/O is not the bottleneck, cores cannot be shared among processes, which results in significant under-utilization and wasted CPU. Furthermore, when more than one polling thread shares the same processor, the CPU contention between them coupled with the lack of synchronization lead all polling threads to experience degraded tail latency and significantly lower overall throughput. Recent work has highlighted this issue [54] and we reproduce it in §6.2.

2.2 BPF Primer

BPF (Berkeley Packet Filter) is an interface that allows users to offload a simple function to be executed by the kernel. Linux's framework for BPF is called eBPF (extended BPF) [23]. Linux eBPF is commonly used for filtering packets (e.g., TCPdump) [5, 6, 28, 52], load balancing and packet forwarding [5, 18, 25, 60], tracing [2, 4, 50], packet steering [46], network scheduling [53, 58] and network security checks [15]. Functions are verified by the kernel at install-time to ensure they are safe; for example, they are checked to make sure they do not contain too many instructions, unbounded loops, or accesses to out-of-bounds memory addresses [29]. After verification, which typically takes a few seconds or less, the eBPF functions can be called normally.

2.3 The Potential Benefit of BPF

BPF can be a mechanism for avoiding data movement between the kernel and user space in cases when a logical lookup requires a sequence of "auxiliary" I/O requests that generate intermediate data not needed directly by the application, such as in pointer-chasing workloads. For example, to traverse a B-tree index, a lookup at each level traverses the kernel's entire storage stack only to be thrown away by the application once it obtains the pointer to the next child node in the tree. Instead of a sequence of system calls from user space, each of the intermediate pointer lookups could be executed by a BPF function, which would parse the B-tree node to find the pointer to the relevant child node. The kernel would then submit the I/O to fetch the next node. Chaining a sequence of such BPF functions could avoid the cost of traversing kernel layers and moving data to user space.

	Latency	Speedup	Throughput	Speedup
User Space	78 µs	1×	109K IOPS	1×
Syscall Layer	68 µs	1.15×	130K IOPS	1.2×
NVMe Driver	40 µs	1.95×	276K IOPS	2.5×

Table 2: Average latency and throughput improvement with respect to user space when resubmitting I/O from the given layer; for kernel layers, resubmission is executed with a BPF function. Results shown for lookups on an on-disk B-tree of depth 10 [85].

Other popular on-disk data structures, such as log-structured merge trees (LSM trees) [70], also have such auxiliary pointer lookups which can be accelerated using BPF functions. Other types of operations that would benefit from such an approach include range queries, iterators, and other types of aggregations (e.g., obtain the maximum or average value in a range of key-value pairs). In all of these cases, only a single result or a small subset of the objects that might be accessed by the storage system ultimately need to be returned to the application.

The BPF function that resubmits (dispatches) I/O in auxiliary I/O workloads could be placed at any layer of the kernel. Figure 2 shows the I/O paths for both normal user space dispatch and for two possible locations of BPF resubmission hooks: in the syscall layer and in the NVMe driver. Zhong et al. [85] compared the performance improvement from a resubmission hook in both locations on workloads with auxiliary I/O by measuring the speedup of lookup queries on an on-disk B-tree of depth 10. The baseline for comparison is reading I/O through the `read` system call. Table 2 summarizes the results.

Best Case Acceleration. Dispatching the I/O requests from the NVMe driver provides a significant latency reduction (up to 49%) and corresponding speedup (up to 2.5×), since it bypasses almost the entire kernel software stack. On the other hand, as expected, issuing the BPF functions from the syscall dispatch layer only provides a maximum speedup of 1.25×, since the requests only benefit from eliminating kernel boundary crossings, which only account for 5-6% of the kernel overhead (Table 1). After reaching CPU saturation, the computation savings of reissuing the submissions from the NVMe driver translate into throughput improvements of 1.8-2.5×, depending on the number of threads in the workload [85].

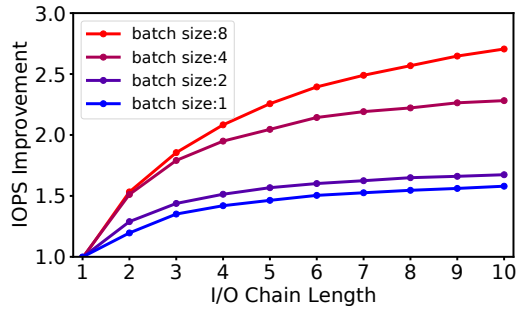

Figure 3: Single-threaded lookups with io_uring syscall, using NVMe driver hook.

Placing an eBPF hook *anywhere* in the kernel may improve throughput between 1.2–2.5×. However, pushing the I/O dispatching as close as possible to the storage device dramatically improves the performance of a traversal. Hence *to obtain the highest possible speedup, XRP's resubmission hook should reside in the NVMe driver*.

What about io_uring? io_uring is a new Linux system call framework [9] that allows processes to submit batches of asynchronous I/O requests, which amortizes user-kernel crossings. However, each I/O submitted with io_uring still passes through all the layers shown in Table 1, so each individual I/O still incurs the full storage stack overhead. In fact, BPF I/O resubmissions are largely complementary to io_uring: io_uring can efficiently submit batches of I/Os that trigger different I/O chains managed by BPF in the kernel.

Figure 3 shows throughput improvements when using io_uring with a BPF hook in the NVMe driver. I/O Chain Length denotes the total number of I/Os, including the initial I/O and the resubmitted I/Os. Figure 3 shows that BPF can increase throughput with respect to io_uring by up to 1.5× for small batch sizes and up to 2.5× as batch sizes increase.

In summary, BPF can benefit both legacy read and io_uring system calls. By placing the hook in the kernel NVMe driver, BPF may increase throughput of both legacy I/O and single-threaded io_uring by up to 2.5×.

3 Design Challenges and Principles

As shown in the previous section, I/O resubmission must occur as close to the device as possible in order to reap the greatest benefits. In the NVMe software stack, this is the NVMe interrupt handler. However, executing the resubmissions from within the NVMe interrupt handler, which lacks the context of the file system layer, introduces two major challenges.

Challenge 1: address translation and security. The NVMe driver has no access to file system metadata. In the example of an index traversal, XRP issues a read I/O to a particular block and executes a BPF function that would extract the offset of the next block it would like to query. However, this offset is meaningless to the NVMe layer, since it cannot tell which physical block the offset corresponds to without having access to the file's metadata and extents. Even if the application developer made the effort to embed physical block addresses to avoid the translation of the file system offset, which would be burdensome, the BPF function could access *any* block on the device, including blocks that belong to a file that the user does not have permissions to access.

Challenge 2: concurrency and caching. It is challenging to enable concurrent reads and writes issued from the file system with XRP. A write issued from the file system will only be reflected in the page cache, which is not visible to XRP. In addition, any writes that modify the layout of the data structure (e.g., modify the pointers to the next block) that are issued concurrently to read requests could lead XRP to accidentally fetch the wrong data. Both of these could be addressed by locking, but accessing locks from within the NVMe interrupt handler may be expensive.

Observation: most on-disk data structures are stable. Both of these challenges would make it difficult to implement arbitrary concurrent BPF storage functions. However, we make the observation that the files of many storage engines (e.g., LSM trees and B-trees) remain relatively stable. Some data structures simply do not modify on-disk storage structures in-place. For example, once an LSM tree writes its index files (called SSTables) to disk, they are immutable until they are deleted [12, 27, 44]. Accessing these immutable on-disk storage structures requires less synchronization effort. Similarly, even though some on-disk B-tree index implementations support in-place updates, their file extents remain stable for long periods of time. We verify this in a 24-hour YCSB [41] (40% reads, 40% updates, 20% inserts, Zipfian 0.7) experiment on MariaDB running TokuDB [20], which uses a fractal tree (an on-disk B-tree variant) as its lookup index. We found the index file's extents only changed every 159 seconds on average, with only 5 extent changes in 24 hours unmapping any blocks, making it possible to cache file system metadata in the NVMe driver without the overhead of frequent updates. We also make the observation that in all of these storage engines, the indices are stored on a small number of large files, and each index does not span multiple files.

Design principles. These observations and experiments inform the following design principles.

- **One file at a time.** We initially restrict XRP to only issue chained resubmissions on a single file. This greatly simplifies address translation and access control, and it minimizes the metadata that we need to push down to the NVMe driver (the *metadata digest*, §4.1.3).
- **Stable data structures.** XRP targets data structures, whose layout (i.e. pointers) remain immutable for a long period of time (i.e. seconds or more). Such data structures include the indices used in many popular commercial storage engines, such as RocksDB [44], LevelDB [12], TokuDB [12] and WiredTiger [27]. Since the cost of im-

plementing locks in the NVMe layer is high, we also initially do not plan to support operations that require locks during the traversal or iteration of data structures.

- **User-managed caches.** XRP does not interface with the page cache, so XRP functions cannot safely be run concurrently if blocks are buffered in the kernel page cache. This constraint is acceptable since popular storage engines often implement their own user space caches [20,27,39,44]; Commonly they do this to fine-tune their caching and prefetching policies and to cache data in an application-meaningful way (e.g., cache key-value pairs or database rows instead of physical blocks).
- **Slow path fallback.** XRP is best-effort; if a traversal fails for some reason (e.g., the extent mappings become stale), the application must retry or fall back to dispatching the I/O requests using user space system calls.

4 XRP Design and Implementation

This section presents XRP's design and implementation with Linux eBPF and ext4. We describe the kernel modifications that enable XRP's resubmission logic in the interrupt handler, and how applications are modified to use XRP. We also discuss XRP's synchronization and scheduling limitations.

4.1 Resubmission Logic

The core of XRP augments the NVMe interrupt handler with resubmission logic that consists of a BPF hook, a file system translation step, and the construction and resubmission of the next NVMe request at the new physical offsets (Figure 4). Our modifications to the Linux kernel consist of ~900 lines of code: ~500 lines for the BPF hook and the changes to the NVMe driver, ~400 lines for the file system translation step.

When an NVMe request completes, the device generates an interrupt that causes the kernel to context switch into the interrupt handler. For each NVMe request that is completed in the interrupt context, XRP calls its associated BPF function (`bpf_func_0` in Figure 4), the pointer of which is stored in a field in the kernel I/O request struct (i.e. `struct bio`). After calling the BPF function, XRP invokes the metadata digest, which is usually a digest of file system state that enables XRP to translate the logical address of the next resubmission. Finally, XRP prepares the next NVMe command resubmission by setting the corresponding fields in the NVMe request, and it appends the request to the NVMe submission queue (SQ) for that core.

For a particular NVMe request, the resubmission logic is called as many times as necessary for subsequent completions as determined by the specific BPF function registered with the NVMe request. For example, for traversing a tree-like data structure, the BPF function would resubmit I/O requests for branch nodes and end resubmission whenever a leaf node is found. In our current prototype there is no hard limit on the number of resubmissions before the completion returns control to the application; such a limit would be necessary to prevent unbounded execution. A hard limit can be enforced by maintaining a resubmission counter in each I/O request descriptor. Since I/O request descriptors cannot be accessed from user space or from XRP's BPF programs, their hard resubmission limits cannot be overridden by users even if XRP has multiple BPF functions that execute request resubmissions. BPF function contexts are per-request, while the metadata digest is shared across *all* invocations of the interrupt handler across all cores. Safe concurrent access to the metadata digest relies on read-copy-update (RCU) (§4.1.3).

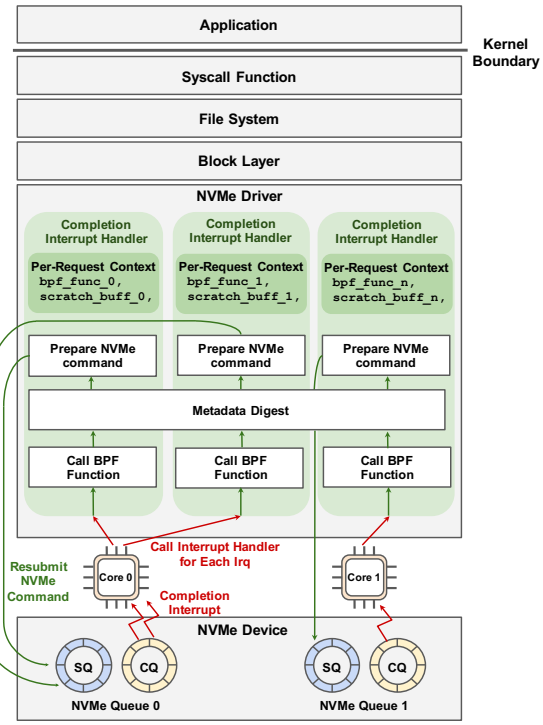

Figure 4: XRP architecture.

```
struct bpf_xrp {
  // Fields inspected outside BPF
  char *data;
  int done;
  uint64_t next_addr[16];
  uint64_t size[16];
  // Field for BPF function use only
  char *scratch;
};
uint32_t BPF_PROG_TYPE_XRP(struct bpf_xrp *ctxt);
```

Listing 1: Signature of BPF programs that can be loaded by XRP.

4.1.1 BPF Hook

XRP introduces a new BPF type (`BPF_PROG_TYPE_XRP`) with the signature shown in Listing 1 – any BPF function that matches the signature can be called from the hook. §5 presents one concrete BPF function matching this signature that is used in our application. For example, for on-disk data structure

traversal, the BPF function typically contains logic to extract the next offset to fetch from the block.

`BPF_PROG_TYPE_XRP` programs require a context with five fields, categorized into fields that are inspected or modified by the BPF caller (resubmission logic in the interrupt handler), and fields that should be private to the BPF function. Fields that are accessed externally include `data`, which buffers data read from the disk (e.g., a B-tree page waiting to be parsed by the BPF function). `done` is a boolean that notifies the resubmission logic whether to return to the user or continue resubmitting I/O requests. `next_addr` and `size` are arrays of logical addresses and their corresponding sizes that indicate the next logical addresses for resubmission.

In order to support data structures with fanout, multiple `next_addr` values can be supplied. By default we limit fanout to 16; on-disk data structures align their components to small multiples of device pages, so we have not encountered a need for higher fanout per completion. For example, chained hash table buckets are likely implemented as a chain of individual physical pages and the elements of an on-disk linked list are likely implemented at the granularity of physical pages. Setting a corresponding size field to zero issues no I/O.

`scratch` is a scratch space that is private to the user and the BPF function. It can be used to pass the parameters from the user to the BPF function. Also, the BPF function can use it to store intermediate data in between I/O resubmissions and to return data to the user. For example, in the first BPF invocation, the application can store a search key in the scratch buffer so that the BPF function can compare it with the keys in the disk block in order to find the next offset. When the I/O chain reaches the leaf node of the B-tree, the BPF function then places the key-value pair in the scratch buffer to return it back to the application. For simplicity, we assume that the size of the scratch buffer is always 4 KB. We find that a 4 KB scratch buffer is sufficient to support a BPF function for a production key-value store (§5). BPF functions can also use BPF maps to store more data if their intermediate data cannot fit into the scratch buffer. Each BPF context is private to one NVMe request, so no locking is needed when working with BPF context state. Letting the user supply a scratch buffer (instead of using BPF map) avoids the overhead of processes and functions having to call `bpf_map_lookup_elem` to access the scratch buffer.

4.1.2 BPF Verifier

The BPF verifier ensures memory safety by tracking the semantics of the value stored in each register [14]. A valid value can either be a scalar or a pointer. `SCALAR_TYPE` represents a value that cannot be dereferenced. The verifier defines various pointer types; most of them include extra constraints beyond the no out-of-bound access requirement. For example, `PTR_TO_CTX` is the type for the pointer to a BPF context. It can only be dereferenced using a constant offset so the verifier can identify which context field a memory operation

```
void update_mapping(struct inode *inode);
void lookup_mapping(struct inode *inode,
                    off_t offset, size_t len,
                    struct mapping *result);
```

Listing 2: Metadata digest: XRP exposes an interface to share logical-to-physical-block mappings between the file system and the IRQ handler.

accesses. Each BPF function type also defines a callback function `is_valid_access()` to perform additional checks on context accesses and to return the value type of the context field. `PTR_TO_MEM` describes a pointer referring to a fixed-size memory region. It supports dereferencing using a variable offset as long as the access is always within bounds. The `data` and `scratch` fields of the `BPF_PROG_TYPE_XRP` context are `PTR_TO_MEM` and the rest are `SCALAR_TYPE`. We augment the verifier to allow the `BPF_PROG_TYPE_XRP`'s `is_valid_access()` callback to pass the size of the data buffer or scratch buffer to the verifier so that it can perform the boundary check. We discussed our proposed modification to the verifier with the Linux eBPF maintainers, and they think it is sensible.

4.1.3 The Metadata Digest

In the conventional storage stack, the logical block offsets in on-disk data structures are translated by the file system in order to identify the next physical block to read. This translation step also enforces access control and security, preventing reading in regions that are not mapped to the open file. In XRP, the next logical address for a lookup is given by the `next_addr` field after the BPF call. However, translating this logical address to a physical address is challenging since the interrupt handler has no notion of a file and does not perform physical address translation.

To solve this, we implement the metadata digest, a thin interface between the file system and the interrupt handler that lets the file system share its logical-to-physical-block mappings with the interrupt handler, enabling safe eBPF-based on-disk resubmissions. The metadata digest consists of two functions (Listing 2). The update function is called within the file system when the logical-to-physical mapping is updated. The lookup function is called within the interrupt handler; it returns the mapping for a given offset and length. The lookup function also enforces access control by preventing BPF functions from requesting resubmissions for blocks outside of the open file. The inode address of the open file is passed to the interrupt handler in order to query the metadata digest. If an invalid logical address is detected, XRP returns to user space immediately with an error code. The application can then fall back to normal system calls to attempt its request again.

These two functions are specific to each file system, and even for a particular file system, there may be multiple ways to implement the metadata digest, presenting a tradeoff between ease of implementation and performance. For example, in

our implementation for ext4, the metadata digest consists of a cached version of the extent status tree, which stores the physical-to-logical block mappings. This cached tree is accessed by the update and lookup function of the interface, and it uses read-copy-update (RCU) for concurrency control. RCU enables the lookup function to be lockless and fast (96 ns on average).

To keep the cached tree up-to-date with the extents in ext4, the update function is called in two places in ext4: whenever extents are inserted or removed from the main extent tree. To prevent a race condition where an extent is modified while there is an inflight read on it, we maintain a version number for each extent to track its changes. After data is read, but before it is passed to the BPF function, a second metadata digest lookup is performed. If the corresponding extent no longer exists or its version number has changed, XRP will abort the operation. Since application-level synchronization usually prevents concurrent modifications and lookups on the same region of a file at the same time, version mismatches should only occur if the application is buggy or malicious.

An alternative, simpler implementation of the metadata digest for ext4 could simply pass through to existing update and access functions of the extent tree in ext4. In this case, the update function would be a no-op, because ext4 already keeps its extent tree up-to-date. However, such an implementation would be much slower on the lookup path, because the extent lookup function in ext4 acquires a spinlock, which would be prohibitively expensive in the interrupt handler.

For now, XRP only supports the ext4 file system, but the metadata digest can be easily implemented for other file systems. For example, in f2fs [64], logical-to-physical-block mappings are stored in the node address table (NAT). Similar to the ext4 implementation, an implementation of its metadata digest could cache a local copy of the NAT, which would be consulted in `lookup_mapping`. Then `update_mapping` would need to be called anywhere in f2fs where the NAT is updated.

4.1.4 Resubmitting NVMe Requests

After looking up the physical block offsets, XRP prepares the next NVMe request. Because this logic occurs in the interrupt handler, to avoid the (slow) `kmalloc` calls needed to prepare NVMe requests, XRP reuses the existing NVMe request struct (i.e. `struct nvme_command`) of the just-completed request. XRP simply updates the physical sector and block addresses of the existing NVMe request to the new offsets derived from the mapping lookup. Reusing NVMe request structs for immediate resubmission is safe because neither user space nor XRP BPF programs can access the raw NVMe request structs.

While `struct bpf_xrp` supports a maximum fanout of 16, in the current implementation a resubmitted I/O request can only fetch as many physical segments as the initial NVMe request. For example, if an initial NVMe request only fetches a single block, then all subsequent resubmissions for that request can only fetch a single physical segment. During a resubmission chain, if the BPF call returns multiple valid addresses in `next_addr`, XRP will abort the request. This limitation can be worked around by allocating and setting up 16 dummy NVMe commands in the first I/O request so that subsequent resubmissions can express fanout if necessary.

4.2 Synchronization Limitations

BPF currently only supports a limited spinlock for synchronization. The verifier only allows BPF programs to acquire one lock at a time, and they must release the lock before returning. Also, user space applications do not have direct access to these BPF spinlocks. Instead, they must invoke the `bpf()` syscall; the syscall can read or write the lock-protected structure while holding the lock for the duration of that operation. Hence, complex modifications that require synchronizing across multiple reads and writes cannot be accomplished in user space.

Users can implement custom spinlocks using BPF atomic operations. This allows both BPF functions and user space programs to acquire any spinlock directly. However, the termination constraint prohibits BPF functions from spinning to wait for a spinlock infinitely. Another option for synchronization is RCU. Since XRP BPF programs are run in the NVMe interrupt handler, which cannot be preempted, de-facto they are already in an RCU read-side critical section.

4.3 Interaction with Linux Schedulers

Process scheduler. Interestingly, we observed that a microsecond-scale storage device like Optane SSD interferes with Linux's CFS when multiple processes share the same core, *even when all I/O is issued from user space*. For example, in the case where an I/O-heavy and compute-heavy process share the same core, the I/O interrupts generated by the I/O-heavy process will be handled in the timeslice of the compute-heavy process. This may cause the compute-heavy process to be starved of CPU; in the worst case in our experiments, the compute-heavy process only received about 34% of what would be a "fair" allocation of CPU time. We experimentally verified this does not occur when using a slower storage device, which generates interrupts much less frequently. While XRP exarcerbates this problem by generating chains of interrupts, this issue is not specific to eBPF, and can also be caused by network-driven interrupts [59]. We leave this problem for future work.

I/O scheduler. XRP bypasses Linux's I/O scheduler, which sits at the block layer. However, the noop scheduler is already the default I/O scheduler for NVMe devices, and the NVMe standard supports arbitration at hardware queues if fairness is a requirement [17].

5 Case Studies

To use XRP, applications use the interface shown in Listing 3. Applications call libbpf [13] function `bpf_prog_load` to load a BPF function of type `BPF_PROG_TYPE_XRP` to be offloaded

```
int bpf_prog_load(const char *file,
                  enum bpf_prog_type type,
                  struct bpf_object **pobj,
                  int *prog_fd);
int read_xrp(int fd, void *buf, size_t count,
             off_t offset, int bpf_fd,
             void *scratch);
```

Listing 3: The XRP application interface consists of a libbpf function to load BPF functions into the kernel and a read syscall that requests that a BPF function be used. `bpf_prog_load` is an existing function in libbpf. `bpf_prog_load` returns a file descriptor for the loaded function, which must be passed to `read_xrp`. `read_xrp` adds two arguments to the standard `pread` [21] syscall: this file descriptor and a pointer to a 4 KB scratch space that is passed to the BPF context.

in the driver and call `read_xrp` to apply a specific BPF function to the read request. Applications can load multiple BPF functions with XRP. For example, a database can load a function for filtering and calculating aggregations from values on-disk and a function for `GET` point lookups. XRP allows the application to load multiple BPF functions into the kernel and to specify the BPF function to use in each `read_xrp` syscall. We present two case studies on how applications should be modified to use XRP.

5.1 BPF-KV

We built a simple key-value store, called BPF-KV, with which we can evaluate XRP against other baselines: Linux's synchronous and asynchronous system calls and kernel bypass (SPDK [82]). BPF-KV is designed to store a large number of small objects and to provide good read performance even under uniform access patterns. BPF-KV uses a B^+-tree index to find the location of objects, and the objects themselves are stored in an unsorted log. For simplicity, BPF-KV uses fixed-sized keys (8 B) and values (64 B). The index and the log are both stored in one large file. The index nodes use a simple page format with a header followed by keys followed by values. Leaf nodes contain a file offset pointing to the next leaf node, enabling efficient index traversal for range queries and aggregation. Object sizes are fixed, so updates occur in-place in the unsorted log. Newly inserted items are appended to the log; their index is initially stored in an in-memory hash table. Once the hash table fills, BPF-KV merges it with the on-disk B^+-tree file.

Caching. BPF-KV implements a user space DRAM cache for index blocks and objects. To reduce the number of I/Os it needs to issue for lookups, BPF-KV caches the top k levels of the B^+-tree index. With a sufficiently large number of objects, it is not possible to fit the entire index in the cache. Consider the case where BPF-KV is used to store 10 billion 64 B objects. In BPF-KV's index, each node is 512 B (matching the access granularity of the Optane SSD); hence, the tree has a fanout of 31 (i.e. each internal node can store pointers to 31 children). Therefore, 10 billion objects would require an index with 8 levels. Fitting 6 index levels in DRAM is expensive and would require 14 GB, while fitting 7 levels or more becomes prohibitively expensive (437 GB of DRAM or more). So, to support a large number of keys, BPF-KV would require at the minimum 3-4 I/Os from storage for each lookup, including a final I/O to fetch the actual key-value pair from disk. Also note that having a hard memory budget for caching the index is common in many real-world key-value stores (e.g., RocksDB [45], DocumentDB [78], SplinterDB [40], TokuDB [20]), since the index cache often competes with other parts of the system that need memory, such as filters and the object cache.

BPF-KV also maintains a least recently used (LRU) object cache of the most popular key-value pairs. Before looking up an object on disk, BPF-KV first checks whether it is stored in the object cache. If not, it checks whether it is indexed in the in-memory hash table. If the item is not found in the in-memory hash table, it looks up the object by accessing the first k cached levels of the index. Once it encounters an index node that is not cached, it completes the index and the final lookup on disk.

To find an object without XRP, BPF-KV traverses the B-tree until the desired value is found using an I/O request per level. For example, if the index contains 7 levels and the first 3 are cached and read from DRAM, then the traversal will issue 4 I/Os to navigate the rest of the tree, followed by a final I/O to fetch the object from the log.

BPF function. Listing 4 shows the BPF function used in BPF-KV to lookup a key-value pair. We omit the code to handle the final lookup in the log for simplicity. `struct node` defines the layout of B^+-tree index nodes whose size is 512 B. The BPF function `bpfkv_bpf` first extracts the target key stored in the scratch buffer, and then it linearly searches the slots in the current node to find the next node to read.

Interface modifications. We replace `read` calls with `read_xrp`. Before calling into `read_xrp`, BPF-KV first allocates a buffer for the scratch space and calculates the offset at which to start the lookup.

Range queries. BPF-KV supports range queries returning a variable number of objects. We implement a BPF function that runs as a state machine, allowing the operation to be suspended and resumed when objects are returned to the application for processing. The BPF function state, including the beginning and end of the range, and the retrieved objects, are stored in the scratch space (up to 32 72-byte key-value pairs). On the initial invocation, the function traverses to the leaf node that contains the starting key. Once the first key in the range is found, the function stores the leaf node in the scratch space and requests the block containing the corresponding value. On the next BPF invocation, the function stores the value in the scratch space and it continues the index scan

```
struct node {
  uint64_t num; uint64_t type;
  uint64_t key[31]; uint64_t ptr[31];
};
uint32_t bpfkv_bpf(struct bpf_xrp *ctxt) {
  uint64_t key = *((uint64_t*)ctxt->scratch);
  struct node *n = (struct node *)ctxt->data;
  if (n->type == LEAF_NODE) {
    ctxt->done = true;
    return 0;
  }
  int i;
  for (i = 1; i < n->num; i++)
    if (key < n->key[i]) break;
  ctxt->done = false;
  ctxt->next_addr[0] = n->ptr[i - 1];
  ctxt->size[0] = 512;
  return 0;
}
```

Listing 4: BPF function for BPF-KV.

on the cached leaf node. When the leaf node has been read completely, the function submits a request for the next leaf node using the node's next-leaf file offset. The function returns to the application in three cases: 1) the function reaches a key past the end of the range; 2) the function reaches the end of the index; 3) the function fills the scratch space with values read from the log. In the last case, the application can process the values and re-invoke the BPF function with the range query state, allowing the range query to resume from where it left off.

Aggregations. BPF-KV also supports aggregation operations, such as `SUM`, `MAX` and `MIN`. We implement these operations on top of the BPF range query function by setting a bit that causes the function to perform the corresponding aggregation instead of returning the individual values. Since aggregation queries return a single answer, storing values in the scratch space does not limit the number of I/O resubmits the BPF function can request.

5.2 WiredTiger

WiredTiger is a popular key-value store that is the default backend for MongoDB [27]. We use it as a case study since it is a relatively simple and open key-value store that is used in production. WiredTiger provides an option to use an LSM tree where data is split into different levels; each level contains a single file. Each file uses a B-tree index with the key-value pairs embedded in the tree's leaf nodes. The files are read-only; updates and inserts are written into a buffer in memory. When the buffer is full, the data is written out in a new file. We configure the B-tree page size to be the same as our Optane SSD's block size (512 B). Our modification to WiredTiger is around 500 lines of code, which mainly consist of buffer allocation, extending function signatures and wrapping the XRP syscall. XRP helps accelerate reads that are serviced from disk, and it does not affect updates or inserts, which are always absorbed by WiredTiger's in-memory buffer.

BPF function. To use XRP, WiredTiger installs a BPF function similar to the one shown in Listing 4. The difference is in order to find the next lookup address from the current page, the BPF function contains a port of WiredTiger's B-tree page parsing code. This parsing logic replaces the `for` loop in Listing 4.

The WiredTiger BPF function also makes several modifications to make the BPF program compile correctly and pass the BPF verifier. The modifications mainly consist of adding bounds on loops to avoid infinite loops, masking pointers to eliminate out-of-bound access, and initializing local variables to prevent access to uninitialized registers. We also use the BPF function-by-function verification feature [3] to break a complex function into several simple sub-functions. This allows BPF functions to be verified independently, so the functions that have been verified do not need another round of verification when being called by other functions. The function-by-function verification feature also supports more complex BPF programs without exceeding the verifier's restrictions on function length.

Caching. WiredTiger maintains a least recently used (LRU) cache for its B-tree internal pages and leaf pages. When looking up a new key-value pair, WiredTiger caches the entire lookup path including the leaf page in the cache. In order to comply with WiredTiger caching semantics, the BPF function described in the previous section also returns all traversed pages so that WiredTiger can cache them. The BPF function stores traversed pages in the scratch buffer of its context. When the scratch buffer is exhausted, the BPF function will stop resubmitting requests and return to user space immediately. After WiredTiger adds those pages into its cache, it will call `read_xrp` again to continue the lookup starting at the previous page. Since we set the size of the scratch buffer to 4 KB, a BPF function can store up to 6 traversed 512 B pages in the scratch buffer, which leaves room for necessary metadata such as the search key.

Interface modifications. To integrate WiredTiger with XRP, we replace normal read calls with `read_xrp`. `read_xrp` is called when the next page is not in the cache and needs to be read from disk. The eviction policy of WiredTiger enforces that only the pages without any cached children pages can be evicted, so any uncached page will not have cached descendants. Therefore, it is safe to call `read_xrp` to read all of the remaining path from disk without checking the application-level cache again. If `read_xrp` fails for any reason, WiredTiger falls back to the normal lookup path. We allocate a data and scratch buffer for each WiredTiger session to avoid the overhead of allocating and freeing buffers for every request. WiredTiger sessions synchronously process

Average Lookup Latency (µs)				
# Ops	SPDK	io_uring	`read()`	XRP
1	5.2	13.6	13.4	10.7
2	7.8	20.2	20.6	14.2
3	11.2	28.0	27.4	18.0
4	14.3	35.0	34.0	21.7
5	17.2	42.4	41.5	25.4
6	20.2	49.3	48.8	29.3

Table 3: Average latency of a random key lookup with BPF-KV as a function of the depth of the B^+-tree stored on-disk. # ops is the number of index I/Os per lookup.

one request at a time, which avoids concurrency issues.

6 Evaluation

In this section we seek to answer the following questions:

1. What are the overheads of using BPF for storage (§6.1)?
2. How does XRP scale to multiple threads (§6.2)?
3. What types of operations can XRP support (§6.3)?
4. Can XRP accelerate a real-world key-value store (§6.4)?

Experimental setup. All experiments are conducted on a 6-core i5-8500 3 GHz server with 16 GB of memory, using Ubuntu 20.04, and Linux 5.12.0 with an Intel Optane 5800X prototype. All experiments use O_DIRECT, turn off hyper-threading, disable processor C-states and turbo boost, use the maximum performance governor, and enable KPTI [30]. We use WiredTiger 4.4.0 in the experiments.

Baselines. We compare the following configurations: (a) XRP, (b) SPDK (a popular kernel-bypass library), (c) standard `read()` system calls, and (d) standard io_uring system calls.

6.1 BPF-KV

Latency. To answer the first evaluation question, we measure the performance of BPF-KV on a benchmark that performs a million read operations with keys drawn randomly with uniform probability. The experiment varies the number of levels of the tree that are stored on-disk. In this subsection, we disable caching of data objects and index nodes to focus on the overhead of looking up on-disk items. The measured average latency is shown in Table 3. The leftmost column represents the number of chained I/Os that are required to lookup the key in the index (not including the final data lookup). For example, if the number of operations is 4, then BPF-KV is configured with an on-disk tree of depth 4, and it also needs to issue one more I/O to fetch the key-value pair from the log.

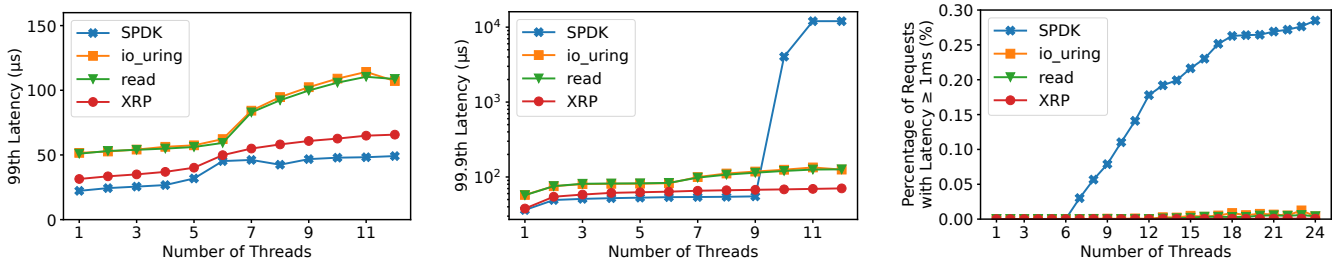
There are a few takeaways from this experiment. First, XRP improves latency over `read()`, because XRP saves one or more storage layer traversals when it traverses the index or moves from the index to the log. Indeed, one can see that XRP's latency increases by about 3.5-3.9 µs for each additional I/O operation, which is close to the device's latency (Table 1). This means that XRP achieves close to optimal latency for resubmitted requests. The same is true for io_uring: in the case of submitting I/O requests synchronously without batching, `read()` and io_uring are almost equivalent. Second, SPDK exhibits better latency than XRP since XRP must pass through the kernel's storage stack once to initiate the index traversal, while SPDK completely bypasses the kernel. Nonetheless, XRP's marginal added latency when the depth of the B^+-tree is increased is close to SPDK's (2.6 µs-3.4 µs). For this reason, in the case of a 6-level index, XRP is only 45% slower than SPDK while `read()` is 142% slower than SPDK. Importantly, XRP achieves this without resorting to polling. This means that, unlike with SPDK, processes can continue to use CPU cores efficiently for other work; XRP's use of CPU time is limited to what is specifically needed to resubmit I/Os in the background and to keep I/O device utilization high.

Figure 5a and Figure 5b present the 99th-percentile latency and 99.9th-percentile latency of XRP, respectively. When running with a single thread, similar to the average latency results, XRP reduces both 99th-percentile latency and 99.9th-percentile latency by up to 30% compared to `read()` and io_uring. Note that our experiment runs as a closed loop, so XRP is running at a higher throughput than `read()` and io_uring. At identical throughput XRP would show additional improvement over these baselines. Interestingly, when the number of threads exceeds the number of cores (6) by more than 3, SPDK's 99.9th-percentile latency increases significantly. This is due to the fact that with SPDK all threads are busy-polling, and cannot effectively share the same core with other threads. To this end, we measure the percentage of requests whose latencies are greater than or equal to 1 ms and present the data in Figure 5c. The results show that SPDK has 0.03% of such requests with 7 threads, and this percentage increases to 0.28% when the number of threads reaches 24. In contrast, io_uring, `read()`, and XRP always have fewer than 0.01% of such requests.

Throughput. Figure 6a shows the throughput of XRP. As expected, as the index depth increases, XRP's speedup is higher compared to standard system calls. Figures 6b and 6c show the throughput speedups with a varying number of threads with an index of depth 3 and 6, respectively. Both figures show the speedup of XRP relative to issuing standard system calls does not decrease even as I/O and XRP BPF functions are scaled across several cores. Once again, XRP provides equal to or higher throughput compared to SPDK once the number of threads is 9 or higher.

6.2 Thread Scaling

Since storage applications often use a large number of concurrent threads that access I/O devices, for example in order to process concurrent requests and to perform background garbage collection [12, 20, 27, 44], XRP needs to be able to provide good tail latency and throughput under a large number threads. We analyze how XRP scales as a function of the num-



(a) 99th-percentile latency. **(b)** (Log scale) 99.9th-percentile latency. **(c)** Percentage of requests with latency $\geq$ 1 ms.

ber of threads and compare it to SPDK. We run an open loop experiment, where the amount of load matches the maximum bandwidth of the Intel device (5M IOPS for 512 B random reads). Figure 7a compares the throughput of XRP (integrated with io_uring) to SPDK with BPF-KV using 6 on-disk index levels, where each thread represents a different tenant. Two major observations are: 1) when using 6 working threads (the number of CPU cores on the machine) both SPDK and XRP can achieve a throughput close to the hardware limit (the grey dashed line); 2) once the thread count exceeds the CPU cores, SPDK's throughput steadily decreases while XRP still provides stable throughput. SPDK's throughput collapse stems from its polling-based approach; SPDK threads never yield, leaving scheduling up to Linux's CFS which works in coarse 6 ms timeslices. However, idle XRP threads will voluntarily yield the CPU to busy threads, so more CPU cycles are spent on actual work. Figure 7b presents the throughput-latency relationship under 12 working threads as a function of the load. With more threads than CPU cores, both average and tail latencies also increase more significantly in SPDK, as each thread waits longer to be scheduled than in XRP.

6.3 Range Query

Figure 8 compares the average latency and the throughput of running a range query with XRP against performing the query with `read()` system calls. In both cases the range query performs a single index traversal to find the first object, and traverses the leaf nodes of the index to find the address of subsequent objects. The index depth is 6 in this experiment. Even though the XRP range query can only retrieve 32 objects per syscall, the results show this adds negligible overhead. XRP's performance speedup remains relatively constant as a function of the length of the aggregation, since XRP performs only one storage stack traversal for every 32 values retrieved.

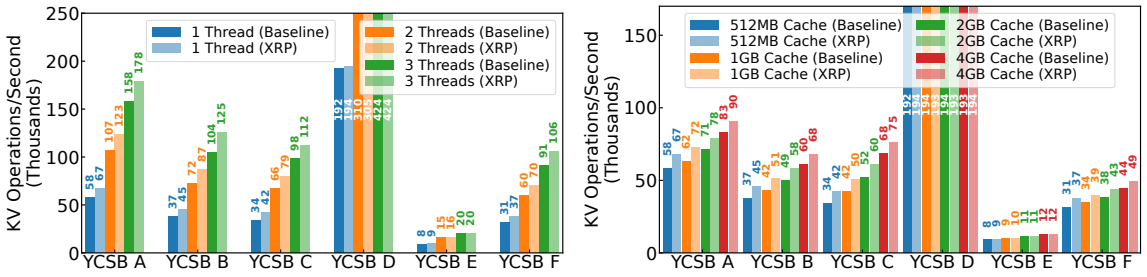

Figure 9: Throughput of reads/scans in WiredTiger with **(a)** varying client threads with a 512 MB cache and **(b)** varying cache size.

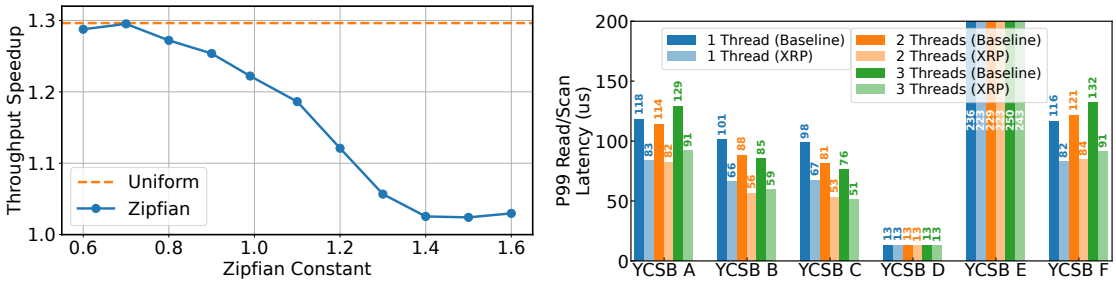

Figure 10: **(a)** Throughput speedup of WiredTiger on YCSB C with a varying Zipfian constant and with a uniform distribution. **(b)** 99th-percentile latency of reads/scans in WiredTiger with varying number of threads with 512 MB cache.

6.4 WiredTiger

To understand whether XRP can benefit a real-world database, we evaluate the performance of WiredTiger with and without XRP on YCSB [41]. We run the different YCSB workloads so that their runtime takes more or less the same time: YCSB A, B, C and E use 10M operations, D uses 50M operations and E uses 3M. The baseline WiredTiger uses `pread()` to read B-tree pages, while the WiredTiger with XRP uses `read_xrp()`. We populate the database with 1 billion key-value pairs and set the size of both key and value to 16 B. The total size of the database is 46 GB. WiredTiger runs eviction threads to evict pages when its cache usage is close to full, and we set the number of eviction threads to 2.

Throughput. Figure 9 shows the total throughput of WiredTiger with different cache sizes and different numbers of client threads. We configure WiredTiger with 512 MB, 1 GB, 2 GB, and 4 GB cache sizes to ensure that WiredTiger can cache at least 1% of its database while not exhausting all the available memory on the machine. We run up to 3 client threads to avoid context switches. The results show that XRP speeds up most workloads consistently by up to 1.25×. The throughput improvements are mostly affected by the cache size. The speedup generally goes down when the cache size becomes larger. In general, XRP provides a lower speedup on WiredTiger than on BPF-KV, because WiredTiger is less optimized than BPF-KV for reading from fast NVM storage, and only spends 63% of its total time on I/O. In particular, XRP does not provide significant improvements on YCSB D and YCSB E. This is because YCSB D follows a latest distribution where the newly inserted items are the most popular ones. Since new inserts are always written into in-memory buffers, most read operations read from those buffers in YCSB D. On the other hand, YCSB E only has inserts and scans. WiredTiger supports scans via an iterator interface, which only looks up one key-value pair at a time. XRP can only benefit the lookup of the first key-value pair of a scan operation, since the rest of the key-value pairs mostly either reside on the same leaf node or require only one additional I/O to fetch the next leaf node.

To study the effect of access distribution on XRP, we run YCSB C with a varying Zipfian constant and with a uniform distribution. Figure 10a shows that XRP's benefit decreases when the Zipfian constant becomes larger (i.e. , the distribution is more skewed) because of the increased cache hit ratio. Note that skews greater than 0.99 represent very high skew levels. We also see that the throughput gain on WiredTiger is lower than that on BPF-KV with the uniform YCSB C. This is again because WiredTiger spends 37% of its total time on non-I/O operations.

Tail latency. We measure the tail read latency of WiredTiger with and without XRP under a fixed load: 20 kop/s per client thread for YCSB A, B, C, D, F, and 5 kops/s per client thread for YCSB E. Since YCSB E has scans instead of reads, we set a lower load for it and measure the tail scan latency instead of the tail read latency. Figure 10b shows that XRP can reduce the 99th-percentile latency by up to 40%. Similar to the throughput, the 99th-percentile latency improve-

ment mostly decreases with a larger cache size, and XRP does not have significant effect on YCSB D and E.

7 Related Work

There are four areas of related work: (a) using BPF to accelerate I/O (typically networking), (b) kernel-bypass systems, (c) near-storage compute, and (d) extensible operating systems and library file systems.

BPF for I/O. There is a large number of systems and frameworks that use BPF to accelerate I/O processing, primarily focused on networking and tracing use cases [2,4–6,15,18,25,28,37,46,49,50,52]. Most closely related to XRP, XDP [28] accelerates networking I/O by adding a hook in the NIC driver's RX path. It then provides an interface for eBPF programs that either filter, redirect, or bounce the packet.

There are no existing systems that use BPF to resubmit storage requests from within the kernel. Kourtis et al. [62] propose a system that uses eBPF functions as an interface to submit disaggregated storage requests in order to avoid crossing the network. In their system, resubmissions occur from a user space service sitting at the host and are not serviced by the kernel itself, since the network is the primary bottleneck (not the kernel software stack). ExtFUSE [36] allows user space file systems on Linux to load BPF functions into the kernel to serve low-level file system requests and thus eliminates unnecessary context switches. While ExtFUSE accelerates user space file systems, it provides no performance benefits for an application that already uses a standard kernel file system (e.g., ext4), since it does not allow applications to bypass the kernel's storage stack. BMC [49] uses BPF to accelerate memcached by intercepting packets on the network path at the host. The BPF functions can then access a separate small kernel-based cache, which serves as a first-level cache and is not synchronized with the user space memcached application. Zhong et al. [85] provide motivation for using BPF for accelerating storage from within the kernel, but do not provide a concrete design, implementation or evaluation.

Kernel bypass. In order to reduce the kernel's overhead when processing I/O, several libraries and operating systems have been designed to let users directly access I/O devices [7,33,34,42,47,57,65,69,71,72,82–84]. Most relevant to our work, Intel's SPDK [82] is a popular kernel-bypass library for storage. In general, the downside of allowing users to access I/O directly is that applications must directly poll for I/O to obtain high performance. This means that cores cannot be shared among processes, which leads to significant underutilization when I/O is not the bottleneck.

Near-storage compute. There are several systems that allow applications to offload their storage functions to the processor embedded within or attached to a storage device [16, 22, 31, 38, 43, 51, 55, 61, 63, 74, 75, 77, 81]. The downside of this approach is that it requires specialized storage devices, dedicated hardware, or both.

Extensible operating systems and library file systems. Our approach is reminiscent of extensible operating systems and library file systems from the 1990s. Extensible operating systems (e.g., SPIN [35] and VINO [76, 79]) allow extension of kernel functionality via user-defined functions. For example, a client can write kernel extensions that read and decompress video frames from disk. Another related approach is library file systems, such as XN [48,56]. Similar to XRP, XN allows userspace library file systems to load untrusted metadata translation functions into the kernel, while guaranteeing disk block protection without understanding file systems' data structures. These approaches required using dedicated operating and file systems, while XRP is compatible with Linux and its standard file systems. ExtOS [32], a more recent extensible OS, minimizes data movements in `read()` and `splice()` by using BPF functions to filter data before copying them to user space or another file, but it still incurs the full storage stack overhead and does not allow I/O request resubmissions.

8 Conclusions and Future Work

BPF has the potential to accelerate applications using fast NVMe devices by moving computation closer to the device. XRP lets applications write functions that can resubmit dependent storage requests to achieve speedups close to kernel-bypass while retaining the advantages of being OS-integrated. Beyond fast lookups, we envision XRP can be used for many types of functions such as compaction, compression and deduplication. In addition, XRP in the future can be developed as a common interface for other use cases where computation needs to be moved closer to storage, such as programmable storage devices and networked storage systems. For example, XRP could be used as an interface that can dynamically support both in-kernel offloading, as well as offloading functions to a smart storage device or an FPGA. Another direction we plan to explore is networked storage. XRP storage functions could be chained with XDP networking functions to create a datapath that bypasses both the kernel's networking and storage paths.

9 Acknowledgments

We would like to thank our shepherd, Ymir Vigfusson, and the anonymous reviewers for their helpful comments. We also thank Kostis Kaffes and Tom Anderson for providing valuable feedback on earlier versions of our work. This work was supported by NSF grants CNS-2143868, CNS-2104292, and CNS-1750558, and an equipment gift from Intel.

A Artifact Appendix

Abstract

We open-source XRP, a high-performance storage data path using Linux eBPF. The artifact includes the implementation of XRP in the Linux kernel and two key-value stores that leverage XRP to significantly improve throughput and latency.

Scope

The artifact allows readers to run all the experiments in §6 and generate Table 3, Figure 5, Figure 6, Figure 7, Figure 8, Figure 9, and Figure 10.

Contents

The artifact provides the following parts.

1. XRP: the implementation of XRP in the Linux kernel v5.12.0.
2. BPF-KV: a simple key-value store that uses XRP to accelerate both point and range lookups.
3. WiredTiger: a modified WiredTiger (based on v4.4.0) that integrates with XRP to speed up index lookups.
4. My-YCSB: an efficient YCSB benchmark written in C++ for WiredTiger.

Test scripts and drawing scripts are also provided for all the experiments and results in §6.

Hosting

The artifact is hosted on the main branch (commit `fae90c5`) of the Github repository https://github.com/xrp-project/XRP.

Requirements

XRP requires a low latency NVMe SSD on which the overhead of the Linux storage stack is significant. We use Intel Optane SSD P5800X in all the experiments. In the test scripts, we assume that the operating system is Ubuntu 20.04, and there are 6 physical CPU cores on the machine. Other configurations may require changing the scripts accordingly.

TriCache: A User-Transparent Block Cache Enabling High-Performance Out-of-Core Processing with In-Memory Programs

Abstract

Out-of-core systems rely on high-performance cache subsystems to reduce the number of I/O operations. While the page cache in modern operating systems enables transparent access to memory and storage devices, it suffers from efficiency and scalability issues on cache misses, forcing out-of-core systems to design and implement their own cache components, which is a non-trivial task.

This study proposes TriCache, a cache mechanism that enables in-memory programs to efficiently process out-of-core datasets without requiring any code rewrite. It provides a virtual memory interface on top of the conventional block interface to simultaneously achieve user transparency and sufficient out-of-core performance. A multi-level block cache design is proposed to address the challenge of per-access address translations required by a memory interface. It can exploit spatial and temporal localities in memory or storage accesses to render storage-to-memory address translation and page-level concurrency control adequately efficient for the virtual-memory interface.

Our evaluation shows that in-memory systems operating on top of TriCache can outperform Linux OS page cache by more than one order of magnitude, and can deliver performance comparable to or even better than that of corresponding counterparts designed specifically for out-of-core scenarios.

1 Introduction

NVMe [45] Solid State Drives (NVMe SSDs) have drawn a wide range of interest because of their high I/O performance. The U.2 interface [48] and PCIe 4.0 standard [47] have also increased the storage density of NVMe SSDs in recent years. For instance, a dual-socket commodity server can mount an array of more than 16 NVMe SSDs to provide tens of TB of storage capacity, tens of millions of random IOPS, and dozens of GB/s of bandwidth while being 20–40 times cheaper than Dynamic Random Access Memory (DRAM).

Although NVMe SSD arrays can improve the aggregated performance and capacity of the system, they still suffer from block-wise I/O accesses and have latencies at least 100 times longer than those of DRAM. To efficiently process datasets that are significantly larger than available memory, out-of-core systems rely on cache sub-systems to maintain frequently operated data in memory. I/O operations can be merged or skipped on cache hits, bridging the performance gap between DRAM and SSDs.

Page cache [46] is a cache sub-system in modern operating systems (OS) that manages data on the granularity of pages (typically 4KB) across DRAM and SSDs. It enables in-memory applications to support out-of-core processing on SSDs without requiring any rewrite through swapping [44] or memory-mapping [43] based on virtual memory.

However, current implementations of page cache encounter issues related to scalability and performance on cache misses owing to global locking on internal data structures [29]. Recent literature [27, 34, 55] indicates that the heavy I/O stack, page faults, and context switching overheads also limit kernel swapping and I/O performance on fast storage devices such as NVMe SSD arrays.

Therefore, data-intensive applications such as databases and data processing systems [6, 12, 15, 20–22, 52, 54] usually design and implement their own user-space block caches (also known as buffer managers) that manage data by blocks (typically of a fixed size that is a multiple of the physical sector size). In contrast to OS page cache, block cache reduces context switching overhead by running mainly in the user space, and supports customization in terms of tuning block sizes and replacement policies to further improve performance.

Nevertheless, designing and implementing block caches and upper-level components imposes expensive development costs. Existing block caches in the user space usually ask users to explicitly acquire/release blocks [12, 20] or manipulate data through an asynchronous interface [54]. Developers often have to re-design and re-implement the entire system according to the API requirements of the block cache, which is non-trivial. To fill the gap between out-of-core performance and development costs, we investigate a new general cache mechanism that can transparently extend in-memory systems

for efficient out-of-core processing on NVMe SSDs without requiring any manual modification.

Efficient kernel-bypass I/O stacks, such as SPDK [50], can achieve good out-of-core performance in the user space by avoiding expensive kernel I/O operations to take advantage of the high IOPS from the NVMe SSD array. It inspires us to explore a user-space solution that can eliminate the overhead due to page faults and context switching. A solution in the user space is cross-platform, easy to deploy and customize, and avoids introducing potential security vulnerabilities caused by kernel modifications.

To ensure transparency for the user, a *virtual memory interface* is expected to fill the semantic gap between fine-grained memory accesses in existing in-memory programs and block-wise I/O operations on physical block devices as in the case of the virtual memory provided by OS. A virtual memory interface makes it possible for in-memory software to run on NVMe SSDs without requiring any modification if we can automatically redirect memory accesses to the block cache.

Several challenges need to be addressed to implement a user-space block cache with a virtual memory interface. First, the cache system requires good scalability to achieve high out-of-core performance so that it can fit in the hundreds of CPU cores and the tens of millions of SSD IOPS in use today. Second, it requires an efficient address translation mechanism that looks up in-memory addresses for cached blocks, to provide a virtual memory interface with fine-grained accesses. Such fine-grained accesses and per-access address translations pose a much more significant challenge than block lookups in current user-space block caches. Third, it requires a scheme to redirect the memory accesses of existing in-memory systems to the cache system without any manual modification.

To address the above challenges, we propose the following contributions:

- We build a scalable block cache based on a concurrency mechanism named *Hybrid Lock-free Delegation* that combines message passing based delegation with lock-free hash tables. It can utilize the NVMe SSD array with only a few server threads.
- We design a two-level *Software Address Translation Cache* (SATC) to support lightning-fast address translation in the user space, replacing human effort for writing block-aware code with an automatic mechanism by exploiting locality at runtime. SATC can accelerate software address translation by some orders of magnitude.
- We propose a pure software-based scheme to supervise memory accesses based on *compile-time instrumentation* and library hooking techniques. Existing in-memory applications can efficiently run on NVMe SSDs through the block cache without requiring any code modification.

Based on these techniques, we design and implement a user-transparent block cache providing a virtual memory interface, named TriCache. Our results show that TriCache enables in-memory programs to efficiently process out-of-core datasets without requiring manual code rewrite, by using various domains of application. TriCache can outperform OS page cache by some orders of magnitude, and can often reach or even exceed the performance of specialized out-of-core systems.

2 Background and Motivation

In this section, we briefly introduce the two types of general caches that can be used for out-of-core processing, OS page cache and user-space block cache, and use a motivating example to show the benefits as well as the challenges of a new approach that combines the advantages of both.

Page cache is a transparent cache for pages originating from storage devices [46]. Modern operating systems keep the page cache in unused portions of the main memory. Some accesses to storage devices can be handled by the page cache to improve performance. The page cache is implemented in kernels through virtual memory management and is mostly transparent to applications. Users can use a memory-mapping system call [43] to map a file to a segment in virtual memory, or rely on swapping [44] to swap out/in pages to/from disks on-demand, thus accessing storage just like memory.

While the memory interface of the page cache provides maximal user transparency for developing out-of-core applications [9, 26], its use can lead to severe performance bottlenecks, especially on cache misses when the backed storage is an array of high-performance NVMe SSDs. It results from various factors, including but not limited to its global locking in the kernel, the heavy I/O stack, page faults, and context switching overheads [27, 29, 34, 55]. Although some studies have attempted to modify the kernel to improve the performance of the page cache [27–29, 39, 41], it is challenging to apply the relevant modifications in the kernel space, which may introduce potential portability and security issues.

To this end, most out-of-core systems design and implement their own block caching components in the user space to mitigate and even eliminate the above issues. Like the OS page cache, a block cache manages a pool of pages in memory, and loads/evicts pages from/to disks upon user requests. The major difference is that the block cache runs mostly in user space and provides a block interface. Users first `pin` the blocks to be accessed in memory, then read/write data in corresponding blocks, and finally invoke `unpin` to mark the blocks that can be evicted or flushed to storage later, when needed according to the replacement policy [15, 20]. There are also some other forms of the block interface, such as asynchronous `read`/`write` routines with user-defined callbacks [54]. Block cache may be further customized for better performance according to the needs of the application. For example, it is unnecessary to support writing blocks back to the storage if cached contents are known to be read-only [12].

While an efficient and scalable block cache can make full use of storage devices in terms of performance, its block interface requires a considerable amount of work to be put

```
size_t strlen_memory(char* str) {
  size_t len = 0;
  while (str[len] != '\0')
    ++len;
  return len;
}
```

```
size_t strlen_block(str_in_block s) {
  size_t len = 0;
  size_t block_id = get_block_id(s);
  size_t block_off = get_block_offset(s);
  char* raw_ptr = pin(block_id);
  while (raw_ptr[block_off] != '\0') {
    len += 1;
    block_off += 1;
    if (block_off == BLOCK_SIZE) {
      unpin(block_id);
      block_id += 1;
      block_offset = 0;
      raw_ptr = pin(block_id);
    }
  }
  unpin(block_id);
  return len;
}
```

Figure 1: Out-of-core implementations of `strlen` with memory (upper) and block (lower) interfaces

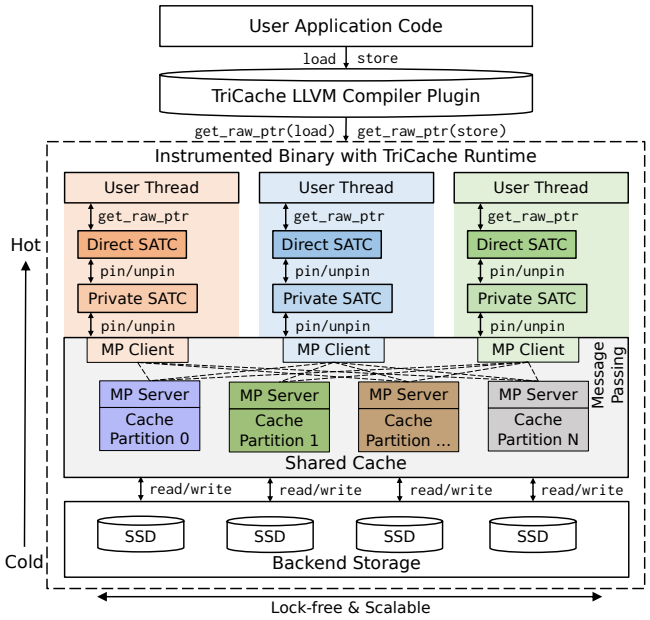

Figure 2: High-level architecture of TriCache

into use. Figure 1 illustrates this with a concrete example: calculating the length of a string. The upper part presents the implementation by using a memory interface, and the lower part shows an alternative version with a block interface. It is evident that the block version is far more complex than the memory version because system developers have to take care of more details, such as checking the block boundaries and making `pin`/`unpin` calls manually, while the memory version only needs to perform memory accesses.

It thus motivates us to explore a block cache providing a virtual memory interface in the user space, that can combine the advantages of high out-of-core performance and high user transparency from both types of caches. The user-space approach drops some functional capabilities of the OS page cache, such as sharing memory across processes with consistency guarantees. However, it allows us to redesign the cache sub-system towards new high-performance storage. Although the virtual memory interface forces applications to manipulate the cache synchronously and manage data in fixed-size blocks (rather than objects or rows), such an interface enables user transparency and saves developers considerable effort.

However, a user-space block cache with a virtual memory interface is not as easy as it might appear. Since every memory access now needs to involve a pair of `pin` and `unpin` calls to ensure that the data accessed reside in memory, as well as given that `pin` and `unpin` imply storage-to-memory address translation and concurrency control operations[1], we need optimizations in addition to those in current block cache designs to make `pin`/`unpin` as fast as possible.

[1] In case of cache misses, the victim blocks resident in memory need to be replaced with the requested blocks on storage; in case of cache hits, the reference counts need to be updated with locks/latches or atomic operations.

3 Design and Implementation of TriCache

In this section, we first present an overview of the system design of TriCache, and then describe its efficient multi-level block cache runtime in a bottom-up manner, including how to build a scalable block cache and reduce the cost of cache accesses in the user space to support transparent usage. Finally, we introduce how to automatically apply TriCache to in-memory applications via compiler techniques.

3.1 Overview of TriCache

Figure 2 shows the high-level architecture of TriCache. It consists of an LLVM compiler plugin and a runtime module.

TriCache LLVM Compiler Plugin first instruments each memory instruction, such as load and store, in the user application code, inserting a software address translation call (named `get_raw_ptr`) before the memory instructions. Upon execution, the instrumented binary calls the interface every time it tries accessing a storage address and retrieves a memory address pointing to data cached in memory. The translated address is then used as usual for the memory instruction.

TriCache Runtime is the core of TriCache (the dashed box in Figure 2). It is a multi-level block cache that supports fast address translation and provides a virtual memory interface. It implements `get_raw_ptr` to translate blocks to their corresponding cached memory addresses, manages the in-memory data cache for recently accessed blocks, handles I/O operations when the cache misses, and evicts blocks when the cache is full.

In the implementation of `get_raw_ptr`, TriCache Runtime introduces a two-level *Software Address Translation Cache*

(SATC) on top of the conventional block cache (*Shared Cache* in Figure 2). The first level is a directly mapped Direct SATC, and the second level is a set-associative Private SATC (under the three *User Threads* in Figure 2). They serve purposes similar to those of the hardware TLB, and accelerate address translations for hot blocks. We implement them as thread-local metadata caches for storage-to-memory address mappings. Direct SATC is responsible for efficient translation when operating the most recently used entries, while Private SATC aims to provide sufficient entry caching capacity and merge inter-thread operations. Meanwhile, the SATC employs a `pin`/`unpin` protocol (as mentioned in Section 2) to implement an inclusive two-level metadata cache. TriCache deploys SATC to automatically exploit localities in running programs for address translation and reduce the cost of runtime API calls, rather than relying on manually programming against blocks to reduce the number of API calls and amortize the runtime overheads.

Below SATC, TriCache Runtime manages data with Shared Cache (in the middle of Figure 2, gray background). Shared Cache is a full-featured block cache shared by multiple threads that maintains an in-memory cache pool for reading and writing the underlying storage. It manages a block table for all in-memory blocks and serves address translations when SATC misses. The block table exposes a `pin`/`unpin` interface to SATC as well, with the guarantee that recently used data pinned by SATC are not swapped out to external storage. To prevent scaling bottlenecks introduced by locking, the block space is partitioned, and each partition is owned by a single thread. Message passing based delegation is used to render critical operations (including block replacements and I/O accesses) single-threaded and lock-free. Moreover, Shared Cache can use kernel-bypass I/O stacks to eliminate context switching for I/O operations.

For Shared Cache, we propose a Hybrid Lock-free Delegation based concurrency control scheme. First, we distinguish between address translations and data accesses. Only address translations call `pin`/`unpin` remotely through message passing, while data accesses directly manipulate memory and rely on the CPU cache to ensure data consistency. The cached data are thus stored only in the Shared Cache and directly accessed by threads without any redundant memory copies. Second, we design and implement the per-partition block table as a concurrent lock-free hash table to further reduce inter-thread message passes. With this concurrent block table, only pinning operations that are missed in Shared Cache require a synchronous remote call.

In Figure 3, we present an example of a user program, a follow-up of Figure 1, instrumented by and then running with TriCache. The C program is first compiled to LLVM IR (Intermediate Representation) with Clang, with the memory read compiled to a load instruction. TriCache LLVM Compiler Plugin instruments the load instruction into two operations: one calls `get_raw_ptr` to retrieve the translated memory address, and the other loads the cached data. Upon execution, the `get_raw_ptr` call of TriCache Runtime results in an address translation operation sequence. If Direct SATC hits, the result is returned; otherwise, it pins the corresponding block in Private SATC. If the block is found in Private SATC, the result is returned; otherwise, it pins the corresponding block in Shared Cache. If Shared Cache is holding the block, the pin operation finds the memory address of the cached block in the concurrent block table. Otherwise, as invoked by a remote call, Shared Cache reads the block from storage and loads it into memory.

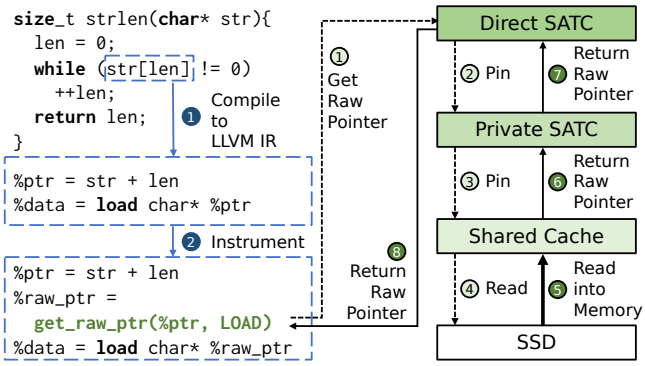

Figure 3: An example of a user program running on TriCache

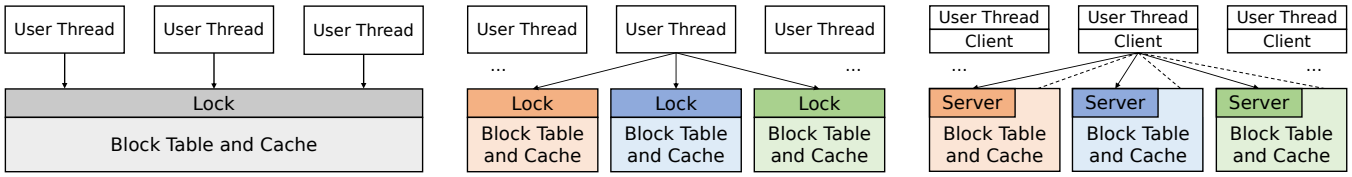
3.2 Shared Cache

As the core module of TriCache, Shared Cache determines TriCache's throughput, especially its I/O performance. Therefore, good scalability is the primary design goal of Shared Cache for the effective use of hundreds of CPU cores, tens of NVMe SSDs, and millions of IOPS.

Design Decisions. Figure 4a shows a straightforward design used by the current Linux Kernel. It uses a global lock to protect the block table (or page table) and the cache. However, the single lock leads to heavy lock contention and is difficult to scale for high-performance storage devices [29]. The sharding technique can help mitigate the scalability issue, as shown in Figure 4b. The block cache [12, 29] can use a predefined function (usually hashing) to partition the blocks into several shards and then assign a lock to each shard. In addition, recent work proposes that well-designed delegation based on message passing can provide better scalability and hotspot tolerance than locks [23, 33, 53] on NUMA (Non-uniform Memory Access) architectures.

Therefore, we propose a Hybrid Lock-free Delegation for Shared Cache of TriCache, as shown in Figure 4c. The Shared Cache adopts a client-server model based on message passing (solid lines in Figure 4c). Each client-server pair shares a lightweight message queue with a size of two cache lines, similar to ffwd [33]. Each user thread corresponds to a client, and several dedicated servers handle requests from clients.



(a) Global Locking (b) Sharded Locking (c) Hybrid Lock-free Delegation

Figure 4: Different designs and concurrent mechanisms for the shared block cache

Each server is single-threaded, lock-free, and only responsible for managing a part of the blocks (e.g., partitioned by hashing block IDs). Multiple partitions and servers can achieve concurrency and scalability, and more servers can be added when a higher throughput is desired. In addition to message passing based delegation, clients can directly access per-partition block tables on cache hits to reduce server-side CPU consumptions (dashed lines in Figure 4c; more details are provided in the *Client-side Fast Paths on Cache Hits* paragraph below).

Metadata-only Delegation. When a user thread accesses block data, TriCache divides the block access into a metadata operation and a data operation. Metadata operations include address translations, reference count management, and evict policy enforcement. Data operations are memory accesses, such as load and store. In TriCache, only metadata operations are processed by servers through delegation while clients issue data operations by themselves.

A block is accessed in three stages. In the first stage, the client asks the server to cache the block in memory (`pin`) and translate the storage address to its address in memory. The server updates the metadata of the requested block, reads uncached blocks, and evicts unused blocks, without touching the actual data. In the second stage, after receiving the response, the client will directly perform its memory access on the translated memory address. In the last step, the client notifies the server that the block has been released and can be further evicted by the server (`unpin`).

This design eliminates redundant memory copies between servers and clients. Servers focus on metadata operations so that a few server threads can achieve good performance. Meanwhile, it helps TriCache provide the same consistency and atomicity guarantees as memory, which is necessary for user transparency and compatible with in-memory applications. CPU directly executes data operations on the client side via memory instructions, and cache coherence is ensured by hardware. TriCache only needs a memory fence to ensure that the updates are visible before evicting modified blocks.

Client-side Fast Paths on Cache Hits. We propose using concurrent block tables to avoid server-side synchronizations on cache hits. A client first tries to directly find a block in the block table and update the block reference counts (number of clients in use) by using atomic operations. If it succeeds,

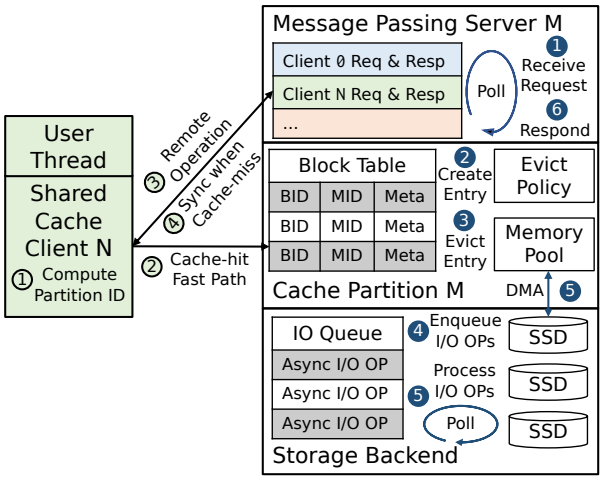


Figure 5: Shared Cache of TriCache

the client can translate the address from the concurrent block table by itself, thus skipping synchronous message passing. The client then sends an asynchronous message if this direct operation changes the reference count from 0 to 1 or conversely, to notify the server to update the evict policy for the block. Multiple asynchronous messages can be batched and processed together to amortize message passing overheads.

Workflow and Implementation. Figure 5 shows the workflow and implementation of Shared Cache. Each user thread corresponds to a Shared Cache Client and gets its unique Client ID. Each partition has a polling-based message passing server that is used to process requests sent from clients and return results to them. In addition, each partition maintains a concurrent block table for blocks cached in the memory, and each entry in the block table stores the Block ID (BID) of the block, Memory ID (MID) of its in-memory cache, and its metadata (Meta). The metadata include information on whether the block is available and whether it has been modified, and the reference count pertaining to the clients in use. We use the compact hashed block table similar to [51], in which each entry occupies only an average of 8 bytes, and uncached blocks do not occupy memory.

The cached blocks are indexed by their Memory IDs and stored in a Memory Pool. Meanwhile, an Evict Policy tracks all cached blocks with a zero reference count as they can be

safely evicted. Every time the cache is full, the Evict Policy chooses and evicts one or more blocks based on its statistics and strategies. TriCache uses the CLOCK algorithm [40] by default, and it is replaceable, allowing users to customize the policy based on their application characteristics. In addition, policy implementations in TriCache are completely single-threaded, so users do not need to consider any concurrency issues. At the bottom, an asynchronous I/O backend (Storage Backend) manages pending IO requests in an I/O Queue to continuously poll and process I/O operations. The I/O backend is also customizable and defaults to SPDK that is backed by user-space NVMe drivers. A kernel-space alternative based on Linux AIO is also supported as another candidate.

When a user thread operates on a block, its client (*N* in the figure) first computes the Partition ID (*M* in the figure) by a predefined partition function. The client then searches for a valid block entry from the block table of Partition *M*, and if such an entry exists, the client tries increasing the reference count by using atomic operations. If the atomic operations succeed on cache hits (*Cache-hit Fast Path* in Figure 5), the client pins the block in memory and can directly query the memory address of the cached block. The client may further send an asynchronous request to the server if it is updating the reference count from 0 to 1, or the converse. The server then performs the corresponding actions according to the Evict Policy, such as enabling or disabling evictions of the block.

If the atomic operations fail on cache misses or when the block is being swapped in/out, the client requests a remote operation via synchronous message passing, immediately releases CPU resources, and waits for responses from the server (*Remote Operation* in Figure 5). After receiving the request, the server creates a block table entry and sets its valid bit to `false`. If the block table is full, the server evicts blocks according to the Evict Policy and sets their valid bit to `false`. The server then appends I/O operations for new blocks and the evicted blocks to the I/O queue. The I/O Backend processes the I/O requests by polling and controlling NVMe SSDs to perform DMA operations directly on the Memory Pool. And the server sets valid bits to `true` once the I/O requests have been processed, and it sends the memory addresses of the blocks to clients via message passing. After receiving the response, the client resumes and performs its memory accesses.

We use a micro-benchmark on a 128-core machine to test the effectiveness of TriCache Shared Cache. It can scale linearly to 256 threads (1/8 of the threads are servers), reaching 96.8M ops/s, and the hybrid mechanism provides an improvement of 52% compared with the delegation-only approach.

3.3 Software Address Translation Cache

The Shared Cache of TriCache provides scalable I/O performance and an efficient set-associative cache. However, block table lookups and atomic operations are required for each access on cache hits, still limiting the performance of TriCache.

Guiding Ideas. Considering the manual use of the block cache (e.g., Figure 1), users call the `pin` interface to get the in-memory address for a block, and then use the memory address to perform multiple operations; they finally call the `unpin` interface to release the block. Multiple read and write operations can be performed between a pair of manual `pin` and `unpin` operations to reduce the number of cache lookup operations. Users manually take advantage of data locality while investing extra effort in development.

In contrast, we design TriCache to automatically exploit locality to simulate manual coding without requiring human effort. We propose to build a two-level Software Address Translation Cache (SATC) on top of Shared Cache. The higher-level cache stores hotter data and provides faster access and smaller capacities than the lower-level cache, similar to the multi-level cache of the CPU and hierarchical storage [32, 49, 56]. Based on this idea, we now show how to implement the multi-level cache in software and where to divide the levels.

SATC Design. In our design, only the last-level cache manages data, and higher-level translation caches manage only metadata, such as modifying the reference counts of the blocks and translating block IDs to memory addresses. Managing metadata instead of data can help avoid redundant memory consumption, additional memory copies, and memory consistency issues caused by the multi-level design. The multi-level cache of TriCache is designed to be an inclusive cache, which means that all blocks in the higher-level cache are also present in the lower-level cache. With this inclusive policy, higher-level caches need to only interact with their next level. Moreover, TriCache guarantees that the capacity of higher-level caches is no greater than the lower-level cache, thus eliminating out-of-space errors from the lower-level cache when the higher-level cache requests to swap in blocks.

On top of the Shared Cache, we build a thread-local set-associative cache called Private SATC. When the Private SATC hits, the user thread uses its thread-local block table and evict policy, and only when the Private SATC swaps in/out blocks does the user thread need to operate on the Shared Cache. Private SATC is purposed to reduce Shared Cache operations for the hot data of its thread. Examples include thread-local hot data when each thread computes a segment of data independently, and hot elements shared by all threads when processing skewed data. Private SATC also helps reduce concurrent block table operations with cross-NUMA memory accesses and false sharing, which could take about 3–8 times higher latency than local memory accesses in our evaluation.

We further build a direct mapping cache called Direct SATC on top of the Private SATC to alleviate overheads due to hash table lookups and evict policy maintenance. Direct SATC maintains a few recently accessed pages in a fixed-size array to speed up address translation to a few bitwise operations and avoid having to update the evict policy for each access. The goal of Direct SATC is to cover multiple consecutive

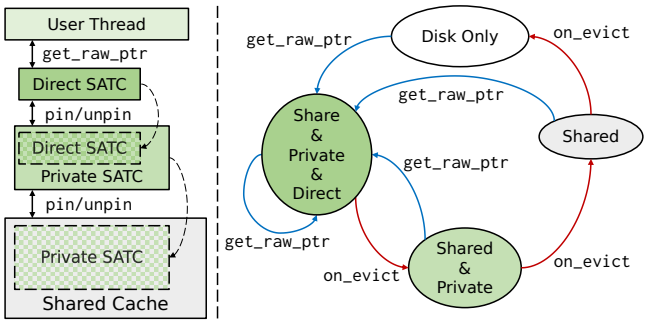

Figure 6: Software Address Translation Cache

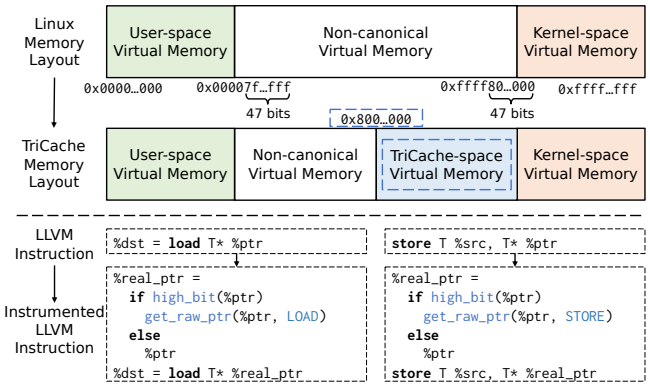

Figure 7: Memory layout and LLVM instrumentation

operations on the hottest blocks, such as sequential reads and writes, and displace manually written `pin`/`unpin` operations.

Implementation. As shown in Figure 6, we implement an inclusive multi-level cache with `pin` and `unpin` interfaces. Blocks in Direct SATC must exist in Private SATC, and blocks in Private SATC should also be present in Shared Cache. Private SATC calls the `pin` interface of Shared Cache to load blocks into the Private SATC, thus increasing reference counts to ensure that Shared Cache does not swap out the blocks. When blocks are evicted from Private SATC, it calls the `unpin` interface of Shared Cache to release the reference count. On top of Private Cache, Direct SATC also uses a scheme similar to Private SATC but provides a single `get_raw_ptr` interface implicitly combining a `pin` call and a following `unpin` call. It implies caching a block and translating the block ID into its raw address in memory. The raw address is valid until the next `get_raw_ptr` call because the subsequent access can evict any previous block from Direct SATC and possibly call the `unpin` interface of Private SATC or Shared Cache.

The right-hand side of Figure 6 presents the state machine maintained in TriCache. Starting from Disk Only state, the user thread loads blocks into Shared Cache, Private SATC, and Direct SATC by calling `get_raw_ptr`. When Direct SATC evicts blocks, Shared Cache and Private SATC still hold them. When the last thread in use evicts a block from its Private SATC, the block enters Shared Cache Only state. Any `get_raw_ptr` re-loads the block into all three levels of caches. If Shared Cache also evicts the block, it is removed from the in-memory cache and written back to storage when it is dirty, ending in Disk Only state.

In our implementation, the aggregated capacity of Private SATC entries is equal to that of Shared Cache entries, and the Direct SATC has a size 1/4 of that of the Private SATC.
