Our evaluation shows that SATC can improve performance by tens of times over Shared Cache on real-world workloads. When SATC can absorb all accesses, TriCache can reach 57% and 91% of the in-memory performance for purely random and nearly sequential access patterns respectively, making it practical to operate the block cache at per-access granularity.

3.4 Compile-time Instrumentation

With the help of SATC, TriCache opens up opportunities to provide a virtual memory interface and make TriCache fully transparent to users. To this end, we propose a purely user-space scheme based on compile-time instrumentation and library hooking techniques.

Memory Layout. We first modify the memory layout as shown in the upper part of Figure 7. In Linux, the current x86_64 virtual memory layout (with four-level page tables) consists of three main parts. User-space takes 47 bits at the beginning, kernel-space occupies 47 bits at the end, and most of the space in the middle is a hole of non-canonical virtual memory. We map the TriCache-managed disks into unused holes by block size, starting from 0x800...000 as TriCache-space virtual memory. Memory addresses in TriCache-space can be translated into an actual user-space memory address by calling the `get_raw_ptr` interface of TriCache Direct SATC.

Instrumentation. To enable transparent read and write operations on top of the TriCache block cache, we perform a translation before each memory operation (e.g. load, store, and atomic operations), so that TriCache-space addresses can be used just like user-space memory. TriCache does not require any manual code modifications with the help of compile-time instrumentation. The lower part of Figure 7 shows pseudo-codes for instrumenting load and store instructions in LLVM IR. TriCache instrumentation takes the highest bit of addresses to determine whether a memory address refers to user-space memory or TriCache-space virtual memory.

While instrumentation provides the virtual memory interface for TriCache-space memory, we still need to determine what data should be placed in TriCache-space memory. First, data on the stack is not necessary to enter the block cache. We perform a data flow analysis from LLVM `alloca` instructions to eliminate unnecessary instrumentation and overhead for the stack. Second, we set a runtime threshold for TriCache so that only memory allocations greater than the threshold will

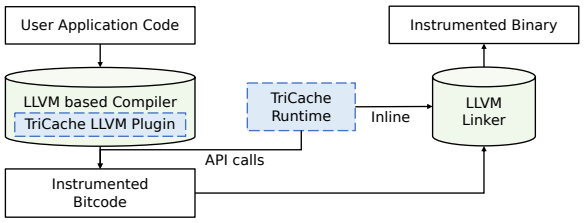

Figure 8: Compiling workflow of TriCache

belong to TriCache-space memory. In contrast, small chunks of data, usually short-term temporary data, remain in-memory allocation. Finally, TriCache supports limiting the total size of data allocated in memory by a predetermined memory quota. If in-memory data exceed the memory quota, TriCache is able to take over later allocations. Users can adjust the above runtime parameters to obtain a balanced trade-off between the memory usage and the performance.

Implementation. Figure 8 illustrates the compiling workflow of TriCache. The user application code is compiled by a compiler based on LLVM. The TriCache LLVM plugin instruments the code and generates instrumented LLVM IR bitcode. The plugin performs instrumentation after all the optimization passes, so it does not affect the compiler optimizations on applications, such as automatic vectorization. Also, TriCache supports vector instructions since TriCache leaves the CPU to perform memory operations.

Then, the bitcode links with the pre-compiled TriCache runtime (including `get_raw_ptr` implementations). TriCache forces to inline the cache-hitting implementations of Direct SATC and Private SATC through link-time optimization (LTO) to avoid intensive function call overheads.

The TriCache runtime also contains APIs on top of the virtual memory interface for manual optimizations, including `pin` and `unpin`. Optionally, users can optimize some bottlenecks of their applications through these APIs, such as using block-wise accesses and prefetching, while leaving other parts to transparently support out-of-core processing by instrumentation. In the TriCache runtime, some common utility functions, such as `memcpy` and `memset`, are already manually implemented by block-wise `pin` and `unpin` to reduce overheads of per-byte address translation from common components.

4 Evaluation

We set up our experiments on a dual-socket server equipped with two AMD EPYC 7742 CPUs (64 physical cores and 128 hyper-threads per CPU) and 512GB DDR4-3200 main memory. The storage devices are 8 PCIe-attached Intel P4618 DC SSDs which provide 51.2TB capacity, 9.6M 4KB-read IOPS, and 3.9M 4KB-write IOPS in total. The server runs Debian 11.1 with Linux kernel 5.10 and uses Clang 13.0.1 to compile TriCache and other systems.

In our evaluation, we limit the total available capacity of DRAM by `cgroups` to evaluate out-of-core performance. For TriCache and other systems with block caches, we ensure that the overall memory is less than the expected memory limit by adjusting the cache sizes. The SSDs are configured in SPDK mode for TriCache and as raw blocks for swapping. If the system requires a single filesystem, we construct a software RAID-0 by `mdadm` and use the XFS filesystem. TriCache launches 16 background threads (bound to 8 cores) for Shared Cache and uses 4KB blocks by default. And the total number of threads are searched to maximize performance over powers of two from the number of hardware threads (i.e. 256).

We first evaluate TriCache on four representative domains in terms of end-to-end performance: graph processing (Section 4.1), key-value store (Section 4.2), big-data analytics (Section 4.3), and transactional graph database (Section 4.4).

We then conduct a micro-benchmark, by using a configurable number of threads that issue load/store instructions. We adjust the hit rates and access patterns to explore circumstances in which TriCache outperforms OS page cache and to assess whether the design of TriCache provides a reasonable trade-off between in-memory (i.e. cache hit) and out-of-core (i.e. cache miss) performance (Section 4.5).

Finally, we use a series of breakdown experiments to evaluate the performance-related impact on TriCache, including I/O backends, hit rates and hit latency of SATC, and number of threads (Section 4.6).

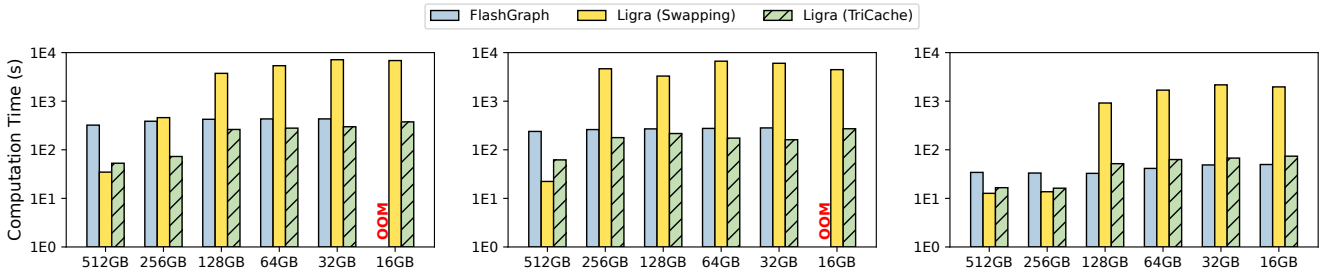
4.1 Performance on Graph Processing

Experimental Setup. Graph processing is a demanding workload for cache systems due to many small and random accesses on large datasets. We transparently apply TriCache to an in-memory graph processing framework Ligra[2] [37] and extend it to out-of-core. The baselines are Ligra with OS swapping and FlashGraph[3] [54], an efficient semi-external memory graph processing framework designed for SSDs.

Both Ligra and FlashGraph use 32-bit vertex IDs, and we force Ligra to use push mode to align with FlashGraph. For FlashGraph, we follow its recommended configuration of creating an XFS filesystem for each SSD block device and binding the device to the corresponding NUMA nodes. Meanwhile, FlashGraph is a semi-external memory graph engine that always stores vertex states in memory and edge lists on SSDs. We thus make TriCache to manage at least edge lists in the cache for a fair comparison.

We evaluate FlashGraph, Ligra on swapping, and Ligra on TriCache by three common graph algorithms: PageRank (PR), Weakly Connected Components (WCC), and Breadth-First Search (BFS). The dataset is a real-world graph dataset, UK-2014 [7, 8], with 788 million vertices and 47.6 billion edges. It requires more than 400GB for Ligra in-memory execution.

[2] https://github.com/jshun/ligra [commit 7755d95]
[3] https://github.com/flashxio/FlashX [commit 2a649ff]



(a) PageRank (b) Weakly Connected Components (c) Breadth-First Search

Figure 9: Computation time of FlashGraph, Ligra on swapping, and Ligra on TriCache (lower is better)

In-memory Performance. Figure 9 shows the computation time of FlashGraph, Ligra on swapping, and Ligra on TriCache under different memory quotas. With 512GB of memory, Ligra can process all three algorithms in memory, and TriCache and FlashGraph can buffer all data in their cache. Under this setting, TriCache incurs overheads of only 34.4% for PageRank, 64.0% for WCC, and 23.5% for BFS. The in-memory performance shows that TriCache can provide efficient address translations and cache hits with its virtual memory interface, owing to the two-level SATC. Meanwhile, TriCache outperforms FlashGraph by 6.08×, 3.85×, and 2.06×, respectively. It illustrates that FlashGraph yields much higher in-memory overheads than TriCache because the block cache of FlashGraph involves redundant memory copies on cache operations with its `read`/`write` interfaces.

Out-of-core Performance. Under 256GB memory limitation, the caches start swapping in/out blocks/pages. Compared to the in-memory performance, Ligra on TriCache saves about half of memory and yields 47.7% performance on PageRank, 12.5% performance on WCC, and 78.4% performance on BFS. And TriCache's speedups over OS swapping and FlashGraph are 6.30× and 5.31× on PageRank, 26.1× and 1.46× on WCC, and 0.85× and 2.05× on BFS, respectively.

As the usable memory further decreases, I/O efficiency becomes the main factor affecting performance. For example, in the case of 64GB of memory, the performance of TriCache is 19.3×, 38.3×, and 26.8× better than that of swapping. Compared with FlashGraph, TriCache can still provide improvements of 54.8% and 58.3% on PageRank and WCC respectively, while the performance of Ligra with TriCache is 34.3% lower than FlashGraph on the BFS algorithm. This is because FlashGraph adopts two-dimension partition for out-of-core graph processing, resulting in a 50.1% cache hit rate that saves 2.68× of I/O volume compared to TriCache. Still, TriCache provides an average I/O bandwidth 1.78× better than FlashGraph and thus reduces the performance gap.

It is noteworthy that the semi-external memory FlashGraph cannot fit vertex states of PageRank and WCC with 16GB of memory. It leads to out-of-memory errors, whereas TriCache can operate the same dataset fully out-of-core.

The above results indicate that TriCache can extend an in-memory graph framework to support out-of-core processing without manual modification and can deliver performance comparable to a well-designed external memory framework. Meanwhile, TriCache outperforms OS swapping by up to 38.3× while providing the same user transparency.

4.2 Performance on Key-Value Stores

Experimental Setup. We use RocksDB[4] [12], a persistent key-value store widely used in production systems, for evaluation in this part. RocksDB organizes on-disk data in immutable Sorted Sequence Tables (SSTs). It provides a block-based table format on top of its user-space block cache, and a plain table format optimized for in-memory performance via `mmap`. We use TriCache to buffer RocksDB plain tables without manual modification and compare it with plain tables based on OS memory-mapped files and block-based tables on RocksDB's own cache.

We use the mixgraph [10] (prefix-dist) workload proposed by Facebook, which models production use cases at Facebook and emulates real-world workloads of key-value stores with hotness distribution and temporal patterns. The keys and values are 48 and 43 bytes on average, respectively, and there are 83% reads, 14% writes, and 3% scans. We generate 2 billion key-value pairs (consuming 180GB of space) and execute 100 million operations. Both plain and block-based tables use the hash index with a 4 bytes prefix. We set the sharding number of the RocksDB block cache to 1024 to avoid lock contentions on our 256-thread server and use the direct I/O mode for the RocksDB block cache. We also disable WAL to prevent log flushing from becoming a performance bottleneck.

In-memory Performance. Figure 10 illustrates the throughput of Plain Tables on TriCache, Plain Tables on `mmap` and Block-based Tables on the RocksDB user-space cache with different memory quotas. In memory, RocksDB Plain Tables with `mmap` provides the best performance, which is 4.28M ops/s. TriCache reaches about 53.5% throughput of `mmap`, and 73.7% throughput of the RocksDB block cache.

[4] https://github.com/facebook/rocksdb [tag v6.26.1]

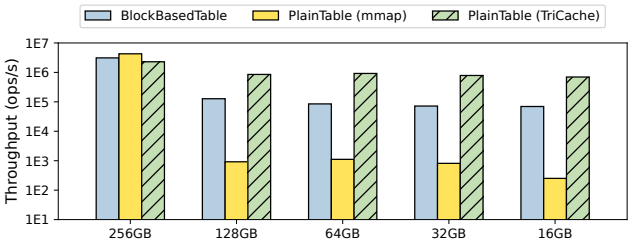


Figure 10: RocksDB throughput with varying memory quotas

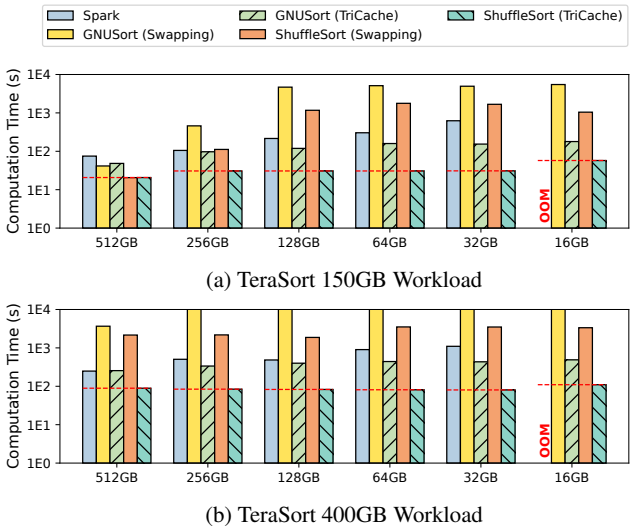
Out-of-core Performance. When RocksDB runs out-of-core, TriCache brings performance improvements of 2–3 orders of magnitude compared with `mmap`. Plain Tables with TriCache outperforms Block-based Tables by 6.69× under 128GB memory, 10.8× with 64GB, 10.9× with 32GB, and 10.0× with 16GB. Some performance benefits of TriCache come from the efficient I/O stack of SPDK, while the excellent scalability of Shared Cache is another key factor. For example, the RocksDB block cache can deliver a throughput of 122K ops/s with 256 threads. However, our eight NVMe SSDs require about 1024 I/O in-flight requests to maximize the I/O performance. Unfortunately, when the number of threads is increased from 256 to 1024, the throughput instead gradually drops. In the case of 1024 threads, RocksDB only provides 71.3% throughput of 256 threads. In contrast, the performance of RocksDB with TriCache improves by 2.15× from 256 threads to 1024 threads.

The in-memory performance indicates that user-transparent TriCache can provide similar performance as manually managed block cache in RocksDB. Meanwhile, TriCache has the potential to help existing systems with in-memory backends, such as RocksDB with Plain Tables, to achieve better out-of-core performance without any manual modifications.

4.3 Performance on Big-Data Analytics

Experimental Setup. TeraSort [1] is a representative application and an important performance indicator in the domain of big-data analytics [16]. Its typical distributed or out-of-core implementation consists of a shuffle phase followed by a sort phase. The shuffle phase produces parallel sequential reads and writes, which is I/O bound [16] and can stress sequential I/O throughput on cache systems. The sort phase requires the cache to buffer the working partition in memory and issues a vast number of string comparisons and copies that can examine the runtime overhead of cache systems.

We generate two TeraSort workloads, 1.5B records (about 150GB) and 4B records (about 400GB). For TriCache, we first use the parallel sort based on multi-way merge sort in GNU `libstdc++` [38] (named GNU Sort) to implement an out-of-core TeraSort, which requires only a single function call. We also implement a shuffle-based parallel sort by partitioning the first byte of the keys (named Shuffle Sort), which takes 15 additional lines of C++ code. Compared with the multi-way merge sort, the shuffle-based parallel sort mainly issues sequential read/write I/O operations, so it is more friendly to out-of-core processing. We use TriCache to manage memory allocations during sorting and compare TriCache with OS swapping. For Shuffle Sort, we configure the page size of TriCache to 128KB to maximize the sequential I/O performance. We also use a widely used big-data framework Spark[5] [52] as a baseline, which supports both scale-up and scale-out processing.



(a) TeraSort 150GB Workload

(b) TeraSort 400GB Workload

Figure 11: Computation time for TeraSort workloads with different memory quotas (lower is better)

In-memory Performance. Figure 11 shows the computation time of TeraSort. On the 150GB dataset, both GNU Sort and Shuffle Sort occupy about 300GB of memory and fit in 512GB of memory. In this case, Shuffle Sort is 2.01× faster than GNU Sort. Meanwhile, the overheads of TriCache amount to only 14% for GNU Sort and nearly zero (less than 1%) for Shuffle Sort. The reason is that the Shuffle Sort algorithm mainly generates sequential reads and writes for each thread, which can be well handled by thread-local Direct SATC and Private SATC. Compared with Spark, GNU Sort and Shuffle Sort on TriCache is faster by 1.55× and 3.62×, respectively.

Out-of-core Performance. When the memory quota is less than 256GB for the 150GB workload, TriCache can provide tens of times speedups over swapping, up to 39.3× for GNU Sort at 128GB memory and 57.8× for Shuffle Sort at 64GB memory. Meanwhile, the performance of Shuffle Sort with TriCache is up to 20.2× better than Spark at 32GB memory.

For the 400GB dataset, both algorithms keep executing out-of-core. Shuffle Sort on TriCache is faster than swapping by

[5] https://github.com/apache/spark [tag v3.2.0]

up to 43.6× at 32GB memory and outperforms Spark by up to 13.7× with the same amount of memory. GNU Sort based on swapping is 41.2× slower than TriCache Shuffle Sort with 512GB memory and about 128× slower when the memory quota is less than 256GB because of its sub-optimized algorithm and the limited performance of the OS page cache.

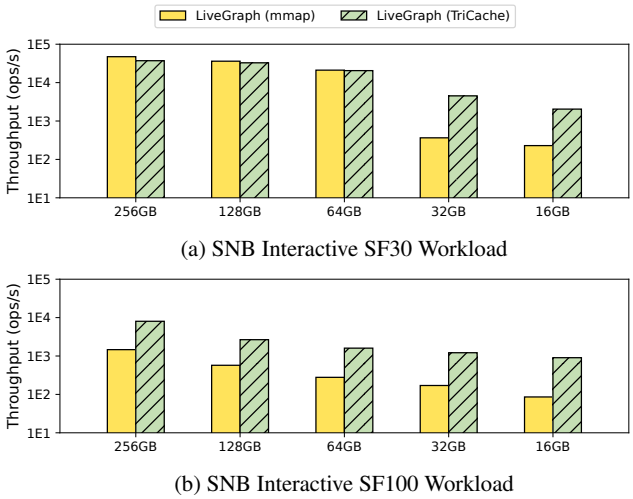
Compared with the in-memory processing of the 150GB dataset, Shuffle Sort with TriCache saves 90% memory with 32GB memory, while its processing time is only 49.3% longer than the processing time at 512GB. We also compared the distributed Spark and TriCache-based scale-up solutions. We use four servers with the same hardware configuration and connect them with 200Gb HDR Infiniband NIC. TriCache under 32GB memory outperforms in-memory distributed Spark by 7.20× using Shuffle Sort and 1.33× with GNU Sort on the 400GB workload. So TriCache with NVMe arrays can use less memory and provide nearly in-memory performance for TeraSort. In addition, TriCache can nearly utilize the peak bandwidth of our 8 NVMe SSDs, reaching 44GB/s for read-only operations and 31GB/s for mixed read/write operations.

In summary, developers can write in-memory programs (e.g., less than 20 lines of C++ code for Shuffle Sort), and TriCache then helps them to fully utilize the high-performance NVMe SSD array, especially when the algorithm is friendly to out-of-core processing.

4.4 Performance on Graph Database

For workloads in graph databases, we evaluate TriCache on LiveGraph[6] [57], an efficient transactional graph database based on OS memory-mapped files. LiveGraph treats memory-mapped files as in-memory data and relies on atomic memory accesses and cache consistency to support transactional queries. It can examine whether a user-transparent block cache is able to provide the same semantics as in-memory operations. We replace the memory-mapped files with TriCache and compare it with the original LiveGraph. We evaluate their performance on the LDBC SNB interactive benchmark, which simulates user activities in a social network and consists of 14 complex-read queries, 7 short-read queries, and 8 update queries. As the SNB driver occupies part of the memory, we limit LiveGraph to use up to 256GB memory and generate two workloads: SF30 and SF100 datasets. With LiveGraph, these datasets take about 100GB and 320GB memory, respectively. SNB clients request 1.28M operations for the SF30 workload, and 256K operations for the SF100 workload during the benchmark run.

Figure 12 shows the SNB throughputs of LiveGraph on TriCache and `mmap`. When the dataset can fit into a 256GB memory, the instrumentation and user-space cache of TriCache incur only 21% runtime overheads on the SNB benchmark. As the memory quota gradually decreases, the advantage of TriCache becomes increasingly prominent, e.g., TriCache outperforms `mmap` by 12.4× at 32GB memory as its scalable Shared Cache and the efficient I/O backend supply much higher throughputs. For SF100, LiveGraph keeps running in out-of-core states. TriCache improves the throughput by 5.48× compared with `mmap` at 256GB memory, and the speedup can grow up to 10.5× at 16GB memory.



(a) SNB Interactive SF30 Workload

(b) SNB Interactive SF100 Workload

Figure 12: Throughput of LiveGraph on TriCache and `mmap`

We then take a closer look at the latency metrics when running SF100 with 256GB of memory. TriCache cuts the average latency on complex queries by 11.5×, on short queries by 1.79×, and on update queries by 21.1× (geometric means). The P999 tail latency of TriCache keeps 10.9× lower than `mmap` on complex queries and 1.35× lower on short queries. Meanwhile, TriCache shortens the P999 latency of update queries to 34.6× shorter than the original LiveGraph because TriCache is additionally aware of thread locality while `mmap` is not. Although TriCache and `mmap` are both user-transparent, the Private SATC of TriCache can automatically hold recently updated data for writer threads in memory even when writers are waiting for group commits. On the contrary, `mmap` may evict these dirty pages under memory pressure. Our design helps LiveGraph to reduce tail latencies on update operations.

4.5 Micro-benchmarks

We conduct two custom multi-threaded micro-benchmarks which issue random memory-load instructions. The first generates random accesses in 8-bytes (named 8B Random workload), which can stress the systems in the case of completely random memory accesses. We control the random pattern to generate operations with different hit rates of block caches, and we also adjust the hit rate of Private SATC to examine its performance impact. The second randomly chooses 4KB pages and sequentially accesses each page in 8-byte words (named 4KB Random workload) to evaluate the performance when a page is accessed multiple times.

[6] https://github.com/thu-pacman/LiveGraph [commit eea5a40]

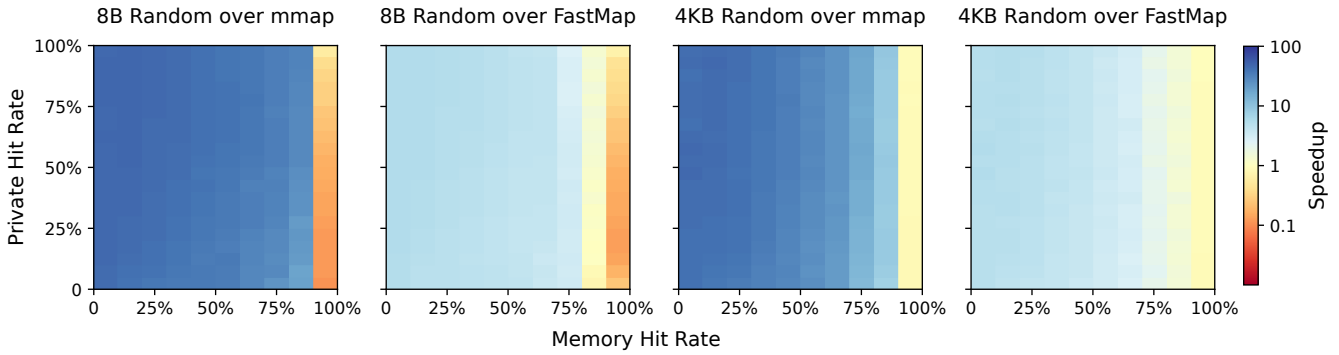


Figure 13: The speedup of TriCache compared with mmap and FastMap on 8B Random and 4KB Random workloads

We compare TriCache with Linux mmap and FastMap [29] (both given a hint of random accesses, MADV_RANDOM). FastMap optimizes the mmap path in the Linux kernel, including sharding locks (discussed in Section 3.2) and batching TLB invalidations. It mainly aim to mitigate the scalability limitation of Linux mmap. For FastMap, we downgrade the kernel version to 4.14 as FastMap relies on it, and configure a RAID-0 with mdadm as suggested by the authors of FastMap, and leverage FastMap to manage bare block devices.

Figure 13 shows TriCache's speedup compared with mmap and FastMap with 8B Random and 4KB Random workloads.

For 8B Random workloads, the performance of TriCache is about 11% of the in-memory (with mmap) performance in the worst case, when the memory hit rate is 100% and Private SATC hardly hits. Under the same 100% memory hit rate, when the hit rate of Private SATC grows up to 100%, TriCache can attain 57% of the in-memory (with mmap) performance, with a performance improvement of up to 6.07×.

Once the memory hit rate drops to 90%, TriCache can provide improvements of 18.6× to 31.5× over mmap whose performance is severely limited by lock contentions in the kernel. At the same time, TriCache outperforms FastMap by 1.22× on average. As the memory hit rate gradually decreases, the advantage of TriCache becomes increasingly significant. For instance, TriCache outperforms mmap by 33.6× and FastMap by 3.34× with an 80% hit rate. When the memory hit rate reaches 10%, TriCache performs 45.0× to 47.2× better than mmap, and 5.38× to 5.60× better than FastMap. In this case, TriCache provides 12.4 million random accesses per second and fully saturates our 8 NVMe SSDs. However, FastMap can only support 2.22 million accesses per second with all the hardware cores, where this is equivalent to about the I/O performance of only two NVMe SSDs. This indicates that FastMap cannot accommodate currently available high-performance NVMe SSD arrays because it still suffers from the heavy I/O stack of the kernel, page faults, and context switching overheads [27, 34, 55].

For 4KB Random workloads, Direct SATC can mainly absorb the in-memory overheads of TriCache. The performance of TriCache reaches 84% to 91% of the in-memory (with mmap) performance when the memory hit rate is 100%. With a 90% memory hit rate, TriCache can provide a speedup of 8.43× on average over mmap and 1.46× over FastMap. Under a 10% memory hit rate, TriCache can provide 12.3 million random accesses per second, which outperforms mmap by 43.1× and FastMap by 5.08× on average.

Table 1: Performance slowdown relative to TriCache

	Linux AIO	W/O Direct	W/O Private	Shared Only
PageRank	1.15×	2.75×	1.03×	40.1×
RocksDB	2.16×	1.27×	1.02×	22.0×
ShuffleSort	1.69×	1.87×	4.67×	10.1×
GNUSort	2.36×	2.51×	4.25×	57.9×
LiveGraph	1.21×	1.07×	1.01×	7.55×

4.6 Performance Breakdown

We select five cases under 64GB of memory for the breakdown experiments: PageRank, RocksDB, Shuffle and GNU Sort for the 400GB Terasort dataset, and LiveGraph for the SNB SF100 workload.

SPDK and Linux AIO. TriCache currently supports SPDK and Linux AIO as its storage backend. In the default configuration, TriCache uses SPDK to handle I/O operations. We compared the performance of these two backends. The first column in Table 1 shows the performance slowdown when using the AIO backend compared with the SPDK backend.

In terms of the (geometric) average, SPDK performs 1.64× better than Linux AIO, demonstrating that the user-space NVMe driver enables better IO performance. Nevertheless, SPDK has some drawbacks, such as high programming complexity, deployment difficulties, and not easy for supporting multiple applications. Luckily, TriCache hides SPDK programming details from users, allowing users to code in-memory programs and achieve efficient out-of-core performance. Moreover, the design of TriCache is not coupled with SPDK and can provide comparable performance with Linux AIO. If using or deploying SPDK is not feasible, AIO can serve as a reasonable alternative backend for use in TriCache.

Breakdown Analysis of SATC. The three columns on the right side of Table 1 break down the performance impact of SATC on TriCache by gradually removing SATC levels. *W/O Direct* disables Direct SATC, *W/O Private* disables Private SATC, and *Shared Only* uses only Shared Cache by removing both SATC levels.

According to the performance degradation listed in Table 1, SATC is an essential component contributing to the good performance of TriCache. The slowdown that occurs by disabling SATC (*Shared Only*) is 20.8× on average for the five cases. And even when the memory quotas are less than 1/5 of the working set (i.e., running out-of-core), SATC still yields a speedup of 40.1× for PageRank, 10.1× for Shuffle Sort, and 57.9× for GNU Sort.

Meanwhile, both Direct SATC and Private SATC are indispensable to TriCache. Without Direct SATC, the performance of PageRank is degraded by 2.75× because accessing each edge incurs a heavy overhead due to hash table lookups and evict policy maintenance. However, PageRank is not sensitive to Private SATC because the size of the dataset is more than 5× larger than the available memory, and the edges are visited only once for each iteration. For the shuffle phase of Shuffle Sort, the performance drops by 5.39× without Private SATC but remains almost the same (only 4.8% slower) without Direct SATC. The reason is that string copies constitute the bottleneck in the shuffle phase and are optimized by the compiler to `memcpy`, which is implemented by manually calling `pin`/`unpin` in the TriCache runtime. For GNU Sort, removing Direct SATC and Private SATC degrades the performance by 2.51× and 4.25×, respectively.

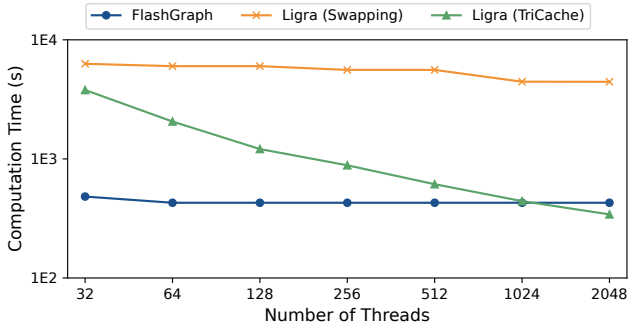
Multi-level Cache in TriCache. Next, we use PageRank, Shuffle Sort, and GNU Sort to further examine the design of the multi-level cache in TriCache. Table 2 lists the miss rates for each level of the cache, the average hit cycles (*HitC.*) for Direct SATC and Private SATC, and the average access cycles (*Acc.C.*) for Shared Cache.

According to the miss rates listed in Table 1, Direct SATC and Private SATC can handle most memory accesses. The miss rate of Direct SATC is less than 5% for all the three workloads, and the miss rate of Private SATC is less than 1% for Shuffle Sort and GNU Sort. The results show that SATC can cover most accesses to meet the above performance.

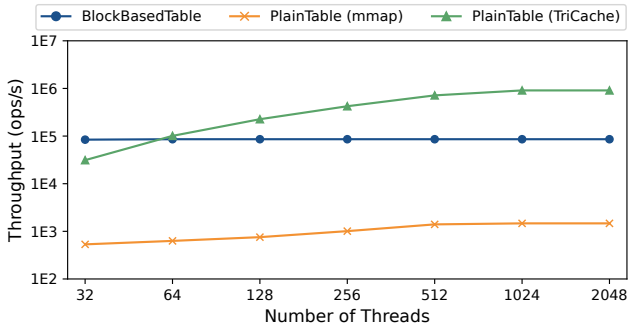
And the hit cycles of Direct SATC and Private SATC in Table 1 show that the software address translation of TriCache is quite efficient. The average costed cycles of Direct SATC hits in PageRank and Shuffle Sort are approximately 50 cycles; Direct SATC hits in GNU Sort and Private SATC hits in Shuffle Sort take about 150 cycles; Private SATC hits in GNU Sort use about 450 cycles. To give an idea of how much time they take, we list some hardware latencies: 50 cycles are close to a NUMA-local L3 cache hit or an L2 cache false sharing within a NUMA node; 150 cycles correspond to about the half of a NUMA-local memory access; 450 cycles are less than a cross-NUMA memory access or a cross-NUMA cache false sharing. Therefore, TriCache with SATC is efficient enough to provide a virtual memory interface and also to deliver memory-comparable performance.

Table 2: Miss rate and average cycles on each cache level

	Direct SATC		Private SATC		Shared Cache	
	MissRate	HitC.	MissRate	HitC.	MissRate	Acc.C.
PageRank	0.003	52.6	0.063	321	0.626	2.36M
ShuffleSort	0.001	63.0	0.001	162	0.969	1.68M
GNUSort	0.045	143	0.007	488	0.926	789K



(a) Computation time of PageRank (lower is better)



(b) Throughput of RocksDB

Figure 14: Performance of TriCache and baselines under different numbers of threads

Performance and Numbers of Threads. We also compare the performance of TriCache and baselines under different numbers of threads for PageRank and RocksDB with 64GB of memory. More precisely, "the performance under a given number of threads" means the maximum performance with less than or equal to this number of threads (only searched over powers of two). Since TriCache uses 16 server threads as the default configuration in the evaluation section, the number of threads starts with 32 threads (including server threads).

As shown in Figure 14, TriCache achieves good scalability for the workloads of both PageRank and RocksDB, which is one of the reasons for why TriCache performs well. For example, from 32 threads to 256 threads (the number of hard-

ware threads), Ligra with TriCache (in Figure 14a) achieves a 4.29× speedup, and RocksDB with TriCache (in Figure 14b) yields a 13.5× performance improvement.

Meanwhile, with a small number of threads, TriCache's performance is worse than that of manually optimized prefetch and asynchronous I/O because of TriCache's synchronous scheme for triggering I/O and its lack of program-specific optimizations (similar to `mmap`). In order to mitigate these limitations, over-subscription can help to utilize the queue depth of SSDs as much as possible. Through over-subscription, the performance of TriCache is improved by 2.58× for PageRank and 2.15× for RocksDB, thus enabling good performance for TriCache even without manual optimizations.

5 Related Work

There is a series of work that tries to improve the page caching performance with customized memory-mapped file I/O paths or swapping approaches [27–30, 39, 41]. Kmmap [28] provides several improvements to reduce the variation in performance owing to the aggressive write-back policy of Linux. FastMap [29] addresses scalability issues by separating clean and dirty pages and using per-core data structures to avoid centralized contentions, with the help of a custom Linux kernel. Still, our evaluation shows that FastMap cannot saturate current high-performance NVMe SSD arrays. Aquila [27] offers a library OS solution that eliminates the need for kernel modifications, relying on hardware support for virtualization, which makes it not easy to deploy on cloud environments. Umap [30] provides an `mmap`-like interface to user-space page fault handlers based on `userfaultfd` [2] in Linux, but is faster than `mmap` only with large page sizes. LightSwap [55] redesigns the swapping system to reduce context switching and page fault overheads, but it requires both kernel and program modifications. TriCache exposes a memory interface like these kernel-involved solutions, but runs completely in the user space to achieve maximal out-of-core performance.

Block caches (or buffer managers) are critical components in data-intensive applications for supporting out-of-core processing [6, 12, 15, 20, 52, 54]. Some attempts try to improve the performance of block caches. SAFS [53], the storage backend for FlashGraph [54], adopts a lightweight cache design based on NUMA-aware message passing. Users need to program with its asynchronous I/O interface to exploit maximal I/O performance on SSD arrays. LeanStore [20] proposes to use pointer swizzling so that pages residing in memory can be directly referenced without page lookups. However, it requires pages to form a tree-like structure, and thus is applicable to limited scenarios. TriCache shares similar goals but provides a memory interface that is user-transparent and more general.

Remote cache systems [14, 24] have been developed upon ideas of the disaggregated architecture [3, 11, 13, 18, 19, 25, 31, 34–36], which utilizes high bandwidth and low latency of modern networks. In this paper, we focus on scaling-up through NVMe SSD arrays. And we intend to consider support for disaggregated architectures in our future work.

Non-volatile memory (NVM) enables larger capacity compared with DRAM, and researches have been devoted to memory management instead of paging strategies to render memory access efficient on hybrid NVM and DRAM architectures [17, 32, 42, 56]. Nevertheless, block caches such as TriCache are still better suited for NVMe SSDs due to their higher latencies than NVM or DRAM.

6 Discussion

In TriCache, SATC does not need to be notified by its Shared Cache when a block is swapped out. In contrast, hardware TLB in processors, which also accelerates address translation as SATC, requires OS page cache to explicitly invalidate evicted pages through *TLB shootdown*, incurring considerable overhead [4, 5] due to inter-processor interrupts (IPIs). A comparison of the mechanisms of SATC and TLB shows that SATC utilizes reference counting to prevent evicting blocks currently being used by clients, while the OS is not directly aware of how many TLB entries are still referring to the pages to be evicted. It is possible to extend the design of SATC to TLB. Processors could mark the reference counts for page tables entries (PTEs), e.g., recording the number of TLB entries that currently hold a specific PTE. The OS can then adapt its page swapping and evict policies to avoid evicting pages currently present in TLBs, thus mitigating the performance issue brought by TLB shootdown.

7 Conclusion

In this paper, we explore a new user-space approach to achieving efficient out-of-core processing with in-memory programs, by providing a virtual memory interface on top of a block cache. We implement TriCache based on a novel multi-level design and applies it to various in-memory or `mmap`-based programs without manual code modification. TriCache achieves out-of-core performance that is orders of magnitude higher than that of the Linux OS page cache, and is often comparable to or even faster than specialized out-of-core solutions.

The open-source implementation of TriCache and instructions to reproduce the main experimental results are accessible from: `https://github.com/thu-pacman/TriCache`.

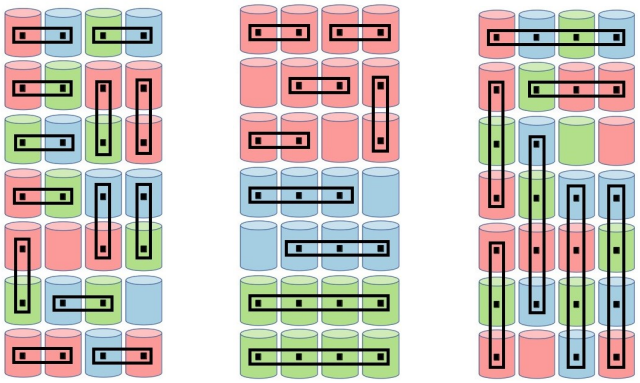
Abstract

Large-scale cluster storage systems use redundancy (via erasure coding) to ensure data durability. Disk-adaptive redundancy—dynamically tailoring the redundancy scheme to observed disk failure rates—promises significant space and cost savings. Existing disk-adaptive redundancy systems, however, pose undesirable constraints on data placement, partitioning disks into subclusters that have homogeneous failure rates and forcing each erasure-coded stripe to be entirely placed on the disks within one subcluster. This design increases risk, by reducing intra-stripe diversity and being more susceptible to unanticipated changes in a make/model's failure rate, and only works for very large storage clusters fully committed to disk-adaptive redundancy.

Tiger is a new disk-adaptive redundancy system that efficiently avoids adoption-blocking placement constraints, while also providing higher space-savings *and* lower risk relative to prior designs. To do so, Tiger introduces the *eclectic stripe*, in which redundancy is tailored to the potentially-diverse failure rates of whichever disks are selected for storing that particular stripe. With eclectic stripes, pre-existing placement policies can be used while still enjoying the space-savings and robustness benefits of disk-adaptive redundancy. This paper introduces eclectic striping and Tiger's design, including a new mean-time-to-data-loss (MTTDL) approximation technique and new approaches for ensuring safe per-stripe settings given that failure rates of different devices change over time. In addition to avoiding placement constraints, evaluation with logs from real-world clusters shows that Tiger provides better space-savings, less bursty IO for changing redundancy schemes, and better robustness (due to increased risk-diversity) than prior disk-adaptive redundancy designs.

1 Introduction

"A Tiger never changes its stripes", but can it be made to? In this context, the Tiger is a cluster storage system and its *stripes* are the erasure coded data that is placed across multiple disks in order to ensure data reliability. In today's cluster storage systems, most of the data reliability is via erasure coding [13, 21, 37, 40, 50, 58].



(a) Conventional cluster storage **(b)** Pacemaker (subcluster-based) **(c)** Tiger (this paper)

Figure 1: Stripe placements and configurations in different erasure coding systems: Disks of same color have similar annualized failure rates (AFRs), with red being least reliable (highest AFR), then blue, then green. Rectangles represent stripes with shorter stripes having higher redundancy. Conventional one-scheme-fits all designs (1a) impose no placement restrictions, but make no distinction of disk AFRs and therefore overprotect much of the data—all stripes use the widest redundancy scheme, shown as 2-wide for illustration. Pacemaker (1b) and Tiger (1c) tailor redundancy based on disk AFRs, resulting in different stripe widths in the illustration, and thereby reduce storage overhead. Pacemaker does this with rigid AFR-based subcluster boundaries, whereas Tiger requires no such boundaries.

Conventionally, a single cluster-wide redundancy scheme is selected for each data corpus (or for all data corpuses) [11, 14, 15, 21, 33]. This approach fails to account for the disk-reliability heterogeneity present in modern storage clusters, which consist of hundreds-of-thousands of hard disk drives (HDDs or just "disks") of multiple makes/models deployed at different times. This forces conventional storage clusters to use excessive redundancy (wasting capacity, and thus money and energy) to guarantee data safety, given that different disks have different failure rates. Absent other information, redundancy schemes are usually chosen to be safe for stripes fully stored on the least reliable disks (e.g., Fig. 1a). Recent research has showed that adapting redundancy scheme selection

*Equal contribution

to the observed failure rates of specific disks can reduce the space (=cost) overhead of redundancy by up to 20% [23].

Existing disk-adaptive redundancy designs [24, 25], however, face several significant adoption hurdles. At their core, these designs rigidly partition a storage cluster into subclusters of disks (called redundancy groups or Rgroups) that have similar failure rates, so they can use a subcluster-wide redundancy scheme tailored to meet the required data reliability target (e.g., Fig. 1b). Key adoption hurdles include: (1) Since each stripe must be entirely within a single Rgroup, this subcluster-based design can interfere with other data placement considerations, such as enhancing risk-diversity by spreading data across fault domains and different makes/models/batches of disks. Indeed, many of the Rgroups consist of a single make/model. (2) To provide reasonable degrees of performance and reconstruction speed scalability, subclusters must be sizable, making these designs only suitable for very large storage clusters. (3) When failure rates rise for a given make/model, as it ages, the redundancy scheme for an entire Rgroup (potentially 100s of PBs) may need to change to maintain target data reliability levels—all at once. The Pacemaker design [24] proposes to predict such changes and start them early, but they need to predict a month or more in advance to avoid reliability problems given the huge amount of data being transitioned, which is inherently a risky proposition. (4) The subcluster-based designs assume full adoption of disk-adaptive redundancy, not allowing for selective adoption for some data corpuses but not for others.

We present Tiger, a disk-adaptive redundancy system that eliminates the placement constraints posed by subcluster-based disk-adaptive redundancy designs while providing equal or greater benefits. Tiger's core new abstraction is the *eclectic stripe*, in which disks of different AFRs can be used to store a stripe that has redundancy tailored to the set of AFRs for those disks. In terms of placement flexibility, eclectic stripes are identical to stripes in conventional (non-disk-adaptive redundancy) designs. But, unlike conventional stripes, eclectic stripes do not conservatively assume the worst-case AFR for all disks. Instead, with eclectic stripes, the redundancy scheme is dynamically set for each stripe based on the AFRs of the chosen disks (e.g., Fig. 1c). Tiger's eclectic stripe approach avoids all the adoption hurdles discussed above, while simultaneously increasing the effectiveness (higher space-savings) and robustness (lower burstiness of urgent transition IO) of disk-adaptive redundancy.

Efficiently incorporating the proposed new abstraction of eclectic stripes is challenging due to multiple reasons. Tiger introduces several new design elements to overcome these challenges. First, calculating the exact reliability in terms of mean-time-to-data-loss (MTTDL) of a stripe can be prohibitively expensive, since accounting for different failure rates can lead to an exponential number of states in the traditional Markov chain reliability model. To address this, we provide a novel approximation technique that speeds up MTTDL calculation by 2-4 orders of magnitude while always preserving accuracy of over 95%, and on average over 99.5%. Second, while disks for a stripe can be chosen based on pre-existing placement policies, the chosen disks may not form an adequately-reliable stripe for a planned redundancy scheme, since the reliability is dependent on the chosen disks' AFRs. Tiger uses an AFR-aware stripe-width-reduction policy to quickly achieve sufficient reliability. Third, disk AFRs change over time [25], which can require changing the redundancy schemes of some eclectic stripes. Keeping track of AFRs for each stripe and triggering the redundancy schemes can significantly increase the overhead for metadata and background operations. Tiger introduces an *eclectic volume* abstraction to reduce metadata overhead and make identification of required changes efficient. It also introduces policies to reduce transition IO: the IO involved with enacting changes to stripe redundancy schemes.

Evaluating the feasibility and efficacy of eclectic stripes requires analysis of long-term effects on huge storage clusters. We evaluate Tiger using the same logs as used to evaluate Pacemaker [24], enabling an apples-to-apples comparison. These logs contain all disk-deployment, failure, and decommissioning events from four production storage clusters: three 160K–450K-disk Google clusters and a ≈110K-disk cluster used for the Backblaze Internet backup service [3]. Simulation driven by production logs allows us to analyze reliability, space usage, and redundancy maintenance traffic for multiple clusters each with over 100K disks and over multiple years, which would be infeasible otherwise as part of a research setup. For all four clusters, Tiger provides equal or better space-savings than Pacemaker, while requiring at most 0.5% of daily IO bandwidth for transition IO. More importantly, the transition IO is both less bursty, in terms of when it is needed, and less urgent, in terms of how unsafe an unsafe stripe might be if the scheme transition were delayed. For instance, in response to a tiny rise in AFR ($< 0.25\%$) for disks of a given make/model, Pacemaker would need 196% of the total IO bandwidth from each of those disks in order to make the data safe—to avoid stealing more than 5% of IO bandwidth for transition IO, Pacemaker would have to know to start 40 days in advance—but Tiger would need $<$1.6% even for a 1% AFR increase because of the diversity of its eclectic stripes. And, most importantly, Tiger exhibits significantly better risk-diversity, stemming from removing placement constraints and allowing differently-reliable disks (and hence disks of different makes/models) to belong to the same stripe. For example, even with random selection of disks for each stripe, most of Tiger's eclectic stripes span most of a cluster's make/models; Pacemaker's strict Rgroup boundaries disallow use of more than one make/model for most stripes.

Contributions. In this paper, we make four main contributions. First, we introduce eclectic stripes as a tool for realizing disk-adaptive redundancy without the placement restrictions posed by prior designs. Second, we present a reliability model

and its approximation to efficiently calculate the MTTDL of eclectic stripes. A surprising outcome is that a homogeneous stripe with the same scheme and average disk AFR as an eclectic stripe is less reliable! Third, we present the design and architecture of Tiger, the first disk-adaptive redundancy system for supporting and efficiently managing eclectic stripes. Fourth, we evaluate Tiger and compare it to the state-of-the-art, using logs from four large real-world storage clusters, demonstrating its effectiveness in realizing disk-adaptive redundancy without prior designs' adoption challenges and with greater space-savings and lower risk.

2 Background and Motivation

We first provide a primer on data redundancy done using erasure coding followed by the gist and importance of disk-adaptive redundancy. We then describe the problems with existing disk-adaptive redundancy systems, which is the motivation for this paper.

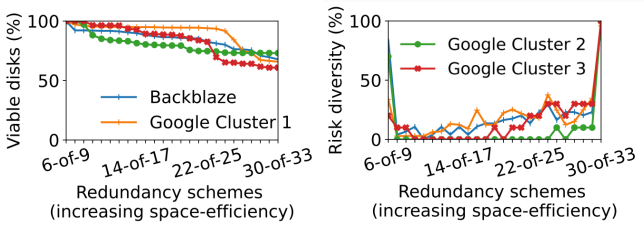
Erasure Coding for data durability. Modern storage clusters often comprise of hundreds-of-thousands of disks of multiple make/models deployed over time. The sheer scale of the storage clusters makes disk failures a common occurrence [15], which necessitates some form of redundancy to ensure data durability and availability. While replication is popular for availability of hot data, erasure coding (a more space-efficient alternative to replication) is more common for the durability of colder data, which forms the majority of the stored data. In erasure coding (EC), data is split into k chunks, and $n-k$ *parity* chunks are subsequently generated to form a *stripe* with n chunks. Each chunk is stored on a separate disk. This k-of-n EC scheme (also called "redundancy scheme") can withstand up to $n-k$ failures with a storage overhead of $\frac{n}{k}$. Any k chunks of an n-chunk stripe are sufficient to construct the original data.

Reliability Metrics: MTTDL and AFR. The reliability of a stripe is determined by its *mean-time-to-data-loss* (MTTDL). A stripe's MTTDL is calculated using a continuous-time Markov chain shown in the left side of Fig. 3. Each state represents the number of simultaneously lost chunks in a stripe. The MTTDL is the mean time to reach state DL (where $n-k+1$ chunks are simultaneously lost) from state 0; this is when data is irrecoverably lost. This model assumes a *homogeneous stripe*, where all disks fail with the same rate λ. Downward transitions denote failures, which happen with a rate of λ times the number of available chunks, while upward transitions denote repairs, which happen with a fixed rate μ. Failure rates are commonly expressed as an *annualized failure rate* (AFR), which is defined as the expected fraction of failed disks in a year, assuming that failed disks are replaced and the disk population remains fixed.

Disk-adaptive redundancy. Storage clusters have conventionally been using a one-scheme-fits-all redundancy scheme by assuming that all disks fail similarly. Prior work has shown that disk AFRs are highly correlated with their vintage [26, 35]. With modern clusters having a mix of disk makes/models/batches, there can be over an order of magnitude difference between AFRs of different groups of disks [25]. Additionally, over their lifetime, disk AFRs follow a "bathtub curve" with multiple failure regimes: infancy (high AFR) followed by useful life with potentially multiple phases (piecewise linear phases with low AFR that increases gradually) and finally wearout (high AFR) [24].

Disk-adaptive redundancy capitalizes on differences in disk AFRs and dynamically tailors data redundancy to observed disk failure rates [23]. Disk-adaptive redundancy systems take into account various constraints including the reconstruction costs when making the decision of a target stripe width to adapt to. Specifically, wide schemes are used only when a stripe's average AFR is low enough to keep the reconstruction cost contained below a configured limit. More generally, wide stripes provide cost savings in terms of smaller storage overhead at the cost of higher reconstruction costs and higher degraded mode reads. We know from conversing with architects of large-scale storage clusters that the cost of the excess byte footprint matters more than the cost of excess IO required in the context of redundancy, given existing workloads. This is especially so since, in general, large-scale capacity-tier storage cluster workloads tend to be cold (have low IO/s per byte). Additionally, cold data experiences fewer reads, and therefore has very few costly degraded mode reads. Backblaze is an example where, for archival data that has low IO access rates, administrators have publicly confirmed use of wide redundancy schemes such as 17-of-20 [4]. By using more space-efficient redundancy schemes during low AFR regimes, disk-adaptive redundancy can provide substantial space-savings ($> 20\%$) in clusters with over 100K disks.

Prior disk-adaptive redundancy systems. Two disk-adaptive redundancy systems have been proposed in the literature: HeART [25] and Pacemaker [24]. In HeART, the authors propose a tool to statistically learn the AFRs of different disk groups and identify change-points for safe redundancy transitions. By transitioning to an encoding scheme with minimum storage overhead that still meets the target MTTDL, HeART was able to obtain $\approx 20\%$ space-savings when tailoring erasure codes, and $\approx 33\%$ space-savings when tailoring replication. Although lucrative, HeART overlooked an important practical hurdle in performing disk-adaptive redundancy: *transition overload*, i.e. the IO overhead of performing redundancy transitions. Crippling transition overload when thousands of disks require simultaneous redundancy transitions forms the basis for Pacemaker [24]. The gist of Pacemaker is to convert urgent redundancy transitions into schedulable ones by making conservative predictions of the rise in AFR and proactively issuing redundancy transitions. This allows the transition overload to be spread out over time, such that it can be completed within tolerable IO limits without compromising data safety.



(a) Placement constraints **(b)** Risk-diversity

Figure 2: 2a shows Pacemaker's placement constraints by highlighting the fraction of the disk fleet that is viable for different schemes exercised on four production clusters. Fig. 2b shows the risk-diversity obtained by the same clusters on particular dates in their lifetime. A risk-diversity of 100% implies at least one chunk stored on every possible make/model, whereas a 0% risk-diversity implies that the particular scheme was not feasible in the cluster. Pacemaker performs poorly in both placement constraints and risk-diversity.

2.1 Existing designs are impractical

Despite remarkable space-savings and low IO costs, existing disk-adaptive redundancy systems remain impractical in real-world settings.

Placement restrictions. The primary hurdle stems from the placement restrictions posed by reliance on redundancy groups (*Rgroups*). An Rgroup is a set of disks with similar AFRs, such that they can use the same redundancy scheme. Prior systems redundancy management techniques rigidly partition the cluster's disks into Rgroups, and every stripe must be stored entirely within a single Rgroup. Fig. 2a shows the percentage of disks that are rendered infeasible for various redundancy schemes Pacemaker can employ on a particular day in four large storage clusters. More than 30% of the disks are deemed infeasible for space-efficient schemes beyond 22-of-25, because their AFRs are not low enough for those disks to participate in an Rgroup for which schemes beyond 22-of-25 can meet the target MTTDL. Furthermore, in order to maintain proper redundancy, stripes are typically constrained to span across different racks, servers, power lines, etc. Adding another placement constraint may be close to impossible.

Lower risk-diversity. Due to high correlation of AFRs and makes/models/batches [26,35], and in order to enable efficient transitioning mechanisms, many Rgroups contain disks from just one make/model. This is undesirable from a risk-diversity perspective. Fig. 2b shows the fraction of makes/models that are covered for the same stripe configurations in the same four clusters described above. Higher risk-diversity is valuable for mitigating consequences of bulk failure situations (e.g., from rapid degradation due to manufacturing defects), especially in a disk-adaptive redundancy system where redundancy is tuned rather than regularly excessive.

Reliance on AFR prediction. With lower risk-diversity, Pacemaker's Rgroups are already susceptible to data loss due to bulk failures in a single make/model (uncommon, but not impossible). Furthermore, Pacemaker's IO cost reduction is highly dependent on being able to accurately predict an AFR rise well in advance. Currently AFR is calculated only on the basis of age. Prior work has highlighted that it is dependent on various factors such as vintage, temperature, vibration, etc. [7, 26, 27, 35]. This makes an already difficult task of accurate AFR prediction even harder.

All-or-nothing. Current disk-adaptive redundancy designs depend on forming Rgroups, and work efficiently if entire Rgroups perform redundancy transitions together (for step-deployed disks). This implies that the entire cluster must commit to performing disk-adaptive redundancy for all of their data stored on all disks. Such a restriction makes disk-adaptive redundancy unusable without a major overhaul of the architecture of the existing storage cluster.

The key takeaway is that additional data placement restrictions create adoption-blocking limitations and risks. In order have have both placement flexibility and disk-adaptivity, we need a new approach that includes the ability to reason about and tune the reliability of stripes that span disks with different AFRs. We achieve this via ***eclectic stripes***.

3 *Eclectic Stripes* and their challenges

Eclectic stripes are central to Tiger's approach of providing disk-adaptive redundancy without placement restrictions. An eclectic stripe is an EC stripe placed on a collection of disks that can have different failure rates. The reliability model of conventional EC stripes forces them to be allocated on disks having (or worse, assumed to be having) the same failure rate. In terms of composition an eclectic stripe is no different than what a conventional EC stripe would be. Specifically, the same disks that make up a conventional stripe can also make up an eclectic stripe, just that eclectic stripes are cognizant of the AFR differences of the underlying disks and can accurately reason about the resulting reliability. A disk-adaptive redundancy system that supports eclectic stripes has to overcome several challenges.

1. Ensure efficient creation of sufficiently reliable eclectic stripes. Taking AFR differences of all disks in a stripe into account makes exact MTTDL calculation of eclectic stripes prohibitively expensive (see §4.1.1). Since stripe creation is a critical-path operation, it is imperative that a disk-adaptive redundancy system supporting eclectic stripes reasons about its reliability in an efficient and accurate manner.

2. Ensure efficient management of eclectic stripes. All underlying disks of an eclectic stripe will not experience an AFR rise or fall together. A system supporting eclectic stripes must efficiently identify which stripes need to change their redundancy in response to changing AFRs.

3. Support unchanged placement policies. While tweaking the placement policies might provide additional optimizations, a system that supports eclectic stripes must support existing placement policies without any change.

4. Retain key benefits of disk-adaptive redundancy. Dynamic redundancy adaptation at a low transition IO cost; continuously providing adequate reliability; providing space-savings by using more space-efficient redundancy schemes in low-AFR regimes are the key benefits of disk-adaptive redundancy. Any proposed disk-adaptive redundancy system should strive to maintain these benefits.

5. Ensure an adoption-friendly design. Apart from placement restrictions, existing disk-adaptive redundancy system designs require that the entire cluster commits entirely to perform disk-adaptive redundancy, or it cannot gain any of its benefits. Moreover, only the very large-scale storage clusters can use existing disk-adaptive redundancy designs, whereas the small and medium sized clusters are outside their scope. High emphasis on usability and showcasing a way for easy adoption of disk-adaptive redundancy in existing storage clusters of all shapes and sizes is an important design challenge.

4 Mechanisms to enable eclectic stripes

In this section, we address the two main challenges of eclectic stripes: their reliability and their management.

4.1 Interpreting reliability of eclectic stripes

We first shed light on key takeaways from our study of the reliability of eclectic stripes and then provide the detailed theory and the associated analysis.

Calculating MTTDL of eclectic stripes is efficient and accurate. The exact calculation of the MTTDL of an eclectic stripe is computationally expensive. We provide a novel approximation that provides the MTTDL with over 99.5% accuracy (on average), and always provides over 95% accuracy in our tests. In practice, a difference of 5% in MTTDL typically translates into a difference of around 0.1% AFR for a homogeneous stripe, which is negligible. The exact MTTDL calculation and the approximation are detailed in §4.1.1, 4.1.2.

Eclectic stripes are more reliable than homogeneous stripes. When comparing the MTTDL of an eclectic stripe with a homogeneous stripe having the same EC scheme and same avg. AFR, the MTTDL of the eclectic stripe is always higher than the MTTDL of the corresponding homogeneous stripe for typical system parameters (§4.2, Fig. 4).

Eclectic stripes are robust to AFR changes of individual disks. The MTTDL of the eclectic stripes does not react abruptly to the increase in AFR of a few disks. Compared to the conventional approach of treating stripes as homogeneous with AFR equal to the maximum AFR in the stripe, MTTDL of eclectic stripes react very gradually to AFR changes.

Eclectic stripes are more robust to AFR misestimations. Due to the nature of empirical data, any system that measures AFR has to estimate it. Since the AFRs of different disk make/models are estimated independently, it is unlikely that there will be simultaneous underestimation of the AFR of every disk in an eclectic stripe, and hence the impact of estimation errors is smaller (Fig. 5) and may even cancel each other out. Furthermore, disk-adaptive redundancy systems are made even more robust against misprediction by the use of confidence intervals. Thus, eclectic stripes are more robust to AFR misestimations compared to homogeneous stripes.

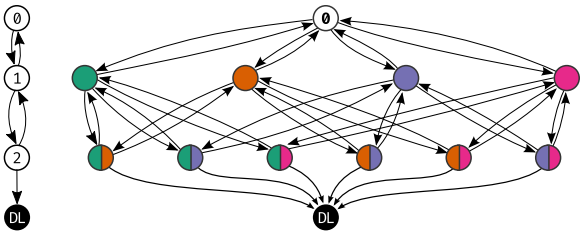


Figure 3: Left: Classic Markov chain model for the MTTDL of a 2-of-4 homogeneous stripe. Right: Markov chain model for the MTTDL of a 2-of-4 eclectic stripe.

4.1.1 Exact MTTDL calculation is costly

Using a Markov chain model to calculate the MTTDL of storage systems is a classic approach [16]. A generalization of this approach helps us take into account disks with different failure rates. Consider an EC stripe of a k-of-n scheme, placed over n disks with failure rates $\lambda_i (i \in [n])$ and a disk repair rate of μ. The state of the system is given by an n-length vector $\mathbf{s} = (s_0, \ldots, s_n)$ with $s_i = 1$ if disk i has failed, and $s_i = 0$ otherwise ($i \in [n]$). The state space is given by states $(s_i)_{i=1}^{n}$ such that the total number of failure $\sum_{i=0}^{n} s_i$ is at most the number of parities $n-k$, and a data loss state labeled DL. Therefore, the total number of states is $1 + \sum_{i=0}^{n-k} \binom{n}{i}$. The rate of transition from state $\mathbf{s}$ to $\mathbf{s}'$ is defined as:

- λ_i if $s_i = 0, s'_i = 1$, and $s_j = s'_j$ for $i \neq j$ (i^{th} disk fails),
- μ if $s_i = 1, s'_i = 0$, and $s_j = s'_j$ for $i \neq j$ (i^{th} disk repaired),
- $\sum_{i=1}^{n} (1 - s_i)\lambda_i$ if $\sum_{i=1}^{n} s_i = n - k$ and $\mathbf{s}' = DL$ (any disk fails when $n-k$ disks have failed and are not repaired).

The MTTDL is defined as the mean time to state DL from the initial state $\mathbf{0} = (0, \ldots, 0)$.

Given the values of $n, k, (\lambda_i)_{i=1}^{n}$, and μ, one can compute the MTTDL by using the standard approach of solving a system of equations. However, this approach is not tractable, due to the exponential explosion on the number of states with respect to $n-k$ (see Fig. 3 to compare conventional Markov chain with that of an eclectic stripe). For example, the Markov chain of a 10-of-14 eclectic stripe has 1472 states, compared to 6 states in the case of a 10-of-14 homogeneous stripe. Reasoning about this model can be hard too, since it is not directly clear how disk AFRs affect MTTDL. Furthermore, this approach tends to be numerically unstable, which makes obtaining precise MTTDLs hard. We find that computing a single MTTDL using this approach with realistic parameters can take up to several seconds using the Mathematica 12

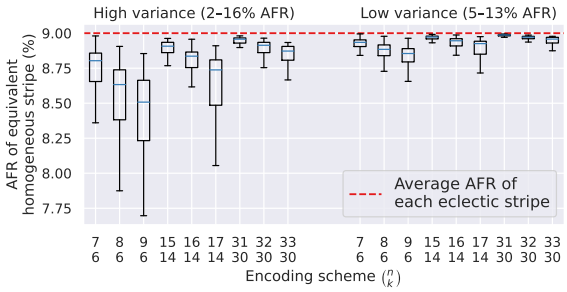

Figure 4: Reliability of eclectic stripes compared to homogeneous stripes. For each scheme, we sample 1000 eclectic stripes and for each stripe we compute its MTTDL ρ and then compute the AFR λ of a homogeneous stripe with the same scheme and MTTDL equal to ρ. The boxes show the distribution of λ over the 1000 stripes. The AFR of the first $n-1$ disks in a eclectic stripe are sampled uniformly at random from the range 2–16% (high variance) or 5–13% (low variance), and the AFR of the last disk in a stripe is chosen to ensure that the average AFR of the disks *in each stripe* is fixed at 9%. E.g. the median 6-of-9 eclectic stripe from the high-variance group is as reliable as a 6-of-9 homogeneous stripe with AFR 8.5%, despite having an average AFR of 9%.

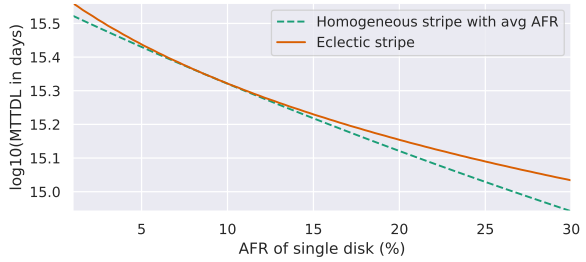

Figure 5: Reliability of a 6-of-9 eclectic stripe when the AFR of a single disk varies. The eclectic stripe is composed of 8 devices with AFR 9%, and one device whose AFR varies from 1% to 30% (x axis). The dashed line denotes the MTTDL of a 6-of-9 homogeneous stripe with the same average AFR as the eclectic stripe. The solid line denotes the MTTDL of the eclectic stripe. Reliability of the eclectic stripe is always above the corresponding homogeneous stripe.

software [52] on a desktop PC. This is too slow in practice, because not only do we need to compute the MTTDL when creating new stripes, but we also need to periodically compute the MTTDL of every stripe in the system (typically billions) as device AFRs change. The next section describes an efficient approximation that makes the MTTDL calculation of eclectic stripes computationally tractable and highly accurate.

4.1.2 Efficient and accurate MTTDL approximation

In order to compute and better understand the MTTDL of eclectic stripes, we propose an approximation formula, building on the approach presented in [2] for homogeneous stripes. This approximation is extremely good when $\mu \gg \max_i \lambda_i$, which is true for modern cluster storage systems.

The main idea behind this approximation is to note that (in the steady state) disk i will be available a fraction $A_i = \mu/(\mu+\lambda_i)$ of the time, and that the system will reach the *DL* state when exactly $k-1$ of the disks are available. Therefore, the MTTDL can be approximated with the following formula (see appendix A for the full derivation):

$$\text{MTTDL} \approx \left(\mu(n-k+1)\,\text{PBin}(k-1;n,(A_i)_{i=1}^n)\right)^{-1}, \quad (1)$$

where $\text{PBin}(k;n,(p_i)_{i=1}^n)$ is the probability of obtaining exactly k heads when flipping n biased coins with probability of heads p_i for coin i. PBin is known as the Poisson-binomial distribution, and it can be efficiently evaluated [12, 19].

We tested this approximation against the Markov chain approach over all values of $6 \le k \le 30$, $1 \le n-k \le 3$, and AFRs of 1–16%. The relative difference between the two output MTTDLs never exceeded 5% and was less than 0.5% on average[*]. As a benefit, the approximation is 2–4 orders of magnitude faster to evaluate (in the order of milliseconds), more numerically stable, significantly simpler to implement, and gives direct insight into how the parameters affect MTTDL.

4.2 Understanding MTTDL of eclectic stripes

The main difference between the reliability of an eclectic stripe and a homogeneous stripe is given by the Poisson-binomial factor in Eq. 1, which becomes Binomial when all probabilities are equal. Notice that the difference between A_i in Eq. 1 will be small because $\mu \gg \max_i \lambda_i$, and therefore the corresponding Poisson-Binomial distribution will not deviate too much from a Binomial distribution with trial success probability $A = \sum_{i=1}^n A_i/n$ [6]. Furthermore, we have:

$$\sum_{i=1}^n \frac{A_i}{n} = \frac{1}{n}\sum_{i=1}^n \frac{1}{1+\lambda_i/\mu} \approx \frac{1}{n}\sum_{i=1}^n \left(1-\frac{\lambda_i}{\mu}\right) = 1 - \frac{\sum_{i=1}^n \lambda_i/n}{\mu},$$

where we use the approximation $1/(1+x) \approx 1-x$ for small x. This means that the reliability of an eclectic stripe will tend to be close to the reliability of a homogeneous stripe with AFR equal to the average AFR of the eclectic stripe.

To measure how close the MTTDL of an eclectic stripe will be to that of a homogeneous stripe with the same scheme and average AFR, we conduct two numerical experiments. Fig. 4 compares eclectic stripes against homogeneous stripes that have the same MTTDL, across different schemes and AFR ranges. In this experiment, instead of directly showing an MTTDL ρ (which is hard to interpret) in the y-axis, we show the AFR λ of a homogeneous stripe that has MTTDL equal to ρ (under the relevant scheme). The results show that eclectic stripes are *more* reliable than homogeneous stripes with the same scheme and average AFR. In other words, for a homogeneous stripe composed of disks with AFR λ to match

[*]The median relative difference between the exact and approximated eclectic stripe MTTDL was 0.1%, the 90^{th} percentile error was 0.5%, and the 95^{th} percentile error was 0.7%.

the reliability of an eclectic stripe with AFRs $(\lambda_i)_{i=1}^n$, the disks in the homogeneous stripe have to be more reliable on average, i.e., $\lambda < \sum_{i=1}^n \lambda_i/n$. The difference, however, becomes small when the ratio n/k is small, or the range of AFRs is small. Fig. 5 shows the reliability of an eclectic stripe when the AFR of a single disk in the eclectic stripe varies in the range 1–30%. This experiment shows that eclectic stripes provide a dampening effect against AFR rises of a small number of devices in two ways: (1) a small number of devices have a smaller impact on the average AFR of the stripe (slope of the dashed line), and (2) the convex shape of the curve shows that the eclectic stripe is even more reliable than a homogeneous stripe with the same scheme and average AFR.

Checking if a stripe is safe: Typically, a minimum level of reliability is set in the cluster by setting a *MTTDL threshold* that all stripes must satisfy in order to be deemed safe. Given the results presented in this section, we now describe a simple method to determine whether a stripe is safe. We define the *critical AFR* of a k-of-n scheme and MTTDL threshold θ as the highest AFR that disks in a homogeneous k-of-n stripe can attain while still having an MTTDL of at least θ. The critical AFRs for the different schemes that are used in a system can be precomputed and stored. Then, a simple andx efficient way of checking whether an eclectic stripe under some scheme is safe is to check whether the average AFR in the stripe is less than the critical AFR for that scheme. Since an eclectic stripe is at least as reliable as a homogeneous stripe with the same scheme and average AFR, if the stripe passes this check, then we can be certain that the stripe is safe. If the stripe does not pass the check, then it *may* be unsafe, which can determined by computing its MTTDL. This test can help greatly reduce the amount of work needed in checking whether stripes are still safe, and it also provides a simple way of understanding the reliability of eclectic stripes.

4.3 Eclectic Volumes

Disk AFR changes may trigger redundancy transitions. Prior designs performed disk-adaptive redundancy at the disk level. Thus, if a disk's AFR changed, either all or none of the stripes on that disk required a redundancy transition. With eclectic stripes, each disk may store chunks of stripes with different reliabilities. An AFR change might only require redundancy transitions for a subset of those stripes. With millions of eclectic stripe chunks being stored on each disk, a linear search through all of them for each AFR change is impractical.

An eclectic volume is a collection of eclectic stripes that use the same EC scheme and are stored on the same set of disks. A disk can contain multiple volume fragments identified by their globally unique volume ID. Each disk maintains a map of stripe ID to eclectic volume ID. Since each eclectic volume spans the exact same disks, whenever a disk's AFR changes, Tiger only needs to check whether the EC scheme used for each of the disk's constituent volumes still meets the required

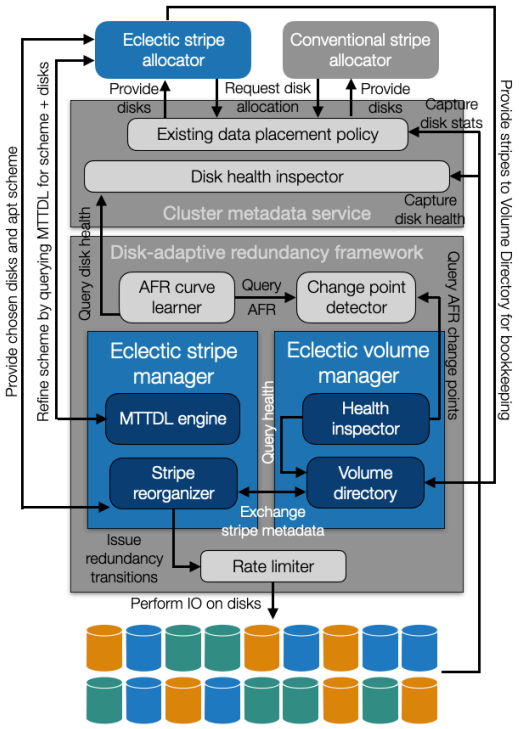

Figure 6: Architecture of Tiger. The blue boxes correspond to Tiger's components. The gray boxes correspond to existing components in cluster storage system architecture and components present in existing disk-adaptive redundancy systems.

MTTDL target. There is no need to check the reliability of each of the individual eclectic stripes within a volume since they are all identically reliable. The details of how Tiger manages eclectic volumes is described in §5.3.

Eclectic volumes prove to be efficient only if they represent a large number of eclectic stripes. Therefore, in Tiger the default size of an eclectic volume is set to 1 TeraByte (TB). This way, even though Tiger performs reliability monitoring at the volume granularity it ensures that each eclectic stripe is always sufficiently reliable.

5 Design and working of Tiger

Tiger is a practical disk-adaptive redundancy system designed to overcome the challenges described in §3. Fig. 6 shows the architectural components of Tiger (colored boxes) and how they interact with existing cluster storage system components and common disk-adaptive redundancy components.

5.1 Data flow in Tiger

We overview Tiger by explaining the lifecycle of eclectic stripes. An eclectic stripe is created via the *Eclectic Stripe Allocator* (ESAllocator), which identifies a set of disks and the corresponding scheme on which this data is to be stored. The ESAllocator uses the existing and unmod-

ified data placement policy to obtain a set of disks. That placement policy uses whatever knowledge designers choose (e.g., available freespace, load balance, and fault domain constraints) in selecting the set of disks. The ESAllocator then queries the *Eclectic Stripe Manager's MTTDL Engine* (ESMTTDLEngine) with the AFRs of the chosen disks, and a stripe configuration, to verify that the planned stripe's MTTDL meets the required target MTTDL. If it does not, the ESAllocator boosts the MTTDL by changing the stripe configuration until an appropriately safe redundancy scheme is found. §5.2 details this process.

Once created, the ESAllocator passes the stripe to the Eclectic Volume Manager (EVManager, see §5.3) to either add the stripe to an existing volume, or create a new volume which will contain the new stripe. The Eclectic Volume Health Inspector (EVHInspector) continuously monitors the reliability of the eclectic volume by querying the change point detector, which identifies significant AFR changes in the data from the AFR curve learner. The AFR curve learner, change point detector and the rate limiter can be reused without change from any existing disk-adaptive redundancy system[*]. In reaction to a significant AFR change (rise or fall), the EVHInspector alerts the EVManager, which fetches the eclectic stripe metadata from the EVDirectory and provides both the AFR change and the metadata to the Eclectic Stripe Reorganizer (ESReorganizer; see §5.2). The ESReorganizer includes techniques to efficiently perform redundancy transitions. If eclectic stripes must change, the ESReorganizer consults the ESAllocator in forming them. Non-urgent redundancy transitions (when the target MTTDL is not at risk of being violated) are throttled by the rate limiter in order to not overwhelm the storage cluster.

Tiger's stripe-by-stripe disk-adaptive redundancy approach enables incremental adoption by allowing data to be stored either as an eclectic stripe or a homogeneous stripe. This is in contrast to subcluster-based designs that are all-or-nothing.

5.2 The Eclectic Stripe Manager

The Eclectic Stripe Manager (ESManager) handles construction, maintenance and reorganization of eclectic stripes.

Constructing eclectic stripes In the absence of an existing eclectic volume that has space (described later in §4.3), the ESAllocator asks the existing data placement policy for disks to store each new eclectic stripe. Since that placement policy is unaware of disk-adaptive redundancy, it may return a set of disks whose AFRs produce an MTTDL that either fails to meet or far exceeds the target MTTDL. Algorithm 1 describes the process to build a space-efficient, yet adequately reliable eclectic stripe.

To give itself flexibility, ESAllocator asks the placement policy to provide a set of disks for the maximum-width-allowed stripe (e.g., 33 for 30-of-33). The ESAllocator then queries the ESMTTDLEngine with the provided disks and its planned scheme to get the MTTDL value. If the MTTDL does not meet the target MTTDL, ESAllocator discards a disk from the set and increases the redundancy of the corresponding scheme (e.g., 29-of-32 instead of 30-of-33) to boost the stripe's MTTDL, repeating this process until sufficient MTTDL is achieved. This process is guaranteed to terminate, since the least space-efficient scheme in a storage cluster must meet the target MTTDL. Moreover, by iterating from the most space-efficient scheme allowed, the algorithm terminates at the most space-efficient scheme for the provided disks.

Algorithm 1

$\theta_{\text{MTTDL}} \leftarrow$ target MTTDL
$n_{\max} \leftarrow max\{n \mid (n,k) \in \text{schemes}\}$
$(d_1,\ldots,d_{n_{\max}}) \leftarrow n_{\max}$ randomly sampled devices
for $(n,k) \in$ schemes in order of increasing n/k **do**
  if $\text{MTTDL}(n,k,(d_1,\ldots,d_n)) \geq \theta_{\text{MTTDL}}$ **then return** (n,k)

Ensuring reliability amid disk failures. The reliability of each eclectic stripe is a function of the AFRs on the disks on which it is stored. So, when a disk fails, the reconstructed data cannot simply be placed on a randomly chosen disk, since its AFR might be high enough to cause the eclectic stripe's MTTDL to exceed the target. Recall, from §4.2, that the critical AFR of an EC scheme is the highest AFR that a homogeneous stripe of that scheme can reliably support, and a simple way to test that an eclectic stripe is safe is to check that its average AFR is below the critical AFR for its EC scheme. Therefore, we can ensure that reliability will be preserved if we choose a disk that keeps the average AFR of the affected stripes under their respective critical AFRs.

When a disk in Tiger fails, the EVManager is notified. This triggers a lookup in the EVDirectory for eclectic stripes whose chunks need to be reconstructed. The EVManager forwards the list of chunks to the ESReorganizer. For each stripe, the ESReorganizer asks the ESAllocator for disks to replace the failed disks, providing the critical AFR for the stripe. The ESAllocator returns suitable disks, if they are found, otherwise, it allocates (one or more) new eclectic stripes and moves the prior stripe's data (including any reconstructed data) to the new stripes. Finding sufficiently reliable disks to store the reconstructed data results in lower transition IO than allocating new eclectic stripes, since the latter involves moving data of disks that did not fail. After the reconstruction process (whether or not new eclectic stripes are formed), ESReorganizer informs the EVManager of the changes, which then updates the EVDirectory accordingly.

Dealing with AFR changes over time A disk's AFR is not constant throughout its lifetime [9, 10, 23, 56]. In addition to building and maintaining eclectic stripes, ESManager must also ensure that data is kept safe when a disk's AFR changes.

Ensuring data reliability with increasing AFRs. The EVManager monitors AFR by querying the change point detector.

[*]Tiger reuses the Ruptures change-point detection library [47, 48], the AFR curve-learner and the rate-limiter from HeART [25] and Pacemaker [24].

Whenever the AFR rises, the EVManager identifies any eclectic volumes whose data is at a risk of becoming under-reliable. It alerts the ESReorganizer, with the necessary stripe metadata of such stripes, which calls the ESAllocator with the current and previous disk AFR values and the number of chunks that need reallocation onto safer disks.

As with failed data reconstruction, ESAllocator prefers finding suitable disk alternates whose AFRs are less than or equal to previous AFRs values of the disks whose AFRs rose. If ESAllocator cannot find suitable disks, new eclectic stripes are formed and data is moved, as described previously.

Reducing data over-protection with reducing AFRs. When a disk's AFR decreases, there is no reliability threat to the data stored on that disk, but there may be an opportunity to reduce redundancy and obtain space-savings.

The simplest way (that also entails no transition IO cost) of reducing a stripe's redundancy is by deleting excess parities[*]. However, deleting parities is rarely an option for two reasons. First, most storage clusters have a minimum requirement on the number of parities per stripe, set by the system administrator. Second, adding/deleting a parity has a much higher impact on the MTTDL value of a stripe than adding/deleting a data chunk— deleting even a single parity usually makes the stripe miss the target MTTDL. When ESReorganizer receives metadata of possibly over-redundant stripes from the EVManager, it queries the ESMTTDLEngine whether reducing parities is feasible and, if so, enacts the change.

When deleting parities is not an option, there are two additional ways redundancy can be reduced. First, the ESAllocator could find candidate disks with AFR higher than the current disk's AFR, but low enough that the mean AFR is below the stripe's critical AFR. This method is cost-effective, since it involves only reading and writing those chunks that are on over-protected disks. Second, if the ESAllocator cannot find suitable disks, it performs new stripe allocations if it can find a new eclectic stripe with lower storage overhead. Although re-allocation has a high IO overhead (since it involves copying data over to the new stripe), it is not urgent when lowering redundancy and can be throttled by the rate limiter without putting any data at risk.

The eclectic stripe reorganizer (ESReorganizer). The ESReorganizer uses several techniques to ensure adequate reliability and provide maximum space-savings.

At any given time, the ESReorganizer might be dealing with multiple eclectic stripes seeking possible changes. ESReorganizer processes requests in priority of maintaining reliability: failed data reconstruction, then near-risk stripes that need to increase their redundancy, then requests of decommissioning disks to move data off of them, and then stripes seeking a redundancy reduction. It processes eclectic stripes that are requesting reduction in redundancy in descending order of their storage overhead.

[*]Deleting parities may not work reducing redundancy of non-MDS codes.

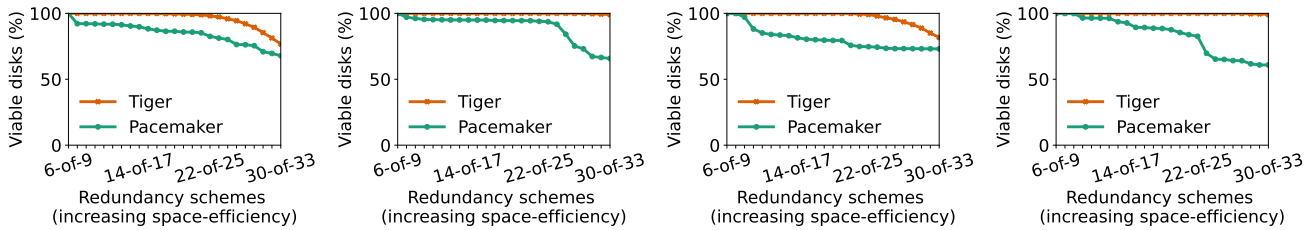
5.3 The Eclectic Volume Manager

The EVManager is responsible for creating, maintaining and monitoring the health of eclectic volumes. Recall (from §4.3) that an eclectic volume (typically in TBs) contains hundreds-of-thousands of eclectic stripes (typically in MBs). Along with health, the EVManager maintains usage statistics (e.g., freespace and load) for each eclectic volume.

Constructing and populating eclectic volumes. Similar to how ESManager manages eclectic stripes, EVManager dynamically creates and destroys eclectic volumes. The construction of the first eclectic stripe forces the creation of the first eclectic volume on the same set of disks that are chosen by the ESAllocator. When creating subsequent eclectic stripes, the ESAllocator first queries the EVManager to check if there are eclectic volumes that are conducive for storing new stripes. The EVManager does this by maintaining capacity and load-balancing metrics for each eclectic volume. Thus, the EVManager also avoids hot-spotting within eclectic volumes by spreading hot data evenly across multiple eclectic volumes. Once the target eclectic volume is identified, the set of disks comprising the eclectic volume are returned to the ESAllocator. If there is no space available, the ESAllocator gets a new set of disks from the placement policy which causes EVManager to create a new eclectic volume atop those disks. Tiger's eclectic volumes operate similar to Ceph's placement groups [51].

The Eclectic Volume Directory. Recall from §4.3 that eclectic volumes are simply a logical grouping of all the eclectic stripes with the same redundancy scheme on the same set of disks. Each eclectic volume has a unique entry in the EVDirectory and stored against the eclectic volume ID are the disks on which the eclectic volume is stored. In addition, the EVDirectory also contains a mapping from disk serial number to list of volume IDs whose fragments are stored on that disk. Note that the size of this metadata is very small. With TB-sized volume fragments, even a 100K disk storage cluster with 20TB disks will have an EVDirectory less than 100MB.

The tiny size of the EVDirectory also implies that it is unlikely to be a bottleneck. The EVDirectory will typically be queried and updated whenever disks fail, or their AFR increases significantly (in order to fetch the eclectic volumes IDs stored on the affected disks). It might also be queried to fulfill an allocation request in order to get the disks on which an eclectic volume is stored, if the eclectic-volume-to-disks mapping is not cached. Even a cluster with 500K disks has at most a few hundred disk failures in a day and typically not more than 10 makes/models, thus limiting the EVDirectory updates to less than 1000 per day. Although allocations are more frequent, caching can filter most queries for them, and their rate is also much lower than the rate of file metadata lookups in a cluster with billions of files. And, if necessary, traditional metadata scaling techniques can be employed to prevent EVDirectory from becoming a bottleneck.



(a) Backblaze **(b)** Google Cluster 1 **(c)** Google Cluster 2 **(d)** Google Cluster 3

Figure 7: Placement constraints posed by Tiger compared to Pacemaker by observing the percentage of the disk fleet that is viable for the different redundancy schemes. Tiger has lower placement constraints than Pacemaker. Tiger has over >75% disks being viable for all four clusters for all scheme configurations. Pacemaker's placement constraints are more pronounced in Google clusters since they are mostly step-deployed. This results in strict Rgroup boundaries disallowing disks from different makes/models being a part of the same Rgroup.

Reacting to failures and AFR changes. The EVHInspector continuously polls the change point detector and the cluster metadata service to gather information about disk failures and significant AFR changes. For all significant changes, the EVHInspector reconfirms the MTTDL of the affected volumes by querying the ESMTTDLEngine with the changed AFRs. Even though it is technically not a stripe, a EVDirectory has all information required to calculate the reliability of an eclectic volume, viz. the AFRs of the disks on which the volume resides, and the redundancy scheme configuration. Due to its small metadata footprint, EVHInspector can check the health of billions of stripes by checking the reliability of only thousands of eclectic volumes.

Whenever a disk fails, or a disk's AFR increases, the EVHInspector looks up the EVDirectory to find the volumes affected due to this failure / AFR rise. If the disk in question is alive, the volume manager queries the disk to obtain the stripe IDs belonging to that volume ID. If the disk has failed, the EVHInspector queries other disks of that particular eclectic volume and gathers the stripe IDs from them. Note that all disks storing a particular eclectic volume have the same list of eclectic stripe IDs in common (but they also each may have other stripes as well from non-overlapping eclectic volumes).

The EVHInspector then forwards the list of stripe IDs to the ESReorganizer along with the updated and previous AFR information and the action to be taken (reconstruct data, increase redundancy or reduce redundancy). On performing the appropriate task, the ESReorganizer communicates the metadata changes back to the EVManager, and the EVManager subsequently reflects it in the EVDirectory. For reconstruction and increase in redundancy, if a replacement disk is found, and has enough capacity to accommodate all chunks of the failed disk / disks whose AFR has increased, the eclectic volume of all constituting eclectic stripes after the operation remains the same. For redundancy reductions, or in case of not finding a replacement disk, or not finding one with enough capacity, the eclectic stripes depart from their original eclectic volume (unlike Ceph's placement groups) since they will now be stored on potentially different subset of disks.

6 Evaluation of Tiger

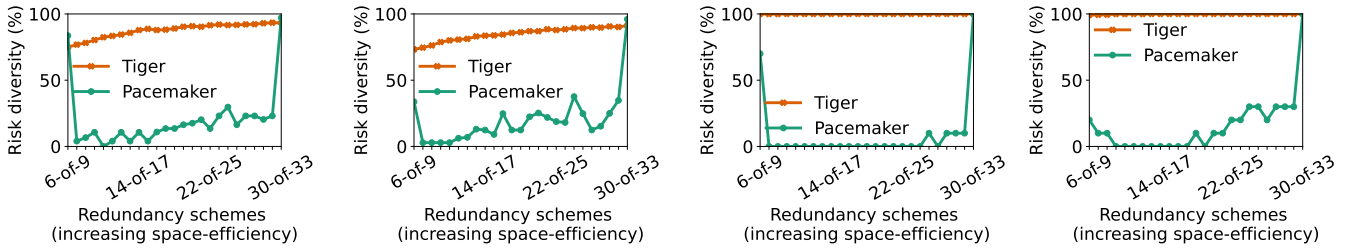
We now evaluate how Tiger performs on real-world data, and show how it fulfills the challenges laid out in §3. Tiger is evaluated using real-world deployment and failure logs from four production clusters at two different organizations (Google and Backblaze). Each cluster has a multi-year lifetime and disks from multiple makes/models/batches. Backblaze uses *trickle*-deployed disks. These disks are added to the cluster every few days in the tens or hundreds. Google Cluster 2 and Cluster 3 have *step*-deployed makes/models where disks are introduced into the cluster in large batches of tens-of-thousands of disks within a very short span of time. Google Cluster 1 is a mix of step- and trickle-deployed disks.

The highlights of our evaluation are (1) Tiger significantly lowers placement restrictions posed by Pacemaker (existing state-of-the-art disk-adaptive redundancy system); (2) Tiger's eclectic stripes provide much higher risk-diversity compared to Pacemaker; (3) Tiger is closer to the target MTTDL, and thus more efficient than existing disk-adaptive redundancy approaches; (4) Tiger outperforms Pacemaker in space-savings while keeping the average transition IO $<= 0.5\%$ and peak transition IO $< 5\%$ of cluster IO bandwidth and (5) Tiger's eclectic stripes are less sensitive to rising AFR and provide better data safety.

6.1 Tiger enables flexible data placement

We capture the flexibility in data placement by measuring the percentage of the disk fleet that is considered viable for storing data using a particular redundancy scheme. The viability is decided by whether the data stored on those disks will meet the target MTTDL. The X-axis in Fig. 7a shows the various schemes that can be supported in each storage cluster[*]. For estimating Tiger's viable disk candidates, we perform a Monte-Carlo simulation on specific days in each

[*]The narrowest scheme is set to 6-of-9 and widest is set to 30-of-33. Schemes with higher width have lower redundancy since the number of parities are kept the same. This is based on reference to prior work [24, 25], and also on the basis of communication with storage administrators of large-scale cluster storage systems at various organizations.



(a) Backblaze risk-diversity **(b)** Google Cluster 1 risk-diversity **(c)** Google Cluster 2 risk-diversity **(d)** Google Cluster 3 risk-diversity

Figure 8: Risk-diversity achieved by Tiger over three large-scale cluster storage systems. All three plots are average risk-diversity measurements taken over 5 days spread equally over the lifetime of the clusters. Pacemaker due its Rgroup based design has much lower risk-diversity compared to Tiger, more evident in Fig. 8c and 8d which are entirely step-deployed clusters.

of the cluster's lifetime. We allocate 1000 eclectic stripes by picking disks uniformly at random and check how many of the possible schemes can use the chosen disks. For Pacemaker, we bin the disks by AFRs to mimic Rgroups and measure the ratio of the population of the Rgroups to the entire disk fleet.

Tiger has almost all disks available for allocation for any scheme in Google Clusters 1 and 3 (Figs. 7b, 7d), whereas in Backblaze and Google Cluster 2 (Figs. 7a, 7c) at most 25% disks are deemed not viable for the widest schemes (beyond 22-of-25). When a large fraction of disks of the cluster have a high AFR (as is the case with Backblaze and Google Cluster 2 for the chosen dates), formation of eclectic stripes ends up with mostly high AFR disks. In such situations, Tiger cannot employ a very space-efficient redundancy scheme. Pacemaker's strict Rgroup boundaries, on the other hand, limit all disks in an Rgroup to a single scheme that may not be very wide. Therefore, for Pacemaker, all clusters see a significant drop in viable disks as the width increases.

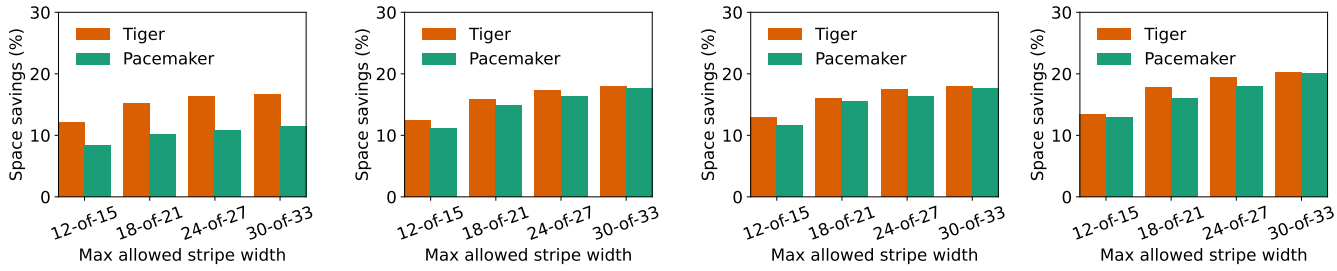
6.2 Tiger achieves high risk-diversity

Risk-diversity of a stripe is directly proportional to the number of unique makes/models participating in that stripe. If all makes/models in the storage cluster have representation in the stripe, its risk-diversity is defined to be 100%. A 0% risk-diversity implies that there were no disks in the cluster that could be used for the particular scheme. The setup used for evaluating risk-diversity is a Monte-Carlo simulation, where 100 stripes were allocated for each scheme configuration by choosing disks uniformly at random. For Tiger, we measure risk-diversity by capturing the average number of unique disk makes/models on which the chunks of an eclectic stripe are stored for each stripe configuration. For Pacemaker, we again bin the disks by AFR to form Rgroups, and count the unique number of makes/models within each Rgroup. We take the average of this simulation performed on five equally spaced days in the cluster lifetime to get an overall sense of risk-diversity of both systems.

Tiger significantly outperforms Pacemaker in providing high risk-diversity. Fig. 8 captures the risk-diversity achieved by Tiger vs Pacemaker. Since Tiger has no partitioning of disks, all disks of any make/model are viable for allocating any scheme. The minimum risk-diversity achieved by Tiger is 60% across all four clusters, that too for the narrowest scheme (6-of-9) for Backblaze (Fig. 8a) and Google Cluster 1 (Fig. 8b) clusters. Both these clusters have seven makes/models, and it is unlikely that seven out of nine chunks will be across different makes/models. As the stripe width increases, Tiger's risk-diversity also improves. Entirely step-deployed clusters, Google Cluster 2 (Fig. 8c) and Google Cluster 3 (Fig. 8d) have four and three makes/models respectively. Tiger achieves perfect risk-diversity for all possible schemes in those clusters. For Pacemaker, it is more likely that clusters where all makes/models are trickle-deployed will have a better risk-diversity because multiple makes/models can be a part of the same Rgroup so long as their AFRs are in the same range, for e.g. Backblaze (Fig. 8a). Nevertheless, even clusters with all trickle-deployed disks do not see perfect (or even good) risk-diversity since different makes/models are deployed at different times, and they go through different phases of life at different dates. Risk-diversity is poorer for Pacemaker in clusters with step-deployed makes /models as seen in Figs. 8c and 8d. This is because Rgroups and steps have a 1:1 mapping and each step only contains disks of a single make/model. The reason Pacemaker has 100% risk-diversity for 30-of-33 is because when averaging over multiple days (5 for this experiment), all makes/models on some date belonged to an Rgroup with the 30-of-33 redundancy scheme.

6.3 Tiger adapts redundancy efficiently

The efficacy of disk-adaptive redundancy performed by Tiger is evaluated using three metrics. First, we discuss the MTTDL distribution of data stored using Tiger. Subsequently, using the same four clusters used by Pacemaker we evaluate the resulting space-savings obtained by Tiger because of disk-adaptive redundancy, and finally we measure the IO overhead needed to perform necessary redundancy transitions. For fair comparison, when evaluating Tiger, we employ the same configurations (such as the IO constraints and permitted redundancy schemes) and tools (such as the AFR curve learner and the change-point detector) that are used in Pacemaker.



(a) Backblaze space-savings **(b)** Google Cluster 1 space-savings **(c)** Google Cluster 2 space-savings **(d)** Google Cluster 3 space-savings

Figure 9: Space-savings achieved by Tiger for disk-adaptive redundancy simulated on four production clusters compared to Pacemaker over conventional one-scheme-fits-all redundancy approaches. Figs. 9a–9d show that across all clusters with different maximum stripe width configurations, Tiger provides up to 5% higher average space-savings compared to Pacemaker.

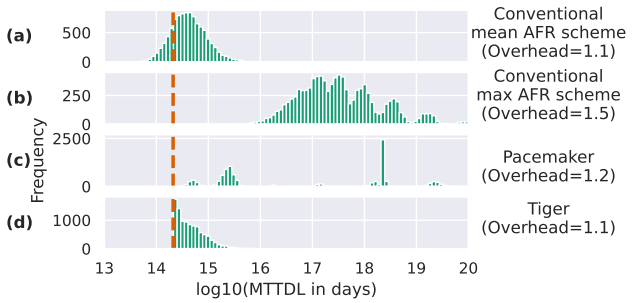


Figure 10: Comparison of MTTDL distributions for different approaches. We form 10000 random stripes for each approach using the AFRs from Google Cluster 1 (notice the different scales in the Y-axis). In a conventional system, a single scheme is chosen for all stripes based on the average AFR (*a*) or maximum AFR (*b*). (*c*) In Pacemaker, stripes must reside within an Rgroup, and the scheme depends on the Rgroup. (*d*) In Tiger, the scheme for each stripe is chosen based on the AFRs in the stripe. The dashed vertical line denotes the target MTTDL.

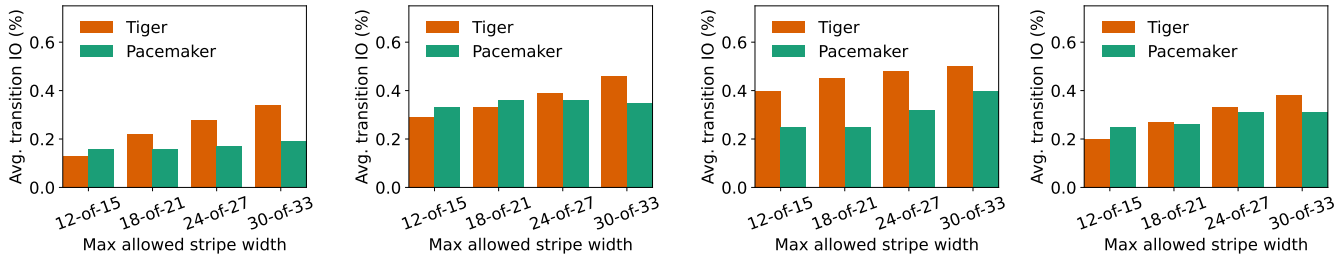
Tiger's achieves tight reliability. Storage clusters have to ensure that all data in the cluster always meets a specified target level of reliability typically specified as a MTTDL value. Tiger's target MTTDL is set as the lowest acceptable MTTDL in the system. This is calculated using the MTTDL of the most conservative homogeneous stripe possible (6-of-9) having the maximum possible AFR (16%). These settings are borrowed from Pacemaker's evaluation for a fair comparison with Tiger.

Fig. 10 shows a comparison in the distribution of stripe MTTDL with different approaches to redundancy selection for a specific day in Google Cluster 1. Fig. 10(a) shows conventional systems choosing the redundancy scheme based on the avg. AFR, which results in small storage overhead, but puts a big fraction of the stripes at risk. Fig. 10(b) shows conventional systems that choose the redundancy scheme on the basis of max AFR. Although all stripes are sufficiently protected, the storage overhead is the highest among all four alternatives. Fig. 10(c) shows Pacemaker where the different MTTDL clusters represent different Rgroups with different redundancy schemes. Pacemaker achieves good reduction in storage overhead, and keeps all stripes above the target MTTDL. In fact, some Rgroups (with higher MTTDL values) are too over-protected and denote lost opportunities for space-savings. Finally, Fig. 10(d) shows Tiger's MTTDL distribution. Despite all its eclectic stripes being above the MTTDL threshold, Tiger has least storage overhead.

Tiger achieves attractive space-savings. Akin to Pacemaker, by dynamically tailoring redundancy to disk AFRs, Tiger's eclectic stripes can use more space-efficient redundancy schemes to meet the required MTTDL target. Fig. 9 shows that Tiger achieves equal or better average space-savings compared to Pacemaker in all four clusters. For Google Clusters 1, 2 and 3 (Figs. 9b, 9c, 9d), the highly cost-efficient redundancy transitions of Pacemaker allows a large step-deployed make/model to spend more time in lower redundancy. This boosts Pacemaker's overall space-savings for these clusters and prevents Tiger from surpassing it easily.

In the Backblaze cluster (Figs. 9a), the reason for Tiger achieving better space-savings is because eclectic stripes allow high AFR disks to be mixed with low AFR disks and yet use an optimized redundancy scheme. In Pacemaker, high AFR disks cannot be mixed with other disks, resulting in lower space-savings. In the Backblaze cluster, all the seven makes/models are trickle-deployed. This results in a non-trivial fraction of disks constantly being in high-AFR regimes of infancy or wearout. While Pacemaker is forced to use the default, most conservative redundancy scheme on these disks, Tiger can use these disks for more space-efficient redundancy schemes by combining them with other, more robust disks. As a result, Tiger is able to achieve up to 5% higher space-savings compared to Pacemaker.

Tiger has very low IO overhead. Fig. 11 shows the IO overhead comparison between Pacemaker and Tiger. Although both systems are capped at 5% and in general require very low IO (compared to background tasks such as scrubbing that requires $\approx 7\%$ [5]), our evaluation shows that Tiger can achieve all its benefits with an average IO bandwidth required for redundancy transitions of at most 0.5%. In an absolute sense, Tiger's low IO overhead is mainly attributed to Tiger's efficient redundancy transitions for an AFR rise (detailed in §5.2), where Tiger moves the potentially risky chunk from



(a) Backblaze IO overhead **(b)** Google Cluster 1 IO overhead **(c)** Google Cluster 2 IO overhead **(d)** Google Cluster 3 IO overhead

Figure 11: IO overhead of redundancy scheme transitions of Tiger versus Pacemaker. In most configurations, Tiger has a higher IO overhead compared to Pacemaker due to Pacemaker leveraging its IO-efficient transitioning mechanisms. Despite being higher, the average IO overhead of Tiger is still at most 0.5% of the overall cluster's IO bandwidth; much lower than existing background tasks such as scrubbing, that require approximately 7% IO bandwidth [5]

an unsafe disk to a safe disk rather than re-encoding it or reallocating it; both having a significantly higher IO cost.

Compared to Pacemaker, Tiger still incurs slightly higher IO overhead. This is due to Tiger's mechanism of coalescing space-inefficient (high-redundancy) eclectic stripes into new space-efficient (low-redundancy) eclectic stripes in response to AFR reduction by moving all chunks. It leads to more data movement compared to moving just the chunks of the high-AFR disks (as is the case when AFR rises). This is a conscious design choice made in Tiger in order to maximize space-savings for non-urgent redundancy transitions at the expense of a minor increase in the IO overhead. Moreover, Pacemaker's IO-efficient redundancy transitioning mechanisms (that are more suitable for its Rgroup-based design) further help in reducing its IO overhead.

Tiger does not experience urgent IO bursts. In order to understand the burstiness of the IO that can be experienced by Tiger compared to Pacemaker, we artificially increase the AFR of a make/model and measure the resulting transition IO load for maintaining data reliability. Fig. 12 shows the comparison of IO loads experienced by Pacemaker vs Tiger for three instances of increasing AFR of a single step-deployed make/model. Performed on three different dates in two Google clusters (Cluster 1 and Cluster 2), we observe that Pacemaker needs orders of magnitude higher IO bandwidth than Tiger to achieve the required transitions. In fact for Google Cluster 2, in both instances none of Tiger's stripes needed transitioning despite observing a 1% rise in AFR.

We explain Pacemaker's high IO requirement with an example. Suppose a 20TB disk, which can perform 100MB/s needs to transition away from using a 30-of-33 scheme. Despite using Pacemaker's optimized Type 2 transitions*, simply reading the data to recalculate new parities would require 196% of the disk's possible IO bandwidth in a day (assuming 90% fullness to match Pacemaker's setup). In a step-deployed make/model all disks of an Rgroup transition together. In order to spread out the resulting IO burst over time, Pacemaker relies on predicting the AFR rise well in advance. To maintain a 5% IO cap, Pacemaker would need to know the AFR rise at least 40 days in advance. Long-term AFR predictions are both non-robust and non-trivial.

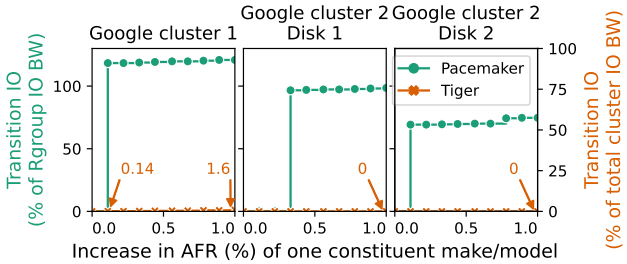


Figure 12: IO cost of redundancy transitions associated with the increase of AFR for one constituent make/model. IO cost is measured as a percentage of the total IO bandwidth of the Rgroup for Pacemaker, whereas it is the total cluster IO bandwidth for Tiger. It is calculated by scaling up a simulation of 1000 random stripes in each system and measuring the number of stripes that become unsafe after the given increase in AFR.

In contrast, Tiger for the same transition does not suffer from any IO bursts. Firstly, because of eclectic stripes, even if the disk AFR increases, only a limited fraction of data stored on it will need a redundancy transition, since other stripes might be residing on more robust disks and might continue to meet the target MTTDL. Secondly, other disks over which the eclectic stripes needing an increase in redundancy are spread need not (and probably will not) belong to the same make/model/batch. Therefore, they will not require a simultaneous increase in redundancy and can assist in transitioning data from the affected stripes. Thus disks in Tiger are spared from any sudden IO bursts.

6.4 Challenging situations for Tiger

There are certain situations that create fundamental challenges for Tiger and other disk-adaptive redundancy systems.

Sudden rise in AFRs mimicking bulk failures. Although

*In Type 2 transitions, Pacemaker re-encodes data from one scheme to another without re-writing any data. It simply recalculates new parities, writes them and deletes the old ones.

Fig. 12 shows that Tiger is robust to AFR rises in any make/model in a cluster, there could be bulk failure scenarios where large fraction of the disks in the cluster fail together. On such occasions, any system (including Tiger) that depends on redundancy will suffer from potential data loss unless the system includes cross-cluster redundancy.

A cluster with a single step-deployed make/model. Suppose a cluster had only one make/model, deployed in a step-deployed manner (note: we have not come across such an example for the large clusters targeted): there would be no diversity to exploit and all disks of the cluster would undergo redundancy transitions together. Not only would this produce bursty IO, but also will potentially result in a capacity crunch (when increasing redundancy). Such clusters would either need to keep some space unutilized to account for the bulk redundancy-increasing transitions, or will need to make provisions to add more disks to the cluster before the redundancy-increasing transitions are issued.

7 Additional Related Work

The closest related works, HeART and Pacemaker, are discussed in §2 together with other background. Additional related works can be divided into works that study the reliability of disks and distributed storage, and systems that manage multiple EC schemes and transitions between them. One essential part of disk-adaptive redundancy is the monitoring of disk AFRs, which are used by Tiger to assess the reliability of stripes. Many works have studied the behavior of disk AFRs and their impact on distributed storage reliability [5, 8, 18, 22, 26, 34, 35, 41–44]. Also, multiple works have studied the prediction of disk AFRs based on different features [1, 17, 27, 32, 45, 49, 59].

Many existing distributed storage systems allow for multiple EC schemes to coexist in the same cluster [11, 14]. There are systems that propose choosing different EC schemes for different data [46, 55]. The problem of transitioning data from one EC scheme to another has been widely studied in the Coding Theory literature, with many works studying its cost, as well as proposing special code designs that reduce the cost of transitions [20, 28–31, 36, 38, 39, 53–55, 57, 60]. Such designs could be used with Tiger, though our evaluations indicate that transition IO is not a significant problem.

8 Conclusion

Tiger enables disk-adaptive redundancy without the placement restrictions and associated problems that plague prior designs. Tiger's eclectic stripes tailor redundancy to whichever disks are chosen for each stripe. Our evaluations indicate that it reduces risk in two major ways: by increasing disk-type diversity in stripes and by reducing burstiness of transition IO urgency. Taken together, Tiger makes disk-adaptive redundancy practical for adoption in real storage clusters.

9 Acknowledgements

We thank our shepherd Gala Yadgar and the anonymous reviewers for their valuable feedback and suggestions. We extend special thanks to Larry Greenfield and numerous other researchers and engineers at Google. This research is supported in part by NSF grants CNS1956271 and CNS1901410. A Derivation of approximation of MTTDL of eclectic stripes

In order to approximate the MTTDL of an eclectic stripe, we will assume that the stripe can be repaired in the data loss state and we will approximate the MTTDL as the mean time between visits to the data loss state. In particular, we will analyze the stripe as an alternating renewal process. Let A_s be the stripe availability (i.e., the fraction of the time that the stripe is not in the data loss state), μ_s be the repair rate in the data loss state, and λ_s the stripe data loss rate. As described above, the MTTDL is approximately λ_s^{-1}. For an alternating renewal process, we have that:

$$A_s = \frac{\mu_s}{\mu_s + \lambda_s} \iff \frac{1}{\lambda_s} = \frac{A_s}{\mu_s(1-A_s)} \tag{2}$$

The repair rate in the data loss state is simply the number of failed disks in that state:

$$\mu_s = (n-k+1)\mu. \tag{3}$$

We assume that each disk in the stripe fails independently from the rest, and that it is repaired with rate μ if it fails. Then, in steady state, disk i is available with probability:

$$A_i = \frac{\mu}{\mu+\lambda_i}. \tag{4}$$

Let $P(j)$ be the probability that we find the stripe in a state where exactly j disks are available in the stripe. Since there are no states with more than $n-k+1$ failed disks, we have that:

$$P(j) = \frac{Q(j)}{Q(k-1)+\cdots+Q(n)}, \text{for } k-1 \le j \le n, \tag{5}$$

where $Q(j)$ is the probability that exactly j disks are available. Since disks are independent, $Q(j)$ is equal to a Poisson-binomial distribution, with probabilities $(A_i)_{i=1}^n$. Given this,

the availability of stripe is given by:

$$A_s = P(k) + \cdots + P(n). \tag{6}$$

Thus, we have:

$$\frac{1}{\lambda_s} = \frac{Q(k) + \cdots + Q(n)}{\mu(n-k+1)Q(k-1)} \approx \frac{1}{\mu(n-k+1)Q(k-1)}. \tag{7}$$

Where the approximation comes from the fact that $Q(n) \approx 1$ because $\mu \gg \max_i \lambda_i$ and thus all A_i are close to 1.

In summary, we have that:

$$\text{MTTDL} \approx \frac{1}{\mu(n-k+1)Q(k-1)}. \tag{8}$$

zIO: Accelerating IO-Intensive Applications with Transparent Zero-Copy IO

Tim Stamler[1] Deukyeon Hwang[1] Amanda Raybuck[1] Wei Zhang[2] Simon Peter[3]
[1]UT Austin [2]Microsoft [3]University of Washington

Abstract

We present zIO, a transparent zero-copy IO mechanism for unmodified IO-intensive applications. zIO tracks IO data through the application, eliminating copies that are unnecessary while maintaining data consistency.

Applications often modify only a part of the data they process. zIO leverages this insight and interposes on IO stack and standard library memory copy calls to track IO data and eliminate unnecessary copies. Instead, intermediate data locations are unmapped, allowing zIO to intercept and resolve any access via page faults to maintain data consistency. To avoid harming application performance in situations where data tracking overhead is high, zIO's tracking policy decides on a per IO basis when to eliminate copies. Further, we demonstrate how to use zIO to achieve *optimistic network receiver persistence* for applications storing data from the network in non-volatile memory (NVM). By mapping socket receive buffers in NVM and leveraging kernel-bypass IO, we can rely on zIO to transparently eliminate all copies from the network, through the application, to storage.

We implement zIO as a user-space library. On top of kernel IO stacks, zIO eliminates application-level IO copies. We also integrate zIO with kernel-bypass IO stacks, where it can additionally eliminate copies incurred by the IO stack APIs and enable optimistic network receiver persistence. We evaluate zIO with IO-intensive applications, such as Redis, Icecast, and MongoDB. zIO improves application throughput by up to 1.8× with Linux and by up to 2.5× with kernel-bypass IO stacks and optimistic network receiver persistence. Compared to common uses of zero-copy IO stack APIs, such as memory mapped files, zIO can improve performance by up to 17% due to reduced TLB shootdown overhead.

1 Introduction

Zero-copy IO has been a long-standing performance goal. Copies introduce memory and CPU overhead, limiting the performance of IO-intensive applications. IO data copies are performed within IO stacks, by their application programming interfaces (APIs), and within applications. Existing work has focused on eliminating copies within IO stacks [27, 28] and within IO stack APIs by developing zero-copy IO APIs [1, 11, 12, 15, 17, 28, 32], including some that strive for transparency [8, 9, 22].

Despite these advances, data from IO is still copied. We find that IO-intensive applications perform up to 8 copies of request data for each IO request (cf. §2.1). Many of these copies occur among subsystems within the applications themselves (*application copies*). Only a fraction is performed at the IO stack API (*IO copies*—for example, many standard POSIX socket and file IO system calls copy data between system and user-provided buffers).

A reason for the continued adoption of copies is that they simplify development. Copies are used as a robust mechanism to pass ownership of data among independent subsystems. A data buffer local to a subsystem cannot be touched by a caller of the subsystem, allowing for subsystem-internal use of the data without worry of corruption or deallocation of the memory backing the data from the outside. For example, copies are used to simplify asynchronous IO. POSIX allows kernel IO stacks to provide internal buffers to IO devices that operate asynchronously. Applications request and copy IO data into user-space buffers, allowing applications synchronous processing of a single buffer at a time, while the IO stack recycles its internal buffers for further asynchronous IO. Finally, applications use copies to simplify data handling, for example to perform alignment, padding, serialization and deserialization, as well as bucketization (cf. §2.2).

Unfortunately, copying is an imperfect tool. While copies provide the aforementioned benefits, they also introduce overhead. Using the Redis [21] key-value store as an example IO-intensive application, we study the overhead of copies for IO, both using Linux kernel IO stacks (§2.2) and using kernel-bypass IO stacks for high-bandwidth IO devices (§2.3). IO copying overhead scales with the amount of copied IO data. As IO devices, in particular for storage and networking, increase bandwidth, copies become the performance-limiting factor in IO-intensive applications [7].

The question we ask is: can we attain the benefits of simple development offered by copying, while alleviating its increasing overheads? As we have seen, application developers opt for copies regardless of the availability of zero-copy IO APIs. We find that zero-copy APIs require application modification, increase code complexity, and are not widely supported (§2.4). Hence, we strive for a solution that allows application developers the freedom to program with copies and to use any IO API, while *transparently* eliminating copies where it makes sense, without requiring application modification.

We present zIO, a transparent zero-copy IO mechanism for IO-intensive applications. IO-intensive applications act between IO stacks, examining and potentially transforming input data before output. zIO tracks data that is read by applications from IO stacks to its final destination (typically another

IO stack, but the data may also be held in memory). In the process, zIO eliminates copies that are unnecessary while maintaining consistency for data that the application accesses. By tracking data and eliminating copies, zIO minimizes the overhead incurred by copies, improving application performance.

zIO works under the assumption that IO-intensive applications often touch only a part of the data they process. Untouched data may remain in its original place, while touched data continues to be copied. However, the challenge is that we do not know a priori what data will be touched. zIO optimistically assumes that most data will remain untouched and, by interposing on IO system calls and C standard library calls like memcpy and memmove, eliminates copies, instead simply marking the target memory area as *intermediate*. zIO can do so transitively for entire copy chains. To maintain consistency, each target area remains unmapped. If the application attempts to touch any intermediate memory area, zIO intercepts the access via a page fault. In this case, zIO performs the copy for touched pages and remaps them. Another challenge is to deal with unaligned memory areas. In this case, zIO performs the copy of unaligned sections of the area and leaves only page-aligned portions unmapped. Unaligned sections are small and copying them does not harm performance.

To avoid harming application performance due to data tracking overhead, zIO dynamically decides on a per IO basis when to track and when to copy (via its *tracking policy*). If the size of an IO buffer is smaller than 16KB, zIO copies the buffer. zIO also tracks the average number of page faults and eliminated copied bytes per buffer. If the ratio of bytes accessed to bytes eliminated from copies exceeds 6%, we impose too much overhead handling page faults to improve application performance and zIO copies the buffer instead.

In addition to eliminating application copies, we also use zIO to eliminate copies across IO stack APIs. To do so, we use kernel-bypass IO stacks in addition to zIO. Kernel-bypass stacks use shared memory to implement their APIs, allowing zIO to track IO as it arrives from the IO devices and eliminate copies, even across the IO stack API. We implement these changes in the TAS [18] network stack and the Strata [20] file system. We discuss how to apply these principles to any IO stack in (§3.4).

By leveraging non-volatile memory (NVM), we achieve a further optimization: *optimistic input persistence*. If input received from an IO stack is persisted in NVM via a storage stack by applications, optimistic input persistence enables end-to-end transparent elimination of copies through to storage. To do so without violating application data persistence requirements, we extend zIO to identify NVM mappings. Data copies to NVM may be eliminated if the original data already resides in NVM. Otherwise, a copy is necessary to enforce persistence. Using this technique, we demonstrate how to achieve *optimistic network receiver persistence* by mapping socket receive buffers in NVM and relying on zIO to transparently eliminate all copies through to the file system.

We make the following contributions:

- An analysis of copying in IO-intensive applications (§2). We study the number of copies made in popular IO-intensive applications and find that copies are common, in particular within applications themselves. We conduct a case study of copies in the Redis key-value store, analyzing when and why copies are carried out. Finally, using the Redis case study, we demonstrate that copies are a performance bottleneck for IO-intensive applications, especially when leveraging optimized kernel-bypass IO stacks.
- We present zIO, a transparent zero-copy IO system for IO-intensive applications. zIO addresses the presented overheads due to copying. We show how to use zIO to eliminate application-level copies. We show how to eliminate IO stack API copies when combining zIO with kernel-bypass IO stacks. We show how to achieve optimistic input persistence by leveraging NVM.
- We implement zIO as a user-space library. When executing on top of the Linux kernel network and storage stacks, zIO successfully eliminates application copies of IO buffers. We also integrate zIO with the kernel-bypass IO stacks TAS [18] and Strata [20], enabling it to additionally eliminate copies performed by the IO stack APIs.
- We break down zIO's performance contributions with microbenchmarks and analyze the overheads of buffer tracking. We evaluate the performance benefit to IO-intensive applications, like Redis [21], Icecast [37], and MongoDB [25] and compare to Linux and kernel-bypass IO without copy elimination, where zIO improves performance by up to 1.8× and 2.5×, respectively. We also compare zIO's performance to common uses of zero-copy IO stack APIs, such as memory mapped files, where zIO can improve performance by up to 17% due to reduced TLB shootdown overhead.

2 Background

IO-intensive applications often make several copies of IO data while processing it. We survey the prevalence of these copies in IO-intensive applications (§2.1). To learn how copies are used for IO, we study one of these applications, Redis, and investigate how it uses copies to do IO processing (§2.2). Looking forward, we investigate how copies can become a limiting factor to IO performance (§2.3). Zero-copy APIs are a potential alternative to IO copies. We study their intended use and the tradeoffs they make (§2.4).

2.1 Copies in IO-Intensive Applications

We study the prevalence of IO data copies in popular IO-intensive applications. We identify the call site of these copies and break down occurrences into copies that are involved in an IO stack API call and copies occurring within application subsystems. Our methodology involves a source code analysis of IO data flows through application subsystems from input to output. We identify what methods applications use

Application	Operation	Copy call site App	IO Stack
Redis [21]	SET	4	2
	GET	2	1
Icecast [37]	Cast to N clients	0	1 + N
Ceph [34]	Write	1	2
	Read	0	2
Anna [36]	PUT	5	3
	GET	4	3
MongoDB [25]	Insert	3	2
	Disk sync	1	1
	Read	2	2
Tensorflow-serving [26]	Inference	2	1
Nebula Graph [33]	Insert vertex	5	2
	Store a vertex	4	3

Table 1. Number and call site of copies between input and output for various application operations.

to copy IO data and how copies are affected by the executed functionality and its parameters. We find that all applications investigated use C standard library functions, such as `memcpy` and `memmove`, to copy data. We use this insight to validate our source code analysis via an execution of the relevant application operations under a debugger set to break on these C library memory copy APIs. For each application operation, we count the number of breakpoints hit on IO code paths between input and output and check that the count matches that of our source code analysis.

Table 1 presents the number of copies made at the IO stack and within various IO-intensive applications, broken down by operation. We are specifically interested in the copy of potentially large IO data, as small data copies do not significantly impact application performance. For example, the Anna [36] key-value store conducts up to 45 copies of keys during a PUT operation. We ignore these copies in the table.

While the number of copies varies among applications and operations, we can see that IO-intensive applications extensively copy IO data between input and output. We can also see that applications often make more internal copies of IO data than at the IO stack API. For example, Redis [21] makes twice as many application-internal copies than at the IO stack for a SET request. IO-intensive applications also often employ third-party libraries. For example, the Anna [36] key-value store uses gRPC [14] and Protobuf [13] to serialize and deserialize data. We observe that these libraries incur up to 3 per-IO data copies for this task, leading Anna to make up to 5 internal IO copies. This indicates that zero-copy IO APIs are only going to eliminate a fraction of the overhead due to copies. Application-internal copies, including in third-party libraries, often constitute a similar or even larger fraction of copy-induced CPU overhead.

2.2 Copy Case Study: Redis

To better understand these IO data copies, we study the Redis SET request. Redis [21] is a popular key-value store providing a rich RPC-based network API to an in-memory store, persisted via snapshots or operation logging. We configure Redis to log SET operations to study a use-case that is equally network and storage IO intensive. In our study, each SET request provides a new value, identified by a 32 byte key. We run a single-threaded Redis server instance on the evaluation platform described in Section 5. We use `redis-benchmark` [21] to attach 64 clients over a 100G network, enough to saturate the server. We configure Redis to use an append-only file to persist data without delay. This configuration provides strong crash consistency—every operation is persisted before it is acknowledged. We evaluate the number of memory copies that Redis performs per SET request and we study these copies.

#	Source	Destination	Call site
IO_1	Socket buffer	`c.socket_buf`	`readQueryFromClient`
A_1	`c.socket_buf`	`c.socket_buf`	`processInputBuffer`
A_2	`c.socket_buf`	`hash_node`	`dbAdd`
A_3	`c.socket_buf`	`c.write_to_aof`	`feedAppendOnlyFile`
A_4	`c.write_to_aof`	`aof_buf`	`flushAppendOnlyFile`
IO_2	`aof_buf`	Append-only file	`flushAppendOnlyFile`

Table 2. Copies in Redis SET request. IO_i are IO stack copies, A_j are application copies. `c` is a per-client structure.

As reported in Table 1, we find that Redis copies request data 6 times for each SET request. We list these copies and their call sites in Table 2. As we can see, Redis performs copies to read and deserialize the SET request and to store the request both in an in-memory hash table and in the append-only file. After reading a number of kilobytes from the network socket to an input buffer (copy IO_1), Redis identifies the next request within the input buffer and removes its headers from the buffer (copy A_1). If the identified SET request is admissible, Redis creates a copy of the key and value data to store in its in-memory hash table (copy A_2). Redis then reformats the request so it can be logged to its append-only file and appends the request to a per-client log (copy A_3). Redis uses per-client logs to support *group commit*—Redis can process a number of pending client requests in-memory and then persist and acknowledge these requests in a batch, eliminating storage stack overheads incurred for small IO. To do so, Redis first combines all pending per-client logs into a single log stream (copy A_4) and then writes the log stream to the append-only file (copy IO_2).

All of these copies could have been avoided. However, it would have required the Redis developers to design a complex set of coordinated, reference counted buffer descriptors that can track each request and its data in each source buffer (in this case, a network socket buffer). Reference counts provide use-after-free protection. Use-after-free [38] is an error condition where one part of an application or IO stack frees an allocated IO data buffer and re-uses it for other purposes while another part of the application or an IO device still uses the data. Use-after-free protection requires complex ownership tracking, including APIs to convey ownership transfer. Further, fine-grained memory management is required, including the ability to free fragments of a previously allocated memory

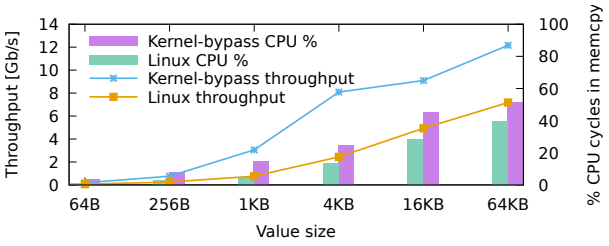

Figure 1. Redis SET throughput and fraction of CPU cycles in `memcpy` over value size, with and without kernel-bypass.

buffer. For example, the headers of incoming SET requests can be freed after each request is processed, while the keys and values remain in their original buffers for as long as they are stored in the key-value store. This creates buffer fragmentation that is difficult to resolve via memory management alone, requiring further APIs to defragment buffers over time. All of these APIs are complex and it is often impossible to support them in an application when third-party libraries or IO stacks are used that do not support the APIs.

2.3 When is IO Performance Copy-Limited?

As hardware IO bandwidth continues to increase and IO stacks become lighter-weight to keep up with increasing application demand for bandwidth, copies start to limit IO performance. In light of these trends, we investigate the performance impact of copying for Redis SET requests over increasing value sizes, while using heavy-weight in-kernel and light-weight kernel-bypass IO stacks. We use the same Redis configuration described in Section 2.2, evaluating the Linux network stack and the ext4 file system, as well as TAS [18] and Strata [20] for kernel-bypass. As we vary the value size, we measure throughput and the fraction of CPU cycles spent in data copies per request with Linux `perf`.

The results are presented in Figure 1. We can see that larger value sizes imply higher per-core throughput. Also, kernel-bypass IO improves throughput by up to 4×. This is intuitive. Kernel-bypass IO is lighter-weight than in-kernel IO, while larger IO granularity amortizes IO stack overheads. As hardware IO bandwidth continues to increase, it is likely that applications will employ larger IO sizes to leverage the available bandwidth. At the same time, IO stacks will become lighter-weight to provide the necessary performance to keep up with the increasing IO speeds.

We can also see that larger value (and thus IO) sizes cause a noticeable increase of per-request CPU cycles spent in memory copies. We already know that Redis makes 6 copies of IO data for each SET request. As value sizes increase, the amount of CPU cycles spent copying them must naturally also increase. Even moderate value sizes of 64KB cause 39% of per-request CPU cycles to be spent in memory copies using the heavy-weight Linux kernel IO stacks. The lighter-weight kernel-bypass IO causes an even larger fraction of up to 52% of per-request CPU cycles to be spent in memory copies, owing to a reduction of per-request CPU cycles spent in IO stack processing. For even larger value sizes of 512KB, CPU cycles spent in copying reaches 60%.

2.4 Limitations of Existing Zero-Copy IO APIs

Various zero-copy APIs have been proposed to limit the number of copies involved in IO-intensive applications. Zero-copy IO APIs fall into two categories. (1) Single-stack APIs, and (2) cross-stack APIs. Single-stack APIs eliminate copies for a particular IO API, such as the network sockets system call API. Cross-stack APIs eliminate copies across IO APIs. For example, across network and storage APIs. We study the tradeoffs made by each category in this section.

Single-stack APIs. Single-stack APIs provide zero-copy IO for single IO stacks. The API is specific to the IO stack and is often provided in the form of new parameters or tweaks to a familiar IO API that enable zero-copy, typically along with a set of invocation and environment requirements that have to be met by the application developer for the API to function. We describe a number of storage and networking zero-copy APIs here, including memory mapped files, Linux FreeBSD, and Solaris zero-copy networking, remote direct memory access (RDMA), and the Arrakis [28] zero-copy networking API.

Memory mapping files is one of the oldest zero-copy storage IO APIs. Applications map (parts of) files into their virtual address space, which the OS implements by loading the file into the page cache and providing direct application access to the relevant pages. Page cache entries may be directly written to disk, without further copies. More recently, applications may also map non-volatile memory (NVM) directly into virtual memory, referred to as direct access (DAX) [2]. Memory mapped files restrict some file IO. For example, memory mapped files cannot be appended to. Instead, an application developer has to determine the file size in advance and `truncate` the file to the desired length before memory mapping it. Further, the interface does not allow applications to make atomic modifications to file data without copying data to their own buffers first.

Linux provides two networking zero-copy APIs [11, 12] for TCP sockets. A zero-copy `send` will lock a given application buffer into memory and start the transmission. If transmission is not complete by the time `send` returns, the application must take care not to touch the buffer. The zero-copy mechanism will place a notification message in the error queue associated with the socket, which has to be monitored by the application. When an "error" packet appears, it can be examined to determine the status of the operation, including whether the transmission succeeded and whether it was able to run in zero-copy mode.

For zero-copy receive, Linux allows to memory map a TCP socket. If several network conditions are met, including the next incoming data chunk being page-sized and page-aligned,

the socket buffer containing the incoming chunk will be mapped into the calling process's address space, where it can be accessed directly. When the incoming data has been processed, the application calls `munmap` to release the pages and free the buffer for another incoming packet. The mechanism only works if the application developer has knowledge of exactly what each incoming packet will look like.

RDMA [30] provides zero-copy IO either by directly reading/writing remote memory or by pre-registering buffers with the network card for receive and transmit operation. Similarly, Arrakis [28] provides a zero-copy IO network socket interface that returns buffers and consumes them, rather than letting the application specify its own buffers. All of these interfaces introduce the same complexities of buffer ownership management and knowledge of network conditions. These conditions are often difficult to meet and the additional buffer management burden is cumbersome for many developers.

A limited solution proposed by SocksDirect [22] and also implemented in FreeBSD [8] and Solaris [9] to *transparently* avoid copies in the network sockets API is to simply remap the pages carrying IO data from the network stack to the application-provided buffer location, instead of copying the data. This works in cases where both buffers are page-aligned and it requires the NIC to be able to isolate packet payloads and place them into page-aligned buffers. To isolate payloads, SocksDirect requires RDMA, while Solaris requires ATM. FreeBSD supports traditional Ethernet NICs, but requires that the maximum transfer unit is configured to be greater than the hardware page size, which may be undesirable or difficult. Unfortunately, applications often misalign IO buffers, even if memory allocators return aligned memory. For example, when headers are inserted into a buffer and IO is read to a location after the header. Our investigation into Redis shows that only about 40% of IO data can be remapped using this approach. Further, transmit buffers must be kept until acknowledged, leaking memory if acknowledgments lag. The limited applicability, security concerns (including from malicious NICs [24]), and hardware requirements led the FreeBSD developers to abandon the transparent zero-copy socket API in FreeBSD 11.

Cross-stack APIs. A variety of cross-stack APIs attempt to eliminate copies across IO stacks, in particular the networking and storage stacks. To do so, they offer new and often higher-level APIs that the application developer must use. These new APIs avoid copies. We describe three example cross-stack APIs here, the Linux `sendfile` family of system calls, PASTE, and Demikernel.

The Linux `sendfile` system call (and cousins `splice` for pipes and `copy_file_range` for files) transmits data from the storage stack via the network stack without user-level copies. The API is restricted to network and storage IO and does not permit the application developer to inspect data before transmission. To add any application data, such as headers, the developer must use the `TCP_CORK` option, requiring them to add the necessary data within a 200 millisecond time window. `sendfile` does not allow sending or receiving from/to user memory. The API is used to send static files across the network but is increasingly obsolete with the prevalence of dynamic in-memory content.

PASTE [15] provides an API that combines the network stack with persistent data structures in NVM to avoid copies. PASTE builds on the Netmap [31] kernel framework to place packets from the network interface card (NIC) directly in NVM. Developers can refer to these packets from application-specific persistent data structures. However, PASTE operates at the packet level and requires developers to track network connections and decode byte streams to find relevant data to persist. PASTE also requires the developer to implement a copy-on-write scheme to efficiently return packet buffer space to the NIC after use. Due to the complexity of its API, PASTE's intended use is constrained to run-to-completion processing of requests that fit in individual network packets.

Demikernel [38] eliminates copies between kernel-bypass networking stacks, like DPDK and RDMA, and kernel-bypass storage stacks, like SPDK. The Demikernel memory manager allocates memory to applications from DPDK's memory pool and it registers that memory with RDMA. This allows Demikernel applications to receive data over the network and to store it without any copies. Demikernel offers a queue-oriented interface, PDPIX, which replaces datapath IO calls with pushes and pops to and from queues that may return tokens if data is unavailable. Demikernel's interface requires application developers to implement run-to-completion IO processing. This simplifies zero-copy IO for Demikernel, but it limits the application developer. The Demikernel interface does not support making in-place updates to IO data or allow developers to schedule input and output beyond handling each input request to completion, and it cannot eliminate any further copies an application might make internally to process input.

Summary. Both categories of zero-copy IO stacks seek to eliminate copies involved in IO stack APIs. However, in doing so they introduce complexities, such as buffer ownership management involving special API calls. They also introduce restrictions, such as requiring run-to-completion processing, buffer alignment, or disallowing in-place updates. Finally, they may enforce external IO properties, such as packet layout and MTU size. These complexities and restrictions are difficult for developers to navigate and external IO properties are often difficult or impossible to enforce. Further, **none of the existing zero-copy APIs provide transparent copy elimination across IO stacks or eliminate copies that are made within the application**. For these reasons, both application and kernel developers forgo zero-copy APIs, as they often struggle to outperform APIs that involve copies and are deemed not worth the complexity they introduce [12].

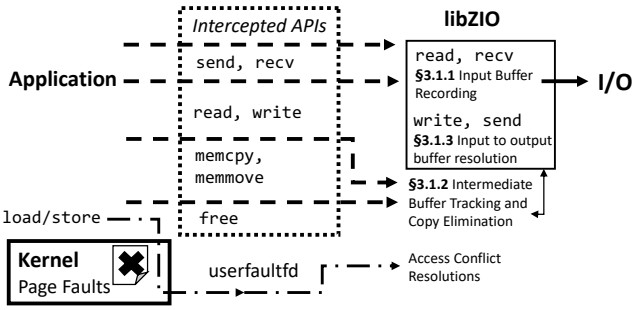

Figure 2. zIO overview.

3 zIO Design

zIO is a user-level library (libzIO) that may be dynamically and transparently linked to applications. zIO intercepts a number of C standard library and IO system calls (shown in Figure 2), including memory copy and management, and socket and file IO. zIO leverages userfaultfd [5] to intercept page faults, which may be caused by applications touching intermediate memory buffers. We now describe zIO in three parts. First, we describe how zIO tracks data within the application to eliminate *application copies* (§3.1). Second, we describe how we extend zIO with kernel-bypass IO stacks to allow it to eliminate *IO stack copies* (§3.2). Third, we describe how to realize *optimistic input persistence* by mapping appropriate IO buffers into NVM (§3.3).

3.1 Application Copy Elimination

To eliminate application copies, zIO tracks IO data buffer locations transitively through the application. zIO intercepts any copies of IO buffers and optimistically forgoes them. To provide data consistency in the face of the application accessing any intermediate, uncopied buffer locations, zIO leverages page faults to detect and resolve these accesses.

Figure 3 shows the mechanisms involved in this process via an example involving a key-value pair being read from an input IO stack, processed by the application, and written to an output IO stack. On input (e.g., IO stack `read/recv` calls), the provided location of the application buffer is recorded by zIO (①). For the purpose of application copy elimination, this is the original location of the IO data. zIO uses this information to track and eliminate any application-level copies of this data. Upon memory copy of any tracked data (`memcpy/memmove` calls), zIO unmaps the destination buffer, forgoes the copy, and tracks the destination buffer as *intermediate* (②). Some buffer locations may not be page aligned, in which case, *buffer fringes* have to be copied (`app_buf3` in Figure 3 is unaligned, causing copies in ③ and ④, where it is used as destination and source buffer, respectively). To provide consistency when applications access intermediate buffers, zIO leverages page faults. If a page fault to any intermediate buffer occurs, zIO finds the original buffer location to resolve the page fault with the appropriate data by lazily copying faulted pages (⑤). Finally, when tracked data is written to another IO stack (e.g., `send/write` calls), zIO intercepts the call and provides the original buffer instead of the application-provided intermediate buffer, but including any intermediate data updates (⑥). Before we detail each of these mechanisms, we describe zIO's tracking granularity and data structure.

Page granularity copy elimination. To be able to provide data consistency via page faults, zIO eliminates copies only at page granularity. However, buffers may reside at any address in virtual memory. To resolve this issue, zIO will only eliminate the part of a copy that lies within page boundaries of the provided buffer (i.e., unaligned buffer start addresses are rounded up to the page boundary, while unaligned buffer end addresses are rounded down)—the *core buffer*. The *left and right buffer fringe*—the beginning and end of an application buffer that is beyond the core buffer page boundaries, respectively—is always copied. While this approach involves small copies for unaligned buffers, we find that it often helps performance. The left and right buffer fringe often contain headers and footers that applications are more likely to access than the core.

Intermediate buffer tracking via skiplists. zIO records the locations of all application data buffers containing IO data. As buffer tracking has to incur minimal overhead and records are frequently mutated, we choose a skiplist for probabilistic fast search and insertion. Each entry in the skiplist keeps track of the original buffer address, a corresponding core intermediate buffer address, the length of the core intermediate buffer as a number of base pages, the size of the left intermediate buffer fringe in bytes, a timestamp of the last copy (cf. §3.1.7), and a free flag (cf. §3.1.4, not shown in Figure 3). The skiplist is sorted by intermediate buffer address. We evaluate the performance of buffer tracking via skiplists in §5.2.1.

3.1.1 Input buffer recording. When data is read from an IO stack via a function or system call, zIO intercepts these operations. We have implemented intercepts for all common POSIX network and file system calls. According to its policy (cf. §3.1.6), zIO records the application-provided destination buffer as the original buffer, along with an identity core intermediate buffer (①). This record filters IO buffers for copy tracking—zIO only eliminates copies for data originally read from an IO stack.

3.1.2 Copy tracking and elimination. zIO identifies copies within the application by interposing on the standard library memory copy calls `memcpy` and `memmove`[1]. These calls take a source and destination buffer address, as well as a size (in bytes) to copy. On each call, according to policy (cf. §3.1.6), instead of executing the copy, we record in the skiplist the core

[1]Variations of these calls use `memcpy` and `memmove` in our standard C library. For other C libraries, variations may need to be explicitly intercepted.

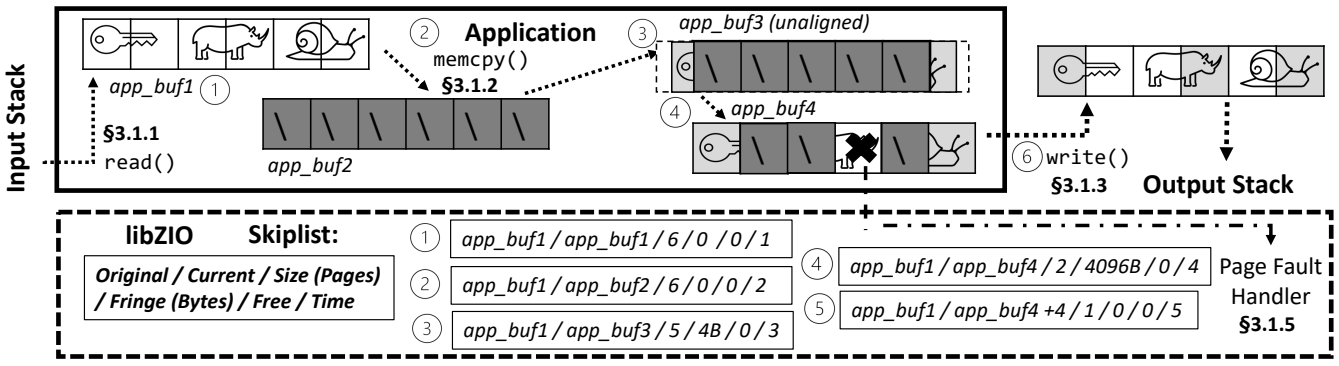

Figure 3. zIO application copy elimination example with an IO buffer spanning 6 pages. Original buffer pages are unshaded. Shaded pages are copied. Dark shaded pages are unmapped.

destination buffer and its size as intermediate location and size (e.g., ②, where `app_buf1` and `app_buf2` do not have a fringe).

To determine the original buffer location, we first use the core source buffer address to search through the skiplist to see if it falls within any existing intermediate buffers. If it does, we use that buffer's original buffer location, and, if this is the first time this original buffer is copied, zIO also remaps the core original buffer read-only to detect any application modification to it. If we find no intersecting intermediate buffer, then this data did not originate from IO (cf. §3.1.1) and we execute the copy, forgoing any tracking of this buffer. Finally, if the data originated from IO, we record the size of the left intermediate buffer fringe (③, where `app_buf3` is unaligned and has a left fringe of 4 bytes—it also has a right fringe, but we do not need to record it). The left buffer fringe is necessary to resolve access conflicts (cf. §3.1.5). If the destination location is within a buffer that is already tracked in the skiplist, the skiplist entry is updated with the new buffer information.

zIO unmaps the core intermediate buffer and registers it with userfaultfd to intercept application access. The union of left and right buffer fringes of original and intermediate buffer is copied. For example, if the source buffer has a left fringe of 4 bytes and the target buffer has no left fringe, then the left fringe of the target buffer becomes 4KB, as the original left fringe taints the first 4 bytes of what could have been a core page of the target buffer, making the entire page part of the fringe (④, where `app_buf3` has a left fringe of 4 bytes, `app_buf4` acquires a left fringe of 4KB).

The cost of unmapping intermediate buffers is often avoided or amortized. For example, buffers that are allocated on the heap are backed with physical memory and mapped only on first access (this *lazy memory allocation* is the default in Linux, for example). zIO can simply register these unmapped buffers with userfaultfd. Statically allocated buffers are often reused across requests instead of freed and reallocated. These buffers remain unmapped across requests if they are not otherwise accessed by the application. Upon reuse, zIO simply updates the skiplist when new IO data is processed.

3.1.3 Input to output buffer resolution. Whenever data is written to an IO stack, zIO interposes on the IO stack API and searches the skiplist to see if the core buffer being written intersects with any intermediate buffers tracked in the skiplist. If a match is found, zIO modifies the write operation to use any original buffer addresses recorded in the skiplist. This may result in a single IO stack source buffer location being transformed into multiple buffer locations (⑥, where shaded areas of the output are copied, unshaded areas are sourced from original buffer locations). If the IO stack API supports gather IO, we leverage that API to refer to the appropriate buffer pages when generating the output IO call. If the IO stack does not support gather IO, zIO breaks up the output call into multiple calls that refer to each individual buffer.

3.1.4 Freeing buffers. Finally, zIO interposes on `free`. This interposition allows zIO to look up and delete skiplist entries that are potentially no longer needed. If an intermediate buffer is freed that means we have successfully eliminated a copy; the contents of the buffer were not touched and the application has specified that it no longer needs it. At this point, the skiplist entry can be deleted and the memory region unregistered from userfaultfd. If an original buffer is being freed, the skiplist entry is only marked as freed to prevent use-after-free violations. Buffers marked as freed are deleted upon garbage collection (see below).

3.1.5 Access conflict resolution. When a core intermediate buffer is touched by the application, it will trigger a page fault. zIO looks up the faulting page number in the skiplist. zIO then maps the faulting page, potentially allocating it (lazy memory allocation), and copies the data from the original buffer, as recorded in the skiplist entry. zIO uses the left buffer fringe size to determine the byte offset of the intermediate core buffer, which is used as an offset into the recorded original buffer to determine the copy source address.

If a page at the beginning or end of a buffer is faulted in, it is removed from the tracked buffer core and thus copied going forward. If a page is faulted in the middle of a buffer, a

new skiplist entry must be created for the second section of the buffer, if it meets the appropriate size threshold (⑤). The original buffer is effectively split; the buffer before the faulting page is considered part of the originally tracked buffer and the buffer after the faulting page is a newly tracked buffer.

If a core original buffer is modified by the application, it also triggers a page fault. In this case, zIO walks the skiplist to determine any intermediate buffers derived from the core original buffer page. zIO copies the faulting original buffer page to the relevant intermediate buffers and resets the access permissions to the relevant original and intermediate pages.

3.1.6 Tracking policy. We determine experimentally (cf. §5.1.2) that for data buffers smaller than 16KB, the overhead of tracking outweighs any performance benefits from eliminating copies. Hence, we configure zIO to track and elide only sufficiently large copies (core buffer sizes of 16KB or larger).

There is also an overhead for handling page faults. We determine this experimentally (§5.1.4) under a number of conditions. For example, we find that if the ratio of bytes accessed by the application to bytes eliminated from copies exceeds 6%, we no longer see a performance benefit with a single application thread. This number can change with a different number of threads and is fully explored in §5.1.3. After these thresholds, we stop eliding copies for these buffers.

3.1.7 Intermediate buffer garbage collection. zIO avoids tracking an arbitrary number of entries to prevent memory exhaustion and skiplist performance reduction. For example, tracked intermediate buffers may be kept indefinitely in memory by the application, causing skiplist entries to accrue. Hence, skiplist entries are garbage collected periodically (once every second in our prototype). For each collected skiplist entry, we must fill any intermediate buffers with consistent data. This is done via the same process as conflict resolution. The region is mapped and the data is copied from its original location at the appropriate offset. Buffers marked free can be freed immediately.

zIO's garbage collection policy collects intermediate buffers that have been least recently used in copies. A timestamp on each skiplist entry (not shown in Figure 3) keeps track of the last time the entry was involved in a copy. If the skiplist grows beyond a threshold, zIO collects the least recently used entries.

3.2 IO Stack API Copy Elimination

Simply linking zIO when kernel-bypass IO stacks are used already provides transparent zero-copy IO. However, we can achieve further performance benefits by modifying these IO stacks to integrate with zIO more tightly. We now describe how we integrate zIO with kernel-bypass IO stacks to optimize IO stack API copy elimination.

Kernel-bypass IO stacks are a good fit for zIO, as they communicate with the application via shared library calls and shared memory—mechanisms that zIO can transparently process at user-level—rather than system calls. We choose the TAS [18] and Strata [20] kernel-bypass network and storage stacks, which are state-of-the-art. Strata, in particular, is a good fit, as it uses a per-process operation log in NVM, mapped into userspace, to persist file writes. zIO transparently intercepts Strata's memory copies into this log and can provide transparent copy elimination, provided that the original buffer already resides in NVM.

Input API copy elimination. POSIX file and socket input calls (e.g., `read` and `recv`) require applications to provide a buffer that input data is copied into. In TAS and Strata, these library calls internally call `memcpy` to copy from an IO stack internal buffer to the application-provided buffer. zIO transparently tracks and eliminates this copy across the IO stack API (cf. §3.1). As the source buffers are IO stack-private, we do not need to protect the original source data buffer by remapping it read-only. Instead, we modify the IO stacks to execute zIO's garbage collection protocol for any tracked buffers that the IO stack intends to free or overwrite. To prevent this from happening frequently, we can configure the IO stack internal buffers to be sufficiently large. For example, socket receive buffers can be resized to hold at least the expected size of input data per IO request.

Output API copy elimination. POSIX file and socket output calls (e.g., `write` and `send`) require applications to provide a source buffer that output data is copied from. As with the input API calls, zIO already transparently eliminates stack-internal memory copies. As output buffers are IO stack-private, no unmapping is necessary. Instead, we modify the IO stacks to fetch the original buffer locations from zIO when the output data is processed. For example, when TAS sends payload from the socket transmit buffer or when Strata "digests" [20] the update log. When zIO has to resolve copies due to mis-speculation or garbage collection, the relevant output buffer fields are simply filled in with the appropriate data. When the IO stacks ask zIO for original buffer locations, filled output buffers will not be marked as intermediate.

3.3 Optimistic Input Persistence

To realize optimistic input persistence for end-to-end IO copy elimination when data is persisted in NVM by a storage stack, we simply have to ensure that the original data already resides in NVM. zIO automatically detects the type of memory backing a virtual memory mapping. If original and intermediate buffers are backed by NVM, zIO can eliminate and track any copies among the buffers, while ensuring persistence. We describe here how we use this feature to realize *optimistic network receiver persistence*, where incoming data from the network does not need to be copied to storage.

Optimistic network receiver persistence. TAS uses shared memory for socket receive buffers between its TCP fast-path process and processes linking the kernel-bypass libTAS library. The fast-path writes incoming payload directly into

socket receive buffers residing in this shared memory. We can realize optimistic network receiver persistence simply by mapping the socket receive buffers into NVM. zIO will detect that original buffers are backed by NVM and eliminate copies end-to-end to the Strata update log, which also resides in process-local NVM.

3.4 Discussion

Huge pages. Huge pages (pages larger than the system's base page size) are desirable for improved memory address translation performance. However, tracking IO buffers requires fine-grained page protection, as tracked buffers may be smaller than the huge page size. In this case, zIO's fine-grained page mapping requests force the OS to break huge pages into base page mappings. Indeed, an investigation of the Redis YCSB benchmark with 512KB value size (cf. §5.2) shows that Linux with transparent huge page (THP) support maps 40% of Redis' working set with huge pages when zIO is not used, while mapping only 35% of the working set with huge pages when zIO is used.

Unfortunately, if the application stores IO buffers in reserved huge page memory using Linux's `hugetlbfs` mechanism, fine-grained page protection is disallowed and zIO can only track buffers at huge page granularity. Note that Linux could technically allow fine-grained protection for reserved huge page memory, while still allocating memory at huge page granularity. This would be compatible with zIO.

Luckily, transparent zero-copy and huge pages do not need to be at odds. zIO operates on the assumption that tracked IO buffers are seldom touched by applications. Hence, leveraging fine-grained page protection for tracking IO buffers does not impact application performance in the common case, as these mappings are seldom exercised. On mis-speculation, zIO's policy reverts to copying IO buffers and the OS may again map them with huge pages. This may happen transparently when THP support is enabled in the OS. Our application benchmarks run with THP, showing that transparent zero-copy IO still outperforms any potential slow-down from fine-grained page protection.

Linux kernel IO stack API copy elimination. While we present IO stack API copy elimination with kernel-bypass stacks (§3.2), we believe it is possible to provide IO stack API copy elimination for the Linux kernel IO stacks in certain cases by leveraging Linux's zero-copy IO APIs (cf. §2.4). For example, using Linux's zero-copy socket receive API (cf. §2.4), zIO can memory map kernel TCP socket receive buffers into user-private memory when sockets are created. It can then intercept application `recv` calls and track the target application buffer as an intermediate buffer, with the private socket buffer mapping as the original. This eliminates the IO stack API copy for `recv`, similar to our integration with TAS, as described in §3.2. Network receiver persistence may also be realizable, albeit with kernel modifications, by mapping socket buffers into a file stored in NVM and then using the `FICLONERANGE` ioctl to remap core data buffers to their final destination upon input to output resolution to a file. We leave IO stack API copy elimination for the Linux kernel IO stacks for future work.

4 Implementation

Our zIO implementation consists of two key components. The first component is tracking data through an application and eliminating copies along the way. The second component is closely integrating this tracking with the kernel-bypass network and storage stacks TAS and Strata, respectively, to provide transparent zero-copy across IO stack APIs, as well as optimistic input persistence.

Application copy elimination. This component of zIO is written in 1,608 lines of C code and is dynamically loaded with `LD_PRELOAD`.

IO stack API copy elimination. To integrate zIO with TAS and Strata to provide IO stack API copy elimination, we modify 184 lines of code in TAS and 66 lines of code in Strata.

5 Evaluation

We analyze zIO's performance via a number of experiments based on a multi-threaded IO microbenchmark, using network and storage stacks, and varying relevant IO and copy parameters. We also evaluate zIO with the IO-intensive applications Redis [21], MongoDB [25], and Icecast [37]. We compare zIO to Linux and kernel-bypass IO stacks without any copy optimizations.

Our evaluation answers the following questions:

- What is the impact of copies on IO performance? What benefits to IO processing throughput does zIO provide by transparently eliminating copies? How do the number of copies per IO (§5.1.1), IO size (§5.1.2), and number of IO threads (§5.1.3) affect the observed performance?
- What are the overheads zIO introduces by tracking data? How do overheads increase as applications touch the data they copy, causing zIO to mis-speculate? How effective is zIO's tracking policy in avoiding mis-speculation? (§5.1.4)
- How do zIO performance improvements break down into its mechanisms? By how much can we improve IO performance when employing optimistic input persistence with NVM? (§5.2.1)
- What benefits to IO processing throughput and latency does zIO provide by eliminating copies within IO-intensive applications, such as Redis (§5.2), Icecast (§5.3), and MongoDB (§5.4)? In what situations might zIO hurt application performance (§5.3.1)?
- How does zIO perform compared to zero-copy IO APIs, such as memory mapped files and `sendfile`? (§5.3.1)

Evaluation platform. We run our evaluation on a single socket of a dual-socket Intel Cascade Lake-SP system running at 2.2GHz with 24 cores per socket and a 100 GbE ConnectX-5

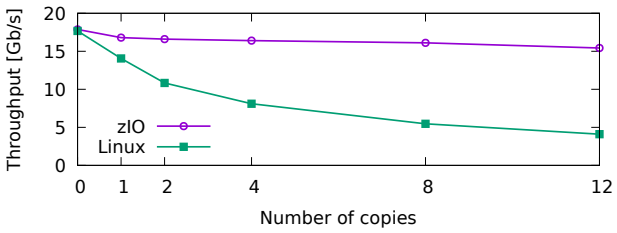

Figure 4. Linux throughput versus zIO application IO copy elimination (512KB IO size).

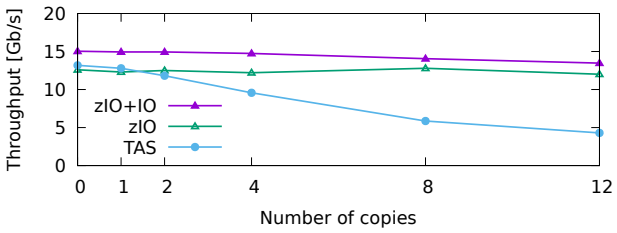

Figure 5. TAS throughput versus zIO application and IO stack API copy elimination (512KB IO size).

NIC. Each socket has 192 GB of DDR4 DRAM and 3 TB of Intel Optane DC NVM. To leverage all 6 memory channels per processor, there are 6 DIMMs of DRAM and NVM per socket. The machine runs Fedora 27 with Linux kernel version 5.10.0. We use the latest master branches of TAS [3] and Strata [4].

5.1 Microbenchmarks

We quantify the overhead introduced by copies of IO data and the benefit that zIO provides for various IO parameters via a simple echo server benchmark. Our evaluation setup is the same as in §2.2, but in place of Redis we run a simple TCP echo server that echoes client messages back to the sender. To simulate IO-intensive application processing, our echo server can make a configurable number of copies to the IO data. Beyond the number of copies, we also vary other IO parameters, such as IO size, fraction of IO data accessed, and number of echo server threads. We report the average echo server throughput, measured at the client, over 3 runs for each configuration, using the steady-state throughput of each run.

5.1.1 Number of Copies. We first evaluate IO performance with a varying number of copies of the IO data made before it is echoed. We compare four scenarios: Vanilla Linux (Linux), Linux with zIO application copy elimination (zIO), vanilla kernel-bypass (TAS), kernel-bypass with zIO application copy elimination (zIO), and kernel-bypass with zIO application and IO stack API copy elimination (zIO+IO). We run this experiment with 512KB IO, using a single server thread. For each run, we vary the number of times the request is copied before being echoed.

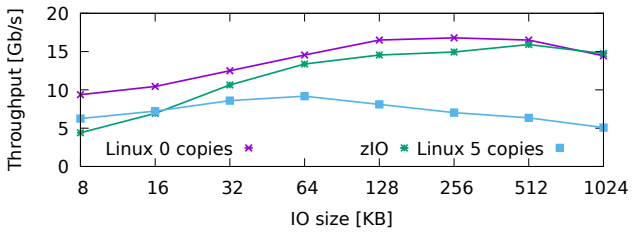

Figure 6. zIO throughput versus Linux with 0 and 5 copies.

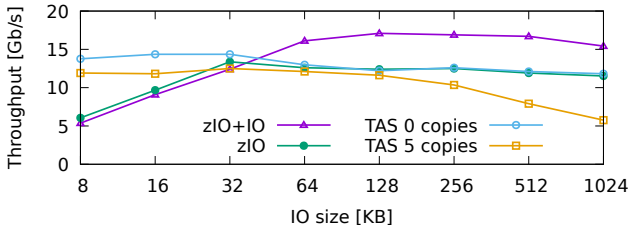

Figure 7. zIO throughput versus TAS with 0 and 5 copies.

Figures 4 and 5 present the results. We can see that an increasing number of application IO copies decreases the achieved throughput for Linux and TAS networking[2], due to the involved copying overhead. Kernel-bypass maintains high throughput with more copies than Linux, as more CPU cycles are available for copies due to the lighter-weight kernel-bypass network stack. zIO maintains performance close to the configuration without copies for both stacks, showing that it successfully eliminates these copies with negligible overhead. With 12 copies, zIO improves throughput by 3.8× with Linux and by 2.8× with TAS. Finally, zIO+IO improves throughput by up to 21% versus zIO by additionally eliminating IO stack API copies.

5.1.2 IO Size. We next investigate how IO size affects performance, using a single echo server thread. To evaluate the overhead of tracking small IO, we disable zIO's IO size threshold for this benchmark, causing zIO to always track buffers and eliminate copies. We vary the IO size from 8KB to 1MB and evaluate two extreme copy scenarios (cf. Table 1): 5 application copies and 0 application copies. Figures 6 and 7 present the results.

zIO benefits large IO. Firstly, we can see that Linux has poor performance with small IO, but performance improves as IO size increases. TAS performs better with smaller IO size. This is expected, as kernel-bypass stacks are light-weight. When copies are involved, both Linux and TAS perform worse, in particular as IO size increases. This is also expected, as

[2]We consistently observe TAS throughput to be lower than Linux with large IO sizes. TAS is optimized for small IO and does not do the necessary batching to handle large IO efficiently.

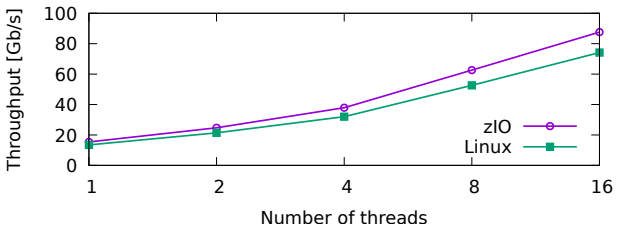

Figure 8. zIO scalability.

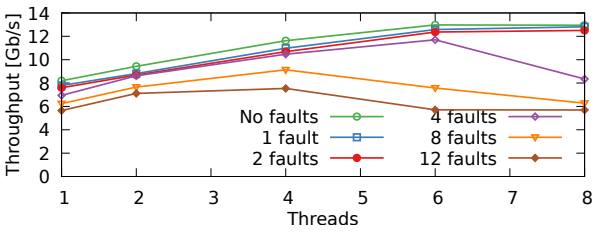

Figure 9. zIO scalability with page faults.

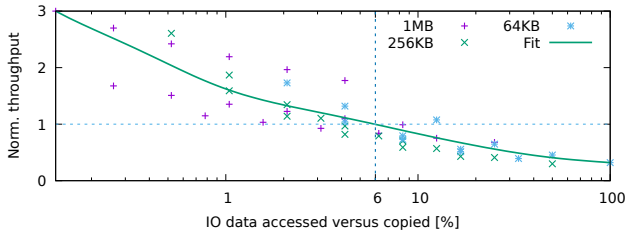

Figure 10. zIO throughput improvement under data access.

larger copies require more CPU time. zIO improves throughput by up to 2.9× with Linux and up to 2× with TAS as IO size increases, reaching zero-copy performance with IO sizes larger than 512KB for Linux and 32KB for TAS. zIO+IO improves throughput further, by up to 40% versus zIO, for a combined improvement of up to 2.7× versus TAS.

Limits of zIO with small IO. zIO transparent copy elimination is no panacea, as the overhead of zIO tracking with small IO limits throughput. For IO smaller than 16KB, zIO reduces throughput by up to 30% versus Linux. For IO smaller than 32KB, zIO reduces throughput by up to 49% versus TAS. IO sizes smaller than 8KB would incur even further throughput reduction. Based on this measurement, we set zIO's tracking policy to avoid tracking IO buffers smaller than 16KB (cf. 3.1.6).

5.1.3 Scalability. We evaluate two scalability aspects. zIO tracking scalability and the impact of page faults.

zIO tracking. We configure the echo server to make 1 application copy of each 512KB IO buffer and vary the number of server threads. Each thread handles a private pool of clients and uses private IO buffers. Figure 8 shows that zIO improves throughput scalability over Linux by up to 19% due to copy elimination. Copies pollute the CPU caches, causing Linux's scalability to be impacted.

Page faults. Page faults can affect scalability when faulting pages are mapped, requiring TLB shootdowns. In theory, information about newly mapped pages may be lazily synchronized among TLBs, avoiding TLB shootdowns. Other cores accessing the same unmapped page simply fault on the stale TLB information, synchronizing the TLB at this moment. Most IO-intensive applications use thread-private IO buffers and access across cores is rare. Unfortunately, Linux does not support lazy mapping of pages. Hence, page faults do affect scalability.

To show this effect, we configure the echo server to access a number of pages of each 512KB IO buffer, without application copies, and vary the number of server threads. We supply the same IO buffer each time, requiring zIO to unmap it for each IO request. The results can be found in Figure 9. We can see that, up to 2 page faults, server throughput still scales well. Increasing the number of page faults per IO beyond this point starts limiting server throughput due to TLB shootdowns. With Linux modifications, many of these TLB shootdowns could be avoided.

5.1.4 Mis-speculation. To evaluate the impact of zIO mis-speculation on performance, we configure the echo server to access a number of bytes in each IO request before echoing a response. We run this experiment under a variety of IO sizes (64KB, 256KB, and 1MB) and copies (1, 3, and 6), using the Linux network stack.

Figure 10 presents the results as a scatter plot, where we compare zIO throughput improvement over vanilla Linux to the ratio of IO bytes accessed versus elided in copies. This ratio clearly limits zIO's throughput improvements. Applications accessing copied IO data means that zIO mis-speculated. zIO has to resolve the elided copies for the accessed data, which incurs a performance penalty. Less IO data accessed implies better performance improvements. At the same time, more IO data elided in copies also implies better performance improvements and creates headroom for mis-speculation. Fitting a Bezier curve to the scatter plot shows that zIO improves throughput when the ratio of data bytes accessed by an application versus data bytes elided in copies is less than 6%. Above 6%, overheads created by zIO mis-speculation decrease throughput. As an example, for an input buffer of size 200KB that is copied twice, the application may incur up to 6 page faults before output to still yield a speed-up. If the same buffer is copied 4 times, up to 12 page faults are permissible.

5.2 Redis

We evaluate how zIO improves Redis throughput with Linux and kernel-bypass IO stacks (TAS and Strata). Our benchmark setup is identical to the one presented in §2.2. We evaluate two

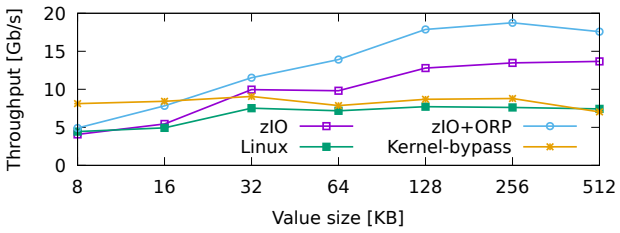

Figure 11. Redis throughput (100% SET).

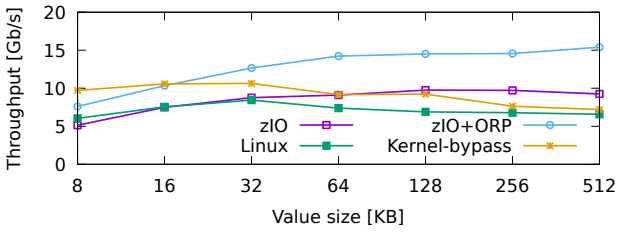

Figure 12. Redis throughput YCSB A (50% SET, 50% GET).

benchmark configurations: 1) 100% SET, and 2) YCSB Workload A, which has a distribution of 50% SETs and 50% GETs. We vary the value size over independent runs for each of these configurations. In addition to zIO's improvement over vanilla Linux with application copy elimination, we investigate the performance of zIO with additional optimistic receiver persistence and IO stack API copy elimination (zIO+ORP) over kernel-bypass IO stacks. The zIO size threshold is disabled for these experiments; enabling it would allow zIO to match vanilla IO stack performance for smaller values, evaluated in §5.2.1.

We first look at 100% SET throughput. This case involves 2 IO copies (one from the network and one to storage), as well as 4 IO application copies per request (cf. Table 1). The results can be found in Figure 11. zIO with Linux eliminates all application copies, which allows for a throughput improvement of up to 1.8×, especially for larger values. zIO+ORP with kernel-bypass IO stacks improves performance by up to 2.5×, as the IO paths consume noticeably less CPU time.

We now look at YCSB workload A, with 50% GET requests and 50% SET requests. These results can be found in Figure 12. As the 50% GET requests require fewer application copies, zIO with Linux provides less of a performance improvement than in the first benchmark, up to 1.3×. However, GET requests provide an opportunity for zIO+ORP to eliminate IO stack API copies, maintaining a speedup of up to 2× over vanilla kernel-bypass.

5.2.1 zIO Performance Breakdown. We use the Redis 100% SET benchmark to break down the performance contributions of zIO. To do so, we evaluate zIO throughput with kernel-bypass IO in two IO size configurations, progressively

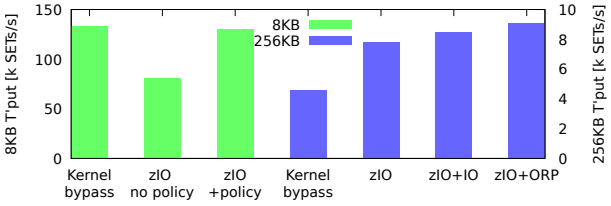

Figure 13. zIO performance breakdown.

	Storage to net **Throughput**	Net to net **Listeners**
Kernel-bypass	0.89 GB/s (1.00×)	812 (1.00×)
zIO+IO	1.08 GB/s (1.25×)	944 (1.16×)

Table 3. Icecast throughput.

enabling different zIO optimizations. These results can be found in Figure 13.

The first configuration uses 8KB SET requests. We evaluate zIO with and without its tracking policy, which applies a 16KB size threshold (§3.1.6). We can see a drastic slowdown of 40% when zIO does not apply this policy, due to the overhead of tracking small IO. Enabling zIO's policy instead copies the IO buffers and attains a negligible slowdown of 2% versus vanilla kernel-bypass.

We further evaluate a configuration with 256KB SET requests. When eliminating application copies, zIO provides a speedup of 1.7×. When adding IO stack API copy elimination, zIO+IO improves performance by another 9%. Adding optimistic receiver persistence in zIO+ORP finally improves performance by another 7%, for a combined improvement over vanilla kernel-bypass of 2×.

Intermediate buffer tracking overhead. We investigate the overhead of buffer tracking via zIO's skiplist. For the same 100% SET request Redis configuration, we find an average of 5 skiplist entries per client connection. With 64 clients, we measured a maximum of 640 entries in the skiplist over the duration of the benchmark. For this scenario, we measure the average skiplist operation latency for lookup and insert to be 190ns. This confirms that intermediate buffer tracking via skiplists is lightweight.

5.3 Icecast

Icecast [37] is an audio broadcasting service. Icecast can stream audio from a source client to a number of listener clients or read data from a local file and serve it to a number of listener clients via HTTP. Table 1 shows that Icecast makes no application copies, but it uses the IO stack APIs. We evaluate both Icecast configurations, providing insight into network to network and storage to network performance. We use the kernel-bypass IO stacks for our evaluation, as they support IO stack API copy elimination. The results are shown in Table 3.

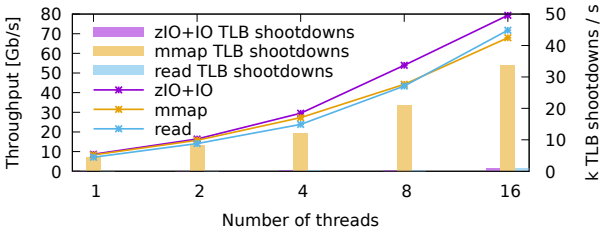

Figure 14. Icecast throughput scalability.

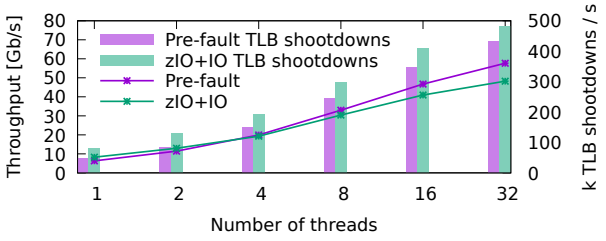

Figure 15. Icecast scalability with pre-faulted buffers.

Storage to network. We configure Icecast to broadcast a 1.1MB audio file to a number of listener clients. We evaluate the amount of audio that a single Icecast file-serving thread can deliver. Icecast reads and sends the audio file in a configurable chunk size, which we set to 64KB. Listener clients request the audio stream via `curl-loader` [16], a HTTP benchmark tool. We connect enough clients to saturate Icecast server throughput and measure throughput over a 30 second period. We can see that zIO+IO improves Icecast maximum throughput by 1.25× by eliminating IO stack API copies, freeing CPU cycles for audio streaming.

Network to network. Next, we evaluate Icecast receiving data from a single client and broadcasting it to a number listeners via a single relay thread. We configure Icecast to relay 64KB at a time and measure the number of concurrent listeners that Icecast can broadcast to. We see a zIO+IO improvement of 1.16× by eliminating IO stack copies. Icecast uses a static buffer for relay, which remains unmapped across IO chunks. This allows zIO+IO to eliminate IO stack copies with minimal overhead.

5.3.1 Scalability. Icecast is a single-threaded application when serving local files to listeners. To evaluate IO-intensive application scalability with zIO, we modify Icecast to create a thread-pool, where each thread can handle listener client HTTP requests from storage via a thread-local IO buffer. This configuration makes Icecast behave like a web server, such as Apache [6]. This version of Icecast is using the `read` system call to read from each file (read).

zIO scalability versus zero-copy IO interfaces. Web servers (like Apache) often use zero-copy IO interfaces to accelerate service, such as memory mapped files and the `sendfile` system call. To compare application performance with a zero-copy IO interface to that of zIO's transparent zero-copy IO, we create a version of Icecast that maps a requested file into memory (cf. §2.4) and sends data to the clients from the memory-mapped file via the socket `send` call (mmap). Memory mapping each requested file eliminates an IO stack copy on input, but also incurs a TLB shootdown. Common usage (cf. Apache) of the mmap API unmaps each file after serving it, incurring another TLB shootdown. zIO+IO can eliminate copies without having to incur TLB shootdowns if buffers are re-used and remain untouched in the common case.

We evaluate these configurations with a 512KB audio file with an increasing number of threads and measure throughput, as well as the number of TLB shootdowns. These results are found in Figure 14. We can see that zIO+IO consistently performs the best, as it does not incur TLB shootdowns. For a small number of threads, memory mapping input files performs similarly to zIO+IO. However, as the number of threads increases, the number and cost of performing TLB shootdowns increases, which negatively affects mmap performance. The number of TLB shootdowns when using `read` and zIO+IO are negligible, as no memory mapping calls happen in the common case. zIO outperforms memory mapping of input files by up to 17%.

Finally, we evaluate versions of Icecast using the Linux `sendfile` API to transmit files to listeners. The first version uses mmap to memory map each file to validate its header before using `sendfile` to transmit it. The second version uses the `read` system call to read the file's header. These versions cannot use the kernel-bypass IO stacks, as `sendfile` is kernel-specific, and `read+sendfile` performs up to 7% worse than zIO+IO, while `mmap+sendfile` performs up to 30% worse than zIO+IO. The scalability trend of `read+sendfile` follows that of zIO+IO, while `mmap+sendfile` scales similarly to mmap.

zIO scalability with pre-faulted buffers. We have already evaluated zIO scalability when buffers are touched, incurring page faults (§5.1.3). zIO can detect these cases and stop copy elision (§3.1.6). However, if the application causes page faults before buffers are tracked by zIO, for example by pre-faulting mapped memory (cf. `MAP_POPULATE` flag for `mmap`) before using it to buffer IO, then zIO can incur TLB shootdowns by unmapping these buffers for tracking.

To evaluate this scenario, we modify Icecast to pre-fault the IO buffer before reading into it via `read` and unmapping it after it was sent over the network (pre-fault). This forces zIO+IO to unmap the IO buffer to track potential access. We run these two configurations with a 512KB audio file, a 32KB chunk size, and an increasing number of threads. We measure throughput and TLB shootdowns for both cases. We present these results in Figure 15. With a small number of threads, zIO+IO outperforms pre-fault, as it still eliminates copies in the IO stack API. However, as the number of threads increases, performance is affected by the additional TLB shootdown overhead and

zIO+IO performance degrades. Note that pre-faulting memory causes TLB shootdowns by itself and the scalability of this scenario is already limited.

5.4 MongoDB

We run MongoDB [25] on Linux, with and without zIO. We connect a client over the network running the YCSB [10] load phase and measure request throughput with 1MB values, divided into 10 fields. The YCSB load phase is a workload with 100% inserts of a uniform random distribution. We repeat this benchmark 5 times and report the average throughput for each configuration.

We find that zIO is not able to provide a performance benefit for this workload, with a performance of 191 requests/s compared to 194 for Linux without zIO. zIO is disabling all optimizations due to a large number of page faults. We find that the page faults are generated by MongoDB reading each inserted value in its entirety to calculate a checksum before writing it to the file system.

If we modify MongoDB to skip checksum calculation, zIO is able to eliminate 2 out of 3 application copies (cf. Table 1). Similar to Redis (cf. Table 2), MongoDB copies the inserted value first into an in-memory B-tree (similar to Redis' copy A_2) and then into a log (copy A_3). Finally, MongoDB reallocates the IO buffer, causing a copy, before inserting it into an on-disk index. All three copies are initially elided by zIO, the file system writes complete and their buffers are freed. However, the next IO request re-uses the original IO buffer, forcing zIO to execute the elided copy of the previous buffer to the B-tree data structure. zIO achieves a throughput of 222 requests/s, a 6% improvement over Linux' throughput of 209 requests/s.

We also run MongoDB with the TAS kernel-bypass network stack, allowing us to use zIO+IO to elide an IO stack API copy in `recvmsg` that MongoDB uses to read data from the network. Doing so additionally implies that original buffer reuse, which is now internal to the IO stack and directly communicated to zIO+IO, is lighter weight, as it is not initiated via a page fault. TAS without zIO+IO achieves a throughput of 191 requests/s, while TAS with zIO+IO achieves a throughput of 229 requests/s, a 19% performance improvement.

6 Related Work

In this section, we cover related work beyond the zero-copy IO APIs studied in §2.4.

Zero-copy networked storage. Reflex [19] is a networked storage system designed to provide fast access to remote flash devices. Reflex gains performance by eliminating software copies between network interface cards and flash storage. Unlike zIO, ReFlex does not focus on eliminating application-level or IO stack API copies.

Hardware-accelerated serialization. Recent work has looked at accelerating serialization with help from hardware. Zerializer [35] proposes DMA hardware with data transformation logic to offload serialization. Breakfast of Champions [29] proposes using existing scatter-gather capabilities of NICs to offload serialization. Unlike these works, zIO provides zero-copy without assuming specialized hardware and can eliminate application copies beyond those needed for serialization.

Custom user-level IO stacks. Sandstorm [23] addresses the idea of specially tailoring user-level IO stacks to meet the specific needs of applications to maximize performance, including zero-copy. However, similar to cross-stack APIs, these customizations are not transparent. Either the IO stack has to be modified to work with the application, the application has to be modified to use new APIs, or both. zIO offers transparent cross-stack zero-copy.

7 Conclusion

We present zIO, a transparent zero-copy IO mechanism for unmodified IO-intensive applications. zIO tracks IO data through the application, eliminating copies that are unnecessary while maintaining data consistency. We implement zIO as a user-space library, supporting Linux kernel and kernel-bypass IO stacks. We evaluate zIO with IO-intensive applications, like Redis, Icecast, and MongoDB. zIO improves application throughput by up to 1.8× with Linux, as well as by up to 2.5× with kernel-bypass IO stacks with optimistic network receiver persistence.

Abstract

This paper develops a new approach to verifying a performant file system that *isolates crash safety and concurrency reasoning* to a transaction system that gives atomic access to the disk, so that the rest of the file system can be verified with *sequential reasoning*.

We demonstrate this approach in DaisyNFS, a Network File System (NFS) server written in Go that runs on top of a disk. DaisyNFS uses GoTxn, a new verified, concurrent transaction system that extends GoJournal [9] with two-phase locking and an allocator. The transaction system's specification formalizes under what conditions transactions can be verified with only sequential reasoning, and comes with a mechanized proof in Coq [37] that connects the specification to the implementation.

As evidence that proofs enjoy sequential reasoning, DaisyNFS uses Dafny [26], a sequential verification language, to implement and verify all the NFS operations on top of GoTxn. The sequential proofs helped achieve a number of good properties in DaisyNFS: easy incremental development (for example, adding support for large files), a relatively short proof (only 2× as many lines of proof as code), and a performant implementation (at least 60% the throughput of the Linux NFS server exporting ext4 across a variety of benchmarks).

1 Introduction

File systems are important to implement correctly because applications rely on them to safely store user data. Formal verification offers a promise of showing that the implementation of a file system always meets its specification, including a crash safety property that says the file system recovers correctly from a sudden crash and reboot. However, efficient implementations are internally complicated, especially because they support concurrency and aim to minimize disk writes. Complexity makes the code more error-prone and motivates the desire for formal verification, but also poses a challenge: how can a proof cover concurrency, crash safety, and functional behavior while remaining tractable for a program the size of a file system?

The main contribution of this paper is a new approach to verifying a file system that *isolates crash safety and concurrency reasoning* to a transaction-system implementation. This use of a transaction system wraps the file-system data structures and logic inside a transaction, and permits *sequential reasoning* for the body of each transaction. Sequential reasoning keeps the proof burden manageable even with an efficient implementation that supports many features, such as large files and in-place updates of serialized metadata.

There are three challenges in realizing this approach. The most important lies at the interface between the transaction system and the file system: intuitively, transactions make things simpler, but how do we exploit this for a proof engineer verifying the code running in a transaction? This paper proves a *simulation transfer theorem* that formalizes how the proof engineer can verify the body of each transaction using sequential reasoning, and yet still obtain a proof about concurrent and crash behavior, due to the use of a verified transaction system. This specification and its proof are not specific to the file system written on top and could be applied to another storage system implemented using transactions. We use the transaction system with file-system code verified using Dafny [26], a verification-oriented programming language that is limited to sequential reasoning but in exchange has good automation.

The second challenge is how to implement and verify the transaction system itself. The performance and concurrency of the overall system can only be as good as the transaction system, so efficiency and fine-grained locking are important. To that end we implement a new transaction system called GoTxn by extending GoJournal [9] (a verified journaling system) with two-phase locking. GoJournal's specification guarantees crash safety but requires the caller to implement concurrency control (enforced with separation logic) to achieve atomicity. In proving GoTxn we give a new separation-logic proof of two-phase locking's correctness based on local reasoning rather than the typical textbook approach that reasons about the global conflict graph for a set of transactions. GoTxn cannot make arbitrary transactions appear atomic (for example, if they access global variables), and so the specification for GoTxn applies only to a carefully formalized subset of "safe" transactions that access shared state only through the transaction system.

The third and final challenge is how to implement the file system using only transactions. GoTxn's safety restriction would appear to preclude an in-memory allocator since it re-

quires other shared state, which we address by incorporating allocation with a non-deterministic specification into GoTxn, which is then used in the file system by validating the allocator's output. For sequential reasoning each operation must be implemented as a single transaction, but operations like removing a file can require a large number of disk writes that might not fit in a transaction. We implement freeing using multiple transactions; a first transaction logically deletes a file, and then asynchronously the implementation can run transactions that recover space from the file but have no other visible effect.

The verified artifact from this work is DaisyNFS, which implements a Network File System (NFS) server in Go on top of a bare disk and comes with a proof that clients observe that each operation follows the NFS specification as laid out in RFC 1813 [4]. Operations appear atomic despite concurrency and crashes. Clients can use the Linux or macOS NFS clients to mount DaisyNFS like any other file system and interact with it using the usual POSIX API. As an end-to-end check that our formalization of NFS is accurate and the implementation is reasonably complete, we tested with both Linux and macOS clients running a variety of programs.

A benefit of this file-system design is that it permits using the sharpest tool for each part of the proof: while we use Perennial [9], a program logic for crash safety and concurrency embedded in Coq, for the transaction system's proof, we use Dafny [26], a verification-aware programming language with powerful automation, for the file-system operations. Dafny is a purely sequential language, but we are able to use it despite this limitation due to the transaction system's proof. The value of sequential proofs can be seen in the proof-to-code ratio for the transaction system, which is 20×, versus the Dafny proofs which required about 2× as many lines of proof as code. Further evidence can be seen in the incremental development of DaisyNFS, which we elaborate on in §9.4.

To evaluate DaisyNFS's performance, we compare it to that of the Linux NFS server exporting an ext4 file system. DaisyNFS achieves within 90% of the throughput of Linux with the ext4 `data=journal` option (which gives the same crash-safety guarantees as DaisyNFS) across a variety of benchmarks both on an NVMe and in-memory disk, and at least 60% on the most challenging ones. The comparable performance is due to the efficiency of GoJournal and adding little overhead in the file-system code (e.g., updating data structures in place to avoid copying). We do note that ext4's default `data=ordered` mode can get about 60% better throughput for data-heavy workloads, at the cost of weaker guarantees on crash.

The contributions of this paper are:

- Formalization of a *simulation-transfer theorem* that captures how the transaction system provides sequential reasoning (§5.1) for any system implemented using a transaction per operation.
- A proof that the simulation-transfer theorem holds for the GoTxn implementation (§6). This proof verifies two-phase locking using a new strategy based on *local reasoning* to connect to the GoJournal specification. For the theorem to be true, it needs a precisely formulated definition of *safe* transactions that access shared state through GoTxn in order to behave atomically.
- Techniques to implement a file system using GoTxn, including a validation approach to integrating in-memory allocation into GoTxn and an approach for splitting file removal into multiple transactions of bounded size.
- DaisyNFS, a concurrent, crash-safe file system that is verified in Dafny with sequential reasoning thanks to the above techniques. The Dafny proofs for the file-system code enjoy low overhead compared to the concurrent proofs for GoTxn (2× vs. 20×). A performance evaluation shows that DaisyNFS gets throughput at least 60% that of Linux ext4 exported over NFS for the most challenging benchmarks, and within 90% for many workloads.

Our approach and DaisyNFS have some limitations. The proof approach relies on transactions appearing to run sequentially, which prevents modifying state outside the transaction system. There are cases where that would get better performance in exchange for a more difficult proof. The transaction system does not have a proof of liveness, and we do not prove that transactions avoid deadlock. DaisyNFS does not support NFS unstable writes, which improve performance by not committing writes to stable storage until explicitly requested. Our NFS implementation does not cover some features, such as symbolic links, hard links, and paginated `READDIR`; we believe these features could be implemented and specified with the same approach but have not done so in our prototype.

This paper describes work that is part of the first author's Ph.D. thesis [5], which provides more detail. The thesis also describes the Perennial logic for verifying concurrent and crash-safe systems, the specification and proof of GoTxn (including GoJournal), and Goose, the tool we use to verify GoTxn's implementation written in Go. It goes into more detail about the DaisyNFS proof and evaluation as well.

2 Related work

Our main contribution is a way to use transactions to enable sequential reasoning for a concurrent file system. Our approach allows using Dafny and produces a file system that gets good performance. Prior work has also explored how to compose proofs across layers for modularity, to contain concurrency, or to cross between proof systems in complementary and distinct ways; none use transactions or any similar mechanism to isolate concurrency or crash safety reasoning.

2.1 Verifying storage systems

Directly related systems DaisyNFS directly builds upon GoJournal [9] to implement the transaction system, together with

its new version of the Perennial framework [8] that is used to verify the transaction system's proof. This infrastructure is a program logic designed for storage systems that need a combination of concurrency and reasoning about crashes at any time, built on top of the Iris framework [23] in Coq.

The transaction system differs from GoJournal in that the GoJournal specification requires the caller to prove that concurrent transactions do not attempt to read or write the same objects, whereas the transaction system guarantees this automatically with per-object locks. The specification styles are also different: whereas the GoJournal proof is a set of specifications within the Perennial logic, the transaction system's proof uses a more general refinement-based definition that we can apply to the Dafny code. This is necessary to combine the tools, since Dafny cannot express the GoJournal specification's concurrency restrictions directly.

Directly related applications In prior work with the Perennial framework, we verified a crash-safe, concurrent mail server under the assumption that the file system is crash-safe [8]. DaisyNFS is a crash-safe file system and its complexity is significantly larger than a mail server: the mail server is about 150 lines with a monolithic proof while DaisyNFS combines a transaction system (itself 1,600 lines) with a 4,000-line file system, each of which involve many intermediate abstractions.

The authors of GoJournal verify a simple NFS file server on top of GoJournal, but that server is not complete enough to run real applications (it supports only one directory and 4KB files). Furthermore, the simple NFS server does its own locking and so the proof must reason about concurrency, increasing the proof overhead compared to DaisyNFS.

Other verified file systems Flashix [33] is a verified file system for flash storage, recently extended to support concurrency by Bodenmüller et al. [2]. File-system operations are proven to be atomic using a variant of Lipton's movers [28] technique with additional conditions to ensure crash-atomicity [31]. In contrast, DaisyNFS proves once and for all that operations encapsulated in a transaction are atomic. Flashix uses per-file locks to enable concurrent file accesses, but the directory tree is protected by a single reader-writer lock, so operations creating or moving files cannot proceed concurrently. DaisyNFS's two-phase locking system allows operations to proceed in parallel if they access disjoint parts of the file system.

VeriBetrKV [18] is a verified key-value store similar to the one that underpins the BetrFS [22] file system. It uses Dafny for crash-safety reasoning but does not layer any file-system proof on top. This file-system design does not involve general transactions, so the code on top of the key-value store must still carry out crash reasoning. The system has I/O concurrency but no CPU concurrency.

AtomFS [39] is a verified concurrent file system that does not persist data. It uses a custom concurrent relational logic implemented in Coq. Because the system does not persist data, AtomFS does not have any transaction system and implements the file-system operations together with appropriate locking for concurrency control.

2.2 Concurrency verification

A number of verification frameworks address concurrency, including CIVL [20], CSPEC [6], Armada [29], Iris [24], CCAL [16, 17], and FCSL [34], among many others. These frameworks use a range of methods, such as movers [28] and concurrent separation logic [3]. Although there has been much recent progress in using these frameworks to verify shared-memory concurrent systems, handling concurrency still brings additional proof burden compared to verification of sequential systems. DaisyNFS's design isolates this verification overhead to the transaction system's proof, and then uses Dafny to reason about file-system operations. Furthermore, it would be challenging to extend a concurrency framework with crash safety compared to starting with Perennial, which required non-trivial extensions to add crash-safety support to Iris.

IronFleet [19] applies Dafny's sequential reasoning to a non-sequential setting, namely to verify event handlers for distributed systems. Each event handler is structured in phases: first messages are received, some local computation is done, and then messages are sent. This structuring enables a reduction argument [28] which makes it sound to treat each event handler as if it ran in an atomic step, with no interleaving of steps by other machines. Instead of a reduction argument, DaisyNFS uses the transaction system to make operations atomic. Although DaisyNFS operations may only access shared state through the transaction-system API, there are no phases or constraints on the ordering of reads and writes within a transaction.

2.3 Verified two-phase locking

Chkliaev et al. [11] verify serializability of two-phase locking and other transaction concurrency control mechanisms in the PVS theorem prover. Their proof formalizes two-phase locking as an abstract protocol consisting of sequences of read, write, and locking operations, as opposed to a concrete implementation as in DaisyNFS. Pollak [32] uses a variant of the CAP separation logic [15] to give a pencil-and-paper proof of serializability for a two-phase locking implementation.

Lesani et al. [27] developed a framework for verifying software transactional memory algorithms, modeled as I/O automata. They applied their framework to sophisticated STM algorithms, such as the NOrec algorithm [14]. The STM algorithms considered do not handle persistence and the framework does not address crash-safety reasoning.

2.4 Unverified file systems

We chose to verify an NFS server because it is widely used in practice and the expected behavior of NFS operations is well

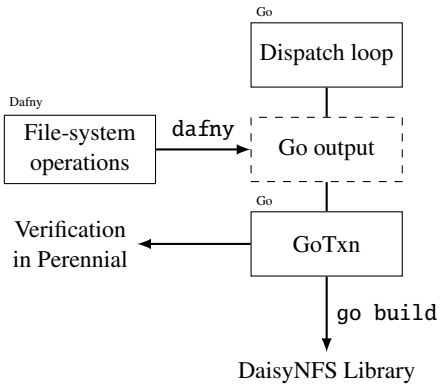

Figure 1: The structure of the code.

documented in RFCs. FUSE is an alternative for implementing file systems in user space, but its operations have a less clear specification.

Isotope [35] is a block-level transaction system similar to GoTxn in its API which was used to implement a file system called IsoFS. Its logging design is based on multi-version concurrency control (MVCC) [1] rather than our use of pessimistic locking. IsoFS has a similar design to DaisyNFS: it factors out isolation and atomicity to the transaction system, making it easy to handle crashes and concurrency. Unlike GoTxn and DaisyNFS, Isotope is unverified and thus prone to subtle concurrency bugs in the transaction system and bugs in the IsoFS code, whereas DaisyNFS uses the split design to verify both the transaction system and the transactions themselves.

To be conducive to verification, DaisyNFS is implemented differently than many NFS servers; the main differences are that using two-phase locking is not common practice, and most NFS servers are implemented on top of an existing file system. For example, the Linux NFS server can export any underlying file system supported by the kernel. An exported file system such as ext4 may use a journaling system, but the file system and VFS layers perform locking and are still prone to concurrency bugs. WAFL [21] is an NFS appliance that provides snapshots and logs NFS requests to NVRAM. It has evolved its locking plan to obtain good parallelism [13]. Both the Linux NFS server and WAFL are more complicated and have more features than DaisyNFS.

3 System design

As shown in Figure 1, DaisyNFS is implemented in three layers: 1) a dispatch loop that speaks the NFS wire protocol and calls the appropriate method for each operation; 2) a Dafny class that implements each method; and 3) a transaction system that applies the updates of each method to the disk atomically. The dispatch loop is unverified; we assume that the server correctly decodes messages, calls the right method for an operation, and encodes the response. The middle layer implementing the file-system operations is written and verified in Dafny, which has a backend for Go. The third layer is directly written in Go and verified using Coq and Perennial. By implementing the file system on top of the transaction system, we can implement each NFS method in Dafny as sequential code calling into a concurrent transaction system library. The NFS operations supported by DaisyNFS are listed in Figure 6.

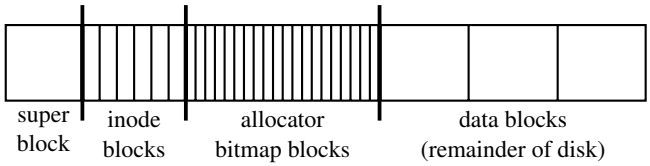

Figure 2: The layout of the file system on top of the transaction system's disk. The number of inode blocks and data bitmap blocks are compile-time constants, but easy to change without affecting the proofs.

3.1 Dafny file system

The file system is responsible for implementing files and directories onto an array of disk blocks that is exported by the transaction system. The disk layout used by the file system is shown in Figure 2, with regions for inode blocks, bitmap blocks, and data blocks for files and directories. This figure is in terms of the disk exported by the transaction system; the transaction system itself has a 513-block write-ahead log to support multi-block atomic writes to the disk.

The high-level organization of the file system separates three concerns, each building upon the previous: (1) implementing indirect blocks so files can be up to 512GB, (2) implementing byte-granularity reads and writes on top of blocks, and (3) implementing directories by encoding them as files with a special type together with operations to manipulate those files. §7 explains the internals of the file-system design in more detail, alongside the structure of the Dafny proof.

3.2 Transaction system

The transaction system handles concurrency and crash safety, and its API is listed in full in Figure 3. The file system creates an empty transaction by calling `Begin()`. The entire transaction appears to execute atomically when the caller finishes with `Commit`, or the transaction is discarded with no effect on `Abort`. Reads and writes operate on addresses which specify a position by giving a block number and an offset in bits (always less than $4096 \cdot 8$, the number of bits in a block). The `Read` method requires an explicit size argument while the size of a `Write` is implicit in the size of the `data` slice. We separate out the bit-sized operations to `ReadBit` and `WriteBit` (rather than using a single-element byte slice) to simplify the specification.

Figure 3 also shows the allocator API alongside the transaction API because its implementation is part of the interface that the Dafny code has access to. Allocation does not behave atomically along with the rest of the transaction, which the proof handles by allowing allocation to return any value. In

```
type Addr struct {
  Blkno  uint64
  Offset uint64
}

// starting and stopping a transaction
func Begin() *Txn
func Abort(tx *Txn)
func Commit(tx *Txn)

// operations within a transaction
func Read(tx *Txn, a Addr, sz uint64) []byte
func ReadBit(tx *Txn, a Addr) bool
func Write(tx *Txn, a Addr, d []byte)
func WriteBit(tx *Txn, a Addr, d bool)

// allocator API
func NewAllocator(max uint64) *Allocator
func Alloc(a *Allocator) uint64
func Free(a *Allocator, n uint64)
```

Figure 3: The API for the transaction system and allocator, both of which are available within the Dafny file-system implementation. Reads and writes between `Begin` and `Commit` appear to execute atomically on disk and for other threads, while `Abort` guarantees the transaction has no effect. The allocator's `Alloc` and `Free` operations are safe to call concurrently.

practice the way the file system uses such a non-deterministic specification is to store the ground-truth allocation state in the transaction system, and then to use the allocator as a hint to find free bits. As a result the return value of `Alloc()` must be checked against the durable bitmap with `ReadBit()`. Similarly, to free an address it must be both freed in memory and on disk with `WriteBit()`.

The transaction system builds upon GoJournal, verified in prior work [9], adding two-phase locking on top to implement transactions. While a transaction is running, it acquires locks for any addresses it reads or writes, and on abort or commit, it releases all locks held. Transactions that don't conflict can prepare in parallel, and GoJournal will batch concurrently committed transactions for efficiency.

Acquiring multiple locks during a transaction creates the possibility for deadlocks, for example if two threads acquire a pair of locks in the opposite order. The two-phase locking implementation does not implement a specific lock acquisition order, leaving it to the file system to avoid deadlock — the most interesting case is `RENAME`, which is discussed in more detail in §7.1.1.

4 Specifying DaisyNFS

The specification for DaisyNFS is a state machine describing an ideal NFS server in the form of an abstract state and a transition for each operation. The implementation of DaisyNFS is a binary `daisy-nfsd` that implements the NFS protocol, running on top of a disk. Then the DaisyNFS correctness theorem is a *refinement* property, which intuitively says that for any interaction with the implementation, the ideal, atomic NFS state machine could produce the same responses; §4.2 gives a more formal definition. As a result a client interacting with the server can pretend that it is the NFS state machine and ignore the complexities of its implementation.

4.1 Formalizing NFS

RFC 1813 specifies the NFS protocol, which we make mathematically precise with a state-machine representation defined in Dafny. The formalization requires first defining what state operations modify, and then a transition for each NFS operation that specifies how it changes the state and what return values are allowed. While most of the specification is deterministic, some operations have to be specified with non-determinism; for example, we allow returning an out-of-space error in many operations, and the specification allows any timestamp to be picked for the current time. The RFC is precise about arguments and allowed return values, and the text is good about explaining the intended behavior, but it does not describe the state an NFS server maintains. We define the NFS server state as shown in Figure 4.

```
// the abstract state of the file system
type FilesysData = map<Ino, File>

datatype File =
  | ByteFile(data: seq<byte>, attrs: Attrs)
  | Dir(dir: map<FileName, Ino>, attrs: Attrs)

type Ino = uint64
type FileName = seq<byte>
datatype Attrs = Attrs(mode: uint32, ...)
```

Figure 4: Dafny definition of the NFS server state (simplified).

This definition says that an NFS server conceptually maintains a mapping from inode numbers to files, where a file can either be a regular file with bytes, or a directory. Both types of files have a number of attributes, storing metadata like the file's mode (permission bits) and modification time. A directory is a partial map from file names (which are just bytes) to inode numbers. Note that DaisyNFS doesn't represent the file system as a tree but as a collection of links, which is sufficient to model all NFS operations, because NFS clients resolve pathnames.

The NFS state machine models each operation as a non-deterministic transition, written as a predicate that holds when it is allowed for an operation to change the state from `fs` to `fs'` and return `r`. The return value is always wrapped in a `Result` type, which can be either `Ok(v)` for a normal return or an error code for one of the errors defined in the standard. We systematically guarantee that the state is unchanged when an operation returns an error (though this is stronger than what the RFC requires); the transaction system makes this easy to achieve by aborting the whole transaction. For example, Figure 5 shows the specification for a (hypothetical) `GETSZ` operation that returns the size of the inode `ino`.

There are four clauses in the specification. The first just says that this operation is read-only. The second is one possi-

```
predicate GETSZ_spec(ino: Ino, fs: FilesysData,
  fs': FilesysData, r: Result<uint64>)
{
  fs' == fs &&
  (r.ErrBadHandle? ==> ino !in fs) &&
  (r.ErrIsDir? ==> ino in fs && fs[ino].Dir?) &&
  (r.Ok? ==> ino in fs && fs[ino].ByteFile? &&
            r.v == |fs[ino].data|)
}
```

Figure 5: Specification of a hypothetical `GETSZ` operation, a simplification of the real `GETATTR` operation.

Category	Operations	Verified
File and directory ops	`GETATTR`, `SETATTR`, `READ`, `WRITE`	✓
	`CREATE`, `REMOVE`, `MKDIR`, `RENAME`	✓
	`LOOKUP`, `READDIR`	✓
Unsupported features	`READLINK`, `SYMLINK`, `LINK`, `MKNOD`	✗
	`READDIRPLUS`, `ACCESS`	✗
Configuration	`FSINFO`, `PATHCONF`, `FSSTAT`	✗
Trivial operations	`NULL`, `COMMIT`	✓

Figure 6: NFS API and which operations DaisyNFS supports and verifies.

ble error: if the server returns `ErrBadHandle`, then `ino` is not allocated. The third is a different error, which says this operation returns `ErrIsDir` for directories. Finally the fourth case says that if the operation is successful, it returns the length of the data in `fs[ino]`. Dafny checks several consistency properties of this specification itself; for example, a use of `fs[ino]` will not even compile if the specification does not earlier imply `ino in fs`.

We developed a state-machine model of the regular file and directory operations in NFS in this style, including specifying what certain errors signify. Figure 6 lists the entire NFS API and what parts we verified.

DaisyNFS implements `FSINFO` and `PATHCONF`, which give the client static configuration information about the file system (for example, the maximum supported write size). These return constants and thus have no specification. DaisyNFS also implements `FSSTAT` to report total and free space, but it does not have a meaningful specification.

DaisyNFS could support some of the remaining operations with some more effort. Support for symlinks and `MKNOD` would require mostly mechanical changes to accommodate new file types. `LINK` is more complicated because in addition to tracking the link count of every file in the state, the specification for `REMOVE` needs to say that the link count is decremented and that the file is deleted if its link count drops to zero.

4.2 Specifying correctness for DaisyNFS

The transition system in §4 describes the abstraction of an NFS server, but what does it mean for the `daisy-nfsd` binary to implement this specification? To formalize DaisyNFS's correctness we use a definition of *concurrent, crash-safe refinement*, which informally says that every execution of that server binary — including with concurrent operations and crashes — has user-visible behavior that the specification could also produce (that is, the behavior is allowed by the specification). In DaisyNFS's specification the visible behavior is defined to be network requests and responses.

To define the specification, we need to be more precise about what a program is and how it executes, since these programs are used to model the DaisyNFS code and specification. We write $p : \texttt{Go}\langle \text{X} \rangle$ to say p is a Go program written using operations from layer X, where X is one of NFS, Txn, or Disk. Layer operations are always atomic transitions in a state machine. In the NFS layer, the operations behave according to the NFS state machine described previously in §4.1 and defined formally in Dafny. The Txn layer is specified both in Coq where it is part of the transaction system's correctness theorem and in Dafny where it appears as an assumption. The Disk transition system is formalized in Coq as part of the GoJournal proof, and assumes reads and writes of 4KB blocks are atomic. Each layer includes concurrent threads that interleave layer operations, basic heap operations on pointers, slices, and maps, and computation on primitives like integers and structs.

The correctness of DaisyNFS is stated in terms of a program that repeatedly receives a request, processes it in a background thread, and sends a response, which is intended to model the core behavior of the `daisy-nfsd` server. A schematic depiction of this server loop is given in Figure 7. This code starts by recovering the state of the system on line 3. Then it repeatedly accepts new requests from the network, abstracted with `GetRequest()` (including parsing the NFS wire protocol). These requests are each processed in a background thread due to the goroutine spawned on line 6. The processing for each request dispatches to the appropriate file-system operation (e.g., lines 9 and 12). The implementations of these operations are compiled from Dafny to Go and then linked with the transaction system.

The correctness theorem references three versions of this loop, at different levels of abstraction. At the top, the specification is a loop $\texttt{s}_{\text{NFS}} : \texttt{Go}\langle \text{NFS} \rangle$ which atomically processes each NFS operation according to the NFS state machine.

Below the NFS layer, $\texttt{s}_{\text{dfy}}$ models the server where each operation is replaced with its Dafny implementation, wrapped in a transaction. In this layer we write $\texttt{atomically}\{\texttt{f}\}$ to represent a transaction running `f`, which by definition in the Txn layer runs atomically for specification purposes. An `atomically` block corresponds to executable code that follows a pattern like `tx := Begin(); f(tx); tx.Commit()` to run `f` in the context of a GoTxn transaction (some additional code handling aborts is omitted in this snippet).

The final layer that models the executable code is given using a function $\text{link}(p, i)$, which takes a program p using operations from layer S and substitutes each operation with an implementation according to $i : S \to \texttt{Go}\langle \text{T} \rangle$. The notation "link" is intended as an analogy to the linking phase of compilation, taking a program p with some undefined symbols

```
// this is the core of daisy-nfsd
func main() {
  fs := filesys.Recover()
  for {
    req := GetRequest()
    go func() {
      switch req.Op {
      case CREATE:
        ret := fs.CREATE(req.Args)
        SendReply(req, ret)
      case LOOKUP:
        ret := fs.LOOKUP(req.Args)
        SendReply(req, ret)
        // ... other cases ...
      }
    }()
  }
}
```

Figure 7: A schematic depiction of the server loop, written in Go. $\mathtt{s}_{\mathrm{NFS}}$ looks like this code, but by definition all operations (for example the calls to `fs.CREATE` and `fs.LOOKUP`) are processed atomically and according to the NFS transition system. As far as the proof goes `GetRequest()` and `SendReply()` just produce a trace of I/O behavior and are unverified.

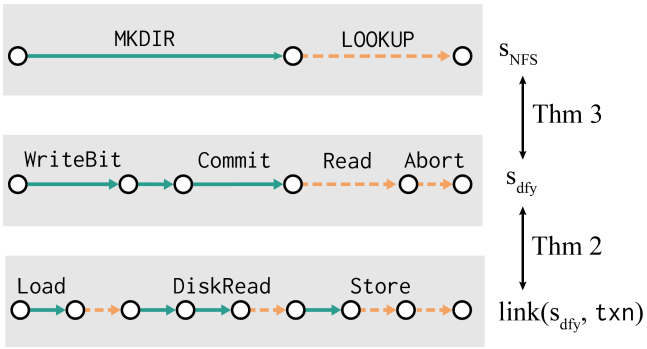

Figure 8: Illustration of the DaisyNFS proof strategy in terms of one possible execution of DaisyNFS, receiving parallel `MKDIR` and `LOOKUP` operations, at its three abstraction levels. Operations in each row are coded green and solid or orange and dashed according to which operation they correspond to (the top-level `MKDIR` or `LOOKUP` respectively). The refinement proof first shows that for every code execution (bottom row), there exists an atomic execution at the Txn layer (middle row), as proven in Theorem 2. This justifies sequential reasoning to show the transactions follow the NFS specification (top row), as proven in Theorem 3. Finally Theorem 1 puts the two together.

and substituting each symbol s with a call to an implementation of that method given by the library code $i(s)$. We write $\mathrm{link}(\mathtt{s}_{\mathrm{dfy}}, \mathtt{txn})$ to represent linking the Dafny code with the transaction system's implementation `txn`.

The proof is about the server loop at the core of `daisy-nfsd` at three layers of abstraction. Figure 8 illustrates one execution of the DaisyNFS server where two clients issue `LOOKUP` and `CREATE` in parallel, at the three levels of abstraction: the bottom shows an execution of $\mathrm{link}(\mathtt{s}_{\mathrm{dfy}}, \mathtt{txn})$ at the Disk layer, the middle a corresponding atomic execution of $\mathtt{s}_{\mathrm{dfy}}$ at the Txn layer, and finally the top-level has a single transition for each operation at the NFS layer.

Refinement relates two programs in terms of their visible behavior, which we will use to connect the server loop at the disk layer to the transaction layer and finally to the NFS layer. For the purposes of this paper, all of the programs involved are servers that issue network I/O, either receiving an NFS request or responding to one. Regardless of the level of abstraction, each model of the server defines a trace of network I/O consisting of requests and responses, and this is the behavior refinement talks about:

Definition (Concurrent, crash-safe refinement)**.** An implementation program p_c is a *concurrent, crash-safe refinement* of a specification program p_s, written $p_c \sqsubseteq p_s$, if whenever there are initial states σ_s and σ_c satisfying $\mathrm{init}(\sigma_s, \sigma_c)$ and p_c can execute from σ_c and produce a trace of network I/O tr, then p_s can execute from σ_s and produce the same trace tr. Execution might involve crashing and restarting a program (potentially multiple times), wiping out any in-memory state after each crash. When we state $p_c \sqsubseteq p_s$ we leave implicit the definition of initial states $\mathrm{init}(\sigma_s, \sigma_c)$, which will generally say both states are all zeros and of the same size.

The intuition behind the notation $p_c \sqsubseteq p_s$ is that the set of behaviors of p_c (the set of traces of network I/O tr) is a subset of the behaviors of p_s.

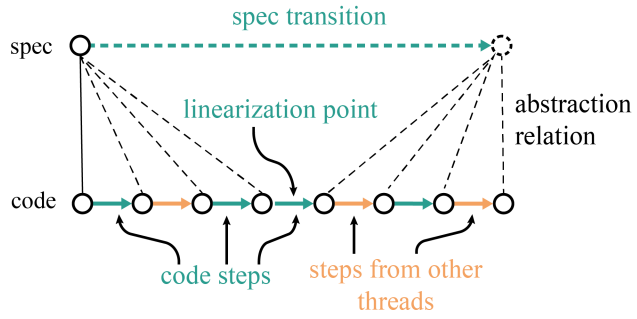
Now we have enough to state the final DaisyNFS correctness theorem:

Theorem 1 (DaisyNFS correctness)**.** $\mathrm{link}(\mathtt{s}_{\mathrm{dfy}}, \mathtt{txn}) \sqsubseteq \mathtt{s}_{\mathrm{NFS}}$.

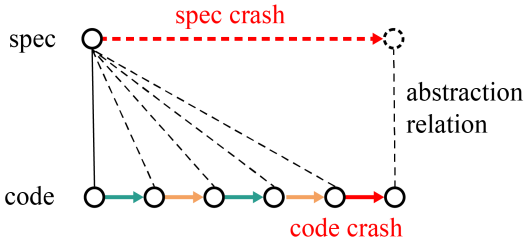
In this correctness theorem, initialization requires running a Dafny method on an empty disk. Subsequently the system boots by first recovering the transaction system, then restoring the file system. Theorem 1 will follow from the correctness of the transaction system combined with the results from Dafny.

5 Verification approach

DaisyNFS's concurrent, crash-safe refinement is a much more sophisticated property to verify than sequential refinement. Figure 9 illustrates the complexity of proving a concurrent and crash-safe refinement, whereas Figure 10a shows the relatively simple per-operation obligation for sequential reasoning. For both forms of refinement, the basic proof technique is to construct a *forward simulation* from the code execution to the specification transition system, which requires an abstraction relation connecting their states and a proof that shows the abstraction relation is preserved by operations. In a sequential, non-crash simulation, it is sufficient to show that each operation restores the abstraction relation when it returns since its intermediate states are invisible. The complication in a concurrent simulation is that the code can have many concurrent threads, each running a different operation at the specification level. The proof of any given operation must also show that the intermediate states satisfy the abstraction relation, since at any time other threads might run. Similarly, the proof of each operation's implementation must consider interference with its execution from other threads at any time.



(a) Linearizability obligation (for each operation)



(b) Crash-safety obligation (for each operation)

Figure 9: Obligations for verifying a concurrent, crash-safe refinement. The proof of refinement must show that every operation simulates the abstract specification for the operation at some *linearization point* (as illustrated in 9a), and that a crash simulates a specification crash transition (as illustrated in 9b). The abstraction relation must be preserved at all intermediate points, including after a crash.

5.1 Simulation transfer

The design of DaisyNFS uses transactions, and in particular GoTxn, to simplify the proof of concurrent refinement. Transactions appear to run sequentially, and thus should permit reasoning about the body of each transaction sequentially even though the actual execution interleaves multiple transactions. A key contribution of this paper is the formalization of a *simulation-transfer theorem* which proves that a system implemented with transactions that is verified with a *sequential* forward simulation against some specification refines the same specification in the sense of a *concurrent, crash-safe refinement* when run through GoTxn.

Due to simulation transfer, we can use the simpler verification methodology of sequential simulation for the DaisyNFS file-system code, compared to the Perennial program logic used to verify the transaction system underneath. To fully take advantage of this difference, DaisyNFS is verified using Dafny [26], an entirely different tool. Dafny is a verification-oriented programming language that is restricted to sequential proofs. The use of Dafny greatly reduces the proof burden for verifying DaisyNFS, because sequential proofs are well-suited to automation and Dafny's automation is well-developed (in contrast automation for concurrent proofs is still nascent, and would need to be integrated into Perennial to be used for these proofs).

The value of sequential proofs can be seen in the proof-to-code ratio for the transaction system, which is around 20×, versus the Dafny proofs which required about 2× as many lines of proof as code. Further evidence can be seen in the incremental development of DaisyNFS, which §9.4 further elaborates on.

To make simulation transfer this precise, let us first define "sequential reasoning" more formally. Suppose we have an implementation of layer S using operations from T. Note that all the proofs about the transaction system are for an arbitrary system with operations in S; though we use the system with an implementation of NFS, the GoTxn proof is more general. The implementation i consists of a function $i(op) : \texttt{Go}\langle \text{T} \rangle$ for each operation $op \in S$. The statement seq_refinement$\langle T, S \rangle(i)$ says that i is a correct sequential implementation of S using T. To specify the normal behavior of each operation, the definition refers to $s \overset{op}{\rightsquigarrow} s'$, which says op can transition from s to s' according to the definition of layer S. To specify correctness under crashes, this definition refers to crash(t,t') and crash(s,s'), which are the crash transitions for layers T and S respectively and model, for example, clearing the contents of memory.

Definition (Sequential refinement)**.** The implementation $i : S \to \texttt{Go}\langle \text{T} \rangle$ is a *sequential refinement*, written seq_refinement$\langle T, S \rangle(i)$, if there exists an abstraction relation $R \subseteq \Sigma_S \times \Sigma_T$ such that:
(1) for every operation $op \in S$, the following sequential Hoare triple holds:

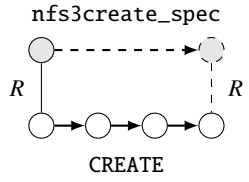
$$\{\lambda t.\, R(s,t)\}\ i(op)\ \left\{\lambda t'.\, \exists s'.\, R(s',t') \wedge s \overset{op}{\rightsquigarrow} s'\right\},$$

(2) init(s,t) must imply $R(s,t)$, and
(3) if $R(s,t)$ and crash(t, t') hold, then there exists an s' such that $R(s',t')$ and crash(s,s').

Conditions (1) and (2) in this definition are standard for sequential verification of refinement, while condition (3) is a standard condition for sequential crash-safety [7]. Though condition (3) requires the abstraction relation to be preserved by crashes, the proof engineer does *not* have to reason about crashes in the middle of operations. The diagram in Figure 10 depicts the main refinement condition (1) diagrammatically.

Simulation transfer takes a proof of *sequential* refinement conditions for a system implemented using transactions and derives a *concurrent and crash-safe* refinement. A transaction must satisfy some conditions to ensure atomicity. We write safe(p) to say that p is a valid transaction. The main restriction is that p cannot access global state such as the heap, since the transaction system does not make such accesses atomic. The implementation i in this theorem gives only the body of each transaction; the theorem instead references atomically $\circ\, i$ where $(\text{atomically} \circ i)(op) = \texttt{atomically}\{\, i(op)\,\}$ uses the macro from the Txn layer to specify that the operation is wrapped in a transaction and is thus by definition atomic.

Theorem 2 (Simulation transfer)**.** Let S be a spec layer implemented using transactions with $i : S \to \texttt{Go}\langle \text{Txn} \rangle$, such that



(a) Obligation for sequential refinement.

```
method CREATE(d_ino: uint64,
              name: Bytes)
 returns (r: Result<Ino>)
 requires R(txn_disk, fs)
 ensures R(txn_disk, fs)
 ensures r.Ok? ==>
 nfs3create_spec(d_ino, name,
   old(fs), fs, r.v)
```

(b) Dafny encoding

Figure 10: Illustration of seq_refinement(i_{NFS}) (left) and its encoding in Dafny seq_refinement$_{\text{dfy}}(i_{NFS})$ (right), for one particular operation. In the diagram, the solid parts are assumed, and the dashed parts must be shown to exist. The complete Dafny spec is more precise about errors.

seq_refinement(i) and $\forall op.\,\text{safe}(i(op))$ hold. Then

$$\forall p : \texttt{Go}\langle \text{S}\rangle, \text{link}(\text{link}(p, \text{atomically} \circ i), \texttt{txn}) \sqsubseteq p.$$

Simulation transfer says that if an implementation of S using transactions is correct in a sequential sense, then this is sufficient for any spec program p to have atomic and correct behavior for its primitives when run with GoTxn. The executable code for p derived in two steps: $\text{link}(p, \text{atomically} \circ i)$ replaces the operations in S with their atomic implementations at the GoTxn API level, while $\text{link}(\text{link}(p, \text{atomically} \circ i), \texttt{txn})$ takes the result of this process and substitutes the actual GoTxn implementations of `Begin`, `Read`, `Commit`, and so on. In §6 we discuss how this theorem is proven using Perennial and Coq.

5.2 Putting simulation transfer together with Dafny proofs

In order to use simulation transfer to obtain Theorem 1, we need to prove that DaisyNFS's implementation, i_{NFS}, satisfies the sequential refinement conditions. To do so, we define seq_refinement$_{\text{dfy}}(i)$, an encoding of sequential refinement using Dafny pre- and post-conditions (as illustrated in Figure 10), and prove that DaisyNFS satisfies these conditions in Dafny. The crash refinement condition (3) is straightforward; crashes have no effect in both the Txn layer and the NFS layers because they do not have ephemeral state. Details on how the Dafny obligations handle initialization and recovery are found in the first author's thesis [5: §6.4].

Lemma 3. seq_refinement$_{\text{dfy}}(i_{NFS})$ holds.

From here we can apply Theorem 2 to Lemma 3 and obtain Theorem 1, which says $\text{link}(\texttt{s}_{\text{dfy}}, \texttt{txn}) \sqsubseteq \texttt{s}_{\text{NFS}}$ (note that $\texttt{s}_{\text{dfy}} = \text{link}(\texttt{s}_{\text{NFS}}, \text{atomically} \circ i)$). Figure 8 illustrates just one execution that the theorem covers: the transaction system proof guarantees an atomic execution while the sequential refinement guarantees the transactions themselves are correct. There are two trusted assumptions needed for the theorems to compose. First, seq_refinement$_{\text{dfy}}(i_{NFS})$ should imply seq_refinement(i_{NFS}). That is, the encoding of the refinement conditions in Dafny must be correct, but also the semantics of the transaction system operations modeled in Dafny must match the Coq proof. Second, every Dafny transaction must be valid, meaning safe($i_{NFS}(op)$). The Dafny code satisfies safety due to a simple syntactic check: the only mutable state in the file-system Dafny class is the transaction system, so file-system operations cannot make mutations other than through GoTxn.

6 Verifying the transaction system

This section describes the implementation and proof of the transaction system, GoTxn. A contribution of this paper detailed in this section is to verify the powerful specification of Theorem 2 on top of a real implementation, which required verifying two-phase locking using local reasoning in Perennial unlike the more typical textbook proofs that reason about the global execution of many concurrent transactions. Note that this section is only about the transaction system and has nothing specific to the file system implemented on top.

6.1 GoTxn's implementation

GoTxn is implemented as an extension to GoJournal [9], a journaling system verified in Perennial. The journaling system provides the ability to write multiple objects atomically, with an implementation that provides good concurrency. For correctness GoJournal relies on the caller to guarantee that concurrent operations do not access the same disk objects. GoTxn automatically provides the concurrency control to guarantee this precondition using two-phase locking (2PL). The result is an interface that behaves atomically without any concurrency reasoning from the caller.

The two-phase locking system logically maintains a lock per object. The algorithm gets its name from an *expanding* phase in which reads and writes acquire locks as needed, followed by committing the transaction's writes to the journal and a *contracting* phase where all the acquired locks are released. Instead of committing, a transaction can abort early to abandon buffered writes and release the locks acquired so far, in which case the disk is unaffected. The whole operation appears to execute atomically at commit time; reads return their results early, but the locks ensure these values remain consistent up until the commit point. The GoTxn proof makes the informal correctness argument precise by giving a proof of a refinement-based specification.

6.2 Verifying two-phase locking with local reasoning

In §5.1, we gave Theorem 2 as the specification for the transaction system. Recall that this theorem converts sequential refinement proofs for transactions into concurrent refinement. To prove this, we first use Perennial to show that code encapsulated in a transaction truly behaves atomically, formalized with the following theorem:

Theorem 4. The GoTxn implementation `txn` is a *transaction refinement*, meaning for all $p : \texttt{Go}\langle\text{Txn}\rangle$ where $\text{safe}(p)$ holds, $\text{link}(p, \texttt{txn}) \sqsubseteq p$. The definition of $\text{init}(s,t)$ in this refinement relates an all-zero physical disk to an all-zero transactional disk of the same size.

Theorem 4 captures the intuition that transactions provide atomicity, while Theorem 2 formalizes why atomicity provides sequential reasoning. The proof of Theorem 2 from Theorem 4 is conceptually straightforward. Since the `atomically` blocks in p ensure transaction operations run without interruption, the sequential refinement diagram can be applied to code inside these blocks.

The proof of Theorem 4 itself in Perennial is more involved. The high-level approach is to encode refinement as Perennial Hoare triples, one for each operation [8, 38]. To make this sound for concurrent refinement, (1) the proof must identify and verify the *linearization point* of an operation, the time at which the operation appears to have executed; and (2) the proof tracks logical *ownership* of state, and threads may only modify state that they have "acquired" ownership of through synchronization. The resulting proof style is called "local" because we reason about each thread in isolation, considering just the parts of state it accesses. Using Perennial enables us to re-use the existing GoJournal proof, but this local proof-style is quite different from standard proofs of serializability for two-phase locking, which reason globally about the set of transactions and ordering constraints imposed by locks.

In more detail, the refinement proof must show that the code `tx := Begin(); f(tx); tx.Commit()` has a subset of executions of the `atomically{f}` construct. The difficulty in proving this is that the linearization point is at the very end when the code calls `Commit`, at which point the actual earlier execution of `f` becomes visible to other threads. We must argue that at this point the entire `atomically{f}` block's effect has occurred by tracking the behavior of `f`.

As the transaction executes, the proof tracks the initial value of any objects accessed in a map J. The domain of this map $\Sigma = \text{dom}(J)$ is the *footprint* of the transaction, which two-phase locking keeps locked during the transaction. The intuition behind the invariant is that if the transaction only depends on J, the transaction's execution can be delayed to take place atomically at the call to `Commit`, because locking prevents the subset J of the journal from being accessed by other threads. In particular the proof sets up a set of *lock invariants* that say the lock for address a is needed to access the GoJournal resource $a \mapsto_d o$, which gives permission to read and write to a. See the thesis for a more formal connection to the GoJournal specification [5: §5.5].)

The proof maintains a refinement relation during the execution of a transaction `f`, which is formally expressed using the GoJournal resources but explained more intuitively here. Let J be a map with the values of each object in the transaction's footprint Σ at the first time they are accessed by `f`, and let J' be a map with the transaction's current buffered in-memory view of the same addresses. Then, the invariant requires that after n steps of execution:

1. The transaction holds the lock for every address $a \in \Sigma$.
2. Executing n steps of `f` in *any* starting state that has the same values as J for the addresses in Σ can lead to a state with values given by J'.

At the start of a commit, the locking described by the first part of the invariant ensures that the durable value of each address still match the value in J, and is required to call the GoJournal `Commit` operation. The second part of the invariant means that even though other parts of the state outside of Σ may have changed, those changes do not affect the execution of `f`. Thus, executing `f` at this point in a single step would have the same behavior as the implementation has observed. The GoJournal `Commit` specification ensures that the durable values of objects in the footprint are atomically updated to match J'.

Showing that the second part of the invariant holds requires that code within a transaction must not access global state outside of the transaction system, as mentioned at the end of §5.1. Accesses to such global state would violate the invariant because their behavior would then depend upon things outside of the footprint Σ. Because those global values could change by the time the transaction commits, the above argument would no longer work if they were allowed.

The allocator creates another subtlety related to the second part of this invariant. Allocations do not hold the allocator lock throughout the remainder of a transaction. This seems to violate the two-phase locking pattern, since allocations could be implicitly observed by other concurrent transactions from the fact that an allocated address is no longer free. Correspondingly, in the proof, the footprint J of a transaction does not describe the allocator state. Thus, at the linearization point, the addresses returned by the allocator may no longer be free. However, because the specification for the allocator does not guarantee that returned addresses are actually free, the second part of the invariant above still holds.

7 Verifying the Dafny implementation

We follow the standard approach for verifying software in Dafny: each file-system operation is implemented as a method on a class and its specification is given using pre- and post-conditions. §5.1, explains how the Dafny proof shows the code is a correct implementation of NFS in terms of sequential refinement. This section provides details about the file-system design and proof.

DaisyNFS is implemented and verified in several layers of abstraction, depicted in Figure 11. Each layer is implemented as a class that wraps the lower layer as a field. The transaction system is an assumed interface in Dafny, while the complete server implements the NFS wire protocol and calls into the top-level Dafny class for each operation.

Layer	Functionality
dir	Directories and top-level NFS API.
typed	Inode allocation.
byte	Implement byte-level operations using blocks.
block	Gather blocks for each file into a single sequence.
indirect	Triple-indirect blocks organized in a tree.
inode	In-memory, high-level inodes; block allocation.
txn	Assumed interface to GoTxn.

Figure 11: Layers in the Dafny implementation and proof of the file-system operations.

Between the layers of the file system there are three difficult pieces of functionality: organizing data blocks into metadata and data (the indirect and block layers), translating byte-level operations into block operations (the byte and typed layers), and implementing directories as special files that the file system itself reads and writes (the dir layer). The modularity was essential to complete the proof in manageable chunks (to avoid overwhelming the developer and prover), and it would have been natural even without verification.

7.1 Implementing the file system using transactions

The design of DaisyNFS is broadly similar to the file system in xv6 [12], as well as Yggdrasil [36], a verified sequential file system. We also adopt the recursive strategy for implementing and verifying indirect blocks from DFSCQ [25]; recursion simplifies the implementation of triple-indirect blocks, which are needed to reach a reasonable maximum file size of 512GB. Unlike most file systems, DaisyNFS is designed to fit every operation into a transaction in order to support our goal of sequential reasoning. This is a non-standard design and we encountered some unique challenges in doing so. In this section we highlight difficulties in fitting two features into transactions: renaming and freeing space from deleted files.

7.1.1 Avoiding deadlock in renames

The NFS RENAME operation is similar to the `rename` system call: it moves a source file or directory to a destination location. What makes it tricky is that it involves more than one inode and hence introduces the possibility for deadlock. We use the standard strategy of enforcing a global ordering where inodes are always locked in numerical order (smaller inode numbers first); this avoids a deadlock where a cycle of threads is waiting on each other.

In a rename operation, the source and destination are each specified by a combination of the parent directory inode and name within that directory. Rename has an additional functionality of overwriting the destination if the source and destination are files, or if both are directories and the destination is empty. It is this latter check that makes deadlock avoidance difficult: it is necessary to lock the source and destination directories first to lookup the source and destination names, but those might be files that are earlier in the inode lock order. We address this in the code by returning an error from the Dafny transaction before the lock order would be violated. The error comes with the set of inodes that should have been acquired. The rename is then re-run with this set of inodes as a lock hint; these are first acquired in the correct order, then compared against the current source and destination in case they have been renamed concurrently.

At this point it is worth discussing the performance considerations that lead to handling lock ordering in the file system, rather than generically in GoTxn. The transaction system could avoid deadlocks by either enforcing a global order over addresses or by timing-out operations. Enforcing a global order is inefficient for the file system; data blocks will never cause deadlock because the file system only accesses a block after locking the (unique) inode that owns it. Timing-out operations would lead to slow and spurious transaction failures that could more rapidly be avoided in the higher-level code, hence we do not attempt to detect deadlock dynamically.

7.1.2 Freeing space

Freeing space becomes surprisingly tricky with large files. The problem is that a large-enough file may reference too many blocks to be freed in a single transaction. DaisyNFS handles freeing by removing a file from its directory and marking it free in one transaction, and in separate transactions reclaiming the space it took by deallocating its blocks.

Removal is implemented as a combination of two transactions, one which performs the logical operation but leaks space, and an operation `ZeroFreeSpace(ino)` which frees and zeroes the unused space in an inode that we prove has no effect on the file-system state. Because this operation is a logical no-op, it is safe to call it at any time. In practice the implementation is careful to call it after any operation that leaves unused blocks, in particular `SETATTR`, which can shrink a file by reducing its size, and `REMOVE`, which deletes a file. Furthermore since `ZeroFreeSpace` doesn't affect the user-visible data, it may return early to avoid overflowing a transaction, which GoJournal limits to 511 blocks.

There is one case where freeing blocks is important for correctness and not just to reclaim space. Growing a file is supposed to logically fill the new space with zeros. If the file had old data in that space, it would not be zero but some previously written and deleted data, which both violates the specification and is a potential security risk. The way we handle this with background freeing is with a run-time check: when the `SETATTR` operation grows a file checks, it checks if the free space is already zero first, and if not fails with a special error code. The unverified code interprets this as a signal to immediately call `ZeroFreeSpace` and try the operation again. The same support also handles holes created by writing past the end of a file, which are similarly supposed to be zero.

The freeing implementation is an interesting example of using validation in verification. The specification for much of the freeing code is loose, allowing any data to be written

	proof	code	spec
GoJournal	29,000	1,419	
Transaction system	10,000	250	932 (Thm 2)
File system	6,787	4,051	630 (Thm 3)
Trusted interfaces	—	—	558
`daisy-nfsd`	*unverified*	1,144	—

Figure 12: Lines of proof, code, and trusted specification. GoJournal is included only for comparison; its specification is subsumed by the transaction system's.

to the free space. We only needed a strong specification for the code that checks if the zeroing is done; the rest of the code needs to be correct for this check to ever succeed, but we aren't required to prove it.

7.2 Achieving good performance

An important aspect of the Dafny proof was to write code in a way that produces high-performance Go code. Compared to Dafny's C# backend, the generated Go code for Dafny's built-in immutable collections has much additional pointer indirection and defensive copying. Using these data structures for byte sequences would simplify proofs, but has unacceptably poor performance in Go.

To avoid this performance problem we use an axiomatized interface to Go byte slices (`[]byte` in Go) whenever raw data is required, including file data and paths, and then modify these slices in-place. It was possible to axiomatize this API without any changes to Dafny; we use a standard Dafny feature of `extern` classes to specify a Dafny class `Bytes` in terms of ghost state of type `seq<byte>` but then implement it as in Go as a thin wrapper around the native `[]byte` type. This API is trusted, so we test it: for example to catch off-by-one errors in the specification, we wrote tests like `[]byte{1,2,3}[2]` and ran them in Go and (equivalent) Dafny.

The on-disk data structures—inodes, indirect blocks, and directories—are represented in memory in their serialized form and modified by updating this representation directly, avoiding copies to move between representations. These were first written with slower purely functional code, which was then migrated to imperative code that used the functional code as a specification.

Dafny's default integer type `int` is unbounded and compiled to big-integer operations. We used Dafny's `nativeType` support to instead define a type of 64-bit integers (that is, natural numbers less than 2^{64}) and compile this to Go's `uint64`. This requires overflow reasoning, but automation makes this palatable in the proof and the performance gain is significant.

8 Development effort

We implemented DaisyNFS in a combination of Go and Dafny, with proofs in the Perennial framework (which is a library in the Coq proof assistant, heavily based on Iris [23]) and inline in Dafny. The Go side uses GoJournal, which we extend with a transaction system and concurrent allocator. The implementation is publicly available.[1]

The lines of proof, code, and specification for the layers of the system are summarized in Figure 12. GoJournal is prior work but included for comparison purposes. The GoTxn correctness proof, Theorem 2, is relatively large because code executed in `atomically` blocks can include many Go operations modeled by Perennial, and the proof has cases to handle each operation. However the result of the proof is a relatively concise specification as a plain Coq statement that doesn't refer to the Perennial logic.

The file-system operations are implemented in Dafny, which helped us verify a relatively complete system without too much tedium. The proof-to-code ratio (where code is the number of lines extracted by Dafny's `/printMode:NoGhost` flag) is about $2\times$ for the file system code. The proof summarizes the implementation well, with about $1/7$th as many lines of specification as code (about half that specification is quite verbose and concerns error codes and attributes). For efficiency, the Dafny code has trusted interfaces to primitives like byte slices and integer-to-byte encoding. Together these are written in 558 lines of trusted Dafny code. Finally, to complete the NFS server required around 1,000 lines of Go code, about half of which bridge between the Dafny method signatures and the actual NFS structs.

Similar to VeriBetrKV [18], we followed a discipline of identifying and addressing timeouts in the proof. As a result, the overall build is fast: compiling the proofs takes only 12 minutes on a slow machine in continuous integration and 4 minutes on a laptop using eight CPU cores.

9 Evaluation

In this section we evaluate DaisyNFS along the dimensions of performance (§9.1 and §9.2), correctness (§9.3), and ease of change (§9.4).

9.1 Performance

To evaluate the performance of DaisyNFS, we ran three benchmarks: the LFS smallfile and largefile benchmarks, and a development workload that consists of `git clone` from a local repository followed by running `make`. These are the same benchmarks used by DFSCQ [10] (a state-of-the art sequential verified file system) and for an unverified NFS server implemented on top of GoJournal [9]. To evaluate the benefit of concurrency, we also evaluate against a "seq txn" variant of DaisyNFS that replaces its per-address locking with a single global transaction lock. In non-concurrent workloads, this variant performs slightly better, demonstrating the overhead of fine-grained locking.

As a baseline, this evaluation uses a Linux NFS server exporting an ext4 file system mounted with `data=journal`

[1]The Dafny implementation of DaisyNFS is at `github.com/mit-pdos/daisy-nfsd`. It imports the transaction system from `github.com/mit-pdos/go-journal`.

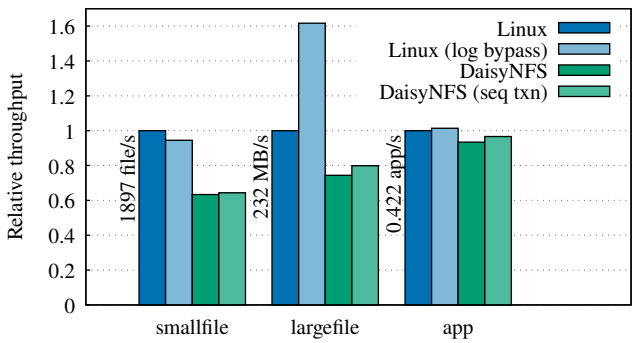


Figure 13: Performance of Linux NFS and DaisyNFS for `smallfile`, `largefile`, and `app` workloads, on an NVMe disk. DaisyNFS achieves comparable performance to ext4 in `data=journal` mode.

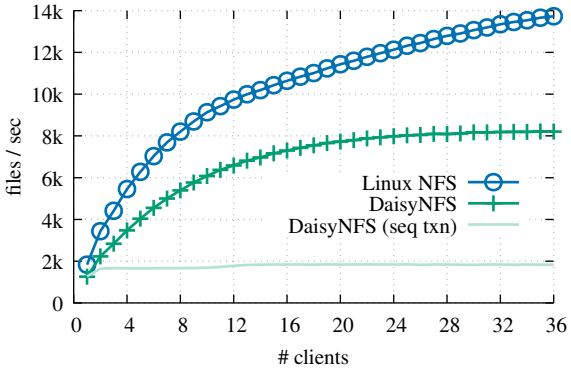

Figure 14: Combined throughput of the smallfile microbenchmark running on an NVMe disk while varying the number of concurrent clients. DaisyNFS's performance scales with the number of cores, though not as well as Linux; both eventually saturate the disk and scale sub-linearly.

mode. The NFS server lets us compare fairly since both go through the Linux NFS client and use the same underlying protocol. Using `data=journal` forces all data to go through the journal and disables log-bypass writes, which ensures that ext4 and DaisyNFS both guarantee NFS RPCs are committed durably when they return. The evaluation also presents results with ext4's log-bypass optimization (in `data=ordered` mode), which gets better performance for some benchmarks but can lose recently written data if the system crashes.

All of these benchmarks were run using Linux 5.15 and Go 1.18.1 on an Amazon EC2 i3.metal instance, which has 72 cores, 512 GB of RAM, and a local 1.9 TB NVMe SSD. To reduce variability we limit the experiment to a single 36-core socket, disable turbo boost, and disable processor sleep states; the coefficient of variation for all experiments is under 5% so we omit error bars for visual clarity.

The results are shown in Figure 13. DaisyNFS gets about 60% the throughput of Linux on the smallfile benchmark, which is intended to be metadata-heavy. The smallfile benchmark repeatedly creates a file, writes 100 bytes to it and syncs the file, then deletes it. Performance is lower than with Linux due to less efficient use of the drive; we used `blktrace` to confirm that Linux issues fewer I/O requests per iteration and that those writes are entirely sequential, unlike with DaisyNFS. Performance is comparable when run on an in-memory disk (not shown in the graph).

DaisyNFS gets comparable throughput to Linux on the largefile benchmark, which is intended to measure bulk data writes. The benchmark creates a 300 MB file by appending repeatedly, then syncs it. Note that in this benchmark ext4 is 60% faster with its log-bypass optimization due to no longer writing all data through the journal. For this workload, the Linux NFS client buffers the entire append process until the final sync, at which point it issues the writes in many chunks in parallel. These RPCs are challenging to support efficiently because they do not arrive at the server in order, so some are past the end of the file. The semantics of such a write are to fill the gap with zeros, but both DaisyNFS and Linux get good performance despite this because they implicitly encode those zeros without even allocating a block.

DaisyNFS achieves good performance on the app workload, which consists of running `git clone` on the xv6 repo followed by `make`. xv6 is an operating system, so building it requires running the usual development tools—`gcc`, `ld`, `ar`—but also running `dd` to generate a kernel image. Builds take about 3s (of which about 1.2s are spent compiling and not in the file system), which are reported as a throughput number so higher is better.

9.2 Scalability

DaisyNFS executes NFS operations concurrently to achieve better performance with multiple cores. The transaction system is built on GoJournal, which already demonstrated scalability. Here we report a similar experiment to demonstrate that DaisyNFS can take advantage of GoJournal's scalability, after accounting for the transaction system's two-phase locking and any overhead added by the transactions themselves. The benchmark used is the smallfile benchmark from §9.1, with a varying number of cores. Because this experiment runs on a physical drive, other threads have a chance to prepare transactions while the journal is committing to disk.

The results are shown in Figure 14. The graph shows that DaisyNFS gets higher throughput with more clients, though its scalability is not as good as the Linux NFS server and its peak throughput is 60% that of Linux. DaisyNFS scales sublinearly due to a lock in GoJournal that serializes installation of writes into disk blocks at commit time. As expected, with a global transaction lock performance does not improve with more clients.

9.3 Testing the trusted code and spec

For the NFS server to satisfy Theorem 1, we trust that (1) the Dafny code is a "safe" use of the transaction system, (2) sequential refinement is correctly encoded into Dafny, (3) the libraries for Go primitives are correctly specified in Dafny, and (4) the unverified Go code calling the Dafny methods

Bug	Why?
XDR decoder for strings can allocate 2^{32} bytes	Unverified
File handle parser panics if wrong length	Unverified
WRITE panics if not enough input bytes	Unverified
Directory REMOVE panics in dynamic type cast	Unverified
Panic on unexpected enum value	Unverified
Concurrent writes can conflict	Unverified
The names `.` and `..` are allowed	Not in RFC 1813
RENAME can create circular directories	Not in RFC 1813
CREATE/MKDIR allow empty name	Specification
Proof assumes caller provides bounded inode	Specification
RENAME allows overwrite where spec does not	Specification

Figure 15: Bugs found by testing at the NFS protocol level.

and implementing the NFS wire protocol is correct. Finally, the user must follow the assumed execution model and run initialization from an empty disk, run recovery after each boot, and the disk should preserve written data and not corrupt it.

Beyond satisfying this formal theorem statement, we want two more things from the implementation and specification: first that the specification as formalized actually reflects the RFC, and second we would like DaisyNFS to be compatible with existing clients, including implementing enough of the RFC's functionality. These fall outside the scope of verification so we cover them with testing.

To evaluate the file system we mounted it using the Linux NFS client and ran the fsstress and fsx-linux tests, two suites used for testing the Linux kernel. In order to look for bugs in crash safety and recovery, we also ran CrashMonkey [30], which found no bugs after running all supported 2-operation tests.

While elsewhere in this paper we interact with DaisyNFS via the Linux client, a collaborator (but not an author) tested it more directly using an NFS-specific testing tool.[2] This testing produces a wider range of requests than are possible via the Linux client. This process helped us find and fix several bugs in the unverified parts of DaisyNFS and in the specification itself. These are reported in Figure 15.

Two of the specification bugs are particularly interesting. The bounded inode bug was due to an `ino` argument of type `Ino`; this type is a Dafny *subset type*, thus adding an implicit precondition that `ino < NUM_INODES`, which is violated by the (unverified) Go code. The fix is to instead use a `uint64` and check the bound in verified code. The RENAME bug was due to having an incomplete specification (and implementation) that did not capture that RENAME should only overwrite when the source and destination are compatible.

9.4 Incremental improvements

DaisyNFS was implemented and verified over the course of three months by one of the authors, until it had support for enough of NFS to run. We added several features incrementally after the initial prototype worked, both to improve performance and to support more functionality. Some of the interesting changes are listed in Figure 16. To improve performance, we switched to operating on the serialized representation of directories directly (decoding fields on demand and encoding in-place) and then added also multi-block directories. We added support for attributes so that the file system stores the mode, uid/gid, and modification timestamp for files and directories. Finally, we implemented the freeing plan described in §7.1.2, which required additional code through the whole stack (but by design no changes to the file-system invariant). We believe additional features such as symbolic links could be added incrementally with modest effort because of sequential reasoning and proof automation.

Feature	Time	Lines
In-place directory updates	2 days	600
Multi-block directories	5 days	800
NFS attributes	4 days	500
Freeing space (§7.1.2)	3 days	1400

Figure 16: Incremental improvements were implemented quickly and without much code (which includes both implementation and proof).

10 Conclusion

This paper presented DaisyNFS, a verified crash-safe, concurrent file system. DaisyNFS was built with verification in mind in two parts: a transaction system called GoTxn, and a file system on top implemented with one transaction per operation. This design allowed us to use the sharpest tool for each part: Perennial for concurrency and crash-safety reasoning and Dafny for sequential reasoning with much proof automation inside a transaction. The specification of the transaction system was designed to support sequential reasoning from Dafny. Overall this approach results in proof overhead of about $2\times$ for the file system part (vs. $20\times$ for the transaction system), allowing us to verify and build a functional file system with good performance.

Acknowledgments

Many people helped improve this paper, including the anonymous reviewers, the PDOS students who gave feedback, Henry Corrigan-Gibbs, and our shepherd, Manos Kapritsos. James Wilcox provided expert debugging assistance. Robert Morris tested DaisyNFS and reported the bugs in Figure 15. This research was supported by NSF awards CNS-1563763 and CCF-1836712.

Abstract

The increasing use of sensitive private data in computing is matched by a growing concern regarding data privacy. System software such as hypervisors and operating systems are supposed to protect and isolate applications and their private data, but their large codebases contain many vulnerabilities that can risk data confidentiality and integrity. We introduce Realms, a new abstraction for confidential computing to protect the data confidentiality and integrity of virtual machines. Hardware creates and enforces Realm world, a new physical address space for Realms. Firmware controls the hardware to secure Realms and handles requests from untrusted system software to manage Realms, including creating and running them. Untrusted system software retains control of the dynamic allocation of memory to Realms, but cannot access Realm memory contents, even if run at a higher privileged level. To guarantee the security of Realms, we verified the firmware, introducing novel verification techniques that enable us to prove, for the first time, the security and correctness of concurrent software with hand-over-hand locking and dynamically allocated shared page tables, data races in kernel code running on relaxed memory hardware, integrated C and Arm assembly code calling one another, and untrusted software being in full control of allocating system resources. Realms are included in the Arm Confidential Compute Architecture.

1 Introduction

The use of sensitive private data in many applications from advertising to healthcare, often in the context of machine learning models, has raised concerns regarding the privacy of data in computing. These applications increasingly run on commodity cloud providers. For example, data and computation may be contained in virtual machines (VMs) running on shared hardware in the cloud, relying on a hypervisor to preserve VM isolation to protect applications and their data in VMs.

Software stacks generally require applications to trust system software which they rely on, such as hypervisors and operating systems (OSes). Although hypervisors and OSes are supposed to protect applications and their private data, their large codebases contain vulnerabilities that can risk data confidentiality and integrity. Vulnerable system software running at more privileged levels that can access application data is a significant security issue.

To address this problem, we introduce the *Arm Confidential Compute Architecture (Arm CCA)*. CCA provides *Realms*, secure execution environments that are completely opaque to privileged, untrusted system software such as OSes and hypervisors. CCA retains the ability of existing system software to manage hardware resources for Realms while preventing it from violating Realm confidentiality and integrity. For example, a hypervisor should retain its ability to dynamically allocate memory to or free memory from a Realm VM, but must never be allowed to access the protected memory contents of a Realm VM. CCA guarantees the confidentiality and integrity of Realm code and data in use, that is data in CPU registers and memory, but makes no guarantees regarding their availability. Confidentiality means that any change that a Realm makes to its private data cannot be observed by other Realms or untrusted system software. Integrity means that a Realm will not observe any changes to its private data that it did not make. Because CCA does not guarantee availability, a Realm data access is allowed to halt Realm execution.

CCA avoids hardware complexity by only introducing core hardware mechanisms for attestation and basic address space protection, then relying on firmware to manage the use of those mechanisms. Specifically, CCA introduces *Realm world*, a new physical address space for Realms orthogonal to privilege levels and separate from the existing *Non-Secure (NS) world* used today for running software stacks. Within each world, the normal privilege levels apply and instructions retain their existing semantics, but software in NS world cannot access CPU state and memory used by software in Realm world. CCA introduces a new *Realm Management Monitor (RMM)*, firmware which runs in Realm world at a higher privilege level than Realms. Untrusted system software such as a hypervisor running in NS world can then make requests to RMM to manage Realms, including creating and running Realms. RMM protects the confidentiality and integrity of Realms while handling such requests. System software in NS world is expected to retain full control of the dynamic allocation of hardware resources to Realms, including memory allocation and CPU scheduling.

Because any compromise of RMM could violate the security guarantees of Realms, it is crucial to formally verify its security and functional correctness. However, verifying RMM poses at least four significant challenges. First, RMM employs fine-grained synchronization mechanisms such as hand-over-hand locking to improve performance. Second, RMM has data races and runs on Arm multiprocessor hardware with relaxed

memory behavior. Third, RMM contains both C and Arm assembly code integrated together which call one another freely. Finally, RMM must protect the confidentiality and integrity of Realms even though untrusted system software has full control over the dynamic allocation of Realm resources. Previous verification approaches have not been able to verify system software with these properties [10, 11, 13, 26, 42, 43, 50, 62]

To verify RMM, we introduce VIA (Verification Infrastructure for Armv9-A), which supports four key verification techniques. First, VIA introduces *mover oracle queries* to combine a local CPU model with mover types [44]. These queries encapsulate how operations on other CPUs are interleaved with local CPU operations and can be reordered using mover types to group local CPU operations together. Along with the local CPU model, this allows easier sequential reasoning and modular verification. This makes it possible for the first time to verify hand-over-hand locking with dynamically allocated shared multi-level page tables in system software.

Second, VIA decomposes concurrent code into data race free (DRF) and not-DRF components, then introduces *permutation conditions* for the latter such that proofs on a sequentially consistent memory model will hold on relaxed memory hardware for all concurrent code. Instead of having to verify all of the code directly on relaxed memory hardware, all that is required is to prove that the code satisfies the permutation conditions, which ensure equivalent behavior on sequentially consistent and relaxed memory hardware. VIA allows any permutation conditions to be defined, supporting verification of a broad class of programs.

Third, VIA bridges incompatibilities between C and assembly code due to CPU register state being hidden by the former but explicitly used by the latter. To accomplish this without dependencies on a specific compiler, VIA introduces a register accounting mechanism to correctly verify integrated C and Arm assembly code. It leverages the machine-level procedure call standard for the Arm instruction set to specify how registers are potentially used when assembly code calls a C function or is called by a C function. VIA tracks CPU register state across invocations of both C and assembly code primitives, capturing any information flow through CPU registers even if hidden by C semantics.

Finally, VIA introduces an ideal/real paradigm for verifying security properties that can be applied to Realms, even though untrusted system software is in full control of system resources and can reclaim system resources such as memory without Realm permission, breaking noninterference. VIA defines an *idealized secure machine model* that supports declassification. Realm private data is stored in physically isolated memory and CPU registers. Data channels, governed by security policies, are used to exchange information between Realms and untrusted software. We can then prove the security guarantees of Realms by verifying that the implementation refines its specification and the real system captured by the specification simulates the idealized secure machine model. This approach allows us to prove, for the first time, the integrity and confidentiality of Realms. A key feature of the proof is that it only needs to trust the specification of the small idealized secure machine model; the much larger specification of the real system does not need to be trusted.

We implemented, evaluated, and verified an early prototype of CCA firmware. Although CCA hardware is not yet available, we demonstrated CCA on a functionally accurate Arm Fast Model with CCA support. We modified the Linux KVM hypervisor [19–21] to run on CCA and manage Realm VMs, and ran various VM workloads on the model. We also ported CCA firmware to current Arm hardware to obtain preliminary data on CCA performance, which shows that KVM on CCA incurs modest overhead versus vanilla KVM on real application workloads. We verified the correctness of both the C and Arm assembly CCA firmware implementation, including RMM, proving its implementation refines its specification through 43 abstraction layers. We then proved the specification is equivalent to the behavior of the idealized secure machine model to verify the confidentiality and integrity guarantees of Realms. The proof only needs to trust roughly 200 lines of Coq specification, making the formal security guarantees easy to read and understand. This is the first proof of the security guarantees of a confidential computing architecture. Realms will be included in Armv9-A, the next version of the Arm architecture.

2 Threat Model

We consider an attacker without physical access to the machine and assume the attacker's goal is to compromise the confidentiality and integrity of VM data. Confidentiality and integrity attacks in scope include compromising the hypervisor or any other software to read or modify private VM memory or register state, including by controlling DMA-capable devices, or via memory remapping and aliasing attacks. We assume a VM does not voluntarily reveal its own private data whether on purpose or by accident, but attacks from other compromised VMs, including confidentiality and integrity attacks, are in scope. Availability attacks by a compromised hypervisor are out of scope. Protection against known software error injection attacks and side-channel attacks require appropriate usage of architectural mitigations and are beyond the scope of this paper. DRAM attacks, such as cold boot attacks, live probing, or replay, require additional hardware and are outside of the scope of the threat model.

3 CCA Design

A key challenge with introducing Realms is how to provide backwards compatibility with a widely-used existing architecture that, like other CPU architectures, was designed based on the fundamental assumption that more privileged levels have greater control and access than less privileged levels of

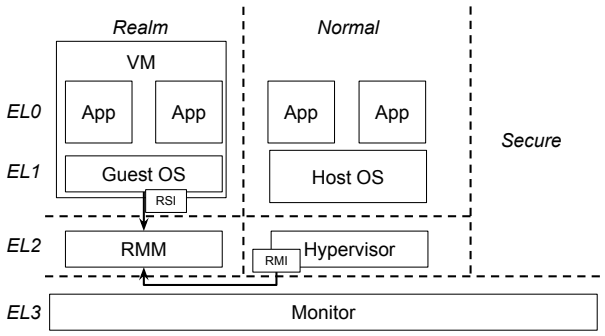

Figure 1: Arm Confidential Compute Architecture.

software. One issue is understanding the potential interactions of Realms with all the features in the Arm architecture. For example, debug registers defined in the Arm architecture are explicitly designed to allow hypervisors to peer into VM state, which is fundamentally at odds with Realms. The behavior of each instruction could be redefined in the context of Realms, but this would be an enormous undertaking with unclear compatibility implications, given that the Arm instruction set was designed over multiple decades.

Another issue is how to provide memory protection and isolation for Realms. The way this works for VMs is that hypervisors manage *nested page tables (NPTs)* [9] to isolate physical memory between VMs and protect hypervisor memory from VMs. The physical addresses perceived by a VM are *intermediate physical addresses (IPAs)*, which are translated by an NPT to physical addresses for the hardware. Physical memory not mapped to the NPT is not accessible to the VM. However, NPTs are under full control of the untrusted hypervisor, providing no protection against hypervisor access to VM data. While it would be possible to introduce an additional data structure to track memory ownership for each frame of physical memory [3], this approach comes with several problems. First, the amount of information required for each frame of memory would be substantial and significantly impact TLB design and performance. Second, this data structure would have to be managed either via a separate more privileged software entity than the hypervisor or via complex instructions capable of capturing measurements of data assigned to a Realm. Such complex CISC-like instructions would almost certainly require introducing extensive microcode into an architecture, which does not currently use any.

CCA avoids these problems by only introducing simple hardware mechanisms orthogonal to existing privilege levels and then relies on firmware to manage the use of those mechanisms. This reduces hardware complexity at the cost of depending on the firmware for the security guarantees of the architecture. As a result, verifying CCA firmware is of crucial importance.

Figure 1 shows how CCA extends the Arm architecture. Armv8-A provided two statically partitioned worlds, NS world used by most software stacks and Secure world to host

Security State	PAS			
	NS	Secure	Realm	Root
NS	Allow	Block	Block	Block
Secure	Allow	Allow	Block	Block
Realm	Allow	Block	Allow	Block
Root	Allow	Allow	Allow	Allow

Table 1: CCA access control policy. The entity accessing a granule belongs to a security state, while the PAS is a property only of the granule being accessed.

platform security services [4]. CCA introduces Realm world, which is fully compatible with NS world so that existing software stacks that run in NS world can also run in Realm world. CCA provides three privilege levels in each of the NS, Realm and Secure worlds: EL0 for user, EL1 for kernel, and EL2 for hypervisor. Because Realm and Secure worlds are mutually distrusting, CCA introduces a fourth, more privileged Root world to manage switching between the other worlds.

Each world has its own *Physical Address Space (PAS)*. Each 4 KB frame of physical memory, which we refer to as a *memory granule*, belongs to one PAS at any given time. Individual memory granules can be dynamically transitioned from NS PAS to Realm PAS; there is no static partitioning of resources between NS and Realm worlds. Hardware performs a PAS check on each memory access against a *Granule Protection Table (GPT)* that tracks the PAS of each memory granule and enforces the access control policy shown in Table 1, forbidding invalid accesses. NS world can only access its own memory. Realm and Secure worlds can access their own respective memory and NS memory, but cannot access each other's memory. CCA hardware requires all DMA accesses be subject to GPT checks, protecting the Realm PAS against DMA-based attacks. We focus on the interactions between NS and Realm worlds and omit further discussion of Secure world due to space constraints.

CCA relies on two trusted firmware components: RMM and the *EL3 Monitor (EL3M)*. RMM runs at EL2 in Realm world. It controls the execution of Realms and provides services to untrusted system software running in NS world. It isolates Realms from each other using existing virtualization technologies such as NPTs and CPU register save/restore sequences. Because RMM only enforces the security guarantees of CCA, it can be orders of magnitude smaller than bare-metal hypervisors which must also provide virtualization functionality. For example, to run Realm VMs, RMM protects the confidentiality and integrity of Realms while relying on existing hypervisors for everything else, including resource allocation and scheduling, physical hardware support, and complex device emulation.

EL3M runs in Root world at EL3, the highest level of privilege. It is responsible for context switching CPU execution among the three other worlds and managing the GPT. EL3M can access memory in any PAS. Only EL3M can change the PAS of a granule, which involves updating its entry in the GPT. Software running in the three other worlds can issue a *Secure Monitor Call (SMC)* to EL3M to request a PAS change.

In the current version of CCA, the Realm isolation boundary

Command	Description
`Version`	Query RMI ABI version.
`Granule.Delegate`	Change granule (from NS) to Delegated.
`Granule.Undelegate`	Change granule (from Delegated) to NS.
`Realm.Create`	Create Realm Descriptor (RD).
`Realm.Destroy`	Destroy Realm identified by RD.
`Realm.Activate`	Change Realm (from New) to Active.
`REC.Create`	Create Realm Execution Context (REC).
`REC.Destroy`	Destroy REC.
`REC.Run`	Enter REC (i.e. run VCPU).
`Data.CreateUnknown`	Change granule to Data with unknown content.
`Data.Create`	Change granule to Data, copy NS content.
`Data.Destroy`	Change Data granule to Delegated, zeroed.
`RTT.Create`	Create Realm Translation Table (RTT).
`RTT.Destroy`	Destroy RTT.
`RTT.MapProtected`	Map Data granule in RTT.
`RTT.UnmapProtected`	Remove mapping from RTT.
`RTT.MapUnprotected`	Map NS granule in RTT.
`RTT.UnmapUnprotected`	Remove NS mapping from RTT.
`RTT.ReadEntry`	Return content of an RTT entry.

Table 2: RMM Realm Management Interface (RMI).

is at the level of entire VMs; applying Realms to secure other entities such as containers [59] is future work. Similar to normal VMs, a Realm VM can concurrently run multiple virtual CPUs (VCPUs) and the number of Realm VMs on a system is only limited by the amount of physical memory available, not by any arbitrary limits. The untrusted hypervisor always has the ability to stop scheduling a Realm and can always reclaim memory assigned to a Realm, but in no circumstances does it have access to Realm CPU or memory state.

This split of responsibility between an untrusted hypervisor and RMM, where the untrusted hypervisor allocates memory, and RMM provides integrity and confidentiality guarantees for the data and code stored in that memory, is accomplished through a simple but powerful delegation concept. The hypervisor *delegates* memory to Realm world, and *undelegates* memory back to NS world. All memory used by Realms must first be delegated by the hypervisor; RMM does not itself manage a pool of memory for Realms. Once memory is delegated to Realm world, the hypervisor can request RMM to use it for various purposes, such as storing metadata or data for a Realm. Whenever a memory granule is delegated to Realm world but not used by RMM, RMM ensures that the granule contains only zeros, reducing the risk of accidental information flow when a granule is reused or undelegated.

RMM provides a *Realm Management Interface (RMI)* for the hypervisor to request RMM to delegate memory, create Realms, execute Realms, and allocate memory to Realms. Each RMI command is implemented as an SMC, so when the hypervisor invokes the command, it traps to EL3M, which in turn switches execution to RMM in Realm world to handle the command. Upon completion of the RMI command, RMM issues an SMC to EL3M, which switches execution back to the hypervisor in NS world. Table 2 lists the RMI commands.

RMM must know the state of each memory granule on the system to uphold the security guarantees of Realms, which it accomplishes by maintaining its own *Granule Status Table (GST)* to track the delegation status and current use of each granule. RMM uses the GST to ensure that a granule is in a valid state to perform the requested action. For example, when the hypervisor delegates a memory granule, RMM checks its GST to confirm the granule has not already been delegated, then issues an SMC to EL3M to request a change to Realm PAS. EL3M checks that the granule is currently in NS PAS, then updates the GPT to move it to Realm PAS. Finally, RMM updates its GST to record that the granule has been delegated. If the hypervisor attempts to delegate a granule which is already delegated, or undelegate a granule which is in active use by RMM, RMM returns an error code to the untrusted hypervisor. This pattern of checking valid states and either performing a discrete action or returning an error is used for all RMI commands, allowing RMM to remain in overall control of the consistency of the system, while complex logic for policy and resource allocation remains in the hypervisor. Unlike the GPT, the GST is not checked by hardware and is only a software bookkeeping mechanism. By maintaining a separate GST from the GPT, the GPT can be kept simple so that it only needs to contain information required for hardware-enforced checks.

The hypervisor creates Realms, *Realm Execution Contexts (RECs)*, and *Realm Translation Tables (RTTs)* using the respective commands in Table 2. RECs correspond to VCPUs and RTTs correspond to NPTs for normal VMs. RTTs are Arm stage 2 page tables that translate from an IPA to a physical address. RTTs use the same format and topological layout in Realm world as NS stage 2 page tables, but also provide a bit which allows Realms to access NS granules under the control of RMM, for example, for virtual I/O between a Realm and the hypervisor. On each of the Realm, REC, and RTT create commands, RMM checks the GST entry for the address provided to confirm the granule is already delegated, and updates the GST entry to track that it is being used for Realm, REC, and RTT metadata, respectively. We refer to a Realm's metadata as its *Realm Descriptor (RD)*.

A Realm provides a *Protected Address Range (PAR)* within its IPA space, which RMM ensures can only be mapped to Realm PAS granules. For accesses within the PAR, RMM guarantees confidentiality and integrity to the Realm; outside the PAR, the hypervisor is free to map NS PAS granules or emulate accesses. This provides an OS running inside a Realm VM with a reliable mechanism to determine whether it is accessing its own private memory, or memory which can be shared with untrusted agents, for example, buffers used for untrusted DMA with virtual or physical network and block devices.

During Realm creation, the hypervisor can assign a granule to the Realm at a specific IPA and copy data to it from an NS granule. The IPA and data are cryptographically hashed and the hash is included in the attestation token of the Realm. The attestation token allows a Realm owner to reason about its initial state and content. Once a Realm has been activated, the measurement is fixed, and memory can only be added to otherwise unused IPAs with unknown content. We refer

to delegated granules used to store data for a Realm as *Data granules*. The hypervisor can request that RMM maps NS granules outside the PAR at any time. Physically contiguous delegated memory can be mapped to a Realm in blocks larger than 4 KB granules to optimize TLB usage.

The hypervisor can reclaim memory from a Realm at any time. RMM zeros a granule before undelegating it and returning it to the hypervisor. Subsequent accesses from a Realm to the IPA where the memory was reclaimed result in a stage 2 abort to RMM which prevents further execution of the Realm and preserves the CCA integrity guarantee. The hypervisor cannot subsequently map a granule to a previously-backed IPA within a PAR without Realm permission.

As a system designed to scale to many cores, RMM makes extensive use of fine-grained locking to support a high degree of concurrent operation. For example, each memory granule has its own lock so many granule operations can be done in parallel. Similarly, an RTT is a multi-level page table, for which each level has its own lock, and hand-over-hand locking is used to support concurrent operations on RTTs, as discussed in Section 4.1. For example, two Realm VCPUs can each cause a stage 2 page fault at the same time but at different IPAs, which can be resolved by the hypervisor in parallel on two CPUs to improve performance. This is a key requirement to support large Realms. Although most of RMM is written in C, Arm assembly code is also used to implement memory accesses with acquire/release semantics where lockless concurrent accesses are used for performance reasons, and to implement the locking primitives themselves.

CCA firmware is designed for security following best practices. Systems such as Linux map all physical memory to the kernel page table. RMM and EL3M do not. RMM's own page table statically maps code and metadata exclusively accessed by RMM, such as the GST and locks for each granule. Additional entries in RMM's page table are used to statically assign a virtual address range to each physical CPU in the system, resulting in a fixed number of virtual address slots per CPU. Memory is then mapped on demand when needed. RMM maps Data granules and metadata granules, such as RD and REC, on demand, and unmaps them once the respective operation is completed. EL3M's own page table only statically maps the EL3M code, a small fixed size stack, and the GPT; no other memory is mapped to its page table. Furthermore, SMC parameters are only interpreted as values in EL3M, never as pointers used to access memory. Even if a bug is introduced in some future version of CCA firmware that is not completely verified, these defense-in-depth measures make it much harder for a return-oriented or jump-oriented programming attack to succeed.

4 VIA Framework

Because CCA relies on firmware to guarantee the security of Realms, we verify that firmware, namely RMM and EL3M. We prove the CCA firmware implementation refines its layered specification in Coq, then use the top-level specification to prove the system's security properties hold for the implementation. To accomplish this, we developed the VIA verification framework, which supports layered verification of CCA firmware. VIA introduces four key verification techniques: mover oracle queries, relaxed memory support via permutation conditions, register accounting for C and assembly code integration, and a new ideal secure system model for proving security properties that cannot be verified using traditional noninterference-based approaches.

4.1 Mover Oracle Queries

To verify RMM, it is essential to simplify reasoning about possible interleavings of executions of concurrent software across multiple CPUs. For example, RMM uses hand-over-hand locking to synchronize access to RTTs, which are 4-level page tables, allowing multiple CPUs to manipulate the same page table concurrently. Figure 2 shows the steps to allocate delegated granules as new level `T1`, `T2`, and `T3` tables of a Realm's RTT using `RTT.Create` and then, in step 4, allocate a delegated granule to the Realm for its data and map its physical address to the leaf-level `T3` table using `RTT.MapProtected`, which would typically occur on a page fault. Figure 2 also shows how step 4 uses hand-over-hand locking, in which RMM first acquires `T0`'s lock so it can lookup and acquire `T1`'s lock and release `T0`'s lock. It can then lookup and acquire `T2`'s lock and release `T1`'s lock, so it can lookup and acquire `T3`'s lock and release `T2`'s lock, and finally update `T3`'s page entry. At the same time, RMM running on other CPUs can do other page table operations, such as acquiring `T0`'s lock to work on a different level 1 table.

To verify the page table operations with hand-over-hand locking, we need to reason about the correctness of all possible interleavings of operations. However, reasoning about all possible interleavings of all operations all at once is too difficult to do for a system as complex as RMM. To address this problem, VIA introduces mover oracle queries, a new mechanism that combines the power of local CPU reasoning with mover types [44], building on previous work on CertiKOS [24–27] and CSPEC [10].

To explain how mover oracle queries work, consider first an explicit multiprocessor machine model, whose machine state consists of per-physical CPU private state (e.g., CPU registers) and a global logical log, a serial list of events generated by all CPUs throughout their execution. Instead of explicitly modeling shared objects, events incrementally convey interactions with shared objects, whose state may be calculated by replaying the logical log. An event is emitted by a CPU and appended to the log whenever that CPU invokes a primitive that interacts with a shared object. Our abstract machine is formalized as a transition system, where each step models some atomic computation taking place on a single CPU; concurrency is realized by the nondeterministic interleaving of steps across all CPUs. However, reasoning

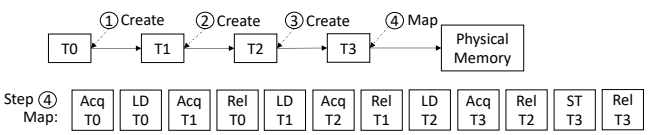

Figure 2: Page table creation and hand-over-hand locking execution.

about interleavings directly with multiple CPUs is difficult.

To simplify reasoning about all possible interleavings, we instead lift multiprocessor execution to a local CPU model, which distinguishes execution taking place on a particular CPU from its concurrent environment [27, 36, 42]. All effects coming from the environment are encapsulated by and conveyed through an *event oracle*, which yields events emitted by other CPUs when queried. Querying the event oracle can be thought of in the context of the explicit multiprocessor machine model as returning events from the global log generated by all other CPUs; only new events since the last query are returned. How the event oracle synchronizes these events is left abstract, its behavior constrained only by rely-guarantee conditions [35]. Since the interleaving of events is left abstract, our proofs do not rely on any particular interleaving of events and therefore hold for all possible concurrent interleavings.

A CPU captures the effects of its concurrent environment by querying the event oracle between local CPU steps. A CPU only needs to query the event oracle when interacting with shared objects, since its private state is not affected by these events. In other words, the CPU repeatedly performs two steps when interacting with shared objects: querying the event oracle to obtain events from other CPUs, then generating a local CPU event. The result is a composite log of events from other CPUs interleaved with events from the local CPU. This is equivalent to the logical log in the explicit multiprocessor model, but without the complexity of directly reasoning about multiple CPUs.

If possible, we would like to move the interleaved event oracle queries out of the way of the local CPU events so we can use sequential reasoning regarding the local execution of any given CPU. By using mover types, we can identify how we can reorder event oracle queries with respect to local CPU events without changing the machine's behavior. Thus, these queries are mover oracle queries. We classify all local CPU events in the composite log as RightMover, LeftMover, or NoneMover. Mover oracle queries can be reordered before a RightMover and after a LeftMover. For example, acquiring a lock is a RightMover because if other CPUs do something after acquiring the lock on the local CPU, they must be able to do the same thing before acquiring the lock. The oracle queries which capture the other CPUs' events can be reordered before acquiring the lock. Mover oracle queries cannot be reordered with a NoneMover. For example, an oracle query followed by a NoneMover then a LeftMover cannot be reordered after the LeftMover.

VIA can then reduce the interleaving of events in the log that need to be considered in two ways, which we refer to as *log refinement*. First, we can reorder oracle queries with local CPU

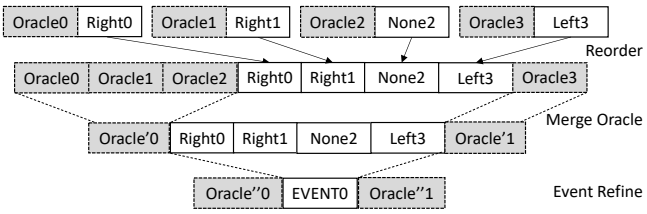

Figure 3: Log refinement with mover oracle queries.

events based on the local events' mover types. By reordering, consecutive oracle queries will be merged to one. Second, we can prove local sequences of events generated by the machine refine an aggregate local event generated by a higher-level machine. This refinement can be applied to any arbitrary CPU, therefore, it applies to all CPUs, so that the entire log of events refines the log of the higher-level aggregate events.

Figure 3 shows an example of log refinement to reduce interleavings of events across CPUs into an atomic event. We identify the mover type of each local event, i.e. [`Right 0`, `Right 1`, `None 2`, `Left 3`], and initially query the oracle before each event. Based on the mover types, we can reorder all oracle queries before the NoneMover to the beginning, and all remaining queries to the end, such that the log before and after reordering have the same machine behavior. We then define a new oracle that can be queried to return the consecutive events from the previous oracle queries [`Oracle 0`, `Oracle 1`, `Oracle 2`], allowing those events to be merged into a single oracle query [`Oracle' 0`]. We then refine the local sequence of events [`Right 0`, `Right 1`, `None 2`, `Left 3`] into a single higher-level aggregate local event `EVENT 0`. This can be done for all CPUs so we can reason further only using the higher-level aggregate event `EVENT 0` with oracle queries `Oracle" 0` and `Oracle" 1` that also return higher-level aggregate events, instead of the many `Left/Right/None` events of lower-level machine.

4.2 Permutation Conditions

To verify RMM, we must account for the relaxed memory behavior of the Arm architecture on code that is not data race free (DRF). For example, Figure 4 shows how a Realm's list of `RECs` is updated in `REC.Create`, `REC.Destroy`, and `Realm.Destroy` without holding a common lock. Each Realm's `RD` has a `RECLIST` (`rd->rec_list`), an array that stores the pointers to all its `RECs`. The `RECLIST` can be referenced from both the Realm's `RD` and each of the Realm's `RECs` (`rec->rec_list`). Each `REC` records its index in the `RECLIST` (`rec->id`). `RD`'s `counter` keeps tracking of how many `RECs` are in a Realm. The hypervisor must destroy all `RECs` of a Realm before destroying its `RD` because once `RD` is destroyed, the Realm can no longer be referenced. Access to the `RECLIST` is not synchronized by its own lock, to avoid potential deadlock issues due to needing to hold multiple locks. Instead, in `REC.Create`, the `RD`'s lock must be held to insert a new `REC` in `RECLIST` to ensure mutual exclusion. However, in `REC.Destroy`, the `REC`'s lock is held instead of the `RD`'s

```
Rec.Create(rd, id) {
    acq(rd->lock)
    ...
(a) if (rd->rec_list[id] == NULL) {
(b)   rd->rec_list[id] = NEW_REC;
(c)   atomic_inc(rd->counter);
    ...
    rel(rd->lock);
}
```

```
Rec.Destroy(rec) {
    acq(rec->lock);
    ...
(d) rec->rec_list[rec->id] = NULL;
(e) atomic_dec(rec->rd->counter);
    rel(rec->lock);
}
```

```
Realm.Destroy(rd) {
    acq(rd->lock);
    ...
(f) if (rd->counter == 0) {
      // rec_list should be EMPTY
(g)   destroy(rd->rec_list);
    ...
    rel(rd->lock);
}
```

Figure 4: Pseudo code of `RECLIST` data races, marked in bold blue.

locks when clearing the `REC`'s entry from the `RECLIST` so that multiple CPUs can destroy different `REC`s of the same Realm concurrently. Furthermore, the `RD`'s `counter` is increased or checked in `REC.Create` and `Realm.Destroy` while holding `RD`'s lock, but it is decreased in `REC.Destroy` without holding any lock. As a result, data races can occur when concurrently executing `REC.Destroy` with `REC.Create` or `Realm.Destroy`.

To address this problem, VIA builds on VRM [57]. VRM verifies programs on Arm relaxed memory hardware that are DRF except for synchronization methods and virtual memory hardware. VRM verifies a program on a sequentially consistent (SC) multiprocessor hardware model, defines and proves that a fixed set of conditions hold for the program running on relaxed memory hardware, and proves that the conditions guarantee that the program has the same behavior on SC and relaxed memory hardware so that its SC proofs also hold for relaxed memory hardware.

VIA generalizes this approach for programs that are not DRF. It ensures that such a program will have the same behavior on SC and relaxed memory hardware by first decomposing the program into components that are DRF and not DRF. Previous work already shows that the DRF components will have the same behavior on SC and relaxed memory hardware [57]. VIA then introduces *permutation conditions* $\mathcal{P}$ on the non-DRF components such that $\mathcal{P}$ can be verified to hold for the program on relaxed memory hardware, and $\mathcal{P}$ can be proven to guarantee that the non-DRF components will have the same behavior on SC and relaxed memory hardware. Our experience suggests that even for programs that are not DRF, only a small percentage of the code in these programs is not DRF, so non-DRF programs can be verified on relaxed memory hardware by only proving a small number of permutation conditions in practice. This observation holds for RMM, in which almost all of the code is DRF.

VIA uses VRM's extended Promising Arm model [57] to model Arm's relaxed memory hardware, such that $\mathcal{P}$ needs to be verified against all instruction permutations of the program allowed by VRM's Promising Arm model. Unlike VRM which defines a fixed set of conditions that do not all hold for RMM, VIA allows any condition $\mathcal{P}$ to be specified for non-DRF components that will result in their behavior being in the same on SC and relaxed memory hardware and that can be proven to hold for the program on relaxed memory hardware. The condition is essentially a constraint based on the program's semantics that restricts the possible instruction reorderings that can occur on relaxed memory hardware so that resulting program behavior is the same on SC and relaxed memory hardware.

For example, to handle the non-DRF code in Figure 4, we identify $\mathcal{P}$ to be when `Realm.Destroy` finds `rd->counter` equals 0, `rd->rec_list` must be empty. This is necessary because `rd->rec_list` must be empty when destroying it in `(g)`, otherwise the system may crash due to reclaiming non-empty memory. Since `REC.Create` and `Realm.Destroy` use the same lock, data races can only occur when either runs concurrently with `REC.Destroy`. We prove each function always behaves the same on SC and relaxed memory. For `REC.Create`, since `(b)` and `(c)` cannot be reordered with `(a)` due to the branch dependency, as required by Promising Arm, its possible executions are `(a)(b)(c)` or `(a)(c)(b)`. Since `(a)` confirms that `rec_list[id]` is empty, all concurrent `REC.Destroy` on other CPUs must destroy slots other than `id` because `REC.Destroy` will only work if the `rec` exists, which must be a non-empty slot in the `rec_list`. Therefore, swapping `(b)` and `(c)` will never change any CPU's behavior and `(a)(c)(b)` is equivalent to `(a)(b)(c)`, which is the order on SC. For `REC.Destroy`, if `(e)` executes before `(d)`, $\mathcal{P}$ will be broken because when `Realm.Destroy` checks `counter` concurrently on other CPUs, it may find `counter` is 0 but `rec_list` is not empty, as shown below:

This was actually a real bug in the prototype implementation of RMM. Therefore, we must enforce that `(d)` always executes before `(e)` by adding a barrier between them so it must follow program order as on SC. For `Realm.Destroy`, the proof is trivial because the branch dependency between `(f)` and `(g)` guarantees that they execute in program order as on SC. Therefore, this non-DRF code will not generate more behavior on relaxed memory hardware than on SC.

4.3 Register Accounting

To verify CCA firmware with both C and assembly code, we must account for the interactions of C and assembly code primitives that call one another across language boundaries. However, C code hides the details of how it uses CPU registers, as the use of registers during C code execution is decided by the implementation of specific C compiler used. Although register behavior is not expressed by C language semantics, ignoring it causes problems when attempting to verify programs in which C and assembly code call one another, as shown in Figure 5, which illustrates a real bug in the original prototype RMM implementation detected during our verification. Existing verification approaches cannot support bidirectional calls between C and assembly code, such that the example in Figure 5 would be erroneously verified without detecting the information leakage [10, 11, 23, 26, 37, 42, 43, 46].

To address this problem, VIA introduces a novel register accounting mechanism to correctly verify integrated C and Arm assembly code while making minimal assumptions

```
ENTRY(store_inner):
    str x5, [x1]
    ret
ENDPROC(store_inner)
```
Spec: mem[%x1] = %x5;

```
void store_c() {
  int s = secret;
  // s stored in x5
  store_inner();
}
```
Spec: mem[%x1] = %x5;

```
ENTRY(store_outer):
    mov x5, #0
    bl store_c
    ret
ENDPROC(store_outer)
```
WRONG Spec: mem[%x1] = 0;

Figure 5: An example of incorrectly combining C and assembly specifications. Assembly function `store_outer` clears register `x5` to 0, then calls C function `store_c`. `store_c` calls assembly function `store_inner`, which stores register `x5` into memory. The intended behavior is that the value 0 will be stored to memory. The actual behavior is that `x5` stores C temporary variable `s` which contains secret data, resulting in undetected information leakage.

regarding compiler behavior. VIA leverages the *Arm64 Procedure Call Standard (AAPCS64)* [7] to specify how registers are potentially used when assembly code calls a C function or is called by a C function. It then conservatively marks all registers used by C code whose values cannot be determined based on AAPCS64 as of `Unknown` value, and requires assembly code to not depend on registers with `Unknown` values.

AAPCS64 constrains how some Arm registers are used. In CCA firmware, C functions pass no more than eight integer or pointer parameters and return an integer or pointer. For such functions, AAPCS64 specifies that a C compiler will only pass parameters through registers `r0-r7` and save the return value in `r0`. It also specifies registers that must have their values preserved through a function call, namely all callee-saved registers `r19-r29` and the stack register `sp`. The use of other general-purpose registers (GPRs) may depend on the specific C compiler implementation.

For an assembly function that calls a C function, VIA checks that the assembly code does not read any `Unknown` registers. Legal assembly code can either keep such `Unknown` registers untouched or overwrite them before using them. VIA uses AAPCS64 to model the register behavior of the C function by identifying register `r0` as containing the return value, and registers `r19-r29` and `sp` as preserving the values. It marks the values of other registers after the C function call as `Unknown`, including caller-saved registers `r1-r18` and the link register `lr`.

For an assembly function that can be called from a C function, VIA checks that its behavior does not depend on `Unknown` registers, and that it obeys AAPCS64 C calling conventions so that it will not cause unexpected behavior in its caller. VIA checks that (1) callee-saved registers `r19-r29` and `sp` preserve the values; (2) the program counter `pc` after the call is equal to `lr` before the call so the assembly primitive returns like a function call; (3) if the caller expects a return value, `r0`'s value is never `Unknown`; and (4) the assembly code behavior remains the same if we initialize all GPRs to `Unknown` except for those carrying parameters. The last condition implies that the assembly code does not read any `Unknown` registers, except for saving and restoring callee-saved registers.

VIA also supports GNU Compiler Collection (GCC) inline assembly extensions within a C function. This is used in inline assembly memory accessors in RMM which guarantee

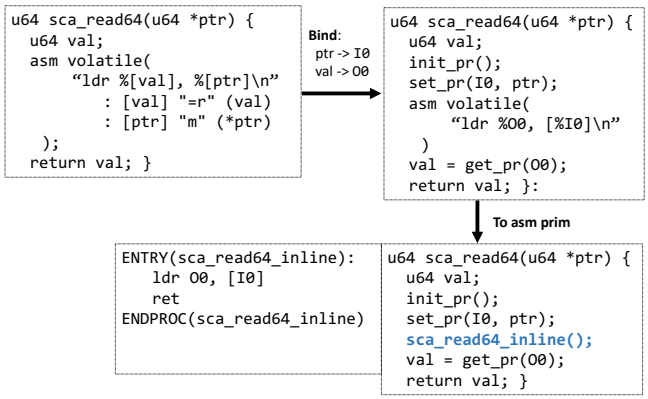

Figure 6: Translation of parameterized inline assembly.

atomicity or memory order semantics, as shown in the `sca_read64` example in Figure 6. `sca_read64` implements a 64-bit single-copy-atomic read in one line of assembly code plus an interface, which can specify a list of input registers, output registers and clobbered registers. VIA translates inline assembly code into an assembly function according to the interface constraints; "r", "Q", and "m" constraints are currently supported. It then checks its correctness like any other assembly function.

Translation is done using a set of logical registers `I0-In` for inputs and `O0-On` for outputs so that verification does not depend on the specifics of GCC register assignment. Input registers are defined read only. VIA also defines abstract accessors `init_pr`, which initializes all logical registers to `UNKNOWN`, `set_pr`, which writes to a register, and `get_pr`, which reads from a register. As shown in Figure 6, the translated `sca_read64` function first calls `init_pr` for initialization, saves parameters to input registers by calling `set_pr`, uses the input and output registers in the assembly code, and gets the return value from the output register by calling `set_pr`.

For simplicity, VIA imposes additional requirements to guarantee GCC generates correct machine code whose behavior is the same as VIA's translated code. VIA forbids inline assembly code from explicitly using any GPRs or goto labels. For inline assembly with multiple instructions, VIA enforces that all output registers are constrained by "&" or "+". Thus, an output-only register never doubles as an input register, and the same register is used for input and output of an operand. This avoids any unexpected overlap in the assignment of input and output registers [53].

Finally, because assembly code functions may be at the interface to outside programs that are untrusted, VIA enforces that all register values are not `Unknown` when returning from those assembly functions. This ensures that there is no unintentional information leakage from assembly code functions to untrusted programs through registers with `Unknown` values.

4.4 Ideal Secure System Model

CCA protects the confidentiality and integrity of Realms' private data during their lifetime. Confidentiality means any

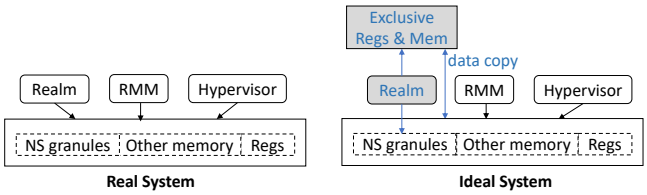

Figure 7: The real and ideal secure system model.

change a Realm makes to its private data is only observable by that Realm. Integrity means a Realm will not observe any changes to its private data that it did not make, but does not imply availability; data access should either fail or return the data previously stored. The confidentiality definition is standard, but the integrity definition allows untrusted software to modify a Realm's private data as long as the Realm does not observe the change. For example, to reclaim memory from Realms, a hypervisor can unmap a Realm's private data without the Realm's permission. This is allowed because the Realm's access to the unmapped data will trigger a page fault so the Realm cannot observe future changes to the data content. However, this breaks noninterference, which therefore cannot be used to to prove security as is done for other verified systems [16, 23, 29, 34, 42, 49, 55].

To address this problem, VIA introduces an ideal/real paradigm, shown in Figure 7, inspired by the idea from formal verification of separation kernels [22, 30]. The *real system* is defined by the RMM top-layer specification, which builds on and incorporates EL3M, in which all memory and CPU registers are shared by Realms, RMM, and the hypervisor. The *ideal system* is defined by an ideal system model specification, in which each Realm has its own exclusive memory, and each REC of the Realm has its own exclusive CPU registers, while other software can only access the same non-exclusive memory and registers as in the real system.

If each Realm only accesses its exclusive memory and registers in the ideal system, we could then show that RMM guarantees confidentiality and integrity by proving that the real system simulates the ideal system. This would mean that each Realm only accesses its exclusive memory and registers in the real system as well, so nothing other than a Realm can access its own data. However, such a simplistic model does not work in practice. For CCA, we need a model that allows declassification so Realms can access NS granules for initialization and I/O, and CPU registers can be used to pass parameters between Realms and RMM, or Realms and the hypervisor.

VIA introduces a new ideal system model for Armv9-A that supports declassification of memory and registers based on a set of well-designed rules that define when declassification is allowed. The model has six declassification rules, listed in Table 3. In this model, Realm exclusive memory consists of all memory in its PAR and exclusive CPU registers consists of all registers accessible by a Realm or that can affect its execution, such as system registers. A Realm will only access its exclusive memory and registers, unless it accesses a granule outside its PAR or it accesses a granule or register that is `Unknown`. If it accesses memory outside its PAR, the Realm will access non-exclusive memory directly. If it accesses a granule or register that is `Unknown`, the data will be copied from a special initialization buffer or non-exclusive register, respectively, before accessing it. A granule is `Unknown` if it is not yet initialized. A register is `Unknown` if it is used by the Realm to communicate with RMM or the hypervisor. For example, when a Realm invokes a hypercall, it exposes the arguments in registers `r0-r6`, which RMM will provide to the hypervisor, then return the results back in those registers. Marking a granule or register as `Unknown` is used to represent declassification in the model.

Type	Rule
Mem	When a Realm accesses an IPA within its PAR but it is `Unknown`, the Realm will copy the data from a special initialization buffer in memory to exclusive memory before accessing the IPA. This can only be done once per granule. The buffer is populated before the Realm is activated, and cannot be changed once it has been activated.
Mem	When a Realm accesses an IPA outside of its PAR, it will directly access memory, not exclusive memory.
Reg	On any trap from a Realm to the RMM, a Realm exposes the contents of various exclusive system registers, marking them `Unknown`, and marks various timer-related exclusive registers `Unknown`.
Reg	If a trap is due to system register emulation, a Realm will mark a specified exclusive GPR as `Unknown`.
Reg	If a trap is due to a hypercall, a Realm will expose and mark the seven exclusive GPRs `r0-r6` used for parameter passing as `Unknown`.
Reg	If a trap is due to an RMM call, a Realm will expose and mark the four exclusive GPRs `r0-r3` used for parameter passing as `Unknown`.

Table 3: Declassification rules.

We can then use this ideal system model with declassification to verify that RMM guarantees Realm confidentiality and integrity. The key is to establish a simulation relation in which all machine states are equivalent between the ideal and real systems and show that, at any step in the two systems satisfying the simulation relation, the same data is obtained when accessing memory or registers. This involves proving a one-to-one mapping of data between the two systems. With declassification, the mapping will change such that a different mapping will be used depending on whether the data is declassified or not. For example, if a granule within a Realm's PAR is not declassified, we will want to show that accessing that granule in non-exclusive memory in the real system correponds to accessing it in exclusive memory in the ideal system to get the same data. On the other hand, if a granule within a Realm's PAR is declassified, because its contents were initialized from an NS granule, we will want to show that first accessing that granule in non-exclusive memory in the real system correponds to accessing it in non-exclusive memory in the ideal system since the respective exclusive memory is initially `Unknown` so the data is first copied from non-exclusive to exclusive memory.

5 CCA Implementation and Verification

We used VIA to verify an early prototype implementation of CCA firmware, which includes both RMM and EL3M as

Description	LOC	Description	LOC
Machine model	1.4K	RMM refinement proofs	6.1K
Lock proof	1.7K	Top-level specification	1.1K
EL3M layer specifications	.2K	Ideal secure system model	.2K
EL3M refinement proofs	.9K	Security simulation proofs	3.4K
RMM layer specifications	4.4K	Permutation condition proofs	1.2K
Total			**20.6K**

Table 4: Lines of Coq code for verifying CCA firmware.

described in Section 3. The verification outcomes, including the discovery of several latent bugs, were confirmed by Arm's development team and used to further improve the firmware implementation. RMM contains 3.2K lines of code (LOC) in C and .3K LOC in assembly. The runtime critical parts of EL3M contain .1K LOC in C and .7K LOC in assembly; all of the C code is for updating the GPT. All RMM and EL3M code is verified, except for the portion of assembly code for initialization (.1K LOC in RMM and .5K LOC in EL3M). For remote attestation, RMM also uses functions provided by a crypto library, which was not verified, though a verified crypto library could be ported and used instead [42, 61].

Table 4 shows our proof effort, measured in LOC in Coq. 45 abstraction layers were used. The bottom layer machine model is based on VRM's Promising Arm model [57] to model Arm's relaxed memory. Another layer was used to verified the spinlock implementation on the relaxed memory model and lift it to an SC model. We verify the EL3M implementation refines its layered specification through three layers. On top of that, we verify the RMM implementation refines its layered specification through 39 layers. The top-level specification reflects RMM's interface, combining both RMM and EL3M functionality. Another layer defines the ideal secure system model. We verify that the top-level specification simulates the ideal secure system model.

5.1 Concurrent Multi-level Page Tables

The most challenging refinement proofs were for verifying RMM's RTT implementation. RTT primitives use hand-over-hand locking to synchronize access to dynamically allocated 4-level page tables, allowing fine-grain concurrent operation on different page table levels. This required nine layers. We leverage mover oracle queries and log refinement, discussed in Section 4.1, to refine all of RMM's page table operations to atomic operations, verifying the correctness of hand-over-hand locking in a real system for the first time.

Figure 8 visualizes the proof. Since acquiring a lock is a RightMover, releasing a lock is a LeftMover, and reading the page table entry is both a LeftMover and RightMover, we can reorder mover oracle queries to refine the procedure of walking the page table until acquiring the lock of `T1` into an atomic step. We group the local CPU events into a single higher-level aggregate "walk until level 1" event. Similarly, we can group events together from creating a level 1 table into a "create level 1 table' event, and destroying a level 1 table

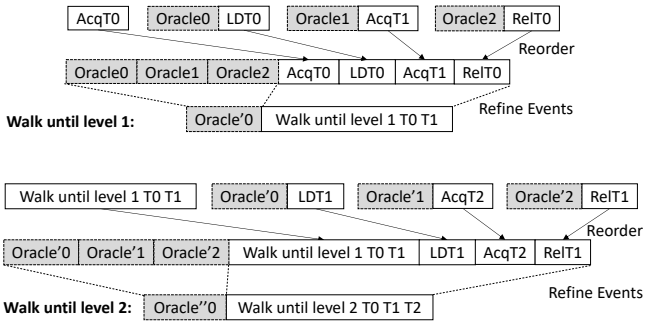

Figure 8: Proving atomicity for page table operations.

into a "destroy level 1 table" event.

We then refine the procedure of walking the page table until acquiring the lock of `T2` into an atomic step. We first prove that "walk until level 1" is a RightMover because any subsequent events at this layer from other CPUs can be reordered with it, i.e., "create level 1 table", "destroy level 1 table", "walk until level 1", and `acq`/`rel`/`LD`/`ST` events for `T2` and `T3` level tables. A "create level 1 table" from other CPUs is irrelevant to the local "walk until level 1" because it can only create other level 1 tables and cannot overwrite `T1` since RMM only allows creating a table that does not exist yet. Events "destroy level 1 table" and "walk until level 1" from other CPUs are irrelevant because they cannot hold `T1`'s lock so can only access other level 1 tables, not `T1`. Other events are also irrelevant because they do not manipulate `T0` and `T1` tables. Therefore, "walk until level 1" is a RightMover and all subsequent mover oracle queries can be reordered before it. Thus, we refine "walk until level 2" into an atomic step, as shown in the bottom of Figure 8. In a similar fashion, we prove "walk until level 2" to be a RightMover and refine the steps of "walk until level 3." Continuing in this manner, we eventually refine all RTT operations into atomic steps.

Proving RTT operations to be atomic allows us to prove desired properties about RMM's RTT management. The key property to prove is that each non-empty entry in the RTTs, including both intermediate entries pointing to lower-level RTTs and leaf mappings, uses a unique delegated granule. This prevents page remapping attacks while still allowing fine-grained access to the RTTs for improved performance. The proof is straightforward because every operation on an RTT entry is proved to be atomic, only the PA of a delegated granule is used to populate a previously empty RTT entry, and each such granule is guaranteed to be unused and zeroed. Once a granule is used for an RTT entry, its state changes from delegated to RTT or Data, preventing it from being used for other RTT entries. By using mover oracle queries and log refinement, we complete the first proof of hand-over-hand locking in a real system, and the first proof of a system with fully dynamically allocated shared page tables.

5.2 Relaxed Memory

We prove permutation conditions as discussed in Section 4.2 to verify the proofs hold on Arm relaxed memory hardware. Veri-

fying CCA firmware only requires six permutation conditions, the `RECLIST` empty condition discussed in Section 4.2, and five conditions previously introduced by VRM, namely (1) NO-BARRIER-MISUSE, (2) TRANSACTIONAL-PAGE-TABLE, (3) SEQUENTIAL-TLB-INVALIDATION, (4) WRITE-ONCE-KERNEL-MAPPING, and (5) MEMORY-ISOLATION. NO-BARRIER-MISUSE requires that barriers are correctly placed. We verified that all lock acquisitions have `acquire` memory semantics and all lock releases have `release` memory semantics. We also proved that memory accesses to shared objects outside critical sections have `release` semantics so that they cannot be reordered, preserving program ordering and SC behavior.

TRANSACTIONAL-PAGE-TABLE requires that shared page table writes within a critical section are transactional. This ensures that page table writes will not result in any behavior on relaxed memory hardware that cannot be produced on an SC model. In RMM and EL3M, each critical section contains at most one page table write, so they are obviously transactional.

SEQUENTIAL-TLB-INVALIDATION requires that a page table unmap or remap be followed by a TLB invalidation, with a barrier between them. This precludes relaxed memory behavior in TLB management code. There are no remaps in RMM or EL3M. We verified that all page table unmaps are followed by a TLB invalidation with a barrier between them.

WRITE-ONCE-KERNEL-MAPPING requires that if RMM or EL3M's own page tables are shared, they can only be written once—only empty page table entries can be modified. This precludes relaxed memory behavior due to out-of-order reads of these page tables. For EL3M, this holds as it uses a statically reserved hardcoded page table shared across all CPUs that is never changed after booting. For RMM, although its kernel page table is shared across all CPUs and can be changed, we prove that it is logically partitioned into two tables, as discussed in Section 3. We prove one table is shared but never changed once initialized, and the other table is not shared because it is statically divided into per-CPU ranges private to each CPU.

MEMORY-ISOLATION requires that the memory space accessible by RMM and EL3M is partially isolated with Realms and NS hypervisors. This ensures that any relaxed memory behavior of Realms or NS hypervisors cannot be propagated to RMM or EL3M. We verify that Realms and the hypervisor will only access `Data` and `NS` granules. Realms' memory accesses are managed by RTTs, We prove RTTs will only map `Data` granules and `NS` granules. A hypervisor's memory accesses are controlled by the GPT. We prove all delegated granules are in the Realm PAS state in the GPT so the hypervisor cannot access them. We further prove that RMM and EL3M behavior do not rely on what Realms or the hypervisor may do with `Data` or `NS` granules. We prove EL3M never accesses memory other than its own, RMM will not access the contents of `Data` granules, and whenever RMM accesses `NS` granules, it may obtain arbitrary data because the hypervisor can make arbitrary changes to the data. Thus, we show RMM's proof on SC does not rely on the concrete implementation of Realms or NS hypervisors.

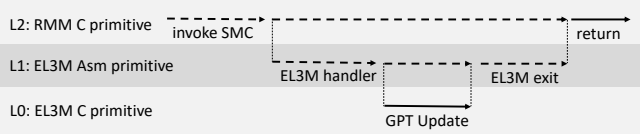

Figure 9: Verify RMM and EL3M GPT update operations. Solid arrows represent C code and dashed arrows represent assembly code.

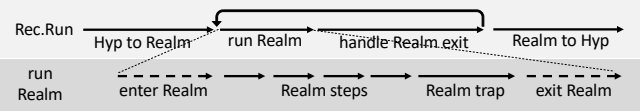

Figure 10: Verify `REC.Run` and its inner `run_realm` loop. Solid arrows represent C code and dashed arrows represent assembly code.

Figure 11: Verify `rmm_handler` in the top layer. Solid arrows represent C code and dashed arrows represent assembly code.

5.3 C and Assembly Code Integration

Another key aspect of the refinement proofs was verifying the interactions between RMM and EL3M, RMM and Realms, and RMM and the hypervisor, which required the C and assembly code integration techniques discussed in Section 4.3. For RMM and EL3M, we verified the correctness of GPT updates. Figure 9 shows how to verify a C primitive in RMM which issues an SMC to EL3M to update the GPT. Layer `L0` verifies the C code for EL3M's GPT operations. Layer `L1` verifies EL3M's assembly code handler, which handles traps from RMM and calls the GPT operations in C. Finally, layer `L2` verifies the C code in RMM that traps to EL3M's assembly code handler.

For RMM and Realms, we verified `REC.Run`, which runs a VCPU of a Realm and required five layers. Figure 10 shows this C primitive, which calls the `run_realm` assembly code primitive, which restores the Realm's VCPU contexts and enters the Realm. We proved that all GPRs are correctly restored such that there is no information leakage from RMM to the Realm through registers with `Unknown` values.

For RMM and the hypervisor, we verified the RMM handling of RMI calls from the hypervisor. Figure 11 shows when the hypervisor invokes an RMI call, it traps to EL3M first, then jumps to RMM and calls the C function `handle_ns_smc` to execute the RMI call. Eventually, RMM returns to EL3M and then the hypervisor. We proved that when returning to the hypervisor, there is no information leakage to the hypervisor through GPRs with `Unknown` values.

5.4 Security

We prove that the real system specified by the RMM top-level specification simulates the ideal system model with declassification, as discussed in Section 4.4. We discuss the simulation relation in three parts: all machine states except for `Data`

granules, CPU registers, and VCPU contexts stored in REC granules (**Rel 1**), Data granules (**Rel 2**), and CPU registers and VCPU contexts (**Rel 3**). Each relation is proved by induction, in which we assume the relation is initial true at machine boot and prove that it is preserved during RMM, hypervisor, and Realm execution so that the same data is obtained when accessing memory or registers in both real and ideal systems.

We prove that **Rel 1** is preserved during execution and all data accessed from memory is the same. **Rel 1** concerns NS granules, delegated granules, and granules containing Realm metadata including RTTs, none of which involve declassification. We prove two invariants: (1) all RTTs only map IPAs within the respective Realm's PAR to Data granules and IPAs outside its PAR to NS granules; and (2) the GPT only labels NS granules in the NS PAS while all delegated granules are labeled in the Realm PAS. The first invariant ensures that Realms will only access Data and NS granules, and the former will not affect **Rel 1**. The second invariant ensures that the hypervisor can only access NS granules. Since Realms and the hypervisor access NS granules in the same non-exclusive memory in both real and ideal systems, they will obtain the same data. All other granules for **Rel 1** can only be accessed by RMM. Since RMM accesses NS and other granules in the same non-exclusive memory in both real and ideal systems, it will obtain the same data; the VCPU contexts that are part of REC granules are excluded here and considered in **Rel 3**.

We prove that **Rel 2** is preserved during execution. The invariant above ensures that the hypervisor cannot access Data granules, and we prove that RMM does not access Data granules, so **Rel 2** is preserved for both the hypervisor and RMM. Data granules are only accessed by Realms. From **Rel 1**, the RTTs must be the same in both real and ideal systems. If an RTT maps an ipa within a Realm's PAR to a Data granule at host physical address hpa, the Realm will access the same data at exclusive memory ipa in the ideal system as at hpa in the real system, so **Rel 2** is preserved. To ensure that an hpa cannot be mapped to ipas in different Realms, we prove an invariant that if an RTT maps ipa to hpa, then the Data granule at hpa inversely maps to (Realm, ipa). Because there is a one-to-one mapping for each Data granule to (Realm, ipa), any changes at hpa can only be observed by the specific Realm at the specific ipa as is the case in the ideal system, so **Rel 2** is preserved for all other data. If an an ipa within a Realm's PAR is Unknown, the Realm will access the same data at non-exclusive memory hpa in the ideal and real system, so **Rel 2** is preserved.

We prove that **Rel 3** is preserved during execution. We prove if a Realm's VCPU V is running, its register r in the real system equals the corresponding exclusive register r if not Unknown or the non-exclusive register r if Unknown in the ideal system. We prove if a Realm's VCPU V is not running, V's REC context of r in the real system equals the corresponding exclusive register r if not Unknown or the V's REC context of r if Unknown in the ideal system. In the ideal system, Realm's register data is always stored in the exclusive registers except for those being declassified. Exclusive registers are not involved in context switches. We then prove that RMM indeed correctly saves and restores Realms' VCPU contexts, so that **Rel 3** is preserved.

Finally, we note that our simulation proofs between the real system and ideal secure system model verify Realm confidentiality and integrity without even trusting the correctness of the RMM or EL3M specifications. The proofs only need to trust the specification of the ideal secure system model, which encodes the declassification rules and consists of only .2K LOC in Coq. Furthermore, as shown in Table 3, the declassification rules only allow a Realm to disclose its data in two ways, by writing NS granules outside of its PAR or via the eight GPRs used for hypercalls, making the security policy formalization easy to understand.

5.5 Bugs Found

We identified several bugs in the CCA firmware prototype implementation during verification. Through refinement proofs, we detected common bugs such as incorrect boundary checking for some variables and misuse of locks; some locks were released without previously holding them. More importantly, verification of C and assembly code integration identified a serious security bug that neither EL3M nor RMM clear the caller-saved registers when returning to the hypervisor. These registers may carry RMM's private execution states and leak information. For example, RMM saves and restores Realms' VCPU contexts, and some contexts may remain in caller-saved registers and leak to the untrusted hypervisor. Another bug identified was in the REC execution handler. The hypervisor provides an NS granule to communicate entry and exit information with RMM. RMM locks and checks that the given granule is indeed an NS granule, accesses its contents, unlocks the granule, and enters the Realm. However, when exiting from the Realm, RMM did not lock and check the granule state before accessing it. This may lead to RMM unexpectedly receiving a Granule Protection Fault (GPF) from the hardware when accessing the granule using the NS PAS, if the granule was delegated by another CPU. This could lead to a denial of service of RMM or have worse consequences if GPF handling was not properly implemented in RMM.

Through permutation condition proofs, we identified an RMM bug that REC.Destroy does not implement "counter−−" with the release semantics (instruction (e) in Figure 4) such that it can be reordered with (d) on Arm's relax hardware. This may cause Realm.Destroy to wrongly set the RECLIST to be reusable before REC.Destroy clears it because when counter is zero, all RECs in the list should have been destroyed, which was not true due to this relaxed memory bug.

Through security proofs, we identified an RMM bug that allows the hypervisor to create two Data granules for the same memory address of a Realm. Thus, RMM can unmap one Data granule from an IPA of a Realm and map another Data granule to the same IPA, violating the Realm integrity guarantee,

because the Realm could observe a change in Realm data not caused by a Realm memory access.

5.6 CCA KVM

CCA provides a standard application binary interface (ABI) to allow hypervisors to communicate their intents to RMM via RMI commands, which is suitable for adoption by commodity hypervisors. However, existing hypervisors do require some modifications to use CCA to support Realm VMs. Regardless of whether a hypervisor is modified to use CCA, it cannot compromise the confidentiality and integrity of Realms. Without modifications, existing hypervisors cannot run Realm VMs, but can still run non-Realm VMs.

We modified the Linux KVM hypervisor to use CCA, which we refer to as CCA KVM. The modifications involved roughly 3K LOC in C to KVM, including .5K LOC for RMI commands, .4K LOC for handling exits from Realms, .8K LOC for creating and destroying Realms, and 1.1K LOC for stage 2 page table management using RMI commands. The modifications also required roughly .5K LOC in C to QEMU, mostly related to VM boot, initialization, and exit handling. Finally, roughly 40 LOC in C of modifications to the virtio driver in the Linux guest kernel were required so that it uses a bounce buffer to communicate I/O data with the hypervisor. This is needed because the ring buffer normally used by the virtio driver in the VM is in memory not accessible to the hypervisor when using Realms. Our experience with KVM indicates that the modifications required for a commodity hypervisor to use CCA are quite modest and involve changes to a very small percentage of its existing codebase.

6 Performance Evaluation

We have run the CCA software stack, including RMM, EL3M, and modifications to the Linux KVM hypervisor to use Realms, on an Arm Fast Model which implements the Realm Management Extensions (RME) CPU architecture. The Fast Model is a valid software emulation of the CPU architecture, allowing us to demonstrate that the CCA software stack provides the desired security guarantees and system functionality. However, Fast Models do not provide any cycle accurate measure of real performance and are too slow to run real application workloads. While CCA will be available in Armv9-A, Armv9-A hardware is not yet available.

To provide a preliminary measure of CCA performance, we have ported the CCA software prototype to run on currently available Arm hardware, an Arm N1 System Development Platform (N1SDP) [5] with an Armv8.2-A Neoverse N1 SoC. This version of EL3M is based on the the Trusted Firmware-A (TFA) codebase. The N1SDP does not provide GPT or Realm world hardware, so it cannot enforce the security guarantees of Realms, but we can use it to mimic the performance costs of Realms by modifying the EL3M code. Context switching between NS and Realm worlds is mimicked by modifying EL3M to switch between two separate contexts within NS world. EL3M is further modified to support the RMI as well as handle GPT update requests from RMM. We did not include EL3M code that controls GPT registers as they do not exist on the N1SDP, but all data written to the GPT memory can be done, although without any effect.

This setup necessarily will have some performance differences from real CCA hardware, but it provides a useful approximation of actual Realm performance. The cost of GPT checks by CCA hardware are not included since no GPT hardware is available, but are expected to exhibit good caching behavior and will not affect the relative performance of VMs versus Realm VMs since they apply equally in NS and Realm worlds. The cost of some hypervisor operations, such as those that require exiting to userspace, will be overly conservative as controlling timer interrupt behavior requires those operations to write to the Arm Generic Interrupt Controller (GIC) on the N1SDP which is slow, whereas real CCA hardware will have system registers that can be used by RMM to achieve the same functionality. Finally, the current prototype lacks support for directly injecting virtual interrupts without hypervisor intervention, which is expected to be available in future CCA hardware.

We ran both microbenchmark and application workloads in VMs on unmodified KVM and CCA KVM in Linux 5.12 on the N1SDP, which has two dual-core 2.6 GHz Neoverse N1 CPUs, 6 GB RAM, a 240 GB SATA3 SSD and a Intel 82574L 1 Gbps NIC. We used QEMU 4.2.0 [8] to run VMs, with the modifications discussed in Section 5.6 to support CCA KVM. VMs were run using KVM or CCA KVM with 4 cores and 1 GB RAM with the VM capped at 2 VCPUs and 512 MB RAM; VCPUs were pinned to individual cores. VHOST networking was used and virtual block storage devices were configured with `cache=none` [28, 38, 56]. Arm VHE [6, 17, 18] was used for all measurements. For client-server workloads, clients ran on an x86 machine with a 16-core Intel Xeon E5-2690 2.9 GHz CPU, 378 GB RAM and an Intel I350 1 Gbps NIC, connected to the N1SDP via a Linksys LGS108 1 Gbps switch.

6.1 Microbenchmarks

We ran KVM unit tests [39], which execute common micro-level hypervisor operations, plus an additional system register access microbenchmark, as listed in Table 5. For each test, we ran it 2^{16} times and report the average latency. Table 6 shows the microbenchmark measurements in nanoseconds for unmodified KVM and CCA KVM. The measurements show that the security benefits of CCA design do come with a performance cost on most micro-level hypervisor operations, because the cost of transitioning between a VM and the hypervisor is much more expensive on CCA KVM than unmodified KVM, which is most clearly shown for Hypercall.

Hypercall simply traps from the VM to the hypervisor in EL2 and returns for KVM, but involves additional operations

Name	Description
Hypercall	Trap from a VM to the hypervisor and return to the VM immediately. Measures base transition cost of hypervisor operations.
I/O Kernel	Trap from a VM to the emulated interrupt controller in the host OS kernel and return to the VM. Measures cost of accessing I/O devices supported in kernel space.
I/O User	Trap from a VM to read the device ID of virtio mmio device then return to the VM. Measures base cost of operations that access I/O devices emulated in user space.
Virtual IPI	Issue virtual IPI to another VCPU on a different CPU. Measures time from sending virtual IPI until receiving VCPU handles it.
Sysreg	Trap from a VM to emulate access to system register `ID_AA64PFR0_EL1` in the hypervisor and return to the VM. Measures system register access cost.

Table 5: Microbenchmarks.

for CCA KVM: (1) trap from VM in EL1 to RMM in EL2; (2) map NS granule to copy exit info to NS world, unmap granule; (3) trap from RMM to EL3M in EL3; (4) save Realm context, restore NS context; (5) exception return from EL3M to hypervisor in EL2; (6) trap from hypervisor to EL3M in EL3; (7) save NS context, restore Realm context; (8) exception return from EL3M to RMM in EL2; (9) map NS granule to copy entry info from NS world, unmap granule; (10) map and read data in REC and RD granules, unmap granules; (11) exception return from RMM to VM in EL1. The additional operations result in Hypercall costing an additional 1.5 μs on CCA KVM than vanilla KVM. Roundtrip transitions between RMM and the hypervisor take roughly 700 ns, and roundtrip transitions between the VM and RMM take roughly 60 ns. Saving and restoring system registers when transitioning between the VM and RMM takes roughly 200 ns per transition, or 400 ns total. The four map/unmap operations take roughly 100 ns each, 400 ns total. The remaining roughly 250 ns is due to other bookkeeping code, including saving and restoring GPRs and error checking.

I/O Kernel and I/O User include the same transition from the VM to the hypervisor and back as the Hypercall, so they also require more than 1.5 μs to execute on CCA KVM than vanilla KVM. Although the difference between CCA KVM and vanilla KVM is roughly 1.5 μs for I/O Kernel, the difference for I/O User is roughly 2.3 μs. This is because on the N1SDP, CCA KVM must write to the GIC when going to userspace, which is quite slow and takes an extra 800 ns.

Virtual IPI is more expensive on CCA KVM versus vanilla KVM because it involves multiple transitions between a VM and the hypervisor. Sending the virtual IPI involves the source vCPU writing to a system register, causing a trap to the RMM, which forwards the operation to the hypervisor (1). The hypervisor issues a physical IPI to the CPU running the destination vCPU, then returns to the source vCPU (2). The physical IPI causes an exit from the destination vCPU (3). On taking this exit, the hypervisor detects that there is a pending virtual IPI, and returns to the destination vCPU (4). Of these four transitions, approximately two occur in parallel, so the cost is roughly twice that of a Hypercall on CCA KVM for the transitions, plus the cost of the actual operation. Because Hypercall is much faster for unmodified KVM, its Virtual IPI cost is not dominated by the transition cost between VM and hypervisor.

Benchmark	Hypercall	I/O Kernel	I/O User	Virtual IPI	Sysreg
KVM	362	549	1,761	1,806	437
CCA KVM	1,865	2,060	4,049	4,324	70

Table 6: Microbenchmark performance (ns).

The one microbenchmark that is much faster on CCA KVM than KVM is Sysreg. Accessing system registers is roughly 5 times as expensive on KVM versus CCA KVM. On CCA KVM, RMM handles this register access directly without returning to the hypervisor. RMM's system register trap handling mechanism is simpler than KVM's because it does not need to support KVM's more general hypervisor functionality that requires synchronizing accesses to hypervisor-related data structures and additional conditional checks.

6.2 Application Benchmarks

We next ran the application benchmarks listed in Table 7 to measure performance on more realistic workloads. We also ran the workloads on native hardware running the same kernel to provide a baseline for comparison, restricting the system to use 2 CPUs and 512 MB RAM to provide a comparable configuration to the VMs. For each platform, we ran each workload 50 times and measured the average, worst, and best performance.

Figure 12 shows the average performance for each benchmark for unmodified KVM versus CCA KVM, with error bars indicating worst and best performance. Performance was normalized to average native execution on the N1SDP hardware; lower is better. Unlike microbenchmark performance, the application benchmark performance shows that CCA KVM and KVM have much more modest performance differences on more realistic workloads.

CCA KVM has less than 8% overhead versus unmodified KVM for most workloads, but in the worst case, overhead was 18% for MongoDB, an I/O intensive workload. The I/O intensive workloads have higher overhead for a couple reasons. The main reason is because the VM exits more frequently, so the cost of exits has a more significant impact on performance. Exits are more expensive on CCA KVM as shown by the Hypercall microbenchmark results in Table 6, in which an exit to the hypervisor costs an extra 1.5 μs. If there are many exits as will be case for I/O intensive workloads, this additional cost can become significant. For example, Memcached incurs roughly a million VM exits to the hypervisor. This results in roughly 1.5 s of additional overhead, or .75 s of overhead per core if the exits are split evenly across cores for a VM with 2 VCPUs. Memcached takes 9 s to run on vanilla KVM, so this is 8% overhead due to the extra latency for exits on CCA KVM, which roughly matches the actual overhead measured for Memcached on CCA KVM versus vanilla KVM.

A secondary reason is because CCA KVM needs to use a bounce buffer while vanilla KVM does not. CCA KVM needs a bounce buffer to support virtio because Realm memory is protected from the hypervisor. KVM uses the default virtio

Name	Description
Apache	Apache server v2.4.41 handling 100 concurrent requests via TLS/SSL from remote ApacheBench [1] v2.3 client, serving the index.html of the GCC 7.5.0 manual.
Hackbench	Hackbench [54] using Unix domain sockets and 20 process groups running in 500 loops.
Kernbench	Compilation of the Linux kernel v4.18 using allnoconfig for Arm with GCC 9.3.0.
Memcached	Memcached v1.5.22 handling requests from a remote memtier [51] v1.2.11 client with default parameters.
MongoDB	MongoDB server v3.6.8 handling requests from a remote YCSB [14] v0.17.0 client running workload A with 16 concurrent threads and operationcount=500000.
MySQL	MySQL v8.0.27 running sysbench v1.0.11 with 32 concurrent threads and TLS encryption.
Redis	Redis v4.0.9 server handling requests from a remote redis-benchmark client (redis-tools v5.0.7) [52] running `GET/SET` with 50 parallel connections and 12 pipelined requests.

Table 7: Application benchmarks.

mechanism to directly access VM memory, so it does not require bounce buffers and does not need to perform the additional data copying. Since KVM can also be configured to use a bounce buffer, we also measured KVM with this configuration to isolate the impact of using a bounce buffer on performance. The overhead with versus without a bounce buffer was negligible in most cases, but in the worst case as high as 3-4% for the more disk I/O intensive workloads, MongoDB and MySQL.

We expect the overheads for I/O intensive workloads on real CCA hardware to be less than what we measured on the N1SDP hardware. Exits are expected to occur less frequently on real CCA hardware when support for direct virtual interrupt injection is added. Exits that go to userspace are expected to cost less on real CCA hardware as the expensive GIC writes required for N1SDP hardware will be eliminated, though this was not a dominant factor in our results with the use of VHOST networking. This cost can be further mitigated by using device passthrough instead of paravirtual I/O, which will largely avoid these exits and their associated performance overhead. Support for Realm device passthrough will be added to future CCA hardware. Overall, our measurements indicate that CCA's security guarantees can be delivered with acceptable performance overheads for real application workloads.

7 Related Work

Hardware-enforced trusted execution environments have become an important feature of major computer architectures. Arm TrustZone [4] can be used to statically partition and isolate a memory region in Secure world, but most implementations only support a small number of such memory regions, limiting its scalability. Intel Software Guard Extensions (SGX) [33] can be used by application developers to protect userspace memory from other programs, including a potentially malicious OS or hypervisor. SGX is not suitable for securing VMs.

AMD Secure Encrypted Virtualization (SEV) [2] and Intel Trust Domain Extensions (TDX) [32] provide protection at the

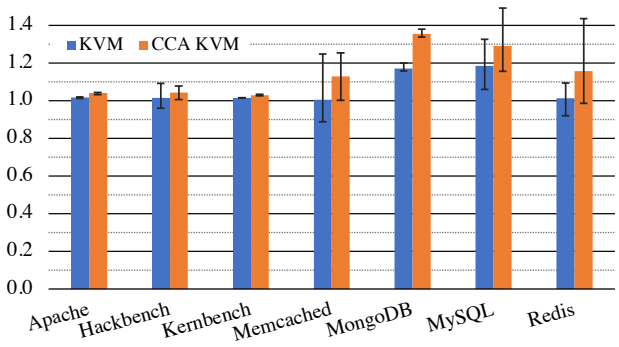

Figure 12: Application benchmark performance.

level of VMs with similar threat models to CCA. The initial version of SEV ensured confidentiality by encrypting VM memory at runtime, but did not ensure memory data integrity, which has been utilized as an attack vector such that a compromised hypervisor can tamper with or steal private VM data [31,40,47,48, 60]. Secure Nested Paging (SNP) [3] now provides the previously missing integrity protection capability. SEV-SNP allows an untrusted hypervisor to directly manage NPTs, but checks accesses against a reverse map table, an additional data structure managed by a security co-processor. In contrast, Intel TDX runs a TDX module in a privileged SEAM (Secure-Arbitration Mode) root CPU mode. The firmware manages NPTs used by protected VMs in response to requests issued by the untrusted hypervisor. Unlike CCA, the security of SGX, SEV, SEV-SNP and TDX relies on complex implementations in unverified microcode and firmware [12, 15]. They are difficult to update, either to patch security flaws or introduce new features.

Komodo [23] draws on ideas from SGX, but is implemented as a software monitor in verified Arm assembly code on top of TrustZone instead of requiring hardware to support complex enclave-manipulation instructions. This avoids hardware complexity and enables deployment of new enclave features independently of CPU upgrades. Komodo does not support multiprocessor execution, largely due to the challenge of verifying low-level concurrent code. CCA retains the advantages of Komodo's approach by relying on a verified software monitor to implement Realms, but supports verified VM protection and multiprocessor execution.

The idea of retrofitting a commodity hypervisor so that its security guarantees are enforced by a small trusted core was first explored by SeKVM [41–43, 57]. SeKVM was the first to show how this retrofitting approach, known as microverification, makes it possible to verify that a commodity hypervisor guarantees the confidentiality and integrity of VMs. CCA allows hypervisors to be modified to support Realm VMs, whose confidentiality and integrity are protected by a verified monitor, reminscient of SeKVM. While SeKVM uses existing Arm hardware, CCA introduces new hardware mechanisms that protect VMs from untrusted software running in both NS and Secure world, and allow hypervisors to make full use of Arm virtualization features such as VHE for better

performance. Furthermore, CCA firmware is designed to support a higher degree of scalability and concurrent operation by allowing data races, leveraging fine-grain synchronization, and enabling the hypervisor to provide fully dynamic memory allocation for all VM-related metadata.

While verifying CCA firmware required new VIA verification techniques, many of them build on previous work. Various concurrent systems have been verified, including CertiKOS [26, 27, 45], SeKVM, and CMAIL using CSPEC [10]. CertiKOS and SeKVM support sequential reasoning with a local CPU model and encapsulate other CPUs' behavior by rely/guarantee conditions, but do not support reordering using mover types, making proving hand-over-hand locking infeasible. Although hand-over-hand locking can theoretically be proved using rely/guarantee reasoning [58], the approach is not machine-checkable or scalable to a real system like RMM. CSPEC provides proof patterns with mover types, but lacks a local CPU model and does not verify C code; it offers little help for RMM code not reducible by movers (e.g. `REC.Destroy` in Figure 4) that still need rely/guarantee reasoning to verify. VIA builds on CertiKOS, SeKVM, and CSPEC to combine a local CPU model with mover types.

Some programs have been previously verified on relaxed memory hardware. Armada [46] supports verifying programs on the x86-TSO memory model, but their approach of verifying the entire program on a relaxed memory model has not been shown to scale to real systems such as RMM. VRM [57] instead allows proofs on an SC model to hold on relaxed memory hardware by ensuring certain conditions hold, making possible the verification of SeKVM, the first machine-checked proof for concurrent systems software on Arm relaxed memory hardware. VIA generalizes VRM to arbitrary non-DRF programs.

Verifying programs with both C and assembly code has been done to varying degrees, but none support bidirectional calls between them. seL4 [37] verifies C code, but its assembly code is unverified. CertiKOS relies on a verified x86 C compiler to verify assembly primitives invoking C primitives by compiling the invoked C primitives into assembly primitives, but cannot verify C primitives that invoke assembly primitives. Since no verified Arm C compiler exists, this approach cannot be used for CCA. SeKVM verifies C and Arm assembly code separately, but does not link the proofs, in part because no verified Arm C compiler exists. Komodo is written entirely in assembly code which is then verified, but this is difficult to scale to a large system as it is hard to write and maintain a large codebase in assembly. Ironclad [29] conducts verification at the assembly level by compiling programs in a high-level language down to assembly. This is also difficult to scale as it is harder to verify the much larger generated assembly code than the original high-level language implementation. VIA allows most proofs to be done at the C level while verifying interactions between C and assembly code are safe.

Noninterference has been frequently used to prove information-flow security [16, 23, 29, 34, 42, 49, 55], but cannot be applied to RMM given the definition of data integrity and confidentiality supported by Realms. While most of these approaches rely on some static partitioning of memory to simplify their noninterference proofs, RMM imposes no such scalability limitations. The ideal/real simulation paradigm has been used to verify information-flow security of a simple 750 LOC two-user uniprocessor separation kernel without page tables [22], but we show for the first time how it can be applied in the presence of declassification to verify data confidentiality and integrity of a real system that supports modern multiprocessor and MMU hardware with page tables.

8 Conclusions

Arm CCA is the first confidential compute architecture backed by verified firmware that is correct and secure. CCA introduces Realms, secure execution environments that protect the confidentiality and integrity of VMs against untrusted system software such as hypervisors. Realms are made possible by hardware support for Realm world, a new physical address space for Realms inaccessible to untrusted system software, and a firmware monitor that runs in Realm world to control CCA hardware to secure and manage Realms, including handling requests from untrusted hypervisors to create Realms, run Realms, and allocate memory to Realms. This design maintains compatibility with the Arm architecture without introducing complex hardware mechanisms by relying on firmware, and avoids complexity in the firmware by relying on existing hypervisors to provide virtualization functionality.

We formally verified CCA firmware, demonstrating the feasibility of relying on trustworthy firmware for the security guarantees of the architecture. We introduced various verification techniques to make it possible to verify for the first time concurrent firmware with data races running on relaxed memory hardware, fine-grain synchronization such as hand-over-hand locking, dynamically allocated shared multi-level page tables, and integrated C and assembly code. We also prove the security guarantees despite untrusted software being in full control of resource allocation decisions. The proof only needs to trust roughly two hundred lines of Coq specification, making the formal security guarantees easy to read and understand. CCA provides its security guarantees with only modest performance overhead compared to running VMs with the Linux KVM hypervisor without verified VM protection.

Abstract

Distributed systems are complex and difficult to build correctly. Formal verification can provably rule out bugs in such systems, but finding an inductive invariant that implies the safety property of the system is often the hardest part of the proof. We present DuoAI, an automated system that quickly finds inductive invariants for verifying distributed protocols by reducing SMT query costs in checking invariants with existential quantifiers. DuoAI enumerates the strongest candidate invariants that hold on validate states from protocol simulations, then applies two methods in parallel, returning the result from the method that succeeds first. One checks all candidate invariants and weakens them as needed until it finds an inductive invariant that implies the safety property. Another checks invariants without existential quantifiers to find an inductive invariant without the safety property, then adds candidate invariants with existential quantifiers to strengthen it until the safety property holds. Both methods are guaranteed to find an inductive invariant that proves desired safety properties, if one exists, but the first reduces SMT query costs when more candidate invariants with existential quantifiers are needed, while the second reduces SMT query costs when few candidate invariants with existential quantifiers suffice. We show that DuoAI verifies more than two dozen common distributed protocols automatically, including various versions of Paxos, and outperforms alternative methods both in the number of protocols it verifies and the speed at which it does so, including solving Paxos more than two orders of magnitude faster than previous methods.

1 Introduction

The world relies on distributed systems, but these systems are increasingly complex and hard to design and implement correctly. To address this problem, developers are starting to turn to formal verification techniques to prove the correctness of distributed systems [11, 20, 35]. This involves formally verifying that desired safety properties hold for the distributed protocol. A safety property is an invariant that should hold true at any point in a system's execution. It ensures the protocol does not reach invalid or dangerous states. For example, the safety property for a distributed lock protocol [11] is that no two nodes in the system hold a lock at the same time. The proof requires finding an invariant that implies the safety property, then proving that it is inductive. An invariant is inductive if it holds for all initial states of the system, and is preserved on all valid transitions so that it holds for any reachable state of the system.

Unfortunately, finding an inductive invariant is often the hardest part of the proof [21]. Invariants can be expressed as logical formulas consisting of universal ($\forall$) and existential ($\exists$) quantifiers with a certain number of variables, and a set of logical relations among the variables. Recent work has focused on automating the process of finding an inductive invariant, but has various limitations. I4 [21] was the first to automate the process, but provides no guarantee that it can find the inductive invariant and does not work for invariants with existential quantifiers. Our previous work DistAI [38] provides speed advantages over I4 and a guarantee of finding an $\exists$-free inductive invariant if one exists, but also does not work for invariants with existential quantifiers. FOL-IC3 [13] was the first to handle existential quantifiers, but is inefficient due to its heavy use of expensive SMT queries. It often fails to find invariants for protocols that can be solved by other approaches such as I4 and DistAI. SWISS [10] can successfully find an inductive invariant for Paxos, but does not work for more complex protocols such as stoppable Paxos [27]. It fails or is much slower than I4 and DistAI for many protocols without existential quantifiers.

We present DuoAI, an automated system to quickly find inductive invariants for verifying distributed protocols, with and without existential quantifiers, including complex versions of Paxos. Even though a distributed protocol may be used in very large systems, its invariants are likely to be concise, as protocols need to be designed and understood by humans to be correct. As a result, DuoAI operates in formula space and considers smaller formulas first to enumerate candidate invariants, which are then checked by an SMT solver. Formula size is defined by a maximum number of quantified variables (a variable and its quantifier $\forall$ or $\exists$) and relations. If DuoAI does

not succeed with smaller formulas, it increases the formula size and repeats the process until an inductive invariant is found. Although the formula space within a given formula size is finite, checking all possible invariants for even a modest size formula is prohibitively expensive, especially since SMT solvers are particularly inefficient at checking invariants with existential quantifiers. It is crucial to avoid too many SMT queries and SMT queries that are too complex. Based on this observation, DuoAI introduces and combines new techniques that avoid the limitations of SMT solvers in checking invariants with existential quantifiers.

First, DuoAI runs protocol simulations at various instance sizes and logs the reached protocol states, which we call *samples*. Instance size refers to the size of distributed system (number of nodes, packets, etc.) running the protocol. These simulations are fast to execute. DuoAI directly checks candidate invariants against the samples, pruning those that do not hold to reduce the number of invariants checked by an SMT solver. To do this systematically, DuoAI introduces the *minimum implication graph*, which for a given invariant, shows all its implied weaker invariants. It then selects the *strongest* candidate invariants in the graph that hold for the samples.

Second, DuoAI combines the strongest candidate invariants with the safety property and feeds them to an SMT solver to check if the conjunction is inductive. If the check fails, it *monotonically weakens* the invariants using the graph and repeats the process until an inductive invariant is found. If the number of candidate invariants is not too large and most are required in the final solution, this method will be effective at reducing the number of SMT queries by feeding all of the candidate invariants to the SMT solver at once.

Third, DuoAI feeds the strongest candidate universal invariants, those without existential quantifiers, from the graph to an SMT solver to check if the conjunction, without the safety property, is inductive. If the check fails, it monotonically weakens the invariants using the graph, only considering candidate universal invariants, and repeats the process until the conjunction is inductive. We call this set of inductive $\forall$-only invariants the *universal core*. It then strengthens the *universal core* by iteratively adding a small subset of the strongest candidate invariants with existential quantifiers from the graph until the conjunction with the safety property is inductive. If the number of candidate invariants with existential quantifiers is large and most are not in the final solution, this method will be effective at avoiding too complex SMT queries, because it only feeds a few invariants to the SMT solver each time.

DuoAI runs these two methods for refining candidate invariants in parallel, a top-down refinement that *weakens* the candidates and a bottom-up refinement that *strengthens* the candidates, returning the result from the method that succeeds first. We prove that both methods are guaranteed to find the inductive invariant that proves the desired safety property, but they may have very different running times and resource requirements depending on the distributed protocol being verified. Using both methods together provides the best of both worlds in addressing the inefficiencies of SMT solvers.

Figure 1: The simplified consensus protocol written in Ivy. Capitalized variables are implicitly quantified. For example, Line 16 means $\forall N:node, V:value.\ decided(N,V) := false$. "~" stands for negation.

We evaluated DuoAI using 27 widely-used distributed protocols in a head-to-head comparison against other approaches, including I4, DistAI, FOL-IC3, and SWISS. DuoAI outperforms all of the other approaches in terms of both the number of protocols for which it finds an inductive invariant and the speed at which it does so. DuoAI solves Paxos more than two orders of magnitude faster than any other approach, and is the only system that can solve more complex versions of Paxos including multi-Paxos, stoppable Paxos, and fast Paxos.

2 Overview

We use a simplified consensus protocol as an example to show how DuoAI works. Figure 1 shows the protocol written in Ivy [28], a language and tool for specifying, modeling, and verifying distributed protocols built on top of the Z3 SMT solver. Each node can vote for another node to be the leader, and when a node receives votes from a quorum of nodes, it can become the leader and decide on a value. The protocol state at any moment is represented by five relations (Lines 5-9). $vote(n_1,n_2)$

indicates whether node n_1 has voted for node n_2. $voted(n)$ indicates whether node n has ever casted a vote. $leader(n)$ indicates if n is the leader among nodes. $decided(n,v)$ indicates whether node n has decided on value v. $member(n,q)$ indicates if node n belongs to quorum q, where each quorum is a set of nodes. The axiom (Line 10) dictates a property of the member relation: any two quorums of nodes must have at least one node in common. After initialization (Lines 13-16), the protocol can non-deterministically transition from one state to another as described by the three actions *cast_vote*, *become_leader*, and *decide* (Lines 19-34). For example, $cast\_vote(n_1,n_2)$ lets a node n_1 vote for another node n_2, under the precondition that n_1 has not voted before (Line 20). Then the protocol will transition to a new state where $vote(n_1,n_2) = true$ and $voted(n_1) = true$. Finally, the safety property (Line 36) encodes the desired property of correctness of the protocol that the system cannot decide on two different values.

The safety property is an invariant of the protocol, but is not inductive as taking an action from a state satisfying the safety property may result in a new state that breaks the safety property. To verify the protocol, we need four additional invariants:

$$\forall N_1,N_2 : node.\ vote(N_1,N_2) \rightarrow voted(N_1) \quad (1)$$

$$\forall N_1,N_2,N_3 : node.\ vote(N_1,N_2) \wedge vote(N_1,N_3) \rightarrow N_2 = N_3 \quad (2)$$

$$\exists Q : quorum.\ \forall N_1,N_2 : node.$$
$$leader(N_1) \wedge member(N_2,Q) \rightarrow vote(N_2,N_1) \quad (3)$$

$$\forall N : node.\ V : value.\ decided(N,V) \rightarrow leader(N). \quad (4)$$

The first invariant says that if a node has voted for another node, then it must be recorded as *voted* in the protocol. The second says that one node cannot vote for two different nodes. The third says that a leader must be endorsed by a quorum of nodes. More specifically, we can find a quorum Q that every node N_2 in the quorum must have voted for the leader N_1. The fourth says that only a leader can decide on a value. The conjunction of the four invariants and the safety property is inductive.

To find this inductive invariant, DuoAI simulates the protocol using different instance sizes and logs the samples. It then builds a minimum implication graph, a small fragment of which is shown in Figure 2. The full graph for simplified consensus has over 35K nodes and 170K edges. Nodes represent formulas and edges represent implication between formulas. A stronger formula will have a directed edge to an implied weaker formula. DuoAI enumerates possible candidate invariants following the graph and adds it to the candidate invariant set if it holds on the samples. For example, DuoAI checks the root node in Figure 2 and it does not hold on the samples. DuoAI then checks its implied weaker formulas, the two nodes in the second layer, iteratively going down the graph. For the simplified consensus protocol, enumeration ends with 19 candidate invariants, including equivalent forms of Eq. (1), (2), (3), and (4).

After enumeration, DuoAI runs top-down and bottom-up refinement in parallel. Top-down refinement feeds all candidate invariants and the safety property to Ivy to see if their conjunction is inductive. For simplified consensus, the conjunction is inductive, so no further weakening is required. Bottom-up refinement feeds all ∀-only invariants from the initial candidate set to Ivy then weakens them until the set of invariants is itself inductive, but may not imply the safety property. For simplified consensus, this universal core includes three invariants Eq. (1), (2), and (4). DuoAI then tries to search a small number of ∃-included invariants to add to the universal core along with the safety property so that the resulting set is inductive. DuoAI uses counterexamples from Ivy to guide the search for additional invariants and eventually identifies invariant (3) for the simplified consensus protocol, forming an inductive invariant set. For simplified consensus, top-down refinement succeeds more quickly than bottom-up refinement.

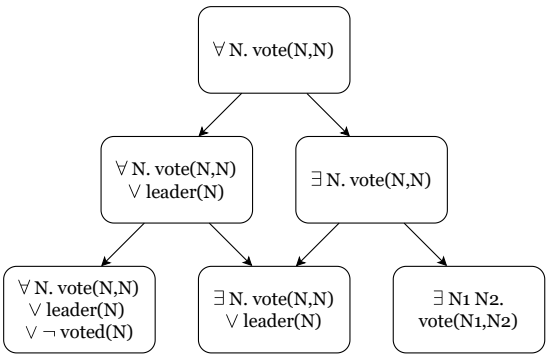

Figure 2: Fragment of the minimum implication graph for the simplified consensus protocol.

3 Minimum Implication Graph

The backbone of DuoAI is the minimum implication graph, which encodes implication relations among formulas. The graph is used to determine the order of formulas to be enumerated, and how invariants are weakened. We present formulas in prenex normal form, where the quantified variables, called the prefix, appear at the beginning of the formula followed by quantifier-free relations, called the matrix. The matrix is required to be in disjunctive normal form (DNF). For simplicity, here we only consider predicate symbols with equality. The methods can be extended to uninterpreted functions in the same manner as DistAI [38].

A formula P is strictly stronger than Q if $P \Rightarrow Q$ and $Q \not\Rightarrow P$. For two formulas $P,Q \in \mathcal{S}$, where $\mathcal{S}$ is a finite formula search space, there is a directed edge from P to Q in the minimum implication graph if and only if P is strictly stronger than Q and there is no formula R which is strictly weaker than P while strictly stronger than Q. For example, the fragment of the minimum implication graph in Figure 2 includes three formulas:

$$\forall N.\ vote(N,N) \quad (5)$$

$$\exists N.\ vote(N,N) \quad (6)$$

$$\exists N_1,N_2.\ vote(N_1,N_2) \quad (7)$$

Eq. (5) $\Rightarrow$ (6) since if $vote(N,N)$ is true for all N, there must exist some N for which it is true. Eq. (6) $\Rightarrow$ (7) since if $vote(N,N)$ is true for some N, there must exist some $N_1 = N_2$ for which $vote(N_1,N_2)$ is true. Because Eq. (5) $\Rightarrow$ (6) $\Rightarrow$ (7), there is an edge from Eq. (5) to (6), an edge from Eq. (6) to (7), but no edge from Eq. (5) to (7), because Eq. (6) is between them.

DuoAI defines the search space $\mathcal{S}$ as all formulas in disjunctive normal form for a given set of quantified variables and formula size. The formula size is defined by four parameters: *max_exists* sets the maximum number of existentially quantified variables, *max_literal* sets the upper bound of the total number of literals in the formula, *max_and* sets the maximum number of literals connected by AND, and *max_or* sets the maximum number of conjunctions connected by OR.

The minimum implication graph has two important properties as stated in Lemmas 1 and 2:

Lemma 1. *The minimum implication graph is a directed acyclic graph (DAG).*

Proof. Suppose there is a cycle $P_1 \rightarrow P_2 \rightarrow \ldots \rightarrow P_k \rightarrow P_1$. The edges $P_1 \rightarrow P_2, \ldots, P_{k-1} \rightarrow P_k$ imply that $P_1 \Rightarrow P_2, \ldots, P_{k-1} \Rightarrow P_k$. From the transitivity of $\Rightarrow$ we know $P_1 \Rightarrow P_k$. Since there is an edge from P_k to P_1, we know $P_1 \not\Rightarrow P_k$, a contradiction. □

Lemma 2. *For any $P,Q \in \mathcal{S}$, there is a path from P to Q in the minimum implication graph if and only if $P \Rightarrow Q \wedge Q \not\Rightarrow P$.*

Proof. We first prove the "if" direction by induction on the number of formulas in S that are strictly weaker than P while strictly stronger than Q. For the base case, if there are zero such formulas, then by definition there is an edge from P to Q. Next we prove the induction step. Suppose for any $P,Q \in S$, if $P \Rightarrow Q \wedge Q \not\Rightarrow P$, and there is no more than n formulas that are strictly weaker than P while strictly stronger than Q, then there is a path from P to Q. Now consider the case that there are $n+1$ formulas that are strictly weaker than P while strictly stronger than Q. Let R be one of the $n+1$ formulas. We know $P \Rightarrow R \wedge R \not\Rightarrow P$, and there can be no more than n formulas that are strictly weaker than P while strictly stronger than R. By the induction hypothesis, there is a path from P to R. In the same manner, we can show there is a path from R to Q. Then we concatenate the two paths and get a path from P to Q.

Next we prove the "only if" direction. If there is a path from P to Q, Let $P, F_1, F_2, ..., F_k, Q$ be the path. We know $P \Rightarrow F_1, \ldots, F_k \Rightarrow Q$, so $P \Rightarrow Q$. We prove $Q \not\Rightarrow P$ by contradiction. Suppose $Q \Rightarrow P$, then $P \Leftrightarrow Q$, so there must be an edge from F_k to P. This forms a cycle $P,F_1,...,F_k,P$, a contradiction to Lemma 1. □

To build the minimum implication graph, we need to determine the "root" nodes in the graph, that is, formulas with no predecessors since they cannot be implied by any other formula, and how to find their successors. In DuoAI, a formula $P \in S$ is added to the set of root nodes if it falls into one of two cases:

1. P has no $\exists$-quantified variable and no logical OR. For example:
$$\forall N : node.\ vote(N,N) \wedge leader(N). \tag{8}$$
2. P has unique $\exists$-quantified variables and no logical OR. For example:
$$\exists N_1,N_2 : node.\ N_1 \neq N_2 \wedge vote(N_1,N_2). \tag{9}$$

Intuitively, if a formula has an $\exists$, then by changing it to a $\forall$, we can get a stronger formula. If a formula has a logical OR, then by removing the OR and any literals followed by it, we can get a stronger formula. So in general, a root formula should have no $\exists$ and no OR, such as Eq. (8). There is one exception, represented by Eq. (9). At first sight Eq. (9) has a predecessor $\forall N_1,N_2 : node.\ N_1 \neq N_2 \wedge vote(N_1,N_2)$. However, this formula is a contradiction because $\forall N_1,N_2 : node.\ N_1 \neq N_2$ cannot be true. The minimum implication graph does not include tautologies and contradictions, so Eq. (9) itself is a root formula.

Starting from the root nodes, DuoAI incrementally builds the minimum implication graph. For formulas $P,Q \in S$, DuoAI adds an edge from P to Q if the shapes of P and Q fall into one of five cases:

1. P and Q share the same matrix. Q replaces the $\forall$-quantified variables of one type with $\exists$-quantified variables. For example:
$$P = \forall N : node, V : value.\ \neg decided(N,V)$$
$$Q = \exists N : node.\ \forall V : value.\ \neg decided(N,V).$$
2. P and Q share the same prefix. Q has one less ANDed literal than P. For example:
$$P = \text{Eq.}(8) \qquad Q = \text{Eq.}(5).$$
3. P and Q share the same prefix. Q has one more ORed conjunction than P. For example:
$$P = \forall N : node.\ vote(N,N)$$
$$Q = \forall N : node.\ vote(N,N) \vee (voted(N) \wedge leader(N)).$$
DuoAI requires that the ORed conjunction be maximal, which means it contains the maximum number of literals for the search space. The conjunction $voted(N) \wedge leader(N)$ in Q is maximal if $max\_and = 2$ or $max\_literal = 3$. For example, $Q' = \forall N : node.\ vote(N,N) \vee voted(N)$ also adds one more ORed conjunction from P, but DuoAI does not add an edge from P to Q', because Q is strictly stronger than Q'.
4. Starting from P, Q projects two $\forall$-quantified variables of the same type into one variable. For example:
$$P = \forall N_1,N_2 : node.\ vote(N_1,N_2) \vee leader(N_1)$$
$$Q = \forall N : node.\ vote(N,N) \vee leader(N).$$
5. Starting from Q, P projects two $\exists$-quantified variables of the same type into one variable. For example:
$$P = \text{Eq.}(6) \qquad Q = \text{Eq.}(7).$$

The graph constructed in this way may differ slightly from the exact minimum implication graph due to equivalent formulas. For example, formulas $\forall X.\ p(X) \vee (\neg p(X) \wedge q(X))$ and $\forall X.\ p(X) \vee q(X)$ fall into the second case, so there is an edge in the constructed graph. However, the two formulas are equivalent so there is no edge in the exact graph. We call the graph constructed by DuoAI an *approximate minimum implication graph*, whose properties are formalized in Lemmas 3, 4, and 5:

Lemma 3. *The approximate minimum implication graph is a directed acyclic graph (DAG).*

Proof. For all of the five cases, we can show that for formulas along any path in the approximate minimum implication graph, there exists one function that is strictly increasing, so there can be no cycle. For example, this is true for the function $(\#\exists\text{-}variables) - (\#\forall\ variables) + (max\_and * (\#\vee)) - (\#\wedge)$, where # denotes "the number of" (e.g., $(\#\vee)$ is the number of logical OR in a formula). □

Lemma 4. *For any $P,Q \in \mathcal{S}$, there is a path from P to Q in the approximate minimum implication graph only if $P \Rightarrow Q$.*

Proof. From the transitivity of $\Rightarrow$, we only need to show that if there is an edge from P to Q in the approximate minimum implication graph, then $P \Rightarrow Q$. This can be proved by showing $P \Rightarrow Q$ holds in each of the five cases. The first three cases are trivial. For the fourth case, in general $P = \ldots \forall X_1 X_2 \ldots matrix(X_1, X_2)$ and $Q = \ldots \forall X_1 \ldots matrix(X_1, X_1)$. Let $P' = \ldots \forall X_1 X_2 \ldots X_1 = X_2 \rightarrow matrix(X_1, X_2)$, then $P \Rightarrow P' \Leftrightarrow Q$. Similarly, for the fifth case, $P = \ldots \exists X_1 \ldots matrix(X_1, X_1)$ and $Q = \ldots \exists X_1 X_2 \ldots matrix(X_1, X_2)$. Let $Q' = \ldots \exists X_1 X_2 \ldots X_1 = X_2 \wedge matrix(X_1, X_2)$, then $P \Leftrightarrow Q' \Rightarrow Q$. □

Lemma 5. *For any formula $P \in S$ that is not a tautology or a contradiction, there exists a directed path from a root node $Q \in S$ to P in the approximate minimum implication graph.*

Proof. We prove this by construction. For a $\exists$-free formula P, if it includes no logical OR, then it is a root formula itself. Otherwise, we find the root formula Q by removing all but one ORed conjunctions. Starting from Q, we can iteratively apply the second and third cases to add conjunctions and remove literals until we reach P. For a $\exists$-included formula P, if it includes unique $\exists$-quantified variables then it is a root formula itself. Otherwise, we iteratively find a predecessor by replacing $\exists$ with $\forall$ for quantified variables of each type, until the formula becomes the $\exists$-free P'. The first case guarantees that there is a path from P' to P, and we have already shown for the $\exists$-free P', there exists a path from a root node Q. Putting it together, we have a path from Q to P in the approximate minimum implication graph. □

In other words, the approximate minimum implication graph is as useful and complete as the exact graph. DuoAI uses the approximate minimum implication graph, which, for simplicity, we will continue to refer to as the minimum implication graph unless otherwise specified.

DuoAI requires that formulas in $\mathcal{S}$ must be in a decidable fragment of first-order logic. In general, satisfiability in first-order logic is undecidable [23], so an SMT solver can get stuck in infinite instantiations and never give the *sat*/*unsat* answer. DuoAI ensures that the formulas are decidable by enforcing a fixed order of types if there is quantifier alternation (i.e., alternating $\forall$ and $\exists$) [1]. If type A is ordered before type B, then for any formula, if there exists a quantified variable V of type A, any quantified variable of type B can only occur after V if there is quantifier alternation. For example, if type *node* is ordered before type *packet*, then $\forall N : node.\ \exists P : packet$ and $\exists N : node.\ \forall P : packet$ are allowed while $\forall P : packet.\ \exists N : node$ and $\exists P : packet.\ \forall N : node$ are not. DuoAI tries to infer the order of types from the protocol specification and obtains input from the user when necessary. For example, for the simplified consensus protocol, DuoAI can infer from Line 10 that type `quorum` must be ordered before type `node`, then ask the user to place type `value` in the order. Absent user input, DuoAI will try different possible orders in parallel.

4 Candidate Invariant Enumeration

Similar to DistAI [38], DuoAI first repeatedly simulates the distributed protocol using various instance sizes, and records the reached states as samples. For example, DuoAI simulates the simplified consensus protocol on concrete instances of different numbers of values, quorums, and nodes. The simulations of different instance sizes are done in parallel and yield samples of different lengths. DuoAI follows the minimum implication graph to enumerate candidate invariants, but rather than feeding all of them to an inefficient SMT solver, it checks them directly on the samples first. A correct invariant must hold on every reachable protocol state and thus on every sample. A key difference between DuoAI and DistAI is that DuoAI keeps the original variable-length samples and uses them in invariant enumeration, while DistAI projects all samples to fixed-length vectors that it calls subsamples. The problem is that DistAI is not exhaustive in its subsampling, so that a formula with existential quantifiers that holds for DistAI's subsamples may not actually hold for the original samples. DuoAI avoids this problem by effectively considering all possible subsamples that can be derived from the original samples.

Algorithm 1 shows the enumeration algorithm, in which *pending* is a queue whose elements are formulas that will be checked on the samples, *candidates* is the set of formulas that hold on all the samples and *invalidated* is the set of formulas that do not hold on at least one of the samples. Both *candidates* and *invalidated* are initially empty (Lines 2-3), and *pending* initially consists of the root nodes of the minimum implication graph, that is, formulas that cannot be implied by any other formula. In each iteration, a formula f is popped from the *pending* queue (Line 5). If one of f's ancestors in the graph has already been added to *candidates*, DuoAI will not check f on the samples or add f to the *candidates* invariants (Lines 6-7). Oth-

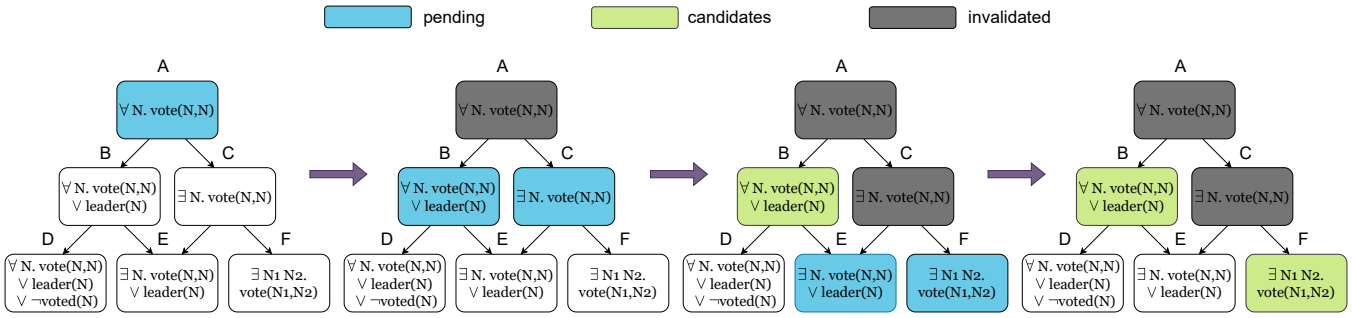

Figure 3: Invariant enumeration procedure based on the minimum implication graph. Suppose formula A and formula C do not hold on all the samples, while the other four formulas hold. Step 1: Only the root node A is in the *pending* queue. Step 2: The root node A is invalidated by the samples. We add its two successors B and C to the *pending* queue. Step 3: Formula B holds on the samples thus being added to *candidates*, while formula C is invalidated and its two successors E and F are added to the *pending* queue. Step 4: Formula E has an ancestor B which is already in *candidates*, so E is simply skipped instead of being checked on the samples. Formula F holds on the samples and is added to *candidates*.

Algorithm 1 Invariant Enumeration Algorithm

Input: Distributed protocol $\mathcal{P}$, invariant search space $\mathcal{S}$, a set of samples from protocol simulation *samples*
Output: Candidate invariants

```
1:  graph := build_minimum_implication_graph(P,S)
2:  candidates, invalidated := ∅,∅
3:  pending := graph.rootNodes
4:  while pending.notEmpty() do
5:      f := pending.dequeue()
6:      if graph.ancestors(f) ∩ candidates ≠ ∅ then
7:          continue
8:      if check_inv_holds(f, samples) then
9:          candidates := candidates ∪ {f}
10:     else
11:         invalidated := invalidated ∪ {f}
12:         for next_f ∈ graph.successors(f) do
13:             if next_f ∉ candidates and next_f ∉ invalidated
                and next_f ∉ pending then
14:                 pending.enqueue(next_f)
15: return candidates
```

erwise, DuoAI will check f on the samples and if it holds, add it to *candidates* (Lines 8-9). If f does not hold on at least one sample, DuoAI will add it to *invalidated* (Line 11), and add its successors, which are formulas weaker than f, to the *pending* queue if they have not already been added (Lines 12-14).

Figure 3 shows an example of invariant enumeration using the graph in Figure 2. DuoAI starts from the root nodes, iteratively goes down the minimum implication graph, and checks formulas against the samples. Because of this design, formulas D and E are never checked against the samples and are not added to the candidates, because their predecessor B, a formula stronger than both D and E, is already a candidate invariant. This design not only saves time checking formulas on samples, but also avoids burdening the SMT solver later with checking the inductiveness of redundant invariants. More importantly, this procedure guarantees that the resulting invariants, formulas B and F in this example, are the strongest candidate invariants that hold on the samples, which is formally stated in the following theorem:

Theorem 1. *For any correct invariant $I \in \mathcal{S}$ held by the protocol $\mathcal{P}$, at the end of invariant enumeration, either 1) $I \in candidates$, or 2) one of I's ancestors $I_{anc} \in candidates$.*

Proof. Consider three cases: 1) I has been checked on the samples, 2) I has been added to the *pending* queue but was not checked on samples, and 3) I has been never added to the *pending* queue. In the first case, since I is a correct invariant held by the protocol, it must hold on all the samples and will be added to *candidates* (Lines 8-9), so $I \in candidates$. In the second case, after I is popped from the *pending* queue, there must be an ancestor I_{anc} of I already in *candidates* (Line 6), otherwise I will be checked on the samples, so $I_{anc} \in candidates$. In the third case, we show that an ancestor $I_{anc} \in candidates$ exists. From Lemma 5, there must be a path from a root node I_0 to I, namely $I_0,I_1,...,I$. On Line 3 the root node I_0 is added to the *pending* queue. Since I_0 is added to the *pending* queue and I is not, let I_k be the last formula on the path $I_0,I_1,...,I$ that is ever added to the *pending* queue. After I_k is dequeued, there are three possible branches to take: Lines 6-7, Lines 8-9, or Lines 10-14. If it takes Lines 6-7, then there is an ancestor I_{anc} of I_k such that $I_{anc} \in candidates$. If it takes Lines 8-9, then I_k will be added to *candidates* so I_k can be the ancestor I_{anc} of I such that $I_{anc} \in candidates$. If it takes Lines 10-14, its successors will be added to the *pending* queue unless the branch condition at Line 13 evaluates to false. From our hypothesis, I_k is last formula on path $I_0,...,I_k,I_{k+1},...,I$ that is ever added to the *pending* queue. Thus, the branch condition for I_{k+1} must evaluate to false, so either $I_{k+1} \in candidates$ or $I_{k+1} \in invalidated$. However, I_{k+1} must be added to the *pending* queue before it can be added to either *candidates* or *invalidated*, a contradiction. □

Theorem 1 says that any correct invariant has either itself or

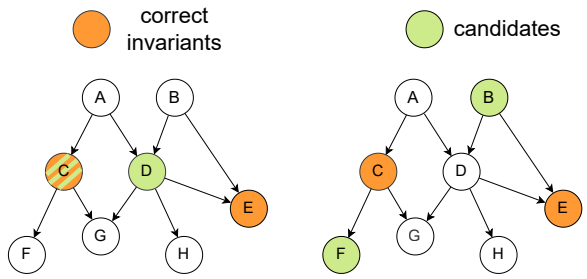

Figure 4: Possible (left) and impossible (right) candidate invariants after enumeration. Formulas C and E are correct invariants held by the protocol. It is possible that after enumeration, $candidates = \{C, D\}$ (left). Correct invariant C is in the candidate invariants itself. For correct invariant E, its ancestor D is in the candidate invariants. Theorem 1 guarantees that $candidates = \{B, F\}$ is not a possibility after enumeration, because for correct invariant C, neither itself nor its lone ancestor A is in the candidate invariants.

its ancestor (a stronger formula) in the candidate invariants. Figure 4 gives an illustration. A direct corollary is that, the set of candidate invariants after the enumeration is at least as strong as the correct invariant in $\mathcal{S}$.

5 Top-down Invariant Refinement

Based on Theorem 1, the candidate invariants can only be *too strong*, so DuoAI can monotonically weaken the candidate invariants until a correct inductive invariant is reached, which we refer to as top-down invariant refinement. Algorithm 2 shows the top-down refinement algorithm. In each iteration, DuoAI feeds the current candidate invariants to Ivy. Ivy invokes the Z3 SMT solver to check the inductiveness of each candidate invariant and the safety property. Ivy will return which invariants fail the check; if there are none, the correct inductive invariant has been found (Lines 4-5). If the safety property fails, there is no point to weaken it, and the system returns NotProvable (Lines 6-7). If one of the candidate invariants fails, DuoAI moves it from *candidates* to *invalidated* (Lines 9-10), then adds its successors (i.e., formulas that can be implied by the failed invariant) to *candidates* so long as the successor does not have a reachable ancestor in *candidates* and has not already been invalidated (Lines 12-13). An ancestor of a node is reachable if there is a path from the ancestor to the node along which no node is invalidated.

Figure 5 shows an example of top-down refinement. Suppose the current candidate invariants include formulas B and F, and by invoking the Z3 SMT solver, Ivy indicates that B is not inductive. Formulas D and E are not in *candidates*, because they can be implied by formula B which is already in *candidates*. After B is invalidated, both D and E will be added to *candidates* to let Ivy decide their inductiveness in future iterations. Alternatively, if formula F is invalidated by Ivy, no formula will be added to *candidates* because F has no successor in the minimum implication graph of search space $\mathcal{S}$.

Algorithm 2 Top-down Invariant Refinement Algorithm

Input: Distributed protocol $\mathcal{P}$, minimum implication graph *graph*, candidate invariants from enumeration *CI*
Output: Either an inductive invariant *II*, or NotProvable

```
1:  candidates, invalidated := CI, ∅
2:  while candidates.notEmpty() do
3:      failed_inv := Ivy_check(P, candidates)
4:      if failed_inv is None then
5:          return candidates
6:      else if failed_inv = safety_property then
7:          return NotProvable
8:      else
9:          candidates := candidates \ {failed_inv}
10:         invalidated := invalidated ∪ {failed_inv}
11:         for next_inv ∈ graph.successors(failed_inv) do
12:             if graph.reachable_ancestors(next_inv) ∩
                candidates = ∅ and next_inv ∉ invalidated then
13:                 candidates := candidates ∪ {next_inv}
14: return NotProvable
```

By weakening failed invariants based on the minimum implication graph rather than discarding them, DuoAI can guarantee that it never overweakens invariants to bypass the correct invariants in between. In other words, top-down refinement has a theoretical guarantee to eventually find an inductive invariant if one exists in the search space, as stated in the following theorem:

Theorem 2. *For any protocol $\mathcal{P}$ and finite search space $\mathcal{S}$, if there exists an inductive invariant $II^* \subset \mathcal{S}$ that can prove the safety property, then Algorithm 1 followed by Algorithm 2 will output such an inductive invariant II in finite time.*

Proof. The key is to prove that the while loop (Lines 2-13) maintains the following loop invariant: For any invariant $I \in II^*$, either 1) $I \in candidates$, or 2) there exists a reachable ancestor I_{anc} of I such that $I_{anc} \in candidates$. The loop invariant says that after any rounds of invariant weakening, the candidate invariants must be still at least as strong as the correct invariants. If Algorithm 2 terminates, it is impossible to have the safety property fail (Line 7). The only possibility is that a correct inductive invariant is returned (Line 5).

Theorem 1 guarantees that the loop invariant holds before entering the loop. We only need to prove that if this loop invariant holds at the beginning of round k of invariant weakening, it must still hold at the beginning of round $k+1$. This proof is done by construction for each $I \in II^*$. From the induction hypothesis, at the beginning of round k, either 1) $I \in candidates$, or 2) a reachable ancestor $I_{anc} \in candidates$. In the first case, I cannot have been invalidated during round k because $I \in II^*$, so $I \in candidates$ still holds at the beginning of iteration $k+1$. In the second case, the invalidated invariant must either be on or

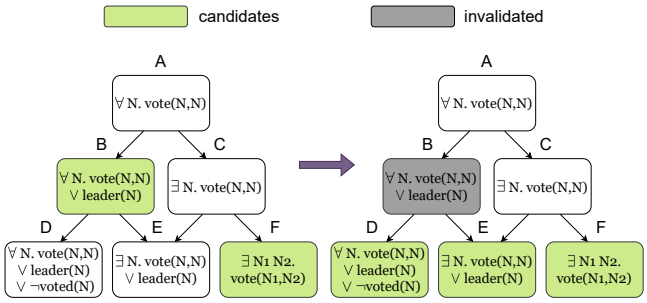

Figure 5: One round of top-down refinement. Suppose candidate invariant B fails the Ivy check. DuoAI removes B from *candidates* and adds its successors D and E to *candidates*.

not on the path from I_{anc} to I. If it is not on the path, I_{anc} remains a reachable ancestor of I and $I_{anc} \in candidates$ still holds at the beginning of iteration $k+1$. If it is on the path, let I_d be the successor of the invalidated invariant on the path. From Lines 11-13, either I_d is added to *candidates*, in which case I_d can be the new I_{anc} for iteration $k+1$, or I_d has a reachable ancestor $I_e \in candidates$, in which case we choose I_e as the new I_{anc} for iteration $k+1$. In all cases, we can find either I or a reachable ancestor I_{anc} in the candidate set, therefore the loop invariant holds.

Now we only need to prove that Algorithm 2 terminates, which follows from three observations: 1) In each loop iteration a formula is removed from *candidates* (Line 9); 2) each formula can only be added to *candidates* once (Lines 10 & 12); and 3) the formula search space $\mathcal{S}$ is finite. □

6 Bottom-up Invariant Refinement

Although top-down refinement provides a strong theoretical guarantee of finding an inductive invariant, it may take too long or run out of memory given limited computing resources if there are too many unnecessary invariants to consider. For the simplified consensus protocol in Figure 1, besides the four invariants (1)(2)(3)(4), many other invariants hold for the protocol but are unnecessary to prove the inductiveness of the safety property, for example,

$$\forall V : value, Q : quorum.\ \exists N : node.\ member(N,Q) \wedge (leader(N) \vee \neg decided(N,V)). \quad (10)$$

Invariants such as Eq. (10) do not affect the soundness of DuoAI, but they will significantly slow down the validation of candidate invariants by the SMT solver. If there are m candidate invariants, validating each invariant takes $O(m)$ time in the worst case, since the inductiveness of one invariant can depend on any other invariant, so checking all candidate invariants can take $O(m^2)$ time. Adding unnecessary invariants can increase validation time quadratically.

The key issue though is not just how many unnecessary invariants there are, but whether they have quantifier alternation (i.e., alternating ∀ and ∃), which we observe causes

Algorithm 3 Bottom-up Invariant Refinement Algorithm

Input: Distributed protocol $\mathcal{P}$, minimum implication graph *graph*, candidate invariants from enumeration *CI*
Output: Either an inductive invariant *II*, or NotProvable

Procedure 1
1: $CI_\forall := \{I | I \in CI \wedge I \text{ is } \exists\text{-free}\}$
2: $core$:= Algorithm2($\mathcal{P}$, $graph_\forall$, $CI_\forall$)
3: $noncore := CI \setminus core$
Procedure 2
4: $CE := \emptyset$
5: **for** *sub* **in** $powerset(noncore)$ **do**
6: **if** $\exists s \in CE$. invs_hold_on_state(sub,s) **then**
7: **continue**
8: result := Algorithm2($\mathcal{P}$, *graph*, $core \cup sub$)
9: **if** result = NotProvable **then**
10: $s \xrightarrow{a} s'$:= get_counterexample()
11: $CE := CE \cup \{s\}$
12: **else**
13: **return** result
14: **return** NotProvable

SMT solvers to struggle. For the Paxos protocol, a correct inductive invariant set of size 14 can be validated in less than a second. If we add 10 correct but unnecessary invariants with quantifier alternation, the validation will take 5 minutes. If we add 20 such invariants, the validation will take over 3 hours.In contrast, the chord ring maintenance protocol [21] with 149 ∀-only invariants only takes 8 seconds to validate.

However, a correct distributed protocol typically has a clear and human-understandable intuition, which leads to concise invariants [10]. This motivates our bottom-up invariant refinement algorithm shown in Algorithm 3. In essence, the algorithm tries to identify a small set of correct *and* helpful invariants that can eventually prove the safety property. §8 shows that the combination of bottom-up with top-down refinement provides fast performance for finding inductive invariants across a wide-range of protocols.

Algorithm 3 consists of two procedures. In Procedure 1, DuoAI first extracts all the ∀-only invariants from the candidate invariants (Line 1), which are guaranteed to be the strongest ∀-only invariants that hold on the samples. Then, DuoAI runs the top-down refinement algorithm (Line 2) using only the universal invariants and the universal portion of the minimum implication graph by removing all nodes representing existentially quantified formulas. The safety property is neglected in this top-down refinement. In this way, the ∀-only invariants are monotonically weakened until they become inductive, regardless of whether the safety property can be proved (it probably cannot). Recall that we call the now inductive ∀-only invariants the universal inductive core. DuoAI then puts every enumerated candidate invariant that is not in the universal inductive core

into *noncore* (Line 3). *noncore* mainly consists of formulas with existential quantifiers, but also includes ∀-only formulas that are not in the core, whose inductiveness may depend on ∃-included invariants. For example, for the simplified consensus protocol, the universal inductive core includes five candidate invariants, which are exactly the equivalent forms of Eq. (1), (2), and (4). There are 14 non-core candidate invariants, 13 of which have quantifier alternation, including Eq. (3) and (10).

Based on our observation that SMT solvers struggle with quantifier alternation, we expect *noncore* formulas will have a much higher cost of checking. Procedure 2 aims to identify a *small* subset of *noncore* to strengthen the candidate invariants, such that the conjunction of the universal inductive core and the subset (denoted as $core \cup sub$), or their weaker forms, can prove the safety property. Procedure 2 enumerates each subset *sub* of *noncore* (Line 5), and runs the monotonic weakening algorithm (Algorithm 2) on $core \cup sub$ (Line 8). If Algorithm 2 returns NotProvable (Line 9), DuoAI moves on to consider the next subset. Otherwise, Algorithm 2 outputs a correct inductive invariant (Line 13). The enumeration of subsets is conducted in increasing order of size, starting from the $\emptyset$, followed by all single formulas from *noncore*, then pairs, triples, and so on.

Whenever Algorithm 2 finds the safety property failed and reports NotProvable, Ivy returns a counterexample of inductiveness $s \xrightarrow{a} s'$ (Line 10), which means starting from a protocol state s satisfying the safety property and the candidate invariants, and taking an action a, the system reaches a new state s' where the safety property is violated.[1] If we view the samples from protocol simulation as positive samples on which the invariants must hold, then we can view these counterexample states s as negative samples which the invariants must exclude. DuoAI needs to identify and include another invariant I that does *not* hold on s, so that the counterexample $s \xrightarrow{a} s'$ can be excluded. When enumerating a subset of *noncore*, Procedure 2 first checks if the subset can exclude all counterexamples seen so far (Line 6). If there exists one counterexample state s on which all invariants in the subset hold, or in other words, the counterexample cannot be excluded, the monotonic weakening algorithm is bound to fail, because if a stronger invariant cannot exclude the counterexample, then its weaker forms cannot either. So Procedure 2 simply moves on to enumerate the next subset (Line 7).

For the simplified consensus protocol, when $sub = \emptyset$, the safety property fails and Ivy gives the counterexample $s = \{vote(n_1,n_1) = vote(n_1,n_2) = vote(n_2,n_1) = vote(n_2,n_2) = false,\ voted(n_1) = voted(n_2) = false,\ leader(n_1) = leader(n_2) = true,\ member(n_1, q) = member(n_2, q) = true,\ decided(n_2, v_1) = true,\ decided(n_1, v_1) = decided(n_1, v_2) = decided(n_2, v_2) = false\}$. Eq. (3) does not hold on s, so it can exclude this counterexample. In contrast, Eq. (10) holds on s, so the counterexample will persist even if Eq. (10) is added to the candidate set. Therefore, DuoAI will skip Eq. (10) and try Eq. (3), and run Algorithm 2 on its conjunction with the universal core, which gives a correct inductive invariant set consisting of Eq. (1)(2)(3)(4).

Although counterexamples can be used for top-down refinement, DuoAI currently does not because Ivy cannot return counterexamples in batch. When Ivy is configured to return a counterexample, it terminates once it identifies the first broken invariant. This is inefficient for top-down refinement, but for bottom-up refinement, counterexamples are only needed for the safety property, so DuoAI puts the safety property on top of other invariants and Ivy will give the desired counterexample.

Like top-down refinement, bottom-up refinement has a theoretical guarantee to eventually find an inductive invariant if one exists in the search space, as stated in the following theorem:

Theorem 3. *For any protocol $\mathcal{P}$ and finite search space $\mathcal{S}$, if there exists an inductive invariant $II^* \subset \mathcal{S}$ that can prove the safety property, then Algorithm 1 followed by Algorithm 3 will output such an inductive invariant II in finite time.*

Proof. We first prove that Algorithm 3 terminates in finite time. This directly follows from three facts: 1) $powerset(noncore)$ is a finite set so the for loop (Line 5) has a finite number of iterations; 2) In each loop iteration, there is at most one invocation of Algorithm 2 (Line 8); and 3) From Theorem 2, Algorithm 2 terminates in finite time.

To prove the soundness of Algorithm 3, we first observe that if Algorithm 3 outputs an invariant, it must be a correct inductive invariant, because the output must come from Algorithm 2, in which the output can only occur when the safety property is proved.

Now we prove that there will be an output invariant eventually. Observe that $noncore \in powerset(noncore)$ (Line 5). When $sub = noncore$, we have $CI \subset core \cup sub$, then Line 8 degenerates to Algorithm 2 in §5. From Theorem 2, we know a correct inductive invariant will be outputted. □

For both the top-down and bottom-up refinement, if NotProvable is returned, we know the protocol cannot be verified using invariants in the search space $\mathcal{S}$. DuoAI will try a larger search space by increasing either *max_literal*, *max_or*, *max_and*, or *max_exists*, or the per-domain number of quantified variables. By default, DuoAI alternates among the five in a round-robin manner. DuoAI sets the initial $max\_literal = 4$, $max\_or = max\_and = 3$, and $max\_exists = 1$ unless the safety property already involves $k \geq 2$ existentially quantified variables, in which case DuoAI sets $max\_exists = k$. DuoAI sets the initial number of quantified variables for domain T as the maximum number of variables of type T in any relation. For example, the relation `vote(N1:node,N2:node)` guarantees type `node` has at least two variables.

Because SMT solvers are much less efficient at checking invariants with existential quantifiers, and many distributed protocols are provable by ∀-only invariants [21], DuoAI runs

[1] In general, other than showing an invariant is not inductive, a counterexample may also show an invariant does not hold at the protocol initial state. But this cannot happen to the safety property, unless the protocol is wrong.

a ∀-only instance (i.e., $max\_exists = 0$) in parallel. The ∀-only instance only runs top-down refinement, as bottom-up refinement degenerates to the same top-down refinement (Line 2).

7 Optimizations Based on Mutual Implication

In using the minimum implication graph, DuoAI introduces several optimizations based on mutual implication relations among formulas. These relations further prune the search space and avoid redundant candidate invariants. DuoAI considers two kinds of mutual implication relations, 1) $P_1 \wedge P_2 \wedge ... \wedge P_k \Rightarrow Q$, and 2) $P_1 \wedge P_2 \wedge ... \wedge P_k \Leftrightarrow Q$. Although the latter is a special case of the former, DuoAI treats them differently. We refer to Q as a *conjunction implied formula* in the former and an *equivalently decomposable formula* in the latter. Since checking inductiveness has a quadratic complexity with the number of invariants, these optimizations have a significant improvement on efficiency.

Conjunction implied formulas. DuoAI identifies conjunction implied formulas to avoid redundant candidate invariants. Given a mutual implication relation $P_1 \wedge P_2 \wedge ... \wedge P_k \Rightarrow Q$, if all $P_1, P_2, ... P_k$ are already in the candidate invariants, DuoAI will mark Q as a conjunction implied formula and not add Q to the candidate invariants. Later during refinement, if one of $P_1, P_2, ... P_k$ is invalidated by Ivy, then the conjunction implied invariant Q is no longer redundant and will be added to the candidate invariants.

For example, suppose we have a disk replication protocol with the following three invariants:

$$\forall E : epoch, R : replica.\ crashed(E,R) \rightarrow \neg readable(E,R) \quad (11)$$

$$\forall E : epoch.\ \exists R : replica.\ readable(E,R) \quad (12)$$

$$\forall E : epoch.\ \exists R : replica.\ \neg crashed(E,R). \quad (13)$$

One can check that among Eq. (11)(12)(13), no formula can imply another. But the conjunction of Eq. (11) and (12) can imply Eq. (13). This is because Eq. (12) says that for every epoch E, there must be a readable replica R. Then from Eq. (11), the readable replica R cannot be crashed. Therefore, for every epoch E, there must be a replica R that does not crash, which is expressed by Eq. (13). If Eq. (11) and (12) are already candidate invariants, DuoAI will mark Eq. (13) as a conjunction implied formula and not add it to the candidate invariants.

There are many classes of mutual implication relations in first-order logic. DuoAI identifies three classes of conjunction implied formulas to prune candidate invariants; in each class, the first two formulas mutually imply the third:

1. Replace a literal with a weaker literal, as discussed in the example Eq. (11)(12)(13):

$$P_1 = \forall X.\ r(X) \rightarrow s(X)$$
$$P_2 = prefix.\ (r(X) \wedge ...) \vee ...$$
$$Q = prefix.\ (s(X) \wedge ...) \vee ...$$

2. Conjunct a literal with a weaker literal:

$$P_1 = \forall X.\ r(X) \rightarrow s(X)$$
$$P_2 = prefix.\ (r(X) \wedge ...) \vee ...$$
$$Q = prefix.\ (r(X) \wedge s(X) \wedge ...) \vee ...$$

3. "Merge" a ∀ formula and an ∃ formula:

$$P_1 = \exists X.\ r(X)$$
$$P_2 = \forall X.\ s(X) \vee ...$$
$$Q = \exists X.\ (r(X) \wedge s(X)) \vee ...$$

In all three classes, r and s can be generalized to conjunctions (e.g., $r_1(X) \wedge \neg r_2(X)$, $\neg s_1(X) \wedge s_2(X) \wedge s_3(X)$). A key advantage of this optimization is that given a finite search space, DuoAI can identify conjunction implied formulas based on invariants within that search space, even though the conjunction of invariants is not in that search space.

Equivalently decomposable formulas. DuoAI also identifies equivalently decomposable formulas to avoid redundant candidate invariants. Given a mutual implication relation $P_1 \wedge P_2 \wedge ... \wedge P_k \Leftrightarrow Q$, DuoAI will mark Q as an equivalently decomposable formula and never add Q to the candidate invariants. Later during refinement, if one of $P_1, P_2, ... P_k$ is invalidated by Ivy, Q will also be invalidated and therefore there is never any reason to consider Q further as a candidate invariant.

For example, suppose the disk replication protocol has invariant:

$$\forall E : epoch.\ \exists R_1, R_2 : replica.\ readable(E,R_1) \wedge writable(E,R_2). \quad (14)$$

There is no need to ever include such an invariant in the candidate set, because it is equivalently decomposable to invariants (15) and (16).

$$\forall E : epoch.\ \exists R : replica.\ readable(E,R) \quad (15)$$

$$\forall E : epoch.\ \exists R : replica.\ writable(E,R). \quad (16)$$

However, suppose we slightly modify invariant (14) to one of the following two formulas:

$$\forall E : epoch.\ \exists R_1 : replica.\ readable(E,R_1) \wedge writable(E,R_1) \quad (17)$$

$$\forall E : epoch.\ \exists R_1, R_2 : replica.\ R_1 \neq R_2 \wedge readable(E,R_1) \wedge writable(E,R_2). \quad (18)$$

These invariants are not equivalently decomposable to invariants (15) and (16). Take Eq. (17) as an example. One can verify that (17) $\Rightarrow$ (15) $\wedge$ (16), but (15) $\wedge$ (16) $\not\Rightarrow$ (17), because Eq. (17) requires the same replica to be both readable and writable, while for Eq. (15) and (16), it is possible to have one readable replica and a different writable replica.

DuoAI identifies if a formula is equivalently decomposable based on the structure of the formula itself by considering two classes of equivalently decomposable formulas. One class is embodied by the following lemma:

Lemma 6. *For a formula F in prenex and disjunctive normal form, we build a graph G_C for each conjunction C in F. G_C has one node for each literal, and an edge between two literals if and only if they share an existentially quantified variable. If for some C in F, the graph G_C has $k \geq 2$ connected components, then F is equivalently decomposable into k formulas.*

Proof. For simplicity, here we show the proof for $k = 2$ (i.e., the literals in C form two connected components). If there are $k > 2$ connected components, then the same analysis below will show that formula F is equivalently decomposable into k formulas.

Literals that share $\exists$-variables must be in the same connected component. So we can divide the $\exists$-variables into two sets $\{Y_1,...,Y_m\}$ and $\{Z_1,...,Z_n\}$. The first connected component can only include $\exists$-variables $Y_1,...Y_m$, while the second can only include $Z_1,...,Z_n$. Assume the quantifier prefix has shape $\forall X_1 ... X_s \exists Y_1 ... Y_m Z_1 ... Z_n$. We use $\vec{X},\vec{Y},\vec{Z}$ to denote $X_1 ... X_s$, $Y_1 ... Y_m$, and $Z_1 ... Z_n$. The proof can be generalized to any alternating $\forall/\exists$ using skolemization.

Let $f(\vec{X}, \vec{Y})$ be the disjunction of literals in the first connected component, and $g(\vec{X}, \vec{Z})$ be the disjunction of literals in the second connected component. Let $h(\vec{X},\vec{Y},\vec{Z})$ be the disjunction of all conjunctions other than C in formula F. Then formula F can be rewritten as:

$$\forall\vec{X}\exists\vec{Y}\vec{Z}.\ (f(\vec{X},\vec{Y})\wedge g(\vec{X},\vec{Z}))\vee h(\vec{X},\vec{Y},\vec{Z}). \tag{19}$$

We now show that, Eq. (19) is equivalently decomposable into:

$$\forall\vec{X}\exists\vec{Y}\vec{Z}.\ f(\vec{X},\vec{Y})\vee h(\vec{X},\vec{Y},\vec{Z}) \tag{20}$$

$$\forall\vec{X}\exists\vec{Y}\vec{Z}.\ g(\vec{X},\vec{Z})\vee h(\vec{X},\vec{Y},\vec{Z}). \tag{21}$$

It is trivial that Eq. (19) implies both Eq. (20) and (21). We now show the interesting direction — the conjunction of Eq. (20) and (21) implies Eq. (19). Suppose both Eq. (20) and (21) hold. For any $\vec{X}$, consider two cases: 1) $\exists\vec{Y}\,\vec{Z}.\ h(\vec{X},\vec{Y},\vec{Z})$. In this case Eq. (19) directly holds. 2) $\forall\vec{Y}\,\vec{Z}.\ \neg h(\vec{X},\vec{Y},\vec{Z})$. Then according to Eq. (20), $\exists\vec{Y}_1\vec{Z}_1.\ f(\vec{X},\vec{Y}_1)$. Similarly, from Eq. (21), $\exists\vec{Y}_2\vec{Z}_2.\ g(\vec{X},\vec{Z}_2)$. If we select $\vec{Y}_1$ and $\vec{Z}_2$, then we have $f(\vec{X},\vec{Y}_1)\wedge g(\vec{X},\vec{Z}_2)$, so Eq. (19) still holds. Putting the two cases together, when both Eq. (20) and (21) are true, Eq. (19) must be true. □

The proof also gives an algorithm to find the k decomposed formulas. Figure 6 shows how to apply Lemma 6 on the aforementioned formulas. For Eq. (14), the two literals $readable(E,R_1)$ and $writable(E,R_2)$ share no $\exists$-quantified variable (E is $\forall$-quantified), so there is no edge between the two literals. The graph has two connected components, so Eq. (14) is equivalently decomposable into two formulas (Eq. (15)(16)). For Eq. (17), the two literals share an $\exists$-quantified variable R_1, so there is an edge between the two literals and the graph is connected, which means Eq. (17) cannot be decomposed in this way. The same analysis can be applied to Eq. (18).

We note a corollary of Lemma 6. For an $\exists$-free formula, it is equivalently decomposable if it has any conjunction.

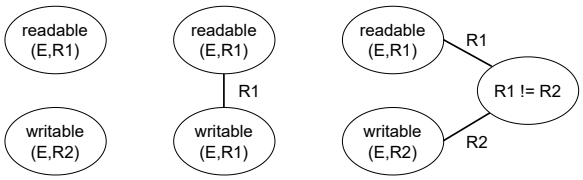

Figure 6: Checking equivalently decomposability of formulas (14)(17)(18) (from left to right).

For example, $\forall X.\ p(X) \wedge q(X)$ is equivalent with the pair $\forall X.\ p(X)$ and $\forall X.\ q(X)$. This indicates that we do not need to consider any conjunction when enumerating $\forall$-only formulas, a significant reduction in search space.

The other class of equivalently decomposable formulas that DuoAI identifies is embodied in the following:

$$\forall X_1 X_2.\ matrix(X_1,X_2) \tag{22}$$

$$\forall X_1.\ matrix(X_1,X_1) \tag{23}$$

$$\forall X_1 X_2.\ X_1 \neq X_2 \rightarrow matrix(X_1,X_2) \tag{24}$$

One can check that Eq. (22) is equivalently decomposable to Eq. (23) and (24), and will therefore not be added as a candidate invariant. In general, DuoAI only considers formulas whose leading $\forall$-quantified variables are unique. Similar optimizations have been used in DistAI [38].

8 Evaluation

Experimental setup. To demonstrate the performance of DuoAI, we implemented and evaluated DuoAI on 27 distributed protocols from multiple sources [12, 13, 21, 27, 28], including those that can only be proved by inductive invariants with $\exists$-quantifiers. The DuoAI implementation consists of 6.1K lines of C++ code for invariant enumeration and refinement, compiled by gcc 7.5.0, and 2.3K lines of Python code running with Python 3.8.10 for protocol simulation. For comparison, we also ran 6 other invariant inference tools: SWISS [10], IC3PO [8, 9], FOL-IC3 [13], DistAI [38], UPDR [12], and I4 [21]. All experiments were performed on a Dell Precision 5829 workstation with a 4.3GHz 28-core Intel Xeon W-2175, 62GB RAM, and a 512GB Intel SSD Pro 600p, running Ubuntu 18.04.

We configured the alternative invariant inference tools following their best practices. SWISS requires the user to bound the search space by specifying 4 parameters, including the number of existentially quantified variables and the number of literals in a formula. For every protocol, we use the same parameter settings as in SWISS's own evaluation [10]. IC3PO and I4 require the user to specify a finite instance size for their model checkers to work on. For IC3PO, we only specified the minimum size and the tool itself could determine how to increase the instance size. For I4, we started from the minimum size where the protocol can function and iteratively increased

the instance size upon failure (e.g., $node = 2, node = 3, ...$). FOL-IC3 provides a ∀-only mode and a default mode. We ran both and report the runtime of whichever succeeded first.

Results summary. Table 1 shows the running time in seconds for each tool on each protocol. For each protocol, we also report the number of relations and lines of code in its Ivy specification; for example, Figure 1 is a simplified version of consensus epr. The top portion of the table shows protocols provable with a ∀-only inductive invariant, while the bottom portion shows protocols that can only be proved with a ∃-included inductive invariant. We allowed each tool to spend up to an entire week trying to solve each protocol. For protocols that a tool fails to solve, we report "fail" if the tool terminated without an inductive invariant, "error" if the tool itself returned an error, "Z3 error" if the underlying SMT solver used returned an error, "memout" if the tool ran out of memory and terminated, and "timeout" if the tool did not complete within a week.

DuoAI dominates all other tools in the number of protocols it solves, solving all but 1 of the 27 protocols. SWISS cannot solve 8 protocols, FOL-IC3 and IC3PO cannot solve 9 protocols, DistAI and UPDR cannot solve 13 protocols, while I4 cannot solve 15 protocols. DuoAI is the only tool that solves all ∀-only protocols, is the only tool that solves Paxos as well as all other non-Paxos protocols with ∃ quantifiers, and is the only tool that solves 3 of the more complex Paxos variants, including multi-Paxos, stoppable Paxos, and fast Paxos. There were no protocols solvable by another tool that were not solved by DuoAI.

DuoAI also dominates all other tools in how fast it solves the protocols, solving 15 of the protocols faster than any other tool. DuoAI is faster than SWISS on all but 3 of the protocols solved by SWISS, is faster than IC3PO on all but 3 of the protocols solved by IC3PO, is faster than FOL-IC3 on all but 2 of the protocols solved by FOL-IC3, and is faster than UPDR on all of the protocols solved by UPDR. DuoAI is up to 3 orders of magnitude faster than each of these protocols. DuoAI is faster than DistAI on all but 5 of the protocols solved by DistAI, and is faster than I4 on all but 2 of the protocols solved by I4. DuoAI is up to an order of magnitude faster than either DistAI or I4. The speed differences versus DistAI and I4 appear less in part because neither could solve any of the protocols with existential quantifiers. In most cases in which DuoAI is slower than other protocols, it is by at most a few seconds.

Detailed comparison and discussion. For the protocols provable with ∀-only invariants, DuoAI is the only tool that solves all 15 protocols. On ∀-only protocols, DuoAI's ∀-only instance is similar to DistAI, without subsampling and with mutual implication optimization and parallelism in simulation. DuoAI beats DistAI on 10 protocols. Unlike DuoAI, DistAI times out on ticket lock, which we discovered is due to a bug in the implementation of its protocol simulation. Chord ring maintenance is the only protocol on which DuoAI is much slower than DistAI. DistAI only allows invariants as disjunction of literals, and implements an invariant as a `vector<int>`. In contrast, DuoAI considers invariants in disjunctive normal form, so an invariant is a disjunction of conjunction of literals, implemented as a `set<vector<int>>`. This makes invariant operation slower in DuoAI. Chord ring maintenance is the only ∀-provable protocol that takes significant time on candidate invariant enumeration so the overhead is exacerbated.

For the protocols that require invariants with ∃-quantifiers to prove, DuoAI solves 11 out of 12 protocols, more than any other tool. DuoAI only fails on vertical paxos, which other tools also fail on. DistAI, I4, and UPDR fail on all of these protocols because they can only generate ∀-only invariants. IC3PO solves 4 protocols and fails on 3 protocols, but runs out of memory on 6 protocols, because it requires model checking to infer invariants on a finite instance. For more complex protocols like fast Paxos, the model checker requires too large of an instance size. In contrast, DuoAI searches in formula space and its performance does not depend (exponentially) on instance size.

For the complex Paxos-family protocols, only SWISS also verified Paxos and flexible Paxos, though it required several hours to do so. All other tools failed on all Paxos-family protocols. In contrast, DuoAI verified Paxos and flexible Paxos in less than 2 minutes. Only DuoAI verified multi-Paxos, stoppable Paxos, and fast Paxos.

As the only other tool that solves Paxos, it is instructive to compare SWISS with DuoAI. Similar to DuoAI, SWISS also enumerates candidate invariants given a bounded search space and checks their inductiveness using the SMT solver. However, it has two fundamental differences compared with DuoAI. First, SWISS relies exclusively on the SMT solver to tell the correctness of invariants, while DuoAI also uses the samples from protocol simulation to filter out invalid invariants. As we demonstrated in §6, SMT calls can be expensive with quantifier alternation and will negatively affect performance. Second, SWISS struggles to find mutually inductive invariants, i.e., a bundle of invariants that are inductive together but none are inductive individually. This is because SWISS can only build the invariant set by adding one and only one invariant each time and keep the set inductive. In the lock server async and the sharded key-value store protocols, where mutually inductive invariants are required to prove the safety property, SWISS has to manually increase the maximum number of literals from 6 to 9. This allows the mutually inductive invariants to be conjuncted into one big invariant, but results in a much larger search space and long runtimes of 44 and 128 minutes, respectively. DuoAI enumerates candidate invariants following the minimum implication graph and generates the strongest candidate invariants. The mutually inductive invariants (or their stronger forms) are guaranteed to be in the candidate invariants together. DuoAI solved both protocols within 2 seconds.

For the vertical paxos protocol, the human-expert inductive invariants include an invariant with 8 literals. Even after the optimization based on mutual implication, it still has 7

Distributed protocol	Relations	LoC	DuoAI	SWISS	IC3PO	FOL-IC3	DistAI	UPDR	I4

c The SWISS authors reported that FOL-IC3 solved chord ring maintenance [10], but we found that the `chord.pyv` file they used has 3 bugs.
i The IC3PO authors [8, 9] reported that IC3PO succeeded on client server db ae (17 s), hybrid reliable broadcast (587 s), Paxos (568 s), and flexible Paxos (561 s). However, they retrofitted the protocols and manually provided clauses with quantifier alternation that could appear in the invariants, which is difficult to do without first knowing the ground-truth invariants. The 4 protocols have much simpler inductive invariants when expressed on top of these clauses, with all except the simplest, client server db ae, becoming $\exists$-free. Ivy fails when checking the invariants generated by IC3PO for Paxos and flexible Paxos. The IC3PO authors [9] imply that the invariants had to be manually checked against the human-expert invariants.

Table 1: Comparison of different tools for finding inductive invariants for 27 distributed protocols (running time in seconds).

literals. Under the minimum per-domain number of quantified variables that can encode the human-expert invariants, there are 60 predicates that can appear in the invariants. Considering their negations, the size of the invariant search space is at the magnitude of $120^7 \approx 4e14$, well exceeding the computational power of a normal workstation. In comparison, for fast paxos, the largest invariant includes 5 literals, and there are 38 predicates. The size of the search space is at the magnitude of $3e9$. For vertical Paxos, DuoAI ends with a universal core and a set of checked non-core invariants when exhausting memory. These invariants are inductive and can be utilized as hints, although they cannot imply the safety property.

As explained in §6, DuoAI runs top-down refinement, bottom-up refinement, and a $\forall$-only instance in parallel. Not surprisingly, the $\forall$-only instance generates the inductive invariants first for all 15 protocols that do not require existential quantifiers. Among the 11 protocols solved by DuoAI that require existential quantifiers, the top-down refinement gives the inductive invariants first for the 5 simpler protocols — client server ae, client server db ae, toy consensus epr, consensus epr, and sharded kv no lost keys. The bottom-up refinement also succeeded but took longer. For example, for client server db ae, there are 8 candidate invariants in *noncore*. A subset of size 3 was sufficient to prove the safety property. However, the bottom-up refinement would first enumerate and fail on all single invariants and pairs before enumerating the correct triple. This takes more than 3 times longer than top-down refinement, in which after a single round of weakening, DuoAI found an inductive invariant.

For the 6 more complicated protocols with existential quantifiers, including hybrid reliable broadcast and the 5 Paxos-family protocols solved, only the bottom-up refinement generated the inductive invariants. The top-down refinement got stuck at checking the inductiveness of the invariants. For example, for multi-Paxos, after enumeration, DuoAI has a candidate invariant set of size 615, and 581 of them have quantifier alternation. Checking inductiveness of this many formulas is a hopeless task for the Z3 SMT solver. However, to prove the safety property, only 2 of the 581 candidate invariants are needed. In the bottom-up refinement, each time only a

small subset of *noncore* invariants conjuncted with the ∀-only core are fed to Ivy, so the Z3 SMT solver could handle the candidate invariants. For Paxos, flexible Paxos, multi-Paxos, and stoppable Paxos, a subset of size 2 were sufficient, while a subset of size 6 was needed for fast Paxos. This also validates our assumption that real-world distributed protocols should have concise invariants, and should not require too many invariants with quantifier alternation to verify.

Limitations By requiring quantifier alternation to conform to a fixed order of types, DuoAI ensures that the verification condition is in a decidable fragment of first-order logic. However, without decidability, an SMT solver may still succeed. For client server db ae and hybrid reliable broadcast, the invariants written by human experts are not in a decidable fragment, yet they can be efficiently verified by the SMT solver. For both protocols, DuoAI found alternative inductive invariants within the decidable fragment. If a protocol cannot be verified in decidable logic, DuoAI will fail to prove it.

9 Related Work

Many studies [11, 17, 20, 31, 34–36] verify the correctness of distributed protocols with manually given inductive invariants. Early systems [12, 21, 29, 38] for automatically inferring inductive invariants do not work for invariants with ∃-quantifiers which are required for protocols such as Paxos, though pdH [29] can find inductive invariants for retrofitted Paxos-family protocols without ∃-quantifiers.

Recent systems consider invariants with ∃-quantifiers. FOL-IC3 [13] generates an invariant candidate that can separate a positive and negative example set, and iteratively adds more examples until the invariant is correct. It has no theoretical guarantee of success. Its heavy use of SMT queries to validate as well as synthesize invariants makes it slow in practice, timing out on even protocols with ∀-only inductive invariants.

SWISS [10] iteratively strengthens an invariant by adding small inductive formulas until the invariant is strong enough to prove the safety property. It was the first tool to automatically verify Paxos. Its inefficiency in exploring the search space and inability to infer mutually inductive invariants make it fail on several protocols solved by alternative tools.

IC3PO [8, 9] applies model checking on a finite instance similar to I4, while adding support to generalize existentially quantified invariants. The model checker functions well on small instances, but frequently exhausts memory on complex protocols that require larger instances, as shown in Table 1.

P-FOL-IC3 [14] is concurrent work that extends FOL-IC3 by exploiting parallelism in formula search, introducing the invariant-friendly *k-Term Pseudo-DNF* to bound the search space, and randomly guessing some not-yet-inductive formulas to be eventually inductive, forcing their counterexamples to be excluded. P-FOL-IC3 has no theoretical guarantee and is less robust in practice due to its randomized nature; it failed in three out of five trials on stoppable Paxos, and two out of five trials on fast Paxos.

The tools discussed above, along with DuoAI, only verify safety properties of distributed protocols. Complementary work has explored connecting verification of protocols to their practical implementations [11, 31], and verifying liveness properties of distributed protocols [26].

AutoML [5, 18, 33] searches for machine learning models and hyperparameters, which may appear similar to finding inductive invariants. However, the inductiveness of invariants has strong correlation, which is difficult to capture for AutoML.

Many automated invariant inference tools have been built for other domains, mostly on learning loop invariants to verify sequential programs [3, 4, 6, 7, 15, 24, 25, 30, 32, 37, 39]. Invariant inference has been used to prove properties on inductive algebraic data types [16, 22], integer linear dynamical systems [19], and deep neural networks [2]. None of these methods consider nondeterminism in concurrent or distributed settings, thus they cannot be directly applied to distributed protocols.

10 Conclusions

DuoAI automatically and efficiently infers inductive invariants for verifying distributed protocols by reducing SMT costs. It introduces the minimum implication graph to define the structure of the invariant search space. This enables efficient enumeration of possible invariants, which are checked on samples from protocol simulation to reduce SMT queries. DuoAI guarantees that the enumerated candidate invariants are at least as strong as any correct invariants. DuoAI then runs top-down and bottom-up refinement in parallel. The former monotonically weakens the candidate invariants following the minimum implication graph. The latter divides the candidate invariants into an SMT-friendly universal inductive core and other noncore invariants, and searches for a small subset of noncore invariants that can be added to the core to prove the safety property of the protocol. Both top-down and bottom-up refinement have strong theoretical guarantees for finding inductive invariants, and their combination is effective at reducing SMT query costs for invariants with existential quantifiers. DuoAI dominates alternative tools in both the number of protocols it verifies and the speed at which it does so, including giving automated proofs for several Paxos variants.

Verifying Hardware Security Modules with Information-Preserving Refinement

Anish Athalye, M. Frans Kaashoek, and Nickolai Zeldovich
MIT CSAIL

Abstract

Knox is a new framework that enables developers to build hardware security modules (HSMs) with high assurance through formal verification. The goal is to rule out all hardware bugs, software bugs, and timing side channels.

Knox's approach is to relate an implementation's wire-level behavior to a functional specification stated in terms of method calls and return values with a new definition called *information-preserving refinement (IPR)*. This definition captures the notion that the HSM implements its functional specification, and that it leaks no additional information through its wire-level behavior. The Knox framework provides support for writing specifications, importing HSM implementations written in Verilog and C code, and proving IPR using a combination of lightweight annotations and interactive proofs.

To evaluate the IPR definition and the Knox framework, we verified three simple HSMs, including an RFC 6238-compliant TOTP token. The TOTP token is written in 2950 lines of Verilog and 360 lines of C and assembly. Its behavior is captured in a succinct specification: aside from the definition of the TOTP algorithm, the spec is only 10 lines of code. In all three case studies, verification covers entire hardware and software stacks and rules out hardware/software bugs and timing side channels.

1 Introduction

A powerful approach for building secure computer systems is to factor out the core security functionality onto a separate device. For example, on the server side, certificate authorities use hardware security modules (HSMs) to store their signing key and sign certificates [10, 58]; credit card networks use HSMs for pin translation, secure re-encryption of payment requests during routing; cloud providers use HSMs to safeguard PIN-protected backup keys [9, 43, 47]; and some tax authorities require the use of an HSM to timestamp invoices. On the client side, the iPhone uses its secure enclave processor to enforce PIN guessing limits for unlocking the phone [15]; and users often rely on USB security keys to protect their authentication private key in the face of a compromised computer [65]. For simplicity, this paper refers to all of these types of devices as HSMs. These devices are in widespread use; e.g., there are hundreds of millions of deployed secure enclaves and security keys.

This approach defends against a broad class of attacks where an adversary gains access to any host computer that the HSM might be connected to, regardless of the specific attack vector (exploiting a buffer overflow, missing access control checks, or even gaining access to the administrator's SSH key). As long as the security of the overall system is rooted in the device, an adversary that controls the host cannot undermine the security of the overall system. Of course, the device must be correctly implemented to make sure that the adversary cannot compromise it, which in practice means that the device must provide simple, well-defined functionality.

Although HSMs are relatively simple, any vulnerability in their hardware or software can undermine their security. HSMs have suffered from bugs throughout the hardware/software stack, such as logic bugs, memory corruption, hardware bugs, and timing side channels [1–8, 21, 31, 45, 51, 68]. This paper presents an approach for ruling out such bugs through formal verification, with a particular focus on eliminating leakage through timing side channels.

Our approach is to relate the behavior of the HSM implementation at the wire level interface — the ground truth of what the host machine controls and observes at the digital level, which captures timing channels at a cycle-accurate level — to a functional specification of the methods that the HSM exposes. Figure 1 shows the implementation of a simplified PIN-protected backup HSM, which we use as a running example through the paper. The host connects to this HSM via two input wires and two output wires, which the host can read/write at every cycle. Figure 2 shows the functional specification for this HSM. It exposes two operations, `store` and `retrieve`. The specification does not have an operation for reading back the PIN, and it enforces a guess limit on PINs.

We relate a physical implementation to a functional specification with a new definition called *information-preserving refinement (IPR)*, inspired by definitions of zero-knowledge proofs in cryptography [40, 41]. IPR captures the notion that the implementation implements the spec, and that its wire-level I/O behavior leaks no additional information. In IPR, a *driver* describes the I/O protocol that a host computer can follow to get correct results from the HSM, describing how each spec-level operation translates to wire-level I/O with the HSM. The driver is a part of the specification (and is trusted). Its dual, an *emulator*, is a proof artifact that describes how wire-level behavior can be explained in terms of spec-level operations. The existence of an emulator shows that no matter what wire-level inputs are given to the device (including inputs that violate the I/O protocol), its outputs reveal no more information than the specification.

Applied to HSMs, IPR can capture subtle security bugs: for example, Figure 3 shows code that is correct and even crash safe but has a subtle bug involving persistence and

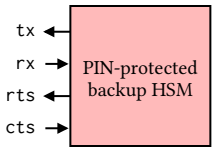

Figure 1: The physical implementation of the PIN-protected backup HSM. It connects to the host via 4 wires, speaking UART with flow control.

```
var bad_guesses = 0, secret = 0, pin = 0

def store(new_secret, new_pin):
  secret = new_secret
  pin = new_pin
  bad_guesses = 0

def retrieve(guess):
  if bad_guesses >= 10:
    return 'No more guesses'
  if guess == pin:
    bad_guesses = 0
    return secret
  bad_guesses = bad_guesses + 1
  return 'Incorrect PIN'
```

Figure 2: A functional specification for a PIN-protected backup HSM. The spec doesn't support reading out the PIN, and retrieval of the secret requires supplying the correct PIN. Limiting guesses prevents brute-forcing.

timing. The way this code gets compiled, the circuit takes longer to persist the incremented guess count, in the case of an incorrect guess, than it takes to zero the guess count, in the case of a correct guess (it takes longer to take the branch than to fall through). This can be abused to reset the guess count by repeatedly guessing every possible PIN and powering off the device after just enough cycles to reset the guess count in the case that the guess is correct (but not waiting long enough to persist if the guess is incorrect). Verifying IPR caught this bug in our implementation (§7.1.1). The buggy implementation doesn't enforce guess limits, which leaks more information than the specification, and this is prohibited by IPR.

Existing security definitions like noninterference or declassification either do not apply or are insufficient to capture the security of wire-level observations and arbitrary wire-level I/O as in the Knox setting (§9).

To be able to verify HSMs with IPR, we developed the Knox framework. Developers using Knox write HSM implementations using standard languages (i.e., Verilog and C code), write specifications in Knox DSLs, and use a combination of lightweight annotations and interactive proofs to show that the implementation is an information-preserving refinement of the specification.

To demonstrate that IPR and the Knox framework can be applied to HSMs and catch bugs in their implementations, we developed and verified three HSMs: a PIN-protected backup HSM, a password-hashing HSM, and an RFC 6238-compliant TOTP token [54]. The Knox HSMs do not have the implementation complexity of commercial HSMs: for example, the RISC-V processor they use is simpler than the ARM Cortex-M series embedded processors ubiquitous in security tokens such as SoloKeys. Still, the HSMs demonstrate many of the hardware and software complexities present in real HSMs. They all use an embedded processor (a RISC-V CPU) and interface with the host via digital I/O (UART), and the password hasher and TOTP token include hardware cryptographic accelerators. All three run application-specific C code, with some including cryptographic functionality, such as HMAC in the TOTP token. Knox proofs are end-to-end, encompassing hardware and software and showing that the implementation is free of exploitable hardware bugs, software bugs, and timing side channels.

```
// return error if PIN guess limit exceeded
// ...

// check PIN guess and update guess_count accordingly
if (!constant_time_cmp(&entry->pin, guess)) {
    entry->bad_guesses++;
    uart_write(ERR_BAD_PIN);
    return;
}
entry->bad_guesses = 0;

// output secret
// ...
```

Figure 3: Code snippet from an insecure `retrieve` implementation. `entry` points to persistent memory. The commit point depends on whether the PIN guess is correct.

In summary, this paper makes the following contributions:

- The definition of information-preserving refinement (IPR), which relates a physical implementation to a functional specification and captures that it: (1) implements the specification, and (2) leaks no additional information
- The Knox framework for proving that an HSM implementation satisfies its specification under the IPR definition
- An evaluation of the IPR definition and Knox's application to three simple HSMs

This paper applies IPR to HSMs, but we believe the definition is broadly applicable to other contexts for capturing non-leakage properties.

This paper has several limitations. The three HSMs verified using Knox are relatively simple: for example, they do not use public-key signatures, which are common HSM operations, because it is difficult to scale up proofs in Knox to handle sophisticated arithmetic needed for public-key implementations. Relatedly, for cryptographic operations such as public-key signatures, IPR requires the emulator to be efficient. Knox currently relies on a manual audit to ensure that the emulator does not brute-force secrets or run in exponential time (§8.1). Finally, IPR does not support true random number generators (TRNGs) — the functional specification has to be deterministic. We believe that a pseudo-random number generator is a reasonable workaround that fits into IPR (§8.2).

2 Threat model and security goal

This paper considers a powerful adversary that gains direct access to the wire-level digital I/O of the HSM, with the ability to set logic levels on the input wires and read logic levels on the output wires at every cycle. This captures many realistic attacks, such as an adversary that compromises the host computer and is able to send malformed commands or observe all wire-level outputs at every clock cycle. Such an adversary may be able to extract secrets from an HSM, even if that HSM operates correctly when the host computer is well-behaved.

Our threat model is focused on remote compromise of the host machine, one of the primary attacks that HSMs aim to defend against, so it does not include physical attacks on the HSM. While the adversary can perform arbitrary digital I/O to the HSM through a compromised host, remote compromise is unlikely to allow the adversary to violate the HSM's electrical specifications (e.g., supply 5V into an input wire expecting 3.3V logic or supply current to an output pin of the HSM) or observe analog characteristics of the I/O interface (e.g., measure analog voltage on a pin).

While the threat model includes (digital) timing side channels due to the level at which we model the host-HSM interface (wire-level I/O at every cycle), the threat model does not include arbitrary side channels [73] such as electromagnetic radiation [12], temperature [44], and power [49], because a remote attacker is unlikely to able to make such observations.

The goal of a Knox HSM is to be as secure as its specification. A host machine should be able to follow an I/O protocol to invoke spec-level operations on the HSM and obtain the correct outputs, but the host machine should not be able to abuse the wire-level interface to subvert the HSM and bypass its API or cause it to leak secrets.

3 Information-preserving refinement

The goal of information-preserving refinement (IPR) is to define what it means for an implementation with a wire-level physical interface to implement a functional specification and leak no additional information. IPR achieves this by establishing a bi-level correspondence between implementation and specification, at both the level of the functional interface (spec-level operations) and the physical interface (wire-level I/O). Illustrated in Figure 4, IPR is defined as an indistinguishability between two worlds: the real world, and an ideal world that is correct and secure by construction.

The real world models the host machine connected to the actual HSM implementation. The host can take a physical view of the device and directly perform arbitrary wire-level I/O (reading and writing the I/O pins at every cycle). The host can also take a functional view of the device and follow the HSM's I/O protocol, which is described by a *driver* that is part of the specification. The driver translates spec-level operations to wire-level I/O, describing how the host invokes

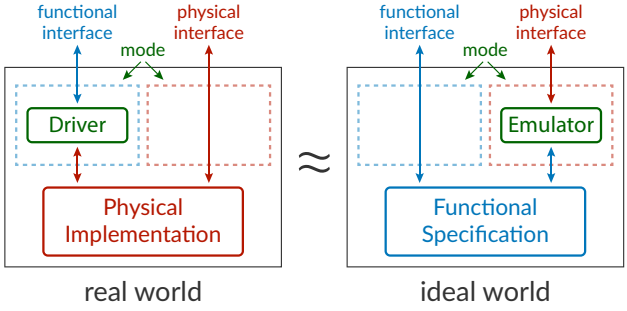

Figure 4: Information-preserving refinement (IPR), defined as an indistinguishability between a real world and an ideal world that is correct and secure by construction.

the operation and reads the return value by interacting with the HSM over its wire-level interface.

The ideal world is set up to provide the same interface as the real world but be correct and secure by construction. In the ideal world, a host machine that takes a functional view of the device invokes operations directly on the specification. To provide a physical view, an *emulator* mimics wire-level behavior, given only query access to the functional specification. The emulator is a dual of the driver; it translates wire-level I/O into spec-level operations. Unlike the driver, the emulator is merely a proof artifact. The ideal world can be instantiated with *any* emulator, and it remains secure by construction. IPR is defined to hold if there exists some emulator such that the real and ideal worlds are indistinguishable.

The host can switch between the functional view and the physical view at any time. Switching from the functional view to the physical view models compromise of the host machine; switching from the physical view back to the functional view models recovery (for example, by unplugging the device and moving it to an uncompromised machine). When switching views from physical to functional, in the real world, the driver is re-initialized; when switching from functional to physical, in the ideal world, the emulator is re-initialized.

The ideal world is correct and secure by construction. When the host takes a functional view of the device, operations are invoked directly on the specification, so the behavior is correct and secure by definition. Under the functional view, spec-level operations are not seen by the emulator. When the host takes a physical view of the device, the wire-level I/O behavior it observes is produced by an emulator that only has query access to the specification, so the physical interface leaks no more information than the specification exposes through its API. Furthermore, when the host switches back to the functional view of the device, it continues interacting with the same specification that was queried by the emulator, so the effect of any queries made by the emulator in order to mimic wire-level outputs is present in the specification state. In the ideal world, any execution, no matter how it switches between functional and physical interfaces, maps to some sequence of operations invoked on the specification.

Due to the indistinguishability that IPR requires between real and ideal worlds, any execution in the real world also maps to some sequence of operations invoked on the specification. In other words, when IPR holds, any attack that an adversary could execute on the real device could be transformed into an attack on the specification itself: the adversary could run the emulator and then execute the original attack using the emulator, which matches the implementation's wire-level behavior, given only query access to the specification. Indistinguishability between real and ideal worlds guarantees that the implementation is as secure as the specification.

Definition (Information-preserving refinement)**.** A physical implementation is an *information-preserving refinement* of a functional specification with respect to a driver if there exists an emulator such that the real world is indistinguishable from the ideal world as illustrated in Figure 4. ■

3.1 Applying IPR to HSMs

IPR, without explicitly talking about hardware, software, or timing side channels, captures exploitable bugs in all of those. If there were such exploitable bugs, IPR would not be satisfied: when there are implementation behaviors that can't be explained in terms of the specification, there does not exist an emulator that makes the real world and ideal world indistinguishable.

IPR relates any wire-level interaction with the HSM to an interaction with the specification. For example, suppose that the host machine follows the driver to perform a number of spec-level operations, and then it gets compromised, at which point it begins performing arbitrary I/O in an attempt to subvert the HSM. IPR, by requiring indistinguishability between the real and ideal worlds, says that this scenario corresponds to some sequence of spec-level operations, and that the arbitrary I/O reveals no more information than those spec-level operations do. Furthermore, IPR says that after the HSM is moved to an uncompromised host, normal operation can resume (as the host follows the driver), and that the behavior of the device will reflect any specification state changes that were a result of queries made by the emulator (any operations that were effectively invoked during arbitrary wire-level I/O).

The definition directly addresses host machine compromise by an adversary while the host is in between spec-level operations. It might seem like IPR only addresses arbitrary I/O that begins between these operations; however, a compromise in the middle of an operation can be thought of as a compromise that happens slightly earlier, at the start of the operation, and IPR covers this case.

Information-preserving refinement transfers both cryptographic and non-cryptographic security properties from the specification to the implementation. For example, the PIN-protected backup specification limits PIN guesses, and so IPR implies that the implementation enforces the guess limit as well. If it didn't limit guesses, it would reveal more information than the specification (through subsequent retrieve operations), which IPR prohibits. This rules out the subtle bug shown in Figure 3, even though the information disclosure manifests after the buggy code executes. If a specification computed signatures without revealing a key, then IPR would imply that the implementation also doesn't leak the key, including through its timing behavior.

4 Proving IPR

Knox models the specification and the implementation (§4.1) as state machines, relates the two with a refinement relation, and proves three properties: an initialization property (§4.2), functional equivalence (§4.3, indistinguishability of the functional view), and physical equivalence (§4.4, indistinguishability of the physical view), tying together these properties with the refinement relation. Together, these properties imply IPR.

4.1 Physical implementation

Knox models HSM implementations with a cycle-accurate description of their wire-level I/O behavior, covering hardware and software. Figure 1 shows the interface of a circuit implementing PIN-protected backup. The HSM interface allows for: (1) setting input wires, (2) reading output wires, and (3) waiting for the HSM to execute for a clock cycle of the HSM's internal clock.

In the case of the PIN-protected backup HSM, the UART `rx` and `cts` wires can be set and the `tx` and `rts` wires can be read at every cycle. The baud rate is independent of the HSM clock frequency; the IPR formalism itself has no notion of a serial port or baud rate, only wires and hardware-level clock cycles. The three main Knox case studies use UART, but simpler Knox examples use different I/O protocols.

The HSM model comprises the circuit state, a step function describing behavior for a single cycle, the initial state of the HSM (contents of non-volatile memory, such as ROM containing code and read-write persistent memory being zero-initialized), and a description of the power-on / reset behavior of the circuit (losing the contents of volatile memory).

4.2 Refinement relation and initialization

Knox uses a refinement relation R, a proof artifact supplied by the developer, to relate the state of the implementation to the state of the specification *in between spec-level operations*. That is, it is not required to hold at arbitrary steps of the circuit, only before/after spec-level operations, or after switching from the physical view to the functional view, which involves re-initializing the driver (which in our implementations, resets the circuit). Use of a common R connects functional equivalence and physical equivalence.

R relates states and usually includes an invariant that captures circuit quiescence (it holds in between spec-level operations). Figure 5 shows the refinement relation used in

$$\begin{aligned} \text{spec.bad\_guesses} = \text{swap32}(\text{impl.fram}[0..3]) \quad &\wedge \\ \text{spec.pin} = \text{impl.fram}[4..9] \quad &\wedge \\ \text{spec.secret} = \text{impl.fram}[10..19] \quad &\wedge \\ \text{Inv}(\text{impl}) \end{aligned}$$

Figure 5: A simplified version of the refinement relation used in the proof of PIN-protected backup. *impl.fram* refers to the persistent memory of the implementation. *swap32* performs a byte order swap. *Inv* is the invariant (not shown here).

```
(define (store secret pin)
  (send-byte #x02) ; command number
  (send-bytes pin)
  (send-bytes secret)
  (recv-byte)) ; wait for ack

(define (wait-until-clear-to-send)
  (while (get-output 'rts))
    (tick))) ; wait a cycle

(define (send-bit bit)
  (set-input 'rx bit)
  (for ([i (in-range BAUD-RATE)])
    (tick)))

(define (send-byte byte)
  (wait-until-clear-to-send)
  (send-bit #b0) ; send start bit
  ;; send data bits
  (for ([i (in-range 8)])
    (send-bit (extract-bit byte i)))
  (send-bit #b1)) ; send stop bit

(define (send-bytes bytes)
  (for ([byte bytes])
    (yield) ; wait for arbitrary number of cycles
    (send-byte byte)))
```

Figure 6: A code snippet from the PIN-protected backup driver. The function corresponding to a spec-level operation is shown in blue. Driver-language primitives are in red.

the proof of the PIN-protected backup HSM. It relates each variable in the specification to the persistent memory of the circuit.

Knox requires that the initial implementation state is related by R to the initial specification state.

4.3 Functional equivalence

Functional equivalence states that spec-level behavior is obtained from the implementation's wire-level interface by following the I/O protocol described by the driver. The driver is a program, written in Knox's driver language, that is part of the specification of the HSM. For every spec-level operation, the driver has a corresponding function that describes how the host invokes the operation on the HSM over its wire-level I/O interface.

For example, Figure 6 shows the driver for the PIN-protected backup HSM. The driver exposes a function corresponding to each spec-level function, such as `(store ...)`, implemented in terms of driver-language primitives for interacting with the implementation: `(set-input ...)` and `(get-output ...)` write the input wires and read the output wires, respectively; `(tick)` waits for the HSM to execute for a single cycle; `(yield)` models situations where the host is allowed to wait for an arbitrary number of cycles, e.g., in between sending bytes in an asynchronous protocol.

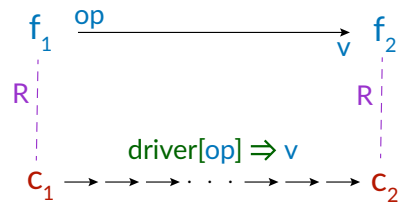

Figure 7: Functional equivalence: for all implementation states c_1 and spec states f_1 that are related by R, and for all spec-level operations op:
(1) the spec-level output v matches the driver output
(2) the final states c_2 and f_2 are related by R

Figure 7 defines functional equivalence: starting from circuit/spec states related by R, invoking an operation on the specification gives the same result as running the corresponding driver function against the circuit, and the final circuit/spec states continue to be related by R.

The HSM runs asynchronously from the host: its clock keeps ticking even if there is no operation to perform. To model this, the driver also describes a spec-level no-op: e.g., in the case of the PIN-protected backup HSM, the host sets the `rx` line high, indicating that it has nothing to transmit. Functional equivalence also covers this no-op case.

4.4 Physical equivalence

Physical equivalence states that wire-level behavior matching the real circuit's behavior can be obtained by running an emulator (with query access to the specification), capturing the notion that the circuit leaks no more information than the specification. The emulator in IPR is a dual of the driver: it is a program, written in Knox's emulator language, that implements wire-level interactions in terms of spec-level operations. Unlike the driver, the emulator is a proof artifact: if there exists an emulator that mimics circuit behavior, then physical equivalence holds.

An emulator exposes a function corresponding to each wire-level interaction: setting the input, getting the output, and running for a cycle. These are implemented in terms of emulator-language primitives for invoking spec-level operations (e.g., `(store ...)` and `(retrieve ...)`, for the PIN-protected backup). Besides the ability to make black-box queries to the functional specification, the emulator can maintain auxiliary state across emulating multiple cycles; the auxiliary state is initialized to a null value whenever the emulator is re-initialized.

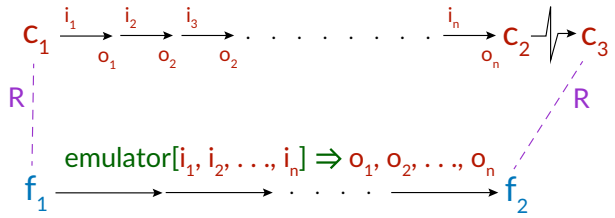

Figure 8: Physical equivalence: for all spec states f_1 and implementation states c_1 that are related by R, and for all wire-level inputs $i_1 \ldots i_n$:
(1) the circuit outputs $o_1 \ldots o_n$ match the emulator outputs
(2) the final states f_2 and c_3 (c_2 after a reset) are related by R

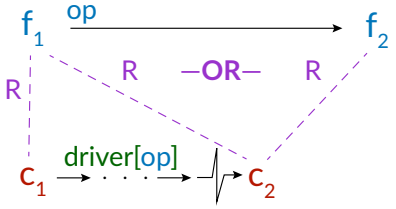

Figure 9: Crash safety: for all implementation states c_1 and spec states f_1 that are related by R, and for all spec-level operations op: if the driver is interrupted at any point, the post-reset state of the circuit c_2 is related by R to *either* f_1 or f_2.

Figure 8 defines physical equivalence: starting from circuit/spec states related by R, any wire-level I/O behavior exhibited by the circuit is matched by the emulator, which makes queries to the specification as it runs. Furthermore, the final specification state is related by R to the final circuit state (after the circuit is reset).

IPR is satisfied as long as there exists some emulator such that the real and ideal worlds are indistinguishable. Proofs of physical equivalence in Knox involve constructing an emulator (i.e., writing a program in the emulator language) that satisfies the definition of physical equivalence. Because the emulator is merely a proof artifact, the details of the construction do not matter, as long as the program satisfies the definition. The Knox case studies (§7) describe the techniques used in practice to write emulators.

4.5 Crash safety

Physical equivalence already covers the case of an interrupted spec-level operation, because an interrupted protocol-following execution can be viewed as a case of arbitrary I/O: physical equivalence guarantees that any wire-level I/O corresponds to *some* sequence of spec-level operations. However, we can state an additional property that is stronger: when the HSM is interrupted in the middle of an operation while the host is following the driver, the implementation is crash safe, acting either as if the operation never started or as if the operation completed successfully. Figure 9 defines this crash-safety property.

5 The Knox framework

The Knox framework uses hybrid symbolic execution [67] and SMT solvers to help developers prove IPR. Knox includes techniques to handle the challenges that arise when applying symbolic execution for proving functional equivalence and physical equivalence. In functional equivalence proofs, Knox handles the nondeterminism of `yield` in drivers by automatically finding fixed points (§5.1). In physical equivalence proofs, Knox supports reasoning about unbounded-length inputs using an approach we call *guided symbolic model checking* (§5.2). In both, Knox allows the proof developer to supply *hints*, untrusted guidance where the framework invokes the solver as necessary to ensure soundness (§5.3).

5.1 Nondeterminism

Knox verifies the functional equivalence property using symbolic execution of the driver-language program against the HSM implementation, comparing the execution of each driver operation against the corresponding spec operation. However, symbolic execution cannot directly handle the nondeterminism of `(yield)`, which has the semantics of the driver waiting for an arbitrary number of cycles while the HSM runs.

Knox addresses this by finding a fixed point of the circuit's step function at every yield point. During symbolic execution, the circuit's state is a symbolic term. Stepping the circuit produces a new symbolic term, and so on. At yield points, Knox computes a set of symbolic terms such that the set is closed under the circuit's step function, and it forks symbolic execution for each term in the set.

Closure is defined in terms of symbolic state subsumption. A symbolic term t under a path condition p, written as $t|p$, can be thought of as representing a set of concrete values, $[\![t|p]\!]$, the set of values that t can evaluate to for all possible assignments satisfying p of values to t's symbolic variables. A term t_1 under path condition p_1 is subsumed by a term t_2 under path condition p_2, written as $t_1|p_1 \subseteq t_2|p_2$, if $[\![t_1|p_1]\!] \subseteq [\![t_2|p_2]\!]$. For a set S of symbolic terms paired with path conditions, let $[\![S]\!] = \{[\![t|p]\!] : t|p \in S\}$. Finally, call S a fixed point of the step function if $\forall x \in [\![S]\!], \text{step}(x) \in [\![S]\!]$.

Knox includes an efficient algorithm for subsumption checks, and fixed points are found through iteratively calling the step function on the symbolic circuit state to build up a set of symbolic terms. Once a fixed-point S is found, symbolic execution proceeds for each of the $t|p \in S$, similar to how branching produces multiple paths to be checked.

Left unchecked, multiple `(yield)`s can result in an exponential number of cases to check, analogous to the problem of branching resulting in path explosion in symbolic execution. For this reason, Knox uses untrusted `(merge)` hints in the driver at points where some branches could be merged together. At merge points, Knox uses subsumption checks to automatically find a smaller set of symbolic terms $|S'| \leq |S|$ that still represent all the concrete values included in the original, i.e., $[\![S]\!] \subseteq [\![S']\!]$, which addresses case explosion.

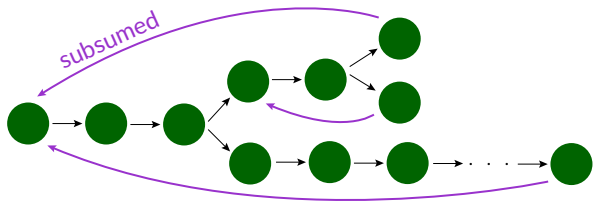

Figure 10: An illustration of *guided symbolic model checking* exploring a state space. Each green circle is a symbolic term representing a set of states. Black arrows show STEP invocations and purple arrows show SUBSUMED invocations.

5.2 Unbounded-length inputs

In Knox, emulators can be symbolically executed with black-box query access to a functional specification. Unlike the functional equivalence property which considers a single (spec-level) input, the physical equivalence property considers an arbitrary-length sequence of (wire-level) inputs, so Knox can't prove the physical equivalence property in the same way. Symbolic execution could verify this property for a fixed-length input, but it cannot directly handle arbitrary-length input.

The standard approach to handling arbitrary-length inputs is to write down an inductive invariant and reason about one step at a time. This approach does not work for large circuits because of the infeasibility of manually writing down the inductive invariant. It would have to include an invariant of circuit execution, capturing which states are reachable and which are not, and it is infeasible to manually write down exactly how CPU microarchitectural registers, peripheral registers, RAM state, etc. are related to each other at every cycle of execution of the software.

Instead, Knox uses an approach that we describe as *guided symbolic model checking*. At a high level, Knox uses a model-checking-style approach to start from the initial states of the circuit and emulator in the definition of physical equivalence, explore all reachable states, and ensure that the circuit's behavior matches the emulator's behavior and the recovery condition holds at every step. Exploration starts out at a circuit state c_1, an emulator state e_0 (the initial emulator auxiliary state, null), and functional spec state f_1, where both f_1 and c_1 are symbolic terms, and R is assumed to relate f_1 and c_1. Knox can step the circuit and step the emulator, given the same symbolic input, and check that their outputs match. Knox repeats this process until it has explored all reachable states.

This model-checking process involves guidance from the developer in the form of a proof script. Knox provides two primitives that allow the developer to guide exploration of the state space:

- STEP steps the circuit and the emulator/spec (with the same symbolic input) for one cycle and verifies the output equivalence and recovery properties for that single cycle
- SUBSUMED checks that the state currently under consideration is subsumed by a state that was explored earlier, "tying the knot" and finishing a branch of the exploration

Figure 10 illustrates how STEP and SUBSUMED let the developer guide the model checker to explore the state space. In addition to these primitives, the developer uses additional *hints* (§5.3) to safely manipulate symbolic terms and help the model checker efficiently explore the state space.

An alternative view of this process is that it incrementally builds up the induction hypothesis that would have been used in an induction-based approach. Once model checking has explored all reachable states, it has visited a set of states S that includes the initial circuit/emulator/spec state where R holds, and the set S has the property of being closed under the circuit/emulator step functions, and the property of matching outputs for a single cycle holds for every state in S. The induction hypothesis is that the state is contained in S.

The proof script is untrusted, and Knox checks that the state space is fully explored. At worst, an incorrect proof script can result in poor performance or Knox reporting that the state space has not been fully explored.

5.3 Hints

In both functional equivalence proofs and physical equivalence proofs, relying only on hybrid symbolic execution quickly results in an explosion in term size, and in the case of HSMs involving cryptography, queries that make the SMT solver time out.

Knox addresses this with untrusted (solver-checked) human guidance called *hints*. Knox has 8 primitive hints:

- CASE-SPLIT performs case analysis
- CONCRETIZE invokes the solver to prove that a symbolic term is concrete and replaces it with the concrete value
- OVERAPPROXIMATE replaces a term with a fresh variable
- WEAKEN weakens the current path condition
- REPLACE rewrites or simplifies terms
- REMEMBER, SUBSTITUTE, and CLEAR effectively allow marking terms as opaque to symbolic execution and substituting in their values later

Furthermore, Knox supports writing higher-level *tactics* that can reflect on the current state of symbolic execution and invoke primitive hints (or other tactics). A tactic might, for example, analyze the state of the circuit to determine if a CPU is about to branch, and in that situation, it can invoke a CASE-SPLIT hint with the appropriate cases constructed based on analyzing the symbolic circuit state.

All invocations of hints are verified by the Knox framework with an call to the SMT solver when necessary. Hints are untrusted: at worst, hints can be incorrect and fail (e.g., when attempting to replace a term with an unequal term), which will result in an error message to the user, or the given hints can be inadequate to ensure good performance, in which case verification will be slow or fail to terminate.

6 Implementation

The Knox framework builds on top of Racket [37] and the Rosette solver-aided programming language [67], and it relies on the Z3 SMT solver [32]. To compile circuits to a shallow embedding in Rosette, Knox uses GCC and its RISC-V backend to compile C code, Yosys [69] and its SMT-LIB backend to process Verilog, and `#lang yosys` (700 LOC of Racket and Rosette) from Notary [16] to convert the SMT-LIB output into a Rosette model.

The Knox framework's core — the semantics for the driver and emulator languages, and the tools for verifying functional equivalence and physical equivalence — is implemented in 3000 lines of Racket and Rosette. Achieving good verification performance required many optimizations and some new techniques, including symbolic state serialization, term substitution, fixpoint finding, state merging, and a new algorithm for symbolic subsumption checking based on a disjoint-set data structure.

The case studies are implemented in Verilog, C, and assembly (summarized in Figure 16). The case studies run on a $65 1BitSquared iCEBreaker development board, which has a Lattice iCE40UP5K FPGA, and use an open-source FPGA toolchain: the Yosys synthesis tool, the nextpnr place and route tool [72], and Project IceStorm [70] to create the bitstream and flash the FPGA. The FPGA connects using an FTDI cable to a host computer running Linux, for which we wrote client libraries for the three HSMs.

Figure 11 shows an overview of the different components that the developer writes when using Knox to verify an HSM. The functional specification, physical implementation, and refinement relation R are common inputs, used when verifying both functional equivalence and physical equivalence. When verifying functional equivalence, Knox takes as additional input the driver, along with hints to guide symbolic execution. When verifying physical equivalence, Knox takes as additional input the emulator and a proof script. The functional specification and the driver, highlighted in green, comprise the code written by the developer that is trusted. Other components, the HSM implementation and proof artifacts, are verified by the framework. Similar to other tools based on symbolic execution, when verification in Knox fails, the framework can provide a concrete counterexample, aiding the developer in debugging the implementation or the proof.

Source code for Knox and the case studies is available at https://github.com/anishathalye/knox.

7 Evaluation

To evaluate information-preserving refinement and the Knox framework, we ask the following questions:

- Can IPR and Knox be applied to HSM hardware/software?
- What types of bugs does verification prevent?
- What is the performance of the Knox framework?
- What is the performance of HSMs verified with Knox?

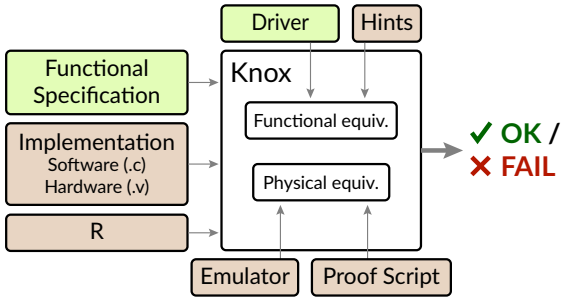

Figure 11: An overview of the Knox workflow. Trusted inputs are shown in green.

Methodology. We evaluate the first two questions through case studies (§7.1) that formally verify three HSMs with different types of specification and implementation complexity: a PIN-protected backup HSM, a password-hashing HSM, and an RFC 6238-compliant TOTP token [54]. To answer questions related to verification performance and the performance of the HSM implementations, we report on measurements (§7.2).

7.1 Case studies

7.1.1 PIN-protected backup HSM

Specification. A simplified PIN-protected backup HSM (Figure 2) was a running example through this paper; we verified an HSM with additional functionality: storing multiple secrets, each protected by its own PIN, and indexed by a slot number. The specification exposes four functions: `status`, `store`, `retrieve`, and `delete`. The specification demonstrates support for non-cryptographic security properties, such as the guess limit on PINs.

Implementation. Figure 12 shows a schematic of the implementation. It uses the PicoRV32 RISC-V CPU and the SimpleUART peripheral from the PicoSoC [71] with minimal modifications: we removed asynchronous reset from the CPU and added hardware flow control to the UART. The HSM uses ferroelectric RAM (FRAM) for persistent storage. Knox requires cycle-accurate models of the entire hardware, and FRAM has simple cycle-precise behavior, supporting durable word-level writes in a single cycle. For convenience, to avoid wiring an external chip, the prototype uses FPGA Block RAM in place of FRAM for the experiments. In total, the HSM hardware is described in 2670 lines of Verilog.

The software is written in a combination of C and assembly. To simplify verification, the HSM uses a strategy inspired by Notary [16] to minimize variation in the states that the hardware can be in. The HSM uses a reset-based design: the SoC is held in an "embryo" state until the host is ready to perform an operation, and after the HSM performs a single operation, it enters the embryo state again until the host begins the next operation. This is done through a combination of hardware and software: the HSM's `cts` input doubles as a signal that the host is ready to perform an operation, and a

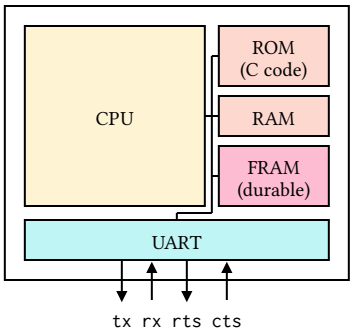

Figure 12: A schematic of the PIN-protected backup HSM.

small amount of logic implemented in hardware holds the rest of the circuit in a reset state until the host is ready to perform an operation. After the HSM performs a single operation, it signals this power management hardware to reset the SoC and return to the embryo state.

The software on the HSM includes a driver for the memory-mapped UART peripheral, along with code to implement each of the operations. The `main` function of the HSM reads a command and arguments from the UART, calls the appropriate handler, and then shuts down. The code for the HSM is written in 150 lines of C and 40 lines of assembly.

Verification and bugs caught. Knox physical equivalence proofs are constructive. We designed the emulator for the PIN-protected backup as follows. The emulator runs a copy of the circuit with dummy data. The emulator does not have access to the data in the real circuit, in particular the read-write persistent memory, but the structure of the circuit and the code in the ROM is common knowledge. The emulator carefully watches the internal state of its copy of the circuit: when the circuit is about to perform an operation, the emulator reads input data out of its circuit's state and translates it into a spec-level input, makes a query to the specification, and injects the result back into its circuit's state, so that the output behavior of the circuit copy matches that of the real circuit. For example, for the retrieve operation, when the emulator sees that its circuit copy has just completed the equality comparison, the emulator extracts the slot number and PIN guess from the circuit copy's RAM, makes a `retrieve` query to the specification, and injects the result (match or no match) back into its copy of the circuit, also injecting the secret into the appropriate location in memory if the guess indeed matched. All of the emulators for the case studies follow this general construction. Through the physical equivalence proof, we show that all implementation-level behavior can be explained with spec-level behavior, proving that the implementation leaks no more than the spec.

Verifying physical equivalence catches classic security bugs, such as a bug where the implementation's timing behavior leaks how many bytes of the PIN guess matches due to using `strcmp`. This information is not revealed by the spec — which only reveals whether or not the guess is correct (and the secret, when the guess is correct), not how many bytes of the guess match the PIN — so IPR prevents the implementation from leaking it. For such a buggy implementation, an emulator satisfying the IPR definition doesn't exist: the emulator doesn't have direct access to the true PIN (only query access through the specification), so its behavior can't match the real circuit's leaky behavior.

```
var secret = 0

def config(new_secret):
  secret = new_secret

def hash(password):
  return sha256(password || secret)
```

Figure 13: The functional specification for the password-hashing HSM.

Verifying physical equivalence caught a subtle security bug involving persistence and timing. Figure 3 shows a code snippet from the insecure implementation. The compiler happens to compile this code using a branch instruction, branching in the case where the guess is incorrect, and the CPU implementation takes longer to take the branch than to fall through to the next instruction. This has the effect that the circuit takes longer to write the updated `bad_guesses` value to persistent memory in the case of an incorrect PIN guess (where it's executing `entry->bad_guesses++`) than in the case of a correct PIN guess (where it's executing `entry->bad_guesses = 0`). An attacker can abuse this to reset the guess count by guessing a PIN, powering off the device after just enough cycles to reset the guess count in the case that the guess is correct (but not waiting long enough that `entry->bad_guesses++` has a chance to run, in the case that the guess is incorrect), and repeating this process for every possible PIN. This is not a correctness or even a crash-safety bug: this insecure implementation is both correct and crash safe. However, physical equivalence prevents this security bug in the implementation. The bug is fixed by using constant-time code to make the commit point of the operation independent of whether the PIN guess is correct.

7.1.2 Password-hashing HSM

Specification. Figure 13 outlines the specification for the password-hashing HSM. It includes a specification of SHA256 (not shown) that follows FIPS 180-4 [57]. The password hasher is configured with a secret, and then it computes salted hashes using the stored secret. There is no function to retrieve the secret after it is stored. The specification also guarantees that future operations cannot leak past inputs, because the secret cannot be read back, and passwords are not stored.

Implementation. The hardware is similar to that of the PIN-protected backup HSM. This HSM adds a hardware SHA256 cryptographic accelerator (about 300 lines of Verilog), which

implements the SHA256 block function. We originally used an off-the-shelf SHA256 core [66], but we switched to a custom implementation to minimize FPGA area so the design would fit on our low-cost board. The software includes a driver for the SHA256 peripheral, which implements the message padding function and drives the memory-mapped SHA256 peripheral, one block at a time. The software is written in 200 lines of C code and 40 lines of assembly.

The HSM needs to be crash safe, and the specification has operations that require updating multi-word values (the secret, in our specification, is 20 bytes), but the FRAM only supports word-level (32-bit) atomic writes. For this reason, the HSM uses a simple journaling strategy where it keeps two copies of the state in persistent memory and uses a flag to determine which one is active. To do an atomic write, the HSM writes to the inactive region and then toggles the flag.

Verification and bugs caught. The functional equivalence proof caught a bug in the hardware implementation, in the integration of the SHA256 peripheral into the SoC. The memory-mapped SHA256 peripheral's chip select input was being set based on the CPU's `mem_addr` bus, but the `mem_addr` is uninitialized on reset (it becomes stable after a couple cycles), so the SHA256 hardware could receive an unintended command right at boot. This bug would be difficult to catch through testing because it is only triggered in rare cases, when the uninitialized address bus contains a particular value on reset. The bug was fixed by adding an additional condition that `mem_valid` was also asserted (which all the other peripherals did, but the SHA256 peripheral didn't when it was first integrated).

Verification caught a security bug in the software, where the code branched on the flag indicating which region of persistent memory was active, and so there was observable timing variation where the circuit leaked more than the spec. Leaking which region of memory was active effectively leaked the parity of the total number of `hash` operations that the HSM had processed, which the specification does not expose. We fixed this by writing more careful C code that GCC compiled without branches so that there was no leakage.

7.1.3 TOTP token

Specification. Figure 14 outlines the specification for the TOTP token. It includes a specification of the TOTP algorithm (not shown) that follows RFC 6238 [54], which relies on HOTP [53], HMAC [46] and SHA1 [57]. The spec doesn't support reading back the secret after it has been set. It allows computing TOTP values given a timestamp supplied by the host machine, but it doesn't allow rewinding the timestamp. It supports an `audit` function to get the last timestamp value, to be able to identify if the HSM was ever abused to compute future TOTP values.

Implementation. The hardware is similar to that of the password-hashing HSM, except this token uses a hardware

```
var secret = 0, last_timestamp = 0

def set_secret(new_secret):
  secret = new_secret

def get_totp(timestamp):
  if timestamp < last_timestamp:
    return 'Cannot rewind timestamp'
  last_timestamp = timestamp
  return totp(secret, timestamp)

def audit():
  return last_timestamp
```

Figure 14: The functional specification for the TOTP token.

```
/* old implementation:
uint32_t s = (buf[offset]   & 0x7f) << 24
           | (buf[offset+1] & 0xff) << 16
           | (buf[offset+2] & 0xff) <<  8
           | (buf[offset+3] & 0xff);
*/
uint32_t s = 0;
for (int i = 0; i < 0x10; i++) {
    uint32_t match = ((i != offset) - 1);
    s += ((buf[i]   & 0x7f) & match) << 24;
    s += ((buf[i+1] & 0xff) & match) << 16;
    s += ((buf[i+2] & 0xff) & match) <<  8;
    s += ((buf[i+3] & 0xff) & match);
}
```

Figure 15: Rewriting TOTP dynamic truncation to avoid symbolic memory addresses.

SHA1 cryptographic accelerator. Its software includes a driver for the SHA1 peripheral that implements message padding, along with a software implementation of HMAC and the TOTP algorithm. Part of the TOTP algorithm is implemented in assembly, carefully written to prevent timing side channels. In one situation, we had to modify C code to be more amenable to symbolic execution, avoiding symbolic memory addresses in favor of fixed addresses and bit-twiddling tricks, as shown in Figure 15. The software for the TOTP token comprises 300 lines of C code and 60 lines of assembly.

Verification and bugs caught. The TOTP token uses a strategy matching the password hasher for achieving atomic state updates. Verifying functional equivalence caught a crash-safety bug where a struct field was missing a `volatile` qualifier and the compiler re-ordered a commit point (toggling the flag) before a write that should happen first (updating state in the inactive region of memory).

The emulator for the TOTP token follows the same basic construction as the others. One interesting detail: the `get_totp` implementation branches based on whether the timestamp is less than the last seen timestamp value; because the timestamp is a 64-bit value and PicoRV32 uses a 32-bit architecture, this turns into a number of comparisons/branches. The emulator, in order to make sure its behavior matches the real circuit's timing behavior, calls the `audit` function to retrieve the real last timestamp value and inject it in place of the

HSM	Spec		Driver	HW	SW	Proof
	core	total				
PIN backup	32	60	110	2670	190	470
PW hasher	5	150	90	3020	240	650
TOTP	10	180	80	2950	360	830

Figure 16: Lines of code for case studies. Lines of code for the spec are broken down into "core" and "total", where core is the main HSM functionality and doesn't include boilerplate or definitions of functions like SHA1, HMAC, and TOTP.

dummy data in the circuit copy, so that the timing behavior matches the real circuit. Also, the commit point for the TOTP operation is right after saving the new timestamp value, before the actual call to the TOTP function, so the emulator calls the functional specification's `get_totp` operation at the commit point in order to satisfy the recovery condition, stashes the output in auxiliary state, and when the circuit copy gets to the point where it's returning from its call to the TOTP function (computing with dummy data), injects the cached return value in place of the dummy value in the circuit.

The physical equivalence proof caught an issue with the TOTP implementation: it was using the C modulus (%) operator to compute the final $\mod 10^6$ operation, but this operation had variable latency dependent on its input, which leaks information that is not available in the functional specification. The spec doesn't reveal the output of the HMAC or dynamic truncation, only the final 6-digit code. The fix was to implement this functionality in constant time, which we did in assembly code using `sltu` and bitwise/arithmetic instructions.

7.1.4 Summary

IPR and Knox can be applied to simple HSM hardware and software. A design goal of the Knox HSMs, the implementations are minimal, using simple hardware throughout the SoC (e.g., a small RISC-V processor, simpler than the ARM Cortex-M found in many security tokens). Still, the Knox HSMs have implementation features found in real-world HSM hardware (e.g., microprocessor, I/O peripheral, persistent memory, cryptographic accelerator) and software (e.g., peripheral drivers, cryptography, crash safety), and Knox verification covers all of these.

Knox specs are succinct and proofs are manageable. Figure 16 shows lines of code in the spec and driver, implementation (hardware and software), and proof required for verifying each HSM. We break down spec lines of code into "core" and "total", where core doesn't include boilerplate or definitions of functions like SHA1, HMAC, and TOTP. Knox specifications are as short as their pseudocode: for example, aside from the definition of the TOTP algorithm as specified in RFC 6238, the core of the TOTP token specification in Knox is only 10 lines of code, as shown in Figure 17.

```
(struct state (secret last-ts))

(define s0 (state (bv 0 160) (bv 0 64)))

(define ((set-secret secret) s)
  (result #t (state secret (state-last-ts s))))

(define ((get-otp ts) s)
  (if (bvult ts (state-last-ts s)) (result (bv 0 32) s)
      (result (totp (state-secret s) ts)
              (state (state-secret s) ts))))

(define ((audit) s)
  (result (state-last-ts s) s))
```

Figure 17: The core of the Knox specification for the TOTP token. The definition of `totp`, not show here, is a pure function that follows the spec in RFC 6238.

HSM	FE-N	FE-N+C	FE	FE+C	PE
PIN backup	1	10	**209**	962	**8**
PW hasher	1	6	**74**	238	**4**
TOTP	3	8	**44**	141	**8**

Figure 18: Time taken (in minutes) for verification by Knox. FE is functional equivalence; the -N variation disables nondeterminism in the driver; +C adds verification of crash safety. PE is physical equivalence. The two bolded columns, FE and PE, together imply IPR.

Knox catches bugs throughout hardware/software. Verification caught bugs across hardware (e.g., SHA256 peripheral initialization, in the password hasher) and software (e.g., compiler re-ordering a commit point, in the TOTP token), including timing side channels (e.g., variable-time modulus, in the TOTP token) and subtle bugs involving hardware, software, timing, and persistence (e.g., commit point dependent on the PIN guess being correct, in the PIN-protected backup).

7.2 Performance

Verification performance. Figure 18 shows Knox's verification performance, evaluated on a 2014-era Intel i7-5930K. The implementation is currently single-threaded. Most of the time in functional equivalence proofs is due to nondeterminism (yield and merge) or verifying crash safety. The relatively low performance of verifying PIN-protected backup is due to performing case analysis on the slot number, which causes many paths to be explored independently.

When developing functional equivalence proofs, we usually begin by disabling driver nondeterminism and verification of crash safety. This significantly reduces verification time, and the tighter feedback loop speeds up the initial proof development process. After verification completes successfully in this simplified setting, we add back complexity and fix up the implementation and proof as needed.

Implementation performance. The case studies showed that hardware or software may need to be modified to satisfy

Metric	Baseline	Verified	
FPGA LUTs	3966	3962	(−0%)
Max clock freq	20.01 MHz	20.53 MHz	(+3%)
Code size	2412 B	2592 B	(+7%)
TOTP op latency	0.73 ms	0.83 ms	(+14%)

Figure 19: Overhead of modifications to TOTP token.

the strict definition of IPR and simplify verification. The TOTP token required the most modifications among the case studies. Figure 19 shows the impact of these modifications on hardware (FPGA area and maximum clock frequency) and software (code size and performance). Code performance was measured at a clock of 12 MHz and baud rate of 2M for the `totp` operation. Most of the slowdown results from the modification to the dynamic truncation code (Figure 15).

The verified TOTP token can perform TOTP operations with a latency of 0.83 ms, which is fast enough for interactive use [50]. The other HSMs have similar per-operation latency.

8 Discussion

This section elaborates on some of the design decisions made in IPR and Knox and discusses their implications.

8.1 Emulator efficiency

To meaningfully apply IPR to specifications that involve cryptography, the adversary must be efficient, and therefore, the emulator must be efficient as well. Without an efficiency requirement, an implementation that, for example, leaks an RSA signing key, could be justified by an emulator that calls the specification to get the public key, factors products of large primes in exponential time to compute the private key, and then perfectly mimics the physical interface because it has determined the implementation's internal state.

The emulator must satisfy a coarse-grained notion of efficiency: being prohibited from performing exponential-time computation and brute-forcing secrets. Without an efficiency requirement, information-preserving refinement captures an information-theoretic notion of information preservation, rather than a computational one.

The Knox framework does not fully formalize or mechanically verify emulator efficiency. Instead, the proofs rely on a manual audit of the emulator code. The emulators we construct are simple, so the efficiency property is easy to check. In fact, the Knox emulators in our case studies satisfy a stricter definition of efficiency than necessary — per cycle of the circuit that they emulate, they perform at most one query to the specification and perform computation roughly equivalent to what the circuit does in one cycle — meaning that an adversary could run the emulator with computational resources equivalent to the circuit itself.

8.2 Randomness

Functional specifications in IPR are deterministic, so IPR cannot be used to verify HSMs that use true random number generators (TRNGs). As an alternative, HSMs can use cryptographically-secure pseudo-random number generators (CSPRNGs), and this fits into IPR, because IPR supports internal state. The specification can internally use a CSPRNG, the spec can be augmented to expose an operation to add entropy to the CSPRNG, and this operation can be called by the host at device initialization time (and again at any time later) to seed the random number generator. IPR ensures that the CSPRNG's internal state cannot be leaked by the implementation.

8.3 Allowed leakage

IPR enforces that the implementation leaks no more than the specification; sometimes, it is desirable to allow the implementation to leak some non-sensitive information, e.g., the current `bad_guesses` count in the PIN-protected backup. This fits in to IPR: the leakage can be expressed as a spec-level `leak` operation. Knox supports leakage specifications using this strategy, and it allows the user to skip proving functional equivalence for `leak` operations (a well-behaved host does not need to invoke this operation; it is only relevant for modeling leakage as part of physical equivalence).

8.4 Monolithic end-to-end verification

Knox performs monolithic end-to-end verification, which has some benefits over modular verification. There is no need to define intermediate specifications and prove that layers satisfy these specs; there is no distinction between hardware and software, or a notion of, e.g., an instruction set architecture. Knox simply reasons about the cycle-accurate behavior of the entire circuit. If the circuit happens to contain a CPU that runs some software, the software is "inlined" into hardware (the initial contents of a ROM, for example).

Knox uses symbolic execution, and due to performing symbolic execution end-to-end across software and hardware, symbolic execution can be kept as concrete as possible, which improves performance. For example, Knox doesn't attempt to prove a CPU correct (that it executes *any* program correctly); this would require reasoning about symbolic instructions/programs. Instead, a proof of a Knox HSM only shows (indirectly) that the CPU executes the HSM's particular software correctly, which is an easier task.

Lack of modularity could be a challenge when scaling up Knox to more sophisticated HSM implementations, because end-to-end symbolic execution across hardware and software will perform poorly as hardware gets more sophisticated, and the proof developer might have trouble with non-modular reasoning as complexity increases. But modular reasoning about security properties is also challenging: e.g., proving software correct with respect to an ISA specification is inadequate for proving absence of timing side channels.

A potential approach to this problem could involve structuring the HSM implementation to delay responses until a worst-case execution time bound, and then specializing the verification framework to reason about HSMs following such a design. With such a structure, precise Knox-style reasoning about software executing on hardware may not be necessary, making it possible to separately reason about correctness (following standard approaches) and then reason about worst-case execution time bounds of software executing on hardware to show a top-level property like IPR.

9 Related work

Noninterference. Noninterference [39] captures confidentiality properties in systems where high-sensitivity inputs should not affect low-sensitivity outputs, which are separate from high-sensitivity outputs. seL4 [55], mCertiKOS [30], Komodo [36], and Nickel [64] verify noninterference properties such as process isolation. HACL* [62, 74], Vale [25, 38], EverCrypt [63], and Jasmin [14] phrase freedom from timing side channels in crypto code as noninterference by defining a leakage trace (the low-sensitivity output) that captures adversary observations, such as every program counter value, and showing that two executions that have matching public inputs but differing secrets (high-sensitivity inputs) produce identical leakage traces.

The Knox setting does not have separate low/high-sensitivity outputs: there is just one output, the logic levels on the output wires at every cycle, and this is what the adversary observes. Noninterference does not hold in the Knox setting: the output can and will be secret-dependent. Instead, IPR says that the output does not leak more information than the spec, which is not a noninterference property.

Declassification. Noninterference with declassification [56] separates low and high-sensitivity inputs (i.e., public and secret inputs) and supports controlled influence of secrets on outputs through an explicit declassify function that marks secret-dependent values as safe to output. Ironclad [42] uses this style of security definition; the proofs cover only software, not hardware, and do not rule out timing side channels.

The Knox setting does not separate low and high-sensitivity inputs. There is just one input, the logic levels on the input wires at every cycle. IPR says that after the HSM receives inputs from the driver (i.e., corresponding to a spec-level operation), its future behavior does not leak more information than the specification, which is not a declassification property.

Ironclad contains a PassHash app similar to the Knox password hasher. PassHash generates a secret internally, from a computer's TPM, and it services network requests: given a password, it returns a hash of the password salted with the secret. The secret is a high-sensitivity input (from the TPM) and the password is low-sensitivity input (from the network); the security definition is phrased as noninterference with declassification, allowing the final output to the network to depend on the secret in a controlled way. In the Knox HSM, the secret is not generated internally but received from the host, and both secrets and passwords are received over the same input wires (there are no separate public and secret inputs). A declassification-style definition does not apply. IPR says that the implementation's behavior can't leak more information than the specification, so for example, after a host sets the secret, the HSM can't leak the secret. IPR also gives the same property with passwords: the HSM can't leak passwords that were input earlier. In contrast, the noninterference property for PassHash doesn't prevent the implementation from leaking passwords, because they are low-sensitivity inputs.

Hardware/software verification. A long line of work performs end-to-end verification of functional correctness properties for hardware/software systems, with an emphasis on modular verification [13, 23, 35, 48]. Proving functional correctness does not rule out timing side channels, while addressing side channels is a central goal of IPR and Knox.

Knox uses Notary's toolchain to convert C/Verilog to Rosette models, and Knox uses Notary's idea of reset-based design for simplifying verification [16, 52]. Knox solves a different problem than Notary. IPR is a new security definition for HSMs that captures the notion that a hardware/software implementation satisfies a functional specification and leaks nothing more, and Knox is a framework for proving this property, including support for writing specifications, encoding drivers and emulators, and proving correctness and security. Notary's focus is a hardware/software architecture for better isolation between multiple mutually-distrustful agents running on the same device, and Notary only verifies a simple (but key) property of an embedded system and its boot code, that all internal state is cleared after reset.

Simulation-based definitions of security. IPR is inspired by simulation-based definitions of security for multiparty computation (MPC) and universal composability (UC) [28, 40, 41]. The Knox emulator is similar to the MPC simulator, which formalizes the notion of zero knowledge in an MPC protocol. Knox uses this concept to define non-leakage for a hardware/software system.

Verified cryptography. Some tools [18, 19, 24, 61] verify cryptographic properties of functional specifications and protocols. These are complementary to Knox, as illustrated by work that formally analyzes HSM interfaces [26, 33].

Other works prove functional correctness of crypto implementations [17, 22, 27, 29, 34]. Some of these provide side-channel resistance with cryptographic constant-time code, which can be compiled to machine code while preserving constant-time [20], but the security property does not go down to the hardware / wire I/O level.

Verifying efficiency. Cryptographic proofs generally reason about efficient adversaries, and some frameworks for verified cryptography support proving polynomial bounds on

programs' running time [18, 61]. Knox could follow their approach, adding a cost semantics for the emulator language, to formally reason about emulator efficiency.

Secure compilation. In Knox, the circuit is not derivable from the specification via compilation, but the IPR definition bears some resemblance to the properties secure compilers guarantee about their compilation results. Fully-abstract compilers [11] preserve and reflect observational equivalence from the source to the target language. Some security properties can be stated as program equivalences [60], but IPR's non-leakage property is not captured by this type of definition. In fact, some Knox specifications such as the password hasher have no instances that are observationally (extensionally) equivalent but not intensionally equal, so a secure-compilation-style equivalence preservation at the circuit level would be vacuous. Trace-preserving compilation [59] preserves trace equivalence between source and target and handles invalid target-level inputs. The definition is not general enough to apply to the HSM setting because source-level inputs don't map to single target-level inputs (function call to wire input for a *single* cycle), and there is no notion of "ignoring invalid inputs" (for any wire-level inputs, the HSM will have wire-level outputs). Furthermore, similar to the case of program equivalence, some Knox specifications such as the password hasher have no instances that are trace-equivalent but not equal, so trace-equivalence preservation at the circuit level would be vacuous.

10 Conclusion

Information-preserving refinement (IPR) is a new security definition that captures the idea that a circuit-level implementation should implement its logical-level specification and leak nothing more. Knox demonstrates that IPR is useful in practice for ruling out bugs in an HSM's hardware and software. We believe that IPR is applicable beyond HSMs and hope that it can serve as a foundation of future security definitions.

Acknowledgments

We would like to thank Henry Corrigan-Gibbs and Joseph Tassarotti for insightful discussions that helped us develop the IPR definition. We are grateful to Emina Torlak and Xi Wang for their guidance on working with Rosette. Abstract

Large-scale Transformer-based models trained for generation tasks (e.g., GPT-3) have recently attracted huge interest, emphasizing the need for system support for serving models in this family. Since these models generate a next token in an autoregressive manner, one has to run the model multiple times to process an inference request where each iteration of the model generates a single output token for the request. However, existing systems for inference serving do not perform well on this type of workload that has a multi-iteration characteristic, due to their inflexible scheduling mechanism that cannot change the current batch of requests being processed; requests that have finished earlier than other requests in a batch cannot return to the client, while newly arrived requests have to wait until the current batch completely finishes.

In this paper, we propose iteration-level scheduling, a new scheduling mechanism that schedules execution at the granularity of iteration (instead of request) where the scheduler invokes the execution engine to run only a single iteration of the model on the batch. In addition, to apply batching and iteration-level scheduling to a Transformer model at the same time, we suggest selective batching, which applies batching only to a selected set of operations. Based on these two techniques, we have implemented a distributed serving system called ORCA, with additional designs for scalability to models with hundreds of billions of parameters. Our evaluation on a GPT-3 175B model shows that ORCA can significantly outperform NVIDIA FasterTransformer in terms of both latency and throughput: 36.9× throughput improvement at the same level of latency.

1 Introduction

Language generation tasks are becoming increasingly paramount to many types of applications, such as chatbot [9, 52], summarization [41,45,54], code generation [13], and caption generation [65,66]. Moreover, recent works published by AI21 Labs [37], DeepMind [26,48], Google [15,21,63], Meta Platforms [10,67], Microsoft [50], Microsoft & NVIDIA [59], and OpenAI [12] have reported that every language processing task, including translation [11,17], classification [20,53], question-answering [32,33,40] and more, can be cast as a language generation problem and have shown great improvements along this direction. The rise of generative models is not limited to the language domain; the AI community has also given growing interest to generation problems in other domains such as image, video, speech, or a mixture of multiple domains [19,38,51,62]. At the heart of generative models lies the Transformer architecture [60] and its variants [15,47–49]. By relying on the attention mechanism [60], Transformer models can learn better representations where each element of the sequence may have a direct connection with every other element, which was not possible in recurrent models [25].

To use generative models in real-world applications, we often delegate the inference procedure to a separate service responsible for ML inference serving. The growing demands for this service, which should provide inference results for client requests at low latency and high throughput, have facilitated the development of inference serving systems such as Triton Inference Server [7] and TensorFlow Serving [42]. These systems can use a separately-developed DNN *execution engine* to perform the actual tensor operations. For example, we can deploy a service for language generation tasks by using a combination of Triton and FasterTransformer [4], an execution engine optimized for the inference of Transformer-based models. In this case, Triton is mainly responsible for grouping multiple client requests into a batch, while FasterTransformer receives the batch from Triton and conducts the inference procedure in the batched manner.

Unfortunately, we notice that the existing inference systems, including both the serving system layer and the execution engine layer, have limitations in handling requests for Transformer-based generative models. Since these models are trained to generate a next token in an autoregressive manner, one should run the model as many times as the number of tokens to generate, while for other models like ResNet [24] and

*Corresponding author.

BERT [18] a request can be processed by running the model once. That is, in order to process a request to the generative model, we have to run multiple *iterations* of the model; each iteration generates a single output token, which is used as an input in the following iteration. Such multi-iteration characteristic calls into question the current design of inference systems, where the serving system schedules the execution of the engine at the granularity of request. Under this design, when the serving system dispatches a batch of requests to the engine, the engine returns inference results for the entire batch at once after processing all requests within the batch. As different client requests may require different numbers of iterations for processing, requests that have finished earlier than others in the batch cannot return to the client, resulting in an increased latency. Requests arrived after dispatching the batch also should wait for processing the batch, which can significantly increase the requests' queueing time.

In this paper, we propose to schedule the execution of the engine *at the granularity of iteration* instead of request. In particular, the serving system invokes the engine to run only a single iteration of the model on the batch. As a result, a newly arrived request can be considered for processing after waiting for only a single iteration of the model. The serving system checks whether a request has finished processing after every return from the engine – hence the finished requests can also be returned to the clients immediately.

Nevertheless, a noticeable challenge arises when we attempt to apply batching and the iteration-level scheduling at the same time. Unlike the canonical request-level scheduling, the proposed scheduling can issue a batch of requests where each request has so far processed a different number of tokens. In such a case, the requests to the Transformer model cannot be processed in the batched manner because the attention mechanism calls for non-batchable tensor operations whose input tensors have variable shapes depending on the number of processed tokens.

To address this challenge, we suggest to apply batching only to a selected set of operations, which we call *selective batching*. By taking different characteristics of operations into account, selective batching splits the batch and processes each request individually for the Attention[1] operation while applying batching to other operations of the Transformer model. We observe that the decision not to batch the executions of the Attention operation has only a small impact on efficiency. Since the Attention operation is not associated with any model parameters, applying batching to Attention has no benefit of reducing the amount of GPU memory reads by reusing the loaded parameters across multiple requests.

Based on these techniques, we design and implement ORCA, a distributed serving system for Transformer-based generative models. In order to handle large-scale models, ORCA adopts parallelization strategies including intra-layer and inter-layer model parallelism, which were originally developed by training systems [55, 58] for Transformer models. We also devise a new scheduling algorithm for the proposed iteration-level scheduling, with additional considerations for memory management and pipelined execution across workers.

We evaluate ORCA using OpenAI GPT-3 [12] models with various configurations, scaling up to 341B of parameters. The results show that ORCA significantly outperforms FasterTransformer [4], showing 36.9× throughput improvement at the same level of latency. While we use a language model as a driving example throughout the paper and conduct experiments only on language models, generative models in other domains can benefit from our approach as long as the models are based on the Transformer architecture and use the autoregressive generation procedure [19, 38, 51, 62].

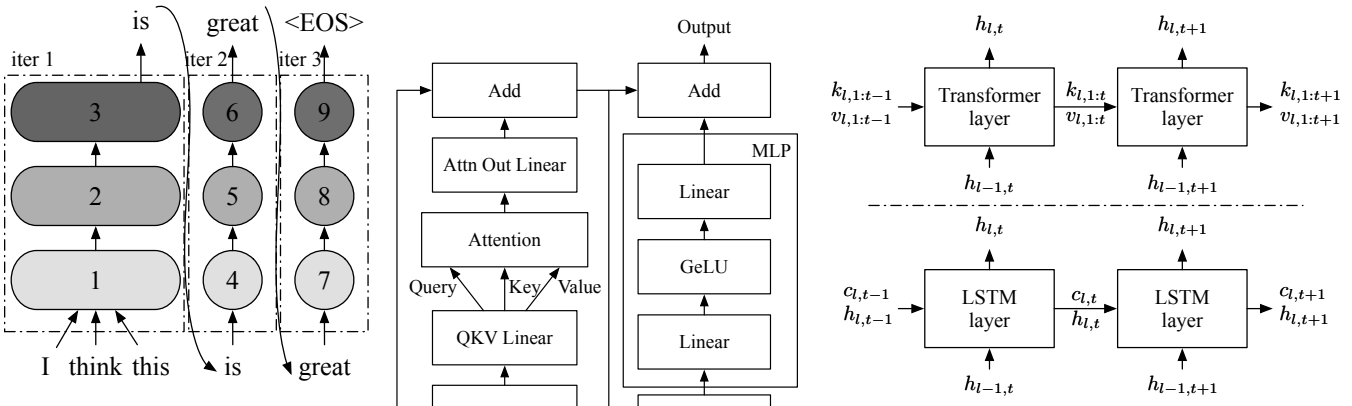
2 Background

We provide background on the inference procedure of GPT [12, 47], a representative example of Transformer-based generative models that we use throughout this paper, and ML inference serving systems.

Inference procedure of GPT. GPT is an autoregressive language model based on one of architectural variants of Transformer [60]. It takes text as input and produces new text as output. In particular, the model receives a sequence of input tokens and then completes the sequence by generating subsequent output tokens. Figure 1a illustrates a simplified computation graph that represents this procedure with a three-layer GPT model, where nodes and edges indicate Transformer layers and dependencies between the layers, respectively. The Transformer layers are executed in the order denoted by the numbers on the nodes, and the nodes that use the same set of model parameters (i.e., nodes representing the same layer) are filled with the same color.

The generated output token is fed back into the model to generate the next output token, imposing a sequential, one-by-one inference procedure. This autoregressive procedure of generating a single token is done by running all the layers of the model with the input, which is either a sequence of input tokens that came from the client or a previously generated output token. We define the run of all layers as an *iteration* of the model. In the example shown in Figure 1a, the inference procedure comprises three iterations. The first iteration ("iter 1") takes all the input tokens ("I think this") at once and generates the next token ("is"). This iteration composes an *initiation phase*, a procedure responsible for processing the input tokens and generating the first output token. The next two iterations ("iter 2" and "iter 3"), which compose an *increment phase*, take the output token of the preceding iteration and generate

[1] In some literature the Attention operation has an extended definition that includes linear layers (QKV Linear and Attn Out Linear; Figure 1b). On the other hand, we use a narrow definition as described in Figure 1b.



(a) A computation graph representing an inference procedure using a GPT model. The graph does not depict layers other than Transformer layers (e.g., embedding) for simplicity.

(b) A Transformer layer used in GPT.

(c) Internal state usage of Transformer. h, k, v, and c refer to layer input/output, Attention key, Attention value, and LSTM internal memory, respectively. l denotes layer index and t denotes token index.

Figure 1: Illustrations for GPT's inference procedure, Transformer layer, and internal state usage.

the next token. In this case, "iter 3" is the last iteration because it produces "<EOS>", a special end-of-sequence token that terminates output generation. Note that while the increment phase comprises multiple iterations because each iteration is only able to process a single token, the initiation phase is typically implemented as a single iteration by processing all the input tokens in parallel.

The original Transformer [60] employs two stacks of Transformer layers, while GPT's architecture consists of a single layer stack, namely decoder. Figure 1b shows a Transformer layer used in GPT. Among the operations that compose the Transformer layer, *Attention* is the essence that distinguishes Transformer from other architectures. At a high level, the Attention operation computes a weighted average of the tokens of interest so that each token in the sequence is aware of the other. It takes three inputs, query, key, and value, computes dot products of the query (for the current token) with all keys (for the tokens of interest), applies Softmax on the dot products to get weights, and conducts weighted average of all values associated with the weights.

Since the Attention requires keys and values of all preceding tokens,[2] we consider the keys and values as internal states that should be maintained across multiple iterations. A naïve, state-less inference procedure would take all tokens in the sequence (including both the client-provided input tokens and the output tokens generated so far) to recompute all the keys and values at every iteration. To avoid such recomputation, fairseq [43] suggests incremental decoding, which saves the keys and values for reuse in successive iterations. Other systems for Transformer such as FasterTransformer [4] and Megatron-LM [3] also do the same.

[2]Language models like GPT use causal masking, which means all preceding tokens are of interest and participate in the Attention operation.

Figure 1c illustrates the state usage pattern of Transformer, along with LSTM [25] that also maintains internal states. The main difference is that the size of the states (k for Attention key and v for value) in Transformer increases with iteration, whereas the size of the states (c for LSTM internal memory and h for LSTM layer's input/output) in LSTM remains constant. When processing the token at index t, the Attention operation takes all previous Attention keys $k_{l,1:t-1}$ and values $v_{l,1:t-1}$ along with the current key $k_{l,t}$ and value $v_{l,t}$.[3] Therefore, the Attention operation should perform computation on tensors of different shapes depending on the number of tokens already processed.

Prior to the Attention operation, there are the layer normalization operation (LayerNorm) and the QKV Linear (linear and split operations to get the query, key and value). Operations performed after Attention are, in order, a linear operation (Attn Out Linear), an add operation for residual connection (Add), layer normalization operation (LayerNorm), the multi-layer perceptron (MLP) operations, and the other residual connection operation (Add).

ML inference serving systems. Growing demands for ML-driven applications have made ML inference serving service a critical workload in modern datacenters. Users (either the end-user or internal microservices of the application) submit requests to an inference service, and the service gives replies on the requests based on a pre-defined ML model using its provisioned resource, typically equipped with specialized accelerators such as GPUs and TPUs. In particular, the service runs a DNN model with input data to generate output for the

[3]$k_{l,1:t-1}$ represents Attention keys of the l-th layer for tokens at indices 1 to $t-1$ while $k_{l,t}$ is for the Attention key of the l-th layer for the token at index t. Same for $v_{l,1:t-1}$ and $v_{l,t}$.

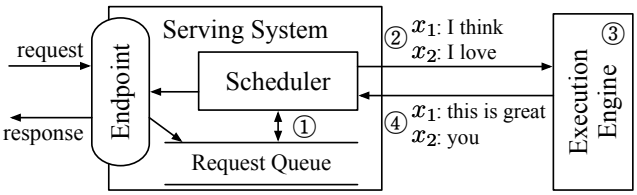


Figure 2: Overall workflow of serving a generative language model with existing systems.

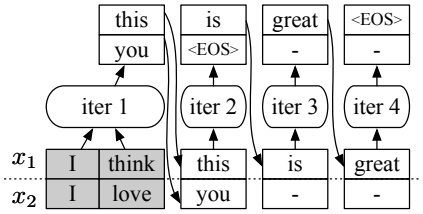

Figure 3: An illustration for a case where the requests have the same input length but some requests finish earlier than others. Shaded tokens represent input tokens. "-" denotes inputs and outputs of extra computation imposed by the scheduling.

request. Just like other services operating on datacenters, a well-managed inference service should provide low latency and high throughput within a reasonable amount of cost.

To meet such constraints, service operators often use ML inference serving systems such as Triton Inference Server [7] and TensorFlow Serving [42]. These systems can be seen as an abstraction sitting atop underlying model *execution engines* such as TensorRT [6], TVM [14], TensorFlow [8], and many others [44, 46], being agnostic to various kinds of ML models, execution engines, and computing hardware. While delegating the role of driving the main mathematical operations to the engines, serving systems are in charge of exposing endpoints that receive inference requests, scheduling executions of the engine, and sending responses to the requests. Accordingly, these systems focus on aspects such as batching the executions [7, 16, 35, 42, 56], selecting an appropriate model from multiple model variants [16, 27, 30, 57], deploying multiple models (each for different inference services) on the same device [7, 29, 35, 56], and so on.

Among the features and optimizations provided by serving systems, batching is a key to achieve high accelerator utilization when using accelerators like GPUs. When we run the execution engine with batching enabled, the input tensors from multiple requests coalesce into a single, large input tensor before being fed to the first operation of the model. Since the accelerators prefer large input tensors over small ones to better exploit the vast amount of parallel computation units, the engine's throughput is highly dependent on the batch size, i.e., the number of inference requests the engine processes together. Reusing the model parameters loaded from off-chip memory is another merit in batched execution, especially when the model involves memory-intensive operations.

Figure 2 shows an overall workflow of serving a generative language model with existing serving systems and execution engines. The main component of the serving system (e.g., Triton [7]) is the scheduler, which is responsible for ① creating a batch of requests by retrieving requests from a queue and ② scheduling the execution engine (e.g., FasterTransformer [4]) to process the batch. The execution engine ③ processes the received batch by running multiple iterations of the model being served and ④ returns the generated text back to the serving system. In Figure 2, the serving system schedules the engine to process two requests (x_1: "I think", x_2: "I love") in a batch and the engine generates "this is great" and "you" for requests x_1 and x_2, respectively.

3 Challenges and Proposed Solutions

In this section, we describe challenges in serving Transformer-based generative models and propose two techniques: iteration-level scheduling and selective batching.

C1: Early-finished and late-joining requests. One major limitation of existing systems is that the serving system and the execution engine interact with each other only when (1) the serving system schedules the next batch on an idle engine; or (2) the engine finishes processing the current batch. In other words, these systems are designed to schedule executions at *request* granularity; the engine maintains a batch of requests fixed until all requests in the batch finish. This can be problematic in the serving of generative models, since each request in a batch may require different number of iterations, resulting in certain requests finishing earlier than the others. In the example shown in Figure 3, although request x_2 finishes earlier than request x_1, the engine performs computation for both "active" and "inactive" requests throughout all iterations. Such extra computation for inactive requests (x_2 at iter 3 and 4) limits the efficiency of batched execution.

What makes it even worse is that this behavior prevents an early return of the finished request to the client, imposing a substantial amount of extra latency. This is because the engine only returns the execution results to the serving system when it finishes processing all requests in the batch. Similarly, when a new request arrives in the middle of the current batch's execution, the aforementioned scheduling mechanism makes the newly arrived request wait until all requests in the current batch have finished. We argue that the current request-level scheduling mechanism cannot efficiently handle workloads with multi-iteration characteristic. Note that this problem of early-finished and late-joining requests does not occur in the training of language models; the training procedure finishes processing the whole batch in a single iteration by using the teacher forcing technique [64].

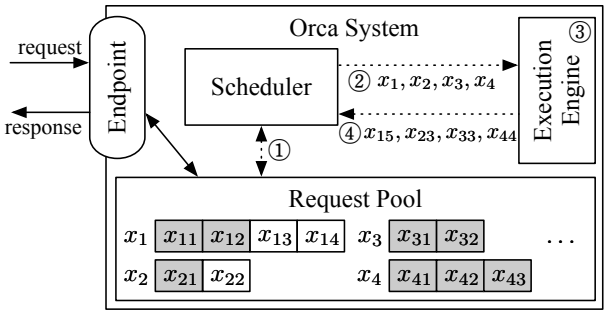

Figure 4: System overview of ORCA. Interactions between components represented as dotted lines indicate that the interaction takes place at every iteration of the execution engine. x_{ij} is the j-th token of the i-th request. Shaded tokens represent input tokens received from the clients, while unshaded tokens are generated by ORCA. For example, request x_1 initially arrived with two input tokens (x_{11}, x_{12}) and have run two iterations so far, where the first and second iterations generated x_{13} and x_{14}, respectively. On the other hand, request x_3 only contains input tokens (x_{31}, x_{32}) because it has not run any iterations yet.

S1: Iteration-level scheduling. To address the above limitations, we propose to schedule executions at the granularity of *iteration*. At high level, the scheduler repeats the following procedure: (1) selects requests to run next; (2) invokes the engine to execute *one iteration* for the selected requests; and (3) receives execution results for the scheduled iteration. Since the scheduler receives a return on every iteration, it can detect the completion of a request and immediately return its generated tokens to the client. For a newly arrived request, the request gets a chance to start processing (i.e., the scheduler may select the new request to run next) after execution of the currently scheduled iteration, significantly reducing the queueing delay. With iteration-level scheduling, the scheduler has a full control on how many and which requests are processed in each iteration.

Figure 4 depicts the system architecture and the overall workflow of ORCA using the iteration-level scheduling. ORCA exposes an *endpoint* (e.g., HTTPS or gRPC) where inference requests arrive at the system and responses to the requests are sent out. The endpoint puts newly arrived requests in the *request pool*, a component that manages all requests in the system during their lifetime. The pool is monitored by the *scheduler*, which is responsible for: selecting a set of requests from the pool, scheduling the *execution engine* to run an iteration of the model on the set, receiving execution results (i.e., output tokens) from the engine, and updating the pool by appending each output token to the corresponding request. The engine is an abstraction for executing the actual tensor operations, which can be parallelized across multiple GPUs spread across multiple machines. In the example shown in Figure 4, the scheduler ① interacts with the request pool to decide which requests to run next and ② invokes the engine to run four selected requests: (x_1, x_2, x_3, x_4). The scheduler provides the engine with input tokens of the requests scheduled for the first time. In this case, x_3 and x_4 have not run any iterations yet, so the scheduler hands over (x_{31}, x_{32}) for x_3 and (x_{41}, x_{42}, x_{43}) for x_4. The engine ③ runs an iteration of the model on the four requests and ④ returns generated output tokens $(x_{15}, x_{23}, x_{33}, x_{44})$, one for each scheduled request. Once a request has finished processing, the request pool removes the finished request and notifies the endpoint to send a response. Unlike the method shown in Figure 2 that should run multiple iterations on a scheduled batch until finish of all requests within the batch, ORCA's scheduler can change which requests are going to be processed at every iteration. We describe the detailed algorithm about how to select the requests at every iteration in Section 4.2.

C2: Batching an arbitrary set of requests. When we try to use the iteration-level scheduling in practice, one major challenge that we are going to face is batching. To achieve high efficiency, the execution engine should be able to process any selected set of requests in the batched manner. Without batching, one would have to process each selected request one by one, losing out on the massively parallel computation capabilities of GPUs.

Unfortunately, there is no guarantee that even for a pair of requests (x_i, x_j), for the next iteration, their executions can be merged and replaced with a batched version. There are three cases for a pair of requests where the next iteration cannot be batched together: (1) both requests are in the initiation phase and each has different number of input tokens (e.g., x_3 and x_4 in Figure 4); (2) both are in the increment phase and each is processing a token at different index from each other (x_1 and x_2); or (3) each request is in the different phase: initiation or increment (x_1 and x_3). Recall that in order to batch the execution of multiple requests, the execution of each request must consist of identical operations, each consuming identically-shaped input tensors. In the first case, the two requests cannot be processed in a batch because the "length" dimension of their input tensors, which is the number of input tokens, are not equal. The requests in the second case have difference in the tensor shape of Attention keys and values because each processes token at different index, as shown in Figure 1c. For the third case, we cannot batch the iterations of different phases because they take different number of tokens as input; an iteration of the initiation phase processes all input tokens in parallel for efficiency, while in the increment phase each iteration takes a single token as its input (we assume the use of fairseq-style incremental decoding [43]).

Batching is only applicable when the two selected requests are in the same phase, with the same number of input tokens (in case of the initiation phase) or with the same token index (in case of the increment phase). This restriction significantly reduces the likelihood of batching in real-world workloads,

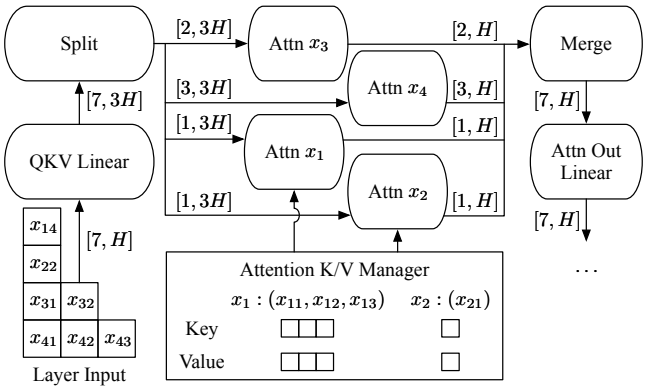

Figure 5: An illustration of ORCA execution engine running a Transformer layer on a batch of requests with selective batching. We only depict the QKV Linear, Attention, and Attention Out Linear operations for simplicity.

because the scheduler should *make a wish* for the presence of two requests eligible for batching at the same time. The likelihood further decreases exponentially as the batch size increases, making it impractical to use a large batch size that can pull out better throughput without compromising latency.

S2: Selective batching. We propose *selective batching*, a technique for batched execution that allows high flexibility in composing requests as a batch. Instead of processing a batch of requests by "batchifying" all tensor operations composing the model, this technique selectively apply batching only to a handful of operations.

The main problem regarding batching described above is that the three aforementioned cases[4] correspond to irregularly shaped input (or state) tensors, which cannot be coalesced into a single large tensor and fed into a batch operation. In the canonical batching mechanism, at each iteration, a Transformer layer takes a 3-dimensional input tensor of shape $[B,L,H]$ generated by concatenating multiple $[L,H]$ input tensors of requests in a batch, where B is the batch size, L is the number of tokens processed together, and H is the hidden size of the model. For example, in Figure 3, "iter 1" (initiation phase) takes an input tensor of shape $[2,2,H]$ and "iter 2" (increment phase) takes a tensor of shape $[2,1,H]$. However, when the scheduler decides to run an iteration on batch (x_1,x_2,x_3,x_4) in Figure 4, the inputs for requests in the initiation phase ($x_3 : [2,H]$ and $x_4 : [3,H]$) cannot coalesce into a single tensor of shape $[B,L,H]$ because x_3 and x_4 have different number of input tokens, 2 and 3.

Interestingly, not all operations are incompatible with such irregularly shaped tensors. Operations such as non-Attention matrix multiplication and layer normalization can be made to work with irregularly shaped tensors by flattening the tensors. For instance, the aforementioned input tensors for x_3 and x_4 can compose a 2-dimensional tensor of shape $[\sum L,H] = [5,H]$ without an explicit batch dimension. This tensor can be fed into all non-Attention operations including Linear, LayerNorm, Add, and GeLU operations because they do not need to distinguish tensor elements of different requests. On the other hand, the Attention operation requires a notion of requests (i.e., requires the batch dimension) to compute attention only between the tokens of the same request, typically done by applying cuBLAS routines for batch matrix multiplication.

Selective batching is aware of the different characteristics of each operation; it splits the batch and processes each request individually for the Attention operation while applying token-wise (instead of request-wise) batching to other operations without the notion of requests. Figure 5 presents the selective batching mechanism processing a batch of requests (x_1,x_2,x_3,x_4) described in Figure 4. This batch has 7 input tokens to process, so we make the input tensor have a shape of $[7,H]$ and apply the non-Attention operations. Before the Attention operation, we insert a `Split` operation and run the Attention operation separately on the split tensor for each request. The outputs of Attention operations are merged back into a tensor of shape $[7,H]$ by a `Merge` operation, bringing back the batching functionality to the rest of operations.

To make the requests in the increment phase can use the Attention keys and values for the tokens processed in previous iterations, ORCA maintains the generated keys and values in the *Attention K/V manager*. The manager maintains these keys and values separately for each request until the scheduler explicitly asks to remove certain request's keys and values, i.e., when the request has finished processing. The Attention operation for request in the increment phase (x_1 and x_2) takes keys and values of previous tokens (x_{11},x_{12},x_{13} for x_1; x_{21} for x_2) from the manager, along with the current token's query, key, and value from the Split operation to compute attention between the current token and the previous ones.

4 ORCA Design

Based on the above techniques, we design and implement ORCA: a distributed serving system for Transformer-based generative models. We have already discussed the system components and the overall execution model of ORCA while describing Figure 4. In this section, we answer the remaining issues about how to build an efficient system that can scale to large-scale models with hundreds of billions of parameters. We also describe the scheduling algorithm for iteration-level scheduling, i.e., how to select a batch of requests from the request pool at every iteration.

4.1 Distributed Architecture

Recent works [12, 31] have shown that scaling language models can dramatically improve the quality of models. Hence,

[4] We use the first case as a driving example, but the argument can be similarly applied to the other two cases.

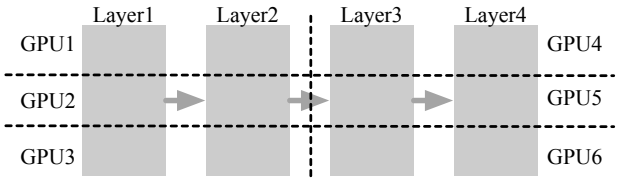

Figure 6: An example of intra- and inter- layer parallelism. A vertical dotted line indicates partitioning between layers and a horizontal line indicates partitioning within a layer.

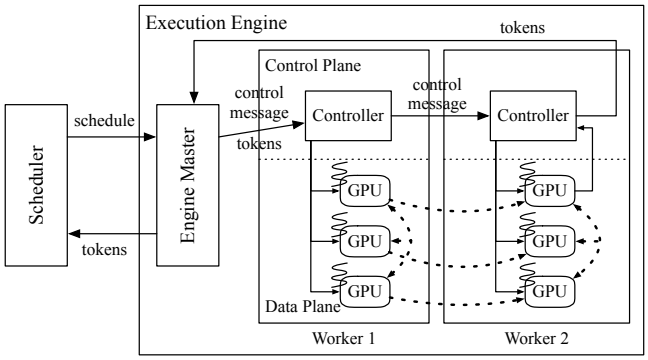

Figure 7: An illustration of the distributed architecture of ORCA's execution engine using the parallelization configuration shown in Figure 6. For example, the first inter-layer partition (Layer1 and Layer2) in Figure 6 is assigned to Worker1, while the second partition is assigned to Worker2.

system support for serving such large language models is getting more importance, especially when the model does not fit in a single GPU. In such a case, one should split the model parameters along with the corresponding computation and distribute them across multiple GPUs and machines.

ORCA composes known parallelization techniques for Transformer models: intra-layer parallelism and inter-layer parallelism. These two model parallelism strategies, which are also used by FasterTransformer [4], have been originally developed for distributed training. Intra-layer parallelism [55, 58] splits matrix multiplications (i.e., Linear and Attention operations) and their associated parameters over multiple GPUs. We omit the detail about how this strategy partitions each matrix multiplication. On the other hand, inter-layer parallelism splits Transformer layers over multiple GPUs. ORCA assigns the same number of Transformer layers to each GPU. Figure 6 illustrates an example application of intra- and inter- layer parallelism to a 4-layer GPT model. The 4 layers are split into 2 inter-layer partitions, and the layers in the partition are subdivided into 3 intra-layer partitions. We assign each partition to a GPU, using a total of 6 GPUs.

The ORCA execution engine supports distributed execution using the techniques described above. Figure 7 depicts the architecture of an ORCA engine. Each *worker process* is responsible for an inter-layer partition of the model and can be placed on a different machine from each other. In particular, each worker manages one or more CPU threads each dedicated for controlling a GPU, the number of which depends on the degree of intra-layer parallelism.

The execution procedure of the ORCA execution engine is as follows. Once the engine is scheduled to run an iteration of the model for a batch of requests, the *engine master* forwards the received information about the scheduled batch to the first *worker process* (Worker1). The information includes tokens for the current iteration and a control message, which is composed of ids of requests within the batch, current token index (for requests in the increment phase), and number of input tokens (for requests in the initiation phase). The *controller* of Worker1 hands over the information received from the engine master to the GPU-controlling threads, where each thread parses the information and issues proper GPU kernels to its associated GPU. For example, the kernel for the Attention operation uses the request id and the current token index to get the GPU memory address of previous keys and values kept by the Attention K/V manager. In the meantime, the controller also forwards the control message to the controller of the next worker (Worker2), without waiting for the completion of the kernels issued on the GPUs of Worker1. Unlike Worker1, the controller of the last worker (Worker2) waits for (i.e., synchronize with) the completion of the issued GPU kernels, in order to fetch the output token for each request and send the tokens back to the engine master.

To keep GPUs busy as much as possible, we design the ORCA engine to minimize synchronization between the CPU and GPUs. We observe that current systems for distributed inference (e.g., FasterTransformer [4] and Megatron-LM [3]) have CPU-GPU synchronization whenever each process receives control messages[5] because they exchange the messages through a GPU-to-GPU communication channel – NCCL [5]. The exchange of these control messages occurs at every iteration, imposing a non-negligible performance overhead. On the other hand, ORCA separates the communication channels for control messages (plus tokens) and tensor data transfer, avoiding the use of NCCL for data used by CPUs. Figure 7 shows that the ORCA engine uses NCCL exclusively for exchanging intermediate tensor data (represented by dashed arrows) as this data is produced and consumed by GPUs. Control messages, which is used by the CPU threads for issuing GPU kernels, sent between the engine master and worker controllers by a separate communication channel that does not involve GPU such as gRPC [2].

4.2 Scheduling Algorithm

The ORCA scheduler makes decisions on which requests should be selected and processed at every iteration. The scheduler has high flexibility in selecting a set of requests to com-

[5]This includes various metadata such as batch size, sequence length, and whether a request within the batch has finished processing.

pose a batch, because of the selective batching technique that allows the engine to run any set of requests in the batched manner. Now the main question left is how to select the requests at every iteration.

We design the ORCA scheduler to use a simple algorithm that does not change the processing order of client requests; early-arrived requests are processed earlier. That is, we ensure iteration-level first-come-first-served (FCFS) property. We define the iteration-level FCFS property for workloads with multi-iteration characteristics as follows: for any pair of requests (x_i, x_j) in the request pool, if x_i has arrived earlier than x_j, x_i should have run the same or more iterations than x_j. Note that some late-arrived requests may return earlier to clients if the late request requires a smaller number of iterations to finish.

Still, the scheduler needs to take into account additional factors: diminishing returns to increasing the batch size and GPU memory constraint. Increasing the batch size trades off increased throughput for increased latency, but as the batch size becomes larger, the amount of return (i.e., increase in throughput) diminishes. Therefore, just like other serving systems [7, 16], ORCA also has a notion of a max batch size: the largest possible number of requests within a batch. The ORCA system operator can tune this knob to maximize throughput while satisfying one's latency budget. We will discuss this in more details with experiment results in Section 6.2.

Another factor is the GPU memory constraint. Optimizing memory usage by reusing buffers for intermediate results across multiple operations is a well-known technique used by various systems [4, 6], and ORCA also adopts this technique. However, unlike the buffers for intermediate results that can be reused immediately, buffers used by the Attention K/V manager for storing the keys and values cannot be reclaimed until the ORCA scheduler notifies that the corresponding request has finished processing. A naïve implementation can make the scheduler fall into a deadlock when the scheduler cannot issue an iteration for any requests in the pool because there is no space left for storing a new Attention key and value for the next token. This requires the ORCA scheduler to be aware of the remaining size of pre-allocated memory regions for the manager.

The ORCA scheduler takes all these factors into account: it selects at most "max batch size" requests based on the arrival time, while reserving enough space for storing keys and values to a request when the request is scheduled for the first time. We describe the scheduling process in Algorithm 1. The algorithm selects a batch of requests from the request pool (line 4) and schedules the batch (line 5). The *Select* function (line 17) selects at most *max_bs* requests from the pool based on the arrival time of the request (lines 20-22). Algorithm 1 does not depict the procedure of request arrival and return; one may think of it as there exist concurrent threads inserting newly arrived requests into *request_pool* and removing finished requests from *request_pool*.

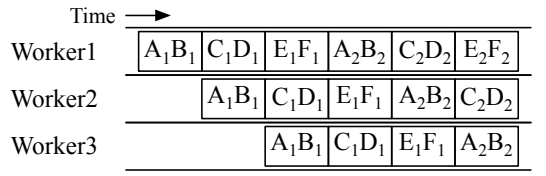
Algorithm 1: ORCA scheduling algorithm

```
   Params: n_workers: number of workers, max_bs:
           max batch size, n_slots: number of K/V slots
1  n_scheduled ← 0
2  n_rsrv ← 0
3  while true do
4      batch, n_rsrv ← Select(request_pool, n_rsrv)
5      schedule engine to run one iteration of
       the model for the batch
6      foreach req in batch do
7          req.state ← RUNNING
8      n_scheduled ← n_scheduled + 1
9      if n_scheduled = n_workers then
10         wait for return of a scheduled batch
11         foreach req in the returned batch do
12             req.state ← INCREMENT
13             if finished(req) then
14                 n_rsrv ← n_rsrv − req.max_tokens
15         n_scheduled ← n_scheduled − 1
16
17 def Select(pool, n_rsrv):
18     batch ← {}
19     pool ← {req ∈ pool | req.state ≠ RUNNING}
20     SortByArrivalTime(pool)
21     foreach req in pool do
22         if batch.size() = max_bs then break
23         if req.state = INITIATION then
24             new_n_rsrv ← n_rsrv + req.max_tokens
25             if new_n_rsrv > n_slots then break
26             n_rsrv ← new_n_rsrv
27         batch ← batch ⋃ {req}
28     return batch, n_rsrv
```

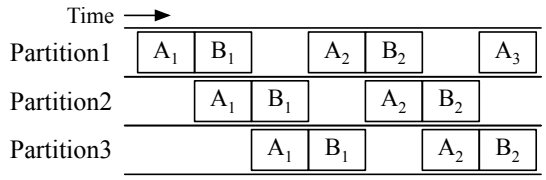
When the scheduler considers a request in the initiation phase, meaning that the request has never been scheduled yet, the scheduler uses the request's *max_tokens*[6] attribute to reserve *max_tokens* slots of GPU memory for storing the keys and values in advance (lines 23-26). The scheduler determines whether the reservation is possible (line 25) based on *n_rsrv*, the number of currently reserved slots, where a slot is defined by the amount of memory required for storing an Attention key and value for a single token. Here, *n_slots* is a parameter tuned by the ORCA system operator indicating the size of memory region (in terms of slots) allocated to the Attention K/V manager. Since the number of tokens in a request cannot exceed *max_tokens*, if the reservation is possible, it is guaranteed that the manager can allocate buffers for the newly generated keys and values until the request finishes.

Unlike the tuning of *max_bs* that requires quantifying the trade-off between latency and throughput, the ORCA system

[6] The *max_tokens* attribute is a per-request option, meaning the maximum number of tokens that a request can have after processing.



(a) ORCA execution pipeline.



(b) FasterTransformer execution pipeline.

Figure 8: Comparison of the use of pipeline parallelism in ORCA and FasterTransformer where X_i is the i-th iteration of request X.

operator can easily configure *n_slots* without any experiments. Given a model specification (e.g., hidden size, number of layers, etc.) and degrees of intra- and inter- layer parallelism, ORCA's GPU memory usage mostly depends on *n_slots*. That is, the operator can simply use the largest possible *n_slots* under the memory constraint.

Pipeline parallelism. ORCA's scheduler makes the execution of workers in the engine to be pipelined across multiple batches. The scheduler does not wait for the return of a scheduled batch until *n_scheduled*, the number of currently scheduled batches, reaches *n_workers* (line 9-10 of Algorithm 1). By doing so, the scheduler keeps the number of concurrently running batches in the engine to be *n_workers*, which means that every worker in the engine is processing one of the batches without being idle.

Figure 8a depicts the execution pipeline of 3 ORCA workers, using a max batch size of 2. We assume that the request A arrives before B, which arrives before C, and so on. At first, the scheduler selects requests A and B based on the arrival time and schedules the engine to process a batch of requests A and B (we call this batch AB), where Worker1, Worker2, and Worker3 process the batch in turn. The scheduler waits for the return of the batch AB only after the scheduler injects two more batches: CD and EF. Once the batch AB returns, requests A and B get selected and scheduled once again, because they are the earliest arrived requests among the requests in the pool.

In contrast, the interface between current serving systems and execution engines (e.g., a combination of Triton [7] and FasterTransformer [4]) does not allow injecting another batch before the finish of the current running batch, due to the request-level scheduling. That is, Triton cannot inject the next request C to FasterTransformer until the current batch AB finishes. To enable pipelined execution of multiple inter-layer partitions under such constraint, FasterTransformer splits a batch of requests into multiple *microbatches* [28] and pipelines the executions of partitions across the microbatches. In Figure 8b, FasterTransformer splits the batch AB into two microbatches, A and B. Since each partition processes a microbatch (which is smaller than the original batch) in the batched manner, the performance gain from batching can become smaller. Moreover, this method may insert *bubbles* into the pipeline when the microbatch size is too large, making the number of microbatches smaller than the number of partitions. While FasterTransformer needs to trade batching efficiency (larger microbatch size) for pipelining efficiency (fewer pipeline bubbles), ORCA is free of such a tradeoff – thanks to iteration-level scheduling – and can easily pipeline requests without dividing a batch into microbatches.

# Params	# Layers	Hidden size	# Inter-partitions	# Intra-partitions
13B	40	5120	1	1
101B	80	10240	1	8
175B	96	12288	2	8
341B	120	15360	4	8

Table 1: Configurations of models used in the experiments.

5 Implementation

We have implemented ORCA with 13K lines of C++, based on the CUDA ecosystem. We use gRPC [2] for the communication in the control plane of the ORCA engine, while NCCL [5] is used in the data plane, for both inter-layer and intra-layer communication. Since we design ORCA to focus on Transformer-based generative models, ORCA provides popular Transformer layers as a building block of models including the original encoder-decoder Transformer [60], GPT [47], and other variants discussed in Raffel et al. [49].

We have also implemented fused kernels for LayerNorm, Attention, and GeLU operators, just like other systems for training or inference of Transformer models [1, 4, 58]. For example, the procedure of computing dot products between Attention query and keys, Softmax on the dot products, and weighted average of Attention values are fused into a single CUDA kernel for the Attention operator. In addition, we go one step further and fuse the kernels of the split Attention operators by simply concatenating all thread blocks of the kernels for different requests. Although this fusion makes the thread blocks within a kernel have different characteristics and lifetimes (which is often discouraged by CUDA programming practice) because they process tensors of different shapes, we find this fusion to be beneficial by improving GPU utilization and reducing the kernel launch overhead [34, 39].

6 Evaluation

In this section, we present evaluation results to show the efficiency of ORCA.

Environment. We run our evaluation on Azure ND96asr A100 v4 VMs, each equipped with 8 NVIDIA 40-GB A100 GPUs connected over NVLink. We use at most four VMs depending on the size of the model being tested. Each VM has 8 Mellanox 200Gbps HDR Infiniband adapters, providing an 1.6Tb/s of interconnect bandwidth between VMs.

Models. Throughout the experiments, we use GPT [12] as a representative example of Transformer-based generative models. We use GPT models with various configurations, which is listed in Table 1. The configurations for 13B and 175B models come from the GPT-3 paper [12]. Based on these two models, we change the number of layers and hidden size to make configurations for 101B and 341B models. All models have a maximum sequence length of 2048, following the setting of the original literature [12]. We use fp16-formatted model parameters and intermediate activations for the experiments. We also apply inter- and intra- layer parallelism strategies described in Section 4.1, except for the 13B model that can fit in a GPU. For example, the 175B model is partitioned over a total of 16 GPUs by using 2 inter-layer partitions subdivided into 8 intra-layer partitions, where the 8 GPUs in the same VM belongs to the same inter-layer partition.

Baseline system. We compare with FasterTransformer [4], an inference engine that supports large scale Transformer models via distributed execution. While there exist other systems with the support for distributed execution such as Megatron-LM [3] and DeepSpeed [1], these systems are primarily designed and optimized for training workloads, which makes them show relatively lower performance compared to the inference-optimized systems.

Scenarios. We use two different scenarios to drive our evaluation. First, we design a microbenchmark to solely assess the performance of the ORCA engine without being affected by the iteration-level scheduling. In particular, we do not run the ORCA scheduler in this scenario. Instead, given a batch of requests, the testing script repeats injecting the same batch into the ORCA engine until all requests in the batch finishes, mimicking the behavior of the canonical request-level scheduling. We also assume that all requests in the batch have the same number of input tokens and generate the same number of output tokens. We report the time taken for processing the batch (not individual requests) and compare the result with FasterTransformer [4].

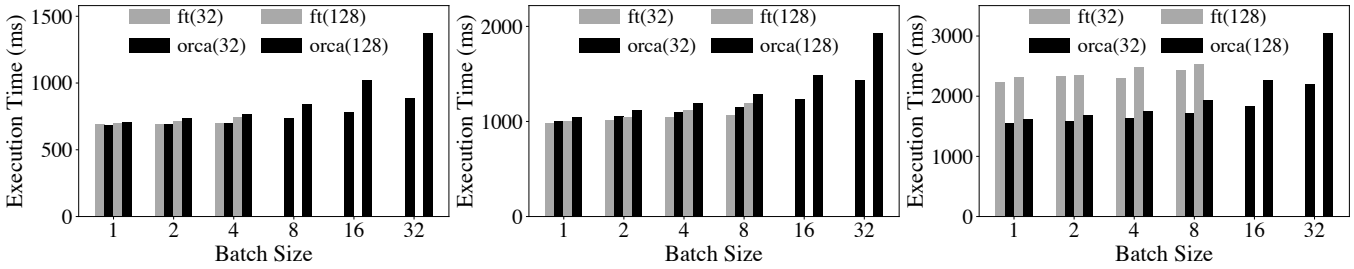
The second scenario tests the end-to-end performance of ORCA by emulating a workload. We synthesize a trace of client requests because there is no publicly-available request trace for generative language models. Each request in the synthesized trace is randomly generated by sampling the number of input tokens and a *max_gen_tokens* attribute, where the number of input tokens plus *max_gen_tokens* equals to the *max_tokens* attribute described in Section 4.2. We assume that all requests continue generation until the number of generated tokens reaches *max_gen_tokens*. In other words, we make the model never emit the "<EOS>" token. This is because we have neither the actual model checkpoint nor the actual input text so we do not have any information to guess the right timing of the "<EOS>" token generation. Once the requests are generated, we synthesize the trace by setting the request arrival time based on the Poisson process. To assess ORCA's behavior under varying load, we change the Poisson parameter (i.e., arrival rate) and adjust the request arrival time accordingly. We report latency and throughput using multiple traces generated from different distributions for better comparison and understanding of the behavior of ORCA and FasterTransformer.

6.1 Engine Microbenchmark

We first compare the performance of FasterTransformer and the ORCA engine using the first scenario. We set all requests in the batch to have the same number of input tokens (32 or 128) and generate 32 tokens. That is, in this set of experiments, all requests within the batch start and finish processing at the same time. We conduct experiments using three different models: 13B, 101B, and 175B. For each model, we use the corresponding parallelization strategy shown in Table 1.

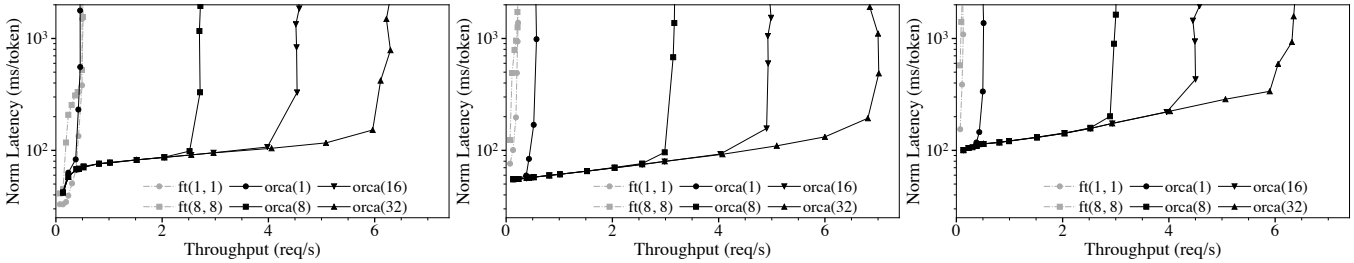
Figure 9 shows the performance of FasterTransformer and the ORCA engine for processing a batch composed of the same requests. In Figure 9a, the ORCA engine shows a similar (or slightly worse) performance compared to FasterTransformer across all configurations. This is because ORCA does not apply batching to the Attention operations, while FasterTransformer apply batching to all operations. Still, the performance difference is relatively small. Despite not batching the Attention operation, the absence of model parameters in Attention makes this decision has little impact on efficiency as there is no benefit of reusing model parameters across multiple requests.

Figure 9b presents similar results for the 101B model that uses all of the 8 GPUs in a single VM. From these results, we can say that the ORCA engine and FasterTransformer have comparable efficiencies in the implementations of CUDA kernels and the communication between intra-layer partitions. Note that FasterTransformer cannot use a batch size of 8 or larger with the 13B model (16 or larger with the 101B model) because of the fixed amount of memory pre-allocation for each request's Attention keys and values, which grows in proportion to the max sequence length of the model (2048 for this case). In contrast, ORCA avoids redundant memory



(a) 13B model, 1 GPU. (b) 101B model, 8 GPUs. (c) 175B model, 16 GPUs.

Figure 9: Execution time of a batch of requests using FasterTransformer and the ORCA engine without the scheduling component. Label "ft(*n*)" represents results from FasterTransformer processing requests with *n* input tokens. Configurations that incurs out of memory error are represented as missing entries (e.g., ft(32) for the 101B model with a batch size of 16).



(a) 101B model, 8 GPU. (b) 175B model, 16 GPUs. (c) 341B model, 32 GPUs.

Figure 10: Median end-to-end latency normalized by the number of generated tokens and throughput. Label "orca(*max_bs*)" represents results from ORCA with a max batch size of *max_bs*. Label "ft(*max_bs*, *mbs*)" represents results from FasterTransformer with a max batch size of *max_bs* and a microbatch size of *mbs*.

allocation by setting the size of buffers for the keys and values separately for each request based on the *max_tokens* attribute.

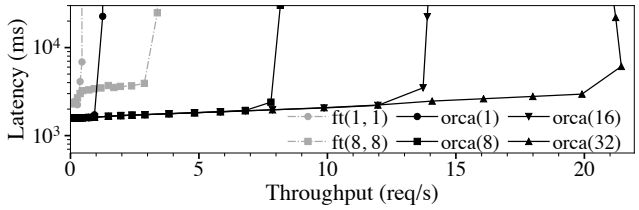
Next, we go one step further and experiment with the 175B model, which splits the layers into two inter-layer partitions. In this case, for better comparison, we disable pipelined execution of the inter-layer partitions for both systems. For FasterTransformer, we set the size of a microbatch to be equal to the batch size to disable pipelining. As shown in Figure 9c, the ORCA engine outperforms FasterTransformer by up to 47%. We attribute this performance improvement to the control-data plane separation described in Section 4.1. We omit the 341B model as it has similar results compared to the 175B model.

6.2 End-to-end Performance

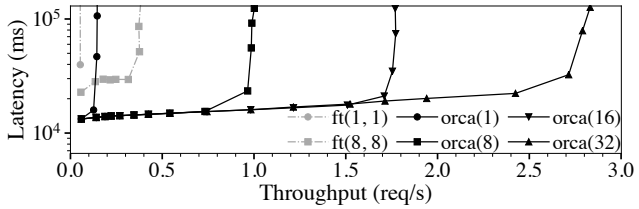
Now we assess the end-to-end performance of ORCA by measuring the latency and throughput with the synthesized request trace under varying load. When synthesizing the trace, we sample each request's number of input tokens from $U(32,512)$, a uniform distribution ranging from 32 to 512 (inclusive). The *max_gen_tokens* attributed is sampled from $U(1,128)$, which means that the least and the most time-consuming requests require 1 and 128 iterations of the model for processing, respectively.

Unlike the microbenchmark shown in Section 6.1, to measure the end-to-end performance, we test the entire ORCA software stack including the ORCA scheduler. Client requests arrive to the ORCA scheduler following the synthesized trace described above. We report results from various max batch size configurations. For FasterTransformer that does not have its own scheduler, we implement a custom scheduler that receives client requests, creates batches, and injects the batches to an instance of FasterTransformer. We make the custom scheduler create batches dynamically by taking at most max batch size requests from the request queue, which is the most common scheduling algorithm used by existing serving systems like Triton [7] and TensorFlow Serving [42]. Again, we report results from various max batch size configurations, along with varying microbatch sizes, an additional knob in FasterTransformer that governs the pipelining behavior (see Section 4.2).

Figure 10 shows median end-to-end latency and throughput. Since each request in the trace requires different processing time, which is (roughly) in proportion to the number of generated tokens, we report median latency normalized by the number of generated tokens of each request. From the figure, we can see that ORCA provides significantly higher throughput and lower latency than FasterTransformer. The only exception is the 101B model under low load (Figure 10a). In this



(a) (# in, # gen) = (32, 32)



(b) (# in, # gen) = (256, 256)

Figure 11: Median end-to-end latency and throughput, using the 175B model with traces composed of homogeneous requests. We do not normalize the latency since all requests have the same characteristic.

case, both ORCA and FasterTransformer do not have enough number of requests to process in a batch. That is, the latency will mostly depend on the engine's performance, which is shown in Figure 9b. As the load becomes heavier, ORCA provides higher throughput with a relatively small increase in latency, because the ORCA scheduler makes late-arrived requests hitch a ride with the current ongoing batch. In contrast, FasterTransformer fails to efficiently handle multiple requests that (1) arrive at different times; (2) require different number of iterations to finish; or (3) start with different number of input tokens, resulting in a peak throughput of 0.49 req/s and much higher latency. If we use the 175B or 341B model (Figures 10b and 10c) that employs more than one inter-layer partitions, ORCA outperforms FasterTransformer under every level of load in terms of both latency and throughput, resulting in an order of magnitude higher throughput when we compare results at a similar level of latency. For example, to match a median normalized latency of 190ms for the 175B model, which is a double of the normalized execution time (by the number of generated tokens) of "orca(128)" shown in Figure 9c, FasterTransformer provides a throughput of 0.185 req/s whereas ORCA provides a throughput of 6.81 req/s, which is a 36.9× speedup.

Varying batch size configurations. Figure 10 shows that the increase of the max batch size of ORCA results in a higher throughput without affecting the latency. This is because the iteration-level scheduling of ORCA resolves the problem of early-finished and late-joining requests. Nevertheless, there is no guarantee that increasing the batch size will not negatively affect the latency, for arbitrary hardware settings, models, and workloads. As mentioned in Section 4.2, the max batch size must be set carefully by considering both the required latency and throughput requirements.

Interestingly, larger max batch size in FasterTransformer does not necessarily help improving throughput. By testing all possible combinations of max batch size (*max_bs*) and microbatch size (*mbs*) on all models under varying load, we find that (*max_bs*, *mbs*) = (1, 1) or (8, 8) are the best options. Per our discussion in Section 4.1, FasterTransformer's microbatch-based pipelining can be less efficient because the engine is going to process at most *mbs* number of requests in the batched manner, which explains why the configurations with the maximum possible *mbs* (which is the same as *max_bs*) have better performance than others. In addition, while increasing *max_bs* can improve performance due to the increased batch size, at the same time, this also increases the likelihood of batching requests with large difference in the number of input tokens or the number of generated tokens. In such cases, FasterTransformer cannot efficiently handle the batch because (1) for the first iteration of the batch, FasterTransformer processes requests as if they all had the same input length as the shortest one; and (2) early-finished requests cannot immediately return to the clients.

Trace of homogeneous requests. We test the behavior of ORCA and FasterTransformer when using a trace of homogeneous requests, i.e., all requests in a trace have the same number of input tokens and the same *max_gen_tokens* attribute. Since all requests require the same number of iterations to finish processing, the problem of early-leaving requests does not occur for this trace. As a result, now the increase of the *max_bs* has a noticeable positive impact on the performance of FasterTransformer, as shown in Figure 11. Still, ORCA outperforms FasterTransformer (*max_bs*=8) except for the case using a max batch size of 1, where ORCA degenerates into a simple pipeline of the ORCA workers that does not perform batching.

7 Related Work and Discussion

Fine-grained batching for recurrent models. We would like to highlight BatchMaker [23] as one of the most relevant previous works. BatchMaker is a serving system for RNNs that performs scheduling and batching at the granularity of RNN cells, motivated by the unique RNN characteristic of repeating the same computation. Once a request arrives, BatchMaker breaks the dataflow graph for processing the request into RNN cells, schedules execution at the granularity of cells (instead of the entire graph), and batches the execution of identical cells (if any). Since each RNN cell always performs the exact same computation, BatchMaker can execute multiple RNN cells in a batched manner regardless of the position (i.e., token index) of the cell. By doing so, BatchMaker allows a newly arrived request for RNN to join (or a finished request

to leave) the current executing batch without waiting for the batch to completely finish.

However, BatchMaker cannot make batches of cells for Transformer models because there are too many distinct cells (a subgraph that encapsulates the computation for processing a token; Figure 1c) in the graph. Each cell at a different token index t must use a different set of Attention Keys/Values. As the cell for each t is different, the graph comprises L different cells (L denotes the number of input and generated tokens), significantly lowering the likelihood of cells of the same computation being present at a given moment (e.g., in Figure 10, L ranges from $33 = 32 + 1$ to $640 = 512 + 128$). Thus execution of the cells will be mostly serialized, making BatchMaker fall back to non-batched execution. BatchMaker also lacks support for large models that require model and pipeline parallelism.

While BatchMaker is geared towards detecting and aligning batch-able RNN cells, our key principle in designing ORCA is to perform as much computation as possible per each round of model parameter read. This is based on the insight that reading parameters from GPU global memory is a major bottleneck in terms of end-to-end execution time, for large-scale models. Adhering to this principle, we apply iteration-level scheduling and selective batching to process all "ready" tokens in a single round of parameter read, regardless of whether the processing of tokens can be batched (non-Attention ops) or not (Attention ops).

Specialized execution engines for Transformer models. The outstanding performance of Transformer-based models encourages the development of inference systems specialized for them. FasterTransformer [4], LightSeq [61], TurboTransformers [22] and EET [36] are such examples. Each of these systems behave as an backend execution engine of existing serving systems like Triton Inference Server [7] and TensorFlow Serving [42]. That is, these systems delegate the role of scheduling to the serving system layer, adhering to the canonical request-level scheduling. Instead, ORCA suggests to schedule executions at a finer granularity, which is not possible in current systems without changing the mechanism for coordination between the scheduler and the execution engine. Note that among these systems, FasterTransformer is the only one with the support for distributed execution. While systems like Megatron-LM [3] and DeepSpeed [1] can also be used for distributed execution, these systems are primarily optimized for large-scale training rather than inference serving.

Interface between serving systems and execution engines. Current general-purpose serving systems such as Triton Inference Server [7] and Clipper [16] serve as an abstraction for handling client requests and scheduling executions of the underlying execution engines. This approach is found to be beneficial by separating the design and implementation of the serving layer and the execution layer. However, we find that the prevalent interface between the two layers is too restricted for handling models like GPT [12], which has the multi-iteration characteristic. Instead, we design ORCA to tightly integrate the scheduler and the engine, simplifying the application of the two proposed techniques: iteration-level scheduling and selective batching. While in this paper we do not study a general interface design that supports the two techniques without losing the separation of abstractions, it can be an interesting topic to explore such possibility; we leave this issue to future work.

8 Conclusion

We present iteration-level scheduling with selective batching, a novel approach that achieves low latency and high throughput for serving Transformer-based generative models. Iteration-level scheduling makes the scheduler interact with the execution engine at the granularity of iteration instead of request, while selective batching enables batching arbitrary requests processing tokens at different positions, which is crucial for applying batching with iteration-level scheduling. Based on these techniques, we have designed and implemented a distributed serving system named ORCA. Experiments show the effectiveness of our approach: ORCA provides an order of magnitude higher throughput than current state-of-the-art systems at the same level of latency.

Abstract

Many intelligent applications like autonomous driving and virtual reality require running both latency-critical and best-effort DNN inference tasks to achieve both real time and work conserving on GPU. However, commodity GPUs lack efficient preemptive scheduling support and state-of-the-art approaches either have to monopolize GPU or let the real-time tasks to wait for best-effort tasks to complete, which causes low utilization or high latency, or both.

This paper presents REEF, the first GPU-accelerated DNN inference serving system that enables microsecond-scale kernel preemption and controlled concurrent execution in GPU scheduling. REEF is novel in two ways. First, based on the observation that DNN inference kernels as mostly idempotent, REEF devises a reset-based preemption scheme that launches a real-time kernel on the GPU by proactively killing and restoring best-effort kernels at microsecond-scale. Second, since DNN inference kernels have varied parallelism and predictable latency, REEF proposes a dynamic kernel padding mechanism that dynamically pads the real-time kernel with appropriate best-effort kernels to fully utilize the GPU with negligible overhead. Evaluation using a new DNN inference serving benchmark (DISB) with diverse workloads and a real-world trace on an AMD GPU shows that REEF only incurs less than 2% overhead in the end-to-end latency for real-time tasks but increases the overall throughput by up to 7.7×, compared to dedicating the GPU to real-time tasks. To demonstrate the feasibility of our approaches on closed-source GPUs, we further ported and evaluated a restricted version of REEF on an NVIDIA GPU with a reduction of the preemption latency by up to 12.3× (from 6.3×).

1 Introduction

Deep Neural Network (DNN) inference has been widely adopted by modern intelligent applications, such as autonomous driving [2, 37, 41, 80], virtual reality [58, 83], speech/image recognition [32, 75], and healthcare [19, 24], just to name a few. Many of them demand real-time inference serving in mission-critical tasks, where GPUs have emerged as a popular accelerator to serve DNN inferences [15, 33, 47, 89].

Although the low-latency demand of DNN inferences can be fulfilled by dedicating the whole GPU to sequentially serve requests from a single DNN application [10, 80, 91], it is hard to fully exploit the massive parallelism of the GPU [47]. Hence, it is a common practice to share a GPU among multiple applications with different timing constraints in emerging intelligent systems [41, 78], which can greatly improve overall throughput, as shown in Fig. 1(a). For example, autonomous vehicles use DNNs to recognize obstacles and traffic lights [9, 59], which are latency-critical tasks (called *real-time* tasks in this paper). Meanwhile, other tasks with no hard real-time requirement [78] (called *best-effort* tasks in this paper), such as monitoring human driver's emotion and fatigue, are also served within the GPU using DNNs [19, 48, 84].

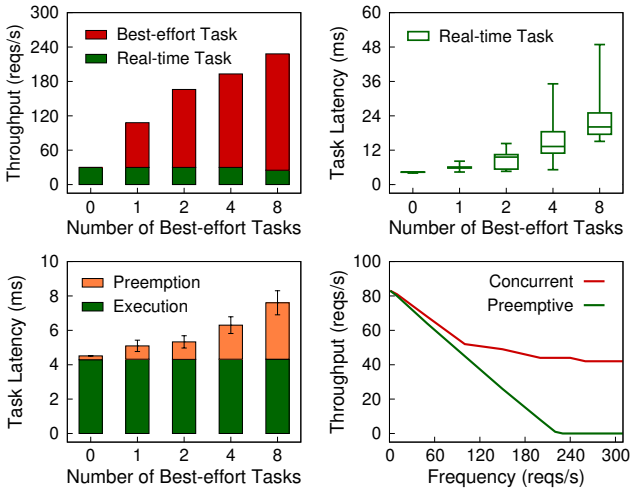

Fig. 1: *(a) The overall throughput of DNN inferences (both real-time and best-effort tasks) and (b) the end-to-end latency of real-time tasks when using concurrent GPU scheduling (i.e., multiple GPU streams [46, 49, 60]), (c) the end-to-end latency of real-time tasks when using preemptive GPU scheduling (i.e., wait-based preemption [12, 77, 90]), and (d) the throughput of best-effort tasks as the frequency of real-time tasks increases.* **Workload**: *VGG [68] (real-time) and ResNet [30] (best-effort).* **Testbed**: *one AMD Radeon Instinct MI50 GPU with 16 GB of memory (see §7 for details).*

Typically, DNN inferences have two potentially conflicting goals for GPU scheduling. First, the real-time tasks should be treated as first-class citizens on the GPU without interference from other tasks to achieve *low end-to-end latency*. Second, both real-time tasks and best-effort tasks should be served concurrently on the GPU to achieve high overall throughput (*work-conserving*).

State-of-the-art GPU libraries (e.g., CUDA [52] and ROCm [3]) commonly provide multiple GPU streams (e.g., CUDA Streams [60]) to concurrently execute multiple tasks on the same GPU. However, as shown in Fig. 1(b), although the end-to-end inference latency of real-time tasks is low (about 4 ms) and stable when monopolizing the GPU, the tail latency of real-time tasks significantly increases by over an order of magnitude (close to 50 ms) when running concurrently with best-effort tasks. This, unfortunately, is unacceptable for real-time scenarios [85].

Similar to operating systems using preemptive scheduling to provide real-time guarantees, an intuitive approach is to provide preemption for GPU scheduling, which is unfortunately missing in commodity GPUs [70]. Prior work [12, 77, 90] proposed a wait-based approach to passively waiting until the completion of running blocks, which may cause a preemption delay of several milliseconds. Although it may be sufficient for traditional GPU workloads, this approach is still far from optimal for DNN inference tasks since the preemption latency is non-trivial compared to the execution time of real-time inference tasks, as shown in Fig. 1(c). Further, when the real-time inference requests arrive at a high frequency (e.g., camera (120 reqs/s) [16] or multiple sensors [41]), the best-effort tasks may even get starved, as shown in Fig. 1(d).

This paper presents REEF, the first DNN inference serving system for commodity GPUs with microsecond-scale kernel preemption and controlled concurrent execution in GPU scheduling to achieve both *real time* and *work conserving*. Specifically, the arriving real-time task should instantly preempt the GPU from the running best-effort kernels without waiting for their completion. Meanwhile, the best-effort kernels should be executed concurrently by using GPU resources leftover from the real-time kernels.

A key insight of REEF is that each kernel in DNN inference is mostly *idempotent*. This implies that the running best-effort kernels can be proactively killed and restored without saving contexts. Based on this, REEF proposes a *reset-based preemption* scheme. To thoroughly flush hundreds of outstanding kernels in both GPU runtime and devices, REEF designs different approaches to resetting different software queues and retrofits the GPU driver to exactly use existing hardware mechanisms to reset compute units while preserving device memory of the GPU. It can improve both kernel preemption and restore. Therefore, REEF can launch a real-time task on the GPU in tens of microseconds, regardless of the number of preempted kernels and their execution time.

REEF further proposes a *dynamic kernel padding* mechanism based on the observation that the execution time of GPU kernels in DNN inferences is deterministic and *predictable*. This implies that the pending best-effort kernels can be carefully selected to pad the real-time kernel without performance interference, based on offline profiling in advance. REEF extended GPU compiler to construct a template of padded kernels by using function pointers. Further, to eliminate the overhead of indirect function calls on the GPU, REEF introduces proxy kernels to address register allocation problem and avoid unnecessary context saving at runtime. Therefore, REEF can concurrently execute the real-time task with best-effort tasks at the expense of negligible performance and memory overhead (less than 1% and about 10 KB).

We have implemented **REEF** by extending Apache TVM [73] (a compiler for deep learning) and AMD ROCm [3] (an open-source GPU computing platform). We evaluate REEF using a new DNN Inference Serving Benchmark (DISB) with diverse workloads and models, as well as a real-world trace from Apollo [7] (an open autonomous driving platform). Our experimental results show that REEF only incurs less than 2% of the end-to-end latency overhead for real-time tasks but increases overall throughput by up to 4.3×, compared to dedicating the GPU to real-time tasks. Our approach further reduces the preemption latency by over one order of magnitude against the state-of-the-art, less than 40 microseconds for all models. To demonstrate the feasibility of our approaches on closed-source GPUs, we further ported and evaluated a restricted version of REEF on an NVIDIA GPU with a reduction of the preemption latency by up to 12.3× (from 6.3×).

Contributions. We summarize our contributions as follows.

- An in-depth understanding on the characteristics of GPU-accelerated DNN inferences such as idempotence and the issues of state-of-the-art GPU scheduling schemes (§2).
- A new reset-based preemption scheme that can launch a real-time kernel on the GPU in a few microseconds, regardless of the number of preempted kernels (§4).
- An elegant mechanism that can dynamically pad the real-time kernel with best-effort kernels to fully exploit the massive parallelism of the GPU (§5).
- An implementation (§6) on both AMD and NVIDIA GPUs and an evaluation that demonstrates the advantage and efficacy of REEF over state-of-the-art (§7).

The source code of REEF is publicly available at https://github.com/SJTU-IPADS/reef. The DNN Inference Serving Benchmark (DISB) framework can be obtained separately from https://github.com/SJTU-IPADS/disb.

2 Background and Motivation

2.1 Characterizing GPU-Accelerated DNN Inference

Deep neural network (DNN) comprises multiple instances of versatile layers, such as convolutional, pooling and fully-connected layers. GPUs have been widely exploited to accelerate DNN inference serving [20, 28, 64]. To serve inference requests on GPUs, the pre-trained DNN model (e.g., ResNet [30]) is loaded into GPU memory ahead of time. Fig. 2 outlines the implementation of GPU-accelerated DNN inference. For each arriving request, all kernels of the DNN

```
# device codes
__global__ void conv_relu(in, weight, out):
1   sum = 0;
2   for i in range(0,3)
3      for j in range(0,3)
4         sum += in[..] × weight[..]
5   out[..] = ReLU(sum)
__global__ void dense(in, weight, bias, out):
6   sum = 0;
7   for i in range(0,512)
8      sum += in[..] × weight[..]
9   out[..] = sum + bias[..]

# host codes
void inference(...):
10  memcpyH2D(in, in_host, in_sz)  # copy in to GPU
11  conv_relu <<<dim(32), ..>>> (in, .., buf_conv)
12  ...  # launch other kernels
13  pooling <<<dim(64), ..>>> (.., buf_pool)
14  dense <<<dim(10), ..>>> (buf_pool, .., buf_dense)
15  softmax <<<dim(1), ..>>> (buf_dense, .., out)
16  memcpyD2H(out_host, out, out_sz)  # copy out to CPU
```

Fig. 2: *An example of DNN inference using a model like ResNet.*

model are executed in turn with the input, and the resulting output is returned to the DNN application.

DNN inference is now used by both *real-time* (RT) tasks, such as obstacle and traffic lights recognition [9, 59], and *best-effort* (BE) tasks, such as emotion and fatigue monitoring [19, 48, 84]. The real-time tasks are latency-critical, because violating the end-to-end latency requirement may cause system failures or even safety problems. In addition, such requests are usually issued periodically at various frequencies by input sensors (e.g., camera and LiDAR [7, 41]). On the contrary, the best-effort tasks have no hard timing requirement, but are repetitively executed in the background.

Idempotence. The GPU-accelerated DNN model for inference tasks consists of a sequence of kernels, which implement one or several DNN layers. We observe that GPU kernels in DNN models are mostly *idempotent* as they consist of almost only dense linear algebra computations without side effects.[1] Hence, the kernel can always produce the same output with the same input no matter it has been retried or not. Meanwhile, in the DNN model, the (k)-th kernel always uses the outputs of the (k-1)-th kernel and static arguments (e.g., weight) as inputs, e.g., `conv_relu` and `dense` kernel in Fig. 2. Therefore, the execution of DNN inference task can be restored from any kernel before the interrupted kernel and will not change the inference results.

Massive kernels. Unlike traditional GPU applications that only contain a few kernels (e.g., at most 14 kernels in Rodinia [11]), it is common to see hundreds of kernels in modern DNN models (see Table 1). In response, large amounts of kernels—usually hundreds or more—would be submitted in advance to hide the lengthy kernel launching time. Further, to fully exploit the GPU, the serving system may concurrently execute multiple kernels from different inference tasks using the same or different DNN models. Therefore, the performance penalty of preempting the GPU would be significant (a few milliseconds) and even comparable to the execution time of hundreds of kernels.

[1] We validated using our tool that all 320 GPU kernels of the 11 DNN models from Apache TVM's test suite [72] are idempotent.

Table 1: *The amount of GPU kernels in DNN models evaluated in §7 and the execution time (in millisecond). The codes are generated by TVM [15] and run on AMD Radeon Instinct MI50 GPU.*

Model	ResNet	DenseNet	VGG	Inception	Bert
#Kernels	307	207	55	146	205
Exec. Time	13.6	3.5	4.4	8.3	5.4

Latency predictability. We observe that the execution time of GPU kernels in DNN inferences is deterministic and predictable when running individually on the GPU (no interference). The reasons are two-fold. First, the kernel is mostly linear algebra computations such as matrix multiplication and convolution, which contains neither conditional branches nor inconstant loops. Second, all kernel arguments (e.g., input and weights) and the output are fixed-size arrays. Therefore, the execution time of such kernels is independent of the input of inference request and can be measured and accurately predicted in advance. In practice, we observe that the variance in kernel execution time of DNN models is typically only a few microseconds (see Fig. 3(a)). This is also confirmed in recent literature [6, 28, 47].

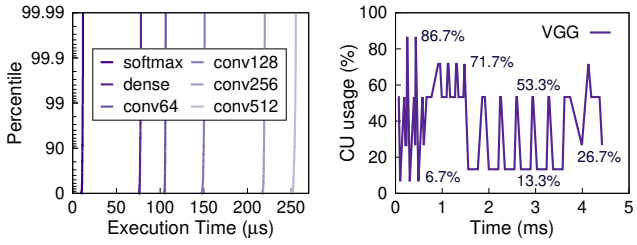

Fig. 3: *(a) The CDF of execution time of several typical kernels in VGG, and (b) the timeline of CU usage during VGG execution on a GPU with 60 CUs. Note that the execution time of GPU kernels in VGG covers a fairly wide range from 10 µs to 255 µs (see Fig. 10).*

Varied parallelism. The GPU kernels in DNN inferences usually exhibit completely different parallelism due to varied input scales. For example, as shown in Fig. 2, the `pooling` kernel uses 64 thread blocks, while the `softmax` kernel just uses 1 thread block. Consequently, the computational demand for DNN inferences, namely the number of compute units (CUs), is ever-changing during the execution. As an example, Fig. 3(b) shows the CU usage during VGG execution varies between 6.7% and 86.7%. Therefore, to efficiently exploit the GPU, it is indispensable to leverage a dynamic mechanism to select and execute multiple kernels from different DNN inference tasks at runtime.

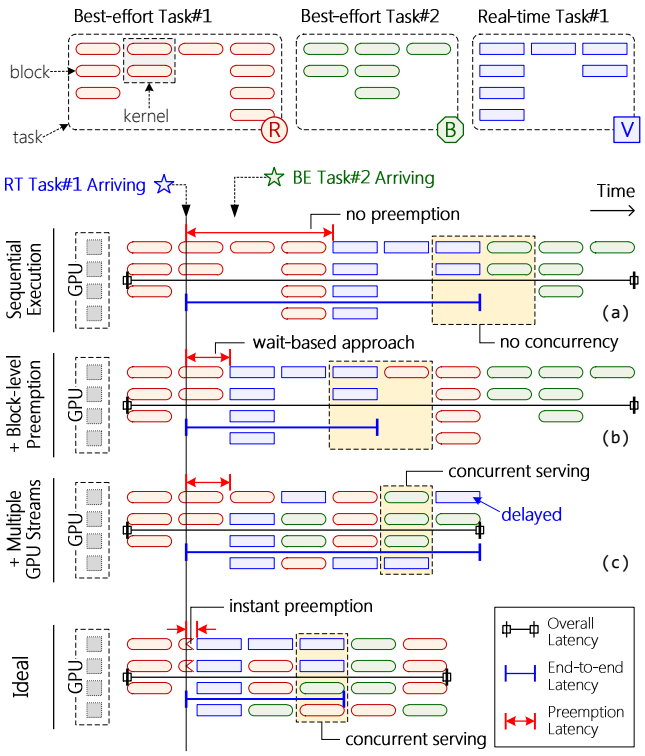

Fig. 4: *An example of GPU task scheduling with different kernel preemption and parallelism schemes for a hybrid workload, which contains two best-effort and one real-time DNN inference tasks. The GPU has four compute units (CUs).*

2.2 State-of-the-art GPU Scheduling

As stated before, DNN inference serving system relies on GPU scheduling to meet two potentially conflicting performance goals: low latency and work conserving. Although GPU scheduling has been widely studied in the HPC community [1, 8, 12, 13, 27, 43, 77, 82, 88], the unique characteristics of DNN inferences and the two performance goals introduce new challenges for GPU scheduling. We review the state-of-the-art schemes of GPU scheduling and discuss the performance issues when serving various DNN inferences through a brief example, as shown in Fig. 4.

Sequential execution. Most existing DNN serving systems, such as Clockwork [28], use sequential execution to avoid interferences among tasks. Thus, each task can achieve optimal execution latency, as shown in Fig. 4(a). However, the end-to-end latency of RT tasks might be significantly extended due to lengthy preemption latency (red dimension line), since it has to wait for the completion of previous tasks (*no preemption*). Further, this scheme has a poor overall throughput, due to sequentially serving inference tasks (i.e., *no concurrency*).

Block-level preemption. To reduce end-to-end latency for real-time tasks, it is necessary to preempt the GPU from running best-effort tasks. However, it is difficult to implement preemptive scheduling on the GPU due to the large context (e.g., a large amount of registers) [56, 70]. Meanwhile, commodity GPUs also lack hardware support for the preemption mechanism.[2] As a compromise, prior work [8, 90] proposes wait-based approaches to implementing block-level preemption for GPU scheduling. The real-time task still needs to passively wait until the completion of running blocks, as shown in Fig. 4(b). Further, the preemption latency will increase with the number of preempted kernels (see Fig. 1(c)). As a compromise, prior work [8, 90] has to limit the number of kernels submitted to the GPU, which is impractical for DNN inferences. Further, a high-frequency real-time task will break the execution of best-effort tasks, even leading to starvation (see Fig. 1(d)).

Multiple GPU streams. To improve overall throughput, modern GPU libraries (e.g., CUDA [52] and ROCm [3]) commonly provide multiple GPU streams (e.g., CUDA Streams [60]) to concurrently execute kernels from independent tasks. The runtime scheduler dispatches kernels from GPU streams on demand to keep all compute units (CUs) busy, as shown in Fig. 4(c). Although leveraging multiple GPU streams can improve throughput (see Fig. 1(a)), the latency of real-time tasks can be significantly degraded by concurrent tasks, e.g., the last kernel of RT Task#1 in Fig. 4(c). Even worse, the latency overhead will increase with the number of concurrent tasks (see Fig. 1(b)).

3 REEF Overview

3.1 System Architecture

The goal of REEF is to provide preemptive GPU scheduling to achieve real time for latency-critical tasks and work conserving for best-effort tasks (see ideal scheduling for the example in Fig. 4). Based on the insight that DNN inference kernels are mostly idempotent and there are a massive number of kernels with varied parallelism and predictable latency, REEF provides two novel designs called reset-based preemption and dynamic kernel padding.

Fig. 5 illustrates an overview of REEF's architecture. REEF consists of (a) an offline part, which compiles and loads user-provided DNN models, and (b) an online part, which schedules and serves DNN inference requests.

DNN model preparation (offline). Typically, DNN models are first compiled and optimized for accelerator back-ends (e.g., GPU) and then loaded into the model pool. Inspired by prior work [12, 36, 77], REEF extends the model compiler (e.g., TVM [15]) with a *code transformer* module, which first validates the idempotence of kernels in DNN models and then transforms the source code to assist GPU scheduling in REEF. Moreover, REEF develops a *kernel profiler* to measure the computational requirements and the execution time for each kernel of the model, which is accurate and practical for DNN models (see §2).

[2] Although NVIDIA claims that their GPUs have been equipped with preemption support since Pascal architecture [51], there is no public available information or a software controllable interface [12, 39, 77].

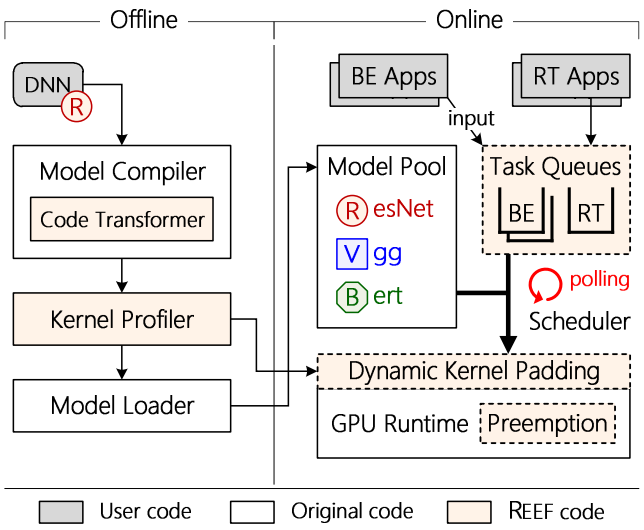

Fig. 5: *Architecture of* REEF. *Modules in boxes with dashed border are on the critical path of serving DNN inference requests. Other modules do not directly impact serving latency and throughput.*

DNN inference serving (online). REEF extends a state-of-the-art GPU runtime (e.g., ROCm [3]) with four major components for DNN inference serving.

Task Queues. REEF maintains one real-time task queue and several best-effort task queues. Each queue is bound to a GPU stream for launching GPU kernels, where inference requests are served in a FIFO order. For simplicity, REEF executes real-time requests one at a time. Note that any scheduling policy that treats the whole GPU as a single device, such as EDF [10], can be adopted by REEF for real-time requests. Further, REEF offers an RPC-based interface for DNN-based applications to deliver inference requests to task queues.

Scheduler. The scheduler in REEF uses busy polling on task queues and assigns tasks to the associated GPU streams. Corresponding to whether there are real-time tasks, REEF provides two execution modes, namely *real-time* mode and *normal* mode. The scheduler will switch from normal mode to real-time mode when encountering real-time tasks, and switch back to normal mode when the real-time task queue is empty.

Preemption module. In normal mode, REEF concurrently serves best-effort tasks from different task queues using multiple GPU streams [3, 60] provided by GPU runtime. In real-time mode, REEF first uses the preemption module to instantly preempt the GPU from all running best-effort tasks (§4) and then launches the real-time task on the GPU immediately.

Dynamic kernel padding (DKP). In real-time mode, before launching a real-time kernel, the DKP module will select appropriate best-effort kernels and dynamically pad them to the real-time kernel (§5). REEF will execute the padded kernel on the GPU to achieve high throughput. Note that the best-effort kernels will only use GPU resources leftover from the real-time kernel.

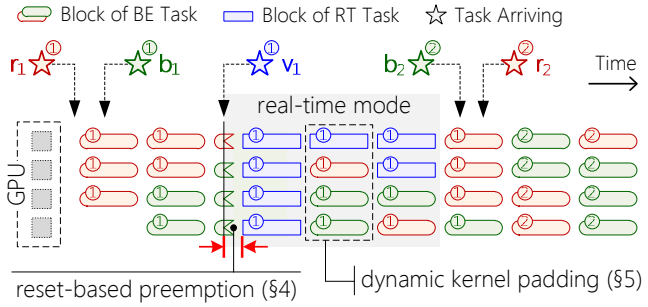

Fig. 6: *An example of timeline in* REEF. *The DNN inference tasks here are the same as that in Fig. 4.*

3.2 An Illustrative Example

Fig. 6 illustrates the timeline of scheduling five DNN inference tasks in REEF. Upon receiving the first two best-effort requests r_1 and b_1, REEF runs in normal mode, and the kernels of two different tasks are scheduled to two different GPU streams. The GPU runtime will concurrently execute the kernels on the GPU. While r_1 and b_1 execute, a real-time request v_1 arrives. The scheduler immediately switches to real-time mode, and GPU runtime instantly preempts the GPU by killing all running kernels of best-effort tasks (i.e., r_1 and b_1). Meanwhile, the DKP module selects appropriate kernels from restored tasks to dynamically pad the kernels of real-time task v_1. After that, the padded kernel will be executed on the GPU alone. While v_1 is completed, the scheduler switches back to normal mode. All running and later best-effort tasks (i.e., r_1, b_1, b_2, and r_2) will concurrently execute on the GPU through two GPU streams.

4 Reset-based Preemption

The key insight behind our idea, namely reset-based preemption, is that the GPU kernels in DNN models are mostly *idempotent*, which enables *proactive* preemption—killing all running kernels on the GPU immediately and restoring them later. The benefits are two-fold. First, it avoids saving and restoring the large context of the GPU (e.g., a 256 KB register file per CU) [70]. Second, there is no need to wait for all running kernels to complete, which can take hundreds of microseconds.

However, there are still new challenges before making our reset-based preemption come true on commodity GPUs. Except for the kernels running on the GPU, hundreds of launched kernels are buffered in multiple queues maintained by GPU runtime. This is necessary to hide the kernel launch time and fully exploit the massive parallelism of GPU. Whereas, evicting all launched kernels makes it indeed difficult to preempt the GPU in tens of microseconds.

Fig. 7 illustrates the lifetime of launched kernels in the GPU runtime and devices. First, the scheduler launches all kernels of an inference task and specifies a GPU stream for each task. The GPU runtime maintains a linked list, called

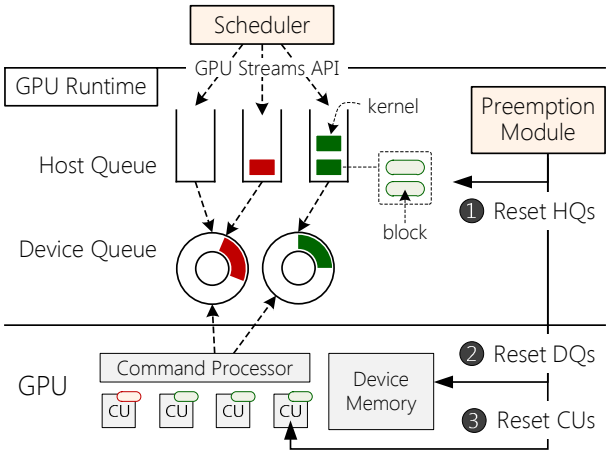

Fig. 7: *Extended GPU runtime in* REEF *for instant preemption.*

host queue, for each GPU stream to buffer launched kernels. Each host queue has a background thread that transmits the buffered kernels asynchronously to a ring buffer, called *device queue*, which is accessed by CPU and GPU simultaneously. The command processor of GPU will poll all device queues to fetch the buffered kernels and eventually dispatches them to *compute units*. Therefore, launched kernels of an inference task may exist in three places, namely host queues (HQs), device queues (DQs), and compute units (CUs). To achieve instant preemption, kernels in all three places must be evicted.

4.1 Evicting Buffered Kernels

The reset-based approach requires proactively evicting all buffered kernels from both host queues and device queues. For host queues, it is straightforward to reset them (❶ in Fig. 7), dequeuing all buffered kernels and reclaiming memory, as they are fully controlled by the GPU runtime. For device queues, however, the GPU runtime cannot evict buffered kernels from device queues, because the command processor of GPU can directly fetch kernels from device queues [23], resulting in data races and unpredictable results. In addition, the CPU also does not provide a way to safely evict kernels from device queues. A potential solution is to notify the GPU to re-register a new device queue [62]. However, it would incur an unacceptable latency overhead (e.g., about 1 ms on our testbed).

Inspired by evictable kernels [12], we propose *lazy eviction* to reset device queues without extending GPU runtime and hardware. The code transformer of REEF injects a piece of code at the beginning of each kernel in advance, which checks the *preemption flag* to realize whether it has been evicted. When the preemption flag is true, the kernel will voluntarily terminate itself. Therefore, when a preemption occurs, the preemption module will immediately set the preemption flag to true in GPU memory (see ❷ in Fig. 7). The kernels buffered in device queues will be fetched and dispatched to the CUs as usual, but will terminate themselves immediately.

Our initial queue eviction mechanism imposes a non-trivial overhead on the preemption process, taking more than 500 µs to preempt a single task (see §7.3). An in-depth analysis shows that the overhead comes mainly from (a) reclaiming memory from the host queue and (b) waiting to fetch kernels from the device queue. Therefore, we propose two optimizations to mitigate overheads.

Asynchronous memory reclamation. The preemption latency is proportional to the host queue length when using synchronous memory reclamation for evicted kernels in the host queues. Therefore, the performance penalty of preempting a DNN inference task would be significant, since it requires buffering hundreds of kernels in the host queue. To instantly evict GPU kernels from the host queue, REEF leverages a background GC thread to reclaim memory asynchronously. Specifically, REEF resets the host queue by simply nullifying the head pointer first and then notifying the GC thread to reclaim memory in the background.

Device queue capacity restriction. Although using lazy eviction can terminate kernels in the device queue immediately at the beginning of execution, the kernels still have to be fetched and dispatched to the CU, which takes around 20 µs per kernel. It is common to buffer hundreds of kernels in a device queue, since it can reduce the frequency of context switches by filling up the device queue with a large number of kernels from host queues at a time. However, it may also increase the preemption delay to even more than 1 ms. Therefore, REEF restricts the capacity of the device queue to achieve microsecond-scale kernel preemption. Tuning the device queue capacity provides a tradeoff between preemption latency and execution time. As the queue capacity decreases, the preemption latency also decreases because fewer kernels need to be evicted, but normal execution time increases because the GPU has more idle time waiting for the runtime to fill device queues with the kernels from host queues. We empirically choose a device queue capacity to 4 on our testbed, since it is sufficient to reset the device queue in 30 µs with negligible overhead on normal execution time (i.e., less than 0.3%). Furthermore, using a smaller device queue also produces slightly higher CPU utilization (e.g., about 15% increase) due to more frequent filling of the device queue.

4.2 Killing Running Kernels

To avoid waiting for the completion of running kernels, the reset-based preemption proactively kills the running kernels in the GPU. Unfortunately, there is neither an API provided by GPU runtime nor a functionality exposed by GPU driver that can kill the running kernels from the host side. We observed that GPU driver has the ability to terminate CPU process and also kill associated GPU kernels, even when the kernel stucks in an infinite loop. It implies that GPU driver can indeed kill an uncompleted kernel. However, this function will also reclaim GPU memory allocated by the process and GPU kernels. Thus, the preempted kernel has to reload DNN model parameters to GPU memory, taking even a few seconds.

To remedy it, REEF retrofits the kernel killing function of GPU driver and exposes it to the preemption module in GPU runtime. The new function will instruct the command processor to kill all running kernels on the CUs but preserve their running state in GPU memory. The preemption module will use it to kill all running kernels (see ❸ in Fig. 7) after evicting host queues and device queues.

4.3 Restoring Preempted Tasks

The best-effort tasks should be restored after being preempted. In general, the task has to be re-executed from the beginning, and is assumed to have no side effects. Fortunately, the *idempotence* characteristic of kernels in the DNN model ensures that the execution of DNN inference task can be restored from any kernel before the interrupted kernel. This implies that the scheduler can safely re-execute the preempted best-effort tasks. However, this may incur severe additional overhead because DNN models commonly have massive kernels (usually hundreds or more). Therefore, it is important to restore the preempted task from the kernel close to where it was interrupted. Unfortunately, it is almost impossible to precisely identify the interrupted kernel, because the kernel running on the CUs is killed directly by the command processor of GPU.

To remedy this problem, REEF adopts an *approximation* approach to ensure that the preempted task is restored from at most a *constant* number (c) of kernels before the interrupted kernel. More specifically, the preemption module first records the last kernel (k_l) transmitted to the device queue when it starts resetting the task queue, and then restores the preempted task from c kernels before k_l, where c denotes the device queue capacity. We observe that the command processor sequentially fetches a kernel from the device queue and runs it on the CUs. This implies that the interrupted kernel will not be earlier than c kernels before the last kernel (k_l) in the device queue. Furthermore, REEF will redundantly execute at most c+1 kernels. Since c is configured to be relatively small (i.e., 4), the restore overhead is negligible (about 30 µs).

4.4 Preemption on closed-source GPUs

Many commodity GPUs (e.g., NVIDIA GPUs) are still closed source. This poses new challenges to our reset-based preemption scheme, which has to treat the GPU runtime as a black box. The primary limitation is that we cannot reset CUs to proactively kill running kernels (❸ in Fig. 7). Apart from that, REEF is also unable to manipulate host queues and device queues directly outside of the GPU runtime. But fortunately, the lazy eviction scheme proposed by REEF for resetting DQs (❷ in Fig. 7) does not require any modification to the GPU runtime.

We propose a restricted version of reset-based preemption, called REEF-N, for closed-source GPUs. REEF-N first wraps each GPU stream, the general abstraction provided by GPU runtime, into a *virtual* host queue (vHQs), which intercepts and buffers all launched kernels. Similar to the (physical) HQ inside the GPU runtime, each vHQ also has a background thread to transmit buffered kernels asynchronously to the GPU runtime. After that, REEF-N treats the whole GPU runtime as several device queues (one for each GPU stream), such that REEF can easily reset vHQs to evict buffered kernels, instead of resetting HQs directly (❶ in Fig. 7). REEF-N still follows the lazy eviction to reset DQs, and then waits for all running kernels to complete. Finally, to simulate DQ capacity restriction, REEF limits the number of outstanding kernels in the GPU runtime; the background thread of vHQ transmits a fixed number of kernels to the GPU runtime in a closed loop.

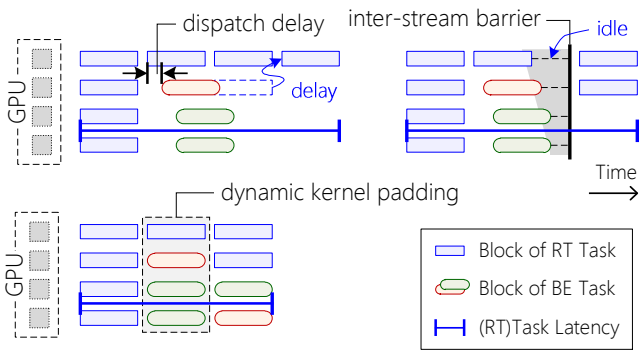

Fig. 8: *An example of serving multiple kernels in parallel with different approaches.*

5 Dynamic Kernel Padding

To achieve high throughput, both real-time and best-effort tasks should be concurrently executed on the GPU to achieve work conserving. However, to avoid interference with real-time tasks, the best-effort tasks should be only served by using GPU resources leftover from the real-time tasks. Regrettably, none of the existing approaches can provide such controlled concurrent execution on the GPU.

First, using different GPU streams to launch real-time and best-effort tasks cannot avoid interfering with each other. As shown in Fig. 8, the dispatch delay between GPU streams (20–40 µs) might postpone the execution of real-time kernels or limit the available resources (e.g., CUs) to them. Using additional inter-stream barriers to synchronize kernel dispatch among CUs will also cause performance overhead.

Second, static kernel fusion [74] can merge multiple kernels from different tasks into a single one at compile time and then launch the fused kernel on the GPU using a single stream. It can avoid interference between real-time tasks and best-effort tasks in advance. However, static kernel fusion has to pre-compile all possible combinations of all kernels in DNN models to enable scheduling at runtime. As mentioned above, DNN inferences have hundreds of kernels in common (see Table 1), which makes it impractical for static kernel fusion. For example, it requires more than 35 GB of GPU memory to store the fused kernels for five DNN models in Table 1—considering only all combinations of no more than three kernels.

```
# device codes
__device__ void dense(in, weight, bias, out): ...

__global__ void dkp(rt_kern, rt_args,
                    be_kerns, be_argss):
1   ncus = rt_kern.ncus  # number of CUs
2   if (cu_id() < ncus) then
3      rt_kern(rt_args)  # run RT/kernel
4   else
5      ncus += be_kerns[i=0].ncus
6      while (cu_id() >= ncus)
7         ncus += be_kerns[++i].ncus
8      be_kerns[i](be_argss[i])  # run BE/kernel

# host codes
void inference(...):
    # set the real-time kernel w/ its args (e.g., dense)
9   rt_kern, rt_args = ...
    # select a set of best-effort kernels w/ their args
10  be_kerns, be_argss = kern_select(rt_kern)
11  dkp <<<..>>> (rt_kern, rt_args, be_kerns, be_argss)
12  ... # launch other dynamic padded kernels
```

Fig. 9: *Pseudocode for dynamic kernel padding in* REEF.

Our approach: dynamic kernel padding. Inspired by kernel fusion, our approach also combines real-time kernels and best-effort kernels into a single one and launches it using a single GPU stream, as shown in Fig. 8. Differently, we construct a template (called *dkp kernel*) at compile time and use *function pointer* to fill and execute kernels at runtime. Further, we dynamically select best-effort kernels to avoid interference with the real-time kernel.

Fig. 9 shows an example of a dkp kernel (`dkp`) for dynamic kernel padding, declared as a *global* function (i.e., kernel entry). Instead of being statically inlined into the dkp kernel, candidate kernel functions (e.g., `dense`) are declared as individual *device* functions, which can be passed as dkp kernel arguments and called by function pointers (line 3 and 8). The dkp kernel partitions the CUs to execute one real-time candidate kernel (`rt_kern`) and a set of best-effort candidate kernels (`be_kerns`) in parallel. It first allocates sufficient CUs for the real-time kernel (line 1–3) and then assigns the leftover CUs to the best-effort kernels (line 5–8). When launching a real-time kernel, the DKP module selects appropriate best-effort kernels to concurrently execute with the real-time kernel (line 10, see also §5.2).

5.1 Efficient Function Pointers

Without specific optimizations, the naive design would significantly decrease the performance of real-time kernels, due to the unique characteristics of *function pointers* on the GPU. We summarize the two key performance issues of the default function pointer mechanism on the GPU.

Limited register allocation. Unlike CPU programs, GPU programs require a diverse yet fixed amount of registers, which is counted at compile time and encoded into the model executable. Such an attribute prohibits the direct use of function pointers in GPU kernels, as the number of registers used by the indirectly called function cannot be determined statically. The default behavior of the GPU compiler is to assign a predefined static upper bound to limit the callee's register usage, which may force the callee to save variables on the stack due to the insufficient registers, leading to poor performance compared to purely using registers [43].

Expensive context saving. Indirect function calls on GPUs are much more expensive than CPU programs, due to the enormous context (e.g., dozens of registers) that needs to be saved and restored before and after the function call. For thousands of threads, there might be MB-sized registers saved and restored, introducing significant overheads. Although the compiler will inline as many functions as possible to avoid this overhead, indirect function calls via function pointers cannot be inlined, which may impose significant performance penalty on dynamic kernel padding.

REEF tackles the two above issues by introducing *global function pointer* as a substitution of the default function pointer mechanism. Since global functions are treated as kernel entries, the compiler neither applies register limitations nor adds context saving/restoring code to them. Thus, declaring candidate kernels as global functions instead of device functions can solve both issues. According to our observation, context saving in candidate kernels is actually unnecessary, as the dkp kernel exits immediately after calling `rt_kern` or `be_kerns[i]` (see Fig. 9). Therefore, the lack of context saving code in candidate kernels does not affect the execution correctness.

However, as the kernel entry, a global function cannot be called by another global function (e.g., dkp kernel). To bypass this restriction, we replace indirect function calls with jump instructions in assembly code, and manually prepare the initial state of candidate kernels by following the conventions [45]. This approach makes no changes to the compiler and only incurs a trivial function call overhead (around 1%).

Dynamic register allocation. The real-time kernel performance is still not ideal after applying the global function pointer technique because of the *over-allocation* problem. To meet the varied register demands of candidate kernels, the dkp kernel has to allocate as many registers as possible (i.e., over-allocation), which may decrease the CU occupancy[3], and thus increase the execution time. An intuitive solution is to overwrite the register count of the dkp kernel just-in-time before it is launched, making it adaptive to selected candidate kernels. Unfortunately, the kernel's register count has been loaded to the GPU memory with the model in the off-line phase (§3), which means overwriting its value requires a CPU-to-GPU memory copy before every kernel execution, severely affecting the execution performance.

REEF addresses the dynamic register allocation problem

[3]The CU occupancy implies how many blocks can be executed on a CU simultaneously. It depends on how many resources (e.g., register) each block demands. Higher CU occupancy can lead to better performance.

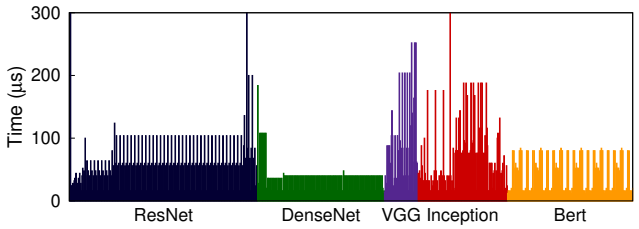

Fig. 10: *The measured execution time of kernels in five DNN models. The details of DNN models can be found in Table 1.*

by introducing a set of *proxy kernels*. Proxy kernels share the same source code as the dkp kernel in Fig. 9, but allocate different number of registers, allowing the scheduler to dynamically pick the proper proxy kernel according to each candidate kernel's register demand. Unfortunately, generating proxy kernels for every possible register count faces the kernel amount explosion problem. For example, on AMD Instinct MI50 GPU with at most 128 scalar registers and 256 vector registers for each thread, it will generate 32,768 proxy kernels to cover all possible register configurations.

To reduce the proxy kernel amount, we generate proxy kernels to cover all possible CU occupancies rather than register counts. Since proxy kernels are introduced to prevent over-allocation from decreasing the CU occupancy, proxy kernels that have different register count yet share the same CU occupancy are actually redundant and can be merged together. More specifically, there are 10 CU occupancy levels on AMD Instinct MI50 GPU we use, corresponding to 10 register count ranges, which allows us to generate only 10 proxy kernels, each allocating the maximum amount of registers allowed in a CU occupancy level. For each candidate kernel, the scheduler picks the proxy kernel with the fewest allocated registers that fulfill the candidate kernel's demand, which achieves the highest CU occupancy possible. This way, the amount of proxy kernels is narrowed down from 32,768 to 10 without affecting the candidate kernel's performance.

Dynamic shared memory. In addition to registers, over-allocation of shared memory may also decrease the CU occupancy of proxy kernels. Fortunately, the kernel is enabled to dynamically allocate shared memory by setting a property (i.e., "dynamic shared memory") when launching the kernel. During model compilation, REEF converts the declaration of variables from *fixed-size* shared memory to *dynamic* shared memory (i.e., adding $extern$ before $\_\_shared\_\_$). Consequently, the amount of shared memory used by proxy kernels can be set at runtime, depending on the maximum demand of candidate kernels.

5.2 Kernel Selection

For dynamic kernel padding, the *kernel selection policy* is important to avoid latency interference with real-time tasks, which selects a set of blocks from candidate best-effort kernels to share the GPU with the arriving real-time kernel. REEF proposes a greedy heuristic to ensure that the best-effort blocks will only use GPU resources (i.e., CUs) leftover from the real-time kernel. Specifically, it first reserves enough CUs for the real-time kernel, and then checks best-effort task queues to select appropriate blocks for the remaining CUs, until there are no free CUs or candidate tasks. The selected best-effort blocks should meet the following two rules.

Rule 1. The execution time of best-effort kernels must be shorter than that of the real-time kernel, since the execution time of the dkp kernel is determined by the slowest block. Based on the observation of latency predictability for GPU kernels in DNN models (see §2.1), we develop an offline kernel profiler to measure the computational requirements and the execution time for each kernels of loaded models.

Rule 2. The CU occupancy of best-effort kernels must be higher than that of the real-time kernel, since the CU occupancy of the dkp kernel is determined by the minimum of kernels. Note that the CU occupancy of kernels can be directly obtained from the source code of DNN models.

The kernel selection policy fully meets the design goal of treating the real-time tasks as first-class citizens on the GPU. It is not only efficient, selecting best-effort kernels in less than 1 µs, but also effective, limiting the latency overhead of real-time kernels to less than 1% on average, see §7.4 for details. However, the policy is also conservative, so the constraint may limit room for improvement in overall throughput. For example, when the execution time of best-effort kernels is often longer than that of real-time kernels (e.g., VGG and DenseNet in Fig. 10), the throughput improvement of dynamic kernel padding may be trivial, even if the real-time tasks only use a few CUs.

6 Implementation

We first implemented and deployed REEF on AMD GPUs because of its open-source platform and ISA [26, 54], which can fully demonstrate the efficacy of reset-based preemption and dynamic kernel padding. REEF was implemented by extending Apache TVM [73] and AMD ROCm [3], with about 5,500 lines of C++ code. Beyond that, to further show the feasibility of REEF on closed-source GPUs, we also ported REEF-N, a restricted version of reset-based preemption, on NVIDIA GPUs with CUDA [52].

Model compiler. REEF extends Apache TVM [15], a machine learning compiler framework, with a code transformer, which mainly adds two modifications to the source code of DNN inference: (1) a *preemption flag*, which is injected into kernel arguments to lazily evict the kernel; (2) a set of *proxy kernels*, which is constructed for the padded kernels.

GPU runtime. For AMD GPUs, REEF builds the preemption module on HIP [63] of ROCm, a portable GPU runtime and programming library. similar to NVIDIA CUDA [52]. Specifically, REEF adds three new APIs to GPU runtime: (1) `hip_reset_hq`, which resets host queues and moves

commands to the GC thread; (2) `hip_set_stream_cap`, which limits the capacity of the device queue used by a GPU stream; (3) `hip_reset_kern`, which resets the compute units by using hardware mechanisms via the GPU driver in Linux [61].

For NVIDIA GPUs, REEF-N intercepts three CUDA APIs related to kernel launch and stream management, and adds the following operations: (1) `cuStreamCreate`, which creates a vHQ and links it to the created CUDA stream; (2) `cuKernelLaunch`, which buffers the launched kernel in the vHQ and transmits it to GPU runtime (i.e., CUDA [52]) in the background; (3) `cuStreamSynchronize`, which waits for GPU runtime to complete all launched kernel of the CUDA stream. Finally, REEF-N provides a new API `cuResetHQ` to reset vHQ by dequeuing all buffered kernels.

7 Evaluation

7.1 Experimental Setup

Testbed. The experiments were mainly conducted on a GPU server that consists of one Intel Core i7-10700 CPU (total 8 cores), 16 GB of DRAM, and one AMD Radeon Instinct MI50 GPU (60 CUs and 16GB of memory). The software environment of the server was configured with ROCm 4.3.0 [3], Apache TVM [73] 0.8.0, and Ubuntu 18.04. The hardware platform resembles the computational resources of autonomous vehicles [4, 71]. We further evaluate REEF-N on a closed-source GPU (NVIDIA V100 GPU) to demonstrate the generality of our approach, using the same server with CUDA 10.2 [52] installed.

Workloads. Inspired by YCSB [17, 18], we build a new DNN inference serving benchmark (DISB) that contains a suite of tools and five workloads: (A) low load, (B) high RT load, (C) high BE load, (D) multi-RT load, and (E) random load, summarized in Table 2. The real-time (RT) clients in DISB A–D uniformly send inference requests at a given frequency, which simulates real-time DNN applications in autonomous driving (e.g., obstacle recognition with cameras [7]), while the clients in DISB E send 20 requests per second with a Poisson arrival distribution, which simulates event-driven real-time DNN applications (e.g., speech recognition [32, 75]). Note that serving 220 RT requests per second sequentially for VGG model would saturate our testbed (see Fig. 1(d)). On the other hand, the closed-loop best-effort (BE) client continuously issues inference requests, which simulates a contention load on the GPU (e.g., driver monitoring).

Five representative DNN models are deployed in DISB, including ResNet-152 [30] (RNET), DenseNet-201 [35] (DNET), VGG-19 [68] (VGG), Inception v3 [69] (IN3), and DistilBert [66] (BERT), all generated by Apache TVM [15]. Each client always submits inference requests for a certain DNN model. Specifically, VGG is used by DISB A–C for their RT clients, and RNET is used by DISB A and B for their BE clients. Workloads with 5 RT/BE clients deploy all five DNN models in their clients separately, which simulates multiple DNN applications in a single scenario (e.g., autonomous vehicles [7, 41]).

Table 2: *DISB workload description.* #/model *denotes the number of clients and their DNN models.* [U/P] *denotes an arrival distribution (i.e., Uniform or Poisson).*

DISB	A	B	C	D	E
Num. of RT clients	1/VGG	1/VGG	1/VGG	5/ALL	5/ALL
Frequency (reqs/s)	100 [U]	220 [U]	100 [U]	20 [U]	20 [P]
Num. of BE clients	1/RNET	1/RNET	5/ALL	5/ALL	5/ALL

Furthermore, we use a real-world trace from an open autonomous driving platform (i.e., Apollo [7]) as the real-time workload, which provides a realistic arrival distribution of real-time tasks in autonomous driving. The trace was collected from the logs of the perception module [5] when running Apollo with SVL simulator [42, 65], and we selected the closest DNN models in terms of execution time from the above five models for the inference requests. Meanwhile, the same best-effort workload as DISB C–E is used, where five clients continuously issue different DNN inference requests.

Currently, each workload in DISB represents a particular mix of real-time and best-effort DNN inference tasks, the number of clients, and request frequency, which focuses on a particular point in the performance space. Users can further extend DISB with new workloads, or even some production traces from specific applications, to model more different scenarios.

Comparing targets. We compare REEF with typical scheduling approaches. **SEQ** sequentially runs each DNN inference task on the GPU with passive task preemption, which is adopted by Clockwork [28]. Specifically, when there are multiple tasks waiting in the queue, it prioritizes real-time tasks, but still needs to wait for the completion of launched best-effort tasks. **GPUStreams** runs both real-time and best-effort tasks simultaneously on the same GPU through multiple GPU streams, which is adopted by TensorRT [50]. As a reference, we further provide **RT-Only**, which represents the optimal end-to-end latency for real-time tasks, as it dedicates the GPU to real-time tasks.[4]

7.2 Overall Performance

We first compare the end-to-end latency of real-time tasks and the overall throughput of REEF with other approaches using DISB workloads and a real-world trace, as shown in Fig. 11.

Single BE Client (DISB A and B). For workloads with a single BE client, the performance impact of using SEQ or GPUStreams is relatively low, since GPU contention from best-effort tasks is not severe, either in terms of wait time (SEQ) or concurrent interference (GPUStreams). For DISB

[4] In this case, additional GPUs are dedicated to best-effort tasks, which also result in extra cost and energy consumption, as well as low GPU utilization.

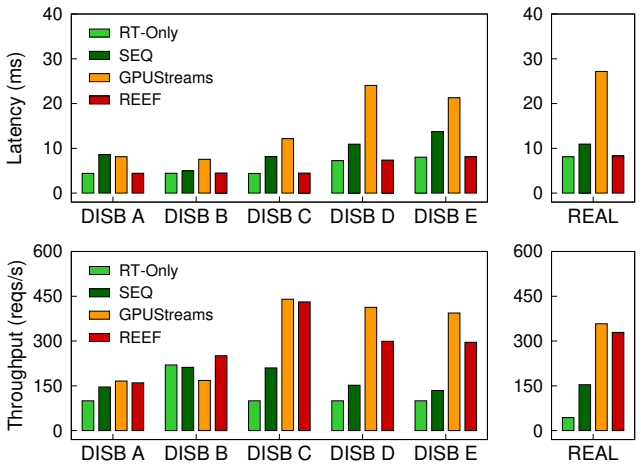

Fig. 11: *Comparison of (a) end-to-end real-time task latency, and (b) overall throughput (including both real-time and best-effort tasks) using different scheduling approaches.*

A, compared with RT-Only, SEQ and GPUStreams improve overall throughput by 1.46× and 1.66×, but also amplify real-time task latency by 1.95× and 1.84×, respectively. In contrast, REEF incurs negligible (0.5%) overhead on real-time task latency, but improves overall throughput by 1.60×, comparable to GPUStreams.

For DISB B, due to running real-time tasks more frequently, SEQ suffers 1.12× slowdown on real-time task latency, slightly better than DISB A, as it only has to wait for fewer best-effort tasks. However, its throughput only achieves 96% of RT-Only, since real-time tasks saturate the GPU and best-effort tasks have little chance to run. For similar reasons, the overall throughput of GPUStreams also drops to 76% of RT-Only, while its real-time task latency is still 1.70× higher than RT-only. Conversely, REEF can still limit the overhead on real-time task latency to 1% (about 60 µs) and provides a 1.14× speedup on overall throughput, thanks to our reset-based kernel preemption and dynamic kernel padding.

Multiple BE Clients (DISB C, D, and E). With the increase of best-effort workloads, the overall throughput of all approaches improve to varying degrees over RT-Only by sharing the GPU between two types of tasks. However, they have very different performance in terms of real-time task latency. Both SEQ and GPUStream make the same tradeoff between real-time task latency and overall throughput, differing only in the magnitude of the performance impact. For three workloads, SEQ improves overall throughput by 1.34× to 2.10×, but also amplifies real-time task latency by 1.51× to 1.86×. For GPUStreams, the above numbers become 3.94× to 8.19× and 2.65× to 3.31×.

Differently, REEF improves overall throughput as much as possible, based on the premise that real-time tasks should not be affected in any way. As a result, REEF offers almost the same real-time task latency as RT-Only in all workloads, with less than 1.5% overhead (0.1 ms). For overall throughput,

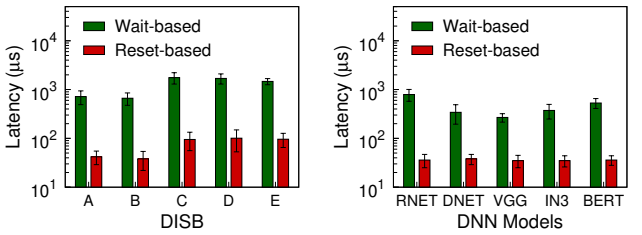

Fig. 12: *Comparison of preemption latency between reset-based and wait-based approaches (a) on DISB workloads, and (b) when preempting one DNN inference task of different DNN models.*

REEF provides a close result of GPUStreams on DISB C, since VGG is easy to be padded with most DNN models (see §5.2). On DISB D and E, the throughput of REEF is about 25% lower than that of GPUStreams, due to using a mix of five DNN models for real-time tasks, while DKP does not always work well on a few combinations of real-time and best-effort tasks (see §7.4 for details). However, REEF still outperforms RT-Only by 3.00× and 2.96×, respectively.

Real-world workload from Apollo (REAL). For the real-world workload, compared to RT-Only, SEQ and GPUStreams increase overall throughput by 3.6× and 8.3×, while amplifying the latency of real-time tasks by 1.35× and 3.35×, respectively. Due to the low load of real-time tasks in the real-world trace (about 43 reqs/s), REEF stays in normal mode to execute best-effort tasks concurrently most of the time, similar to GPUStreams. Therefore, compared to RT-Only, REEF achieves 7.7× throughput improvement with less than 2% latency overhead for real-time tasks, thanks to our reset-based preemption, which can preempt the GPU within tens of microseconds after the real-time task arrives.

7.3 DNN Inference Preemption

The vanilla wait-based preemption approach proposed in prior work [12] is not practical for DNN inference serving, since it only allows executing tasks one by one. Therefore, we extended it to allow concurrent inference serving by removing the limit on the amount of launched kernels and also implementing *lazy eviction*. This version is used as the baseline to demonstrate the efficiency of our reset-based preemption.

Preemption latency. Fig. 12(a) compares the preemption latency of two approaches. The reset-based preemption outperforms the wait-based approach by more than an order of magnitude for all DISB workloads, from 15.3× (DISB E) to 18.5× (DISB C). The main reason is that the wait-based approach has to passively wait for the completion of running kernels in CUs and the eviction of massive kernels in host and device queues, while the reset-based approach is able to proactively kill all kernels (usually much less) in these three places. As expected, both approaches take more time to handle multiple concurrent BE clients (DISB C, D, and E) than a singel BE client (DISB A and B).

Furthermore, we evaluate the preemption latency for di-

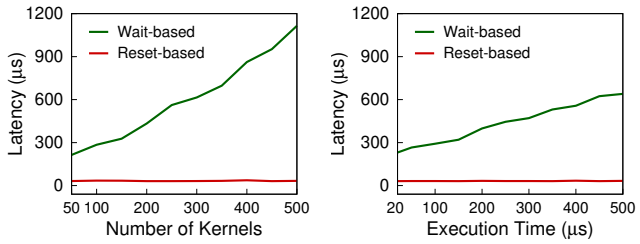

Fig. 13: *Comparison of preemption latency with the increase of (a) launched kernels and (b) kernel execution time.*

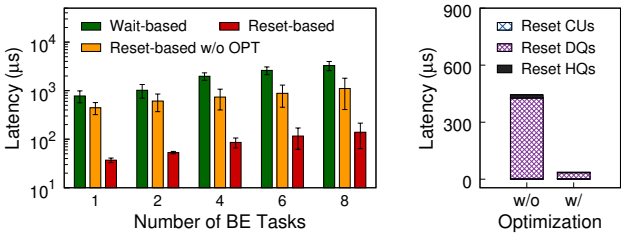

Fig. 14: *(a) Comparison of preemption latency with the increase of BE clients, and (b) the latency breakdown of the reset-based approach w/o and w/ optimizations.*

verse DNN models, where we use a single BE client to send inference requests for a given model and send a real-time request after a random time interval to preempt the GPU. As shown in Fig. 12(b), the wait-based preemption latency highly depends on the type of models, from 268 µs (VGG) to 790 µs (RNET), due to the difference in the number of kernels and the execution time (see Table 1). In contrast, the reset-based approach is not sensitive to DNN models and can preempt the GPU in the range of 35 µs to 38 µs for all five models.

To further investigate the impact of different model properties on the preemption latency, we simulate DNN models with different number of launched kernels and kernel execution times. By default, we set the number of launched kernels and the kernel execution time to 100 and 100 µs, respectively. As shown in Fig. 13, the preemption latency of wait-based approach raises linearly, while our reset-based preemption approach remains stable at very low latency (less than 40 µs). For wait-based approach, the preemption latency is significantly positively correlated with as number of launched kernels and the kernel execution time, since it has to wait for the eviction of launched kernels and the completion of running kernels. In contrast, the reset-based approach proactively resets the host and device queues in GPU runtime, as well as the CUs, where the cost is independent of model properties.

Optimizations. We propose two optimizations on the reset-based preemption approach, namely asynchronous memory reclamation and queue capacity restriction. To demonstrate the effect of optimizations, Fig. 14 shows the preemption latency with the increase of BE clients (RNET), and the latency breakdown for a single BE client. By enabling two optimizations, the preemption latency significantly drops by up to 92% (from 87%), as shown in Fig. 14(a). As a reference, even without optimization, the reset-based approach still outperforms wait-based approach by up to 3.0× (from 1.7×).

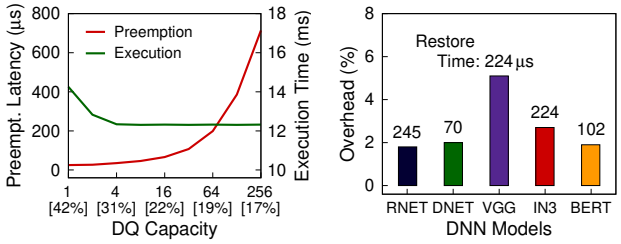

Fig. 15: *(a) The preemption latency and execution time with the increase of device queue capacity, where [%] shows the CPU utilization during normal execution, and (b) the restore overhead for different DNN models, where labels show the restore time (in µs).*

Since the two optimizations are used when resetting host and device queues, respectively, Fig. 14(b) breaks down the preemption latency to show the contribution of two optimizations separately. For a single BE client, using asynchronous memory reclamation reduces the latency of resetting host queue from 17 µs to 3 µs. Meanwhile, using queue capacity restriction further reduces the latency of resetting device queue from 424 µs to 31 µs. Note that using command processor to reset CUs is extremely fast (less than 3 µs).

Queue capacity. We restrict the device queue capacity to mitigate the overhead incurred by lazily evicting the remaining kernels in the queue (see §4.1 for details). However, reducing queue capacity also increases normal execution time and CPU utilization. Fig. 15(a) shows the preemption latency and normal execution time when serving RNET inferences as the queue capacity increases. When the device queue capacity increases from 1 to 4, the execution time reduces from 14.3 ms to 12.3 ms. However, when the capacity further increases, the change in execution time becomes trivial (less than 0.3%). Conversely, the preemption latency increases linearly with the queue capacity. Therefore, as a reasonable tradeoff between preemption latency and normal execution time, REEF adopts a default capacity of 4 for the device queue on our testbed, which has almost zero overhead for normal execution and provides acceptable preemption performance (about 30 µs). Finally, using a smaller device queue also results in higher CPU utilization. For instance, reducing the queue capacity from 256 to 4 increases CPU utilization from 17% to 31%.

Task restore. We further evaluate the execution time overhead of preempted tasks due to task restore. We use a single BE client to send inference requests; for each task, we randomly preempt and restore it. As shown in Fig. 15(b), the restore time for all DNN models is low, ranging from 70 µs to 245 µs, which mainly depends on the kernel execution time of DNN models (see Fig. 10). Note that REEF redundantly executes at most five kernels for restoring preempted tasks, thanks to the queue capacity restriction. Further, the execution time overhead is about 2% for all DNN models, except for VGG (5.1%), as it has the fewest kernels (55), and its kernel

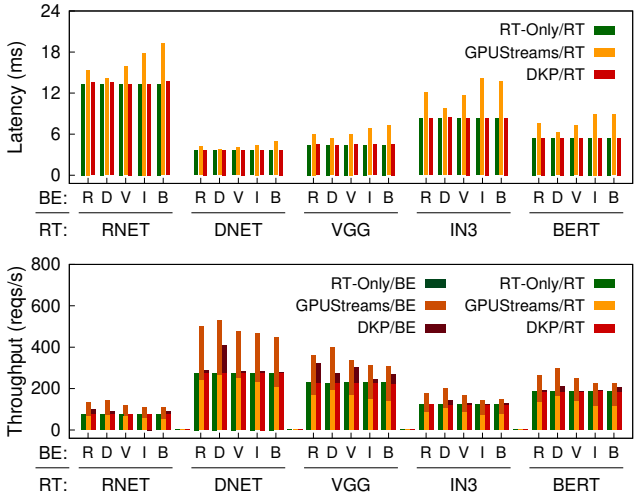

Fig. 16: *Comparison of (a) end-to-end latency of RT tasks and (b) overall throughput using different concurrent execution schemes.*

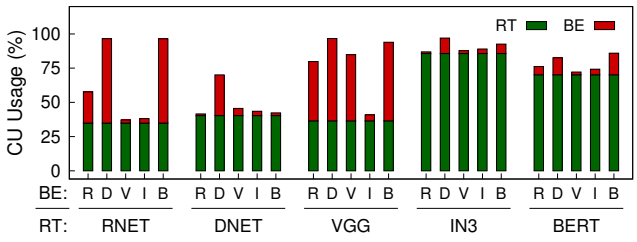

Fig. 17: *The average CU usage for running real-time and best-effort kernels with different combinations of DNN models using dynamic kernel padding.*

execution time is longer (see Fig. 10).

7.4 Dynamic Kernel Padding

To study the efficacy of dynamic kernel padding, we use a high contention workload, where one RT client and one BE client simultaneously send requests at a high-enough frequency to keep the GPU busy. RT-Only serves only real-time tasks to ensure optimal (real-time) task latency, while GPUStreams serves both types of requests concurrently to achieve the highest overall throughput. Differently, dynamic kernel padding also serves only real-time tasks but pads best-effort tasks to avoid starvation and improve overall throughput.

Performance. Fig. 16 reports the experimental results for one-to-one combinations among five DNN models using above workload. As expected, GPUStreams significantly amplifies real-time task latency by an average of 1.35×, ranging from 1.04× to 1.70×, due to severe interference from concurrent best-effort tasks. However, REEF is able to provide almost optimal latency to real-time tasks, with an average overhead of just 1% (up to 3%).

For overall throughput, we separately report the throughput of real-time tasks and the normalized throughput of best-effort

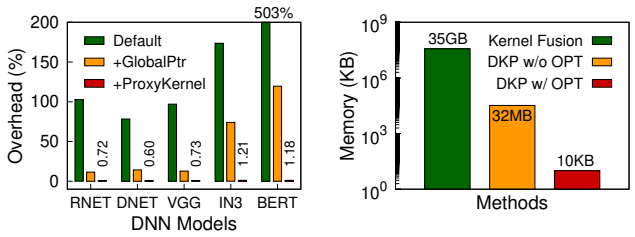

Fig. 18: *Comparison of (a) execution time overhead and (b) memory overhead for padded kernels using different optimizations.*

tasks.[5] For RT-Only, the GPU is busy serving real-time tasks, so the throughput of best-effort tasks is zero (even if RT-Only is willing to serve them). Although GPUStreams increases overall throughput by an average of 1.52×, the throughput of real-time tasks drops by 24.4% on average, due to severe interference in concurrent execution. Conversely, REEF first guarantees throughput for real-time tasks and then leverages dynamic kernel padding to increase overall throughput. The performance improvement mainly depends on two conditions. First, the execution of real-time tasks on the GPU leaves room for improvement. As shown in Fig. 17, the real-time kernels in IN3 and BERT use an average of 85% and 70% of CUs, respectively. Therefore, dynamic kernel padding hardly improves such cases, increasing just 6% on average. Note that GPUStreams can still improve overall throughput of them, but also greatly sacrifices the performance of real-time tasks. Second, the execution time of best-effort kernels must be shorter than that of the padded real-time kernels. This explains why REEF can achieve large improvement (1.41×) by padding VGG with RNET, but not vice versa, which is also confirmed by the increase of CU usage (BE) in Fig. 17

Optimizations. To investigate the impact of optimizations on both performance and memory usage, we first evaluate the overhead using different implementations of the function pointer on the GPU. We measured such overhead by launching real-time kernels through the dkp kernel without padding any best-effort kernels. As shown in Fig. 18(a), the default function pointer implementation (Default) incurs execution time overhead from 78% up to 503% for real-time tasks with different DNN models. By using the global function pointer (GlobalPtr), the overhead is significantly reduced to 46.4% on average (from 11.5% to 120%), as it eliminates the limit on the number of registers for device function pointers and avoids additional register saving and restoring during the function call. Finally, the overhead drops to 0.8% on average (1.21% at most) by using proxy kernel (ProxyKernel), which can dynamically allocate registers to each kernel and maximize CU occupancy. The minimal overhead comes from the logic branch of CU partition and the initial state preparation for global function pointers.

We further evaluate the impact of optimizations on reduc-

[5]The throughput of best-effort tasks is normalized to that of real-time tasks, following the formula: $throughput_{\text{BE}} \times (latency_{\text{BE}} \,/\, latency_{\text{RT}})$.

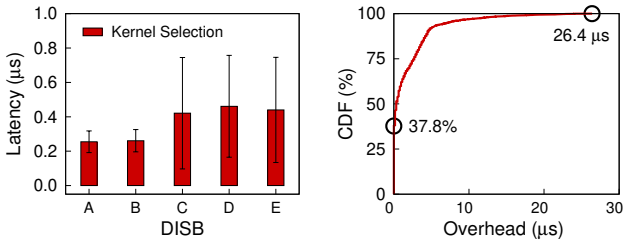

Fig. 19: *(a) The execution time of kernel selection for DISB A-E and (b) the CDF of execution time overhead for real-time kernels using dynamic kernel padding.*

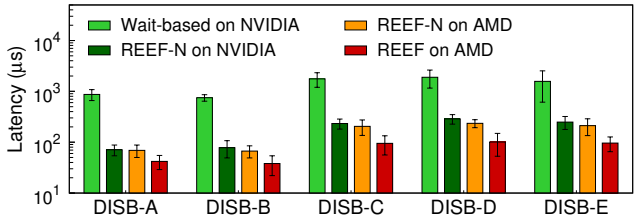

Fig. 20: *Comparison of preemption latency on NVIDIA and AMD GPUs using different preemption schemes with DISB workloads.*

ing GPU memory usage. As shown in Fig. 18(b), using static kernel fusion (Kernel Fusion) requires over 35 GB of GPU memory to store the fused kernels for five DNN models—all combinations of no more than three kernels, which even exceeds the memory capacity of most commodity GPUs. REEF proposes proxy kernels (DKP w/o OPT) to reduce GPU memory usage to about 32 MB. Finally, generating proxy kernels to cover all possible CU occupancies (DKP w/ OPT), instead of all possible register configurations, can dramatically reduce GPU memory usage to only 10 KB.

Kernel selection. Fig. 19(a) shows the average time of kernel selection for DISB A-E during dynamic kernel padding. For workloads with a single BE client (DISB A and B), REEF takes about 0.2 µs to select best-effort kernels for the given real-time kernel. The selection time increases to 0.4 µs for workloads with multiple BE clients (DISB C, D, and E) due to more candidates. In general, the cost of kernel selection is quite trivial and can be easily hidden by kernel execution.

To further study the accuracy of kernel selection, we evaluate the execution time overhead for the real-time kernel due to padding best-effort kernels on all DISB workloads. As shown in Fig. 19(b), over 37% of real-time kernels are not negatively impacted by concurrent execution with best-effort kernels, and the overhead of more than 90% real-time kernels is still less than 4 µs. The increase of execution time is mainly due to the contention on GPU memory and shared L2 cache.

7.5 Closed-source GPUs

Finally, we evaluate REEF-N, a restricted version of reset-based preemption using DISB workloads on both NVIDIA and AMD GPUs, and compare it to the wait-based approach and REEF, respectively. As shown in Fig. 20, even if REEF-N does not reset CUs to proactively kill running kernels, the preemption latency just ranges from 71µs to 288µs, which still outperforms the wait-based approach by up to 12.3× (from 6.3×) on the NVIDIA GPU. By comparing REEF-N and REEF on the AMD GPU, we observe that killing running kernels proactively further contributes to an average speedup of 2.0× in preemption latency, especially for preempting concurrent tasks (e.g., 2.3× for DISB C). In addition, the performance of REEF-N is close on two GPUs.

8 Discussion

Assumption of idempotence. The reset-based preemption in REEF is based on the assumption that each kernel in DNN inference should be idempotent. Currently, all DNN inference kernels we encountered, a total of 320 kernels from 11 models [72], are shown to be idempotent. However, readers might be interested in whether our approach still works with kernels without the idempotence assumption. Strictly speaking, the reset-based preemption demands that the kernel always produces the same output for the same input no matter it has been retried or not. Therefore, a transactionization approach [40] can be used to transform non-idempotent kernels into idempotent ones if necessary. Furthermore, since only best-effort kernels may be preempted in REEF, this transformation only sacrifices the performance of transformed kernels (i.e., best-effort kernels) to ensure that real-time kernels can be instantly executed upon arrival with no performance penalty. We leave the incorporation of this technique to future work until we actually encounter non-idempotent DNN kernels.

Restrictions on kernel selection. The current kernel selection policy is effective but conservative, since the primary goal of REEF is to avoid performance interference with real-time tasks. An obvious limitation is the constraint that the execution time of best-effort kernels must be shorter than that of the padded real-time kernel, which limits room for improvement in overall throughput. We found that the GPU kernel can be tailored towards shorter execution time per block by using more thread blocks during model compilation. For example, Apache TVM automatically tunes the number of thread blocks for overall performance, but also allows developers to customize it [38]. Currently, the overall throughput improvement of REEF is largely attributed to enabling instant kernel preemption, which allows the idle GPU to perform best-effort tasks. Thus, we leave it to future work to overcome the restriction on kernel selection. Furthermore, the policy does not consider the contention for GPU memory between real-time and best-effort kernels, since it is still sufficient for running multiple DNN inference tasks. We also leave it to future work.

Future GPU APIs and runtime. We leverage several subtle hacks on the GPU runtime to enable µs-scale reset-based preemption on commodity GPUs. Our work also informs the design of future GPU APIs and runtime. First, given that com-

modity GPUs are generally capable of resetting compute units (CUs), a separate GPU API to precisely reset CUs is feasible and would be useful to kill and restore all running kernels. Second, we propose a new GPU API that instructs the command processor to discard fetched kernels and stop fetching more kernels from the device queue (DQs). Based on it, DQs can be proactively reset with a hardware-software co-design, replacing our software-only solution (i.e., lazy eviction). Finally, the GPU runtime could provide a high-level API for developers to reset the GPU stream, by discarding kernels buffered in internal data structures (e.g., host queues) and resetting the GPU via two new APIs. We believe that these extensions can greatly simplify implementation, even fully implementing reset-based preemption on closed-source GPUs, and further improve performance, for example instantly preempting the GPU in 10 µs.

9 Related Work

DNN inference serving systems. Prior model serving systems [21, 25, 29, 53, 79] mainly focus on meeting service-level objectives (SLO), typically in the tens of milliseconds [22, 31, 81], and improving overall throughput of datacenter applications. Clockwork [28] leverages the latency predictability of DNN inference to achieve low tail latency. It runs inferences sequentially on dedicated GPUs to provide predictable performance. Clipper [20] and Nexus [67] enables batching inferences on the same model to improve GPU utilization and inference throughput. Abacus [22] enables simultaneous DNN inferences by accurately predicting the latency of the overlapped operators. INFaaS [64] can automatically select the right variant with different optimizations for each inference to meet diverse SLOs. However, the latency SLOs for datacenter applications are much more relaxed than those for real-time systems, for example 2× of their solo-run latencies [22]. Therefore, using non-preemptive scheduling or batching scheme is effective for datacenter applications, but not for real-time scenarios (e.g., autonomous vehicles). Furthermore, the design of REEF is orthogonal to the above distributed serving systems. Two key mechanisms in REEF can also be integrated into them to improve per-GPU throughput and preserve low latency for real-time inferences.

GPU kernel preemption. Apart from the software preemption techniques, prior work also has proposed hardware enhancement to support preemptive GPU scheduling [44, 56, 70]. An intuitive solution is to support context switch on GPUs [70]. However, it is far more expensive on GPU than CPU due to the large context (e.g., a large amount of registers). Zhen et al. [44] proposed lightweight context switching to avoid unnecessary register saving. Tanasić et al. [70] extended the hardware to passively preempt a streaming multiprocessor (SM) of GPU by stopping issuing new thread blocks. Chimera [56] further proposed SM flushing to instantly preempt an SM when detecting idempotent execution. Differently, our approach retrofits existing hardware mechanism and requires no modification on the GPU to implement instant preemption.

GPU multitasking. There have been many efforts to concurrently execute multiple GPU kernels for high throughput [27, 43, 55, 57, 74, 76]. For DNN computation, Rammer [47] takes a holistic approach to exploit both inter- and intra-kernel parallelisms at compile time, which uses static kernel fusion [74] to enforce the CU assignments of the concurrent kernels. However, static kernel fusion requires the fused kernels to be known at compile time, which is not applicable for dynamic task scheduling in REEF. REEF proposes dynamic kernel padding to allow making scheduling decisions at runtime. Prior work has also proposed approaches to model and predict the slowdown of concurrent kernel execution [13, 14, 86, 88]. DASE [34] models the memory contention of concurrent kernels. Themis [87] uses a neural network to predict the performance interference. The prediction can help make scheduling decisions to match the latency requirements of real-time kernels. However, the prediction cannot always be accurate, and the slowdown actually happens. Differently, dynamic kernel padding in REEF enforces concurrent kernels to use only GPU resources leftover from the real-time kernel. Currently, REEF mainly focuses on GPU computational resources (i.e., CUs) and assumes that other resources are sufficient (e.g., GPU memory and bandwidth). We leave it as future work.

10 Conclusion

This paper presented REEF, the first DNN inference serving system for commodity GPUs. It enables microsecond-scale kernel preemption and controlled concurrent execution in GPU scheduling to achieve real time and work conserving. First, REEF can launch a real-time kernel on the GPU by proactively killing and restoring best-effort kernels at microsecond-scale. Second, REEF can dynamically pad the real-time kernel with appropriate best-effort kernels to fully exploit the GPU with negligible overhead. In addition, we built a new benchmark (DISB) for DNN inference serving that contains diverse workloads and a real-world trace. Evaluation using DISB and microbenchmarks confirmed the efficacy and efficiency of REEF on AMD and NVIDIA GPUs.

A Artifact Appendix

This artifact provides the source code of REEF, a detailed readme, and scripts to reproduce the main experimental results from the OSDI 2022 paper—"Microsecond-scale Preemption for Concurrent GPU-accelerated DNN Inferences" by M. Han, H. Zhang, R. Chen, and H. Chen. REEF is the first GPU-accelerated DNN inference serving system that enables microsecond-scale kernel preemption and controlled concurrent execution in GPU scheduling. We provide instructions to build the software package and run experiments. Our artifact obtained the "Artifacts Available", "Artifacts Functional" and "Artifacts Reproduced" badges from the Artifact Evaluation process of OSDI 2022. The DOI of our artifact is https://doi.org/10.5281/zenodo.6586106.

Artifact repository. All project source code, including full instructions on how to build and run the main experiments on REEF and benchmarks is available in the following git repository: https://github.com/SJTU-IPADS/reef-artifacts/tree/osdi22-ae.

Alpa: Automating Inter- and Intra-Operator Parallelism for Distributed Deep Learning

Abstract

Alpa automates model-parallel training of large deep learning (DL) models by generating execution plans that unify data, operator, and pipeline parallelism. Existing model-parallel training systems either require users to manually create a parallelization plan or automatically generate one from a limited space of model parallelism configurations. They do not suffice to scale out complex DL models on distributed compute devices. Alpa distributes the training of large DL models by viewing parallelisms as two hierarchical levels: inter-operator and intra-operator parallelisms. Based on it, Alpa constructs a new hierarchical space for massive model-parallel execution plans. Alpa designs a number of compilation passes to automatically derive efficient parallel execution plans at each parallelism level. Alpa implements an efficient runtime to orchestrate the two-level parallel execution on distributed compute devices. Our evaluation shows Alpa generates parallelization plans that match or outperform hand-tuned model-parallel training systems even on models they are designed for. Unlike specialized systems, Alpa also generalizes to models with heterogeneous architectures and models without manually-designed plans. Alpa's source code is publicly available at https://github.com/alpa-projects/alpa.

1 Introduction

Several of the recent advances [10, 22, 49] in deep learning (DL) have been a direct result of significant increases in model size. For example, scaling language models, such as GPT-3, to hundreds of billions of parameters [10] and training on much larger datasets enabled fundamentally new capabilities.

However, training these extremely large models on distributed clusters currently requires a significant amount of engineering effort that is specific to both the model definition and the cluster environment. For example, training a large transformer-based language model requires heavy tuning and careful selection of multiple parallelism dimensions [40]. Training the large Mixture-of-Expert (MoE) transformers model [16, 31] on TPU clusters requires manually tuning the partitioning axis for each layer, whereas training the same model on an AWS GPU cluster calls for new pipeline schemes that can depend on the choices of partitioning (§8.1).

More generally, efficient large-scale model training requires tuning a complex combination of data, operator, and pipeline parallelization approaches at the granularity of the individual tensor operators. Correctly tuning the parallelization strategy has been shown [30, 33] to deliver an order of magnitude improvements in training performance, but depends on strong machine learning (ML) and system expertise.

Automating the parallelization of large-scale models would significantly accelerate ML research and production by enabling model developers to quickly explore new model designs without regard for the underlying system challenges. Unfortunately, it requires navigating a complex space of plans that grows exponentially with the dimensions of parallelism and the size of the model and cluster. For example, when all parallelism techniques are enabled, figuring out the execution plan involves answering a web of interdependent questions, such as how many data-parallel replicas to create, which axis to partition each operator along, how to split the model into pipeline stages, and how to map devices to the resulting parallel executables. The interplay of different parallelization methods and their strong dependence on model and cluster setups form a combinatorial space of plans to optimize. Recent efforts [17, 38, 55] to automatically parallelize model training are constrained to the space of a single model-parallelism approach, or rely on strong assumptions on the model and cluster specifications (§2.1).

Our key observation is that we can organize different parallelization techniques into a *hierarchical space* and map these parallelization techniques to the *hierarchical structure* of the compute cluster. Different parallelization techniques have different bandwidth requirements for communication, while a typical compute cluster has a corresponding structure: closely located devices can communicate with high bandwidth while distant devices have limited communication bandwidth.

*Lianmin, Zhuohan, and Hao contributed equally. Part of the work was done when Lianmin interned at Amazon and Zhuohan interned at Google.

With this observation in mind, in this paper, we take a different view from conventional data and model parallelisms, and re-categorize ML parallelization approaches as *intra-operator* and *inter-operator* parallelisms. Intra-operator parallelism partitions ML operators along one or more tensor axes (batch or non-batch) and dispatches the partitions to distributed devices (Fig. 1c); inter-operator parallelism, on the other hand, slices the model into disjoint stages and pipelines the execution of stages on different sets of devices (Fig. 1d). They take place at two different granularities of the model computation, differentiated by whether to partition operators.

Given that, a parallel execution plan can be expressed *hierarchically* by specifying the plan in each parallelism category, leading to a number of advantages. First, intra- and inter-operator parallelisms feature distinct characteristics: intra-operator parallelism has better device utilization, but results in communicating at every split and merge of partitioned operators, per training iteration; whereas inter-operator parallelism only communicates between adjacent stages, which can be light if sliced properly, but incurs device idle time due to scheduling constraints. We can harness the asymmetric nature of communication bandwidth in a compute cluster, and map intra-operator parallelism to devices connected with high communication bandwidth, while orchestrating the inter-operator parallelism between distant devices with relatively lower bandwidth in between. Second, this hierarchical design allows us to solve each level near-optimally as an individual tractable sub-problem. While the joint execution plan is not guaranteed globally optimal, they demonstrate strong performance empirically for training various large models.

Guided by this new problem formulation, we design and implement Alpa, the first compiler that automatically generates parallel execution plans covering all data, operator, and pipeline parallelisms. Given the model description and a cluster configuration, Alpa achieves this by partitioning the cluster into a number of *device meshes*, each of which contains devices with preferably high-bandwidth connections, and partitioning the computation graph of the model into *stages*. It assigns stages to device meshes, and automatically orchestrates intra-operator parallelisms on a device mesh and inter-operator parallelisms between device meshes.

In summary, we make the following contributions:

• We construct a two-level parallel execution plan space (Fig. 1e) where plans are specified hierarchically using inter- and intra-operator parallelisms.

• We design tractable optimization algorithms to derive near-optimal execution plans at each level.

• We implement Alpa, a compiler system for distributed DL on GPU clusters. Alpa features: (1) a set of compilation passes that generate execution plans using the hierarchical optimization algorithms, (2) a new runtime architecture that orchestrates the inter-op parallelism between device meshes, and (3) a number of system optimizations that improve compilation and address cross-mesh communication.

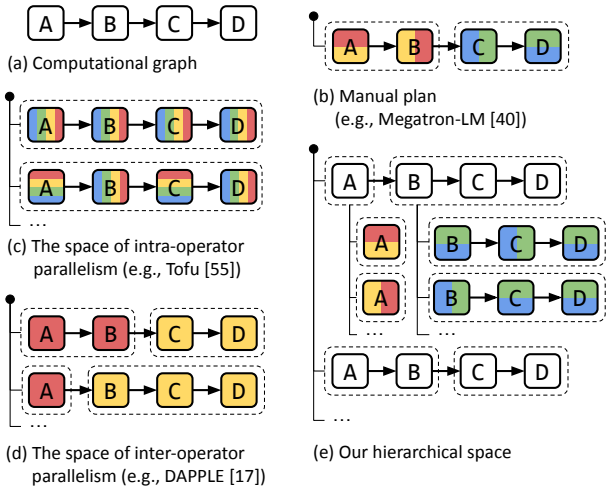

Figure 1: Generation of parallelization plans for a computational graph shown in (a). Different colors represent different devices, dashed boxes represent pipeline stages. (b) creates the plan manually. (c) and (d) automatically generate plans using only one of intra- and inter-operator parallelisms. (e) shows our approach that creates a hierarchical space to combine intra- and inter-operator parallelisms.

• We evaluate Alpa on training large models with billions of parameters. We compare Alpa with state-of-the-art distributed training systems on an Amazon EC2 cluster of 8 p3.16xlarge instances with 64 GPUs. On GPT [10] models, Alpa can match the specialized system Megatron-LM [40,49]. On GShard MoE models [31], compared to a hand-tuned system Deepspeed [45], Alpa achieves a 3.5× speedup on 2 nodes and a 9.7× speedup on 4 nodes. Unlike specialized systems, Alpa also generalizes to models without manual strategies and achieves an 80% linear scaling efficiency on Wide-ResNet [59] with 4 nodes. This means developers can get efficient model-parallel execution of large DL models out-of-the-box using Alpa.

2 Background: Distributed Deep Learning

DL computation is commonly represented by popular ML frameworks [1,9,42] as a dataflow graph. Edges in the graph represent multi-dimensional tensors; nodes are computational operators, such as matrix multiplication (matmul), that transform input tensors into output tensors. Training a DL model for one iteration consists of computing a loss by *forwarding* a batch of data through the graph, deriving the updates via a reverse *backward* pass, and applying the updates to the parameters via *weight update* operations. In practice, model developers define the dataflow graph. An execution engine then optimizes and executes it on a compute device.

When either the model or data is large that a single device cannot complete the training in a reasonable amount of time, we resort to ML parallelization approaches that parallelize the computation on distributed devices.

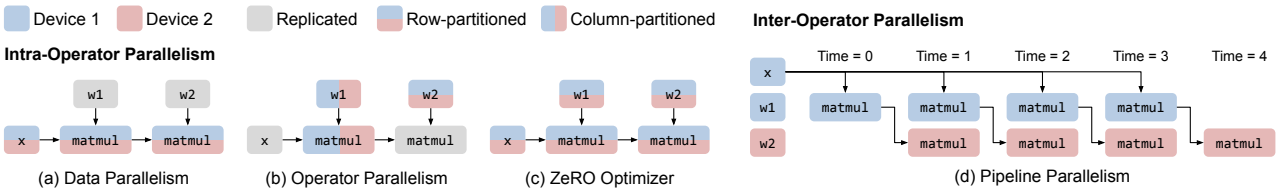

Figure 2: Common parallelization techniques for training a 2-layer Multi-layer Perceptron (MLP). Only the forward pass is shown. "x" is the input data. "w1" and "w2" are two weight matrices.

2.1 Conventional View of ML Parallelism

Existing ML parallelization approaches are typically categorized as data, operator, and pipeline parallelisms.

Data parallelism. In data parallelism, the training data is partitioned across distributed workers, but the model is replicated. Each worker computes the parameter updates on its independent data split, and synchronizes the updates with other workers before the weight update, so that all workers observe consistent model parameters throughout training.

Operator parallelism. When the model is too large to fit in one device, operator parallelism is an effective model parallelism option. Operator parallelism refers to approaches that partition the computation of a specific operator (abbreviated as *op* in the following text), such as matmul shown in Fig. 2b, along *non-batch* axes, and compute each part of the operator in parallel across multiple devices.

Because input tensors are jointly partitioned, when a device computes its op partition, the required portions of input tensors may not reside in its local memory. Communication is thus required to fetch the input data from other devices. When the tensors are partitioned evenly, i.e., SPMD [57], all devices will follow the same collective communication patterns such as all-reduce, all-gather, and all-to-all.

Pipeline parallelism. Instead of partitioning ops, pipeline parallelism places different groups of ops from the model graph, referred as *stages*, on different workers; meanwhile, it splits the training batch as a number of microbatches, and pipelines the forward and backward passes across microbatches on distributed workers, as Fig. 2d shows. Unlike operator parallelism, pipeline parallelism transfers intermediate activations at the forward and backward passes between different workers using point-to-point communication.

Manual combination of parallelisms. Recent development shows the approaches mentioned above need to be combined to scale out today's large DL models [40, 57]. The state-of-the-art training systems, such as Megatron-LM [40, 49], manually design a specialized execution plan that combines these parallelisms for transformer language models, which is also known as *3D Parallelism*. By assuming the model has the same transformer layer repeated, it assigns an equal number of layers to each pipeline stage and applies a hand-designed operator and data parallelism configuration uniformly for all layers. Despite the requirement of strong expertise, the manual plan cannot generalize to different models or different cluster setups (§8.1).

Automatic combination of parallelisms. The configurations of each individual parallelism, their interdependence, and their dependence on model and cluster setups form an intractable space, which prevents the trivial realization of automatically combining these parallelisms. For examples, when coupled with operator parallelism, each time adding a data-parallel replica would require allocating a new set of devices (instead of one single device) as the worker, and figuring out the optimal operator parallelism configurations within those devices. When including pipeline parallelism, the optimal pipelining scheme depends on the data and operator parallelism choices of each pipeline stage and how devices are allocated for each stage. With this conventional view, prior explorations [17, 25, 55, 60] of auto-parallelization are limited to combining data parallelism with at most one model parallelism approach, which misses substantial performance opportunities. We next develop our view of ML parallelisms.

2.2 Intra- and Inter-Operator Parallelisms

Different from the conventional view, in this paper, we recatalog existing parallelization approaches into two orthogonal categories: intra-operator and inter-operator parallelisms. They are distinguished by if they involve partitioning operators along any tensor axis. We next use the examples in Fig. 2 to introduce the two types of parallelisms.

Intra-operator parallelism. An operator works on multi-dimensional tensors. We can partition the tensor along some dimensions, assign the resulting partitioned computations to multiple devices, and let them execute different portions of the operator at the same time. We define all parallelization approaches using this workflow as intra-operator parallelism.

Fig. 2a-c illustrates the application of several typical instantiations of intra-op parallelism on an MLP. Data parallelism [29], by definition, belongs to intra-op parallelism – the input tensors and matmuls are partitioned along the batch dimension, and weight tensors are replicated. Alternatively, when the weights are very large, partitioning the weights (Fig. 2b) leads to the aforementioned operator parallelism adopted in Megatron-LM. Besides operators in the forward or backward passes, one can also partition the operators from the weight update phase, yielding the *weight update sharding* or equivalently the ZeRO [44, 56] technique, commonly comprehended as an optimization of data parallelism.

Due to the partitioning, collective communication is re-

quired at the split and merge of the operator. Hence, a key characteristic of intra-operator parallelism is that it results in substantial communication among distributed devices.

Inter-operator parallelism. We define inter-operator parallelism as the orthogonal class of approaches that *do not* perform operator partitioning, but instead, assign different operators of the graph to execute on distributed devices.

Fig. 2d illustrates the batch-splitting pipeline parallelism as a case of inter-operator parallelism.[2] The pipeline execution can follow different schedules, such as Gpipe [22], PipeDream [38], and synchronous 1F1B [17, 39]. We adopt the synchronous 1F1B schedule throughout this paper as it respects synchronous consistency, and has the same pipeline latency but lower peak memory usage compared to Gpipe.

In inter-operator parallelism, devices communicate only between pipeline stages, typically using point-to-point communication between device pairs. The required communication volume can be much less than the collective communication in intra-operator parallelism. Regardless of the schedule used, due to the data dependency between stages, inter-operator parallelism results in some devices being idle during the forward and backward computation.

By this categorization, the two parallelisms take place at different granularities of the DL computation and have distinct communication requirements, which happen to match the structure of today's compute clusters. We will leverage these properties to design hierarchical algorithms and compilation passes to auto-generate execution plans. Several concurrent work [2, 33, 39, 50] have proposed similar categorization, but Alpa is the first end-to-end system that uses this categorization to automatically generate parallel plans from the full space.

3 Overview

Alpa is a compiler that generates model-parallel execution plans by hierarchically optimizing the plan at two different levels: intra-op and inter-op parallelism. At the intra-op level, Alpa minimizes the cost of executing a stage (i.e., subgraph) of the computational graph, with respect to its intra-operator parallelism plan, on a given device mesh, which is a set of devices that may have high bandwidth between each other (e.g., GPUs within a single server). Different meshes might have different numbers of computing devices according to the workload assigned. At the inter-op level, Alpa minimizes the inter-op parallelization latency, with respect to how to slice the model and device cluster into stages and device meshes and how to map them as stage-mesh pairs. The inter-op optimization depends on knowing the execution cost of each stage-mesh pair reported by the intra-op optimizer. Through this hierarchical optimization process, Alpa generates the execution plan consisting of intra-op and inter-op plans which are locally near-optimal at their respective level of the hierarchy.

To achieve this, Alpa implements three novel compilation passes as Fig. 3 shows. Given a model description, in the form of a Jax [9] intermediate representation (IR), and a cluster configuration, the inter-op compilation pass slices the IR into a number of stages, and slices the device cluster into a number of device meshes. The inter-op pass uses a Dynamic Programming (DP) algorithm to assign stages to meshes and invokes the intra-op compilation pass on each stage-mesh pair, to query the execution cost of this assignment. Once invoked, the intra-op pass optimizes the intra-op parallel execution plan of the stage running on its assigned mesh, by minimizing its execution cost using an Integer Linear Programming (ILP) formulation, and reports the cost back to the inter-op pass. By repeatedly querying the intra-op pass for each allocation of a stage-mesh pair, the inter-op pass uses the DP to minimize the inter-op parallel execution latency and obtains the best slicing scheme of stages and meshes.

Given the output hierarchical plan and a designated pipeline-parallel schedule, each stage is first compiled as a

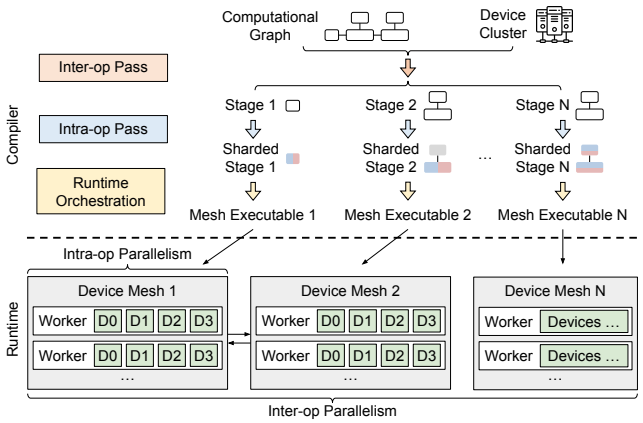

Figure 3: Compiler passes and runtime architecture. A sharded stage is a stage annotated with the sharding specs generated by intra-op pass.

```
# Put @parallelize decorator on top of the Jax functions
@parallelize
def train_step(state, batch):
    def loss_func(params):
        out = state.forward(params, batch["x"])
        return jax.numpy.mean((out - batch["y"]) ** 2)

    grads = grad(loss_func)(state.params)
    new_state = state.apply_gradient(grads)
    return new_state

# A typical training loop
state = create_train_state()
for batch in data_loader:
    state = train_step(state, batch)
```

Figure 4: An example to demonstrate Alpa's API for Jax. The developers uses a Python decorator `@parallelize` to annotate functions that need to be parallelized. The rest of the program is kept intact.

[2]Device placement [36] is another case of inter-op parallelism, which partitions the model graph and executes them on different devices but does not saturate pipelines using multiple microbatches. Hence pipeline parallelism is often seen as a better alternative to it because of less device idle time.

parallel executable on its located mesh. A runtime orchestration pass is invoked to fulfill the communication requirement between two adjacent stages that require communication between the two meshes they locate on. The runtime orchestration pass then generates static instructions specific to each mesh according to the pipeline-parallel schedule and invokes the execution on all meshes.

API. Alpa has a simple API shown in Fig. 4. Alpa requires developers to annotate functions to be parallelized, such as the `train_step()`, using a Python decorator `@parallelize`. Upon the first call to `train_step()`, Alpa traces the whole function to get the model IR, invokes the compilation, and converts the function to a parallel version.

Since the inter-op pass depends on the intra-op pass, in the following text, we first describe the intra-op pass, followed by the inter-op pass, and finally the runtime orchestration pass.

4 Intra-Operator Parallelism

Alpa optimizes the intra-operator parallelism plan within a device mesh. Alpa adopts the SPMD-style intra-op parallelism [31, 57] which partitions operators evenly across devices and executes the same instructions on all devices, as per the fact that devices within a single mesh have equivalent compute capability. This SPMD style significantly reduces the space of intra-op parallelism plans; meanwhile, it conveniently expresses and unifies many important approaches such as data parallelism, ZeRO, Megatron-LM's operator parallelism, and their combinations, which are not fully covered by existing automatic operators parallelism systems, such as Tofu [55] and FlexFlow [25]. Unlike systems that perform randomized search [25] or assume linear graphs [55], Alpa formalizes the problem as an integer linear programming (ILP) and shows it can be solved efficiently for computational graphs with tens of thousands of operators. Next, we describe the space of intra-op parallelism and our solution.

4.1 The Space of Intra-Operator Parallelism

Given an operator in the computational graph, there are multiple possible parallel algorithms to run it on a device mesh. For example, a matrix multiplication $C_{ij} = \sum_k A_{ik} B_{kj}$ corresponds to a three-level for-loop. To parallelize it, we can parallelize the loop i, loop j, loop k, or combinations of them across devices, which would have different computation and communication costs, require different layouts for the input tensors, and result in output tensors with different layouts. If an input tensor does not satisfy the layout requirement, a layout conversion is required, which introduces extra communication costs. The goal of the intra-op pass is to pick one parallel algorithm for every operator to minimize the execution time of the entire graph. Next, we formally define the device mesh and the layout of a tensor and discuss the cost of layout conversion.

Device mesh. A device mesh is a 2-dimensional logical view of a set of physical devices. Each device in the mesh has the same compute capability. Devices can communicate along the first mesh dimension and the second mesh dimension with different bandwidths. We assume different groups of devices along the same mesh dimension have the same communication performance. For a set of physical devices, there can be multiple logical views. For example, given 2 nodes and 8 GPUs per node (i.e., 16 devices in total), we can view them as a 2×8, 1×16, 4×4, 8×2, or 16×1 device mesh. The mapping between physical devices and the logical device mesh view is optimized by the inter-op pass (§5). In the rest of this section, we consider one fixed device mesh view.

Table 1: Sharding specs of a 2-dimentional tensor on a 2×2 device mesh. A is a (N,M) tensor. The device mesh is [[Device 0, Device 1], [Device 2, Device 3]]. Each device stores a partition of A. The first column is the name of the sharding spec. The latter columns use Numpy syntax to describe the partitions stored on each device.

Spec	Device 0	Device 1	Device 2	Device 3
RR	$A[0:N, 0:M]$	$A[0:N, 0:M]$	$A[0:N, 0:M]$	$A[0:N, 0:M]$
S^0S^1	$A[0:\frac{N}{2}, 0:\frac{M}{2}]$	$A[0:\frac{N}{2}, \frac{M}{2}:M]$	$A[\frac{N}{2}:N, 0:\frac{M}{2}]$	$A[\frac{N}{2}:N, \frac{M}{2}:M]$
S^1S^0	$A[0:\frac{N}{2}, 0:\frac{M}{2}]$	$A[\frac{N}{2}:N, 0:\frac{M}{2}]$	$A[0:\frac{N}{2}, \frac{M}{2}:M]$	$A[\frac{N}{2}:N, \frac{M}{2}:M]$
S^0R	$A[0:\frac{N}{2}, 0:M]$	$A[0:\frac{N}{2}, 0:M]$	$A[\frac{N}{2}:N, 0:M]$	$A[\frac{N}{2}:N, 0:M]$
S^1R	$A[0:\frac{N}{2}, 0:M]$	$A[\frac{N}{2}:N, 0:M]$	$A[0:\frac{N}{2}, 0:M]$	$A[\frac{N}{2}:N, 0:M]$
RS^0	$A[0:N, 0:\frac{M}{2}]$	$A[0:N, 0:\frac{M}{2}]$	$A[0:N, \frac{M}{2}:M]$	$A[0:N, \frac{M}{2}:M]$
RS^1	$A[0:N, 0:\frac{M}{2}]$	$A[0:N, \frac{M}{2}:M]$	$A[0:N, 0:\frac{M}{2}]$	$A[0:N, \frac{M}{2}:M]$
$S^{01}R$	$A[0:\frac{N}{4}, 0:M]$	$A[\frac{N}{4}:\frac{N}{2}, 0:M]$	$A[\frac{N}{2}:\frac{3N}{4}, 0:M]$	$A[\frac{3N}{4}:N, 0:M]$
RS^{01}	$A[0:N, 0:\frac{M}{4}]$	$A[0:N, \frac{M}{4}:\frac{M}{2}]$	$A[0:N, \frac{M}{2}:\frac{3M}{4}]$	$A[0:N, \frac{3M}{4}:M]$

Table 2: Several cases of resharding. $all\text{-}gather(x,i)$ means an all-gather of x bytes along the i-th mesh axis. M is the size of the tensor. (n_0, n_1) is the mesh shape.

#	Src Spec	Dst Spec	Communication Cost
1	RR	S^0S^1	0
2	S^0R	RR	$all\text{-}gather(M, 0)$
3	S^0S^1	S^0R	$all\text{-}gather(\frac{M}{n_0}, 1)$
4	S^0R	RS^0	$all\text{-}to\text{-}all(\frac{M}{n_0}, 0)$
5	S^0S^1	$S^{01}R$	$all\text{-}to\text{-}all(\frac{M}{n_0 \cdot n_1}, 1)$

Sharding Spec. We use *sharding spec* to define the layout of a tensor. For an N-dimensional tensor, its sharding spec is defined as $X_0X_1\cdots X_{n-1}$, where $X_i \in \{S, R\}$. If $X_i = S$, it means the i-th axis of the tensor is partitioned. Otherwise, the i-th axis is replicated. For example, for a 2-dimensional tensor (i.e., a matrix), SR means it is row-partitioned, RS means it is column-partitioned, SS means it is both row- and column-partitioned. RR means it is replicated without any partitioning. After we define which tensor axes are partitioned, we then have to map the partitioned tensor axes to mesh axes. We only consider 2-dimensional device meshes, so a partitioned tensor axis can be mapped to either the first or the second axis of the device mesh, or both. We added a superscript to S to denote the device assignment. For example, S^0 means

Table 3: Several parallel algorithms for a batched matmul $C_{b,i,j} = \sum_k A_{b,i,k} B_{b,k,j}$. The notation *all-reduce*(x,i) means an all-reduce of x bytes along the i-th mesh axis. M is the size of the output tensor. (n_0, n_1) is the mesh shape.

#	Parallel Mapping	Output Spec	Input Specs	Communication Cost
1	$i \to 0, j \to 1$	RS^0S^1	RS^0R, RRS^1	0
2	$i \to 0, k \to 1$	RS^0R	RS^0S^1, RS^1R	*all-reduce*$(\frac{M}{n_0}, 1)$
3	$j \to 0, k \to 1$	RRS^0	RRS^1, RS^1S^0	*all-reduce*$(\frac{M}{n_0}, 1)$
4	$b \to 0, i \to 1$	S^0S^1R	S^0S^1R, S^0RR	0
5	$b \to 0, k \to 1$	S^0RR	S^0RS^1, S^0S^1R	*all-reduce*$(\frac{M}{n_0}, 1)$
6	$i \to \{0,1\}$	$RS^{01}R$	$RS^{01}R, RRR$	0
7	$k \to \{0,1\}$	RRR	$RRS^{01}, RS^{01}R$	*all-reduce*$(M, \{0,1\})$

the partitions are along the 0-th axis of the mesh, S^{01} means the partitions take place along both mesh axes. S^0R means the tensor is row-partitioned into two parts – The first part is replicated on device 0 and device 1, and the second part is replicated on device 2 and device 3. Table 1 shows all possible sharding specs of a 2-dimensional tensor on a 2×2 mesh with 4 devices.

Resharding. When an input tensor of an operator does not satisfy the sharding spec of the chosen parallel algorithm for the operator, a layout conversion, namely *resharding*, is required, which might require cross-device communication. Table 2 lists several cases of resharding. For instance, to convert a fully replicated tensor to any other sharding specs (case #1), we can slice the tensor locally without communication; to swap the partitioned axis (case #4), we perform an all-to-all.

Parallel algorithms of an operator. With the definitions above, consider parallelizing a batched matmul $C_{b,i,j} = \sum_k A_{b,i,k} B_{b,k,j}$ on a 2D mesh – Table 3 lists several intra-op parallel algorithms for a batched matmul. Algorithm#1 maps loop i to the 0-th mesh axis and loop j to the 1-th mesh axis, resulting in the output tensor C with a sharding spec RS^0S^1. As the LHS operand $A_{b,i,k}$ and RHS operand $B_{b,k,j}$ both have only one parallelized index, their sharding specs are written as RS^0R and RRS^1, respectively. In this algorithm, each device has all its required input tiles (i.e., a partition of the tensor) stored locally to compute its output tile, so there is no communication cost. In Algorithm #2 in Table 3, when the reduction loop k is parallelized, all-reduce communication is needed to aggregate the partial sum. Similarly, we can derive the sharding specs and communication costs of other parallel algorithms for a batched matmul.

For other primitive operators such as convolution and reduction, we can get a list of possible parallel algorithms following a similar analysis of their math expressions. In the intra-op pass, the model graph is represented in XLA's HLO format [51], which summarizes common DL operators into less than 80 primitive operators, so we can manually enumerate the possible parallel algorithms for every primitive operator.

4.2 ILP Formulation

The total execution cost of a computational graph $G = (V, E)$ is the sum of the compute and communication costs on all nodes $v \in V$ and the resharding costs on all edges $e \in E$. We formulate the cost minimization as an ILP and solve it optimally with an off-the-shelf solver [18].

For node v, the number of possible parallel algorithms is k_v. It then has a communication cost vector c_v of length k_v, or $c_v \in \mathbb{R}^{k_v}$, where c_{vi} is the communication cost of the i-th algorithm. Similarly, node v has a compute cost vector $d_v \in \mathbb{R}^{k_v}$. For each node v, we define an one-hot decision vector $s_v \in \{0,1\}^{k_v}$ to represent the algorithm it uses. $s_{vi} = 1$ means we pick the i-th algorithm for node v. For the resharding cost between node v and node u, we define a resharding cost matrix $R_{vu} \in \mathbb{R}^{k_v \times k_u}$, where R_{vuij} is the resharding cost from the output of i-th strategy of node v to the input of j-th strategy of node u. The objective of the problem is

$$\min_s \sum_{v \in V} s_v^\intercal (c_v + d_v) + \sum_{(v,u) \in E} s_v^\intercal R_{vu} s_u, \tag{1}$$

where the first term is the compute and communication cost of node v, and the second is the resharding cost of the edge (v,u). In this formulation, s is the variable, and the rest are constant values. The term $s_v^\intercal R_{vu} s_u$ in Eq. 1 is quadratic, and cannot be fed into an ILP solver. We linearize [19] the quadratic term by introducing a new decision vector $e_{vu} \in \{0,1\}^{k_v \cdot k_u}$ which represents the resharding decision between node v and u.

Although we can use profiling to get the accurate costs for c_v, d_v, and R_{vu}, we use the following methods to estimate them for simplicity. For communication costs d_v and R_{vu}, we compute the numbers of communicated bytes and divide them by the mesh dimension bandwidth to get the costs. For compute costs c_v, we set all of them as zero following the same motivation in [55]. This is reasonable because: (1) For heavy operators such as matmul, we do not allow replicated computation. All parallel algorithms always evenly divide the work to all devices, so all parallel algorithms of one operator have the same arithmetic complexity; (2) For lightweight operators such as element-wise operators, we allow replicated computation of them, but their computation costs are negligible.

To simplify the graph, we merge computationally-trivial operators, such as element-wise operators, transpose, and reduction, into one of their operands and propagate the sharding spec from the operand. This greatly reduces the number of nodes in the graph, thus the ILP problem size. We do a breath-first-search and compute the depth of each node. The node is merged to the deepest operand.

Once the parallel plan is decided by ILP, we also apply a set of post-ILP communication optimizations, such as replacing all-reduce with reduce-scatter and all-gather, whenever applicable, because the latter reduces the number of replicated tensors and corresponding computations, while keeping the communication volume the same. This achieves the effect of weight update sharding [56] or ZeRO optimizer [44].

5 Inter-Operator Parallelism

In this section, we develop methods to slice the model and device cluster into stage-mesh pairs. Our optimization goal is to minimize the *end-to-end* pipeline execution latency for the entire computational graph. Previous works [17, 33] have considered simplified problems, such as assuming the device for each stage is pre-assigned, and all stages have fixed data or operator parallelism plan. Alpa rids these assumptions by jointly considering device mesh assignment and the existence of varying intra-op parallelism plans on each stage.

5.1 The Space for Inter-Operator Parallelism

Assume the computational graph contains a sequence of operators following the topology order of the graph[3], notated as $o_1, \ldots, o_K$, where the inputs of an operator o_k are from operators $o_1, \ldots, o_{k-1}$. We slice the operators into S stages $s_1, \ldots, s_S$, where each stage s_i consists of operators $(o_{l_i}, \ldots, o_{r_i})$, and we assign each stage s_i to a submesh of size $n_i \times m_i$, sliced from a computer cluster that contains devices, notated as the *cluster mesh* with shape $N \times M$. Let $t_i = t_{intra}(s_i, Mesh(n_i, m_i))$ be the latency of executing stage s_i on a submesh of $n_i \times m_i$, minimized by the ILP and reported back by the intra-op pass (§4). As visualized in Fig. 5, assuming we have B different input microbatches for the pipeline, the total minimum latency[4] for the entire computation graph is written as:

$$T^* = \min_{\substack{s_1,\ldots,s_S; \\ (n_1,m_1),\ldots,(n_S,m_S)}} \left\{ \sum_{i=1}^{S} t_i + (B-1) \cdot \max_{1 \le j \le S} \{t_j\} \right\}. \quad (2)$$

The overall latency contains two terms: the first term is the total latency of all stages, interpreted as the latency of the first microbatch going through the pipeline; the second term is the pipelined execution time for the rest of $B-1$ microbatches, which is bounded by the slowest stage (stage 3 in Fig. 5).

We aim to solve Eq. 2 with two additional constraints: (1) For an operator in the forward pass of the graph, we want to colocate it with its corresponded backward operator on the same submesh. Since backward propagation usually uses the similar set of tensors during forward propagation, this effectively reduces the amount of communication to fetch the required tensors generated at the forward pass to the backward pass. We use the sum of forward and backward latency for t_{intra}, so Eq. 2 reflects the total latency, including both forward and backward propagation. (2) We need the sliced submeshes $(n_1, m_1), \ldots, (n_S, m_S)$ to fully cover the $N \times M$ cluster mesh – we do not waste any compute device resources. We next elaborate on our DP formulation.

[3] We simply use the order of how users define each operator, reflected in the model IR, with the input operator as the origin. This allows us to leverage the inherent locality present in the user's program – closely related nodes in the graph will be more likely to be partitioned into the same stage.

[4] This formulation holds for GPipe and synchronous 1F1B schedules. Other pipeline schedules may require a different formulation.

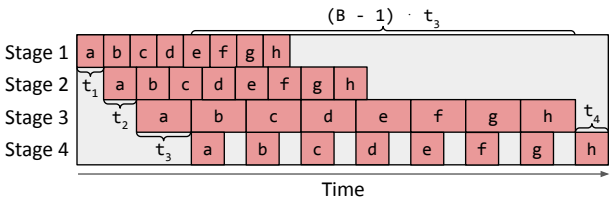

Figure 5: Illustration of the total latency of a pipeline, which is determined by two parts: the total latency of all stages ($t_1 + t_2 + t_3 + t_4$) and the latency of the slowest stage ($(B-1) \cdot t_3$).

5.2 DP Formulation

To ensure all submeshes $(n_1, m_1), \ldots, (n_S, m_S)$ fully cover the $N \times M$ cluster mesh, we reduce the available submesh shapes into two options: (1) one-dimensional submeshes of sizes $(1,1), (1,2), (1,4) \ldots (1,2^m)$ and (2) two-dimensional submeshes of size $(2,M), (3,M), \ldots, (N,M)$ that fully use the second dimension of the cluster mesh (i.e., on a GPU cluster, this means using all compute devices in each physical machine). We include a theorem in Appendix A that proves these submesh shapes can always fully cover the cluster mesh. To assign physical devices in the cluster to the resulting submeshes find by the DP algorithm, we enumerate by assigning devices to larger submeshes first and then to smaller ones. When there are multiple pipeline stages with the same submesh shape, we tend to put neighboring pipeline stages closer on the device mesh to reduce communication latency.

The simplification on submesh shapes works well for most available cloud deep learning setups: On AWS [3], the GPU instances have 1, 2, 4, or 8 GPUs; on GCP [20], the TPU instances have 8, 32, 128, 256 or 512 TPUs. The set of submesh shapes (n,m) excluded by the assumption is with $n > 1$ and $m < M$, which we observe lead to inferior results, since an alternative submesh with shape (n', M) where $n' \cdot M = n \cdot m$ has more devices that can communicate with high bandwidth. With this reduction, we only need to ensure that $\sum_{i=1}^{S} n_i \cdot m_i = N \cdot M$.

To find T^* in Eq. 2, we develop a DP algorithm. The DP first enumerates the second term $t_{max} = \max_{1 \le j \le S} t_j$ and minimizes the first term $t_{total}(t_{max}) = \sum_{1 \le i \le S} t_i$ for each different t_{max}. Specifically, we use the function $F(s,k,d;t_{max})$ to represent the minimal total latency when slicing operators o_k to o_K into s stages and putting them onto d devices so that the latency of each stage is less than t_{max}. We start with $F(0, K+1, 0; t_{max}) = 0$, and derive the optimal substructure of F as

$$F(s,k,d;t_{max}) \quad (3)$$
$$= \min_{\substack{k \le i \le K \\ n_s \cdot m_s \le d}} \left\{ \begin{array}{l} t_{intra}((o_k, \ldots, o_i), Mesh(n_s, m_s), s) \\ + F(s-1, i+1, d - n_s \cdot m_s; t_{max}) \\ \mid t_{intra}((o_k, \ldots, o_i), Mesh(n_s, m_s), s) \le t_{max} \end{array} \right\},$$

and derive the optimal total latency as

$$T^*(t_{max}) = \min_s\{F(s,0,N\cdot M;t_{max})\} + (B-1)\cdot t_{max}. \quad (4)$$

The value of $t_{intra}((o_k,\ldots,o_i),Mesh(n_s,m_s),s)$ is determined by the intra-op pass. It is the lowest latency of executing the subgraph $(o_k,\ldots,o_i)$ on mesh $Mesh(n_s,m_s)$ with s subsequent stages. Note that $Mesh(n_s,m_s)$ is a set of physical devices – hence, we enumerate all the potential choices of logical device mesh shapes (n_l,m_l) satisfying $n_l\cdot m_l = n_s\cdot m_s$. For each choice, we query the intra-op pass with subgraph $(o_k,\ldots,o_i)$, logical mesh (n_l,m_l), and other intra-op options as inputs and get an intra-op plan. We then compile the subgraph with this plan and all other low-level compiler optimizations (e.g., fusion, memory planning) to get an executable for precise profiling. The executable is profiled in order to get the stage latency (t_l) and the memory required on each device to run the stage (mem_{stage}) and to store the intermediate activations (mem_{act}). We check whether the required memory fits the device memory (mem_{device}) according to the chosen pipeline execution schedule. For example, for 1F1B schedule [17, 39], we check

$$mem_{stage} + s\cdot mem_{act} \le mem_{device}. \quad (5)$$

We pick the logical mesh shape that minimizes t_l and fits into the device memory. If none of them fits, we set $t_{intra}=\infty$.

Our algorithm builds on top of that in TeraPipe [33]. However, TeraPipe assumes all pipeline stages are the same, and the goal is to find the optimal way to batch input tokens into micro-batches of different sizes. Instead, Alpa aims to group the operators of a computational graph into different pipeline stages, while assuming the input micro-batches are of the same size. In addition, Alpa optimizes the mesh shape in the DP algorithm for each pipeline stage in inter-op parallelism.

Complexity. Our DP algorithm computes the slicing in $O(K^3NM(N+\log(M)))$ time for a fixed t_{max}. t_{max} has at most $O(K^2(N+\log(M)))$ choices: $t_{intra}((o_i,\ldots,o_j),Mesh(n_s,m_s))$ for $i,j=1,\ldots,K$ and all the submesh choices. The complexity of this DP algorithm is thus $O(K^5NM(N+\log(M))^2)$.

This complexity is not feasible for a large computational graph of more than ten thousand operators. To speed up this DP, we introduce a few practical optimizations.

Performance optimization #1: early pruning. We use one optimization that is similar to that in TeraPipe [33]. We enumerate t_{max} from small to large. When $B\cdot t_{max}$ is larger than the current best T^*, we immediately stop the enumeration. This is because larger t_{max} can no longer provide a better solution. Also, during enumeration of t_{max}, we only evaluate a choice of t_{max} if it is sufficiently larger than the last t_{max} (by at least ε). This allows the gap between the solution found by the DP algorithm and the global optima to be at most $B\cdot\varepsilon$. We empirically choose $\varepsilon = 10^{-6}$ s, and we find that the solution output by our algorithm is the same as the real optimal solution ($\varepsilon = 0$) for all our evaluated settings.

end for

Performance optimization #2: operator clustering. Many operators in a computational graph are not computationally intensive (e.g., ReLU), and the exact placement of these operators has little impact on the total execution time. We develop another DP algorithm [4] to cluster neighboring operators to

reduce the total size of the graph Eq. 2 works on. We cluster the operators $(o_1, \ldots, o_K)$ into a series of layers[5] $(l_1, \ldots, l_L)$, where $L \ll K$. The goal of the algorithm is to merge two types of operators: (1) those that do not call for much computation but lengthen the computational graph and (2) neighboring operators that may cause substantial communication if put on different device meshes. We define function $G(k,r)$ as the minimum of maximal amount of data received by a single layer when clustering operators $(o_1, \ldots, o_k)$ into r layers. Note that G has the following optimal substructure:

$$G(k,r) \tag{6}$$
$$= \min_{1 \le i \le k} \left\{ \left| \begin{array}{l} \max\{G(i-1,r-1), C(i,k)\} \\ FLOP(o_i, \ldots, o_k) \le \dfrac{(1+\delta) FLOP_{total}}{L} \end{array} \right. \right\},$$

where $C(i,k)$ denotes the total size of inputs of $(o_i, \ldots, o_k)$ received from $(o_1, \ldots, o_{i-1})$ and $FLOP_{total} = FLOP(o_1, \ldots, o_K)$ is the total FLOP of the whole computational graph. We make sure that each clustered layer's FLOP is within $1+\delta$ times of the average FLOP per layer while minimizing the communication. For the solutions with the same communication cost, we choose the one with the most uniform structure by also minimizing the variance of per-layer FLOP. With our DP algorithm, we can compute the best layer clustering in $O(K^2 L)$ time. Note that L here is a hyperparameter to the algorithm. In practice, we choose a small L based on the number of devices and the number of heavy operators in the graph. We find different choices of L do not affect the final performance significantly.

Alg. 1 summarizes the workflow of the inter-op pass and illustrates its interactions with the intra-op pass in §4.

6 Parallelism Orchestration

After stages, device meshes, and their assignments are decided, at the intra-op level, Alpa compiles each stage against its assigned device mesh, respecting the intra-op parallelism plan output by the ILP solver. The compilation depends on XLA [51] and GSPMD [57], and generates parallel executables for each stage-mesh pair. When needed, the compilation automatically inserts collective communication primitives (see §4) to address the *within-mesh* communication caused by intra-op parallelism.

At the inter-op level, Alpa implements an additional parallelism orchestration pass to address the *cross-mesh* communication between stages, and generate static instructions for inter-op parallel execution.

Cross-mesh resharding. Existing manual systems, such as Megatron-LM [45, 49], constrain all pipeline stages to have the same degrees of data and tensor model parallelism, so the communication between pipeline stages is trivially realized by P2P send/recv between corresponded devices of two equivalent device meshes (Fig. 6a). In Alpa, the device meshes holding two adjacent stages might have different mesh shapes, and the tensor to communicate between two stages might have different sharding specs (Fig. 6b and Fig. 6c). We call this communication pattern as *cross-mesh resharding*, which is a many-to-many multicast problem.

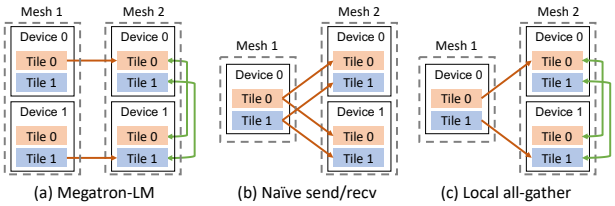

Figure 6: Cross-mesh resharding. Red arrows denote send/recv on slow connections. Green arrows denote all-gather on fast connections. (a) The scatter-gather optimization for equal mesh shapes in Megatron-LM. (b) The naive send/recv for unequal mesh shapes. (c) The generalized local all-gather optimization for unequal mesh shapes.

Given the sharding specs of the tensor on the sender and receiver mesh, Alpa generates a communication plan to address cross-mesh sharding in two iterations. In the first iteration, Alpa calculates the correspondences between tensor partitions (a.k.a. tiles) on the source and destination mesh. Based on that, it generates P2P send/recv primitives between the source devices and destination devices to fulfill the communication. It then takes a second iteration to identify opportunities where the destination tensor has a replication in its sharding spec. In this case, the tensor only needs to be transferred once between two meshes, then exchanged via all-gather across the devices on the destination mesh using its higher bandwidth (Fig. 6) – it rewrites send/recv generated at the first iteration into all-gather to avoid repeated communication.

We call this approach as *local all-gather* cross-mesh resharding. Since the communication between stages is normally small by our design, our experiments show that it performs satisfactorily well (§8.5). We defer the development of the optimal cross-mesh resharding plan to future work.

Generating pipeline execution instructions. As the final step, Alpa generates static execution instructions to launch the training on clusters. Since each stage has different sets of operators and may locate on meshes with different shapes, in contrast to many SPMD pipeline-parallel training systems [40, 57], Alpa adopts an MPMD-style runtime to orchestrate the inter-op parallel execution – Alpa generates distinct static execution instructions for each device mesh.

Alpa develops a set of instructions for inter-op parallel execution, including instructions for allocating and deallocating memory for tensors in a stage, communicating tensors between stages following the cross-mesh resharding plan, synchronization, and computation, etc. According to a user-selected pipeline schedule, Alpa uses a driver process to gen-

[5] Note that the clustering does not exactly reproduce the layers with original machine learning semantics in the model definition.

erate the instructions in advance and dispatches the whole instruction lists to each worker before execution, avoiding driver-worker coordination overheads during runtime.

7 Limitations and Discussion

In this section, we discuss advantages of our view of parallelisms and several limitations of our algorithms.

Compared to existing work that manually combines data, operator, and pipeline parallelism, such as 3D parallelism [45] and PTD-P [40], Alpa's hierarchical view of inter- and intra-op parallelisms significantly advances them with three major flexibility: (1) pipeline stages can contain an uneven number of operators or layers; (2) pipeline stages in Alpa might be mapped to device meshes with different shapes; (3) within each stage, the data and operator parallelism configuration is customized non-uniformly on an operator-by-operator basis. Together, they allow Alpa to unify all existing model parallelism approaches and generalize to model architectures and cluster setups with more heterogeneity.

Despite these advantages, Alpa's optimization algorithms currently have a few limitations:

• Alpa does not model the communication cost between different stages because the cross-stage communication cost is *by nature small*. In fact, modeling the cost in either the DP or ILP is possible, but would require enumerating exponentially more intra-op passes and DP states.

• The inter-op pass currently has a hyperparameter: the number of micro-batches B, which is not optimized by our current formulation but can be searched by enumeration.

• The inter-op pass models pipeline parallelism with a static linear schedule, without considering more dynamic schedules that, for example, parallelize different branches in a computational graph on different devices.

• Alpa does not optimize for the best scheme of overlapping computation and communication; Alpa can only handle static computational graphs with all tensor shapes known at compilation time.

Nevertheless, our results on weak scaling (§8) suggest that Alpa is able to generate near-optimal execution plans for many notable models.

8 Evaluation

Alpa is implemented using about 16K LoC in Python and 6K LoC in C++. Alpa uses Jax as the frontend and XLA as the backend. The compiler passes are implemented on Jax's and XLA's intermediate representation (i.e., Jaxpr and HLO). For the distributed runtime, we use Ray [37] actor to implement the device mesh worker, XLA runtime for executing computation, and NCCL [41] for communication.

We evaluate Alpa on training large-scale models with billions of parameters, including GPT-3 [10], GShard Mixture-of-Experts (MoE) [31], and Wide-ResNet [59]. The testbed is a typical cluster consisting of 8 nodes and 64 GPUs. Each node is an Amazon EC2 p3.16xlarge instance with 8 NVIDIA V100 16 GB GPUs, 64 vCPUs, and 488 GB memory. The 8 GPUs in a node are connected via NVLink. The 8 nodes are launched within one placement group with 25Gbps cross-node bandwidth.

Table 4: Models used in the end-to-end evaluation. LM = language model. IC = image classification.

Model	Task	Batch size	#params (billion)	Precision
GPT-3 [10]	LM	1024	0.35, 1.3, 2.6, 6.7, 15, 39	FP16
GShard MoE [31]	LM	1024	0.38, 1.3, 2.4, 10, 27, 70	FP16
Wide-ResNet [59]	IC	1536	0.25, 1.0, 2.0, 4.0, 6.7, 13	FP32

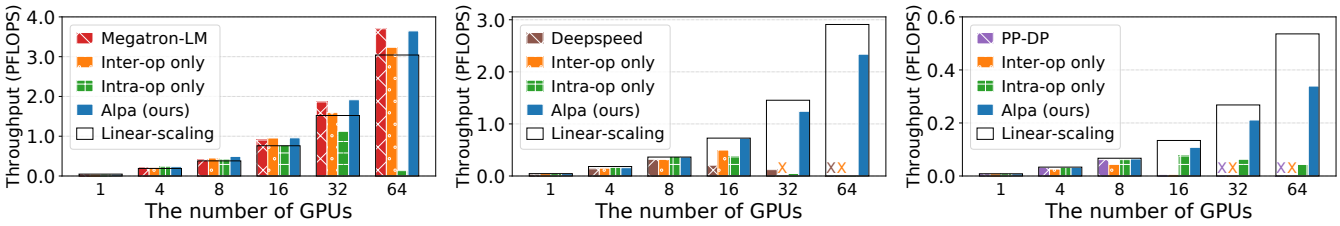
We compare Alpa against two state-of-the-art distributed systems for training large-scale models on GPUs. We then isolate different compilation passes and perform ablation studies of our optimization algorithms. We also include a case study of the execution plans found by Alpa.

8.1 End-to-End Performance

Models and training workloads. We target three types of models listed in Table 4, covering models with both homogeneous and heterogeneous architectures. GPT-3 is a homogeneous transformer-based LM by stacking many transformer layers whose model parallelization plan has been extensively studied [40, 49]. GShard MoE is a mixed dense and sparse LM, where mixture-of-experts layers are used to replace the MLP at the end of a transformer, every two layers. Wide-ResNet is a variant of ResNet with larger channel sizes. It is vastly different from the transformer models and there are no existing manually designed strategies.

To study the ability to train large models, we follow common ML practice to scale the model size along with the number of GPUs, with the parameter range reported in Table 4. More precisely, for GPT-3, we increase the hidden size and the number of layers together with the number of GPUs following [40], whereas for MoE we mainly increase the number of experts suggested by [31, 57]. For Wide-ResNet, we increase the channel size and width factor in convolution layers. For each model, we adopt the suggested global batch size per ML practice [10, 31, 40, 59] to keep the same statistical behavior. We then tune the best microbatch size for each model and system configuration that maximizes the system performance. The gradients are accumulated across microbatches. The detailed model specifications are provided in Appendix B.

Baselines. For each model, we compare Alpa against a strong baseline. We use Megatron-LM v2 [40] as the baseline system for GPT-3. Megatron-LM is the state-of-the-art system for training homogeneous transformer-based LMs on GPUs. It combines data parallelism, pipeline parallelism, and manually-designed operator parallelism (denoted as TMP later). The combination of these techniques is controlled by three integer parameters that specify the parallelism degrees assigned to each technique. We grid-search the three parameters following the guidance of their paper and report the results of the best configuration. Megatron-LM is specialized for GPT-like models, so it does not support other models in Table 4.



(a) GPT (b) MoE (c) Wide-ResNet

Figure 7: End-to-end evaluation results. "×" denotes out-of-memory. Black boxes represent linear scaling.

We use DeepSpeed [45] as the baseline for MoE. DeepSpeed provides a state-of-the-art implementation for training MoE on GPUs. It combines handcrafted operator parallelism for MoE layers and ZeRO-based [44] data parallelism. The combination of these techniques is controlled by several integer parameters that specify the parallelism degree assigned to each technique. We also grid-search them and report the best results. The performance of DeepSpeed on GPT-3 is similar to or worse than Megatron-LM, so we skip it on GPT-3. Note that original GShard-MoE [31] implementation is only available on TPUs, thus we do not include its results, though their strategies [31] are covered by Alpa 's strategy space.

For large Wide-ResNet, there is no specialized system or manually designed plan for it. We use Alpa to build a baseline "PP-DP" whose space only consists of data parallelism and pipeline parallelism, which mimics the parallelism space of PipeDream [38] and Dapple [17].

For all models, we also include the results of using Alpa with only one of intra- and inter-operator parallelism, which mimics the performance of some other auto-parallel systems. The open-source Flexflow [25] does not support the models we evaluate, as it lacks support for many necessary operators (e.g., layer normalization [5], mixed-precision operators). Tofu [55] only supports single node execution and is not open-sourced. Due to both theoretical and practical limitations, we do not include their results and we do not expect Flexflow or Tofu to outperform the state-of-the-art manual baselines in our evaluation.

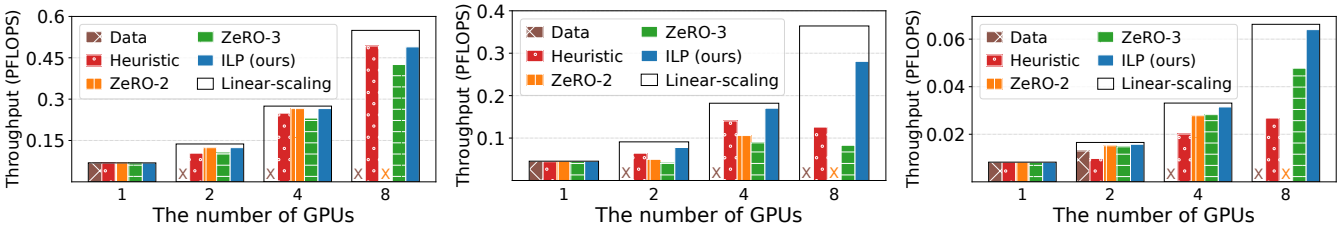
Evaluation metrics. Alpa does not modify the semantics of the synchronous gradient descent algorithm, thus does not affect the model convergence. Therefore, we measure training throughput in our evaluation. We evaluate weak scaling of the system when increasing the model size along with the number of GPUs. Following [40], we use the aggregated peta floating-point operations per second (PFLOPS) of the whole cluster as the metric[6]. We measure it by running a few batches with dummy data after proper warmup. All our results (including those in later sections) have a standard deviation within 0.5%, so we skip the error bars in our figures.

GPT-3 results. The parallelization plan for GPT-3 has been extensively studied [10, 33, 40]. We observe in Fig. 7a that this manual plan with the best grid-searched parameters enables Megatron-LM to achieve super-linear weak scaling on GPT-3. Nevertheless, compared to Megatron-LM, Alpa automatically generates execution plans and even achieves slightly better scaling on several settings. If compared to methods that only use intra-operator parallelism, our results are consistent with recent studies – "Intra-op only" performs poorly on >16 GPUs because even the best plan has to communicate tensors heavily on cross-node connections, making communication a bottleneck. Surprisingly, "Inter-op only" performs well and maintains linear scaling on up to 64 GPUs.

We investigate the grid-searched parameters of the manual plan on Megatron-LM, and compare it to the plan generated by Alpa. It reveals two major findings. First, in Megatron-LM, the best manual plan has TMP as 1, except in rare settings, such as fitting the 39B model on 64 GPUs, where pipeline parallelism alone is unable to fit the model (stage) in GPU memory; meanwhile, data parallelism is maximized whenever memory allows. In practice, gradient accumulation (GA) is turned on to achieve a desired global batch size (e.g., 1024 in our setting). GA amortizes the communication of data parallelism and reduces the bubbles of pipeline parallelism, but the communication of TMP grows linearly with GA steps, which puts TMP disadvantaged. Second, Alpa-generated plan closely resembles the best-performed ones in Megatron-LM, featuring (1) evenly-sized stages, (2) partitioning along the batch dimension in stages when memory is not stressed, but along non-batch dimensions when memory is stressed. One key difference between our plan and the manual plan is that Alpa also partitions the weight update operations when data parallelism exists, which contributes to the slight performance improvement over Megatron-LM. This attributes to the fact that Alpa, as a generic compiler system, can compose a wide range of parallelism approaches, while Megatron-LM, for now, misses weight update sharding support.

MoE results. DeepSpeed adopts a manual operator parallelism plan for MoE models, developed by GShard [31], called *expert parallelism*, which uses a simple rule: it partitions the expert axis for the operators in MoE layers, but switches back to data parallelism for non-expert layers. This expert parallelism is then combined with ZeRO data parallelism and TMP. All of these techniques belong to intra-operator parallelism. Unfortunately, DeepSpeed's specialized implementation does not include any inter-operator parallelism approach, which is

[6] As the models are different for different numbers of GPUs, we cannot measure scaling on the system throughput such as tokens per second or images per second.



(a) GPT (b) MoE (c) Wide-ResNet

Figure 8: Intra-operator parallelism ablation study. "×" denotes out-of-memory. Black boxes represent linear scaling.

required for scaling across multiple nodes with low inter-node bandwidth. Therefore, Deepspeed only maintains a good performance within a node ($\leq$ 8 GPUs) on this cluster. "Intra-op only" fails to scale across multiple nodes due to the same reason. "Inter-op only" runs out of memory on 32 GPUs and 64 GPUs because it is not easy to equally slice the model when the number of GPUs is larger than the number of layers of the model. The imbalanced slicing makes some memory-intensive stages run out of memory.

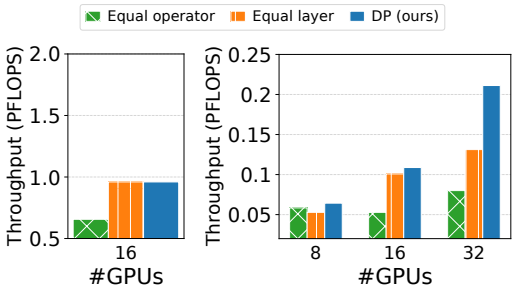
By contrast, Alpa automatically discovers the best execution plans that combine intra- and inter-operator parallelism. For intra-operator parallelism, Alpa finds a strategy similar to expert parallelism and combines it with ZeRO data parallelism, thanks to its ILP-based intra-op pass. Alpa then constructs stages and uses inter-operator parallelism to favor small communication volume on slow connections. Alpa maintains linear scaling on 16 GPUs and scales well to 64 GPUs. Compared to DeepSpeed, Alpa achieves 3.5× speedup on 2 nodes and a 9.7× speedup on 4 nodes.

Wide-ResNet results. Unlike the previous two models that stack the same layer, Wide-ResNet has a more heterogeneous architecture. As the data batch is forwarded through layers, the size of the activation tensor shrinks while the size of the weight tensor inflates. This leads to an imbalanced distribution of memory usage and compute intensity across layers. For this kind of model, it is difficult, if not impossible, to manually design a plan. However, Alpa still achieves a scalable performance on 32 GPUs with 80% scaling. The baselines "PP-DP" and "Inter-op only" run out of memory when training large models, because they cannot partition weights to reduce the memory usage, and it is difficult to construct memory-balanced stages for them. "Intra-only" requires a lot of communication on slow connections, so it cannot scale across multiple nodes. A case study on the generated plan for Wide-ResNet is in §8.6.

8.2 Intra-Op Parallelism Ablation Study

We study the effectiveness of our intra-operator parallelism optimization algorithm. We compare our ILP-based solution against alternatives such as ZeRO optimizer and rule-based partitioning strategies.

Experimental setup. We run a weak scaling benchmark in terms of model size similar to §8.1, but disable pipeline parallelism and gradient accumulation to control variables. The



(a) GPT (b) Wide-ResNet

Figure 9: Inter-operator parallelism ablation study.

benchmark is done on one AWS p3.16xlarge instance with 8 GPUs. In order to simulate an execution environment of large-scale training in one node, we use larger hidden sizes, smaller batch sizes, and smaller numbers of layers, compared to the model configurations in §8.1.

Baselines. We compare automatic solutions for intra-operator parallelism. "Data" is vanilla data parallelism. "ZeRO-2" [44] is a memory-efficient version of data parallelism which partitions gradients and optimizer states. "ZeRO-3" [44] additionally partitions parameters on top of "ZeRO-2". "Heuristic" uses a rule combined with the sharding propagation in GSPMD. It marks the largest dimension of every input tensor as partitioned and runs sharding propagation to get the sharding specs for all nodes in the graph. "ILP" is our solution based on the ILP solver.

Results. As shown in Fig. 8, "Data" runs out of memory quickly and cannot train large models. "ZeRO-2" and "ZeRO-3" resolve the memory problem of data parallelism, but they do not optimize for communication as they always communicate the gradients. When the gradients are much larger than activations, their performance degenerates. "Heuristic" solves the memory issue by partitioning all tensors, but can be slowed down by larger communication. "Auto-sharding" performs best in all cases and maintains a near-linear scaling, because it figures out the correct partition plan that always minimizes the communication overhead.

8.3 Inter-Op Parallelism Ablation Study

We study the effectiveness of our inter-operator parallelism optimization algorithm. We use "DP" to denote our algorithm.

Experimental setup. We report the performance of three variants of our DP algorithm on GPT and Wide-ResNet. The

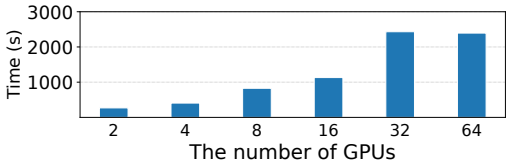


Figure 10: Alpa's compilation time on all GPT models. The model size and #GPUs are simultaneously scaled.

benchmark settings are the same as the settings in §8.1.

Baselines. We compare our DP algorithm with two rule-based algorithms. "Equal operator" disables our DP-based operator clustering but assigns the same number of operators to each cluster. "Equal layer" restricts our DP algorithm to use the same number of layers for all stages.

Results. Fig. 9 shows the result. "DP" always outperforms "Equal operator". This is because "Equal operator" merges operator that should be put onto different device meshes. Alpa's algorithm can cluster operators based on the communication cost and computation balance. Whether "DP" can outperform "Equal layer" depends on the model architecture. On homogeneous models like GPT, the solution of our DP algorithm uses the same number of layers for all stages, so "Equal layer" performs the same as "DP". On Wide-ResNet, the optimal solution can assign different layers to different stages, so "Equal layer" is worse than the full flexible DP algorithm. For Wide-ResNet on 32 GPUs, our algorithm outperforms "Equal operator" and "Equal layer" by 2.6× and 1.6×, respectively.

8.4 Compilation Time

Fig. 10 shows Alpa's compilation time for all the GPT settings in §8.1. The compilation time is a single run of the full Alg. 1 with a provided number of microbatches B. According to the result, Alpa scales to large models or large clusters well, because compilation time grows linearly with the size of the model and the number of GPUs in the cluster. Table 5 reports the compilation time breakdown for the largest GPT model in our evaluation (39B, 64 GPUs). Most of the time is spent on enumerating stage-mesh pairs and profiling them. For the compilation part, we accelerate it by compiling different stages in parallel with distributed workers. For profiling, we accelerate it using a simple cost model built at the XLA instruction level, which estimates the cost of matrix multiplication and communication primitives with a piece-wise linear model. With these optimizations, the compilation and search for a model take at most several hours, which is acceptable as it is much shorter than the actual training time, which can take several weeks.

8.5 Cross-Mesh Resharding

We evaluate our generalized local all-gather optimization for cross-mesh resharding between meshes with different shapes on Wide-ResNet, as shown in Fig. 11. "signal send/recv" is a synthetic case where we only send 1 signal byte between stages, which can be seen as the upper bound of the performance. "w/o local all-gather" disables our local all-gather optimization and uses only send/recv. "w/ local all-gather" enables our local all-gather optimization to move more communication from slow connections to fast local connections, which brings 2.0× speedup on 32 GPUs.

Table 5: Compilation time breakdown of GPT-39B.

Steps	Ours	w/o optimization
Compilation	1582.66 s	> 16hr
Profiling	804.48 s	> 24hr
Stage Construction DP	1.65 s	N/A
Other	4.47 s	N/A
Total	2393.26 s	> 40hr

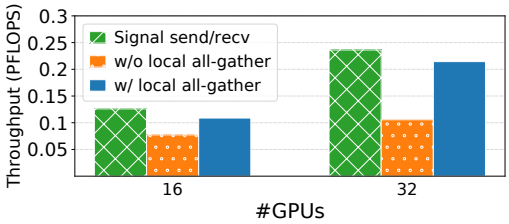

Figure 11: Cross-mesh resharding on Wide-ResNet.

8.6 Case Study: Wide-ResNet

We visualize the parallelization strategies Alpa finds for Wide-ResNet on 16 GPUs in Fig. 12. We also include the visualization of results on 4 and 8 GPUs in Appendix C. On 4 GPUs, Alpa uses only intra-operator parallelism. The intra-operator solution partitions along the batch axis for the first dozens of layers and then switches to partitioning the channel axis for the last few layers. On 16 GPUs, Alpa slices the model into 3 stages and assigns 4, 4, 8 GPUs to stage 1, 2, 3, respectively. Data parallelism is preferred in the first two stages because the activation tensors are larger than weight tensors. In the third stage, the ILP solver finds a non-trivial way of partitioning the convolution operators. The result shows that it can be opaque to manually create such a strategy for a heterogeneous model like Wide-ResNet, even for domain experts.

9 Related Work

Systems for data-parallel training. Horovod [47] and PyTorchDDP [32] are two commonly adopted data-parallel training systems that synchronize gradients using all-reduce. BytePS [26, 43] unifies all-reduce and parameter servers and utilizes heterogeneous resources in data center clusters. AutoDist [60] uses learning-based approaches to compose a data-parallel training strategy. ZeRO [44, 56] improves the memory usage of data parallelism by reducing replicated tensors. MiCS [61] minimizes the communication scale on top of ZeRO for better scalability on the public cloud. In Alpa, data parallelism [27] reduces to a special case of intra-operator parallelism – partitioned along the batch axis.

Systems for model-parallel training. The two major classes of model parallelisms have been discussed in §2. Mesh-

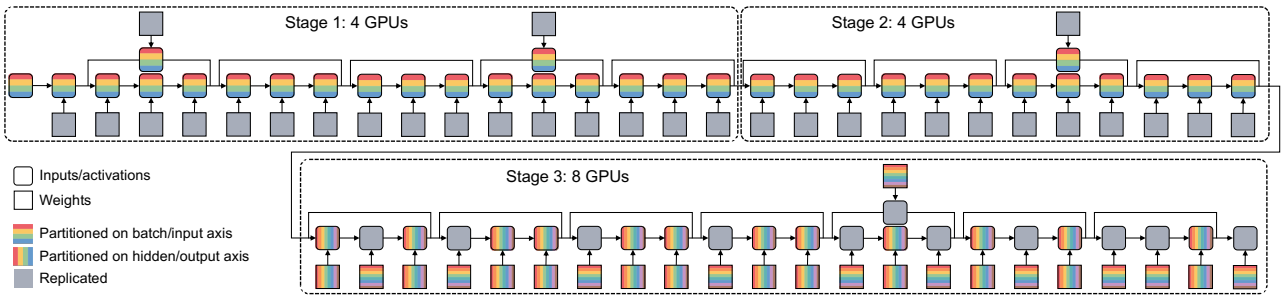

Figure 12: Visualization of the parallel strategy of Wide-ResNet on 16 GPUs. Different colors represent the devices a tensor is distributed on. Grey blocks indicate a tensor is replicated across the devices. The input data and resulting activation of each convolution and dense layer can be partitioned along the batch axis and the hidden axis. The weights can be partitioned along the input and output channel axis.

TensorFlow [48], GSPMD [31,57] and OneFlow [58] provide annotation APIs for users to manualy specifiy the intra-op parallel plan. ColocRL [36] puts disjoint model partitions on different devices *without pipelining*, thereby the concurrency happens only when there exist parallel branches in the model. In contrast, Gpipe [22] splits the input data into micro-batches and forms pipeline parallelisms. PipeDream [38,39] improves GPipe by using asynchronous training algorithms, reducing memory usage, and integrating it with data parallelism. However, PipeDream is asynchronous while Alpa is a synchronous training system. TeraPipe [33] discovers a new pipeline parallelism dimension for transformer-based LMs. Google's Pathway system [7] is a concurrent work of Alpa. Pathway advocates a single controller runtime architecture combining "single program multiple data" (SPMD) and "multiple program multiple data" (MPMD) model. This is similar to Alpa's runtime part, where SPMD is used for intra-op parallelisms and MPMD is used for inter-op parallelism.

Automatic search for model-parallel plans. Another line of work focuses on the automatic discovery of model-parallel training plans. Tofu [55] develops a dynamic programming algorithm to generate the optimal intra-op strategy for *linear* graphs on *a single node*. FlexFlow [25] proposes a "SOAP" formulation and develops an MCMC-based randomized search algorithm. However, it only supports device placement without pipeline parallelism. Its search algorithm cannot scale to large graphs or clusters and does not have optimality guarantees. TensorOpt [11] develops a dynamic programming algorithm to automatically search for intra-op strategies that consider both memory and computation cost. Varuna [2] targets low-bandwidth clusters and focuses on automating pipeline and data parallelism. Piper [50] also finds a parallel strategy with both inter- and intra-op parallelism, but it relies on manually designed intra-op parallelism strategies and analyzes on a uniform network topology and asynchronous pipeline parallel schedules.

Techniques for training large-scale models. In addition to parallelization, there are other complementary techniques for training large-scale models, such as memory optimization [12, 14, 21, 23, 28, 46], communication compression [6, 53], and low-precision training [35]. Alpa can incorporate many of these techniques. For example, Alpa uses rematerialization to reduce memory usage and uses mixed-precision training to accelerate computation.

Compilers for deep learning. Compiler techniques have been introduced to optimize the execution of DL models [13,24,34,51,52,54,62]. Most of them focus on optimizing the computation for a single device. In contrast, Alpa is a compiler that supports a comprehensive space of execution plans for distributed training.

Distributed tensor computation in other domains. Besides deep learning, libraries and compilers for distributed tensor computation have been developed for linear algebra [8] and stencil computations [15]. Unlike Alpa, they do not consider necessary parallelization techniques for DL.

10 Conclusion

We present Alpa, a new architecture for automated model-parallel distributed training, built on top of a new view of machine learning parallelization approaches: intra- and inter-operator parallelisms. Alpa constructs a hierarchical space and uses a set of compilation passes to derive efficient parallel execution plans at each parallelism level. Alpa orchestrates the parallel execution on distributed compute devices on two different granularities. Coming up with an efficient parallelization plan for distributed model-parallel deep learning is historically a labor-intensive task, and we believe Alpa will democratize distributed model-parallel learning and accelerate the adoption of emerging large deep learning models.

A Proof of Submesh Shape Covering

We prove the following theorem which shows we can always find a solution that fully covers the cluster mesh (N,M) with our selected submesh shapes in §5.2: (1) one-dimensional submeshes of shape $(1,1),(1,2),(1,4)\dots(1,2^m)$ where $2^m = M$ and (2) two-dimensional submeshes of shape $(2,M),(3,M),\dots,(N,M)$.

Theorem 1. *For a list of submesh shapes $(n_1,m_1),\dots(n_S,m_S)$, if $\sum_i n_i \cdot m_i = N \cdot M$ and each (n_i,m_i) satisfies either (1) $n_i = 1$ and $m_i = 2^{p_i}$ is a power of 2 or (2) $m_i = M$, then we can always cover the full (N,M) mesh where $M = 2^m$ with these submesh shapes.*

Proof. We start with putting the second type submesh into the full mesh. In this case, because $m_i = M$, these submeshes can cover the full second dimension of the full mesh. After putting all the second kind of submeshes into the mesh, we reduce the problem to fit a cluster mesh of shape (N,M) with submeshes with shape $(1,2^{p_1}),\dots,(1,2^{p_S})$ where all $p_i \in \{0,1,\dots,m-1\}$. Note that now we have

$$2^{p_1} + \cdots + 2^{p_S} = N \cdot 2^m. \tag{7}$$

We start an induction on m. When $m = 1$, we have all $p_i = 0$ and thus all the submeshes are of shape $(1,1)$, which means that all the submeshes can definitely cover the full mesh. Assume the above hold for all $m = 1,2,\dots,k-1$. When $m = k$, note that in this case the number of submeshes with $p_i = 0$ should be an even number, because otherwise the left hand side of Eq. 7 will be an odd number while the right hand side is always an even number. Then we can split all submeshes with shape $p_i = 0$ into pairs, and we co-locate each pair to form a $(1,2)$ mesh. After this transformation, we have all $p_i > 0$, so we can subtract all p_i and m by 1 and reduce to $m = k-1$ case. Therefore, the theorem holds by induction. □

B Model Specifications

For GPT-3 models, we use sequence length = 1024 and vocabulary size = 51200 for all models. Other parameters of the models are listed in Table. 6. The last column is the number of GPUs used to train the corresponding model.

For GShard MoE models, we use sequence length = 1024 and vocabulary size = 32000 for all models. Other parameters of the models are listed in Table. 7. The last column is the number of GPUs used to train the corresponding model.

For Wide-ResNet models, we use input image size = (224, 224, 3) and #class = 1024 for all models. Other parameters of the models are listed in Table. 8. The last column is the number of GPUs used to train the corresponding model.

C Extra Case Study

We visualize the parallelization strategies Alpa finds for Wide-ResNet on 4 and 8 GPUs in Fig. 13.

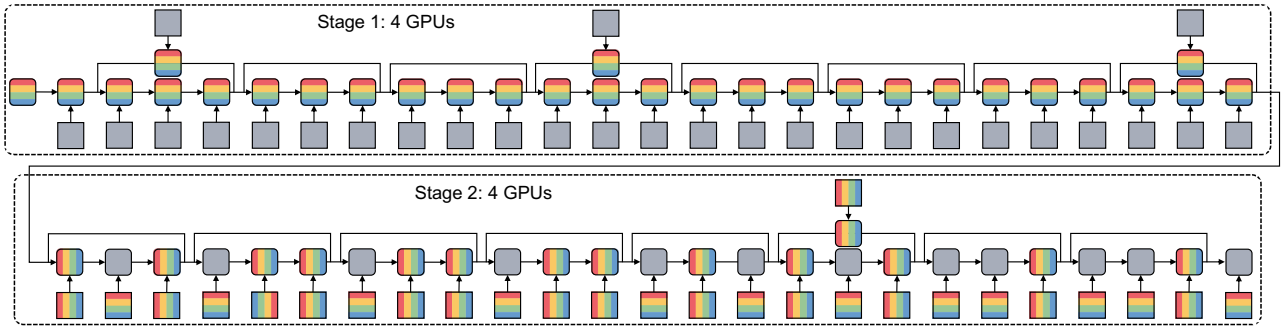
(a) Parallel strategy of Wide-ResNet on 4 GPUs.



(b) Parallel strategy of Wide-ResNet on 8 GPUs.

Figure 13: Visualization of the parallel strategy of Wide-ResNet on 4 and 8 GPUs. Different colors represent the devices a tensor is distributed on. Grey blocks indicate a tensor is replicated across all devices. The input data and resulting activation of each convolution or dense layer can be partitioned along the batch axis and the hidden axis. The weights can be partitioned along the input and output channel axis.

Looking Beyond GPUs for DNN Scheduling on Multi-Tenant Clusters

[⋆]*Microsoft Research* [†]*University of Texas at Austin* [‡]*VMware Research*

Abstract

Training Deep Neural Networks (DNNs) is a popular workload in both enterprises and cloud data centers. Existing schedulers for DNN training consider GPU as the dominant resource and allocate other resources such as CPU and memory proportional to the number of GPUs requested by the job. Unfortunately, these schedulers do not consider the impact of a job's sensitivity to allocation of CPU and memory resources. In this work, we propose Synergy, a resource-sensitive scheduler for shared GPU clusters. Synergy infers the sensitivity of DNNs to different resources using optimistic profiling; some jobs might benefit from more than the GPU-proportional allocation and some jobs might not be affected by less than GPU-proportional allocation. Synergy performs such multi-resource workload-aware assignments across a set of jobs scheduled on shared multi-tenant clusters using a new near-optimal online algorithm. Our experiments show that workload-aware CPU and memory allocations can improve average job completion time by upto 3.4×, by better utilizing existing cluster resources, compared to traditional GPU-proportional scheduling.

1 Introduction

The widespread popularity of Deep Neural Networks (DNNs) makes training such models an important workload in both enterprises and cloud data centers. Training a DNN is resource-intensive and time-consuming. Enterprises typically setup large multi-tenant clusters, with expensive hardware accelerators like GPUs, to be shared by several users and production groups [31, 56]. In addition to the model-specific parameters and scripts, jobs specify their GPU demand before being scheduled to run on available servers. Jobs are scheduled and managed either using traditional big-data schedulers, such as Kubernetes [10] or YARN [51], or using modern schedulers that exploit DNN job characteristics for better performance and utilization [11, 26, 33, 35, 42, 46, 55]. These DNN schedulers decide how to allocate GPU resources to many jobs while implementing complex cluster-wide scheduling policies to optimize for objectives such as average job completion times (JCT), makespan, or user-level fairness.

*Work done as a MSR intern in Project Fiddle.

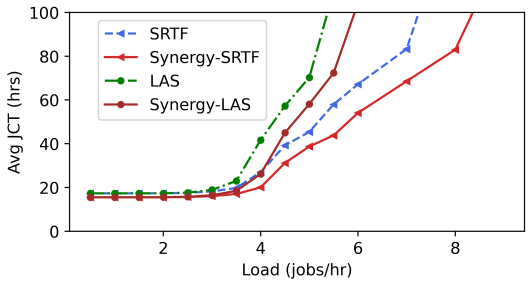

Figure 1: **Average JCT with Synergy**. Synergy is able to significantly reduce average JCT and support higher load for different scheduling policies (shown here on a cluster of 128 GPUs for a Philly-derived trace as we vary load [5]).

Current DNN cluster schedulers assume GPUs to be the dominant resource in the scheduling task [11, 26, 31, 33, 35, 42, 46, 55]; i.e., a user requests a fixed number of GPUs for her DNN job, and when the requested number of GPUs are all available, the job is scheduled to run. Other resources such as CPU and memory are allocated proportional to the number of GPUs assigned to the job (*GPU-proportional* allocation).

However, we identify an important property of DNN training jobs that GPU-proportional allocation is unable to exploit: DNNs exhibit varied sensitivity to the amount of auxiliary resources like CPU and memory allocated to the job. Prior work has shown that ingesting data for ML training jobs, i.e., reading data from storage to memory, and pre-processing them at the CPU is computationally expensive, thereby resulting in *data stalls* in both research [39] and industry scale training at large enterprises such as Google [40] and Facebook [59]. For instance, some image and video recognition models achieve up to 3× speedup by overcoming *data stalls* (§2) when the CPUs allocated exceed their GPU-proportional share, while other models like GNMT are unaffected when the CPUs assigned are less than GPU-proportional share.

Our main insight here is that allocating these auxiliary resources in a workload-aware fashion, rather than the traditional GPU-proportional allocation can significantly improve performance by effectively utilizing *cluster-wide* resources. Based on this insight, we propose *Synergy*, a resource-sensitive scheduler for homogeneous, multi-tenant GPU clusters. Figure 1 shows the average job completion time (JCT)

in the cluster as we vary load, for two scheduling policies; Synergy's resource-sensitive allocation is able to significantly improve average JCT in the cluster and sustain a higher load compared to GPU-proportional allocation.

Synergy profiles the sensitivity of DNNs to auxiliary resources and allocates them disproportionately among jobs rather than using traditional GPU-proportional allocation. While doing so, Synergy ensures that a job gets less than GPU-proportional auxiliary resources *only* if such an allocation does not degrade the job throughput compared to a GPU-proportional allocation. Such allocation enables Synergy to mitigate data stalls in several models, thereby significantly increasing the overall cluster throughput.

Efficiently exploiting the heterogeneity in resource sensitivity among DNN jobs raises two important problems which have not been tackled by prior work:

- What is the ideal resource requirement for each job (with fixed GPU demand) and how can this be determined with low overhead?
- How should we pack these jobs onto servers along multiple resource dimensions efficiently, especially when we can tune the job's demand for these resources?

Optimistic profiling. Synergy exploits the predictability of DNN computation to measure the job throughput as we vary the amount of CPU and memory allocated to the job. This is performed offline by the Synergy scheduler, prior to job execution on the cluster. However, profiling all possible combinations of CPU, and memory values is computationally expensive. Therefore, Synergy introduces optimistic profiling; it empirically profiles the job throughput for varying CPU allocations, assuming maximum memory allocation. It then *analytically* estimates the job throughput for all combinations of CPU and memory.A key insight that makes such analytical modelling feasible is the predictable nature of job performance to memory allocation when using DNN-aware caching like MinIO [39] that guarantees a certain cache hit rate. We show in §3.1 that our optimistically profiled model performance closely resembles the true empirical values, while significantly reducing profiling time (by up to 30×). Using these profiles, Synergy identifies the best resource allocation beyond which the job throughput has diminishing returns.

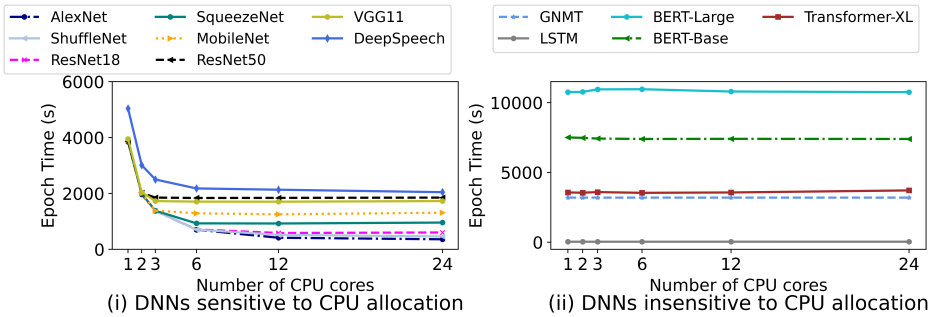
Scheduling mechanism. Synergy makes a round-based scheduling decision similar to prior DNN schedulers [42]. In each round (say 5 minutes), we identify the set of jobs that are runnable in the cluster using a scheduling policy such as FIFO [51, 57], SRTF [12], LAS [26, 43], FTF [35], etc. Synergy's scheduling mechanism then packs these jobs among available servers in the cluster along all resource dimensions identified in the profiling phase. This is analogous to multi-dimensional bin-packing problem, which is NP-Hard [53], and hence requires approximate solutions. But unlike prior work in big-data scheduling which tackles the problem of multi-dimensional bin-packing with fixed resource demands (for *e.g.,* Tetris [23], DRF [21]), Synergy has to contend with fungible resource demands. This introduces two challenges that need to be solved in tandem: First to find an optimal partition of CPU and memory among jobs to maximize throughput while ensuring fair allocations (every job's throughput is at least that of GPU-proportional allocation), and second, a feasible packing of these resources among jobs.

In this paper, we propose two effective algorithms to enable such fungible multi-dimensional bin-packing. Our first algorithm, Synergy-OPT, is formulated as a linear program and enables determining an upper-bound on achievable throughput by an optimal solution for a given workload trace. However, we find that Synergy-OPT is impractical for two reasons: (1) it is computationally expensive as we scale cluster size, and (2) it produces fractional GPU allocations that cannot be achieved in real deployments. Nevertheless, its solution provides an aspirational optimal goal that we can use to measure the efficacy of any practical solution. The second algorithm, Synergy-TUNE, is fast and near-optimal (within 10% of Synergy-OPT in evaluation). If a job to be scheduled does not fit in the cluster along all the resource dimensions, we revert the job demands to GPU-proportional if its current demands are above it. If the job's demands are already GPU-proportional or below, then we find a suitable job in the cluster with higher than GPU-proportional allocation, which is then reverted to GPU-proportional. Synergy-TUNE also outperforms simpler greedy approaches (Synergy-GREEDY) that recursively pack jobs along multiple resource dimensions using a first-fit allocation strategy [20].

We implement a prototype of Synergy and an accompanying event-driven simulator in Python. Synergy transparently communicates with the DNN job using a thin iterator API, that is a wrapper around the existing data iterator, thereby requiring minimal code changes to the DNN job script. Across various scheduling policies, and workload traces, we show that Synergy improves cluster objectives such as average JCT by up to 1.5× on a physical cluster of 32 GPUs. On a large simulated cluster of up to 512 GPUs, Synergy improves average JCT by up to 3.4×. Synergy is open sourced at https://github.com/msr-fiddle/synergy.

In summary, our paper makes the following contributions.

- We identify the importance and need for resource-sensitive scheduling of DNN jobs in multi-tenant GPU clusters (§2).
- We present Synergy, a resource-sensitivity aware scheduler that optimistically profiles the job's resource demands and performs disproportionate allocations such that no job achieves lower than GPU-proportional throughput (§3).
- We present a heuristic scheduling mechanism Synergy-TUNE, that maps the allocations calculated by the profiler onto the cluster, while better utilizing the resources compared to a GPU-proportional allocation (§4).
- In extensive experimentation on physical and simulated clusters, Synergy's techniques improve average JCT by up to 3.4×, thus supporting a higher input load (§5).



(a) CPU sensitivity

CPU: GPU	SKU
3:1	NVIDIA DGX-2 Internal servers at X
4:1	AWS p3.16xlarge
5:1	NVIDIA DGX-1 Azure NDv2
6:1	Azure NC24s_v3

(b) GPU VM SKUs

Figure 2: **CPU sensitivity**. This graph plots the epoch time for DNNs as we vary the CPU:GPU ratio for single-GPU training. Some jobs such as Transformers need as few as 1 CPU core per GPU to achieve maximum training speed; others like ShuffleNet need more than 12 CPU cores per GPU to eliminate data stalls. State-of-the-art GPU VMs have a CPU:GPU ratio as few as 3.

2 Background and Motivation

In this section, we briefly describe DNN scheduling, introduce the terminology used in the rest of the paper, and motivate resource-sensitive DNN cluster scheduling.

Scheduling ML training jobs in a cluster. Training a ML model is a resource intensive and long-running task (order of hours to days). Collocating ML training workloads in a shared, multi-tenant cluster is a very common setup in several large organizations, for both research and production [26, 35, 42, 46, 55]. Our work targets state-of-the-art multi-tenant clusters similar to the ones published by prior large-scale studies by organizations like Microsoft [31] and Alibaba [56]. These clusters use on-premise servers or cloud VMs with pre-defined GPU, CPU, and memory resources. The cluster itself is shared by multiple users and jobs, and each server can host more than one job each with varying resource usage (some heavy on CPU side pre-processing, while others heavy on GPU computation). For example, a server with 8 GPUs can host 8 single-GPU jobs from different users.

Scheduling policy and mechanism. When jobs are submitted to a scheduler, a scheduling policy such as First In, First Out (FIFO) [51, 57], Shortest Remaining Time First (SRTF) [12], Least Attained Service (LAS) [26, 43], or Finish Time Fairness (FTF) [35] decides the set of jobs (J) to be run on the cluster. A scheduling mechanism then identifies where job J should be run, and how much resources to allocate to the job. The GPU demand for a job is fixed (requested by the user), while the CPU and memory allocation is fungible.

GPU-proportional allocation. During DNN training, a mini-batch of data is first fetched from storage to memory, where it is cached for subsequent accesses. It is then pre-processed at the CPU, and then copied over to the GPU for processing. Existing DNN schedulers [26, 35, 42, 55], and those used in real-world GPU clusters [5, 31], including recent schedulers that offer GPU elasticity [30, 48], all allocate CPU and memory resources to a job using a GPU-proportional allocation. For instance, consider a server with 4 GPUs, 16 CPUs and 200 GB memory. If a job requests 1 GPU, then it is allocated 4 CPUs and 50GB memory.

2.1 Motivation : Resource sensitivity

Insight. The main insight that motivates our work is that DNNs co-scheduled on a cluster exhibit different levels of sensitivity to CPU and memory allocations during training. Therefore, it is possible to improve the overall cluster utilization and efficiency by performing resource-sensitive allocations instead of the ubiquitously used GPU-proportional allocation. Prior work on characterization study of jobs in Microsoft's Philly cluster [31] shows that CPU cycles are under-utilized in multi-tenant clusters; we use this as motivation to show that we can *exploit the disparity in resource requirements* ***across jobs*** *to improve overall cluster utilization without any hardware upgrades (storage, CPU, or memory).*

Figure 2a plots the per-epoch time for various DNNs when trained on a single GPU by varying the number of CPUs allocated to the job (ensuring that the dataset is fully cached for each job). Figure 2a(i) shows that most image and speech models are sensitive to CPU allocations; smaller models like ShuffleNet and ResNet18 require 9–24 CPU cores per GPU to pre-process data items. However, state-of-the-art ML optimized servers and cloud GPU VMs have a CPU:GPU ratio as few as 3 as shown in Table 2b [1–3, 6, 18, 34]. Increasing the CPU:GPU ratio from 3 to 12 results in 3.1× faster training for AlexNet, and increasing it to 9 results in 2.3× faster training for ResNet18. On the other hand, most language models are insensitive to CPU allocations as shown in Figure 2a(ii). This is because they have modest input data pre-processing requirements. Transformer models for example, unlike image classification models, do not perform several unique data augmentation operations for each data item in every epoch [39].

Next, to understand the importance of memory alloca-

Job	Model

	$J3$	4	1	100
S_2	$J2$	4	12	450
	$J4$	4	12	50

Table 3: Resource-sensitive allocation

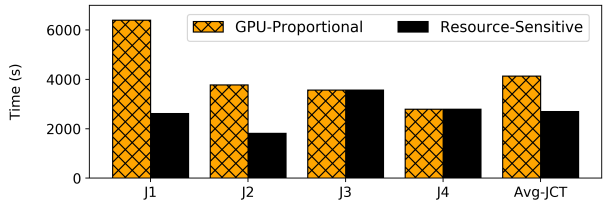

Figure 3: **Resource sensitive scheduling**. We compare the runtime of the jobs with two different schedules; GPU-proportional and resource-sensitive. By allocating resources disproportionately, CPU and memory sensitive jobs see increased throughputs which reduces the average JCT by 1.5×.

tions, we train two models; an image classification model - ResNet18 on OpenImages [22] and a language model GNMT on WMT, with varying memory allocations on a server whose GPU-proportional share of memory per GPU is 62GB. We observe that GNMT is insensitive to memory allocation; even if only 20GB memory is allocated (which is the required process memory for training), the training throughput is unaffected. However, increasing the memory from 62GB (GPU-proportional allocation) to 500GB (max) for ResNet18 speeds up training by almost 2×. This is because, language models like GNMT, and transformers are GPU compute bound. Therefore, fetching data items from storage if they are not available in memory does not affect training throughput. On the other hand, image and speech models benefit from larger DRAM caches. If a data item is not cached, the cost of fetching it from the storage device can introduce fetch stalls in training [39, 40, 59].

Takeaway. *When two jobs have to be scheduled on the same server, it is possible to co-locate a CPU-sensitive job with a CPU-insensitive one. This allows CPU allocation to be performed in a resource-sensitive manner rather than GPU-proportional allocation. Similarly, it is always beneficial to pack a memory-sensitive job with an insensitive one, allowing disproportionate resource-sensitive sharing of memory to improve the aggregate cluster throughput.*

Example. We now show how resource-sensitivity-aware scheduling can improve cluster efficiency using a simple example. We run the experiment on two physical servers each with 8 GPUs, 24 CPUs and 500GB DRAM (internal servers at a large cloud provider X). Let's say we have 4 jobs in the scheduling queue, each requesting 4 GPUs as shown in Table 1. We consider two different schedules; (1) GPU-proportional allocation and (2) resource-sensitive allocation. The results of these schedules are shown in Table 2 and Table 3. Figure 3 compares the epoch time of each of these jobs in the two scenarios. The increased resource allocation to CPU and memory sensitive jobs in Schedule 2 speeds up $J1$ and $J2$ significantly, while leaving the runtime of $J3$ and $J4$ unaffected. The average JCT in the cluster thus drops by 1.5× due to resource-sensitive allocations.

2.2 Synergy Scheduling Policies

Synergy is not constrained to one particular scheduling policy, but is instead general enough to improve a wide range of scheduling policies (*e.g.,* LAS, FIFO, SRTF, FTF, etc), creating Synergy-augmented variants for all of them. The main challenge that Synergy addresses is, finding an efficient partition of available cluster CPU and memory among jobs to maximize throughput while ensuring that every job's throughput is at least that of GPU-proportional allocation. Synergy 's innovation thus lies in exploiting the differences in resource sensitivity across jobs to improve overall cluster metrics.

2.3 Assumptions & Limitations

In the context of this work, we explicitly highlight certain practical assumptions, many of which are derived directly from large multi-tenant clusters we analyze - homogeneous clusters, fixed GPU allocation for the lifetime of a job, and the use of MinIO cache. Synergy 's design is not tied to these assumptions, but it aids in focused profiling (reducing the dimensionality of the search space). In a large scale, multi-tenant, production cluster, it is practical to assume that there are tens of thousands of accelerators per homogeneous cluster, and the GPU allocation for a job remains constant. While recent works explore scheduling DNN jobs in heterogeneous clusters [11, 33, 42], and GPU elasticity [48], there are several practical challenges in seamlessly supporting these features. For instance, with elastic training, the impact of changing batch sizes and hyperparameters on training accuracy is unclear for a wide variety of tasks. We provide a detailed discussion on the practicality of each of these assumptions made by Synergy, and what it means to relax these assumptions for Synergy in Section 6.

3 Synergy: Design

Overview. Synergy is a round-based scheduler that arbitrates multi-dimensional resources (GPU, CPU, and memory) in a

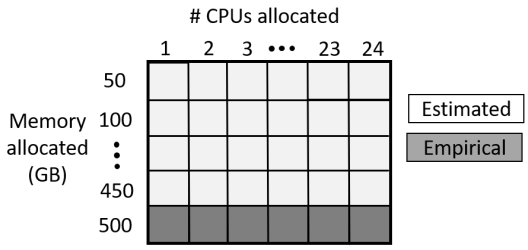

Figure 4: **Optimistic profiling** empirically evaluates the sensitivity of a model to varying # CPUs assuming a fully cached dataset; the rest of the matrix is completed using estimation

homogeneous cluster. Synergy augments existing scheduling policies with *resource sensitivity* in two steps. First, it identifies the job's best-case CPU and memory requirements using *optimistic profiling* (§3.1). Synergy then identifies a set of runnable jobs for the given round using a scheduling policy (*e.g.,* SRTF, FTF, LAS, etc) such that their collective GPU demand is less than or equal to the GPUs available in the cluster. Then, using the profiled resource demands, Synergy packs these jobs on to the available servers along multiple resource dimensions using a near-optimal heuristic algorithm (§4). At the end of a round, the set of runnable jobs are updated using the scheduling policy, and their placement decisions are recomputed. We now discuss both the components of Synergy in detail. Note that Synergy only alters the auxiliary resource allocations; GPU demands are left unaltered for the lifetime of a job and are provided as inputs by the user.

3.1 Optimistic Profiling

A DNN job is profiled for its resource sensitivity once per lifetime of the job, i.e. on job arrival. Each incoming job is profiled by varying the CPU and memory allocated to the job. A *resource sensitivity matrix* is then constructed for discrete combinations of CPU and memory allocations as shown in Figure 4. Since DNN training has a highly predictable structure, empirically evaluating training throughput for a few iterations gives a fair estimate of the actual job throughput [39, 55].

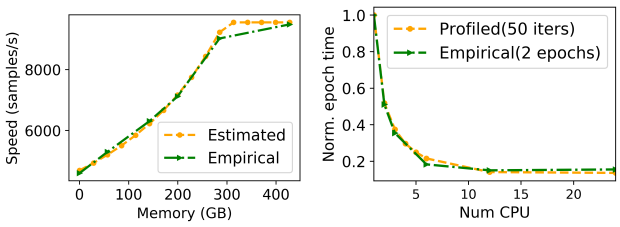
It is easy to see that naively profiling different combinations of CPU and memory can be very expensive. For instance, if the cost of profiling one combination of CPU, and memory for a job is 1 minute, then to profile all discrete combinations of CPU and memory (assuming allocation in units of 50GB) on a server with 24 CPUs and 500GB DRAM takes about 24*10 = 240 minutes (4 hours)!

To tackle this problem, Synergy introduces an optimistic profiling technique that exploits the predictability in the relationship between job throughput and memory allocation. We observe that, with DNN-specific, application-level caches like MinIO [39], it is easy to model the job throughput behaviour as we vary the amount of memory allocated to a job at fixed CPU allocation. This is because, MinIO ensures that a job gets a fixed number of cache hits per epoch. Synergy makes a conscious decision to use application-level MinIO cache instead of Page Cache because MinIO provides memory isolation across independent jobs sharing the machine. If we do not use MinIO, we will have to profile the model at discrete memory allocations which could result in increased profiling costs, and also potentially change the trends in profiling matrix. However, the use of MinIO in Synergy makes cache performance predictable and hence reduces Synergy 's profiling costs – allowing optimistic profiling.

For a given CPU allocation that determines the preprocessing speed, and a known storage bandwidth, it is easy to analytically model the job throughput for varying memory allocation. Therefore, we only need to empirically profile the job for varying CPU values at full memory allocation as shown in Figure 4. All the other entries can be estimated using the above technique. This leads to a 10× reduction in profiling time, bringing it down to 24 minutes! We experimentally validate this in Figure 5a. For a 8-GPU ResNet18 job, we compare the modeled job throughput using Synergy to the empirical results obtained by training the job for 2 epochs with varying memory allocations. As we see in Figure 5a, Synergy's estimations are within 3% of the empirical results, without having to actually run the model.

To further optimize profiling time, we observe that we do not require exact throughput values for a job with varying CPU allocations. We instead need a curve depicting the empirical job throughput. Therefore, instead of profiling the job for all possible CPU values, we pick discrete points for CPU profiling using the following algorithm. We start with the maximum CPU allocation and do a binary search on the CPU values to estimate job throughput. If the profiled point resulted in a throughput improvement that is less than a fixed threshold (say 10%), then we continue binary search on the lower half of CPU values, else we profile more points on the upper half. The idea here is to empirically profile CPU regions that show significant difference in job throughput, while skip those regions with little to no improvement in throughput. We experimentally show the efficacy of our CPU profiling technique in Fig 5b for a 1-GPU ResNet18 job. We compare the normalized job runtime (wrt 1 CPU) using empirical results averaged over 2 epochs of the job and Synergy's optimistic profiling averaged over 50 iterations (approximately, a minute per profile). Synergy is able to mimic the empirical job performance very closely, in under 8 minutes (using just 8 CPU profile points instead of 24). We believe that this is a reasonable overhead as it is incurred only once per lifetime of the job, which typically runs for hours.

After profiling a job on arrival, the job along with its resource sensitivity matrix is enqueued into the main scheduling queue, from which the scheduling policy picks a set of runnable jobs every round.



(a) Memory Validation (b) CPU validation

Figure 5: **Optimistic profiling**. The graphs compare the profiling results to empirical runs for ResNet18

3.2 Scheduling mechanism

Synergy performs round-based scheduling. At the beginning of each scheduling round, Synergy identifies a set of runnable jobs from the scheduling queue that can be packed on the cluster in the current round duration using a scheduling policy such as FIFO, SRTF, LAS, or FTF. Using the resource sensitivity matrix, Synergy packs these jobs onto the available servers in the cluster while satisfying the multi-dimensional resource constraints as opposed to simply performing a GPU-proportional allocation .

Job demand vector. To pack the jobs onto servers, we first construct a job demand vector that indicates the GPU demand, and best-case CPU and memory requirements for the job. We identify the best-case values using the resource sensitivity matrix. We pick the minimum value of CPU and memory that saturates the job throughput.

Packing a job with multi-dimensional resource demands is analogous to multi-dimensional bin packing problem which is NP hard [53]. Therefore, we first evaluate the efficacy of a naive greedy scheduling mechanism as an approximation to tackle the multi-dimensional resource allocation problem.

3.3 Synergy-GREEDY: Greedy Scheduling

A naive greedy multi-resource packing algorithm translates to a first-fit approximation of the multi-dimensional bin packing problem [20]. Given a job demand vector, the greedy algorithm picks the next runnable job decided by the scheduling policy, and places it on the server that can satisfy the job's demands in all dimensions. If no such server exists, the job is *skipped* over for this round and the next runnable job is checked for schedulability. Synergy-GREEDY thus introduces two major problems in the cluster -

- It can result in auxiliary resources being exhausted by jobs, while leaving GPUs underutilized, and fragmented. We show that GPU fragmentation in Synergy-GREEDY severely degrades cluster objectives (5.4).
- It also hurts the fairness of the scheduling policy as some jobs can be skipped over for a long time if their resource demands cannot be satisfied in the cluster.

The challenge ahead of us is to design a scheduling mechanism that eliminates GPU under-utilization due to fragmentation, and upholds the fairness properties of the given scheduling policy, while performing multi-dimensional resource allocation. Before we come up with a heuristic scheduling approach to tackle the above problems, one pertinent question is to understand how good is the allocation produced by our heuristic when compared to an optimal solution.

To this end, we first formulate a theoretical upper bound on the optimal throughput achieved by the cluster given a set of jobs and their resource sensitivity profiles. We then discuss the challenges associated with materializing the optimal allocation on a physical cluster and introduce Synergy-TUNE, an empirically close-to-optimal heuristic solution.

4 Scheduling Algorithms

We first present our formulation of an optimal allocation that provides an upper bound on the achievable cluster throughput.

4.1 Synergy-OPT

Our goal is to allocate CPU and memory to each job so as to maximize overall throughput, while guaranteeing that each job makes at least as much progress as it would do if we allocate its *GPU-proportional share*. It is not hard to show that our problem is NP-hard. So, we resort to finding approximate solutions using LP formulation. To find an *upperbound* on achievable throughput, we solve two LPs. In the interest of space, we describe the first LP formulation here, and summarize the challenges in operationalizing Synergy-OPT. A complete description of Synergy-OPT formulation and proof can be found in the extended version [38]. While the focus of this work is on homogeneous cluster, we show how our formulation can be extended to a heterogeneous GPU cluster in the extended version of the paper [38].

4.1.1 Finding ideal allocation

First, we assume an *idealized setting*: all the CPU and memory available across all the machines is present in one (super) machine. Say there are a total of s homogeneous machines in the cluster. We assume that, there is only one machine with G units of GPU, C units of CPU, and M units of memory. Note that, in reality G_i, C_i, and M_i denote the total GPU, CPU, and memory in each machine i, which is G/s, C/s, and M/s respectively in a homogeneous cluster. Based on this assumption, we find the ideal CPU (c^*_j) and memory (m^*_j) allocation for every job j (whose GPU demand is denoted by g_j) in the set of runnable jobs (J_t) for a round.

The variables of our LP are denoted by $y_{\{c,m,j\}}$, which should be interpreted as follows. If for a job $j \in J_t$, $y_{\{c,m,j\}} = 1$, then it means that in the LP solution c units of CPU and m units of memory are allocated. We further note that for

every job j, there is a variable $y_{\{c,m,j\}}$ for *for every possible* allocation of CPU and memory. We consider these variables in the discrete space as identified by our resource sensitivity matrix (W_j). $W_j[c,m]$ denotes the amount of progress made by job j per round if c units of CPU and m units of (RAM) memory are allocated to job j. For each machine $i \in [s]$, we denote C_g, M_g as the GPU-proportional allocation of CPU and memory. That is, $C_g = C_i/G_i * g_j$ and $M_g = M_i/G_i * g_j$. With a baseline GPU-proportional allocation strategy the progress a job makes in each round is equal to $W[Cg, Mg]$.

Our objective function is to maximize the throughput. We formulate it as follows using our LP variables.

$$\text{Maximize} \quad \sum_{j \in J_t} \sum_{[c,m]} W_j[c,m] \cdot y_{\{c,m,j\}} \tag{1}$$

Now, we enforce constraints such that LP solution is feasible in the idealized setting we talked about.

- Total CPU and memory allocated to jobs is no more than the total capacity available:

$$\sum_{j \in J_t} \sum_{[c,m]} c \cdot y_{\{c,m,j\}} \leq C \tag{2}$$

$$\sum_{j \in J_t} \sum_{[c,m]} m \cdot y_{\{c,m,j\}} \leq M \tag{3}$$

- We want the LP to allocate only one configuration of CPU and memory to each job.

$$\forall \text{j} \in J_t: \quad \sum_{[c,m]} y_{\{c,m,j\}} = 1 \tag{4}$$

- LP solution is atleast as good as the fair allocation.

$$\forall \text{j} \in J_t: \quad \sum_{[c,m]} W_j[c,m] \cdot y_{\{c,m,j\}} \geq W_j[C_g, M_g] \tag{5}$$

Theorem 4.1. Throughput achieved by LP(1-5) is at least the throughput achieved by an optimal solution to our problem.

Proof. Consider an optimal solution O to our problem. Suppose job j receives c^* units of CPU and m^* units of memory in O. Then we define the following feasible solution to our LP (1-5): Set $y_{c^*,m^*,j} = 1$. Clearly, this is a valid solution and satisfies constraints (1-4). □

In our experiments, we solve this as a Integer Linear Program (ILP) where $y_{\{c,m,j\}}$ takes boolean values. For every job, we define the total CPU (c^*_j) and memory (m^*_j) allocated by the optimal ILP solution as follows.

$$\text{For each job } j, \text{ define} \quad c^*_j := c \quad \text{if} \quad y_{\{c,m,j\}==1}. \tag{6}$$

$$\textit{and} \quad m^*_j := m \quad \text{if} \quad y_{\{c,m,j\}==1}. \tag{7}$$

4.1.2 Feasible Allocation on Multiple Machines

Recall that in the LP(1-5), we assumed that all the resources are present on a single machine. In reality, since these resources are spread across machines, we find a feasible allocation on multiple machines by solving a second LP. The objective here is to minimize the number of jobs that get fragmented to account for the communication overhead when jobs are split across machines. The variables of the second LP are denoted by $x_{i,j}$. Here index i denotes the machine and j denotes the job. If $x_{i,j} = 1$, it means that resources of job j (that g_j units of GPU, c^*_j units of CPU, and m^*_j units of memory) are allocated on machine i. Note that $x_{i,j}$ can be fractional; if so, then job j is split across multiple machines. We can prove that the solution to the second LP ensures that the total number of jobs that get fragmented is at most $3s$. Detailed formulation is in the extended version of the paper [38].

4.1.3 Challenges with operationalizing Synergy-OPT

While the allocations identified by Synergy-OPT provides an upper bound on the optimal cluster throughput, it is challenging to materialize these allocations in the real world due to two main reasons;

- Solving two LPs per scheduling round is computationally expensive. As cluster size and the number of jobs per round increases, the time to find an optimal allocation increases exponentially (§5.6)
- The allocation matrix obtained with the second LP can result in fractional GPU allocations when jobs are split across servers; for instance, a valid allocation might assign 3.3 GPUs on server 1 and 2.7 GPUs on server 2 for a 6 GPU job. Realizing such an allocation requires a heuristic rounding off strategy to ensure non-fractional GPU allocations, as GPU time or space sharing, and its impact on job performance is considered beyond the scope of this work.

4.2 Synergy-TUNE

We now describe Synergy-TUNE, our heuristic scheduling mechanism. Our goal is to design a scheduling mechanism that performs multi-dimensional resource allocation for DNN jobs, where the GPU demand is fixed, but the auxiliary resource allocations are fungible. In doing so, we want to ensure that (1) we do not affect the fairness properties of the scheduling policy used, (2) the expensive GPU resources are not underutilized.

Allocation Requirements. Synergy-TUNE's allocation must satisfy the following requirements.

- The GPU, CPU, and memory resources requested by a single-GPU job must all be allocated on the same server.
- A multi-GPU distributed-training job can either be consolidated on one machine, or split across multiple machines.

In the latter case, *the CPU and memory allocations must be proportional to GPU allocations across servers*. For instance, if a job requires (2GPU, 12 CPU, 300GB DRAM), then while splitting it across two servers, we need to ensure that each server gets (1GPU, 6CPU, 150GB DRAM). This is because, multi-GPU jobs train on a separate process on each GPU, and synchronize at regular intervals, i.e., after one or many iterations. The job performance will vary across processes if each GPU does not get the same ratio of resources, and will eventually proceed at the speed of the process with the lowest allocation of CPU and memory.

In a multi-tenant cluster, while carving out resources such as CPUs and memory for jobs, it is import to enforce fairness in terms of throughput achieved by individual jobs. We need to ensure that no job runs at a throughput lower than what it would have achieved if we allocated a GPU-proportional share of CPU and memory resources. Additionally, we need to respect the priority order of jobs identified by the scheduling policy. For instance, a FIFO scheduling policy can be implemented using a priority queue sorted by job arrival times. Synergy-TUNE identifies a set of runnable jobs for a round as the top n jobs from the scheduling queue, whose GPU demands can be exactly satisfied by the available servers in the cluster. Synergy-TUNE picks this runnable job set irrespective of the job's other resource demands - which are fungible. Note that, unlike Synergy-GREEDY, we do not skip over any jobs unless it cannot be scheduled (GPU demand cannot be met). Therefore, we never underutilize the GPUs when the cluster is at full load.

Next, Synergy-TUNE greedily packs each of these runnable jobs along multiple resource dimensions on one of the available servers, with the objective of minimizing fragmentation. To achieve this, Synergy-TUNE sorts the runnable jobs by their GPU demands, followed by CPU, and memory demand. For each job j in order, Synergy-TUNE then picks the server with the least amount of free resources just enough to fit the demand vector of j. If it is a multi-GPU job, then we find a minimum set of servers with sufficient GPU availability that can fit the job's demands in entirety. However, it is possible that the job cannot fit in the cluster along all dimensions. In such a case,

1. We check if the job's demand vector is greater than proportional share of resources, In this case, we switch the job's demand to GPU-proportional share and retry.

2. If the job still does not fit the cluster, or if the job's demand vector was less than or equal to GPU proportional allocation in step (1), then, we do the following.

(a) We repeat step (1) ignoring the job's CPU and memory requirements. We find a server that can just satisfy the job's GPU requirements. We know by construction that there is atleast one job on this server, which is allocated more than GPU-proportional share of resources. We identify the job or a set of jobs (J_s) on this server by switching whom to GPU-proportional share, we can release just as much resources required by the current job j. We switch the jobs in J_s to fair-share and by design, job j will fit this server.

(b) We continue this recursively for all runnable jobs.

In the worst case, all the running jobs in a round could be allocated GPU-proportional share of resources. Therefore, Synergy ensures that its allocations results in job throughputs that are never worse than GPU-proportional allocation. In §5.6, we empirically compare Synergy-TUNE to Synergy-OPT showing that it is practical and near-optimal.

4.3 Implementation

We implement Synergy and an associated simulator in Python. Our scheduler is event-driven. There is a global event queue where job arrivals, schedule events, and deploy events are queued. These events are handled in the order of their arrival time. There is a priority job queue, where all the jobs arriving into the cluster are added, post profiling. This queue is sorted by the priorty metric decided by the scheduling policy; for instance, SRTF sorts the jobs in the order of job remaining time.

When a schedule event occurs, the scheduler collects a list of runnable jobs from the job queue and identifies the appropriate placement for these jobs for the following round, either using Synergy-GREEDY, Synergy-TUNE or Synergy-OPT. Then when a deploy event is triggered, these allocations are deployed on to the cluster. By default, every job requests for a lease update to continue running on the same server [42]. The scheduler then either grants a lease update or terminates the lease for the job, adding it back to the job queue.

The scheduler and the DNN jobs interact via a thin API provided by the Synergy data iterator. DNN job scripts must be updated to call the Synergy iterator which is a wrapper around the default PyTorch [8] and DALI [7] iterators. The iterator handles registering the job with the scheduler, and appropriately sending lease updates. It also checkpoints the job to a shared storage if its lease is terminated. The iterator also synchronizes across GPU processes for a multi-GPU job to ensure that each process makes identical progress. We use `gRPC` [4] to communicate between the scheduler and the jobs.

We implement Synergy-OPT in `cvxpy` [19] for use in our simulator. The optimistic profiling module is also implemented in Python, and it profiles the incoming jobs hooked to the Synergy iterator, prior to the job's initial addition to the scheduling queue (a one time overhead for each job).

5 Evaluation

In this section, we use trace-driven simulations from production cluster traces, and physical cluster deployment to evaluate

Task	Model	Dataset
Image	Shufflenetv2 [58] AlexNet [32] Resnet18 [28] MobileNetv2 [50] ResNet50 [28]	ImageNet [49]
Language	GNMT [54] LSTM [47] Transformer-XL [16]	WMT16 [9] Wikitext-2 [36] Wikitext-103 [36]
Speech	M5 [15] DeepSpeech [27]	Free Music [17] LibriSpeech [45]

Table 4: **Models used in this work**.

Policy (Metric)	Workload Split	Mechanism	Time (hrs) Deploy	Time (hrs) Simulate
FIFO (Makespan)	60-30-10	Proportional	16	15.67
		Tune	11.6	11.33
		Opt	-	11.01
SRTF (Avg JCT)	30-60-10	Proportional	4.81	4.52
		Tune	3.21	3.19
		Opt	-	3.06
SRTF (99 Percentile JCT)	30-60-10	Proportional	17.32	16.85
		Tune	8.59	8.54
		Opt	-	8.21

Table 5: **Physical cluster experiments**. This table compares the makespan, average JCT, and 99th percentile JCT for two different traces; (1) a static trace using FIFO (2) a dynamic trace using SRTF. Synergy-TUNE improves makespan by 1.4×, average JCT by 1.5 × and 99th percentile JCT by 2×.

the efficacy of Synergy. Our evaluation seeks to answer the following questions.

- Does Synergy's resource-sensitive scheduling improve cluster objectives such as makespan and average JCT in a physical cluster (§5.2) and in trace-driven simulations of large-scale clusters (§5.3) ?
- How does Synergy-TUNE and Synergy-GREEDY perform with different workload splits and how well do they utilize available resources (§5.4)?
- How does Synergy perform on different CPU:GPU ratios (§5.5)?
- Compare Synergy-TUNE to Synergy-OPT (§5.6)?
- Compare Synergy to big data schedulers (§5.7)?

5.1 Experimental setup

Clusters. Our experiments run on both a physical and a large simulated, homogeneous cluster. Our experiments are performed on state-of-the-art internal servers at Microsoft - these servers are part of a larger multi-tenant cluster. We run physical cluster experiments on a cluster with 32 V100 GPUs across 4 servers. Each server has 500GB DRAM, 24 CPU cores, and 8 GPUs. Unless otherwise specified, our experiments assume a CPU:GPU ratio of 3 and fair-share memory allocation of 62.5GB per GPU, matching the server configurations above. For simulations, we assume two cluster sizes; a 128 GPU cluster across 16 servers and a 512 GPU cluster across 64 machines, where each machine resembles the physical server configuration mentioned above.

Models. Our experiments consider 10 different DNNs (CNNs, RNNs, and LSTMs) as shown in Table 4. We categorize these models by task (image, language, and speech) and assign a certain weight to these tasks in our traces. We call this a workload *split*. For instance, if the split for a given trace is (30,40,30), then the percentage of image, language, and speech models in the job trace is 30%, 40% and 30% respectively. All experiments are performed on PyTorch 1.1.0.

Traces. We run our physical and simulated experiments using publicly available production traces from Microsoft Philly cluster [5].We show evaluation with the actual Philly trace preserving the job GPU demand, arrival time, and duration, on a cluster of 512 GPUs in §5.3.1. We use a subrange of the trace containing 8000 jobs.

However, to comprehensively evaluate how Synergy reacts to varying cluster load, workload composition, and job duration, for all other experiments, we construct a production-derived trace as follows: we extract job GPU demand from the Philly trace and assign a model based on the chosen *split*. We then appropriately scale the job runtime and arrival time for the chosen cluster size, while keeping the job duration distribution similar to the one in Philly trace as follows:

- **Duration**. The duration of each job for the baseline GPU-proportional allocation is sampled from an exponential distribution: the job duration is set to 10^x minutes, where x is drawn uniformly from [1.5,3] with 80% probability, and from [3,4] with 20% probability similar to the trace duration used in prior work [42].
- **Arrival**. We classify derived traces into two kinds based on the job arrival time : (1) a *static* trace where all the jobs arrive at the start of the workload, and (2) a *dynamic* trace, where the job arrival time is determined by load, a Poisson distribution at a rate λ.

The derived traces with varying job arrival rates uses a 128 GPU cluster. In both cases, we report the average metrics such as JCT across a set of 1000 jobs in steady state.

For the physical cluster experiment, we choose a fixed arrival rate for the derived trace that keeps our cluster at *full load* (GPU demand of all runnable jobs > available GPUs in the cluster). For the simulated experiments, we vary the load λ on the cluster to evaluate its impact on cluster metrics. For the simulated experiments, we show results for two trace categories - (1) all jobs request single-GPU (2) multi-GPU distributed training jobs that request upto 16 GPUs.

Policies and metrics. We evaluate Synergy against GPU-proportional scheduling for 4 different scheduling polices; FIFO, SRTF, LAS, and FTF. For a static trace, we measure makespan (time to complete all jobs submitted at the beginning of the trace) and for the dynamic job traces, we measure

5.2 End-to-End Physical Cluster Experiments

For the physical cluster experiments, we run a Synergy-TUNE (*tune*) and GPU-proportional allocation (*proportional*) for two different workload traces. (1) A static production-derived trace of 100 jobs with a *split* (60,30,10), scheduled using FIFO and evaluated for makespan. (2) A dynamic production-derived trace with continuous job arrivals and a split of (30,60,10), scheduled using SRTF and evaluated for average and 99th percentile JCT. Both scenarios use an appropriately sized trace that keeps the cluster fully loaded. We compare the obtained results to that of the simulator by replaying the same trace. Additionally, we compare our metrics to the upper bound generated by the optimal solution, Synergy-OPT (*opt*). The results are shown in Table 5.

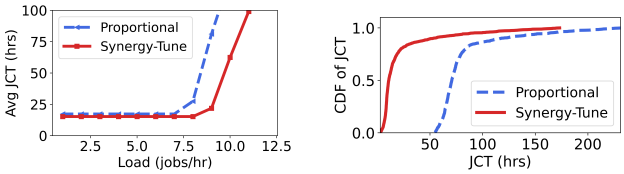
Synergy-TUNE reduces the makespan of static trace by 1.4× when compared to GPU-proportional allocation. For the dynamic trace, Synergy-TUNE reduces average JCT of steady-state jobs by 1.5× while reducing the 99th percentile JCT of these jobs by 2× as shown in Table 5.

We compare the observed results from physical experiments to the same trace replayed on our simulator. As shown in Table 5, the difference between metrics in real and simulated clusters are less than 5%, demonstrating the fidelity of the simulator. We also see from Table 5 that the cluster objectives achieved by Synergy-TUNE are within 4% of the optimal solution in this case. We do not deploy the optimal allocations due to the challenges enumerated in §4.1.3

5.3 End-to-end results in simulation

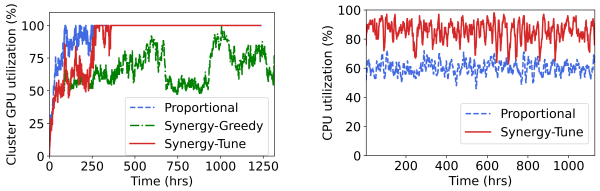
5.3.1 Simulation with production traces

We run simulated experiments on a cluster of 512 GPUs across 64 servers using a subrange of the publicly available Philly trace published by Microsoft [5]. We assume a workload split of (20,70,10) for this trial. Table 6a lists the average JCT with Synergy and GPU-proportional scheduling for three differ-



(a) FIFO (single) (b) CDF (9 jobs/hr)

Figure 9: **Average JCT and CDF for FIFO**. Synergy improves the average JCT significantly compared to alllocation for varying cluster load. At a load of 9 jobs/hr, Synergy reduces average JCT from 81hrs to 22hrs, which is close to the upperbound of 20hrs predicted by Synergy-OPT.



(a) GPU utilization (b) CPU utilization

Figure 10: Cluster resource utilization

ent scheduling policies. Across all policies, Synergy is able to reduce the average JCT compared to GPU-proportional scheduling due to better split of resources between jobs. The gains in Synergy can be attributed to reallocating the underutilized resources from a job to a different, resource-sensitive job whose throughput can improve with the increased allocation.

We show a detailed overview of the average and 99th percentile JCT for SRTF policy in Table 6b.We split the set of 1000 monitored jobs into short (JCT $<$ 4 hrs) and long jobs. Synergy reduces the tail of the distribution by 2.2$\times$ for short jobs and the average JCT of both long and short jobs by 15%. For each of the 1000 monitored jobs, we plot the individual job speedup with respect to GPU-proportional scheduling in Figure 6c. We see that Synergy speeds up jobs by upto 9$\times$ using better resource allocations.

5.3.2 Simulation with varying load

We run simulated experiments on a cluster of 128 GPUs across 16 servers using production-derived traces. We evaluate Synergy against GPU-proportional allocation mechanism for 4 different scheduling policies - FIFO, SRTF, LAS and FTF. We run dynamic workload traces, where jobs arrive continuously at a rate governed by a Poisson distribution. We show results for both single-GPU traces (where all jobs request 1 GPU) and multi-GPU traces (where jobs request upto 16 GPUs). Our metric of evaluation is the average JCT of a set of 1000 jobs in cluster steady state.

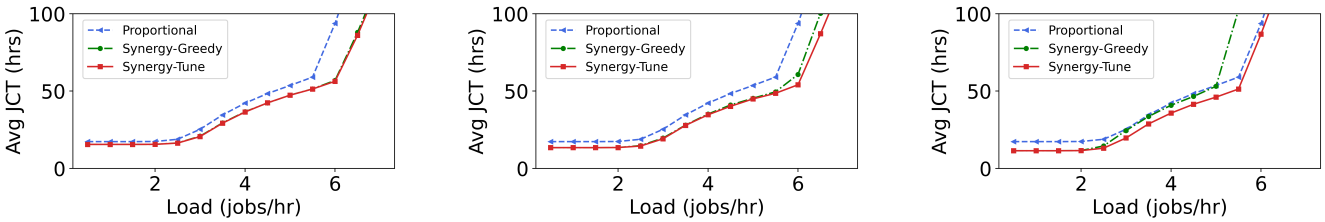
We show the results for three scenarios : LAS (multi-GPU trace) in Figure 7, SRTF (multi-GPU trace) in Figure 8, and FIFO (single GPU trace) in Figure 9. In all cases, we assume a workload split of (20,70,10). We plot both average JCT and the CDF of job completion times for a specific cluster load in both scenarios. For the multi-GPU trace, we split the CDF into those for short and long jobs to distinctly differentiate the tail of the distribution. We make three key observations.

First, Synergy-TUNE improves average JCT by up to 3.4$\times$ in the single-GPU trace, and up to 1.6$\times$ in the multi-GPU trace by speeding up resource sensitive jobs with disproportionate allocation. The improvement in average JCT is higher as the load increases, because at low load the cluster is not at full capacity. As load increases, jobs start to get queued and incur queuing delay before being scheduled on the cluster. Since Synergy significantly speeds up individual jobs using disproportionate resource allocation, pending jobs can get scheduled faster, thereby reducing their queuing delays. Therefore Synergy improves cluster metrics by both reducing queuing delays and speeding up individual jobs. Note that, in GPU-proportional allocation, at higher loads, all CPUs and memory in the system are allocated to the running jobs but they can still be underutilized by individual jobs. We show later in Figure 10b, how Synergy's resource-sensitivity aware allocation improves CPU utilization in the system compared to GPU-proportional allocation. At low load, jobs are spread across the cluster and the unallocated CPU and memory is assigned to the jobs that benefit from additional auxiliary resources. Second, Synergy-TUNE is able to sustain a larger cluster load than GPU-proportional allocation. For multi-GPU scheduling with LAS, Synergy-TUNE reduced the 95th percentile JCT of long jobs by 2$\times$. Third, the average JCT achieved with Synergy-TUNE is within 10% of the optimal solution in all cases.

Similarly, for FTF scheduling policy, Synergy-TUNE observed 2.3$\times$ and 2$\times$ improvement in average JCT for a single-GPU and multi-GPU trace respectively.

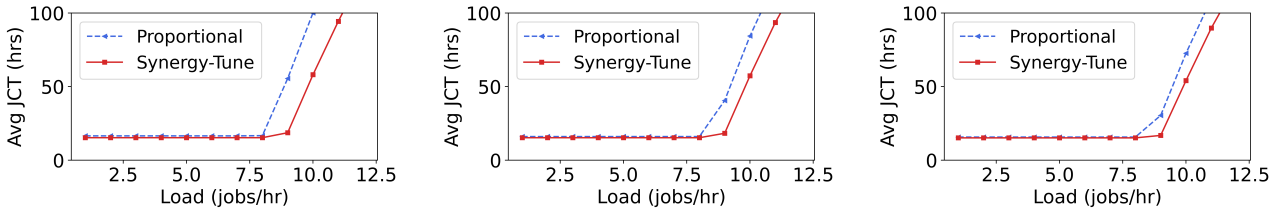
5.4 Impact of workload split

Workload split decides the percentage of resource sensitive jobs in the workload. As the percentage of speech and image models increase in the trace, there may not be enough spare CPU and memory resources to perform disproportionate allocation, as they are mostly CPU- and memory-hungry. Figure 11 plots the average JCT with varying load for 3 different workload splits with FIFO scheduling for multi-GPU jobs. As the percentage of resource-sensitive jobs increase, we observe that Synergy-GREEDY breaks down, and ends up degrading JCTs significantly compared to a GPU-proportional allocation. This is because, the naive greedy technique results in resource fragmentation when the demand along CPU and memory dimensions are high, leaving several GPUs underutilized. Whereas, by the design of Synergy-TUNE, it allocates at least as many resources required to achieve the throughput of GPU-proportional allocation; therefore, even in the worst case workload split shown in Figure 11c, where all the jobs



(a) Split=(20,70,10) (b) Split=(33,33,33) (c) Split=(50,0,50)

Figure 11: Evaluation of Synergy with varying workload split



(a) Ratio 4 (b) Ratio 5 (c) Ratio 6

Figure 12: Evaluation of Synergy across different CPU:GPU Ratio

are CPU- and memory-sensitive, Synergy-TUNE performs as good as GPU-proportional allocation.

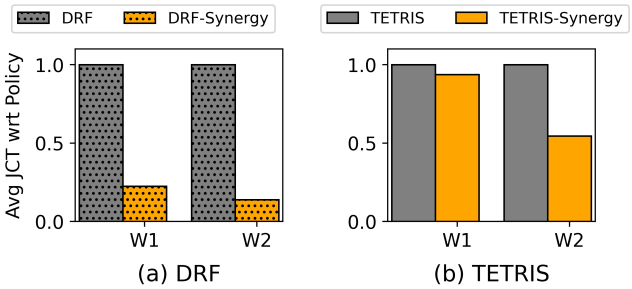
Resource utilization. Figure 10a plots the GPU allocation over time for the workload in Figure 11c at a load of 5.5 jobs/hr where the cluster GPU demand is higher than 100%. While Synergy-TUNE is able to sustain a higher load by finishing jobs faster, Synergy-GREEDY severely under-utilizes GPU resources throughout the workload, trading it off for higher CPU and memory allocation. At low loads, as shown in Figure 10b, GPU-proportional allocation only utilized 60% of the available CPU resources, while Synergy-TUNE utilized it up to a 90%, resulting in 1.5× lower average JCT.

5.5 Impact of CPU:GPU ratio

While our prior experiments assume a CPU:GPU ratio of 3 (similar to the NVIDIA DGX-2), Figure 12 plots the average JCT for a FIFO scheduler on a single-GPU trace as we increase cluster load and vary the CPU:GPU ratio from 4 to 6 (corresponding to other server SKUs in Table 2b). As the CPU:GPU ratio in a server increases, the baseline GPU-proportional scheduler gets more CPU cores per GPU, thereby reducing data stalls in the baseline. This in turn, reduces the gap between GPU-proportional and Synergy-TUNE. Despite that, at a load of 9 jobs/hr, Synergy-TUNE lowers the avg JCT by 3.4×, 3×, 2.2×, and 1.8× for a CPU:GPU ratio for 3, 4, 5 and 6 respectively.

5.6 Comparison to Synergy-OPT

Calculating optimal allocations for every scheduling round with Synergy-OPT can be quite expensive, especially for large



(a) DRF (b) TETRIS

Figure 13: Comparison to big data scheduling policies

cluster sizes. We experimentally validated that the time taken for per-round allocations for Synergy-OPT increases exponentially with increasing cluster sizes, while that for Synergy-TUNE is hardly a second. We also show experimentally that the allocations given by Synergy-TUNE are close to those estimated by Synergy-OPT in §5.2 and §5.3.2. For a cluster size of 128 GPUs used in our experiments, Synergy-TUNE converges at allocations that are within 10% of the optimal value, 200× faster than Synergy-OPT.

5.7 Comparison to DRF and Tetris

Big data schedulers like Dominant Resource Fairness (DRF) [21] and Tetris [23] have explored multi-dimensional resource allocation for map-reduce jobs. DNN jobs have different properties when compared to big-data jobs. DNN jobs are gang-scheduled, meaning they can run only when all the GPUs requested by them are available on the cluster at once. Further, the auxiliary resource requirements like CPU and memory are fungible unlike the GPU demand. DRF and Tetris assume resources to be statically allocated throughout the life-

time of a job, whereas Synergy assumes these resources to be fungible and could result in varied allocations throughout the lifetime of a DNN job. Furthermore, profiling the DNN job's resource demands is unique to Synergy; big data schedulers assume that the job request already encodes resource demands across all dimensions. To evaluate Synergy against these policies, we assume that the best-case resource requirement for CPU and memory is fed as input to the bigdata scheduling policies using Synergy's profiling mechanism.

On a cluster of 128 GPUs, we evaluate these policies on two different workload compositions : W1 (20,70,10), and W2 (50,0,50) and compare the naive policy with its Synergy-variant, which allows resource tuning. W1 represents a workload split with a good mix of resource-sensitive as well as resource-insensitive jobs. W2 is a workload dominated by resource-sensitive jobs, which is one of the worst-case scenarios for multi-dimensional scheduling as it could lead to GPU fragmentation (explained in §5.4)

We plot the results in Figure 13. Tuning resource allocation across jobs using Synergy reduced the average JCT of DRF by 7.2× and that of Tetris by 1.8× for the workload split W2. This is because Synergy is able to allocate auxiliary resources in a fungible-manner every round, whereas the big-data scheduler's static allocations performs similar to greedy techniques, resulting in GPU fragmentation, and thereby degrading the overall cluster metrics. Synergy performs the best in each scenario as it uses the best-case resource demands of jobs to perform fungible, disproportionate allocation.

6 Discussion and Future Work

In this section, we elaborate on some of the assumptions made by Synergy, derived from our experiences with large scale deployed cluster schedulers at Microsoft, and discuss what happens if these assumptions are relaxed.

Homogeneous clusters. Scheduling in Synergy assumes that the GPU cluster is homogeneous. This assumption is based on the practical observation that our clusters have thousands of accelerators per homogeneous cluster [5]. While there is heterogeneity in hardware across clusters, it is often the case that users select one homogeneous cluster to run their job in production. For instance, a production cluster could have two homogeneous virtual clusters (VCs), each comprising of a specific generation of GPU. Each VC is managed separately, and assigned to a specific task - training or inference, for predictable performance. While recent works have explored the impact of blurring these boundaries and scheduling across heterogeneous hardware [11, 33, 42], such co-scheduling poses several practical challenges [52]. For example, some tasks such as low-latency inference are business-critical, user-facing applications which need to run on specific hardware, and need data isolation. Others have specific GPU memory requirements, or need advanced hardware features like NVLink. Hence, users in our production settings specify a specific instance type to run each of their jobs on. Hence it is useful for a scheduler to optimize resource utilization in the context of homogeneous clusters. That said, Synergy 's ideas can also be extended to a heterogeneous cluster by profiling CPU and memory requirements along an additional dimension - GPU type, at an additional profiling cost. The optimal algorithm can then maximize throughput based on a 3-dimensional resource-sensitivity matrix W_j. We present the formulation for this in the extended version of the paper [38].

Use of MinIO. Synergy assumes the use of MinIO [39] because it is a DNN-aware caching mechanism that outperforms traditional OS page caching and allows performance predictability. It provides resource isolation and reduces storage fetch stalls [39]. If we do not use MinIO, we will have to profile the model at discrete memory allocations which will increase the profiling costs, and also potentially change the trends in profiling matrix.

Preprocessing overhead. Preprocessing for vision tasks includes random cropping and transformations of the image in the critical path. Reusing the same transformed images across epochs hurts accuracy [34, 37, 39], whereas it is practically infeasible to pre-process offline due to the prohibitive storage cost (dataset size * epochs). It is possible to alter the extent of CPU intensiveness by varying the number of augmentations performed. In this work, we have assumed that the augmentations required for each model are as specified by the published models themselves and we do not change this so as to not affect accuracy. On the horizon, we do observe recent schemes such as RandAugment [14], AutoAugment [13] which consider more computationally-intensive augmentation schemes (and associated accuracy gains). Such a rising trend in extreme preprocessing, makes a strong case for a system like Synergy.

Sharing storage and network. In our paper, we show how to reallocate CPUs and memory across jobs resident on the same server, for example, by co-locating a CPU-intensive task with a non CPU-intensive task. For our DNN training jobs, we assume that a dataset is downloaded locally and loaded into server memory when the job is started (constrained by the memory allocation limits). Prior work has similarly looked at co-locating network-intensive jobs with non network-intensive jobs [26, 35], but unlike Synergy, reallocation of shared network bandwidth is not explicitly handled by those schedulers. We leave it to future work to explore how ideas in Synergy can also be extended to reason about demands that individual jobs place on storage and network bandwidths.

GPU elasticity and sharing. While some recent works explore transparently changing the GPU allocation during the life of a job [48], the impact of changing batch sizes and hyperparameters on training accuracy is unclear for a wide variety of tasks. It is therefore practical to assume that the

GPU demand of a job is constant throughout its lifetime as is the case for jobs in our production clusters.

Synergy works by improving the throughput of jobs that are bottlenecked on data stalls. For jobs that have data stalls, GPU efficiency cannot be improved by multiplexing (spatial sharing) because they are waiting for input data. However, for a subset of jobs that are insensitive to auxiliary resource allocation, GPUs could be multiplexed between jobs. It would be interesting to explore how to impart resource-sensitivity awareness alongside GPU spatial sharing, which we leave for future work.

Tradeoff between consolidation and allocation. When multi-GPU jobs are split across physical servers, they may incur a penalty due to network communication [41, 55]. DNN jobs therefore prefer consolidation. In this work, we assume that no more than a server's worth of CPU or memory resources can be allocated to a job if its GPU demands can be satisfied by one server. However, we find that some jobs may benefit from giving up consolidation if the throughput gain due to increased CPU or memory allocation is higher than the penalty due to splitting. We leave the exploration of the trade off between consolidation and allocation, while taking into account the network overhead, to future work.

Leveraging model and pipeline parallelism. Our evaluation assumes distributed data-parallel jobs. But model and pipeline parallel execution schemes also have an input stage that ingest and pre-process data. Unlike data-parallel training, each stage in the pipeline might have a different CPU-GPU and memory-GPU requirement. While these jobs would have to be profiled to identify the CPU and memory sensitivity of each stage of the pipeline, Synergy 's contributions directly carry forward to such settings.

7 Related Work

DNN cluster schedulers. A number of recent schedulers for DNN workloads each focus on improving a certain objective; Cluster utilization (Gandiva [55]), JCT (Tiresias [26]), and fairness (Themis [35], Gandiva-Fair [11]). Some have also looked at exploiting performance heterogeneity among accelerators to improve cluster objectives [33, 42]. All these schedulers assume GPU to be the dominant resource in the scheduling task; i.e., a user requests a fixed number of GPUs for her DNN job, and when the requested number of GPUs are all available, the job is scheduled to run. Rather than allocating a fixed number of GPUs, building on GPU-elasticity for a single job [44], some recent schedulers like AFS [30] and Pollux [48] leverage throughput metrics to provide GPU elasticity in multi-tenant clusters (in addition to tuning batch size and learning rate). However, in all these cases, auxiliary resources such as CPU and memory are allocated proportional to the number of GPUs allocated to the job. Existing schedulers thus ignore *resource-sensitivity* of the DNN tasks to CPU and memory. Synergy shows that, irrespective of the number of GPUs allocated, auxiliary resource-sensitive allocation is crucial to achieve better cluster utilization.

Big data schedulers. Our work builds upon the insights drawn from the rich literature of schedulers for big data jobs [21, 23–25, 29, 51]. Big data schedulers like Tetris [23], and DRF [21] have looked at the problem of multi dimensional resource allocation for big data jobs. They propose new scheduling policies aimed at optimizing a specific cluster objective for jobs whose resource demands are prior known. In contrast, the primary resource in a DNN job is the accelerator (GPU), whose requirement is specified by the job; other resources are fungible. Our work exploits this insight to perform disproportionate allocations by profiling job resource sensitivity, and then appropriately packing them onto servers.

Data stalls. Recent, deep characterization studies explored the impact of CPU and memory on individual DNN jobs [39, 40] Unlike prior work that focuses on individual jobs, the focus of our paper is on the tricks we can play when we schedule multiple jobs together in a cluster.

Disaggregated data prep. There have been recent orthogonal efforts that aim at reducing the cost of data preprocessing, and thereby the load on CPUs using disaggregated data prep [59]. However, one has to pay the network cost of shuffling preprocessed tensors, which could quickly become the bottleneck especially for vision models with rich datasets. Synergy on the other hand, assumes standard pre-processing pipelines at the training servers, and aims to reduce the cost of pre-processing using better resource allocation.

8 Conclusion

This paper introduces Synergy, a resource-sensitive scheduler for DNN training jobs. Synergy is based on the insight that not all jobs exhibit the same level of sensitivity to CPU and memory allocation during DNN training; breaking the shackles of GPU-proportional allocation can result in improved utilization of existing cluster resources and improved job and cluster-wide objectives. Our experiments on physical and large simulated clusters show that Synergy can reduce average JCT by upto 3.4× over GPU-proportional allocation.

Acknowledgements

We thank our shepherd Ravi Netravali, the anonymous OSDI reviewers, members of the UT SaSLab, and many of our MSR colleagues for their invaluable feedback that made this work better. Sincere thanks to the fellow Project Fiddle interns Kshiteej Mahajan and Andrew Or for their contributions to the simulator infrastructure. We thank Microsoft Research for their generous support of JM's internships, and for the many resources required to develop and evaluate this work.

Abstract

Cloud stacks must isolate application components, while permitting efficient data sharing between components deployed on the same physical host. Traditionally, the MMU enforces isolation and permits sharing at page granularity. MMU approaches, however, lead to cloud stacks with large TCBs in kernel space, and page granularity requires inefficient OS interfaces for data sharing. Forthcoming CPUs with hardware support for *memory capabilities* offer new opportunities to implement isolation and sharing at a finer granularity.

We describe *cVMs*, a new VM-like abstraction that uses memory capabilities to isolate application components while supporting efficient data sharing, all without mandating application code to be capability-aware. cVMs share a single virtual address space safely, each having only capabilities to access its own memory. A cVM may include a library OS, thus minimizing its dependency on the cloud environment. cVMs efficiently exchange data through two capability-based primitives assisted by a small trusted monitor: (i) an asynchronous read/write interface to buffers shared between cVMs; and (ii) a call interface to transfer control between cVMs. Using these two primitives, we build more expressive mechanisms for efficient cross-cVM communication. Our prototype implementation using CHERI RISC-V capabilities shows that cVMs isolate services (Redis and Python) with low overhead while improving data sharing.

1 Introduction

Cloud environments require application compartmentalization. Today, isolation between application components is enforced by virtual machines (VMs) [10, 32, 63] and containers [2, 40], either separately or in combination. Yet, current applications push the limits of these mechanisms in terms of performance and security: when application components communicate heavily with each other, VMs and containers add substantial overheads, even when they are co-located to improve communication performance; furthermore, the implementation of the isolation mechanisms may also rely on a large trusted computing base (TCB).

VMs provide strong isolation through a relatively narrow hardware interface. Since a guest VM has its own OS kernel, its TCB can be reduced to a relatively small hypervisor, which multiplexes VM access to the hardware [56]. Efficient inter-VM data sharing, however, is challenging to achieve due to performance and page granularity trade-offs [17, 71].

In contrast, *containers* isolate processes into groups [2] and provide faster inter-process communication (IPC) primitives, including pipes, shared memory, and sockets. Similar to VMs, they face problems of page-level sharing granularity and overheads due to frequent user/kernel transitions. Their richer IPC primitives for data sharing come at the cost of a larger TCB—a shared OS kernel implements both namespace isolation between process groups and complex IPC primitives, increasing the likelihood of security vulnerabilities.

Existing cloud stacks thus face a fundamental tension when application components are compartmentalized but must communicate. They must either copy data or modify page tables, both of which are expensive operations that involve a privileged intermediary, e.g., a hypervisor or OS kernel, and lead to coarse-grained interfaces designed around page granularity.

In this work, we explore a different approach to designing a cloud stack that isolates application components, while supporting efficient sharing. We ask the question "if the hardware supported dynamic, low-overhead sharing of arbitrary-sized memory regions between otherwise isolated regions, how would this impact the cloud stack design?" We exploit hardware support for *memory capabilities* [23, 70], which impose flexible bounds on all memory accesses, allowing components to be isolated without page table modifications or adherence to page boundaries. This offers a new opportunity to design memory sharing primitives between isolated compartments with zero-copy semantics.

We describe **CAP-VMs (cVMs)**, a new VM-like abstraction for executing isolated components and sharing data across them. cVMs are enforced by a small TCB that uses memory capabilities to isolate and share data between compartments efficiently. Through the use of a *hybrid* capability model [66], cVMs avoid having to port application components to use

capability instructions, circumventing compatibility issues that typically plague capability architectures.

Using memory capabilities as part of a cloud stack, however, raises new challenges: the cloud stack must (i) support existing capability-unaware software without cumbersome code changes, bespoke compiler support, or manual management of capabilities across isolation boundaries; (ii) remain compatible with existing OS abstractions, e.g., POSIX interfaces, all while keeping the TCB small; and (iii) offer efficient IPC-like primitives for otherwise untrusted components to share data safely and take advantage of the potential zero-copy sharing enabled by capabilities.

To address the above challenges, cVMs make the following design contributions:

(1) Strong isolation through capabilities. Multiple cVMs share a single virtual address space safely through capabilities. Each cVM is sandboxed by a pair of *default* capabilities, which confine the accesses of all instructions inside a cVM to its own memory boundaries. To avoid having to port existing application components to a capability architecture, cVMs allow them to execute unmodified by using CHERI's *hybrid* capability architecture [66], which integrates capabilities with a conventional MMU architecture. In addition, cVMs strictly limit how CHERI capabilities can be used to avoid known capability revocation overheads: cVMs are not permitted to store or export capabilities, and the transitions of communication capabilities are controlled by a trusted component.

(2) Bespoke OS support through a library OS. cVMs are self-contained with a small TCB, reducing reliance on the external cloud stack, while providing POSIX compatibility. They include a bespoke *library OS* with POSIX interfaces for, e.g., filesystem and network operations with cryptography for transparent protection, which is protected from application code using capabilities. In the library OS, each cVM implements its own namespace for filesystem objects, virtual devices, cryptographic I/O keys etc. Only low-level resources, e.g., execution contexts for threads and I/O device operations, are shared and provided by an external host OS kernel.

(3) Efficient data sharing primitives. cVMs offer two low-level primitives to share data efficiently without exposing application code to capabilities, which are hidden behind a small, trusted *Intravisor*: (i) a *CP_File* API allows application components to share arbitrary buffers through an asynchronous read/write interface. Under the hood, the cVM implementation uses capability-aware instructions to exchange the rights to safely access each other's memory, and read/write data at byte granularity at the cost of a single memory copy (whereas traditional file-oriented IPC would require two copies); and (ii) a *CP_Call* API transfers control between cVMs, which, e.g., can be used to implement synchronization mechanisms. By combining these two primitives, higher-level APIs are possible: (iii) a *CP_Stream* API supports efficient stream-oriented data exchange between cVMs with one memory copy.

We implement cVMs on the CHERI RISC-V64 architecture, executable on FPGA hardware with CHERI support and multi-core RISC-V hardware. Our evaluation shows that cVMs provide a practical isolation abstraction with efficient data sharing: using the CP_Stream API for inter-cVM communication reduces latency for Redis by up to 54% compared to classical socket interfaces, and reduces its standard deviation by up to 2.1×. When isolating a cryptography component of a Python-based service, cVMs introduce an overhead of up to 12% compared to a monolithic baseline.

2 Hardware Isolation Support

Next we survey the design space for isolation and sharing in cloud environments in more detail (§2.1), provide background on capability support on modern hardware (§2.2), and describe our threat model (§2.3).

2.1 Isolation and sharing in the cloud

We argue that VMs and containers are two extremes of component isolation. VMs virtualize hardware interfaces such as page tables, instructions, traps, and physical device interfaces to manage both isolation and communication; containers virtualize pure software interfaces such as processes, files, and sockets for the same purposes.

Compatibility. Both VMs and containers are compatible with existing applications, which is critical for adoption in cloud environments. VMs can execute an unmodified guest OS on top of a hypervisor, making virtualization transparent to applications inside VMs. Conversely, containers execute unmodified applications on top of the same host OS kernel that manages other containerized and non-containerized applications. In both cases, OS interfaces and semantics used by the virtualized applications remain unmodified compared to a non-virtualized environment.

But the compatibility offered by these technologies lowers communication performance, which is often exacerbated as we try to achieve better isolation between components.

Isolation. Despite strict isolation between the memory of containers, there is a lack of isolation of the TCB that manages the virtualization mechanism itself. Conventional container platforms, e.g., Linux containers [2], share privileged state, as they employ namespace virtualization: the OS kernel creates separate process identifiers, devices, filesystem views etc., which offer the illusion that a process group exists in isolation. In reality, containers share kernel data structures, and privilege escalation inside one container may lead to the compromise of all containers [3,5]. In comparison, VMs are virtualized through narrower interfaces, resulting in a conceptually simpler hypervisor that is harder to compromise [15,56].

Unfortunately, stronger isolation comes at a performance price from both known hardware inefficiencies [14,41,61] as well as less flexible mechanisms for data sharing.

Sharing. Components of cloud applications typically use

networking as a means of communication. Even if multiple components are co-located on the same host, they may use a reliable network transport protocol, e.g., TCP. While this helps with scalability, it adds overhead for co-located components, making optimizations based on direct memory sharing attractive. Both VMs and containers use page-based memory isolation, which limits the performance of memory sharing: mechanisms must be aware of page boundaries to avoid leaking sensitive data, and page table modifications for on-demand sharing are known to be expensive [62].

Co-location opens up two avenues for performance improvements: (1) sharing can transparently speed up communication of co-located components [44, 47]; and (2) new communication interfaces can be tailored toward efficient sharing between components.

2.2 CHERI capability architecture

In cloud applications with many services [26], traditional network-based communication shows its performance limits between tightly-coupled components [33]. Therefore, we aim to co-locate components and design a cloud stack with efficient isolation and communication interfaces and mechanisms. This requires, however, new hardware support for isolation and sharing that is free of the "MMU tax" of page-level privileged memory protection.

Memory capabilities [18] are a protection and sharing mechanism supported by the hardware. The *CHERI* architecture [64, 70] implements capabilities as an alternative to traditional memory pointers. A capability is stored in memory or registers, and encodes an address range with permissions, e.g., referring to a read-only buffer or a callable function.

CHERI protects capabilities by enforcing three properties: (1) *provenance validity* ensures that a capability can only be "derived", i.e., constructed, from another valid capability, i.e., it is not possible to cast an arbitrary byte sequence to a capability; (2) *capability integrity* means that capabilities stored in memory cannot be modified, which CHERI achieves through transparent memory tagging [70]; and (3) *capability monotonicity* requires that, if a capability is stored in a register, its bounds and permissions can only be reduced, e.g., a read-only capability cannot be turned into a read-write one.

Building capability-based compartments. CHERI capabilities can be used to compartmentalize software components, e.g., plugins or libraries in a program, by giving each capabilities to separate memory regions. The above properties enforced by CHERI ensure that compartments can coexist in the same address space, and remain isolated as long as their initial capabilities point to disjoint data and code in memory. The application can, of course, grant each compartment extra capabilities, e.g., to allow particular cross-compartment memory accesses or function calls.

Pure- and hybrid-cap code. CHERI distinguishes between two execution modes [66]: (i) in *pure-cap* mode, all pointers must be capabilities,[1] and code must use a new set of capability-aware instructions; and (ii) in *hybrid-cap* mode, code can mix ordinary and capability-aware instructions, which allows the coexistence of capability-unaware and pure-cap code via wrapping functions. This facilitates the incremental adoption of capabilities in software.

When accessing memory, pure-cap code must use new instructions that use capability registers instead of regular registers. In addition, secure calls across capability-isolated components must use a `CInvoke` instruction, which requires a pair of capabilities: the target function address, and an arbitrary value that is meaningful to the callee function (e.g., an identifier for an object managed by the callee).

To ensure that both capabilities are used correctly by `CInvoke`, e.g., thwarting a malicious caller from passing a callee object identifier that was meant for a different callee function, the callee can "seal" pairs of capabilities together using the `CSeal` instruction. `CInvoke` only accepts correctly sealed pairs of capabilities.

Hybrid-cap code relies on two new capability registers, the *default data capability* (`ddc`) and the *program counter capability* (`pcc`), which are used implicitly by capability-unaware instructions. The OS starts all processes by setting `ddc` and `pcc` to the entire virtual address space. Capability-aware code then creates new capabilities from these registers, preserving CHERI's provenance, integrity and monotonicity properties.

Pure-cap code thus introduces compatibility challenges:

- All pointers in pure-cap code are capabilities that occupy 16 bytes instead of the ordinary 8 bytes, and must be 16-byte aligned. This decreases CPU cache effectiveness, and may require extra effort to align capability and non-capability elements in data structures.
- It is not possible to cast between addresses and various types of capability-based pointers, because CHERI distinguishes between them and imposes bounds on pointers [65]. C/C++ code that uses raw casts—a commonly found idiom in low-level system software—requires substantial modifications. For example, the strict bounds in capabilities are typically incompatible with memory allocators that place metadata before allocated data.
- While CHERI compresses capabilities, they can still result in memory bloat, because larger sizes are subject to coarser address discretization. Large allocations with capabilities may require stronger alignment and extra padding [69].
- CHERI advocates for a trusted, system-wide *garbage collector* to manage capabilities to dynamically-allocated memory [66]. It is important to ensure that allocations are not reused while valid capabilities pointing to them still exist. Since new capabilities can be derived from existing ones, and stored on the heap, stack, and in registers, all capabilities derived from an allocation must be either invalidated (i.e., revoked), or allocations cannot be reused

[1] CHERI has separate registers for regular data and capabilities.

while such capabilities are valid. A garbage collector (as opposed to expensive hardware support for capability revocation) addresses this issue, but it is a disruptive change in cloud environments, potentially leading to delays in resource reclamation and increased tail latencies.

Removing the need to use capability-aware code is important in cloud environments with limited control over tenant code. Therefore, we want to explore a design for a cloud stack that compartmentalizes application components using CHERI's hybrid-cap mode, without the disadvantages of pure capability-aware code.

2.3 Threat model

Cloud environments support multiple, isolated application components, and thus we consider attacks in which an attacker controls a malicious component that interferes with another component by probing interfaces or trying to escape its sandbox. We assume that the attacker has full control over the application components and a library OS, e.g., by exploiting vulnerabilities inside the compartment or by executing arbitrary code that includes capability-aware instructions.

Our TCB includes the underlying host OS kernel, but the entire application stack (program, libraries and library OS) is considered untrusted. We assume that the CHERI hardware implementation is correct. We do not analyse side-channel attacks against CHERI, which is an important, yet orthogonal consideration that affects both the architectural and micro-architectural levels [67].

3 cVM Design

cVMs are a new virtualisation and compartmentalization abstraction for application components. Such components can often be co-located and exchange data, and cVMs isolate them with support for low-overhead data exchange using CHERI capabilities. The design of cVMs has the following features:

Separate namespaces. Unlike containers, cVMs do not rely on a shared OS kernel for namespace isolation. They use capabilities to add a new userspace-level isolation boundary, moving OS kernel functionality from a privileged to an unprivileged layer. cVMs only use the host OS for execution contexts, synchronisation, and I/O, thus resembling VMs.

Bypassed communication. cVMs are mutually untrusted, but communication bypasses the host OS kernel for performance. They use capabilities for on-demand access to memory regions used for communication, without compromising neighbouring memory.

Low-overhead isolation. cVMs use capabilities for low-overhead isolation of both process and program modules. For example, cVMs can isolate shared libraries with minimal changes to the calling interface.

Compatibility. cVMs use CHERI's hybrid-cap mode. Capabilities are thus hidden from application code, which only needs changes to use new communication APIs.

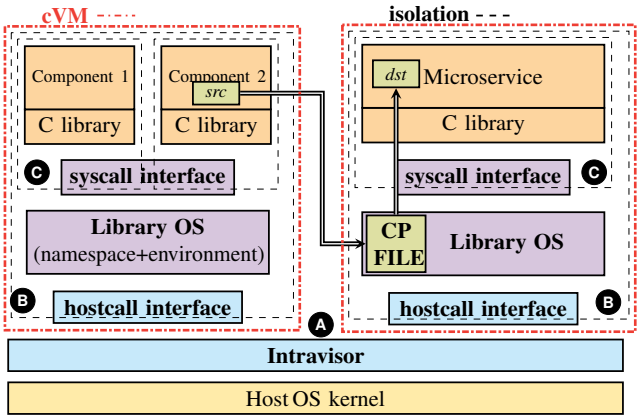

Fig. 1: cVM architecture

3.1 Architecture overview

Fig. 1 shows the architecture of cVMs. Each cVM Ⓐ is an application component, such as a process or library, and has three parts: (i) program binaries and their libraries; (ii) a standard C library; and (iii) a library OS.

cVMs add two new isolation boundaries, enforced through capabilities. The *Intravisor boundary* Ⓑ separates the *Intravisor* from all cVMs, and cVMs from each other. The Intravisor is responsible for the lifecycle and isolation of cVMs, allows safe communication between them, and provides other primitives that cannot be implemented inside the unprivileged library OS (e.g., storage and networking I/O, time, threading and synchronisation). It has access to the memory of all cVMs, but not the other way around.

The *Program boundary* Ⓒ separates programs from the library OS that provides them the namespace for all OS primitives. A single library OS instance can thus host multiple, mutually-isolated programs with their own code and data (left-most cVM in Fig. 1).

These isolation boundaries are enforced by CHERI capabilities; compartmentalized content cannot access memory beyond its boundary, except through the controlled interfaces described next. Finally, there is a classical separation from the host OS, using CPU rings and MMU-based isolation.

3.2 Isolation boundaries

We now describe how cVM are isolated in more detail (see Fig. 2). Each program compartment contains the code and data of its binary, its dependencies (shared libraries), and the standard C library; the cVM also contains the library OS, which provides the OS functionality.

Isolation boundaries are enforced by giving each its own default CHERI capabilities using the `pcc` and `dcc` registers (see §2.2) with non-overlapping address ranges; compartmentalized code thus cannot load, store or jump into memory outside that granted by the capabilities that it holds. To allow ❶ program → libOS and ❷ libOS → Intravisor calls, cVMs use extra capabilities that grant controlled access to functions outside the respective compartment.

Tab. 1: cVM API

Type	API function	Description
Creation	`cp_cvm_make(cp_config_t *cfg, char *libos, char *disk.img, int argc, char *argv[])`	Create new cVM
CP_File	`cp_file_make(char *key, size_t key_size, void *addr, size_t size)`	Make CP_File for buffer `addr` & publish with `key`
	`cp_file_destroy(int file)`	Destroy CP_File
	`cp_file_get(char *key, size_t key_size)`	Get CP_File with `key` from another cVM
	`cp_file_read,cp_file_write(int file, char *key, size_t key_size)`	Read/write data via CP_File `file`
	`cp_file_wait,cp_file_notify(int file)`	Wait/notify signal via CP_File `file`
CP_Call	`cp_call_make(char *key, size_t key_size, void *func)`	Make CP_Call for `func` & publish with `key`
	`cp_call_destroy(int call)`	Destroy previously created CP_Call
	`cp_call_get(char *key, size_t key_size)`	Get CP_Call with `key` from another cVM
	`cp_call(int call, bool async, void *arg, size_t size)`	Call CP_File `call` with arguments
CP_Stream	`cp_stream_make(char *key, size_t key_size)`	Make CP_Stream & publish with given `key`
	`cp_stream_destroy(int stream)`	Destroy CP_Stream
	`cp_stream_get(char *key, size_t key_size)`	Get CP_Stream with `key` from another cVM
	`cp_stream_send(int stream, void *buf, size_t size)`	Send buffer through CP_Stream
	`cp_stream_recv(int stream, long id, void *buf, size_t size)`	Post buffer to receive through CP_Stream.
	`cp_stream_poll(int stream, long *id, size_t nid, int timeout)`	Poll for data on receive buffers of CP_Stream

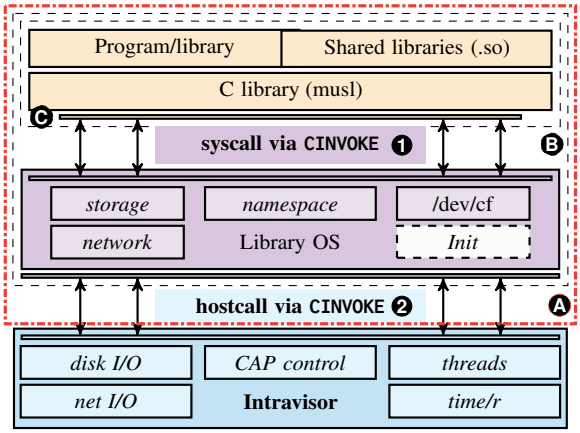

Fig. 2: Anatomy of a cVM

cVMs need to implement the equivalent of user/kernel separation using CHERI capabilities in userspace. When loading a program, a set of capabilities is therefore given to the syscall handler functions of the library OS. The standard C library uses these capabilities to invoke system calls on the library OS through the `CInvoke` instruction, while the rest of the application remains capability-unaware. The library OS has full access to the programs that it manages.

cVMs also need to implement the equivalent of guest/host (or VM/hypervisor) separation using CHERI capabilities in userspace. When creating a cVM, the Intravisor installs capabilities to its own host system call handlers on the new library OS instance; in turn, the library OS uses `CInvoke` to invoke Intravisor operations.

3.3 Creation and communication API

cVMs combine compatibility and flexibility when isolating cloud services. They support the execution of complete application components using a process isolation abstraction, but also that of individual library components.

Tab. 1 shows the cVM API. New cVMs are created by `cp_cvm_make()`; similar to `fork()`/`exec()`, it accepts a disk image file, a program binary to load into the cVM, and a function in that binary to launch. If a cVM isolates a standalone library, `cp_call()` invokes functions in the library.

cVMs use CHERI capabilities for efficient inter-cVM communication. The Intravisor exchanges an initial set of capabilities between cVMs to allow communication.

CP_File. This primitive introduces a file-like API to access memory from another cVM at arbitrary granularity; the use of capabilities in CP_File permits bypassed access to memory without repeated mediation by the Intravisor.

A *donor* cVM registers a memory region with the Intravisor to share with other cVMs via `cp_file_make()`; a *recipient* cVM calls `cp_file_get()` with the same key to obtain access. The cVMs then access data in the memory region via `cp_file_read/write()`. Internally, the library OS uses capability-aware code to copy data directly between the cVMs (using `capcpy`; see §4).

To support asynchronous data transfers, `cp_file_wait()` and `cp_file_notify()` allow callers to wait for and notify events on a CP_File, respectively. Finally, the donor cVM calls `cp_file_destroy()` to destroy it, revoking all access.

CP_Call. This primitive invokes functions outside the calling cVM, e.g., a callback function in the library OS, or a function in a shared library. cVMs manage CP_Calls as follows: `cp_call_make()` registers a function in the donor that recipients can look up using `cp_call_get()` and then call with `cp_call()`. The call is received by the Intravisor, which creates a new thread in the donor's cVM, sets it to execution to the target function with given arguments and, optionally, waits for its completion, based on the `async` argument.

CP_Stream. By composing the CP_Files and CP_Calls APIs, it is possible to construct more complex communication mechanisms. For example, we have built a stream-oriented API for inter-cVM communication in which the sender does not need to know where data is copied.

A recipient cVM calls `cp_stream_recv()` to register buffers for incoming messages (internally, a list of CP_Files); a sender cVM calls `cp_stream_send()` to copy data into any of the buffers available in the recipient. The recipient is then informed of data transfers when calling `cp_stream_poll()`.

3.4 Capability management

The use of CHERI capabilities introduces two problems that cVMs must avoid: avoiding the need for application code to become capability-aware and performance problems when revoking capabilities.

As explained in §2.2, making an application fully capability-aware requires code changes. The design of cVMs avoids this by limiting the use of capability-aware code to a small portion of the standard C library, the library OS and the Intravisor, which explicitly handle the CP_Files and CP_Calls abstractions through syscall trampolines.

In the cVM design, we want to avoid centralized trusted mechanisms for capability revocation (see §2.2), as this goes against our goal of minimizing overheads and TCB size. Therefore, only the Intravisor is permitted to store CHERI capabilities in memory: all capabilities that are passed by the Intravisor to cVMs have the `CAP_STORE` permission withheld. Instead of having to perform expensive garbage collection, revocation can now be done by clearing a small number of capability registers. This can be done efficiently when programs call the cVM API to avoid interrupting execution.

4 Implementation

Next, we report implementation details of cVMs on the CHERI RISC-V64 platform. Our implementation consists of 5,200 lines of C code and 100 lines of assembly for the Intravisor, and 1,800 lines of C code and 200 lines of assembly for the Init service, the Hostcall interface and CAP Devices. It uses the Linux Kernel Library (LKL) v4.17.0 [36] as the library OS and the musl standard C library v1.2.1 [42]. As the host OS kernel, we use CheriBSD [25].

4.1 cVM lifecycle

Initialisation. The boot process of a cVM is trigged by the Intravisor. It receives a deployment configuration for the cVM, which includes the heap size, the disk image location, the permitted interfaces, etc. It also defines the version and location of an Init service (see below) and the library OS binaries. The Intravisor first allocates memory for the cVM binary, stack and heap. It also allocates memory for the thread stack pool. Our implementation of cVMs cannot change the size of heap and stack at runtime, but this is a minor limitation given the size is in terms of virtual memory, and is only committed to physical memory on demand. Just as cloud providers prefer re-instantiating VMs over the use of memory ballooning, we expect large resource size changes to re-instantiate cVMs.

All threads must be created inside a compartment's memory, thus the Intravisor pre-allocates memory for future thread stacks. After that, the Intravisor deploys the image of the Init service into the cVM and spawns the initial thread in the context of the cVM. This thread prepares the hostcall callback tables, and enters the cVM via the `CInvoke`-based interface created by the Intravisor.

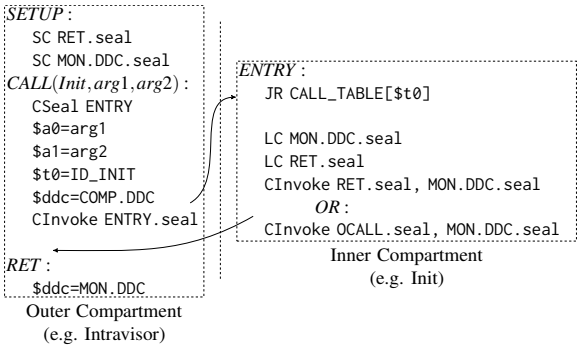

Fig. 3: ICALL and OCALL implementation

The Init service (see Fig. 2) is responsible for initializing all components at deployment, and creates the communication interface between the library OS and the host system. It is part of the library OS isolation layer, which means that it can access the memory of the application component. It initialises the library OS, builds the syscall interface for the program (or library), deploys its binary and calls the entry function (e.g., `c_start()`). For an executable binary, it launches the program; for a library, the entry function initializes a CP_Stream and registers the public library functions with the Intravisor.

Execution. cVMs use the Linux kernel library (LKL) [36] as a library OS that provides a Linux-compatible environment. LKL processes system calls and requests the host OS kernel to perform actions as needed.

LKL's storage and networking backends implement lean interfaces for hardware I/O devices: disk I/O has three hostcalls (`disk_read/write()`, `disk_getsize()`); networking uses only `net_read/write()`. The `disk_read/write` functions are applied to a file descriptor of the disk image; the network functions are invoked on a TAP device. The remaining functions in the hostcall interface are straightforward: they offer support for time and timer functions, debug output, threading and locking, and management of CAP Devices (see §4.3).

Threading. For simplicity, cVMs use a 1-to-1 threading model. When a cVM creates a thread, the `pthread` library requests an execution context from LKL, which in turn, requests a new thread from the host OS kernel. This requires the integration of the `pthread` implementations inside the cVM and the host—both must maintain their own thread-local stores, pointers to `thread_structs`, etc.

When LKL requests a thread, it prepares a structure with an address of the entrance function, and a pointer to the arguments. This is passed to the host OS kernel, and the Intravisor creates a new thread with the provided arguments: it allocates a stack for the thread from the thread stack pool, pre-allocated at boot. After that, the new thread is ready to enter the cVM using `CInvoke` and capabilities are created by the hostcall interface. Prior to entering, the Intravisor switches the thread pointer `tp` register. Inside a cVM, threads have LKL TP values; when processing hostcalls, they have host ones.

4.2 Calls between nested compartments

cVMs use the `CInvoke` instruction to call functions between isolation layers, both (i) from an outer to an inner layer (ICALL), e.g., when the Intravisor invokes Init; and (ii) from an inner to an outer layer (OCALL), e.g., when performing a syscall or hostcall.

`CInvoke` takes two *sealed* capabilities (see §2.2) as arguments: (i) one with a new Program Counter Capability (`pcc`) value and another that points to a memory region that becomes accessible after the instruction execution. The `pcc` is replaced by the first unsealed capability; the second capability moves to the `ct6` (`C31`) register in the unsealed form.

Next, we explain how `CInvoke` is used to implement both ICALLs and OCALLs:

ICALLs. Fig. 3 shows the switching mechanism for ICALLs. In this example, the Intravisor in the outer layer calls Init in the inner layer. To make the call, the caller prepares the first capability that points to the entry point inside the compartment. This capability, together with the corresponding data capability, defines the default capabilities of the inner compartment. Inside the compartment, these capabilities, `COMP.DDC` and `ENTRY.PCC` become `ddc` and `pcc`, respectively. While the `ENTRY.PCC` capability can be passed as the first argument of `CInvoke`, `COMP.DCC` must be loaded by the caller prior to switching (see Fig. 3).

To return from the compartment or grant permission to invoke functions in the outer layer from the inner layer, further capabilities are needed: these are stored in memory by the Intravisor before `CInvoke` is called, in a structure that we call the *Affix*. They include a sealed `ddc` of the outer layer (`MON.DDC.sealed`). Without this capability, the Intravisor could not change `ddc` from the inner to the outer layer on return in order to access the Intravisor's data. This capability can only be fetched from the inner layer—the accessible memory is restricted by the `ddc` of the inner layer.

The Affix also includes `RET.sealed` and `OCALL.sealed`, which are two sealed `pcc` capabilities to entry functions in the outer layer. The former is used to return from the compartment; the latter points to an entry function, which is used when the inner layer calls a function of the outer layer (e.g., `print()`) and returns to continue execution inside the compartment. This is used for the syscall and hostcall interfaces. Capabilities in the Affix are created by the Intravisor and stored on the stack and inside per-compartment private stores.

OCALLs share many similarities with ICALLS. The caller prepares a sealed capability of the return address. After the end of a function, the callee uses `CInvoke` and the execution of the caller continues from the desired address. Together with `CInvoke`, the callee passes the sealed capability `MON.DDC.seal`, which was passed originally inside the Affix. It is put into `ddc` after the function returns.

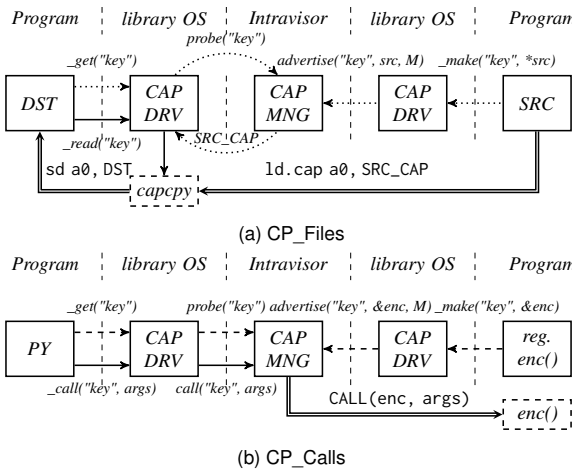

Fig. 4: Implementation of communication mechanisms

4.3 Communication mechanisms

The data sharing API between cVMs from §3.3 is also based on capabilities. Data referenced by capabilities, however, can only be manipulated by capability-aware instructions, which do not exist in native code. To resolve this issue, we *mediate* the interaction between hybrid-cap code and capabilities using virtual devices called *CAP Devices*.

The CP_Files, CP_Calls, and CP_Streams primitives are implemented using character devices, which are created by the library OS and Intravisor. A program can read/write from/to these devices, and the corresponding operations are performed by capability-aware code inside drivers.

This design has two advantages: (i) despite its one memory copy, it is faster than traditional communication interfaces (see §6.5); and (ii) it supports a simple mechanism to revoke capabilities. A remote cVM can inform the Intravisor of the revocation, which then requests the library OS to destroy the corresponding CAP Device. To revoke capabilities in pure-cap code, a Intravisor would have to stop the cVM execution and destroy capabilities manually.

CP_Files support regular POSIX file operations. In contrast to ordinary files, the content of CP_Files is not cached by the page cache, and read/write operations can be unaligned.

Fig. 4a shows the implementation. A donor cVM advertises one or more memory regions defined by *keys*, and a recipient cVM probes the Intravisor for a given key. The Intravisor verifies the access control list and builds a CAP Device for the target CP_File (e.g., `/dev/cf0`). For the donor cVM to revoke access, it uses its own CAP Device to request revocation, and the Intravisor, together with the library OS, destroy the CP_Files (`cf0`) driver along with its capabilities.

When the recipient cVM issues a `cp_file_read()` call, the driver uses *capcpy* to copy data. For `cp_file_read()`, it uses `ld.cap` to read data from a remote cVM and store it via `sd`; a `cp_file_write()` does the reverse.

CP_Calls. To expose a function, a cVM creates an ICALL entry and registers it with the Intravisor (see Fig. 4b). The In-

travisor maintains a table of exported functions for each cVM, called cVM-RPCs. It consists of access control records with capabilities, name identifiers and permissions. Application components interact with the cVM-RPCs via CAP Devices, a management interface (`/dev/cf`), and the Intravisor.

Any function can be invoked by CP_Calls including ones inside the library OS. This enables the use of CP_Calls as a notification mechanism between CP_Files. The donor blocks execution until the recipient cVM reads data. It makes the `wait()` call with the driver, the driver puts the execution thread in the work queue and waits for the signal. Prior to blocking, it registers a wake-up CP_Call with the Intravisor. The recipient cVM, in turn, finishes its operations with the CP_Files, and notifies the donor via this CP_Call.

These basic operations can be composed to create higher-level protocols, and a single CAP Device can handle multiple memory regions. For example, for Redis (see §6.3), we use a series of read/write operations with a single notification as well as batched reads with different capabilities.

CP_Streams. In contrast to CP_Files, when sending data, the destination for CP_Streams is unknown, and `cp_stream_send()` only knows the source. Therefore, one side of the communication pre-registers one or more destination buffers via `cp_stream_recv()`, and uses `cp_stream_poll()` to block. The remote side uses CP_Call to enter the remote compartment, atomically fetches one destination buffer from a pre-registered queue of buffers, and copies into this buffer data via `capcpy`. It then wakes up the poll queue and returns.

Hostcall Interface. The Intravisor does not impose restrictions on the number of calls in the hostcall interface. For the LKL library OS, the Intravisor provides 24 hostcalls for minimal operation. In addition, 2 hostcalls are necessary for disk I/O, 3 for network I/O, and 10 for the capability-based communication primitives.

4.4 Capability revocation

Data transfers (`capcpy`) are performed by the drivers of CAP Devices without direct involvement of the Intravisor, which enhances performance and reduces the TCB. This, however, means that the driver must have access to the capabilities provided by the donor. We do not consider the driver trusted, thus it may be compromised by an adversary who obtains access to capabilities and memory outside the cVM after the end of a communication session. To mitigate against this threat, cVMs support a revocation mechanism. It guarantees that, once the donor cVM revokes capabilities, they are destroyed, and a recipient cVM cannot use them.

First, cVMs or communication capabilities are not created with the `PERMIT_STORE_CAP` permission. Code inside a cVM thus cannot store capabilities to memory: it can load them, modify, create new capabilities, but it fails on `ST`. The communication capabilities are stored once by the Intravisor, when the communication is established, and destroyed at the end. Second, the revoked capabilities in the CPU context are destroyed after a context switch by the host OS kernel.

5 Security Analysis

According to our threat model from §2.3, an attacker can gain control over a cVM. However, we guarantee that they cannot escape the compartment or access memory beyond its boundary due to the CHERI architectural properties (see §2.2): the ddc and pcc capabilities always apply, are non-extensible, and are controlled by the Intravisor.

Hybrid-cap code may be vulnerable to attacks that attempt to break execution flow. An adversary may inject capability-aware instructions (e.g., `CLD`/`CSD`, `CInvoke`) to access data and code outside of the compartment. To do this, the adversary requires capabilities, which they cannot construct from the available data inside a cVM.

To escape a compartment, an adversary must obtain appropriate capabilities. Each cVM, however, only maintains a few capabilities: a compartment (i) receives three sealed capabilities via Affixes, which can be inspected by an adversary but not unsealed to create new capabilities; and (ii) may receive capabilities used by CP_Files and CP_Streams. These capabilities can be exploited by an adversary after gaining full control over the library OS. Since these are data capabilities, they cannot be used to create code capabilities, which are needed to escape the compartment. The adversary also cannot store these capabilities due to their permissions. Finally, they also cannot be exported outside of the compartment via the hostcall interface, because the interface does not handle capabilities and instead corrupts them.

Hybrid-cap code may contain security flaws, but an adversary cannot escape confinement, unless a flaw in the outer level provides them with unsealed capabilities. In our design, this is unlikely due to the Intravisor's small TCB. The adversary cannot export or import capabilities via the hostcall interface or use them beyond a communication session. Vulnerable hybrid-cap code cannot abuse host system calls, escalate privileges or attack other cVMs, because the host OS kernel ignores all direct system calls from cVMs.

cVMs are intra-process compartments that share micro-architectural state and rely on the correctness of the CHERI architecture, which does not have special mechanisms to prevent side-channel attacks. Nonetheless, there are plans for CHERI to include explicit compartment identifiers (CIDs) in a future version of the architecture [67]. This will ensure that sensitive micro-architectural state is appropriately tagged by each cVM, similar to tagged TLB entries. This can be used to prevent attacks, such as training the branch predictor by one cVM to direct speculative execution in another cVM.

6 Evaluation

We now explore the performance of cVMs and the proposed communication interfaces. We begin with an overview of our evaluation platforms and workloads (§6.1). We then compare

the performance of applications deployed with cVMs and Docker containers (§6.2). In §6.3, we validate the efficiency of inter-cVM communication mechanisms; in §6.4, we explore the use of cVMs for component compartmentalisation; and in §6.5, we compare inter-cVM communication mechanisms with existing OS mechanisms. Finally, §6.6 explores the deployment performance of cVMs and Docker containers.

6.1 Experimental environment

The CHERI architecture is under active development and, while ARM's Morello board with CHERI support has been announced [9], it is unavailable at the time of writing. Therefore, we use two **evaluation platforms**: (1) a single-core FPGA-based CHERI implementation [21]; and (2) a multi-core SiFive RISC-V implementation without CHERI support.

FPGA CHERI. We synthesize an FPGA image from DARPA's CHERI FETT program [22] (`agfi-026d853003d6c433a`), that ships with a single-core RISC-V64 CHERI system based on the FLUTE core (5-stage, in-order pipeline, running at 100 MHz) [49], and execute it on AWS F1 [8]. We use CheriBSD as the host OS kernel, compiled as a hybrid-cap system with LLVM v11.0.0 and cheribuild [16].

The FPGA implementation enables a quantitative evaluation of cVMs, but has limitations: (i) it has a single-core CPU with low clock frequency; (ii) its peripheral devices, in particular storage devices, are emulated by the host; and (iii) DRAM latency is disproportionately low compared to the CPU clock speed. As a consequence, we cannot realistically execute typical cloud workloads that are memory- and I/O-bound and use multiple CPU cores. We also cannot eliminate system noise by pinning tasks to separate cores.

SiFive RISC-V. To avoid the abovementioned limitations, we also evaluate cVMs on a HiFive Unmatched RISC-V board [30], which has 4 RISC-V64 (dual-issue, in-order) CPU cores running at 1.2 GHz. The CPU does not have CHERI support, and we instead replace all CHERI instructions with their native RISC-V versions. Our applications execute on Ubuntu v20.04 with Linux v5.11.0 and the RISC-V Docker port [48] with Alpine containers [7]. Our IPC micro-benchmarks execute on FreeBSD 14, as the FPGA version uses CheriBSD, and we run them on both platforms.

This approach allows us to execute realistic cloud applications. We run CHERI-equivalent code and data paths while remaining compatible with existing RISC-V platforms (e.g., by replacing capability loads/stores with ordinary `ld`/`st` instructions, `CInvoke` with `jr`, etc.). Note that security is therefore not enforced.

Application workloads. We explore cVMs using several cloud applications and micro-benchmarks to evaluate their performance and isolation requirements:

NGINX/Redis (§6.2). This is a two-tier microservice deployment that evaluates the YCSB benchmark [72] using the NGINX [43] web server and the Redis [46] key/value store. NGINX acts as an API gateway and translates REST requests into Redis queries. When co-located, these services have a substantial amount of communication between them. We demonstrate that the cVMs interfaces, CP_Files and CP_Streams, significantly reduce overhead, using the SiFive platform to compare cVMs against a deployment using Docker containers [40].

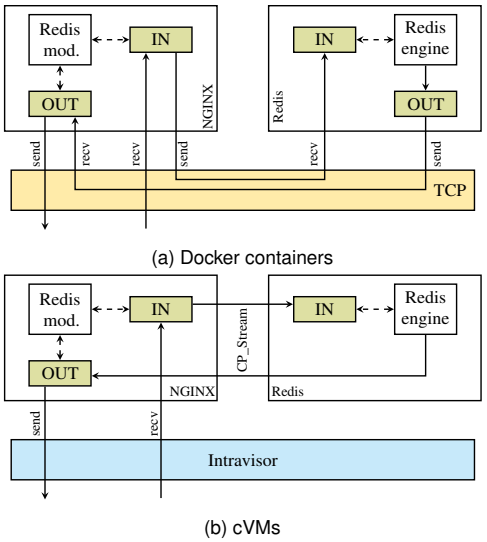

Fig. 5: Control/data flow in multi-tier deployment (NGINX/Redis)

Redis (§6.3). We execute a single-core Redis instance [46] and measure the latency of fixed-size GET and SET operations, comparing sockets and the equivalent cVM interface with CP_Streams. This experiment validates our previous results by also comparing the FPGA and SiFive environments.

Python/Library (§6.4). We measure the cost of using cVMs to isolate the components of a simple cryptographic application in Python, by deploying the Python runtime [58] and the PyCrypto cryptographic library [1] in mutually isolated cVMs that use the CP_Call and CP_File interfaces to communicate. This experiment runs on the FPGA environment.

6.2 Multi-tier deployment with NGINX/Redis

First, we compare the benefits of using cVMs when co-locating communicating components, compared to a traditional deployment with Docker containers [40].

The computational limitations of our FPGA and SiFive platforms make it unfeasible to execute a complete microservice benchmark suite such as DeathStarBench [26]. Instead, we deploy a representative YCSB benchmark [72] (workloadb; 1 KB records; read/update ratio of 95%/5%) on the SiFive platform with two-tiers: the NGNIX web server [43] acts as an API gateway that redirects incoming HTTP requests to the Redis key/value store [46], which acts as a cache for frequently used data. We use *wrk2* [6] to generate NGINX requests over a 1 GbE network, measuring the latency of different configurations (10 connections; 4 I/O threads).

The application components benefit from co-location due to the frequent interaction between the (NGINX) API gateway

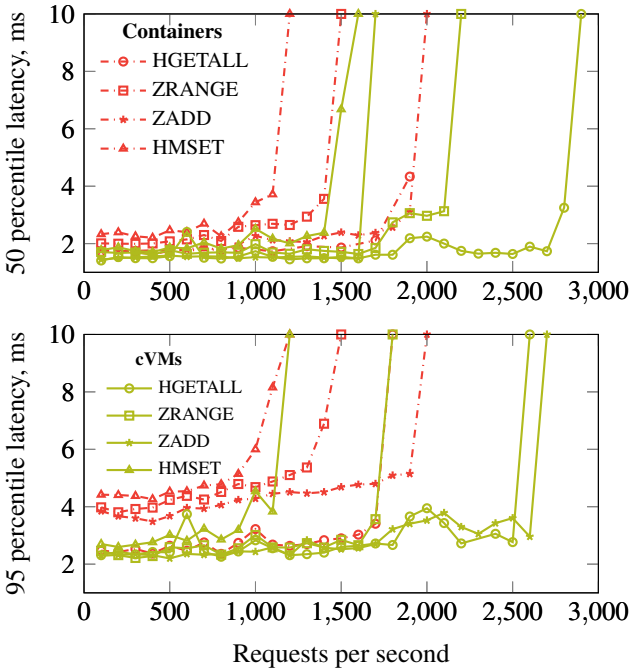

Fig. 6: Multi-tier deployment performance (NGINX/Redis)

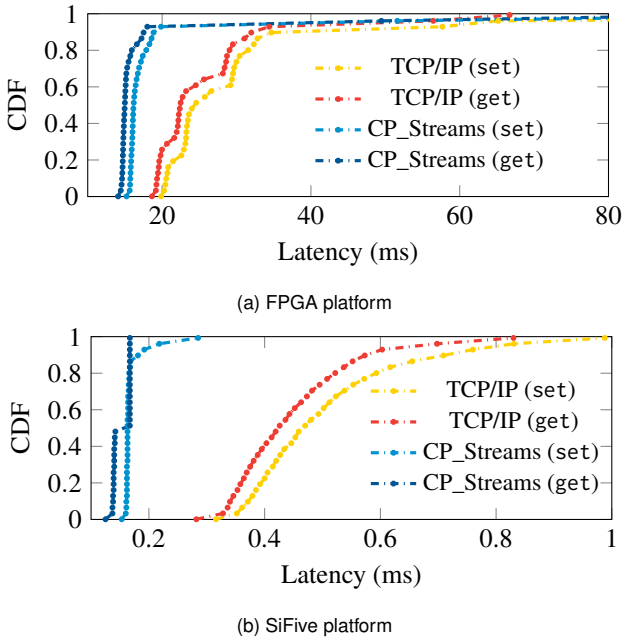

Fig. 7: Latency CDF for Redis (platform validation)

and its (Redis) cache. Fig. 5 compares the Docker and cVM deployments. Docker incurs multiple data copies between the components and the TCP/IP network stacks. As Fig. 5a shows, Redis copies values into a send buffer that is passed to the TCP/IP stack, which NGINX copies into an output buffer that is, in turn, passed to the client's network stack (for a total of 4 copies, including the kernel's TCP/IP stack).

In contrast, cVMs reduce the number of copies. Fig. 5b shows that the CP_Stream primitive requires only 2 copies: Redis values are always copied directly into NGINX's output buffer. To support this optimization, NGINX and Redis must replace their use of sockets with CP_Streams. NGINX registers the output buffer with a CP_Stream, and the CP_Stream write in Redis uses capabilities to copy data directly into the output buffer, which NGINX can then send to the client.

Fig. 6 shows the median and 95th percentile latencies for the 4 YCSB queries under various throughput regimes, comparing the baseline Docker deployment with cVMs. We can see that cVMs are more efficient: they have lower latencies in all cases (20–40% for median latency), and substantially higher throughput, with send latencies below 5 ms (33–50% for median latency).

Conclusion. In a typical deployment with multiple application components, cVMs can achieve isolation while lowering latencies and increasing throughput compared to containers. This performance gain is due to a reduced number of memory copies (via CP_Stream), using fast calls to the capability-hiding TCB in cVMs (via CP_Call within CP_Streams). Furthermore, cVMs come with a smaller TCB compared to containers. We also expect cVMs to outperform VMs because of VMs' higher overheads caused by memory virtualization (especially for memory-bound applications) and communication mechanisms (e.g., extra data copies by the guest OS and/or hypervisor, or cross-VM copies via PCIe with directly assigned devices).

6.3 Platform validation with Redis

We now validate our results by comparing the FPGA and SiFive platforms. We use Redis with a single connection that measures the latency of 1000 GET or SET operations with fixed-size keys (1 byte) and values (100 bytes). We use a simple client application that is co-located with the Redis instance. The baseline system uses separate processes and TCP/IP sockets; we use separate cVMs for each application and CP_Stream for communication (similarly to §6.2).

Fig. 7 shows the latency distribution of the GET and SET requests for all configurations. The results indeed validate our observations from the multi-tier YCSB benchmark in §6.2. cVMs exhibit lower latencies with less deviation on both platforms, compared to a native system with TCP/IP sockets: 90% of cVM requests take 14–19 ms; the baseline takes 19–35 ms on the FPGA platform. The SiFive platform supports the same conclusions, albeit with different absolute numbers. This is because the FPGA device runs at a lower clock frequency, and two processes must be co-scheduled on the same core (with both the baseline and cVMs).

Conclusion. The CP_Stream primitive in cVMs shows better performance on both the FPGA and SiFive platforms, achieving lower communication latencies across the whole throughput spectrum. We thus conclude that our end-to-end evaluation in §6.2 is representative of how cVMs would perform on a real-world CHERI-enabled CPU. In §6.5, we re-validate this by comparing cVMs against IPC primitives on all platforms.

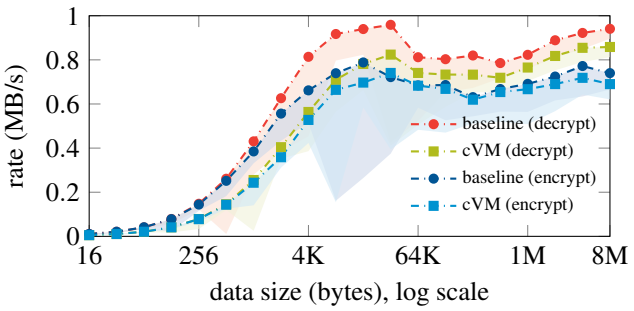

Fig. 8: cVMs with Python (AES cryptographic performance)

6.4 Process compartmentalization with Python library

Next, we explore the overhead of compartmentalizing a shared library with cryptographic operations in Python. In this case, we harden the security of a cloud application by mutually isolating the Python runtime and a native cryptographic module, PyCryptodome [1]. By using separate cVMs, we can safeguard the application against malicious interference by package managers [59], or protect the library against unauthorized access to its cryptographic keys [4].

Python creates CP_Files for the input/output buffers that it passes to the PyCryptodome library, and it uses CP_Call to transfer control to the library, using the CP_Files as arguments. (The original version instead passes raw buffer pointers.) PyCryptodome then uses these CP_Files to read its input and encrypt/decrypt it into the output buffer(using AES-128. Finally, it uses CP_Call to return execution to Python.

Fig. 8 shows the average throughput for encryption/decryption with different buffer sizes for cVMs, using the FPGA platform, and the baseline (non-isolated) system. Note that the low absolute numbers and variance (shown as shaded areas) are due to the platform limitations (single core), described in §6.1. The results in §6.3, however, show the same trend on a platform without these limitations.

We observe that cVMs have a negligible performance impact. Throughput grows until its peak with 32 KB buffers, where the encryption/decryption rates of cVMs are only 7% and 12% lower than the baseline, respectively. This amounts to 0.79 MB/s and 0.96 MB/s for the baseline, and 0.74 MB/s and 0.85 MB/s for cVMs, respectively. As expected, these overheads become even smaller as the buffer sizes grow.

Our experiment shows that CP_Call and calls into the Intravisor are reasonably efficient. For reference, the mean execution time for the AES cryptographic code with a 16 byte buffer is comparable to the time for a C binding invocation in Python. At such sizes, CP_Call invocations account for half of the overhead, which is at 97% and 101% for encryption and decryption, respectively, only slightly above a C binding invocation. The overhead reduces to 7% with larger buffers.

Conclusion. cVMs is effective at hardening applications by isolating some of their components, such as shared libraries. The required changes are minimal and do not change the semantics of the application interfaces, because the CP_File and

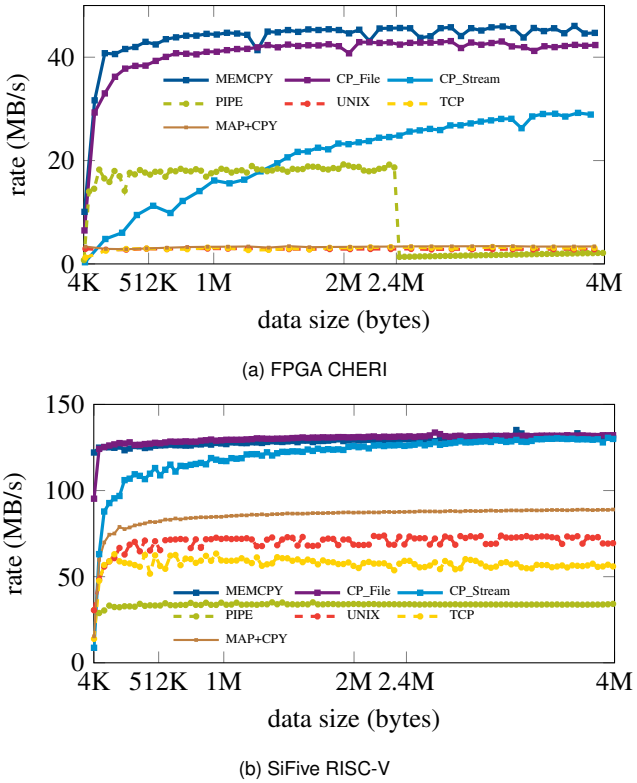

Fig. 9: Comparison of communication mechanisms

CP_Call primitives follow well-understood memory copy and function call semantics. Note that CP_Streams are constructed on top of these. The cost of this extra isolation is small, even for small buffers, and it becomes negligible as the amount of work performed between cVMs-enabled operations increases.

6.5 Inter-cVM communication

We compare cVMs to other IPC primitives in a baseline system, and re-validate our performance results across our two platforms (FPGA and SiFive). The baseline system uses two threads in a single process instead of cVMs; otherwise the FPGA implementation shows low TLB performance. We measure the performance of CP_Files and CP_Streams, pipes (`PIPE`), unix sockets (`UNIX`), TCP/IP sockets (`TCP`) and a combination of `mmap+memcpy+munmap` (`MAP+CPY`). For comparison, we also consider a raw local `memcpy` (`MEMCPY`; 4 instructions; aligned data; double-word load/store operations) as an upper performance bound. We do not evaluate CP_Calls due to the lack of an equivalent operation in the baseline kernel.

Fig. 9 shows the results under different buffer sizes on both the FPGA and SiFive platforms. First, the peak performance of `MEMCPY` on the FPGA platform is limited and fluctuates due to the TLB size and simple indexing function of its Flute CPU—these issues carry onto the other primitives, too.

The overhead of CP_Files is 6% compared to `MEMCPY` on the FPGA platform and negligible for SiFive; it significantly outperforms all baseline IPC mechanisms. This is because we do a simple cross-cVM `memcpy` using CHERI's `ld.cap` and

`cincoffsetimm` instructions to perform the memory access and to increment the capability offset, respectively. The results also show that domain transitions via `CInvoke` are efficient, as every CP_File operation requires one capability call and its return (user→library OS, and back).

All baseline IPC primitives have 2× overhead or more, because they perform more data copies than `MEMCPY` and CP_Files, closely following ideal performance. Interestingly, CP_Streams have worse performance on the FPGA platform, despite the lower number of copies, whereas they show performance close to CP_File on the SiFive platform. This is because CP_Streams offer an asynchronous communication primitive in which two concurrent processes time-share a single CPU core on the FPGA platform when using the cVM API. For the same reason, all IPC primitives have lower relative performance on the FPGA platform compared to SiFive.

UNIX sockets are the closest to CP_Streams, because both are bi-directional, support more than two parties, and have sequenced packet modes. They exhibit only 10% and 54% of the performance of CP_Streams for 4 MB buffers on the FPGA and SiFive platforms, respectively. Here, the impact of MMU manipulation can be seen: the combination of memory copies and remapping reaches 3.4 MB/s and 89 MB/s on the FPGA and SiFive platforms, respectively. This mechanism lacks a notification primitive, and, compared to CP_Files, it is 15× and 1.5× slower on each platform, respectively.

Conclusion. For a multi-core CPU architecture with CHERI, we would expect the results to be close to those of the SiFive platform, with a minor performance decrease, similar to the difference between `memcpy` and CP_Files in Fig. 9a. This potential performance degradation is significantly smaller than the measured improvements: they range between 2× for the multi-core SiFive platform against the best baseline primitive, and 2× to an order of magnitude for the single-core FPGA platform, depending on the mechanism and buffer size.

6.6 Deployment time

We compare the deployment time of cVMs with that of Docker containers. We create a Docker image with a simple "hello world" program and measure the time to execute it using a cVM and a container. For the cVM, we use a debug-free binary with the LKL library OS and the musl standard C library (≈30 MB in size) and a 10 MB application disk image. We measure two intervals, averaged over 5 runs: from the start until the output of the program, and until its termination.

On average, the Docker container requires 1.9 s to produce the output, and 2.8 s until container termination. The times for the cVM deployment are comparable, which demonstrates their low overhead: 1.7 s and 2.6 s, respectively.

7 Related Work

Intra-process compartments. Various projects apply intra-process isolation or introduce isolation primitives. CubicleOS [52] isolates components of a user-level library OS using Intel MPK; unlike cVMs, it cannot readily and efficiently support legacy POSIX calls. Shreds [20], Janus [28], Erim [60], Hodor [29], and Donkey [53] use page tag-based isolation (ARM Domains, Intel MPK, or a custom RISC-V implementation) to implement protection domains and communication. In cases in which tags can be manipulated directly by user code, e.g., using MPK's `wrpkru` instruction, the system requires a trusted toolchain or program verifier, unlike cVMs. Page tags also limit the number of compartments and communication buffers, as well as their granularity, which is not a problem for cVMs with capabilities.

NaCl [73] and WASM [27] face similar problems, as they require obsolete Intel segmentation and/or proof-carrying code that must be verified by a toolchain or loader. ConfLLVM [12] also uses MPK to isolate code inside a process, but only supports two domains with asymmetric data exchange: trusted code can only interact with untrusted code. cVMs do not limit the number of protection domains, and inter-cVM communication is symmetric.

LwCs [37] are an OS abstraction for intra-process protection, but they have page granularity, and switching domains comes at the cost of switching page tables. XFI [24] provides fine-grained memory protection and control flow integrity by extending software-based fault isolation (SFI), but SFI incurs runtime overheads and is error-prone due to its complexity.

Compartmentalisation frameworks. cVMs allow the deployment of isolated shared libraries. Prior work proposes frameworks for such compartmentalization: Wedge [11] identifies code parts that can be isolated; PrivTrans [13] is a source-code partitioning tool that separates trusted and untrusted components; Glamdring [35] does the same for trusted execution. These approaches are orthogonal to cVMs, and they could be used to generate application components.

Trusted execution. Intel SGX [31, 38, 39] provides *enclaves* as an intra-process isolation primitive. Enclaves are part of processes and cannot be accessed by privileged software or other enclaves. Frameworks, such as Graphene-SGX [19], SGX-LKL [45], Panoply [55], and Spons and Shields [51], deploy programs inside enclaves together with a library OS. Such designs decrease the potential impact of the untrusted OS kernel on enclaved software.

cVMs also use a library OS and share design features with these frameworks, but provide effective data sharing that cannot be implemented using enclaves. Enclaves can only share untrusted memory and cannot access each others memory, which is necessary for fast inter-cVM communication. Since enclaves do not trust the host, they must use encryption, impacting performance [50]. Therefore, an interface similar to CP_Files cannot be implemented with enclaves.

Library OSs can be used to de-privilege OS kernel components or create user-level containers. μKontainer [57] offers containers based on the LKL library OS [36]; Williams et al. [68] show that library OSs can be executed efficiently on

top of processes instead of bare VMs; X-Containers [54] offer a cloud platform using library OSs. cVMs share similarities with user-level library OS-based containers but enhance them with strong isolation and a secure communication mechanism using capabilities.

Machine and process isolation. As discussed in §2.1, traditional process-based isolation has shortcomings in terms of performance and TCB size when compared to cVMs. One could envision using virtualization and Intel's `vmfunc` to strike a balance between shared TCB size and communication performance [34]. Virtualization introduces well-known I/O and memory translation overheads, which are costly in a cloud stack, but are not present in cVMs.

8 Conclusions

cVMs are a new VM-like abstraction for cloud applications that use memory capabilities for secure isolation. cVMs include a library OS to minimize how much of the cloud environment is within the TCB. Multiple cVMs safely share an address space, allowing more efficient interaction of application components than when crossing current VM/container boundaries. Their asynchronous read/write and synchronous call interfaces allow capability-unaware, legacy code to run within cVMs.

Abstract

Researchers have shown that recent CPU extensions support practical, low-overhead driver isolation to protect kernels from defects and vulnerabilities in device drivers. With performance no longer being the main roadblock, the complexity of isolating device drivers has become the main challenge. Device drivers and kernel extensions are developed in a shared memory environment in which the state shared between the kernel and the driver is mixed in a complex hierarchy of data structures, making it difficult for programmers to ensure that the shared state is synchronized correctly. In this paper, we present KSplit, a new framework for isolating unmodified device drivers in a modern, full-featured kernel. KSplit performs automated analyses on the unmodified source code of the kernel and the driver to: 1) identify the state shared between the kernel and driver and 2) to compute the synchronization requirements for this shared state for efficient isolation. While some kernel idioms present ambiguities that cannot be resolved automatically at present, KSplit classifies most ambiguous pointers and identifies ones requiring manual intervention. We evaluate our solution on nine subsystems in the Linux kernel by applying KSplit to 354 device drivers and validating isolation for 10 drivers. For example, for a complex `ixgbe` driver, KSplit requires only 53 lines of manual changes to 2,476 lines of automatically generated interface specifications and 19 lines of changes to the driver's code. The KSplit analysis of the 354 drivers shows a similar fraction of manual work is expected, showing that KSplit is a practical tool for automating key tasks to enable driver isolation.

1 Introduction

Device drivers have long been and continue to be a major source of defects and vulnerabilities in modern kernels [19,32, 50,65]. Drivers are expected to support a variety of complex protocols and comply with numerous kernel conventions [23, 76,77], creating challenges in ensuring that device drivers operate correctly in the face of concurrent and asynchronous accesses on multiple CPU cores. In addition, while the core kernel is relatively stable, the number of kernel extensions and device drivers is large and continues to grow. A modern Linux 5.12 kernel contains around 8,960 device drivers that account for 67.7% of the kernel source [3], a number that has nearly doubled since 2013. With a rate of 80,000 commits a year, defects and vulnerabilities are an inherent part of the fast growing and evolving driver codebase.

The recent availability of hardware features for efficient isolation [1,5] and system support that leverages such features [40,43,47,61,63,82] have made low-overhead device isolation frameworks practical [66,68]. The upcoming hardware extensions, e.g., native page-granularity support for isolation of kernel code [5], and 16 byte-granularity isolation with memory tagging extensions (MTE) [1], which are key for enabling low-overhead software fault isolation (SFI) implementations [53], will reduce isolation overheads even more.

Despite the availability of low-overhead isolation mechanisms, the task of isolating existing driver code remains challenging. For decades, device drivers and kernel extensions have been developed in the shared memory environment of a monolithic kernel, where they freely exchange references to large and complex data structures (e.g., hierarchical, cyclic data structures with many data and pointer fields) that mix the state of the driver and the kernel. Isolating a driver requires a careful analysis of the flow of execution between isolated subsystems to identify how the complex state of the system is accessed on both sides of the isolation boundary.

Recent techniques to isolate legacy driver code utilize manual analysis of complex kernel-driver dependencies [18,62, 66,68,80], requiring an immense decomposition effort that limits their applicability. Moreover, proposed techniques to automate such analyses [33,72] only address a small fraction of the task. For example, LXFI, an SFI framework, utilized an iterative procedure to identify all the state required for execution of a driver, gradually annotating the missing parts of the shared state [62]. The scale and complexity of modern drivers make such manual analysis impractical. In the Linux kernel, even simple drivers like `msr`, that provide an interface to model specific CPU registers (MSRs), require analysis of 459 functions and around 10,000 object fields that are transitively reachable from the 21 functions of the driver interface. A more complex network driver, `ixgbe`, requires analysis of

*Contributed equally
†Work done partly at the University of California, Irvine

5,782 functions and over 900,000 object fields—a number that is well beyond the reach of manual analysis. Decaf [72] and Microdrivers [33] took initial steps towards automated analysis for driver isolation prior to the advent of efficient isolation hardware, so these works focused on techniques to isolate only a subset of driver functionalty that could be efficiently executed in isolation. As a result, many challenging parts of the drivers, e.g., interrupt handlers and optimized data-plane functions, remained inside the unisolated kernel. In addition, these techniques did not aim to minimize data synchronization overhead and required several manual tasks.

In this paper, we present KSplit, a new framework for isolating device drivers in the Linux kernel. KSplit performs a collection of static analyses on the source code of the kernel and the driver to generate the synchronization code that is required to execute the driver in isolation. Specifically, KSplit identifies the shared state that is accessed by both driver and kernel, computing how this state is used on either side of the isolation boundary, and how it should be synchronized on each kernel-driver invocation, or when a shared synchronization primitive (e.g. a spinlock or an RCU) is invoked. The result of the analysis is a collection of procedure call specifications in the KSplit interface definition language (IDL). The KSplit IDL compiler then generates glue code that ensures synchronization of data structures between isolated subsystems. Some kernel idioms, such as concurrency and complex data structures, present ambiguities that cannot be resolved automatically at present, so KSplit also identifies these specific problems for developers to focus their effort. This allows one to take an existing driver and produce the data synchronization code necessary to run the driver in isolation, automatically, if possible, and identify remaining tasks that require manual intervention, if needed.

Kernel software presents several challenges for developing accurate and scalable analyses for automating the isolation of legacy drivers, which we address in the design of KSplit.[1]

First, modern kernels have evolved to share fine-grained access to large, hierarchical data structures with their drivers, which enables joint, optimized operation over shared state using complex memory references. To compute shared state accurately, KSplit employs a field-sensitive data flow analysis using a modular alias analysis to identify shared fields while accounting for memory references accurately. To compute shared state scalably, KSplit provides a two-stage analysis to identify the kernel functions that could possibly share access to a data structure with a particular driver, enabling more accurate analysis methods to be targeted to the relevant subset of the kernel.

Second, modern drivers execute in a concurrent, fully-reentrant environment of the kernel, which complicates the challenge of ensuring that the shared state is synchronized correctly when the driver is isolated. KSplit provides algorithms to ensure correct synchronization of shared state for driver invocations, nested calls to kernel functions by drivers, and a variety of concurrency primitives, including spin and sequential locks, read-copy-update (RCU), mutexes, and atomics. KSplit provides an analysis to identify concurrency primitives that operate over shared data, finding that such primitives rarely cross the kernel-driver boundary.

Third, kernels utilize a wide range of low-level idioms that create ambiguities for marshaling in synchronization, e.g., sentinel-terminated and sized arrays, tagged and anonymous unions, self-referential data structures like linked lists, etc. To separate complete drivers, these ambiguities need to be resolved automatically. KSplit partitions these data structures into classes to apply algorithms to determine whether marshaling requirements can be inferred or not. KSplit is able to automate most cases and provide warnings for the rest.

We develop KSplit for the Linux kernel and a recent device driver isolation framework, LVDs [68]. KSplit is a fully parallel analysis that takes only a few seconds to complete for simple drivers, and completes within minutes for complex device drivers like `ixgbe`. We evaluate driver isolation using KSplit on 10 Linux device drivers, intentionally choosing drivers representing a wide variety of functionality and kernel programming idioms. Simple device drivers like `msr` can be isolated with no changes to their code, and only 2 lines of IDL changes are required to resolve ambiguities in the driver's IDL. More complex drivers like `ixgbe` require less than 19 lines of driver code changes and only 53 lines of IDL changes for the 2,476 lines of device interface definitions. We also apply KSplit to 354 drivers, finding that the amount of manual effort is expected to be a similar fraction of the driver size. Drivers isolated using KSplit leverage the low-overhead hardware and software isolation mechanisms, retaining 5.4–18.7% of the non-isolated system's performance. Our experience with isolating device drivers confirms that KSplit is a practical tool for enabling isolation of complete, legacy device drivers through the use of emerging low-overhead hardware and software isolation mechanisms.

2 Background: Device Driver Isolation

Over the years, a range of techniques to isolate kernel extensions explored execution of device drivers in clean-slate microkernels [10,12,13,27,30,35,39,44–46,49,57] and virtual machines [14, 15, 31, 34, 55, 70, 75], re-implementing device drivers in safe programming languages [9,11,37,48,56,67,84], developing backward-compatible driver execution frameworks [8,17,22,24,29,36,38,42,52,71,81,83,86], and finally, isolating unmodified driver code with hardware [33,66,68,80] and software [18, 25, 62] mechanisms. While it is possible to enforce isolation of the driver code through programming language safety [11,48,56] and formal verification [7,20], to achieve isolation of unmodified drivers, driver isolation frameworks rely on either hardware isolation mechanisms (e.g., segmentation, paging, extended page table (EPT) switching),

[1] KSplit is developed for Linux, but our techniques can be applied to other commodity kernels.

core-isolation [66], or techniques of software fault isolation (SFI) [18, 25, 62, 85] that enforce a segment-like isolation boundary around the driver code through instrumentation of control flow and memory instructions.

The main challenge in isolating legacy drivers is to provide controlled access to the state that is shared by the kernel and the isolated driver. Commodity operating systems allow kernels to share an address space, and hence, its entire state with drivers, implementing driver operations on objects jointly accessible to both the kernel and the driver. Often these objects have a complex, hierarchical structure, e.g., `sk_buff` network packet buffers, but only a fraction of these objects (i.e., a small subset of their fields) are accessed by both the kernel and the driver in practice, these forming the shared state. In order for the isolated driver to work correctly, KSplit must identify this shared state comprehensively, but to provide efficient isolation, KSplit must not overapproximate the shared state significantly.

Hardware and SFI frameworks take different approaches to protecting access to the state shared between the kernel and the driver. Hardware approaches control access by executing the driver on an isolated copy of the shared state that is synchronized with the kernel on each driver invocation [33, 66, 68, 80]. SFI approaches, in contrast, execute the driver and the kernel on a single copy of the shared state. This eliminates the need for maintaining two copies of the shared state, but requires access-control checks on each memory access to the shared state [62]. To provide fine-grained access control on the kernel state, SFI systems implement a concept of "capability tables", which allow quick byte-granularity lookup of each kernel field accessible to the driver [62].

Irrespective of the isolation mechanism, however, both solutions require analysis of which state can be accessed by the driver and the kernel, and when each access is allowed [62]. Decaf [72] and Microdrivers [33] took a first step in automated analysis of shared state for isolated drivers by computing the state accessed by the driver on each invocation. However, not all of this state is shared with the kernel, as we find that drivers operate on a significant amount of state that is private to the driver. In addition, these projects only decomposed the non-performance-critical driver code into isolated domains to retain reasonable performance.

Historically, isolation in the kernel remained prohibitive due to the high overhead of hardware and software isolation mechanisms. Recent CPUs, however, signal the growing support for low-overhead isolation primitives. Extended page-table switching with VM functions [6] and user-space memory protection keys (MPKs) [6] already provide support for memory isolation with overheads comparable to system calls for Intel machines [43, 63, 68, 82]. The next generation of Intel machines promises to extend MPK with native support for isolation of ring 0 code [5]. Similarly, the newest ARM CPUs provide support for 16 byte-granularity isolation with memory tagging extensions (MTE) [1], which is key for enabling low-overhead SFI implementations [53].

Recent work has shown that using domain-based isolation can be practical. LXDs [66] and LVDs [68] develop a Nooks-like isolation framework using extended page tables to improve boundary-crossing performance, providing an interface definition language (IDL) for specifying which data requires synchronization in driver interfaces. This work demonstrates the potential for the efficient hardware-based protection domain isolation of legacy drivers. However, such isolation required a significant manual effort to develop IDL definitions for complete drivers. While previous work [33, 72] proposed a method to generate the base IDL, configuring the marshalling requirements for a variety of complex data types and handling concurrency was performed manually. While SFI does not require synchronization on boundary crossings, SFI methods must compute essentially the same information to enable correct isolation with good performance.

A variety of projects have explored techniques to automate various aspects of decomposing user-space programs [16, 21, 41, 58–61, 74, 87–89], called *privilege separation* [78], but these techniques fail to address issues critical to isolating kernel code. For example, PtrSplit [59] proposed techniques to compute marshalling requirements for objects based on runtime tracking, but this adds non-trivial overhead. In addition, these techniques are not designed to handle multi-threaded programs like a kernel.

3 KSplit Overview

KSplit transforms complete, shared-memory device drivers into equivalent drivers that can execute in an isolated domain and on an isolated copy of the driver state. Specifically, KSplit identifies the subset of the kernel state that is required for an isolated driver to run, and derives how this state must be synchronized on invocations that cross the isolation boundary, and also at the points where the driver uses concurrency primitives,[2] e.g., atomics, spinlocks, mutexes, ready-copy-update (RCU), etc.

For example, the kernel submits a network packet to a network device with the `ndo_start_xmit()` function:

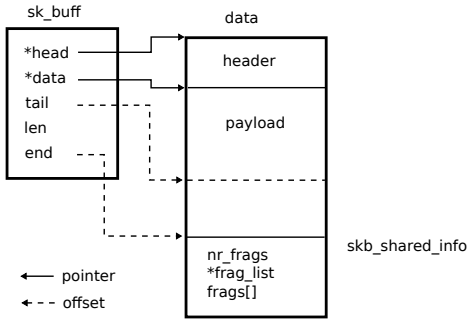
```
1  ndo_start_xmit(struct sk_buff *skb,
2                 struct net_device *netdev)
```

KSplit ensures that all the fields shared between the kernel and driver of all the data structures that are recursively reachable from the two input arguments (i.e., `skb` and `netdev`), and all global kernel variables, are synchronized with the driver. After the invocation completes, the fields updated by the driver are synchronized back to the kernel. Nested invocations into the kernel also trigger synchronization to ensure that the kernel and driver use the current state. If the driver code uses a concurrency primitive that is shared with the kernel, e.g., a global lock, like the `rtnl_lock` used by network device drivers

[2] To distinguish between the synchronization of shared state in general with primitives to synchronize state used in concurrent operations, we refer the latter as *concurrency primitives* in this paper.

```
1  struct sk_buff {
2    struct net_device *dev;
3    unsigned int len, data_len;
4    u8 xmit_more:1;
5    ...
6    sk_buff_data_t tail;
7    sk_buff_data_t end;
8    unsigned char *head, *data;
9    unsigned int truesize;
10 };
```

(a) `sk_buff` definition



(b) `sk_buff` layout in memory

to register with the kernel, KSplit synchronizes the state of the driver with the kernel on entry and exit from the atomic region to maintain up-to-date copies in both domains.

KSplit provides software analysis algorithms that 1) compute the subset of the kernel state that is accessed by the driver (i.e., the shared state) and 2) synchronize the shared state on cross-domain invocations and on the use of concurrency primitives that access shared state. While appearing to be conceptually straightforward, isolating legacy drivers is complicated by several factors caused by how drivers are currently deployed in monolithic kernels, specifically:

Complex shared state Kernel data structures often consist of a large number of fields that may be referenced in a variety of ways. The `sk_buff` structure that represents a network packet has 66 fields (5 pointers and 2 offsets) through which 3,132 fields (1,214 pointers) are recursively reachable in other data structures (Figure 1a). The kernel and driver operate jointly on only a small fraction (52 shared fields) of these fields. In addition, like many kernel data structures, the `sk_buff` structure is accessed through complex memory references (Figure 1b). For example, some `sk_buff` pointers are used for in-place access to parts of the network packet, i.e., `head` and `data` mark the beginning of the packet header, and the data regions from which the packet is assembled, respectively.

To compute shared state accurately under these requirements, KSplit employs a field-sensitive data-flow analysis using a modular alias analysis to capture field references common to the kernel and the driver. To do this efficiently, we apply the parameter tree approach [59], which computes aliases intra-procedurally [79] and propagates those alias results inter-procedurally. This approach was employed previously in user-space privilege separation [59]. However, user-space privilege separation aims to isolate sensitive data selected manually by programmers, whereas KSplit needs to identify the data shared between the kernel and a driver automatically. Prior techniques to estimate sharing between the kernel and a driver [33, 72] greatly overestimate shared data because they collect all the fields that the driver will access, instead of those that are actually shared.

Size and complexity of the kernel In order for the isolated driver and kernel to operate correctly, we must identify all the shared state. Using a sound alias analysis, we can over-approximate the shared state, but the kernel is too large (e.g., contains 53,000 functions) to directly apply the field-sensitive analysis needed to compute shared state accurately. KSplit handles this challenge by first performing an analysis to identify the subset of kernel functions that can access the state involved in interaction with the driver. Then, KSplit performs an accurate shared state analysis on this subset of the kernel functions, along with the driver.

Concurrency and parallelism KSplit must ensure that the kernel and the isolated driver operate on up-to-date shared state, regardless of how the kernel and driver interact. The kernel, however, invokes functions of the driver in parallel on multiple CPUs. Moreover, device drivers are concurrent and fully reentrant. As a result, it is possible that the driver updates the shared state that is concurrently accessed by the kernel or vice versa, using one of various concurrency primitives. For example, most drivers use the read-copy-update (RCU) synchronization pattern to synchronize their state across multiple invocations in a lightweight manner, e.g., the `ixgbe` network driver holds an `rcu_read_lock` to access the ring statistics to prevent deallocation of driver queues by a concurrent thread. However, many drivers rely on atomic primitives and critical sections (e.g., `ixgbe` communicates state updates to the New-API (NAPI) state to the softirq framework with atomic variables). Finally, some device subsystems rely on global locks (e.g., `rtnl_lock` in the network subsystem) during driver registration.

KSplit leverages the critical observation that synchronization mechanisms rarely cross the driver-kernel boundary, e.g., out of 73 uses of concurrency primitives in the `ixgbe` driver, only 3 atomic primitives synchronize state across the isolation boundary. We develop a collection of algorithms that carefully classify shared and private critical sections for a range of kernel concurrency primitives (mutexes, spinlocks, sequential locks, atomic primitives, and RCU locks). For shared concurrency primitives, KSplit computes the state that is accessed within the critical section and requires synchronization.

Low-level C idioms Kernel code utilizes a range of low-level idioms that create ambiguities for static analysis (Figure 2). For example, device drivers rely on sentinel values (e.g., `null`) to represent variable-sized arrays, e.g., the PCI subsystem uses the `pci_id_table` array to store a set of devices supported by a particular driver (Figure 2a). To optimize allocation and

```
struct pci_dev { // sized array
  struct resource resource[DEVICE_COUNT_RESOURCE];
};

static const struct pci_device_id ixgbe_pci_tbl[]
  = {
     { PCI_VDEVICE(INTEL, IXGBE_DEV_ID_82598),
       board_82598 },
    { }, /* sentinel */
  };
```

(a) Sized and sentinel arrays

```
#define skb_shinfo(SKB) \
   ((struct skb_shared_info *)(SKB->end))

static inline void
  *blk_mq_rq_to_pdu(struct request *rq)
{
  return rq + 1;
}
```

(b) Collocated data structures

```
ssize_t msr_read(struct file *file,
                 char __user *buf, ...)

dev->bar = ioremap(pci_resource_start(pdev, 0),
                8192);
```

(c) Special memory regions.

```
struct skb_shared_info {
  struct sk_buff *frag_list;
};
```

(d) Recursive data structures

```
union acpi_object {
  acpi_object_type type; /* tag */
  struct {
    acpi_object_type type;
    u64 value;
  } integer;
  ...
};
```

(e) Tagged unions

```
static int ixgbe_set_mac(struct net_device *netdev,
                  void *p) {
  struct sockaddr *addr = p;
  memcpy(netdev->dev_addr, addr->sa_data,
       netdev->addr_len);
  ...
}
```

(f) Opaque pointers

Figure 2: Code idioms typical of the Linux kernel

deallocation of objects, kernel can collocate multiple data structures into one memory area, and use pointer arithmetic to access them (Figure 2b). Further, the lack of a fast array or vector abstraction forces the kernel to use references in place of arrays and keep the length as a separate field. Some memory regions, like user and device I/O memory, require special treatment, when passed into an isolated driver, e.g., marked as allocated in user memory with the `user` attribute (Figure 2c). While recursive data structures are rarely passed across the kernel-driver interface, some drivers use linked lists, and even generic graphs of recursive objects (Figure 2d). Tagged and anonymous unions are used by the driver to implement polymorphic functions that can take generic arguments of a union type (Figure 2e). Device drivers frequently rely on `void*` pointers to express type polymorphism (Figure 2f). Another typical pattern for the kernel APIs is to return an error as a specially formed pointer—this allows a simple unified function signature, e.g., the `struct rquest *blk_mq_alloc_request()` function from the block driver returns a pointer to the block request on successful invocation, but can return a specially formed pointer that represents an error otherwise. KSplit provides support for these cases, and the necessary IDL annotations and library support to generate correct code.

Prior approaches assumed that programmers would provide the annotations to resolve ambiguities in marshaling manually for most cases [33, 51, 62, 66, 68], but that is impractical when isolating complete device drivers. Instead, KSplit takes the opposite approach, aiming to resolve ambiguities in most cases and providing warnings in the remaining ones. For example, `char *` references, such as the `head*` and `tail*` fields in the `sk_buff` data structure, may refer to singletons, arrays, strings, or even other data types (e.g., for type casts). KSplit utilizes a series of classification methods to distinguish among these caonesutomatically, enabling nearly all ambiguities to be resolved for the drivers we have isolated.

Prior work Microdrivers [33], Decaf [72], and FGFT [51] developed static analysis methods aimed at the isolation of legacy driver code. Due to the sheer complexity of the whole-driver analysis, these past approaches were limited to isolating only select driver functions, and supported only a limited subset of kernel idioms. KSplit leverages advances in static analysis: specifically, a combination of an accurate program dependence graph (PDG) representation, and modular alias analysis with parameter trees [59]. This allows KSplit to scale the analysis and implement isolation of the entire driver. A clean separation of shared and private state allows us to scale static analysis and resolve almost all ambiguous annotations required for marshalling of data in the low-level driver code.

3.1 Threat Model and Security Goal

The goal of KSplit is the same as the majority of prior research on driver isolation [35, 66, 68, 80]. Specifically, KSplit aims to improve kernel reliability, i.e., prevent flaws in the driver domain, such as memory errors, from affecting the rest of the kernel. We trust that the kernel domain is free of software flaws, but assume that the driver domain may contain flaws that, for example, may result in writes to kernel memory, possibly causing the kernel to crash.

We leave the feasibility analysis of whether KSplit driver isolation prevents attacks originating from a driver as future work. We note that LXFI [62] prevents certain driver-originated attacks by generating dynamic checks based on user-specified safety conditions at the kernel-driver boundary. However, identifying and specifying safety conditions for individual drivers is a labor-intensive task. Plus a range of security attacks are still possible, such as resource exhaustion (e.g., the driver can allocate objects to consume memory), protocol violations (e.g., the driver can unregister itself from the kernel), and even use-after-free (e.g., driver can trigger deallo-

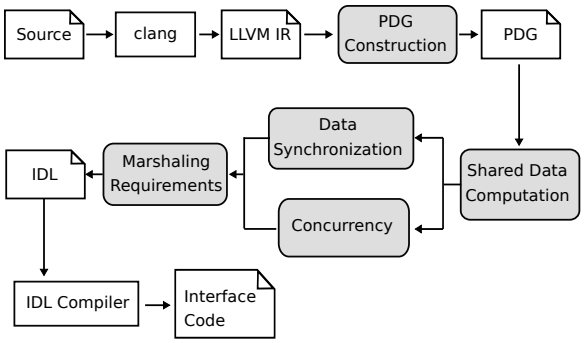

Figure 3: KSplit analysis workflow.

cation of objects in an unexpected way). We, however, believe that KSplit is a critical step towards shaping the foundation of future isolation mechanisms. We plan to study what security guarantees may be possible to achieve automatically as future work. Finally, speculative execution and side-channel attacks are outside the scope of this work as well.

4 KSplit Static Analysis

Figure 3 presents KSplit analysis workflow. KSplit takes the source code (i.e., the code of the kernel and a device driver) as input, and converts it into LLVM IR using Clang, LLVM's frontend. KSplit then provides analyses to: (1) *identify shared data* between the kernel and the driver; (2) *compute data synchronization* on each boundary crossing for that shared data; (3) compute data synchronization for *concurrency primitives* that access shared data; and (4) *infer marshaling requirements* for data types where such requirements are ambiguous, e.g., tagged unions, void pointers, arrays, linked data structures, etc. The result of the analysis is a collection of definitions for the KSplit interface definition language (IDL) compiler. For some cases whose IDL configuration (e.g., size and/or format) remains ambiguous after analysis, KSplit generates warnings for developers to resolve the ambiguity. These warnings must be resolved by developers to obtain a working IDL. The IDL compiler then generates glue code that ensures synchronization of data structures between isolated subsystems.

In this section, we present KSplit's core static-analysis algorithms to address the aforementioned problems. The algorithms are designed to solve these problems in the general case, but the C language is ambiguous about some key information required by the algorithms (e.g., pointer type information). We defer to Section 5 for a discussion of how we leverage C programming idioms used in the Linux kernel to resolve these ambiguities in most cases. While some of these idioms are commonly applied in C programs, some idioms may need to be replaced for other kernels.

4.1 Program Dependence Graph

KSplit reasons about the kernel and drivers using an interprocedural program dependence graph (PDG) [59]. PDG represents individual LLVM instructions as nodes with edges that capture control and data dependencies between instructions. An instruction n_1 is *control dependent* on n_2 if, intuitively, n_2's outcome decides whether n_1 gets executed [26]. An instruction n_1 is *data dependent* on instruction n_2 if n_1 uses some data produced by n_2. Data dependence is critical for determining how the data structures that are exchanged between the driver and the kernel are used in cross-domain invocations. Specifically, KSplit computes how the objects are used by each side of the isolation boundary to then compute data synchronization requirements, as described in Section 4.3. In particular, we need to find all operations that may read or write data, which should be marshaled across the boundary.

Scaling alias analysis with parameter trees A common type of data dependence happens when an instruction writes to a memory region from which another instruction reads. Computing such memory-related data dependenciiiesss requires *alias analysis*, which computes the variables or expressions that may reference (i.e., point to) the same memory object, and are called *aliases*. We must compute aliases in KSplit because we must detect all objects that may be accessed by both the kernel and the drivers. Further, the isolation of the driver code requires an interprocedural alias analysis, as both the kernel and driver code may pass pointers to data objects through function calls, as well as through global variables. The alias analysis problem is known to be undecidable; devising a precise analysis that is scales well and is guaranteed to capture all aliases is a challenge. Current interprocedural alias analysis techniques (e.g., [54,79]), however, do not scale to low-level kernel code with its complex uses of memory references. Instead, we propose to deploy a modular form of alias analysis that enables us to manage scalability more effectively.

In the KSplit approach to modular alias analysis, we employ SVF [79] to compute aliases intra-procedurally and then propagate those alias results inter-procedurally using the parameter tree approach [59]. This allows us to efficiently compute memory dependencies across function boundaries in a context-insensitive way. Specifically, it first constructs PDGs for each function in the program (which includes intra-procedural memory dependencies) and then glues them together by connecting actual parameter trees for arguments at function call sites with formal parameter trees for parameters; details can be found in [59].

To illustrate the idea of parameter trees, consider the `msr_read()` function of the MSR driver. For each argument of the function we construct a parameter tree that represents storage locations that the callee can access. For example, Figure 4 shows a parameter tree for two arguments of the `msr_read()` function: 1) the `file` argument of type `struct file *` and 2) the `int` argument `count`. The parameter tree for the `file` argument has a root node labeled "`file:struct file*`" for representing the storage for the pointer, and a child node labeled "`*file:struct file`" for the memory region that the pointer points to. The references of each storage location in the pro-

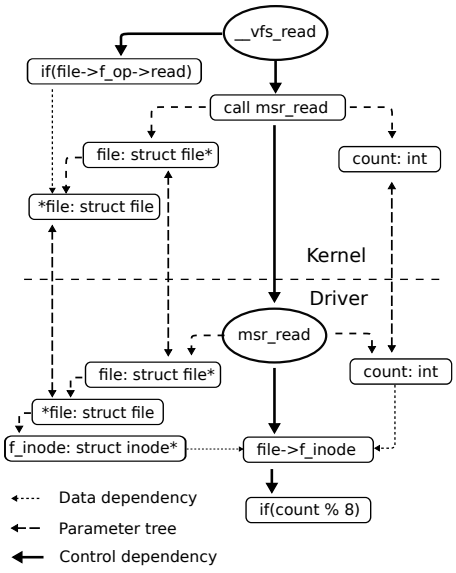

Figure 4: Partial PDG for the `msr_read()` function which is invoked with the `call` instruction from the `__vfs_read()`

gram are connected with corresponding tree nodes through data-dependency edges. We note that, for brevity, the figure does not show the fields of `struct file`; the actual representation maintains information about each field in a separate node to allow field-sensitive analysis.

4.2 Computing Shared and Private Data

Accurate separation of shared and private state is critical for the precision and scalability of KSplit analyses. However, the size of the kernel makes it impractical to perform an accurate analysis to find the shared state at the level of fields (i.e., field-sensitive analysis). On the other hand, the kernel's use of interrupt handlers makes it difficult to ensure that all the code that may impact a particular driver interface invocation has been accounted for. For example, an interrupt handler does not have an explicit caller and is thus unreachable in a typical control-flow graph (CFG) from neither the driver nor regular kernel code. It only runs in response to the corresponding interrupt.

As a result, we develop a shared-state algorithm that first determines the scope of code in the kernel and driver to consider (i.e., the functions and data types that may be shared), as described in steps (1) and (2) of the detailed algorithm below. Then, we perform an accurate, field-sensitive analysis on the PDG. This analysis leverages the modular alias analysis described above to capture the shared state of the kernel and driver in terms of data-structure fields.

The detailed algorithm steps are as follows: (1) the algorithm computes a set of struct types that are accessible by both sides of the isolation boundary. This is performed by collecting all the struct types that are accessible transitively through interface function parameters, global variables, and interrupt handlers. These struct types are referred as *shared struct types*. (2) For each shared struct type, we identify the functions in the kernel and driver that contain variables whose type matches one of the shared struct types. The functions accessible from the isolation boundary in step (1) and those found in step (2) are used to compute the shared state in (3) below. Steps (1) and (2) do not use the CFG and work even for interrupt handlers (unreachable in the CFG). (3) For each set of variables that match a shared struct type, we use the PDG to analyze the accesses via the variables to collect the field accesses for that type. (4) For each field, if the field has accesses from both the kernel and the driver, we consider the field to be shared. Otherwise, the field is private.

The output of the algorithm is a set of shared struct types associated with their shared and private fields. For illustration, the `struct net_device` type contains the following fields (among others): `wanted_features`, `features`, and `hw_features`. By analyzing the `ixgbe` driver and the kernel code, our analysis determines that the `features` field has accesses from both the driver and the kernel, while the other two fields are only accessed in the kernel. Our algorithm determines that `features` is shared, while the other two fields are private to the kernel.

This algorithm relies on two assumptions. First, in step (2), we assume that any state shared between the kernel and driver is accessed using one of the shared struct types from step (1). While this is not guaranteed, the kernel generally obeys typing for the types it shares with the drivers. If we miss a data type, we may under-approximate shared state, causing correctness issues, but we have not found any violations so far. Second, we rely on the observation that the type of a composite object correlates with how it is shared across the isolation boundary. In other words, it is uncommon for one instance of a given type to be shared while a different instance being private; e.g., if a device driver accesses the `inode` field of the `struct file *` object, it is typical that `inode` is shared for all instances of the `struct file *` type. Thus, the analysis cannot determine whether a field of one instance is shared while the same field of another instance is private. The algorithm may over-approximate the shared state, which may cause unnecessary data synchronization, but does not affect correctness.

4.3 Cross-Domain Synchronization

When a function invocation crosses the domain boundary, KSplit synchronizes the shared state required by the callee domain to execute the call. Similarly, when the function returns, the changes the callee made to any shared state must be synchronized back to the caller, to reflect updates on its copy. We develop *parameter access analysis* to compute all data structures and fields that require synchronization.

Basic parameter access analysis At a high level, this algorithm tracks the parameter reads that require data to be synchronized on calls and parameter writes that require data to be synchronized on responses for each cross-domain invocation and any functions reachable from that invocation. Algorithm 1

presents a worklist-based algorithm: 1) for each function in the worklist, it performs an intraprocedural parameter access analysis; 2) it collects call instructions in the function being analyzed and performs an interprocedural analysis; and 3) it repeats steps (1) and (2) until the analysis reaches a fixed point (when the worklist becomes empty). Algorithm 1 computes field usage that is only dependent on parameters passed between domains. Dependence is computed using the parameter-tree alias analysis to ensure an overapproximation.

Algorithm 1: Parameter access analysis

```
Input: G is a PDG, T is a parameter tree, f is the target function of
       a cross-domain call
Output: Access Information Map AM
1  initialize AM to be empty
2  worklist ← {f}
3  while worklist is not empty do
4      f1 ← remove_any(worklist)
5      for node n in T do
6          for instruction i in f1 do
7              if G has a dependence edge from i to n then
8                  AL ← the edge's access label
9                  AM[n] ← AM[n] ∪ AL
10             else if i calls f2 then
11                 worklist ← worklist ∪ {f2}
12             end
13         end
14     end
15 end
```

The analysis goal is to compute a set of *access labels (AL)* for each parameter tree node of a function parameter. The access label of a node represents how the storage represented by the node is used by the callee of a cross-domain call (*READ*/*WRITE*). We further define a global map *AM*, which maps from parameter tree nodes to sets of access labels *AL*. For example, if there is a read access to the `f_inode` field of the `file` data structure, we associate a *READ* label with the parameter tree node that represents the storage of that `f_inode`. After *AM* is computed, the fields for shared state corresponding to nodes with the *READ* label are copied from the caller to the callee when the call happens, and those for shared state with the *WRITE* label are copied from the callee to the caller when the callee returns.

The previous analysis identifies the correct state to synchronize, but might include unnecessary fields because of nested boundary crossings, which cause the call-graph transitive closure to include functions from both sides of the isolation boundary. KSplit distinguishes reads and writes of different domains and avoids sending shared data to a callee if the data is only used in the caller's domain due to a nested call. Similarly, KSplit avoids copying shared data back to the caller if the writes only occur in the caller domain, To do this, KSplit removes shared fields accessed only in the caller domain from the closure computed in Algorithm 1. For the above example, suppose the driver function d reads shared field `fd1` and k' reads shared field `fd2`. The previous analysis determines both `fd1` and `fd2` need to be sent when k calls d. However, our optimization distinguishes the two reads and sends only `fd1`.

4.4 Critical Sections and Atomic Primitives

Modern device drivers are often invoked in parallel on all CPUs of the system, and are fully concurrent outside of small critical sections. The kernel and drivers synchronize access to the shared state through a variety of kernel-provided concurrency mechanisms: atomic operations, spinlocks, sequential and reader/writer locks, read-copy-update critical sections (RCU), etc. To support correct execution of an isolated driver, we provide support for concurrency primitives across the isolation boundary. We identify two large classes of concurrency primitives: locking and lock-free (i.e., atomic operations). For atomic update primitives, e.g., `atomic_inc()`, `atomic_set()`, we perform all updates on the primary copy of the data maintained in the kernel; i.e., drivers call into the kernel to update the primary copy. For synchronization primitives that acquire and release a lock (we support spinlocks, seqlocks, RCU, reader/writer locks, and mutexes), we compute the state that is accessed in each critical section and synchronize it across the isolation boundary. To enforce atomicity across isolated domains, we rely on a mechanism similar to combolocks [33].

The high-level steps for the analysis are as follows: 1) identify *shared* critical sections where cross-subsystem synchronization is required; and 2) identify read/write accesses to shared data in critical sections.

Identifying critical sections To identify critical sections, we perform a search in the CFG of the program, looking for a set of function invocations that implement critical section synchronization primitives, e.g., `spin_lock()`, `mutex_lock()`, etc. For each call to a function marking the beginning of a critical section, we follow the CFG to identify a matching invocation that marks its end, i.e., `spin_unlock()` for `spin_lock()`. Next, we use alias analysis to check whether the beginning (lock) and end (unlock) use the same lock. Finally, we output only critical sections defined by lock/unlock call pairs found by the CFG that are associated with the same lock.

Shared data accesses in critical sections Given a critical section, we identify all shared state that is modified within the critical section. Our goal is to: 1) classify critical sections and atomic operations as either private or shared, i.e., whether the data accessed is private or shared, and then 2) if the critical section operates on shared data, compute the state required for correct synchronization. Specifically, we identify read and write accesses to shared data from inside the critical section (similar to Algorithm 1). For read accesses, we ensure that the state is synchronized right after entering the critical section—this ensures that the code inside operates on a consistent, fresh copy of the state. For write accesses, we synchronize all updates by sending it to the other side of the isolation boundary right before exiting the critical section.

Handling optimized primitives KSplit has support for a variety of concurrency primitives that are optimized to reduce

the use of locking. In most cases, such as sequential locks, the main issue is to determine the corresponding reader and writer critical sections accurately without explicitly locking. For example, we describe how KSplit handles RCU primitives. An RCU lock is often used in manipulating linked list data structures inside the kernel to enable multiple readers and a single writer to access the same data structure concurrently, which reduces the time-consuming lock acquire and release operations. In KSplit, we consider the non-preemptable reader implementation of RCU locks. In this implementation, the start and end of a reader section is defined by calls to `rcu_read_lock()` and `rcu_read_unlock()` functions, respectively. The reader critical section disables preemption. For an RCU writer, KSplit searches for the call sites of functions that may update the data reachable through a pointer used in one of the RCU update primitives, such as `rcu_assign_pointer()` and `rcu_replace_pointer()`. After identifying those reader and writer sections, the same synchronization algorithm as before is used. While this design negates the benefits of RCU locks, they are rarely used across the isolation boundary. Designing a more optimal cross-domain primitive is future work.

5 Low-Level Kernel Programming Idioms

Interface definition language KSplit IDL builds on the ideas from existing driver isolation projects [33, 62, 66]. Specifically, we borrow the idea of "projections", which describe the state synchronized across domains, from LXDs [66] and extend them with rich IDL annotations that provide support for marshaling of low-level C idioms [33]. For every function crossing the boundary of an isolated domain, an IDL remote procedure call declaration is generated.

```
1  rpc netdev_tx_t ixgbe_xmit_frame(
2          projection sk_buff [alloc(callee)] *skb,
3          projection net_device *netdev)
```

For each argument of a composite type, e.g., `struct`, `union`, the IDL includes a projection that lists the shared-state fields that are read or written by the callee function, as determined by the parameter-access analysis (see the example projection for `struct sk_buff` in Section 7.1.1). For ambiguous cases, additional annnotations are included to specify type of the object and in-memory representation (e.g., whether a pointer refers to a singleton or an array, and also type-specific formatting, such as null-termination) and size. KSplit aims to produce these annotations automatically, or generate warnings for programmers to address.

Pointer classification The main challenge for the static analysis is to infer IDL specifications from the low-level type information available in C. For each field type in a projection whose marshaling requirements are ambiguous, we leverage our PDG representation to compute: 1) aliases and def-use chains for references to the ambiguous argument, in order to determine what kinds of operations may be performed on it (e.g., to distinguish singletons and arrays), and 2) all the call sites in which the ambiguous argument is used to infer semantics from uses (e.g., to infer strings from the argument's use in string manipulation functions).

KSplit uses this information to iteratively refine knowledge about the marshaling requirements of arguments, resolving the ambiguities in some cases, and producing specific warnings in others. For example, suppose that an argument has the type `char *`, but we do not know whether this type refers to a singleton, an array, a null-terminated array (i.e., a sentinel array), or another data type altogether (e.g., due to a type cast). KSplit resolves such ambiguities by first leveraging the def-use information of the argument's aliases and then refining the knowledge by applying further analyses. For classification, we employ the CCured method [69], as implemented for LLVM in the NesCheck system [64]. CCured classifies pointers by whether they are involved in type casts (`wild`), are referenced using pointer arithmetic (`sequential`), or neither (`safe`). Pointers classified as safe by CCured/NesCheck are singletons, as these pointers reference only one location. Sequential pointers may be either arrays or structures, although these can be distinguished based on the way they are accessed. Finally, wild pointers involve type cast operations, which make their types ambiguous; although, we can still infer type information in several cases for common patterns.

Once we have performed the classification, we then perform specialized analyses based on the pointer class for further disambiguation:

Sized and null-terminated arrays KSplit can identify arrays whose size is determined at allocation time. It statically detects strings from uses of pointer aliases in any string manipulation functions.

Tagged and anonymous unions Deriving projections for union types is challenging: types and named of the union's fields are lost at the level of LLVM IR, as the compiler treats unions as raw bytes, and simply accesses the fields as offsets. We develop an analysis algorithm that reconstructs field name information by matching the offsets accessed by the IR instructions with the offsets of each field. To marshal the union, the IDL compiler relies on a user-supplied discriminator function to determine the union's active field at runtime.

Recursive data structures KSplit supports marshaling of generic recursive data structures, e.g., linked lists, trees, and graphs. For example, to support a linked list, the static analysis generates a projection that includes a pointer to a projection of the same type as one of the fields. The marshaling code generated by the IDL compiler traverses all the pointers creating a map of visited objects until a fixed point is reached.

Opaque pointers and error pointers If an argument is found to be wild, KSplit can resolve the type in some cases, e.g., void pointers cast to a single type [33]. KSplit handles some other common cases, such as the pattern where kernel APIs may return a reference to either an object or an error.

Other idioms KSplit is able to detect other special cases, such as buffers allocated in user space, co-located data struc-

tures, and "container-of"/"member-of" data structures, to enable special handling (e.g., marshaling of user memory) and targeted warnings (e.g., for marshaling objects collocated within a memory region or a data structure).

6 Implementation

The KSplit system consists of a set of LLVM passes to perform the static analyses, an IDL compiler to generate synchronization code, and a runtime component to track the allocation and deallocation of objects. The LLVM static analysis passes consist of 8,373 SLOC in C++ for PDG construction [59], shared data analysis (Section 4.2), parameter access analysis (Section 4.3), and atomic region analysis (Section 4.4). PDG construction additionally uses the SVF framework [79] for performing the intra-procedural alias analysis. We also use NesCheck [64] for pointer classification required to resolve ambiguities in kernel idioms. To preserve the source semantics, we use optimization level `0` to generate the LLVM bitcode.

We implement KSplit for the LVDs framework, which supports isolation of privileged kernel code through a combination of hardware-assisted virtualization and EPT switching [68]. Specifically, we rely on the LVDs execution environment to run isolated drivers. We, however, implement a new IDL compiler to support synchronization between subsystems; LVDs supported synchronization of only basic types and data structures, but lacked support for arrays, unions, and recursive data structures. The compiler is implemented from scratch in 4,100 lines of C++.

Object lifetimes The main challenge for the runtime is to ensure that object allocation and deallocation on one side of the isolation boundary is reflected on the other side. Tight integration of the kernel and drivers has historically created irregular allocation and deallocation patterns. KSplit relies on a hybrid static and dynamic approach in which the execution runtime tracks new objects and allocates them each time a new object is passed across the isolation boundary. We, however, rely on static analysis to identify deallocation sites and instrument them to propagate deallocations across the isolation boundary.

7 Evaluation

To evaluate KSplit, we utilize CloudLab [73] c220g2 servers configured with two Intel E5-2660 v3 10-core Haswell CPUs running at 2.60 GHz, 160 GB RAM, and a dual-port Intel X520 10Gb NIC. We use an Intel i7-4790K desktop for evaluation of the `alx` network, `xhci` USB host-controller, and Intel ME drivers. Both machines run 64-bit Ubuntu 18.04 Linux, with kernel version 4.8.4.

7.1 Generality of Static Analysis

The main question is whether KSplit can be used as a general tool for the isolation of device drivers in the Linux kernel. To answer this question, we use the KSplit analysis to produce IDL for 354 drivers from multiple Linux subsystems (Table 2), and then evaluate the effectiveness of the analysis and IDL generation algorithms by isolating and validating the correctness of 10 drivers (Table 1). We chose a range of device and protocol drivers that represent typical kernel programming and communication idioms: 1) `msr`: a high-level interface to the model specific registers (MSRs) on the Intel CPUs, which exercises several patterns typical for nearly every Linux device driver—dynamic registration of interfaces and callbacks, synchronization of null-terminated and statically sized arrays; 2) `nullnet`: a software-only network driver that emulates an infinitely fast network adapter, which relies on complex allocation of objects on both sides of the isolation boundary, and implements a fast data plane, requiring careful handling of data structures to achieve optimal performance; 3) `coretemp`: temperature monitoring for CPU cores, which utilizes void pointers and two-dimensional arrays; 4) `sb_edac`: error detection and correction (EDAC) for the Intel Skylake server integrated memory controllers, which requires marshaling of a graph of objects that describe the hierarchy of DRAM banks and memory controllers across the isolation boundary; 5) `null_blk`: a software-only emulation of the NVMe interface; the driver is similar to `nullnet`, i.e., it allows us to stress-test the overheads of isolation on a fast NVMe interface; 6) `ixgbe`: an Intel 82599 10Gbps Ethernet driver, which exhibits several critical characteristics that are interesting for decomposition: first, it relies on atomic operations to update packet statistics in the kernel; second, it exhibits a broad range of asynchronous accesses from system calls, interrupt contexts, software IRQs, and New API (NAPI) threads that implement submission of packets and polling; third, it relies on system timers for several control-plane operations that allow us to test static analysis for support of callback functions dynamically registered with the kernel; 7) `alx`: a Linux Qualcomm Atheros ethernet driver; we select `alx` to compare the complexity and manual effort of decomposing device drivers within the same device class (i.e., we compare three ethernet drivers: `ixgbe`, `alx`, and `nullnet`); 8) `can_raw`: a raw CAN protocol driver using the sockets API, which represents a class of protocol drivers that exhibit typical protocol-layer patterns by interacting with the kernel network stack; 9) `dm_zero` a software block driver that returns `0` on reads and drops writes; `dm_zero` tests if KSplit can fully automate isolation of simple device drivers; 10) `xhci-hcd`: an xHCI protocol driver for supporting USB 3.0, which handles complex interactions of the USB communication protocol.

A wide variety of drivers allows us to examine the generality of the KSplit analyses for producing IDL specifications, and assess the manual effort required for isolation. While we did not run all 354 drivers, we compare metrics related to the effort of isolating an average driver to those we validated. To validate the 10 drivers, we first perform manual tasks required to complete the IDL by resolving all warnings generated by KSplit, and then test the isolated driver trying to evaluate cor-

Table 1: Driver complexity and impact of shared state optimizations.

rectness of isolation what allows us to judge precision and accuracy of the static analysis.

Complexity of driver interfaces To justify the need for automated analysis techniques, we collect several metrics that illustrate the complexity of the 10 drivers isolated using KSplit (Table 1a). The two most complex drivers are `ixgbe` (over 27K SLOC) and `xhci` (over 10K SLOC). The `ixgbe` driver consists of over 2,000 functions, registers 81 callback functions with the kernel, and relies on 134 kernel functions for its operation. Isolation of the `ixgbe` driver involves analysis of the 5,782 functions that may access the state shared between the kernel and the driver. A total of 999,136 fields and scalar arguments are transitively reachable from the arguments of the driver functions that define its isolation boundary (Table 1b). While partial isolation of the `ixgbe` driver was demonstrated before [66, 68], isolation of the complete driver is beyond the reach of manual human analysis.

Impact of shared state optimizations KSplit distinguishes the shared state from the private state, which is critical for the scalability of the analysis algorithms (Section 4.3). We

Table 3: Similarity within a class

collect the total number of fields in all data structures that are recursively reachable from all the arguments passed across the isolation boundary—previous approaches relied on naive "deep copy" [59] and field-access approaches [33] (Table 1b). Out of 999K fields reachable through the isolation boundary of the `ixgbe` driver, only 4,509 fields are accessed, and an even smaller fraction of them, or 3,029, are shared (Table 1a). Furthermore, by reasoning about nested crossings of the isolation boundary, we reduce this number to 2,669. Most critically, the shared-state optimization radically simplifies the isolation of the driver, as in many cases, complex low-level idioms, e.g., tagged unions, stay on only one side of the isolation boundary (Table 1c). For example, out of 73 critical sections in `ixgbe`, only 3 are shared (`ixgbe` relies on the global `rtnl_lock` to register the driver with the kernel); all RCU and seqlocks are private, and do not trigger cross-boundary synchronization.

Pointer classification To understand how well KSplit supports the classification of pointer references, we characterize the number of supported and problematic pointer patterns in our drivers (Table 1d). In many cases, KSplit is able to infer the types and sizes to enable automatic IDL generation. Table 1d shows that for `ixgbe`, out of 1,529 pointers ("Pointers" in Table 1c) that require marshalling across the isolation boundary, only 31 require manual inspection to generate correct marshaling attributes. There is a small number of misclassified pointers ("Ptr. misclassifications" in Table 1g). We found that these misclassified pointers are sequential pointers that are wrongly classified as singleton pointers; CCured fails to identify pointer-arithmetic operations on them. A detailed study of these misclassified pointers revealed the main reason for misclassification is due to not analyzing library code. For example, the `ixgbe` driver calls the kernel function `pci_request_selected_regions()` with a reference to the driver name string, but the kernel function itself does not perform pointer-arithmetic operations on the reference; instead it passes the reference to a string library. This causes CCured to misclassify the pointer as a singleton pointer. It is possible to resolve some misclassification cases by either extending our analysis to kernel libraries (note, some library functions like `printk()` are challenging for static analysis), and by manually annotating how pointers are used in such functions. For example, if a pointer is passed to a string manipulation function, e.g., `strcmp()`, we can classify the pointer as sequential.

Analysis execution time To understand the practicality of KSplit and its fit for the kernel development toolchain, we measure the execution time of the analysis (Table 1e). The execution time is largely influenced by the number of functions that are involved in the analysis (this number is determined primarily by the size of the driver and by the size of the kernel subsystem the driver interacts with). Complex device drivers that interact with multiple subsystems (e.g., `can_raw`, `null_blk`, `xhci`, and `ixgbe`), require 190-546 seconds to complete. Simple device drivers finish in under a minute.

Precision of the analysis and manual effort To understand the precision of the analysis and the manual effort involved in the isolation of a driver, we compare an automatically-generated IDL with the final, manually-checked and tested IDL used for the isolation of the driver. As we do not have the ground truth, to gain confidence in the correctness of the isolated driver, we execute a collection of tests on each driver. We use Gcov to collect the code-coverage metrics for the tests we run (Table 1f). The code coverage is less than 50% in some cases, since we can only trigger the execution of a subset of the driver code. For example, EDAC drivers support multiple generations of Intel CPUs from Ivy Bridge to Xeon Phi; `ixgbe` supports multiple hardware interfaces, e.g., x540, 82599, 82598; `xhci`, being a protocol driver, has a lot of error handling code, e.g., in a representative function `handle_tx_event()` that handles all the USB transmit events, out of 348 source lines, 198 lines (or 56%) are error handling code that we cannot trigger without fault injection; `sb_edac` driver consists of 1162 lines of code, out of which only 492 (42%) are executable on our Haswell hardware, out of which our tests cover 373 lines of code (thus increasing our coverage

from 63% to 76%).

We collect several metrics that characterize the amount of manual effort involved in resolving IDL warnings (Table 1g). The IDL of a complex driver like `ixgbe`, generated by KSplit, consists of 2,476 lines of code. Isolation of the driver required changing 53 lines of automatically-generated IDL (or 2% of the IDL). We only had to introduce 19 lines of changes to the driver's code, which mostly involve redefinition of certain macros as helper functions (e.g., `setup_timer`, `INIT_WORK`, etc.). KSplit misclassified 7 out of 1,529 pointers shared across the isolation boundary. Two pointers were strings that were passed across the isolation boundary, but were not accessed through pointer arithmetic or string-manipulation functions. One pointer was referring to a DMA memory region that was only accessed by the device but was not involved in any pointer arithmetic in the driver. Four pointers were misclassified due to being passed as arguments to the `memcpy()` function. For smaller drivers, isolation required less than 30 lines of IDL changes. Furthermore, most small drivers required no changes to the driver code.

The "False positives" row lists the number of fields falsely classified by KSplit as shared. We identify them as not shared through manual inspection and driver profiling. The ground truth may be incomplete, so this number represents an upper bound on the number of false positives. The fraction of false positives is generally low (<10%). The dominant reason for false positives are aliases in the shared-data analyses (shared data uses a type-based approach that leads to the overapproximation of fields and `in`/`out` attributes).

Finally, the "Warnings" row shows the number of warnings KSplit's static analyses generate for each driver. These warnings must be resolved by developers to obtain a working IDL.

Similarity within a class A key insight for scaling the isolation to a large fraction of all kernel drivers is grounded on the assumption that drivers within the same class have a significant degree of similarity across their interfaces. Isolation of one driver within the class, therefore, could guide the isolation of other drivers in a relatively straightforward manner, hence amortizing manual effort across the class. To understand the effort involved in isolating multiple drivers in the same class, we choose a base driver within a class and compare it with other drivers in its class (Table 3). We compare two network drivers, `alx` and `nullnet`, to the base `ixgbe` driver. The `alx` driver shares 73 function definitions with `ixgbe` (the total number of functions crossing the isolation boundary in both directions is in Table 1a). After `ixgbe` was decomposed, decomposition of `alx` required changes to 6 annotations and a total 41 lines of changes in the shared part of the IDL.

Generality of IDL generation To judge if KSplit can be used as an isolation tool for the entire population of drivers, we apply it to 354 drivers across nine subsystems in the Linux kernel (Table 2). To make a prediction about the manual effort involved in isolation of the average driver, we collect the same metrics as the ones collected for the validated drivers (Table 1), although all the counts in Table 2 are averages per-driver. In general, we see a huge impact due to the shared-state optimizations (Table 2b) and a low number of problematic pointer instances (i.e., cases that are not "singletons") that could result in warnings (Table 2c). We therefore believe that the effort of isolating an average driver in these subsystems is comparable to the drivers we validated.

	Null	Integer	Array	String	Void	Union
Bytes	0	8	32 * 8	256	4096	24 + 32
Cycles	502	532	690	1310	919	710

Table 4: Overhead of marshaling various data structures

IDL warnings KSplit produces IDL warnings for the following patterns in Table 2c: 1) arrays and "strings" of undetermined size; 2) wild pointers whose type cannot be inferred deterministically from "wild (void)"; 3) anonymous unions in "wild (other)"; and 4) potential cases of collocated data structures in "wild (other)". In general, the number of IDL warnings for each driver is dependent not only on the size of the driver, i.e., lines of code, and complexity of the driver interface, i.e., lines of IDL code, but also on the types of kernel idioms used for communication across the isolation boundary. For example, isolation of the `alx` driver involves an IDL file that consists of 674 lines of code and requires analysis of 22 warnings. The `alx` driver contains 17 anonymous unions, 2 undetermined size arrays and 3 non-void wild pointers. At the same time, isolation of the `can-raw` driver that uses a smaller IDL (470 lines of IDL code) yields 35 warnings. The high number of warnings for `can-raw` is attributed to the 30 instances of anonymous unions and 5 indeterminate-size arrays in its interface.

7.1.1 Case Study: Ixgbe Network Driver

To illustate the process of decomposition, we consider an example, the `ixgbe` driver, that combines a representative set of complex kernel data structures, low-level idioms, and synchronization patterns. As discussed above, separation of shared and private state is critical for reducing the complexity of the IDL required for the isolation of `ixgbe`. KSplit automatically resolves all function pointers that `ixgbe` registers with the kernel as its interface, identifies five `user` and `ioremap` memory regions used by the interfaces of the driver. Out of 143 wild void pointers that `ixgbe` exchanges across the isolation boundary only one required manual intervention ("Wild pointer (void)" in Table 1d). We then had to inspect 3 wild pointers that are type casted between non-void types ("Wild pointer (other)" in Table 1d). The driver requires manual inspection of 27 array pointers (out of 119 exchanged across the boundary). The driver uses one function that returns a pointer-as-error, which is successfully identified by KSplit.

One of the most challenging parts of the `ixgbe` interface is the proper handling of the `sk_buff` data structure, representing a network packet (Figure 1). Several integer fields are used

```
1  projection<struct sk_buff> skb_xmit {
2    projection net_device *dev;
3    unsigned int len;
4    unsigned int data_len;
5    ...
6    void * [alloc_sized<callee>(self->true_size)] head;
7    void * [within<self->head, self->true_size>] data;
8    unsigned int [within<_, self->true_size>] tail;
9    unsigned int [within<_, self->true_size>] end;
10 };
```

Listing 1: Projection of an `sk_buff` data structure

as offsets into the data: 1) `tail` marks the end of the packet's data, and 2) `end` represents the start of the `struct skb_shinfo` that is collocated inside the data memory. The low-level PDG representation of the program allows us to derive that the `skb_shinfo` data structure is allocated within the `data` object. As the `tail` and `end` fields participate in pointer-arithmetic operations, KSplit generates a special `within` IDL attribute that instructs the marshaling code to check that the field is within a specific range, but the range has to be specified manually (Listing 1). KSplit's support for recursive data structures allows us to marshal `sk_buff` buffers that consist of multiple fragments (`sk_buff` contains an optional list of fragments).

7.2 Performance

In general, the performance of the isolated driver is largely determined by the performance of the underlying isolation framework, i.e., LVDs, in our current implementation [68]. We, however, quantify the impact of the KSplit marshaling protocol, and conduct an end-to-end performance measurement of an application using the isolated `ixgbe` driver.

Marshaling overheads We perform microbenchmarks to evaluate the overheads of marshaling various data structures that are commonly used in the Linux kernel (Table 4). For each data structure, the test involves marshaling the data structure, passing it across the isolation boundary, and unmarshaling it. We perform ten million iterations and report an average. On the LVDs system, a null call-reply invocation takes 502 cycles, which includes the overhead of executing the `vmfunc` instruction, saving and restoring general registers, and selecting a stack inside the driver domain. KSplit adds 30 cycles for marshaling simple scalar fields, such as integers. For marshaling tagged unions, we rely on a user-supplied discriminator function that identifies the tag and marshals the union according to the active field's type. In our experiment, we marshal a union that represents a string of 32 characters, which incurs an overhead of 208 cycles.

Memcached To understand end-to-end overheads of isolation on real application workloads, we utilize an experiment that runs memcached, a high-performance, in-memory object-caching system [4] and compare a native, non-isolated kernel with the performance of a system that utilizes an isolated version of the `ixgbe` network driver. We run memcached version 1.5.12 with a single service thread and a cache size of 5GB. We use the memaslap [2] load-generator to send random UDP

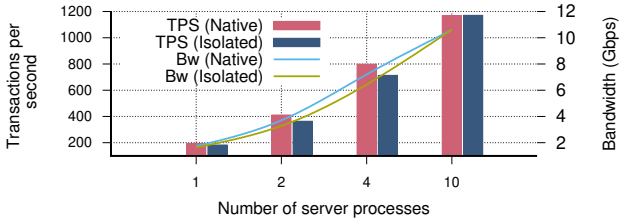

Figure 5: Memcached performance

requests of 64B keys and 1024B values to the server (90% get and 10% set) with a concurrency of 128. To ensure a fair comparison, we limit the number of available cores to 10, as we are limited by the performance of a 10Gbps adapter (all 20 cores would allow isolated drivers to bridge the performance gap, but at a cost of higher CPU utilization). We report both the number of key-value transactions per second and total network bandwidth (Figure 5). For experiments with 1-4 threads, KSplit stays within 5.4-18.7% of the non-isolated system's performance. With 10 threads, both isolated and native drivers saturate the network interface and hence demonstrate nearly identical performance (albeit at higher CPU utilization, due to domain crossings).

8 Conclusions

After decades of research, commodity CPUs are converging on a set of practical hardware mechanisms capable of providing support for low-overhead isolation. With performance no longer being the main roadblock, complexity becomes the main challenge for enabling isolation in commodity systems. Our work on KSplit takes a step forward by enabling isolation of unmodified device drivers in the Linux kernel. A combination of practical static analysis techniques allows us to address the daunting complexity of the driver interfaces—KSplit supports isolation of complex, fully-featured device drivers with only minimal changes or human involvement. While our current implementation works with Linux and a specific isolation framework, we argue that our analysis and state-synchronization techniques are general and can serve as a foundation for a range of isolation solutions enabled by the emerging hardware mechanisms.

Acknowledgments

We thank the ASPLOS'21, OSDI'21, SOSP'21 and OSDI'22 reviewers and our shepherd, Rüdiger Kapitza, for in-depth feedback on earlier versions of the paper. We would like to thank the Utah CloudLab team for continual support in accommodating our hardware requests. Finally, we would like to thank the artifact evaluation committee for numerous comments that greatly improved the artifact. This research is supported in part by the National Science Foundation under Grant Numbers CNS-1527526, OAC-1840197, CNS-1801534, CNS-1816282, and DARPA HR0011-19-C-0106. Vikram Narayanan is partly supported by an IBM PhD fellowship.

A Artifact Appendix

Abstract

We release the source code of all software used in this paper along with detailed build instructions and automated scripts used for running the benchmarks as a collection of publicly-hosted Git repositories.

Scope

The artifact allows one to run static analysis on the set of drivers we isolated for this paper and collect metrics that are reported in Table 1, Table 2, and Table 4.

Contents

The artifact consists of the source code for the following subsystems: 1) KSplit analysis framework used to generate interface definition language (IDL) files `https://github.com/ksplit/pdg`; 2) LLVM bitcode files for the drivers analyzed in the paper `https://github.com/ksplit/bc-files` (we provide detailed instructions for how to re-generate the bitcode files, however, to simplify the process of re-creating results reported in the paper, we provide a collection of pre-generated files); 3) KSplit IDL compiler that generates the glue code required to execute the driver in isolation from the IDL files `https://github.com/ksplit/idlc`; 4) a modified Linux kernel that executes isolated drivers in Lightweight Virtualized Domains (LVDs) [68] `https://github.com/ksplit/lvd-linux`; and 5) a modified Bareflank hypervisor that provides secure and efficient isolation boundary based on VMFUNC EPT switching interface used by LVDs `https://github.com/ksplit/bflank`.

Hosting

The artifact is hosted on GitHub. The `README.md` file under `https://github.com/ksplit/ksplit-artifacts` details the steps required to build and run the benchmarks.

We conduct all experiments in the openly-available CloudLab cloud infrastructure testbed [28] and make our experimentation environment available via an open CloudLab [73] profile that automatically instantiates the software setup required to run KSplit: `https://github.com/ksplit/ksplit-cloudlab/`.

Requirements

The KSplit build infrastructure was tested on an x86-64 Ubuntu 18.04 LTS system. The static analysis framework is built and tested against LLVM v10.0.1. We rely on LVDs [68] to execute isolated drivers. LVDs run on any modern Intel x86-64 hardware (Haswell or later) that supports virtualization (Intel VT-x) and EPTP switching via VMFUNC. LVDs rely on a customized Bareflank hypervisor and a modified Linux kernel based on v4.8.4. We have tested KSplit on the following hardware (available in CloudLab): a Cisco UCS C220 machine configured with an Intel Xeon E5-2660 CPU, and a Dell PowerEdge C6420 machine configured with an Intel Xeon Gold 6142 CPU.

Operating System Support for Safe and Efficient Auxiliary Execution

Yuzhuo Jing Peng Huang

Johns Hopkins University

Abstract

Modern applications run various auxiliary tasks. These tasks gain high observability and control by executing in the application address space, but doing so causes safety and performance issues. Running them in a separate process offers strong isolation but poor observability and control.

In this paper, we propose special OS support for auxiliary tasks to address this challenge with an abstraction called *orbit*. An orbit task offers strong isolation. At the same time, it conveniently observes the main program with an automatic state synchronization feature. We implement the abstraction in the Linux kernel. We use orbit to port 7 existing auxiliary tasks and add one new task in 6 large applications. The evaluation shows that the orbit-version tasks have strong isolation with comparable performance of the original unsafe tasks.

1 Introduction

Applications in production frequently require maintenance to examine, optimize, debug, and control their execution. In the past, maintenance was primarily manual work done by administrators. Today, there are increasing needs for applications to self-manage and provide good observability. Indeed, many modern applications execute *auxiliary* tasks. These tasks are designed for various purposes including fault detection [18, 27, 37, 43], performance monitoring [21, 28, 35], online diagnosis [25], resource management [14, 31], *etc.*

For example, PostgreSQL users can enable a periodic maintenance operation called autovacuum [17] that removes dead rows and updates statistics; MySQL provides an option to run a deadlock detection task [30], which tries to detect transaction deadlocks and roll back a transaction to break a detected deadlock; HDFS server includes multiple daemon threads, such as a checkpointer that periodically wakes up to take a checkpoint of the namespace and saves the snapshot.

Essentially, the structure of applications splits into two logical realms of activities (Figure 1)—the *main* and the *auxiliaries*. Despite being peripheral, the latter tasks are important for the reliability and observability of production software.

At the implementation level, though, auxiliary tasks' execution is mixed with the main program's in the same address space, via direct function calls or as threads. Unfortunately, this choice means the auxiliary tasks can incur severe interference to the application's performance, due to unnecessary blocking and contention on CPU, memory, network, and other resources. In addition to costs, bugs in the auxiliary tasks can easily affect the application reliability, *e.g.*, a null-pointer bug inside a checker function can crash the whole process.

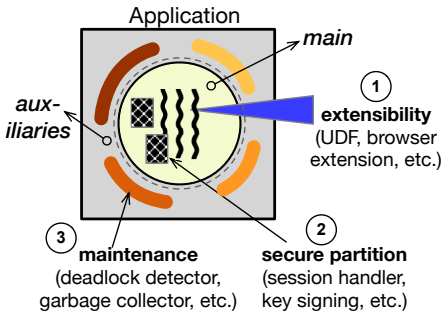

Figure 1: Three protection scenarios for modern applications. This paper focuses on ③.

The alternative is to execute an auxiliary task externally in another process. This choice, however, would impose significant limitations on what can be observed and what can be changed. If the deadlock detector, for example, is run in a separate process, it would not be able to directly inspect the latest transactions or locks; even if it finds a deadlock it could not apply changes to mitigate the issue.

A fundamental problem is that existing OS abstractions for task execution—processes and threads—are designed for the main activities, but are unfit for auxiliary tasks. They force developers to either choose strong isolation but very limited observability and control (in a separate process), or high observability and control but little isolation (in a thread). In this paper, we advocate direct OS support for the trend of *auxiliary execution* to tackle this tension.

OS support for sub-process protection is not new. The systems and security communities have proposed various mechanisms [10, 12, 16, 24, 29, 40, 42, 47]. However, they are designed for two other different purposes. As illustrated in Figure 1, mechanisms such as SFI [42] are designed for *application extensibility* (①). That is, safely execute some *untrusted* third-party extension code, *e.g.*, browser extensions and user-defined-functions in database queries. Another category of abstractions such as Wedge [10] and lwC [24] are designed for *secure partitioning* (②), *i.e.*, protecting some sensitive procedures in the main program, *e.g.*, session handler

or key signing, in case the application is compromised.

These existing mechanisms are insufficient for the third protection scenario (③)—maintenance. The auxiliary tasks are written by the same developers and are trusted. They are also by nature interactive with the main program and need to constantly inspect the latest states of the main program. They often need to additionally alter the main program execution.

In this paper, we investigate this under-explored protection scenario. We summarize the common characteristics of auxiliary tasks, articulate the unique challenges of protecting such tasks, and advocate for special OS support to close this gap.

We then take the first step to propose a new OS abstraction called *orbit* for auxiliary execution. Orbit enables developers to conveniently add a wide range of auxiliary tasks that execute safely and efficiently while assisting the application.

Orbit has several unique features compared to existing sub-process abstractions such as threads, SFI, and lwC. An orbit is a first-class execution entity with a dedicated address space and is schedulable. Each orbit is bound with a main process but provides strong isolation: (i) if an orbit task is buggy and crashes, it does not affect the main process; (ii) orbit executes asynchronously and can be directly enforced with resource control, thus the main process is isolated from an auxiliary task's performance interference. At the same time, orbit provides high observability. Each *orbit*'s address space is mostly a mirror of the main program's. Thus, when the main process calls an orbit, the orbit can run the task functions with the latest main program states. To meet the need for some auxiliary task to change the main process, orbit provides controlled alteration to safely apply updates.

There are two challenges in designing orbit. First, isolation and observability are difficult to achieve together. Second, isolation is known to be costly. Since the main process often calls auxiliary tasks continuously, orbit can incur large performance slowdown to the main process. Optimizations such as using shared memory conflict with the goal of isolation.

To address the first challenge, we design a lightweight memory snapshotting solution that leverages the copy-on-write mechanism and provides *automatic state synchronization* from the main process' address space to orbit's address space whenever the main process calls the orbit task. To address the second challenge, our insight is that while an auxiliary task may inspect various state variables in the main program, the total size of the inspected state *at each invocation* is often a relatively small portion of the entire program state. Thus, we take a simple approach that coalesces only those state variables that an orbit task needs into what we call *orbit areas*. The kernel dynamically identifies the active memory pages in the orbit areas that an orbit invocation requires and only synchronizes these pages to the orbit side.

The lightweight memory snapshotting solution works at page granularity, which has the advantages of simplicity, robustness, and ease of integration with all mainstream OSes without depending on perfect instrumentations as in more complex techniques such as shadow memory. The disadvantage is that the page granularity incurs higher snapshot overhead due to write amplification (snapshot an entire page even if only one small object is changed) and often false sharing (write protection on shared COW pages). We design several optimizations including incremental snapshot, dynamic page mode selection, and delegate objects to reduce the cost.

We have implemented a prototype of orbit in the Linux kernel 5.4.91. To evaluate the generality of the orbit abstractions, we collect 7 auxiliary tasks from 6 large applications including MySQL, Apache, and Redis, and successfully port these tasks using orbit. We also use orbit to write a new auxiliary task for Apache. To demonstrate the isolation capability of orbit, we inject faults to the orbit version of the tasks. Some faults are directly based on real bugs in the task code. The experiments show that the applications are protected from the faults in all cases. We measure the cost of the isolation by comparing the end-to-end application performance. The orbit version applications only incur a median overhead of 3.3%.

In summary, this paper's main contributions are as follows:

- We identify an under-explored category in protection for auxiliary execution and summarize its characteristics.
- We design a new OS abstraction orbit to enable auxiliary tasks that have both strong isolation and high observability.
- We implement orbit in the Linux kernel and evaluate it on real-world auxiliary tasks in large applications.

The source code of orbit is publicly available at:

`https://github.com/OrderLab/orbit`

2 Motivation and Goals

2.1 Auxiliary Tasks

Modern applications often execute various auxiliary tasks designed for assisting reliability, performance, and security. A few typical categories of auxiliary tasks include:

- **Fault detection.** Many applications have checkers to detect faults dynamically. Examples include watchdogs [26] to catch gray failures [19], deadlock checkers, and GC pause detector. Some checkers are instrumented with compilers, such as sanitizers to detect memory leaks.
- **Performance monitor.** It is common for applications to have monitors that collect performance data. For instance, Redis includes a slow log monitor to record queries that take unusually long time.
- **Resource management.** Large applications run resource management routines. For example, Cassandra periodically runs compaction tasks to improve performance for future queries; it also runs a task to asynchronously remove stale records based on past delete requests.
- **Recovery.** Some routines in an application are designed for assisting active recovery. HDFS continuously scans blocks and schedules tasks to reconstruct blocks with low redundancies. Databases also often employ checkpoint threads that flush modified pages and write checkpoint records.

```
const trx_t* check_and_resolve(lock_t* lock, trx_t* trx) {
  do {
    DeadlockChecker checker(trx, lock, mark_counter);
    victim_trx = checker.search();
    if (victim_trx != NULL && victim_trx != trx)
      checker.trx_rollback();
  } while (victim_trx != NULL && victim_trx != trx);
  return victim_trx;
}
```

Figure 2: Deadlock checker function in MySQL.

The workflow of these tasks typically has three steps: (1) read program states; (2) perform inspection work; (3) take actions and modify some states. Depending on their goals, some tasks only read a few program states, while others may inspect lots of states. Some auxiliary tasks are relatively simple that execute synchronously with the main program, *e.g.*, control flow checks [8]. Others are long-running operations that usually execute asynchronously, *e.g.*, in a background thread. Our main focus in this work is the latter type of auxiliary tasks, since they often pose potential issues to the main program.

Note that some existing auxiliary tasks are written in their current forms, *not* because of their inherent nature, but often due to the lack of system support. For example, an existing detection task may execute synchronously, because otherwise the program state may be changed while the task is checking it. However, if an efficient mechanism exists to automatically snapshot the state to be checked, this task could be easily made asynchronous. We aim to provide the support that improves existing auxiliary tasks while enabling novel ones.

2.2 Example: MySQL Deadlock Checker

To make the discussion concrete, we use a representative auxiliary task, the MySQL deadlock checker, as the running example throughout the paper. Figure 2 shows its simplified code snippet. This task is invoked regularly in the main program. Specifically, in handling an update query, MySQL may need to lock a record; if the locking fails, the checking task is invoked. Each checking function invocation takes the blocked lock and the transaction as arguments.

Inside `check_and_resolve`, a deadlock checker instance is created, which runs a search algorithm to inspect the wait-for graph involving the `lock` and `trx` objects as well as other dependent variables. If the checker detects one potential deadlock, it will try to resolve the issue by choosing a victim transaction and rolling it back (modify the state `victim_trx`).

2.3 Safety and Performance Concerns

Developers usually write auxiliary tasks to execute inside the application process. While this choice makes it convenient for the tasks to assist and monitor the main program, their execution poses safety concerns because they execute in the main program's address space. A common issue is a buggy task accessing invalid memory, which crashes the entire application. In other scenarios, a buggy task may cause the main program to get stuck, *e.g.*, a low-priority data gathering thread blocks the high-priority tasks in a similar vein as the infamous Mars Pathfinder incident [36]. Or, the buggy task accidentally modifies some global variables and causes the main program to misbehave. Some issues occur indirectly because of the address space sharing. For example, a defect in HDFS creates too many `SafeModeMonitor` threads and causes the main program to fail with out of memory errors [4].

It might seem that crashing the main program when the auxiliary task is broken is acceptable for some critical auxiliary tasks. For example, since the deadlock detector is important for resolving deadlocks in transactions, if the detector has an invalid memory access, it might be reasonable to crash the main program. However, in practice, crashing the main program is usually too costly (unavailability and slow recovery) and often incurs unintended side effect (inconsistency and data loss), especially considering that the bugs are not from the main program. Alternatively, if we provide strong isolation for auxiliary tasks, we can decouple the fate of the main program from the fates of the auxiliary tasks, which will allow developers to make better choices. For instance, developers can implement a policy that if an auxiliary task dies, it will be automatically restarted and pick up the previous progress, without affecting the main program's execution.

Besides safety, auxiliary tasks can also incur interference to the main program's performance. For instance, we measure the MySQL performance with the deadlock detector task running. The result shows a 3.5%–79.5% drop in the query throughput. This issue was reported by users [1].

In summary, auxiliary tasks are designed to actively improve application reliability and performance, but paradoxically the shared-address-space execution model can cause them to hurt the main program.

2.4 Why Fork or Sandbox Is Insufficient?

To address the safety and performance concerns of auxiliary tasks, two potential alternatives exist: fork and sandbox.

Fork-based Execution Model In this approach, the application makes a `fork()` system call before an auxiliary task executes and switches to run the task functions in the child process. The separate address space provides strong memory isolation. In addition, the task has a copy of address space and thus can inspect any main program states easily. Once `fork()` completes, the main program can continue, while allowing the auxiliary task to execute asynchronously.

Unfortunately, there are several issues. First, the cost is substantial, which includes the creation of a heavy-weight execution entity, as well as the copying of an address space. Even with the copy-on-write optimization, the main program may modify many pages afterward and trigger excessive copying. Moreover, for auxiliary tasks that execute frequently, the fork overhead will be incurred at each task invocation.

Besides overhead, with the auxiliary task running as a child process, it is difficult for the task to perform maintenance work that requires modifying the main program states. For instance, the MySQL checker can identify a victim transaction and

perform a rollback, but the resolution only affects the child process and would not help the parent process.

Sandbox-based Execution Model Another solution is to execute an auxiliary task in a sandbox, which is well-suited to execute untrusted code, *e.g.*, browser renderer. A sandboxed process has reduced privileges in accessing resources including file systems and system calls, and may reside in a separate fault domain using SFI techniques [42].

However, auxiliary tasks are not untrusted codes that sandboxes are designed for. They are written by the application developers and are trusted. Their safety issues arise because of bugs or unintended side effects such as invalid memory access, infinite loops, using too much CPU, etc., rather than accessing unwanted system calls or files. A sandboxed process in a separate fault domain can access only the memory segment allocated to them. It thus gains little observability of the main program and cannot change the main program state.

RPCs or Shared Memory In principle, some aforementioned limitations can be circumvented using RPCs or shared memory. In practice, such workarounds are not favored by developers, because neither model matches with how developers write auxiliary tasks. Developers currently add auxiliary tasks directly in the application codebase and can easily refer to variables in the main program or invoke its functions. To use the RPC model, developers need to convert many variables and functions to be amenable to RPCs. Variables such as `lock` and `trx` in MySQL are difficult to marshal and unmarshal across calls. Frequent RPCs also add large overhead.

The shared memory model similarly requires cumbersome setup and coordination. In addition, the main process would have to wait until the auxiliary task finishes before continuing. Otherwise, the task would inspect inconsistent states. Another issue is that shared memory defeats the isolation purpose. An auxiliary task may need to access variables that scatter across the main program's address space. As a result, the main process may share a large portion of its address space, posing significant safety issues like a thread-based auxiliary task.

3 Orbit: OS Support For Auxiliary Executions

The aforementioned challenges are largely because existing OS abstractions for execution are designed for activities that have clear modularity and isolation boundaries. Auxiliary tasks are inherently interactive with the main program, but it is also desirable to isolate their faults and avoid interference. Developers are forced to choose either an abstraction that offers high observability but weak isolation (*e.g.*, thread), or one with strong isolation but low observability (*e.g.* process).

To address this gap, we propose direct OS support for auxiliary execution with a new abstraction called *orbit*. Orbit offers high observability of another execution entity, while providing strong isolation. Its end goal is to enable developers to create a variety of auxiliary tasks that assist applications in production to enhance the applications' reliability and performance.

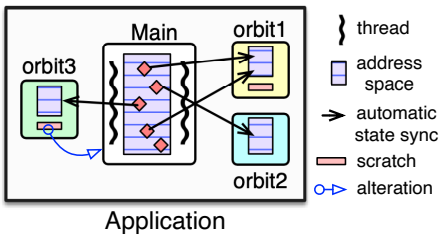

Figure 3: Multiple *orbit*s co-exist with the main program at runtime to provide observability and maintenance support.

3.1 Overview

An orbit task is a lightweight OS execution entity. Each task is bound to "watch" one *target* process. A process can have multiple orbit tasks as shown in Figure 3. They inspect different parts of the target's states for different maintenance purposes. Compared to existing abstractions, *orbit* has several major unique properties:

- **Strong Isolation.** Each orbit task has its own address space. Faults in an orbit would not jeopardize the main program or other orbit tasks. Most orbit tasks execute asynchronously without blocking the main program for a long time.
- **Convenient Programming Model.** The orbit abstraction preserves the current way of how developers write auxiliary tasks. Developers write the orbit task functions within the main program and directly refer to almost any state variables of the main program. They can also easily convert existing functions into orbits. This programming model is close to the thread model that developers are familiar with.
- **Automatic State Synchronization.** A defining characteristic of the orbit task's address space is that it is mostly a mirror of fragments in the target's address space. The fragments are those states that the orbit task needs to inspect. The underlying OS will *automatically* synchronize the specified states to the orbit address space in *one direction*, which occurs before each task invocation in the main program.
- **Controlled Alteration.** A regular orbit only observes the main program, while a privileged orbit is allowed to alter the main program state. However, it cannot change arbitrary state at arbitrary times. The modification has to be made using *scratch space* and well-defined interfaces.
- **First-class Entity.** Orbit tasks are first-class OS entities. They are schedulable like a normal process or thread. This property differs from existing sub-process abstractions such as SFI-based sandboxes and lightweight-context [24], which are subordinates to the main program and *not* schedulable. These abstractions typically have to execute synchronously. An orbit task can be also directly enforced with various limits such as CPU quota.

3.2 Design Challenges and Insight

There are two core challenges that we need to address. First, *how to enable orbit tasks to continuously inspect the main*

API	Description
`orbit *orbit_create(const char *name, orbit_entry entry, void* (*init)(void))`	create an orbit task with a name, an entry function, and an optional initialization function
`int orbit_destroy(orbit *ob)`	destroy the specified orbit task
`orbit_area *orbit_area_create(size_t init_size, orbit *ob)`	create an orbit memory area with an initial size
`void *orbit_alloc(orbit_area *area, size_t size)`	allocate an object of `size` from the orbit area
`long orbit_call(orbit *ob, size_t narea, orbit_area** areas, orbit_entry func_once, void *arg, size_t argsize)`	invokes a synchronous call to the orbit task function with the specific area(s) and arguments, blocks until task finishes
`orbit_future *orbit_call_async(orbit *ob, int flags, size_t narea, orbit_area** areas, orbit_entry func_once, ...)`	invokes an asynchronous call to the orbit task function, returns an `orbit_future` that can be later retrieved
`long pull_orbit(orbit_future *f, orbit_update *update)`	main program waits and retrieves update from orbit future `f`
`long orbit_push(orbit_update *update, orbit_future *f)`	orbit passes update to an existing orbit future `f`

Table 1: Main orbit APIs.

program states conveniently, given that observability and isolation are difficult to achieve together? Second, *how to minimize the performance cost while providing strong isolation?* Isolation inevitably incurs cost. A straightforward design can incur excessive performance slowdowns. Optimizations that can potentially reduce costs, such as using shared memory, are often in conflict with the goal of fault isolation.

Our observations about the characteristics of typical auxiliary tasks reveal insight to address the challenges. While an auxiliary task may inspect various states in an execution, the total size of the inspected state *at each invocation* is often a relatively small portion of the entire program state. In addition, an auxiliary task often performs work incrementally: once the task inspects some state instance in one invocation, the task may not inspect that instance in the next invocation.

4 Orbit Designs

In this section, we describe the designs of the orbit abstraction and how to achieve the properties described in Section 3.

4.1 System Interfaces

The orbit abstraction is exposed through system calls accompanied by a user-level library. Table 1 shows the major APIs.

Developers create an orbit task in place in the application codebase using `orbit_create`, specifying the task entry function. The entry function pointer is defined as `long(*orbit_entry)(void *argbuf, void *store)`, which is similar to the entry function definition in `pthread_create`. However, the orbit entry function executes in a separate address space. This function is also only invoked later by the main program through explicit orbit calls. In other words, the orbit task invocation is decoupled from the orbit creation and can occur *repeatedly*. The `void *argbuf` points to a buffer in the orbit's address space, which is used later during each task invocation to hold the arguments. An optional initialization function can be passed to `orbit_create`. It is useful when some orbit task needs to allocate structure in its address space to keep bookkeeping information. The `orbit_create` returns an orbit handle for the main program to use in later invocations.

```
1  + struct orbit *dlc;
2  + struct orbit_area *area;
3
4  int mysqld_main() {
5  + dlc = orbit_create("dl_checker",check_and_resolve,NULL);
6  + area = orbit_area_create(4096);
7  }
8
9  lock_t* RecLock::lock_alloc(trx_t* trx) {
10   lock_t* lock;
11 - lock = (lock_t*) mem_heap_alloc(heap, sizeof(*lock));
12 + lock = (lock_t*) orbit_alloc(area, sizeof(*lock));
13   return lock;
14 }
15
16 dberr_t lock_rec_lock() {
17   if (status == LOCK_REC_FAIL) {
18 -   check_and_resolve(lock, m_trx);
19 +   dlc_args args = {lock, m_trx};
20 +   orbit_call(dlc, 1, &area, &args, sizeof(dlc_args));
21   }
22 }
```

Figure 4: Using `orbit` to enhance the MySQL deadlock detector. The core logic `check_and_resolve` in Figure 2 remains the same.

The orbit task invocations are done through either the synchronous `orbit_call` or asynchronous `orbit_call_async`. The latter would be particularly common to use. The semantics of the `orbit_call_async` guarantee that the states needed for the task are snapshotted before the API returns. As a result, the main program can continue executing other logic while the orbit task runs concurrently.

This API will return an `orbit_future f`. The main program can wait on `f` later through `orbit_future_get` when it requires knowing the update from the orbit task, just like the typical asynchronous programming models that developers are familiar with. Asynchronous orbit task execution along with the automatic state synchronization feature allows developers to exploit concurrency in the system.

Figure 4 shows an example of using orbit for the MySQL deadlock detector. The task core logic remains the same, but the invocation is split into two steps. Developers use `orbit_create` to create an orbit at the beginning (line 4), which specifies the entry function `check_and_resolve`. An orbit area is created. The allocations of the `lock` (line 12) and `trx` objects are changed to allocate from the orbit area. The original function call (line 19) is replaced with an `orbit_call` to invoke the previously created orbit with the `area` and argu-

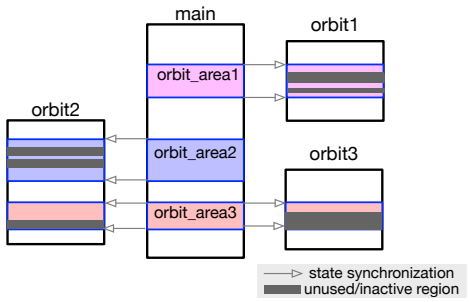

Figure 5: Orbit areas in the main program to be monitored.

ments. Alternatively, developers can use `orbit_call_async` to asynchronously perform deadlock checking.

4.2 Managing Orbit

When a process creates an orbit using `orbit_create`, the kernel internally represents the orbit with a control block and records the target process the orbit is bound with. To avoid intrusive code changes to the Linux kernel function interfaces, we currently re-use the existing `task_struct` (with new fields and a subset of existing fields) to represent the orbit entity.

The main program maintains a `orbit_children` list in its `task_struct`, mapping orbit IDs to the orbit's `task_struct`. Each orbit maintains a `orbit_info` structure in its `task_struct`, that contains the basic execution states of orbit and a FIFO queue of orbit calls.

The kernel also allocates a dedicated address space for the orbit, which is initially kept to a minimum (mostly code pages of the main program). As a first-class OS abstraction, orbit is a schedulable entity and can be enforced with resource limits like a regular process. At the creation time, the orbit is in an *idle* state, waiting for the task invocations. If an orbit task is terminated (*e.g.*, because of its own bugs), it can be configured to be automatically restarted. In that case, after a restart, the orbit task will be reattached to the main program. The main program can explicitly destroy a specific orbit task.

4.3 Synchronizing States to Orbit

Each orbit executes in a separate address space but regularly inspects the state in the main program. To facilitate convenient inspection, the orbit abstraction provides a key feature of automatic synchronization for the referenced state. This automatic synchronization is one-way from the address space of the main to the orbit's. We propose a lightweight memory snapshotting solution for providing this feature.

Determining States One challenge is that an orbit task often inspects state variables that scatter across the main program's address space. Therefore, coarse-grained snapshotting would include too many unneeded objects in the snapshot memory regions, which would not only waste significant memory but also incur large overhead to the application. In addition, while the set of variables an orbit task inspects may be fixed and known at the static compilation time, the dynamic addresses and sizes of these variables can change over time. For example, the MySQL deadlock detector checks different `lock` and `txn` objects in different invocations.

To address this challenge, we take a simple approach that coalesces only those state variables that the orbit tasks need into what we call *orbit areas*. Orbit areas are fragments of the *main program*'s address space. Each orbit area is composed of contiguous virtual pages. An orbit's address space is mostly a mirror of orbit areas (Figure 5). The main program creates an orbit area through `orbit_area_create` with an initial size that is dynamically expandable. This API takes an `orbit` argument. If specified, the kernel will create a memory region in the orbit's address space and ensure it has the same virtual address of the orbit area in the main program before the API returns. Otherwise, this mapping mirroring will be done when an orbit later binds to an orbit area.

For the state variables that may be accessed by some orbit task, their allocation points need to be replaced to allocate from an orbit area through the `orbit_alloc` API. Similarly, these variables can be freed using the `orbit_free` API. The main program can still use these variables like before.

Taking a Snapshot Dynamically, when the main program makes a call to an orbit task function, the kernel identifies the memory pages in the orbit area that contain the variables the orbit task requires. Then the kernel updates the page table entries (PTEs) of these pages to mark them as write protected for copy-on-write (COW). The PTEs are also copied to orbit task's page table with write-protected bit set. For consistent snapshotting, the orbit call will return only after all needed mappings are updated. Afterward, as long as the main program and orbit task do not modify a page, no copying is incurred; otherwise, they will have separate copies of the page. Note that the above snapshotting process occurs on each orbit call, so the mappings in the orbit address space constantly change, but the orbit task is not re-created.

Concurrency To ensure safety under concurrency, the kernel acquires necessary locks (*e.g.*, `mmap_sem` in Linux) while accessing the PTEs in the main program and the orbit. In one orbit call, multiple pages may need to be snapshotted. To provide a consistent snapshot for multi-threaded applications, a conservative solution is to pause all the application threads so that these pages are not modified during the snapshotting. This pausing will incur a significant performance penalty.

We instead rely on application-level synchronization to handle this situation properly. Indeed, if the objects needed in an orbit call may be concurrently modified by some other thread, the application would add proper locks in the original call site to prevent race conditions. For example, the MySQL deadlock checker invocation (Figure 4) is already inside a critical section. Thus, when we port it to an orbit call, the snapshot of the `lock` and `m_trx` objects is consistent.

Locks are intentionally not shared between orbit and the main program, and thus orbit cannot directly alter the main program's lock states. It is possible that a complex orbit task function acquires and releases locks during its execution. In

such cases, acquiring locks can be moved upfront before the orbit call. From our experience of porting tasks that require synchronization (MySQL and Apache), we find that the original auxiliary functions only run within a single global critical section, which makes it straightforward to guarantee consistency. Also, since a consistent snapshot is obtained under a global lock, the orbit task can omit lock acquires in these cases, since it runs singled-threaded in another address space.

Concurrent Orbit Calls Another challenge is to handle state synchronization when some orbit tasks may be invoked concurrently. For example, the MySQL deadlock detector is invoked during request handling. Since MySQL uses multiple threads to handle concurrent requests, the main program may make another orbit call while the previous call is ongoing.

To address this challenge, the kernel maintains a task queue for each orbit (Section 4.4 will describe this part). After introducing the task queue mechanism, we need to ensure `orbit_call(_async)` preserves the semantics that the task invocation will get a consistent snapshot of relevant objects at the time of the API call. The kernel does so by marking COW for the *main program*'s PTEs of relevant orbit area pages, storing the marked PTEs, and returning. The stored PTEs will be installed to the orbit's page table *later* when the queued task executes. This works because, assume that the main program has modified some page in the orbit area while this invocation is in the task queue, COW will be triggered in the main program side and the main program will get a new page. The stored PTEs still point to the old physical page containing the data at the time of the invocation.

Design Choice Rationale Our memory snapshotting leverages the page protection and COW mechanism. Although snapshot at the page granularity can be costly, it integrates well in mainstream OSes and works reliably. Through several optimizations (Section 4.6), we can effectively reduce its performance costs. An alternative solution is to use fine-grained object-level shadow memory, which allocates shadow memory region, uses static analysis to identify and instrument memory writes to the target objects, and checkpoints these writes to the shadow memory region. We did not choose this approach for several reasons. First, the shadow memory consumes significant (often half) of the main program's address space, and because it is in the same address space, the isolation is weak. Second, there can be many objects repeatedly and unnecessarily checkpointed even when the orbit task does not need them. Third, handling concurrency is challenging. Lastly, it makes strong assumptions about the target application and instrumentation accuracies, which are fragile to apply to many complex applications.

4.4 Orbit Task Execution

When an orbit is created, it waits for the main program to make orbit calls. Implementing the task execution is non-trivial, because each call crosses two address spaces. In addition, the orbit may receive different styles of orbit calls, including concurrent calls. The kernel side needs to support these different styles together.

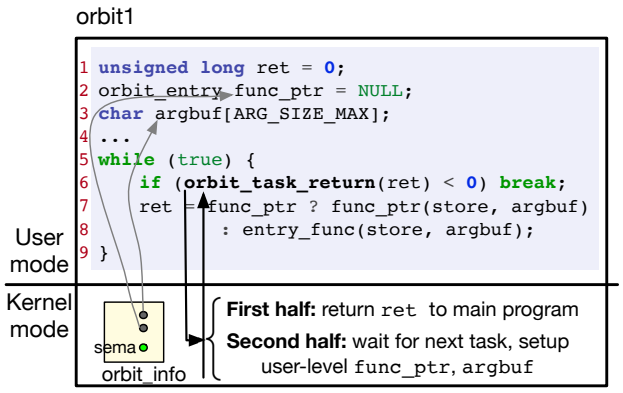

Figure 6: Orbit execution loop waiting for task invocations from main, facilitated by the helper system call `orbit_task_return`.

For supporting potential concurrent calls, the kernel maintains a task queue for each orbit. For each invocation from the main program, the kernel assigns a call id with an internal call struct and inserts it into the queue. The orbit task execution workflow processes the pending invocations in FIFO order. Serializing the task invocation processing makes it much simpler to ensure the correctness of the state synchronization.

To properly implement orbit task execution, we introduce a helper system call `orbit_task_return`. As Figure 6 shows, each orbit is a single-threaded worker executing this loop, and invokes this system call in each iteration. When trapped into the `orbit_task_return` syscall, the kernel knows which main program this orbit corresponds to by looking up the information in its `orbit_info`.

Internally, this kernel function consists of two halves. In the first half, it returns the return value of the *last* orbit call to the main program. Specifically, the kernel stores the passed `ret` value into an internal struct corresponding to the last orbit call, and then *signals* the thread that was executing the last orbit call and blocked waiting for the call to finish. If no orbit call has been made, this first half is skipped.

In the second half, the function waits for the next task from the main program. This is done by waiting on a semaphore in the orbit control block. Once the orbit tasks queue is non-empty, the `orbit_task_return` proceeds and dequeues an invocation. Recall that state snapshotting stores the marked PTEs (Section 4.3) in an array for the pending invocation. The kernel function at this point applies the snapshot by installing the PTEs to the orbit's page table. It then sets up the user-space `argbuf` and `func_ptr`, and returns.

The kernel setups the user-level `argbuf` by copying the orbit call arguments into it. The arguments are typically pointers (*e.g.*, `lock` and `m_trx` in Figure 4), thus only the address values are copied. The actual objects to be referenced in the task are in the orbit area. With the mirroring setup of the orbit area (Section 4.3), the addresses map to equivalent objects. The `func_ptr` is set to either the task entry function or the function pointer specified in the pending `orbit_call`. The

```
void trx_rollback(trx_t *victim) { // within orbit task
 orbit_update *scratch = orbit_update_create();
 orbit_update_add_data(scratch, &victim->version);
 victim->lock.cancel = true;
 orbit_update_add_modify(scratch, &victim->lock.cancel, true);
 orbit_update_add_operation(scratch, pthread_cond_signal,
    &trx->slot->condvar);
 ...
 orbit_push(scratch);
}
void handle_rollback(orbit_future *future) { // in main program
 orbit_update update;
 long ret = pull_orbit(future, &update);
 TrxVersion *version = orbit_update_first(update)->data;
 if (trx_is_alive(version))
  orbit_apply(update);
}
```

Figure 7: Controlled state alteration for MySQL deadlock detector.

latter is particularly useful for an orbit to provide *query* functionalities. For example, if an orbit stores some bookkeeping information, the main program may want to query the orbit about this information occasionally. Finally, the orbit execution loop invokes the appropriate task function with the prepared `argbuf` (line 7 in Figure 6) *at the user level*.

The major task execution workflow described earlier applies to the asynchronous orbit calls as well. The `orbit_call_async` returns an `orbit_future`, which is a reference to the asynchronous task. The main program can later wait on this reference and retrieves updates from the completed asynchronous task, just like the typical asynchronous programming models that developers are familiar with.

4.5 Controlled State Alteration

A privileged orbit is allowed to modify the main program states. One solution is to identify pages in the orbit area that the orbit has modified in its private copies and transparently update the corresponding copies in the main program. The updates are restricted to states belonging to an orbit area. A complication arises if the main program also has since made modifications to some pages in an orbit area. Automatically merging the updates could introduce accidental changes.

To avoid introducing such accidental incorrectness, we instead use a more controlled alteration mechanism by exposing the `pull_orbit` and `orbit_push` system calls. Developers call the `orbit_push` API in the orbit task functions to explicitly decide which updates to push to the main program side. A corresponding call of `pull_orbit` in some main program function will retrieve the updates and explicitly apply the updates to the appropriate state variables. The `orbit_push` API supports pushing flexible data types including raw bytes.

A *scratch* space is backed by some memory region holding the data. The pushing is done efficiently by moving the PTEs of the scratch space pages in the orbit page table to the main program's page table. Besides data, `orbit_push` also supports pushing some operation (function pointer). This is useful if the maintenance operation is difficult to conduct in the orbit side, such as killing some main program's thread.

Example Figure 7 shows an example for the MySQL deadlock detector, which represents a relatively complex use case. Function `trx_rollback` creates a *scratch* `orbit_update` and then pushes a `TrxVersion` by calling `add_data`. This data can later be used to check whether the `victim` transaction is still alive. A following `add_modify` call records the modification of a single field. The next `add_operation` pushes a function with its argument, which will later be invoked in the main program side when the updates are applied and will signal the specified conditional variable. The function pointers are valid for both sides, since the code pages mapping are preserved. The updates are then sent in a batch by calling `orbit_push`.

The `handle_rollback` function then pulls updates from the future. If the task fails, the orbit task is recreated (omitted in the figure). When the main program retrieves an update, it applies the update if the transaction's `version` is still alive.

4.6 Optimizations

We design several optimizations to further reduce the cost of our memory snapshotting. There are two main overhead sources: (1) iterate the PTEs for the active pages in an orbit area, update COW flags, and create mappings in the orbit's address space; (2) page faults when an orbit area is modified.

4.6.1 Incremental Snapshotting

Overhead source (1) is incurred upon each `orbit_call`. In addition, we tear down the orbit's mappings and reset the COW flags of relevant PTEs in the main program when the orbit runs finishes to avoid unnecessary page faults. For orbit areas that have many active pages, this overhead can be significant.

We introduce an incremental snapshotting optimization to reduce this overhead. We keep the mappings after an orbit run finishes. Upon the next `orbit_call`, we iterate through each remained PTE and check if it is the same as the main program's counterpart. If so, we keep it. Otherwise, we recreate the mapping or discard it if the orbit area page is no longer active. Thus, we only pay the mapping cost for the orbit area's pages that are modified by the main program since the last run. One caveat is that keeping the mappings may incur unnecessary page faults. This optimization helps when the main program is not intensively updating the orbit area. We allow developers to pass a flag in an `orbit_call` to indicate whether to enable this mode (keep the mappings).

A second part of this optimization is a region-based marking scheme that aims to reduce the cost of looping through each PTE in an orbit area. We track the PTEs by regions. Specifically, we maintain a bitmap for each range of 512 PTEs (one PMD entry) in the orbit area. A 64-bit bitmap partitions the 512 entries into 64 groups of 8 PTEs. Each bit represents whether the consecutive 8 PTEs have faulted since the last snapshot. During a page fault, the corresponding bit is set to 1. After a snapshot, the snapshotted groups's bits are set to 0. In this way, we can jump to the next group of PTEs that have changed by using bit-wise operation on the bitmap.

```
// allocate with normal malloc
struct trx_t {
  struct {
    ...
-   lock_t* wait_lock;
+   lock_t*& wait_lock;
    ...
  } lock;
+ trx_t_delegate *delegate();
};
```

(a) original full object

```
// allocate with orbit_alloc
struct trx_t_delegate {
  struct {
      lock_t* wait_lock;
  } lock;
};
```

(b) delegate object

Figure 8: Delegate object for the struct `trx_t` in MySQL.

```
// new constructors
trx_t::trx_t(trx_t_delegate *d) : lock(d) {}
trx_lock_t::trx_lock_t(trx_t_delegate *d)
 : wait_lock(d->lock.wait_lock) {}
// creating and binding delegate objects
void trx_init(trx_t *trx) {
 auto delegate = (trx_t_delegate *)orbit_alloc(area,
  sizeof(*trx_delegate));
 new(trx) trx_t(delegate);
}
```

Figure 9: Create and bind delegate object for `trx_t` in MySQL.

4.6.2 Dynamic Page Mode Choice

Overhead source (2) is inherent in the COW mechanism. This cost becomes significant when the orbit area pages are frequently updated by the main program. In this case, COW may perform worse than directly copying the page, which eliminates later page fault penalty to the main program. COW is effective if an orbit area page is infrequently updated.

We support page mode choice (COW or COPY) for an entire orbit area and each page in the orbit area. The former is specified by developers when creating an orbit area. The (likely) update-intensive objects can then be allocated from a COPY-mode orbit area, which will use copying during snapshot. For page-level mode choice, the kernel tracks the statistics of fault rate as `# of faults/# of snapshots` for each page. If the percentage exceeds a heuristic threshold of 30%, we determine the page mode as COPY. Besides, we also impose a limit of 32KB on the total size of COPY pages, and we choose the pages with the highest scores. This is used to prevent exhausting too much memory, and achieve a relatively balanced performance between COPY and COW (because copying large memory region is slower than snapshotting).

4.6.3 Delegate Objects for Large Structs

Complex applications may define large structs, while the states that an orbit is concerned with may be only a small subset of the fields in a large struct. If we allocate the entire large struct from the orbit area, it can incur unnecessary snapshot and page faults due to false sharing.

We use *delegate objects* to mitigate this issue. The basic strategy is to define a delegate struct for the large struct and keep only the fields that are needed in the orbit task functions. Then we allocate the delegate struct from an orbit area but preserve the normal allocation (*e.g.,* `malloc`) for the underlying large struct. Each delegate object has a one-to-one binding to its original struct. It is created at the same time of the original struct as an additional argument to its constructor. To connect the two structs, the relevant fields in the large struct are changed to reference types (*e.g.*, `int` to `int &`, `int *` to `int *&`), and the struct constructor is modified to bind the references to the delegate struct argument. The main program still uses these fields like before without changes.

Figures 8 and 9 show an example of defining and using delegate object for the `trx_t` struct in MySQL. After introducing this delegate object, the main program does not need to change its usages, *e.g.*, `trx->lock.wait_lock` still works. The orbit task function uses the delegate object from `trx->delegate()`.

In our ported systems, we pick those large structs whose total size of accessed fields is smaller than the size of the remaining fields as the target for optimization. Developers can have their own choices to determine what are large structs for delegate object optimization.

4.7 Compiler Support

Our current design requires replacing allocation points for needed state variables (Section 4.3). Some applications already use custom functions to allocate their main objects. In these cases, developers may only need to make minor changes in the custom allocation function to use `orbit_alloc`.

In other cases, developers may need to find individual allocation points and replace them. To help developers with this task, we build an analyzer on top of LLVM [23].

Given an entry function to be converted to an orbit task, *e.g.*, `check_and_resolve` in Figure 2, the analyzer runs forward data-flow analyses to locate all relevant definition and allocation points. Specifically, the analyzer first identifies heap allocation calls in the main program. For each call, it constructs a use graph with the return value variable as the root. Nodes in the use graph include both direct and indirect usage points of the root based on the standard *def-use* chain analysis.

After constructing the use graphs, the analyzer checks whether any use graph can reach the arguments in a callsite of the target function. If so, the allocation point associated with the use graph is included in the result. Besides arguments, the compiler also analyzes the non-local variables referenced in the target function body and leverages the use graphs to identify their allocation points. If no allocation points are found for an argument or non-local variable, the analyzer identifies the definition point (*e.g.*, it is a static global variable) using reaching definition analysis and includes it in the result.

Currently, the analyzer only outputs a list of candidate allocation or definition points. It does not replace these points with `orbit_alloc` automatically, although that is feasible.

5 Evaluation

Our evaluation aims to answer several major questions: (1) *Is orbit general to (re)write auxiliary tasks in complex applications?* (2) *Can orbit-based tasks provide strong isolation?* (3) *How much overhead does orbit incur for achieving isolation?*

No.	Application	Auxiliary Task	Source	Description
t1	MySQL	deadlock detector	port	Automatically detect transaction deadlocks & rollback transaction(s) to break deadlock
t2	Apache	proxy balancer	port	Load balancing to determine suitable proxy backend worker for request
t3	Apache	lock watchdog	new	Periodically check for long mutex lock waits and output notifications to the log
t4	Nginx	WebDAV PUT handler	port	File upload handler for WebDAV PUT requests
t5	Varnish	pool herder	port	Dynamically adjust thread pool sizes
t6	Redis	Slow log	port	A system to log queries that exceeded a specified execution time
t7	Redis	RDB persistence	port	Performs point-in-time snapshots of dataset at specified intervals
t8	LevelDB	background compaction	port	Compact sorted table files to maintain level size limit and improve performance

Table 2: Evaluated auxiliary tasks in six large software.

	small (32 MB)	medium (1G)	large (8G)
orbit	80.51 (8.67)	116.36 (9.12)	115.30 (11.09)
fork	294.24 (27.99)	6859.36 (43.87)	53519.45 (1150.71)

Table 3: Mean latencies (in microseconds) of creating orbit versus process. Numbers in parentheses are standard deviations in 100 runs.

5.1 Evaluation Setup

The experiments are performed in a KVM-enabled QEMU virtual machine with 4-core vCPU and 10GB memory by default, running Debian 10 with our custom kernel. The host machine provides a 20-core Intel Xeon Silver 4114 CPU (2.20GHz), 32GB memory and 480GB SSD running Ubuntu 18.04 LTS. We run all experiments using Linux's default 4KB-sized pages on x86-64, with huge page disabled.

We additionally repeat the experiments on a bare-metal machine, which show matching relative results. Our technical report [20] presents the bare-metal version experiment results.

5.2 Microbenchmark

We first evaluate the performance of creating and invoking orbit with microbenchmarks. We measure the orbit creation under different memory footprint settings of the main program. For a given memory setting, the benchmark program allocates the size, fills it with non-zero data to ensure the kernel actually allocated a physical page for it before running the measured action. It then calls `orbit_create` and measures the latency. We compare the orbit creation with `fork`.

Table 3 shows the result averaged over 100 runs. The initial address space for orbit is minimum with mostly code and stack pages (Section 4.2). Compared to fork, this gives performance benefits for creating isolated address spaces even with a large memory footprint, as most unneeded data are not copied. When the main program has an 8 GB memory footprint, fork is 464× slower than creating an orbit.

We also measure the latency of `orbit_call_async`. Figure 10 shows the result averaged over 20 runs. In general, orbit call time increases almost linearly with the size of orbit area, because it is dominated by the snapshotting cost. For example, making an orbit call with 32MB memory snapshotted takes 272.9 μs, which is comparable to the performance of forking a process with 32MB data shown in Table 3. An orbit call with 8GB snapshotted takes 58.6 ms, which is slightly higher than forking 8GB memory. This is due to the more complicated implementation of snapshotting, such as incremental snapshotting and support for several snapshotting modes.

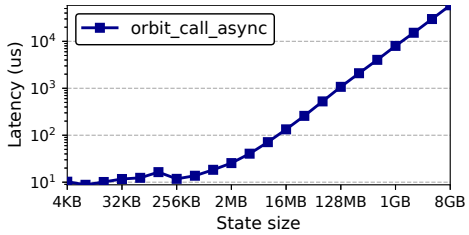

Figure 10: Orbit call latencies with different sizes of snapshot state.

5.3 Applying Orbit on Large Applications

To evaluate the generality of the orbit abstraction, we apply orbit on 6 large applications, MySQL, Apache, Nginx, Varnish, Redis and LevelDB, which have complex codebases and use diverse programming paradigms.

We use orbit to port 7 existing, representative auxiliary tasks in the applications (Table 2). They cover typical auxiliary tasks ranging from fault detection, debugging, resource management, and performance optimization. Two tasks, the Apache proxy balancer and the Nginx WebDAV handler, can be also considered main features. We evaluate them to test the boundaries of tasks that orbit can support. We successfully port all 7 tasks. We run each application's unit tests to verify the ported tasks preserve the original functionalities, even though the tasks now execute the separate address spaces.

We also use orbit to write a new auxiliary task, a lock watchdog, in Apache as an exercise. This task periodically checks if some thread in Apache is stuck and pinpoints the long-holding locks. We add a counter and held locks in thread-local storage. For every lock operation, the main program threads increment the counter, and the number of held locks. A background thread makes an `orbit_call` to the watchdog every second with all threads' counters and held locks. The orbit resets all counters. It also stores historic data of the last held locks and the number of iterations that there is no activity for each thread. When the orbit finds that some thread has has no activity over a threshold (60s), it `orbit_pushes` a return value to inform the main program, which triggers another `orbit_call` to the orbit's diagnosis function that finds the root cause. Figure 11 shows the watchdog thread function.

```
void watchdog_loop() {
 long next_op = WATCHDOG;
 while (true) {
  if (next_op == WATCHDOG)
   next_op = orbit_call(..., wd_areas, wd_func, ...);
  else if (next_op == DIAGNOSIS)
   next_op = orbit_call(..., diag_areas, diag_func, ...);
  ...
 }
}
```

Figure 11: The Apache lock watchdog thread

5.4 Fault Isolation

5.4.1 Fault Injection Testing

We evaluate the isolation capability of orbit by performing fault injection testing on all 8 auxiliary tasks. We inject null pointer deference faults at different times during a task's execution. In all cases, the system successfully isolates the faulty orbit without causing impact to the application and restarts the task gracefully to reattach to the running main process. In some systems, graceful failure handling is implemented by returning an application-specific error code after witnessing an error return code from `orbit_call`. For example, in Apache proxy handler, we return a `HTTP_SERVICE_UNAVAILABLE` after checking the orbit state in main program.

As a first-class OS entity, orbit also provides isolation of performance interference and resource overuse faults in auxiliary tasks. We inject two such faults in Redis slowlog (t6), and mitigate them with `cgroup`. We enforce a memory limit of 256 MB on the orbit task, and inject a memory allocation of 512 MB in orbit task, which this task would never use up. `Cgroup` triggers an OOM kill immediately when the task goes over the memory limit, and the main process gracefully restarts the orbit task. We also inject one CPU hogging for 10 seconds, and modify `cfs_quota` scheduler parameter with `cgroup` to bring CPU usage from taking up one whole core down to 10% of single-core CPU time shown in `top`.

For our newly implemented task in Apache (t3), we inject a long sleep right after one thread has acquired a lock. The watchdog immediately triggers a diagnosis once it finds the counter has not been updated for 60s. The diagnosis function pinpoints the thread ID that holds the lock, along with the location where the lock is acquired.

5.4.2 Real-world Bug Testing

We reproduced 4 *real-world* bug cases from MySQL, Apache, Redis and Nginx that involve the four tasks.

MySQL assertion failure We reproduced the MySQL Bug #28523042 [7]. This bug is introduced in MySQL 8.0 and adds incorrect assertions, which result in assertion failures. We reintroduced this bug into our orbit-enabled MySQL 5.7.31. For demonstration purposes, we modified some part of the expressions that touch the new variables in the 8.0 version, to make the backported code run on the 5.7.31 version.

When a deadlock occurs in the original buggy version, the whole MySQL server crashes, and all clients' connections are dropped. With the orbit-protected deadlock detector, even though the orbit task crashed, the MySQL server is still alive. After the default MySQL lock wait timeout is exceeded, one transaction is chosen as the victim, and all other transactions can continue to finish successfully.

Apache proxy balancer segfault We reproduced Apache Bug #59864 [6]. The user reported that under a proxy balancer configuration with a pair of unavailable fail-over backends pointing to each other, Apache entered infinite recursion when it searched for suitable backend, resulting in stack overflow. We isolate the backend selection in orbit, and successfully catch such failure. Instead of dropping connection, the main program now returns a more meaningful *"Temporary Unavailable"* message when it finds that orbit task has failed.

Furthermore, although web servers like Apache and Nginx often use fault-tolerance mechanisms like multi-process workers, such mechanisms cannot provide fault isolation for concurrent requests within the same worker. When one of the requests triggers a fault, all other connections to this worker also gets disconnected. This applies to both multi-threading (Apache) and event-driven architecture (Nginx) within one worker. Orbit further provides a finer level of isolation by isolating auxiliary tasks within one worker.

Nginx WebDAV segfault Nginx Bug #238 [5] was triggered when a custom WebDAV PUT (*i.e.*, file upload) user request did not include document body. The PUT handler assumes the request body pointer to have been allocated, and thus causes null pointer dereference. Similar to the previous Apache bug, the ported orbit version gracefully catches the failure and returns meaningful messages, while also preventing other requests in the same worker from disruption.

Redis Slowlog memory leak Although Redis uses single-threads for its request processing, its background threads can still cause issues. In case #4323 [2], a race condition happens when both slowlog and asynchronous lazy-free thread decrement a refcount, leading to neither of them freeing the object. Developer mitigated this issue by making a copy of the object. Our orbit implementation, on the other hand, transfers the object from snapshotted orbit area and designates resource management solely to the orbit's address space. Since orbit and the main process do not share the reference counter, race condition is eliminated in the first place.

5.5 Performance Overhead

We measure the end-to-end application performance impact with the orbit-based tasks. We choose application workloads that ensure the auxiliary tasks are triggered frequently.

For MySQL (t1), we run OLTP read-write test provided by the sysbench [3] benchmark tool with 16 clients. We run both Apache watchdog task (t3) and Varnish (t5) using `ab` with 1KB document length and 4 clients. Varnish web cache service uses a stock Nginx as backend. For Apache proxy balancer case (t2), we wrote a custom benchmark using `libcurl` to mix 90% non-proxy requests with 10% proxy requests with 4 clients because `ab` does not support mixed requests. Nginx

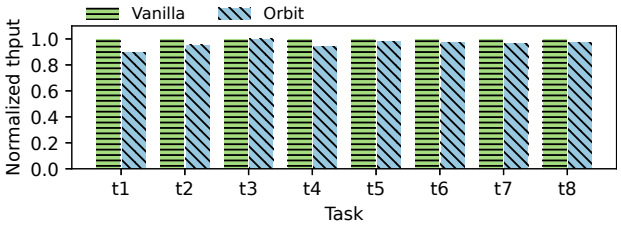

Figure 12: End-to-end application performance with the orbit-based (safe) tasks versus the original (unsafe) tasks.

Task	t1	t2	t3	t4	t5	t6	t7	t8
Calls/s	510.1	1127.8	1	1142.0	1	80.7	0.2	9.9

Table 4: Orbit call frequency in evaluated auxiliary tasks.

WebDAV (t4) benchmark is written in a similar way, with 10% WebDAV upload requests. We run both of the Redis tasks (t6, t7) with YCSB 95% read 5% write test using 32 threads, with either of the tasks enabled separately. We run LevelDB (t8) using a sequential-fill workload with LevelDB built-in benchmark tool to trigger compaction frequently.

Figure 12 shows the normalized throughput for the 8 cases. Most of the (safe) orbit tasks show comparable performance to vanilla (unsafe) tasks. The median overhead is 3.3%. The new task t3 in Apache is compared with the original Apache without our lock watchdog. It has the smallest overhead (0.04%). The largest overhead (10.2%) is the MySQL deadlock checker, which is acceptable considering the strong isolation.

We choose workloads that stress test the orbit tasks. As Table 4 shows, all the tasks are frequently invoked. For example, the MySQL deadlock checker orbit is invoked 510 times per second. In practice, it may not be invoked this frequently. Developers can also add sampling logic for orbit calls.

We also tested less intensive workloads. We reduced the write operations in MySQL (t1)'s OLTP workload, and changed the 90%/10% mix of t2 and t4 to 99%/1% mix. Task t1 and t2 only incur 1.6% and 1.2% overhead, respectively, while t4 has a negligible overhead of 0.18%.

For the MySQL deadlock detector, we implemented a fork version by creating a fork on each invocation to `check_and_resolve`. However, we did not implement IPC to pass results back to the main process, but if implemented, the fork-based performance would become even worse. In comparison, the orbit version has full functionality of pushing updates. We compare the MySQL performance under the three versions of detector: vanilla, fork-based, and orbit-based, using a user workload [1]. Figure 13 shows the result. The orbit version is slower than the vanilla as expected, but 6× faster than the fork-based version. For the orbit version we also compare the performance difference using the synchronous `orbit_call` versus using `orbit_call_async`. Under 8 threads, the performance with asynchronous call is only 1.2% faster than the synchronous call because of limited concurrency opportunities. But under 16 threads, the performance difference becomes much larger as Figure 14 shows.

	Throughput	**Latency**	**Orbit area**	**FPQ**	**TRX size**
No-opt.	1728.0 QPS	340.5 μs	25.7 MB	11.70	912 bytes
Delegate	3308.1 QPS	39.3 μs	1.0 MB	6.91	104 bytes
Changes	+91.4%	-88.5%	-96.1%	-40.9%	-88.6%

Table 5: Optimization effect of delegate object technique. (FPQ stands for page faults per query)

Task	t1	t2	t3	t4	t5	t6	t7	t8
Orbit area	828	20	8	4	8	268	80,644	240
Percentage	0.33	0.40	0.12	0.12	0.001	1.6	76.9	0.65

Table 6: Snapshot sizes (KB) in evaluated auxiliary tasks and their relative percentages (%) of the main program memory footprint.

5.6 Effectiveness of Optimizations

Incremental snapshotting We show the effect of incremental snapshotting by gradually allocating new objects in the orbit area and making orbit calls. We measure orbit call latencies with area sizes from 2 to 256 MB with an increment of 2 MB. Figure 15 shows the result averaged over 20 runs.

Without the optimization, the kernel wastes most cycles walking all the unchanged PTEs and thus requires longer latency. With the optimization, the new data that needs to be snapshotted in every call is a constant (2 MB). For an orbit area of 256 MB, the optimization reduces the latency by 40×.

Delegate Objects We use delegate object technique to minimize states size during snapshots, while also reduce unnecessary page faults due to main process memory writes to the other fields that orbit task does not use.

In the MySQL deadlock detector, we applied delegate object technique to transaction type `trx_t`, lock type `lock_t`, and lock information `lock_sys`. We observe that identifying such optimization opportunities is straightforward. For example, the `trx_t` is 70-field struct with only 4 fields being used in the orbit task, which is clearly an optimization target.

We run the user workload [1] with 16 clients on a 8-core vCPU QEMU VM and compare the throughput, latency, orbit area size, and average page faults per query. Table 5 shows the results. The optimization improves average throughput by 91%, and the orbit call latency to be 7.7× shorter. The total number of page faults throughout the run increases because the throughput also improves, but on average, the number of page faults each request incurs is reduced by 40.9%. In orbit calls, 96.1% of unneeded memory is saved from snapshots. In particular, the delegate object size for `trx_t` is only 11% of the original transaction structure.

5.7 Memory Footprint

Orbit provides efficient snapshotting because orbit only snapshots on necessary data for auxiliary task. We measure the average memory footprint of orbit area that was snapshotted during orbit calls. Table 6 shows the snapshot sizes along with their percentages of the main process's memory footprint. Among the ported tasks, 6 out of 8 allocate less than 1% of process data in orbit area. Redis RDB takes snapshot on its

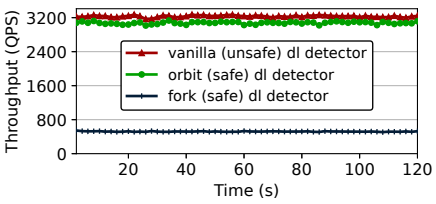

Figure 13: MySQL deadlock detector vanilla versus the orbit-based and fork-based version.

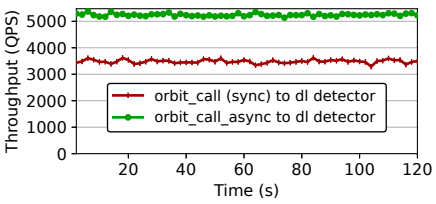

Figure 14: MySQL performance under 16 threads with sync. and async. orbit calls.

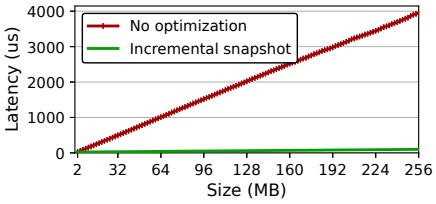

Figure 15: Orbit incremental snapshotting latency on a growing allocation size.

Task	t1	t2	t4	t5	t6	t7	Total
Manual port	7	16	7	3	11	12	56
Compiler	7	56	44	3	20	65	195
Common	5	8	5	1	9	11	39

Table 7: Allocation points in our manual port and compiler result.

key-value dictionary that dominates the memory usage, and thus require the largest portion of memory to be snapshotted.

5.8 Usage Effort

We count the lines of code changes we make to applications in porting the 7 existing auxiliary tasks. The changes include (1) replacing the allocation and free points with orbit allocations; (2) making orbit calls, pushing updates, and applying updates.

The combined changes for (1) range from 40 to 158 lines with a median of 115 lines. The Redis RDB task requires the most changes. We modified some application functions that create certain data structures to provide two versions (one for regular code paths, another for code paths to the orbit task) to avoid putting many unneeded objects in the orbit area. These modifications involved either duplicating the original function or changing its interface. The combined changes for (2) range from 45 to 272 lines with a median of 96 lines.

Our analyzer (Section 4.7) was developed after and motivated by our manual porting effort. We apply it on 6 of the evaluated tasks. The new implementation (t3) case has 0 original allocation points, thus it does not apply. The tool cannot analyze allocations in C++ STL container accurately due to its limited support for STL's complicated internal allocation implementation, thus t8 is excluded.

Table 7 shows the result of manually ported allocation points, detected points and the common ones between the two. From all 56 ported allocation points, our compiler detects 39 of them (70%). The detected points include ported, unported correct points, and false points. For the tasks that have larger number of detected but un-ported points (such as t7), we observe that most of these detected points are correct. They are missed from porting because our workload does not exercise those functionalities. There are also a few cases missing from detection because of unexpected corner cases. For example, a variable in Varnish (t5) used by the auxiliary task was directly allocated on stack instead of using allocator.

6 Discussions and Limitations

As a new abstraction support for auxiliary tasks, our current orbit design has several limitations.

State synchronization Our state synchronization mechanism works at the page granularity, which can incur unnecessary snapshot costs and page faults. Fine-grained object-level snapshotting is feasible but heavily depends on accurate static analysis and instrumentation. We plan to explore potential hybrid solutions that have the advantages of both approaches.

Observable states Our design only considers observing memory states, but not other system states such as file states. Those states would be more complicated to coordinate as they involve kernel and library buffer and position pointer. Creating file snapshots will require a different technique. The tasks we ported are relatively modular and self-contained. For example, our ported checkpointing tasks (Redis RDB, LevelDB compaction) require file operations, but they can create, write, close, and move files within the same orbit context, without the need to share file descriptors with the main program.

Code changes and compiler support We currently require developers to replace the allocation points of needed state variables. For some tasks, a relatively large number of places may need to be replaced. Our future work plans to leverage lightweight memory tracing [32] to dynamically identify the state variables and minimize the code changes.

The analysis in our compiler support for assisting developers to use orbit is basic. Although it supports field-sensitive pointer analysis, it can still miss corner-case allocation points. Developers need to manually find these points. Furthermore, our implementation of *def-use* chain analysis is not accurate enough to determine complex data flow, and thus will yield a handful of false positives. We will enhance the compiler support to enable fully automated porting for developers.

Comparison of programming difficulty Compared to programming with threads, using orbit requires the additional effort to properly change some allocation points. However, although developers do not need to change allocations when using threads, they still need clear knowledge of all the global variables that will be accessed in the thread, and ensure proper synchronizations for them. Thus, developers likely already have some knowledge about the allocation points of these variables. In addition, some of the synchronization would become unnecessary when using orbit. Therefore, the programming overall would be comparable.

Compared to the RPC model, orbit allows developers to write task functions in the same application codebase and directly refer to existing variables and functions. Unlike RPCs

that require code changes to enable object marshalling and unmarshalling, which are difficult for complex objects like transactions and locks, using orbit does not require such changes. With the mirroring orbit area, orbit calls directly access needed objects when crossing the address spaces.

Tolerance of bugs Orbit aims to protect the main program from issues in the auxiliary task execution. It tolerates common bugs such as memory errors in the auxiliary task functions, as well as bugs in the main program that pass bad (or corrupt) values to the auxiliary tasks.

It does not prevent an auxiliary task from sending an incorrect update back to the main program and cause the main program to malfunction. But the orbit abstraction encourages modularization for auxiliary execution, *i.e.*, an orbit task performs most of its operations in a separate address space before pushing updates back. This modularization minimizes the time window for the main program to see bad values and increases the chance that the orbit task itself encounters issues (*e.g.*, dereferencing a bad pointer) before the main program does, which still achieves protection. This is also one reason we choose to provide one-way automatic state synchronization (Section 4.3) with controlled state alteration, instead of a transparent, eager bidirectional state synchronization.

Auxiliary versus main tasks Determining whether a task is auxiliary or main can be subjective. While orbit is designed for auxiliary tasks, it does not require a clear-cut distinction—developers can use it to execute some tasks that they consider as main features for achieving strong isolation. We demonstrate this usage in the evaluation with two cases (t2 and t4).

7 Related Work

There is a wealth of work on protection and fault isolation. They vary widely in their target scenarios (OS extensibility, application extensions, sensitive code, *etc.*), goals (reliability, security, *etc.*), and approaches (software, hardware, hybrid). Our work is complementary to the existing efforts and targets a different, emerging protection scenario—auxiliary tasks in modern applications. Our proposed orbit abstraction aims to provide strong isolation for auxiliary tasks, while also achieving high observability and convenient usage.

SFI [42] is a software isolation technique that restricts the memory accesses of untrusted code in an application by rewriting the application binary. XFI [16] similarly uses binary rewriting to instrument software guards to check memory accesses. Extensive work has followed up this direction, such as NaCl [47] and RLBox [29]. As Section 2.4 elaborates, the sandbox model is not well suited for auxiliary tasks.

Several sub-process OS abstractions [10, 12, 24] provide secure partitioning in applications. They generally use private memory for executing sensitive code to ensure security. Wedge [10] provides the *sthread* primitive to partition an application into compartments and a scheme to tag memory regions and define access rights for the tags. Shreds [12] provides a segment of an execution unit called *shred* and relies on the ARM memory domains hardware feature to provide a private memory pool for each shred. Lightweight context (*lwC*) [24] creates a separate address space for each *lwC* in an application and allows a process to switch to some *lwC* when executing sensitive code. These abstractions typically get executed synchronously and are not independently schedulable.

Determinator OS [9] provides a private workspace model for deterministic parallelism. It runs user code in *spaces* and relies on processes to explicitly synchronize the spaces. Orbit provides automatic, fine-grained state address space synchronization between orbit and the main program. An orbit also has richer features due to its completely different design purpose. SpaceJMP [15] allows a process to define multiple address spaces and switch between address spaces, but with a main goal of enabling applications to use more physical memory rather than fault isolation.

Memory checkpointing takes snapshots of a running program's memory for debugging, failure recovery, quick initialization, *etc.* [11, 13, 22, 46] The checkpoint techniques usually rely on the copy-on-write (COW) mechanism through fork [33, 34, 38] or `mprotect`. On-demand-fork [48] optimizes the fork performance by extending COW to page tables. Orbit synchronizes only needed objects in the orbit areas. Lightweight memory checkpointing [41] uses shadow memory to checkpoint at object granularity. While it is more fine-grained than the page-level COW, shadow memory has several disadvantages for our scenario as described in Section 4.3. Overall, we focus on designing a complete OS abstraction for the isolation of auxiliary tasks. Our work is complementary to existing solutions and can benefit from their optimizations.

Protection schemes are also extensively explored in the context of OS extensibility. To name a few, Nooks [39] provides isolation of device drivers by executing them in different protection domains and using Extension Procedure Call (XPC) for control transfer; Mondrian memory protection (MMP) [44, 45] provides fine-grained protection by using hardware extensions and permission tables.

8 Conclusion

We discuss the trend of auxiliary tasks in applications and the lack of system support for providing safe and efficient execution for these tasks. We propose a new OS abstraction `orbit` to address the gap. Orbit offers high observability and flexible control, while providing strong isolation and efficiency. We evaluate orbit on 8 auxiliary tasks from 6 large applications. The applications achieve enhanced safety with the orbit tasks, and only incur a median of 3.3% performance overhead.

From Dynamic Loading to Extensible Transformation: An Infrastructure for Dynamic Library Transformation

Yuxin Ren, Kang Zhou, Jianhai Luan, Yunfeng Ye,
Shiyuan Hu, Xu Wu, Wenqin Zheng, Wenfeng Zhang, Xinwei Hu
Poincare lab, Huawei Technologies Co., Ltd, China

Abstract

The dynamic linker and loader has been one of the fundamental software, and more than 99% of binaries are dynamically linked on Ubuntu. On one hand, vendors are going to break production software into more and more dynamic libraries to lower the maintenance cost. On the other hand, customers require the dynamic loader to provide rich functionalities to serve their isolation, security, and performance demands. However, existing dynamic loaders are implemented in a monolithic fashion, so they are difficult to extend, configure and optimize.

This paper presents iFed, an infrastructure for extensible and flexible dynamic library transformation. We design iFed in a pass-based architecture to compose various functional and optimization passes. iFed uses a runnable in-memory format to represent libraries and coordinate among multiple transformation passes. We further implement two optimization passes in iFed, which efficiently leverages hugepages and eliminates relocation overhead. iFed is implemented as a drop-in replacement of the current system default dynamic loader. We evaluate iFed and its optimization passes with a wide range of applications on different hardware platforms. Compared to the default `glibc` dynamic loader, iFed reduces an order of magnitude of TLB miss. We improve the throughput of a dynamic website by 13.3%, along with a 12.5% reduction of tail latency without any modifications to the applications.

1 Introduction

Since the 1990s, dynamic linkers and loaders have been one of the most critical software tools for computer programs and applications [11, 15, 23]. Opposite to static linking, which generates a single big application binary, dynamic loading [1] permits complex software to be shipped, delivered, and distributed as a collection of libraries, modules, or components. For low-level languages, such as C/C++ and Rust, these components are implemented as dynamic libraries, also called dynamic-link libraries (`.dll` in Windows) or shared objects (`.so` in Linux). Only when a program starts will its dynamic libraries be integrated to form a runnable application by the dynamic loader. In this way, each dynamic library can be distributed and patched individually without modifying the entire application. As a result, software maintenance cost is greatly reduced while it gains much more flexibility. A study shows that more than 99% of binaries are dynamically linked on Ubuntu [46].

While the dynamic loader's functional structure has been mature and stable for more than one decade, we found it cannot meet the requirements of rapidly developing software and complicated architectures today. Two primary driving factors call out a new infrastructure for extensible and modular transformation on dynamic libraries: (1) the massively increasing number of dynamic libraries used in an application and (2) the emerging diversity of manipulation and operations on dynamic libraries.

Complex commercial software heavily relies on dynamic libraries to decompose a single huge binary into many loosely-coupled, fine-grained modules. This is particularly motivated by two considerations. First, some open source license requires all statically linked code should also be open-sourced. This is so-called "license contamination". GPL license [12] (used by `glibc`) is one such example. Consequently, production software has to use dynamic libraries to avoid "license contamination".

Second, modern software needs frequent updates because of CVE fixes, bug fixes, or adding new features. However, it is painful for vendors to re-compile or link the whole software, and ask customers to reinstall the entire application. Therefore, vendors always break up software into many fine-grained dynamic libraries, and each library can be maintained,

[1] Dynamic loading is also referred to as run-time loading, a mechanism that an application opens, loads, and executes a library by explicitly calling loader interfaces during program execution. As run-time loading shares almost the same backend technology with dynamic loading, throughout this paper, we use dynamic loading to refer to the integrated linking and loading phase when programs are launched.

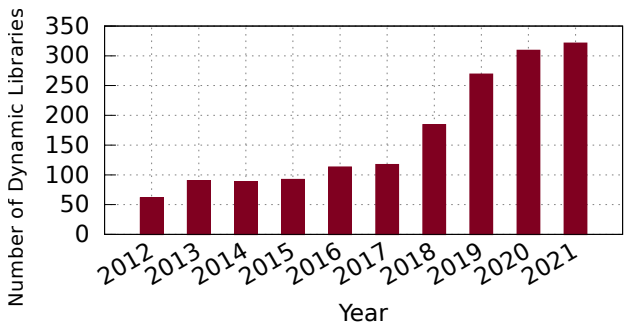

Figure 1: The number of dynamic libraries included in the CUDA Toolkit over the past decade.

updated, or replaced independently. For instance, Figure 1 lists the number of dynamic libraries shipped in the CUDA Toolkit. As it shows, the number has grown rapidly over the last decade. Based on our observation from the industry, this trend will continue in the future.

Along with the growing dynamic library count, the dynamic loader is required to provide more features to make better use of emerging hardware and software technologies. For example, when using recent hardware memory protection (*e.g.* Intel MPK [17] and SGX [16]) to achieve in-process isolation, the dynamic loader has to perform more work. It loads isolated libraries into different memory regions, setups up memory protection and permission properties, and optionally verifies the signature of loaded binaries [7, 14, 37, 38, 40]. Load time code randomization and binary rewriting, provided by the dynamic loader, are widely adopted for profiling, security hardening, and architectural adaptation [51, 53, 54]. Library debloating relies on the dynamic loader to examine and eliminate unused library code from program memory [33, 35]. Control-Flow Integrity (CFI) and Sandbox also require miscellaneous modifications to the dynamic loader, such as analyzing relocation entries and overwriting the entry point [24, 47, 58].

However, the current dynamic loading infrastructure is insufficient and inefficient to offer rich functionalities over a large number of dynamic libraries. This leads to ad-hoc changes to the dynamic loader to satisfy various requirements from different productions. Such customized modifications are incompatible with each other, and cannot be integrated or reused, causing enormous development and maintenance costs. Even worse, the fundamental infrastructure of dynamic loader has been kind of ignored by academia and industry. Thus neither research nor open source community proposes systematic solutions to deal with these issues. For instance, while there are 100+ commits in `glibc` related to the dynamic loader in the last two years, they are almost bug fixes or cleanup without new features developed.

According to our many years' industry experience and realistic production requirements, intrusive and customized modifications cause unacceptable maintenance cost. On the one hand, a large number of source code patches are hard to be accepted by upstream. This also happens to academia work listed above. On the other hand, production departments do not have enough source code level knowledge to maintain patches. Therefore, it is painful for the OS department to maintain many ad-hoc patches and sometimes it has to release different OS distributions with different loaders (along with `glibc`). As a result, it motivates a new infrastructure which satisfies following requirements:

- It offers more functionalities than existing loader.
- It can be flexibly configured for different trade-off and extended to adopt future enhancements.
- Its modifications can be implemented in a modular way that minimizes the effort to align with upstream and fix conflicts due to patch maintenance.

In summary, the issue of current loader design is that it has no interface to allow extensions, thus intrusive modifications cannot be avoided. The loader is historically designed for a few simple functionalities and acts as a "translator". However, now it has to be redesigned, instead of re-engineer, to adopt emerging functionalities and allow future updates in a modular and flexible way, and becomes another platform for application optimization.

We address these challenges by designing iFed, a new infrastructure that achieves extensibility, modularity, and flexibility for dynamic library operations. Our key idea is to organize the iFed as a pipeline of distinct transformation passes instead of a monolithic tool. Each pass only implements some specific manipulation on dynamic libraries to realize its desired functionality, such as security enhancement, memory isolation, or performance optimization. We also design a runnable in-memory format (RiMF) to describe the runtime status and properties of an application and its dynamic libraries (§3.4). RiMF serves as an intermediate representation that every pass operates on, thus different passes are decoupled. By including complete status and information of all dynamic libraries, RiMF further enables iFed passes to do global and aggressive analysis and optimizations. A pass manager orchestrates the series of passes to be applied upon program launch (§3.5). Combined, these features produce the first infrastructure, as far as we know, that satisfies diverse functional requirements without loss of extensibility, flexibility, and modularity.

With various transformation passes plugged in, iFed is able to support much richer features beyond existing dynamic linking and loading. We demonstrate this by implementing two performance optimization passes. The first pass combines the same type of sections from different dynamic libraries into a continuous one, and then leverages hugepages to load the combined section (§3.6). The second one converts relocation branches into direct function calls, thus reducing the overhead of cross-library function calls (§3.7). iFed and its optimization passes are implemented to replace the GNU dynamic loader. We evaluate iFed with a large range of application

benchmarks on different architectures. The results illustrate how iFed optimization passes offer better throughput, latency, and predictability than current dynamic loaders. Without any modifications to the applications in a dynamic website, iFed improves the throughput by 13.3% and reduces the average end-to-end response time by 12.5%.

Our contributions are not only enhancing current loader with some specific optimizations, but also proposing a new infrastructure that is capable to host many other loader features in production. Concretely, the contributions of this paper include:

- We introduce iFed, a pass-based infrastructure for extensible, flexible, and modular transformation on dynamic libraries during load time.
- We design two performance optimization passes in iFed. One pass enables efficient utilization of hugepages by rearrangement and concatenation of multiple libraries. The other pass aggressively eliminates the overhead of cross-library invocations resulting from inefficient relocation.
- We implement iFed infrastructure with the above optimization passes as a drop-in replacement of the default dynamic loader in Linux (`ld.so` in `glibc`). iFed is fully compatible with ld.so and its all interfaces.
- An exhaustive evaluation of iFed on different architectures with a wide range of applications.

The rest of this paper is organized as follows. §2 provides background and motivation for the redesigned dynamic loaders. §3 introduces iFed and discusses its design, while §4 details the implementation of iFed. In §5, we present the performance evaluation of iFed for a wide range of applications. §6 discusses the related work, and §7 concludes.

2 Background and Motivation

2.1 Insufficient Functionality

The basic functionalities of dynamic loading include three parts: (1) library lookup and collection; (2) memory layout preparation; and (3) symbol resolution and name binding. The core jobs to implement these functionalities in existing dynamic loaders are simple. The loader allocates memory and maps libraries into the address space with the given layout specified in library object files. Then it resolves external symbols by populating some lookup tables with the actual memory address. While these steps are just enough to execute programs with dynamic libraries, they are not able to further transform libraries to meet diverse isolation, security, and execution requirements. Thus, many projects have to customize the loader to fulfill their system objectives. We list a few examples here.

- CubicleOS [38] is a library OS that isolates components in MPK protected memory regions, called cubicles. It implements a new cubicle loader who acts as the dynamic loader. The loader is responsible for cubicle creation and component loading. It additionally scans binaries to ensure that there are no any MPK-related operations, and resoles cross-cubicle calls with special trampolines.
- BlankIt [33] is a dynamic loading framework that predicts and loads only the set of library functions that will be used by the application. At load time, BlankIt iterates over all executable's dynamic libraries, wipes out unused functions it predicates, and overwrites these functions with a mispredication trampoline.
- Shuffler [53] patches the loader to support continuous code re-randomization. The modified loader implements constructor prioritization in multiple libraries, and employs binary rewriting to track and update all code pointers.

In summary, while many projects illustrate the necessity and benefit of loader modification, they have to do some redundant work, yet their own work cannot be easily integrated by others. Hence, a new infrastructure for extensible and modular dynamic loading is necessary.

	TLB miss	IPC	99th percentile latency (cycle)	Execution time (s)
`glibc`	1,231,950	1.96	318	6.01
iFed	117,782	2.43	232	4.86

Table 1: Performance comparison between `glibc` and iFed on x86 machine.

2.2 Inefficient Performance

Even worse, current dynamic loaders fail to effectively utilize modern hardware capabilities and global system resources, resulting in sub-optimal performance. A representative case is ineffective hugepage usage.

The current loader loads each dynamic library individually, and within each library, maps code and data section randomly. Thus sections are likely loaded into fragmented memory which only uses small pages (4K) for physical memory. This leads to more TLB miss, slower library function calls, and unpredictable execution time. A better loading strategy is combining the same sections of all libraries into a big one, and loading it into hugepage memory. We study performance penalties incurred by the current loader from `glibc`. On an Intel machine, we conduct a micro-benchmark that simply invokes 100 dynamic libraries, and each library contains only one function accessing memory (full details in §5). Table 1 depicts the micro-architecture impact of (instruction) TLB miss and instruction per cycle (IPC), as well as benchmark results of 99th percentile library function call latency and total execution time. Due to loading libraries with small pages, the benchmark suffers frequent TLB miss, which further leads to slow and unpredictable execution. In contrast, dynamic library concatenation pass in iFed effectively loads libraries

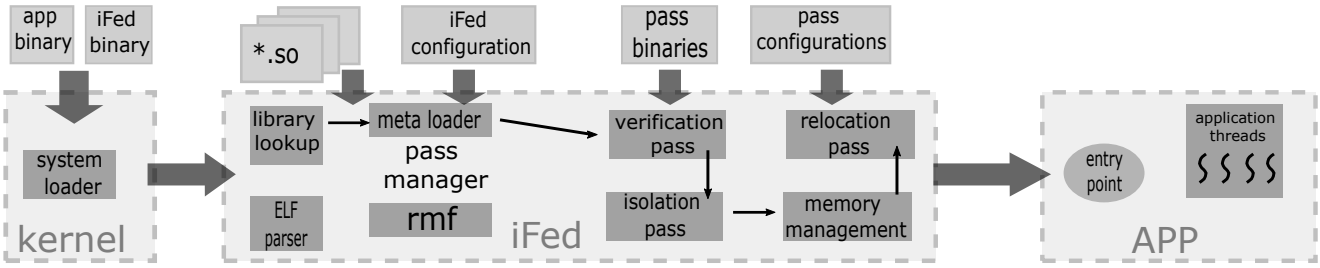

Figure 2: iFed architecture and workflow. The pass manager loads and invokes a series of transformation passes, which interact with RiMF. The workflow of program launch starts from the operating system kernel, which loads both application and iFed binary. After iFed gets the control, it discovers, parses and transforms dynamic libraries and finally boots up the application.

into hugepages, providing an order of magnitude reduction on TLB miss and 23.6% improvement on execution time. Next, we discuss how iFed enables more optimization and transformation of dynamic libraries in a modular and flexible way.

3 iFed Design

3.1 Design Principles

iFed integrates the lessons we learned from the experience of supporting diverse production demands on the dynamic loader. We below outline the key principles, the guidance throughout iFed design.

Extensibility and Modularity (P1). Due to different security or performance considerations, different production always requires a distinct subset of loader features. Therefore, various functionality should be organized in a loosely-coupled way instead of a monolithic implementation. Additionally, iFed should allow applying new features easily without intrusive modification to the loader itself.

Flexibility and Customizability (P2). It is desirable that iFed capabilities can be customized on per-application, customer, or even per-run basis. Such flexibility is important for system managers and end customers to have more control over running applications, opposite to accepting everything from the current loader passively.

Compatibility and Transparency (P3). Compatible with the existing loader interface is critical for iFed to be production-ready. Changes to the loader should be transparent to application developers, and require minimal modification of legacy code. Thus, we aim to design iFed as a drop-in replacement for the existing loader from the beginning.

3.2 iFed Functionality and Usage

As discussed in §2.1, current dynamic loaders cannot keep up with application demands on new functionalities. According to these demands, we summarize the desired features a loader should provide beyond existing ones.

- **Memory management.** The loader should be responsible for memory allocation, library address space layout, and content initialization. This has a large impact on application performance or memory consumption. Some examples of load time memory management are library debloating [33, 35], replaying the profiled hot regions [28], and hugepage optimization (§3.6).
- **Isolation.** The loader is the first place to partition and load different libraries into isolated regions. The customers' strong demand to isolate untrusted or vulnerable third-party libraries paired with the emerging MPK and SGX technologies, motivate the loader to offer more isolation capabilities [7, 14, 40, 50] beyond the traditional read/write/execute permission restrictions.
- **Security enhancement.** The loader is convenient to perform transparent security hardening regardless of running applications. For instance, we can enable CFI or sandbox [5, 24, 47, 58], apply code randomization [26, 51] or perform binary encryption/decryption or signature verification [25, 56].
- **Binary rewriting and execution control.** In addition to traditional relocation, the loader is feasible to perform more advanced binary rewriting and control program execution, such as Shuffler [53] and Egalito [54]. Furthermore, load time transformation is also necessary to migrate applications among heterogeneous environments or offload execution to smart devices [8, 52]. We will discuss a relocation elimination pass in iFed in §3.7.

Current usage of dynamic loader is a mass of interplay among build toolchains, such as compiler and linker. Some configurations and functionalities are scattered in various parts. For example, to prevent GOT overwrite attack [18], the following `gcc` options are widely used: `-Wl,-z,relro,-z,now`. `gcc` passes these options down to the linker, but these options do not take effect until the dynamic loader marks the corresponding memory region as read-only. However, existing usage is not appropriate. We argue that the dynamic loader should be hidden from application developers, but configured and controlled totally by end users or system administrators. This is because customers do not trust that developers properly

build the software to meet their requirements. Thus, iFed consolidates all loader-related operations in one place, and gives the control to end users who actually run the application.

3.3 iFed Architecture

When designing a loader, we should separate functional modules from low-level infrastructure. Functional modules will impact the application run-time behavior and the infrastructure orchestrates these modules. Furthermore, functional modules can be easily replaced or combined without intrusive modifications to the infrastructure and other modules.

We choose pass-based architecture for the loader design. As a result, source code patches are no longer needed, and independent modules with enough semantics can be developed, configured and maintained. The overall iFed architecture is shown in Figure 2. The core component in iFed is a series of transformation and optimization passes that manipulate and transform dynamic libraries for various purposes related to security, isolation, and performance. Each pass is a separate module which can be enabled or disabled independently. Such pass-based modular architecture gives great flexibility and extensibility to users to customize iFed functionality according to their own demands. All passes are managed and controlled by a pass manager (§3.5). Users configure the pass manager to instruct it to construct and execute the pass pipeline. The pass manager also maintains all libraries' in-memory status, and organizes them using RiMF format (§3.4). RiMF is an intermediate representation that is shared by all passes. In this way, passes are able to retrieve global information scatted in many libraries and to perform advanced inter-library transformations. Same as the existing loader, iFed offers other utility components as well, such as library discovery and `elf` parser.

3.4 Runnable In-memory Format

A main goal of iFed is splitting the current monolithic dynamic loader into extensible passes. On the one hand, it is desirable that a pass does not rely on another, thus enabling different passes to be developed and evolve independently. On the other hand, when multiple passes run together, they should be aware of how others transform libraries. Hence, we need a kind of intermediate representation that captures all libraries' status originating from library objects and generated by iFed passes on the fly. Runnable in-memory format (RiMF) is intended to coordinate iFed passes by providing a central place to hold library information at load time.

Passes in iFed do not communicate with each other directly, instead, the shared RiMF is the only interface for library transformation any pass can use. In this way, RiMF hides iFed internal complexity and other pass's implementation details to pass developers. Currently, whenever modifying the dynamic loader to add new features, a developer has to understand most of its codebase, even though much of them are irrelevant. In contrast, all a developer needs to know to write a transformation pass in iFed is the format and properties inside RiMF, and the operations it exposes. iFed maintains a single RiMF image which includes all dynamic libraries a program requires, instead of a separate object file for every library as today. Thus, iFed pass has more opportunities to apply global analysis and optimization. Our dynamic library concatenation pass demonstrates the power of global RiMF. Different from ELF object file which is designed for the dense on-disk format, RiMF rather focuses on load time in-memory representation, such as isolation constraints, memory placement and attributes, and code interposition.

The first-class object in RiMF is the isolation domain, which composes a subset of libraries within the same protection boundary. The actual isolation domain implementation depends on the iFed pass. It could be implemented by MPK, SGX or even device offloading. At the top level, RiMF consists of a list of isolation domains, inter-domain invocations that need to be resolved specially and a global application entry point. Inside each isolation domain, similar to an ELF file, RiMF provides sections, exposed symbols, and relocation records. These information are organized in a set of tables. Primary tables provided by RiMF are: (1) memory-mapping tables which describe library address space layout and memory attributes; (2) symbol tables dealing with symbol definition, binding, reference, and so forth; (3) section metadata tables that associate RiMF sections to original ELF object files. A RiMF section does not contain the actual binary, but maps to one or more ELF sections initially. RiMF varies throughout the iFed transformation pipeline. RiMF exports multiple interfaces to query, insert, modify and commit its internal tables. For example, a pass can update section metadata tables to combine different ELF sections into a new RiMF section. By manipulating symbol tables, a pass is able to remove unused code or override a function call with a customized trampoline. The commit interface is used to apply table modifications to the actual binary, such as interposing them in the library code and loading sections to memory.

3.5 iFed Pass Manager

The iFed pass manager orchestrates transformation passes to operate on RiMF sequentially. The pass manager takes a user-provided configuration file and invokes each pass accordingly. In essence, the pass manager is mainly responsible for two tasks. First, the pass manager maintains the RiMF image and provides interfaces to various passes to query and modify RiMF. Second, the pass manager acts as a meta loader, which loads and executes each transformation pass. Consistent with iFed overall design principle, each transformation pass is also implemented as a dynamic library, which needs to be loaded before execution as well. For simplicity, we reuse the existing `glibc` loader for this minimal meta loader, so any transformation trick is not applied to pass libraries.

Current iFed does not contain a sophisticated scheduling policy for running passes nor supports parallel pass execution. We leave these as future work. Thus, the user has to explicitly deal with pass dependency and pass confliction in the configuration file.

Pass Dependency. In general, passes are not aware of each other because they only use RiMF as the communication medium. However, the order of passes impacts the runtime overhead a lot in some use cases. For example, a binary verification pass is preferred to run as early as possible, so following passes will not waste time on bad libraries. It is also beneficial to place one pass behind another, if it can reuse the analysis result from the previous pass, avoiding repeated work.

Some special cases must be handled carefully. vDSO is one such tricky example. vDSO is a virtual dynamic library (*e.g.* `linux-vdso.so`) inserted into the application by the kernel, but still uses the standard dynamic loading mechanisms. Popular usage of vDSO is mapping some kernel regions into the application's address space, thus some system calls can directly execute on these regions. As a consequence, vDSO libraries must be loaded earlier than any pass that will issue vDSO related system calls. Otherwise, iFed pass itself will fault due to incomplete vDSO even before the application starts running. Similarly, if a pass relies on `malloc` from `libc`, it has to make sure that `malloc` is working properly ahead of the pass execution.

Pass confliction. With more passes integrated together, they are possible to introduce conflict transformations on libraries. Different passes may partition libraries into different isolation domains, or they have opposite optimization objectives. Currently, iFed relies on users to construct the transformation pipeline properly. Automatic dependency extraction and confliction detection will be supported in the future.

Figure 2 demonstrates a potential iFed transformation pass pipeline. All libraries are verified first using security signatures in the first verification pass. Then an isolation pass divides libraries into several isolation domains. Libraries in each domain are loaded into memory, where the memory management pass allocates and sets up memory permissions appropriately. The last binary rewriting pass completes symbol resolution, relocation, and other intent manipulations.

3.6 Dynamic Library Concatenation

Hugepages (superpages) can greatly reduce the address translation overhead, because it eliminates one level page table hierarchy and occupies fewer TLB entries. However, the current loader does not explicitly leverage hugepages. As shown in Figure 3 (a), the current loader individually maps every section in each library into the process's address space. If these sections use a small amount of memory (*i.e.* smaller than the size of a hugepage), the operating system is unlikely to allocate hugepages for them automatically. As a result,

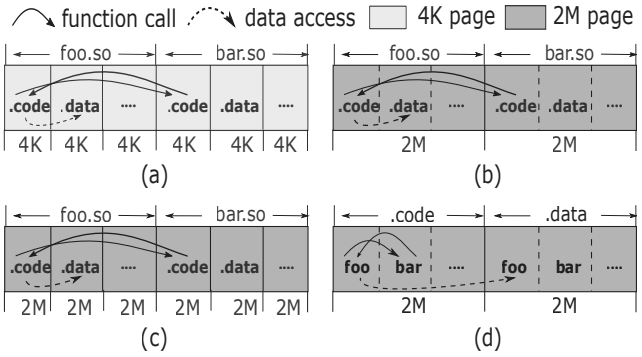

Figure 3: Different hugepage usage schemes for dynamic libraries.

frequent inter-library function calls will trigger more TLB misses, causing expensive page table walk, stalling the CPU instruction pipeline and slowing down applications.

The industry has two approaches to mitigate the impact of high TLB miss, but neither of them is ideal. Figure 3 (b) depicts the first approach, which allocates hugepages to hold all sections in the same library. While this approach reduces the number of used TLB entries, it brings many security vulnerabilities. Since all sections are in the same hugepage, that page should have all read/write/execute permissions required by different sections. For example, `.code` section becomes writeable and `.data` section is executable. Thus, this approach is only used in some closed environments. This, once again, indicates that the loader is capable to alter any policies designated during the development phase, making those policies unreliable. Therefore, the loader should provide capabilities to enforce security policies at load time.

The second method is illustrated in Figure 3 (c), such as the transparent hugepages for file systems proposed in the Linux kernel [27]. In this case, hugepages are used for large sections in each library. While it works well for applications using only a few large libraries, it cannot scale to a larger number of libraries. However, as we discussed in §1, using more and more libraries is the trend for production software, which leads to that such method will be less effective.

In iFed, we design a different approach and implement using in a iFed pass called dynamic library concatenation. The basic idea is intuitive as Figure 3 (d) shows. We collect the same sections, such `.code`, from all dynamic libraries and concatenate them one by one to form a big section. This combined section is large enough to fit in hugepages. More importantly, all the sections share the same memory permissions, so it is safe to place them in the same hugepage. Thanks to RiMF holding all libraries' information, the dynamic library concatenation pass is able to disassemble and rearrange libraries easily.

By combining all libraries `.code` sections into a big one, we might reduce the possible address range used by address space layout randomization (ASLR). To mitigate this security

concern, we have some options. (1) We can concatenate these libraries in random order. [2] (2) Hugepages do not have to be continuous in the virtual address space as long as the original section does not cross two hugepages. (3) We can leverage other code randomization techniques at load time [51] or run time [53], which is easier to employ in iFed.

Another potential negative impact introduced by dynamic library concatenation is library sharing. Dating back to the early days of computing, the motivation for using dynamic libraries is to save limited memory. When multiple running processes require the same library, they only share a single in-memory copy of the libraries. Library concatenation makes the sharing more difficult, as different processes have to use the same set of libraries. However, from our experience, this issue is acceptable for the following reasons. (1) The shared region is mainly the immutable code section. However, the code size of libraries is negligible compared to today's memory capacity. For instance, glibc has around 1.3 million lines of code and its un-stripped binary is only 17 MB, while a common server in the data center has 500 GB memory. (2) Thanks to the customizability of iFed, we can apply library concatenation only to key applications, while other utility or background processes still use the default memory management policy to share dynamic libraries. (3) In some cases, such as edge computing or micro-service, the same process will fork multiple times to serve different customers [36]. Since the forked process has the same address layout, they can share the concatenated library without any problem. (4) In the extreme case where the library must be shared, we align sections from different libraries at the 4K boundary. Thus, the 4K page in the middle of a hugepage can still be mapped to other applications at the cost that others are unable to utilize hugepages.

3.7 Relocation Branch Elimination

An important job accomplished by dynamic loaders is relocation, because the compiler cannot statically resolve cross-library function calls due to lack of address information. After the dynamic loader maps all libraries into process address space, it populates the actual address of unresolved functions in a lookup table. Then every call to a function in a dynamic library first retrieves the address from the lookup table and jumps to that destination. These extra actions result in a trampoline code, which is stored in another table.

Figure 4 (a) shows a simplified execution flow of relocation. The table used to serve address lookup is usually called global offset table (.got) and the procedure linkage table (.plt) saves the trampoline code. When functions in `foo.so` (*e.g.* `foo1` and `foo2`) call the function `bar` in `bar.so`, they call the trampoline (`bar@plt`) instead. The trampoline issues an indirect jump instruction, whose destination address is fetched

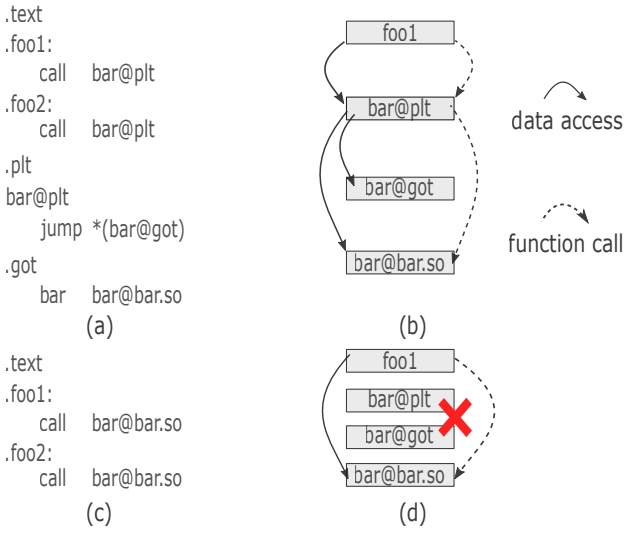

Figure 4: Function call relocation for dynamic libraries. Function `foo1` and `foo2` in `foo.so` call function `bar` in `bar.so`. In (a), function calls are first redirected to `.plt`, and consult `.got` entries to get the destination address, and finally branch to the destination. (b) depicts that the current relocation method incurs three memory access and two code branches. As shown in (c), the relocation branch elimination pass in iFed rewrites the function call sites so that they directly jump to the destination. As a result, only one memory access and code branch is needed in (d).

from an entry in `.got` (`bar@got`). Thus, the execution finally branches to the real address of `bar` (`bar@bar.so`). [3] The above relocation mechanism is applied to every function calls across dynamic libraries, thus incurring pervasive performance overhead. Figure 4 (b) depicts the performance cost in detail.

More executed instructions. Obviously, the single call instruction is expanded to multiple trampoline instructions, consuming more CPU cycles. Even worse, the additional indirect jump puts more challenge on the branch predictor. This is exacerbated by the fact that the trampoline code is not densely packed and `.plt` is often sparsely accessed, leading to more branch misses.

Extra memory access. The existing relocation approach also introduces more memory access. First, `.plt` asks for more memory to store the trampoline. Second, the trampoline needs to load from the extra `.got` memory. More memory access compete for the TLB and cache more frequently. Worse still, they are likely to be evicted from TLB and cache by other data access within the applications, especially in data-intensive scenarios, causing increased function call latency and unpredictability.

[2] Existing loader (*e.g.* `ld.so`) loads libraries in a deterministic way, which is decided by its internal library discovery algorithm according to the dependency information from application binaries.

[3] This simplified execution flow omits some complexities. .got entries are initially populated with a pointer to a loader's own resolver function. So when a library function is invoked at its first time, it branches to the resolver function, which then updates the `.got` entry using the actual address. This also requires additional instructions to be patched into the trampoline.

However, there are no practical solutions to eliminate these performance penalties. Switching to statically linked libraries is not always feasible as discussed in §1, and some hardware methods [1] are not available in production due to architectural modifications. It is also difficult to replace the relocation mechanism in the current dynamic loader with little effort.

Thanks to iFed, we have a chance to insert an optimization pass to reduce the relocation cost in an extensible manner. We design the relocation branch elimination pass for this purpose. The key idea inside relocation branch elimination is pretty intuitive. As shown in Figure 4 (c), we can directly rewrite the `call` instructions to replace their target address using the address of library functions, instead of the address of the trampoline in `.plt`. The performance gain is obvious. We eliminate the extra two memory access and one instruction branch as shown in Figure 4 (d). As a result, we essentially achieve the performance of static linking on top of dynamic libraries. Despite its simple idea, we have to deal with instruction decoding, relocation sites management, and other implementation issues carefully. Implementation details are discussed in §4.

Rewriting instructions causes it more difficult to share libraries among applications, since they have to be organized in the exact same address space layout. Thus, the relocation branch elimination pass is preferred to be used in environments with sufficient memory. Another challenge that needs to be overcome is the distance restriction of a relative branch. When using relative addressing mode, the CPU has restrictions on the distance between the call site and the target address. [4] Therefore, only rewriting the target address is not always possible if the library functions are loaded far from the call sites. This issue can be handled in multiple ways. (1) When combined with the dynamic library concatenation pass, it is rare that the distance exceeds the architectural constraint. (2) We can change the relative addressing to absolute addressing mode at the cost of an extra instruction to load the address into a register. This change can be done by recompiling the code or rewriting the instructions by the loader. For instance, the Linux kernel module loader rewrites the instructions when detecting the constraint violation. (3) For the call sites that are far away from the target function, we can fall back to the existing relocation method using `.plt` and `.got`.

3.8 Discussion and Summary

The pass-based architecture enables iFed to accommodate much more load time technologies and functionalities. However, we do not argue that our architecture is the only or best way to design a loader. Other methods are possible, such as "Linux kernel module" or "systemd service unit" approach. This is an open and new research area, and researchers are welcome to investigate more. iFed also brings side effects to program launch time and binary size, and we discuss these trade-offs below.

Loading Time. While iFed infrastructure itself does not introduce additional overhead to program launch, boot time will increase as more iFed transformation passes are enabled. End users have to make the judgment on the trade-off between longer loading time and securer or faster application in run time. According to our experience so far, the increased loading time in iFed is acceptable. This is because (1) For applications that already require a modified loader to provide new functionalities, they do not suffer more extra launch costs after switching to iFed; (2) For long-running services, such as web server and database, the one-time overhead during the startup is always negligible; and (3) For short-lived tasks in high churn environments, we can explore process template and in-memory caching technology [36] to fork processes from an initialized template, thus all forked processes will bypass iFed loading phase and its associated overhead. We study how our dynamic library concatenation and relocation branch elimination passes impact loading time in §5.

Binary Size. As some iFed transformation passes may need extra binary information to perform in-depth analysis, it is likely to bloat the application binaries. For example, the relocation branch elimination optimization requires the linker to retain all relocations in the executable file, resulting in larger binaries. While it is possible to scan the binary to re-generate these information, it is not wise to waste time on these redundant work. So far, the bloated binaries are not a big deal given the current massive persistent storage, but we argue the ELF-based binary scheme can be improved in the following senses. First, developers should keep relevant binary information (*e.g.* data generated by static analysis or bitcode of LLVM IR) as much as possible to reflect more comprehensive semantics close to the source code, instead of throwing them away at build-time and hiding them from the users. It is the user who makes the decision whether these information should be stripped at deploy- or install-time. Second, while iFed uses ELF-based objects for compatibility now, it is better to have a different object file format in iFed to match the pass-based structure and RiMF image. Particularly, object files can be disassembled into per-pass pieces, and these pieces can be fetched, trimmed, or analyzed through per-pass configuration. These improvements are left as future work.

Summary. We summarize how iFed resolves the issues discussed in §1 based on our design principles. Organizing iFed with a collection of transformation passes inherently achieves modularity (P1). Passes do not directly interact with each other, but rely on the pass manager to mediate and operate on RiMF image as the only interface for collaboration. New passes are easily plugged into iFed, which significantly improves extensibility in iFed (P1). Therefore, vendors do not need to randomly modify the loader nor maintain multiple

[4] This is because only a subset of bits in the branch instruction is available to encode the address. For example, x86 limits the range as $\pm$2 GB, while ARM has a limitation of $\pm$128 MB.

versions to satisfy customers' different demands, and in the meantime, customers are able to enjoy more features for free. Since users can choose which pass to be used in iFed via iFed configuration, they can flexibly construct transformation pipelines to customize the application at load time (P2). Paired with the iFed's capability to transform libraries with a global view, customers are flexible to determine the trade-off among security, isolation, and performance. iFed is implemented to be compatible with the current loader, so no application modification is required (P3). More importantly, iFed enables another level of transparency for system administrators. For example, managers can insert a default security enhancement pass to iFed, regardless of if applications are built with security options.

4 iFed Implementation

Figure 2 depicts the typical workflow of iFed during program launch. A program's binary is first loaded by the operating system, which then loads the dynamic loader's binary if necessary. Next, the kernel returns to user space and hands over the control to iFed. After discovering all required libraries, iFed invokes the pass manager with an initial RiMF image which simply contains all libraries in a single isolation domain. Based on the iFed configuration, the pass manager loads and executes each pass in sequence. Finally, iFed invokes the application's entry point and completes the loading phase.

Compatibility. Current iFed is implemented on top of `glibc` 2.28. We reuse some utility components, such as library discovery and ELF parser from the `glibc`. As a result, iFed is able to load unmodified ELF binaries and supports common loader extensions, such as `LD_PRELOAD`. For compatibility, the existing dynamic loader (*i.e.* `ld.so`) is organized as a special fake pass in iFed. Linux allows an application to specify the dynamic loader it will use. Thus, we use this facility to enable the usage of iFed within applications.

Dynamic Library Concatenation. In this pass, we collect the same sections from all libraries and pack them into continuous memory backed by hugepages. To save memory, the last page is converted to small pages if less than 64 KB memory is occupied. While the implementation is intuitive, we must fixup the global variable access. Global variables are always accessed via offset, which is the difference between the address of the accessing instruction and the variable itself. For example, in Figure 3 (a) and (d), the offset between the `.code` and `.data` section within the `foo.so` is changed due to the rearrangement. Thus accessing variables in the `.data` section is broken. Our current solution is to instruct the compiler to emit all the symbol access information (*e.g.* using `-emit-relocs` options in `gcc`), and to fix the offset during the pass execution. The book-keeping infomation inside iFed is also updated according to the finalized address, so as to serve run-time loader interfaces, such as `dlsym()` and `dladdr()`. We only rearrange the libraries which are position independent.

Relocation Branch Elimination. This pass rewrites the branch instructions so that they do not need indirect jump based on `.plt` and `got`. First, we identify all branch instructions from the relocation records. Each record saves the position of the instruction and the remote symbol it references. The symbol could be either a function or a variable. Then, we find the actual address of the symbol and modify the instruction to use the address instead. Modifying instructions is architecture-dependent. We further optimize the function pointer invocations. In case of the function address can be determined at the loading time, we substitute the function pointer with the actual function.

5 Evaluation

Our evaluation goals include:

- Illustrate the effectiveness of dynamic library concatenation and relocation branch elimination pass using micro-architecture statistics.
- Understand the applicability of iFed along with our optimization with a wide range of applications.
- Assess the generality when running iFed on different hardware architectures.

Setup. We evaluate iFed on two architectures. The first one is two 26-core sockets Intel(R) Xeon(R) CPU @ 2.3GHz, with hyper-threading enabled, resulting in 104 cores in total. The other is ARM Kunpeng-920 CPU @ 2.6GHz with four NUMA nodes, and each node has 24 cores. All experiments run on openEuler 20.03 [30] based on Linux 4.19 kernel. We compare iFed with the system default dynamic loader, `ld.so` in `glibc 2.28`.

5.1 Micro-benchmarks

We conduct a set of micro-benchmarks to evaluate the performance improvement of library concatenation and relocation branch elimination passes in iFed. Each test calls functions provided by a configurable number of dynamic libraries, and each function accesses a certain amount of memory. Figure 5 and Figure 6 study the impact of different library counts and working set sizes in the library function, respectively. All tests are run 500K iterations on the Intel machine. We compare four different implementations, (1) `glibc` – the system default dynamic loader. (2) iFed-`hugepage` – iFed with only dynamic library concatenation pass. (3) iFed-`relocation` – iFed with only relocation branch elimination pass. (4) iFed– iFed with both optimization passes.

Micro-architecture Impact. Figure 5 (a) shows the number of misses in instruction TLB. With more libraries involved, the total iTLB miss grows rapidly. `glibc` incurs the most iTLB miss because it uses 4K pages to load libraries and runs out of the limited number of iTLB entries. iFed-

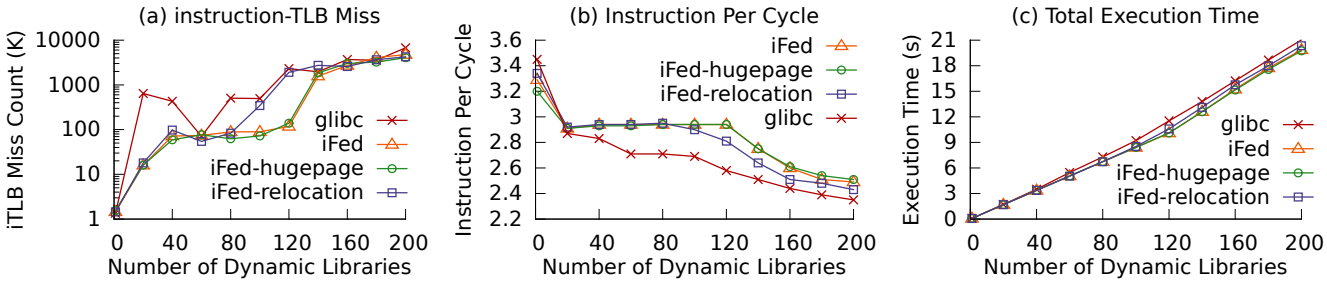

Figure 5: Micro-benchmarks: the working set is fixed at 256 KB.

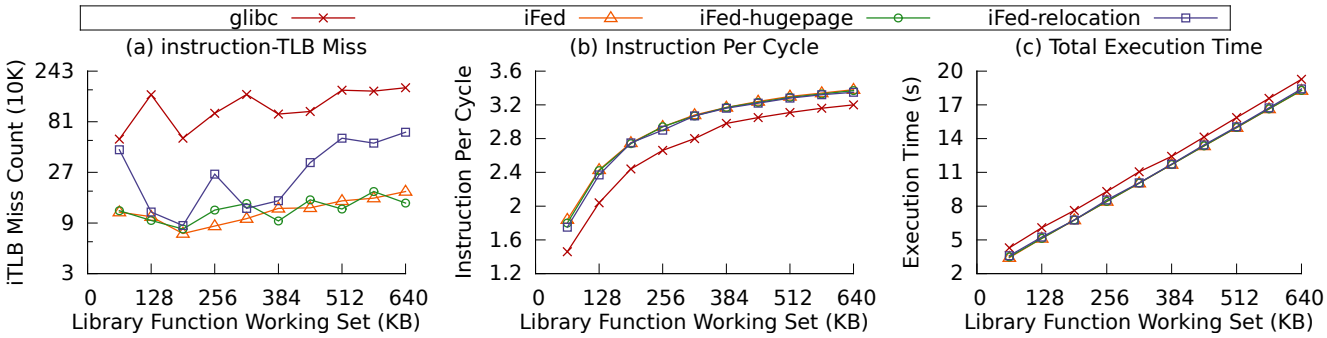

Figure 6: Micro-benchmarks: the number of dynamic library is 100.

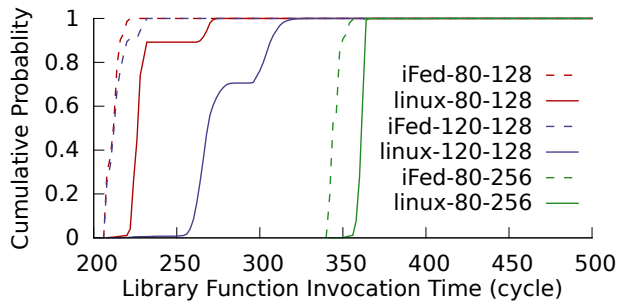

Figure 7: Library function invocation latency distribution.

`relocation` has little difference with `glibc` as it uses 4K pages, too. However, iFed-`hugepage` and iFed perform much better than `glibc` (note the log scale of y axis). Thanks to the usage of hugepage, they reduce the iTLB miss by an order of magnitude when the library count is smaller than 160, and by 40% with larger library counts. Less TLB miss leads to higher IPC as shown in Figure 5 (b). In addition to TLB miss, fewer code branches also decrease IPC. Thus, `glibc` has lower IPC than iFed-`relocation`, and iFed performs the best after integrating both optimizations. While the purposed optimizations almost work on `.code` sections, they also get benefits with a varied amount of data access as shown in Figure 6. With more data access, they compete for the cache and TLB when shared with `.code`, `.plt` and `.got` sections. This

`glibc`	iFed-`hugepage`	iFed-`relocation`	iFed
1.42 ms	5.96 ms	7.02 ms	9.07 ms

Table 2: Loading time overhead comparison. These are the cost to load a redis server which has 36195 relocation sites.

is illustrated in Figure 6 (a) where iFed-`relocation` triggers less TLB miss than `glibc`. In Figure 6 (b), IPC increases with the larger working set, as the memory access dominates the program execution. However, `glibc` performs worse than all iFed variants.

Latency Analysis. The improvements on micro-architecture further lead to the reduction in total execution time as depicted in Figure 5 (c) and Figure 6 (c). All execution time rise linearly with the test scale, but iFed runs faster than `glibc` in all cases. For instance, with 200 libraries and a 256 KB working set, iFed is 6% faster than `glibc`. More importantly, due to less TLB miss and branch, the predictability of library function invocation is improved a lot. To better understand the latency of library function calls, Figure 7 presents a CDF of function call latencies under different configurations. From the results, we observe that `glibc` has higher tail latency than iFed. For the 99th percentile latencies under the three configurations, iFed has improvements of 19%, 27%, and 3%, respectively.

Loading Time Discussion. Since iFed incorporates more functionalities, it inevitability slows down the time to launch a

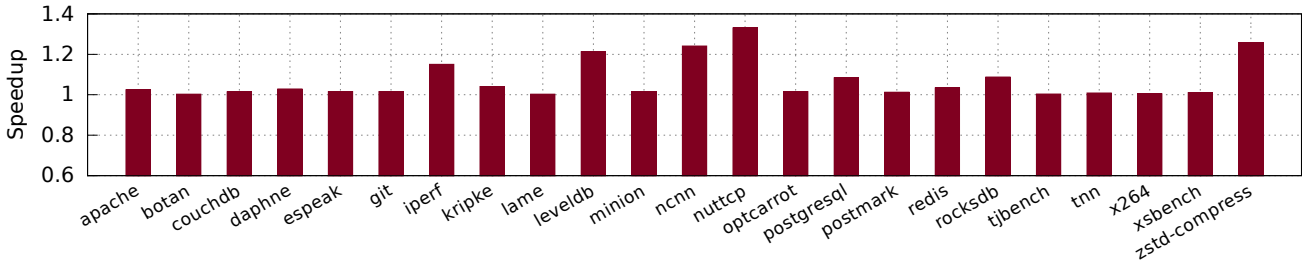

Figure 8: Phoronix test suite on ARM physical machine.

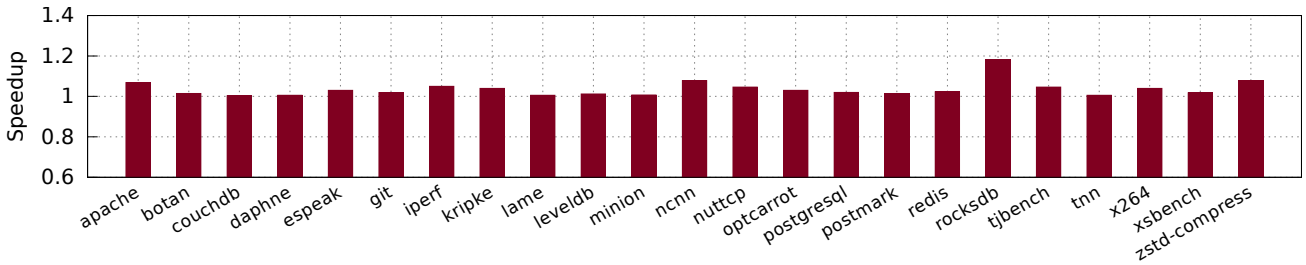

Figure 9: Phoronix test suite on x86 virtual machine.

program. Table 2 reports the loading time spent in the interval from the `exec` system call to the program's `main` function, when loading a redis server. As discussed in §4, the current iFed contains the `glibc` loader for compatibility, thus the result differences indicate the overhead of iFed optimization passes. Dynamic library concatenation overhead mainly comes from memory movement. The cost of relocation branch elimination depends on the number of relocation sites that has to be rewritten, thus it may incur a larger overhead.

5.2 Application Benchmarks

We evaluate iFed with Phoronix test suite v10.4.0 [42], which has a wide range of common applications and realistic workloads. We selected 23 applications from multiple domains that stress different components in the system, such as memory (`zstd-compress`), processor (`botan`), disk (`postmark`) and network (`iperf`). These tests also cover different running forms of multi-process, single- and multi-thread. We run these tests in two environments, the ARM Kunpeng server and a 60-core KVM-based virtual machine hosted in the Intel machine, because VMs are popularly deployed to hold applications today. Hardware virtualization is enabled, and the VM is configured with 128G memory. The guest OS is also openEuler 20.03 based on Linux 4.19 kernel. We enable all optimization passes in iFed, and report the average performance speedup compared to `glibc` in Figure 8 and Figure 9. The data is gathered from the built-in performance comparison tool in Phoronix. Since better hugepage usage and eliminated `.got/.plt` indirection in iFed will improve many tightly correlated micro architecture factors, we use `perf` to measure some typical CPU events for each benchmark. Table 3 lists the percentage of TLB miss reduction, branch miss reduction, and IPC improvement compared to `glibc` on both ARM and Intel testbeds.

Whether an application can get benefits from iFed depends on its bottleneck. For computing intensive applications who do not suffer from TLB miss or branch mispredictions, iFed keeps the same performance with `glibc`. For example, `botan` is a C++ crypto library and the benchmark measures the performance of many cryptographic algorithms. iFed has less than 1.5% performance difference with `glibc` in all test cases. As shown in Table 3, iFed has a negligible impact on IPC. `xsbench` tests a key computational kernel of the Monte Carlo neutronics application OpenMC. iFed does not reduce branch misses on ARM, thus the performance difference between iFed and `glibc` is less than 2%.

When the application is memory bound and its data compete for the shared TLB and cache with the code, iFed is able to mitigate the interference and improve the performance. For instance, the `zstd-compress` benchmark compresses and decompresses a 1 GB Linux kernel image. iFed reduces the number of TLB misses by 16.56% and 19.4% on Intel and ARM machine, respectively. Please note that our dynamic library concatenation deals with both `.code` and `.data` section, thus iFed does not only reduce iTLB misses. As a result, iFed speedups the benchmark by 7.3% on Intel and 25.7% on ARM.

For complicated applications that have complex function call patterns across libraries or use many dynamic libraries, iFed can boost their performance. For example, `leveldb` from Google gets 1.1% and 21.2% better performance on Intel and ARM platform, respectively. On ARM, `glibc` in-

curs 10^9 instruction TLB misses, while iFed just incurs 10^5 iTLB misses! `ncnn` is a mobile neural network inference framework developed by Tencent. Its IPC is improved by 3.04% and 6.36% on Intel and ARM platform respectively, and correspondingly iFed gets 7.7% and 24% overall better performance. `iperf` and `nuttcp` have a large performance boost because both benchmark server and client are loaded by iFed.

In some cases, iFed shows large relative improvements on perf events while has little impacts on the benchmark performance. That is because the event's absolute numbers are so small that slight variations of the event result in large percentage difference. For example, on the Intel machine, `optcarrot` shows 10.45% less TLB misses while its performance is only 2.9% better. After examining the absolute number of TLB misses, we found there are only 1.8 million misses with `glibc` and iFed lowers it to 1.6 million. Those numbers are several orders of magnitude smaller than those in other memory intensive benchmarks. Another example is branch miss reduction in `botan` benchmark on the ARM platform. `botan` experiences around 323K and 311K branch misses under `glibc` and iFed respectively. Despite 3.65% reduction in branch misses, iFed does not have speedup over `glibc`.

To further validate our results, we analyse the `rocksdb` benchmark on the Intel VM in depth. The benchmark contains 3857 `.got` entries and 8153 `.plt` entries, and 94327 relocation sites point to these entries. With `glibc`, 15.6% of total cycles are spent on page table walk due to TLB misses, while this ratio is reduced to 10% after iFed optimization. Relocation branch elimination pass contributes 6% improvement, and dynamic library concatenation pass continues to improve 10%, leading to an overall improvement of 18%. We also tested a statically linked version which performs 9% better than the dynamic one with `glibc`. This improvement is less than iFed with the hugepage optimization, but is better than iFed with relocation elimination since static linking has more chance to apply link-time optimization.

In general, we do not observe the loading time overhead causing performance degradation even for the benchmarks which need to frequently boot up and shut down the test programs. On the Intel virtual machine, compared to `glibc`, the average TLB miss is reduced by 8.58%, the average branch miss is reduced by 3.28%, and the average IPC is improved by 3.02%. iFed is 3.7% better than `glibc` on average and achieves 18% maximum improvement. On the ARM physical

Table 3: Application benchmarks: percentage of TLB miss reduction, branch miss reduction, and IPC improvement..

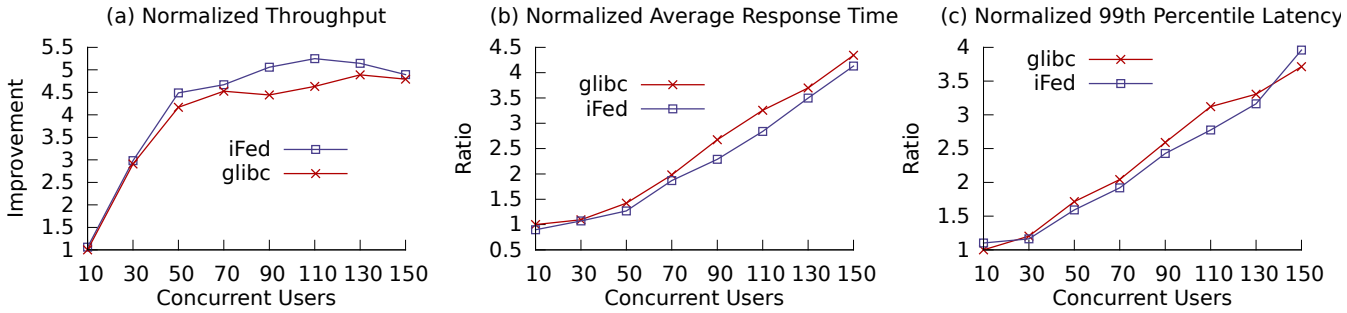

Figure 10: Dynamic web serving performance. All data are normalized to the result of 10 concurrent users with `glibc`. (a) shows the throughput across all operations, the higher the better; (b) shows the average response time of `postwire` operation (similar to posting a tweet), the lower the better; (c) shows the 99th percentile latency of `postwire` operation, the lower the better.

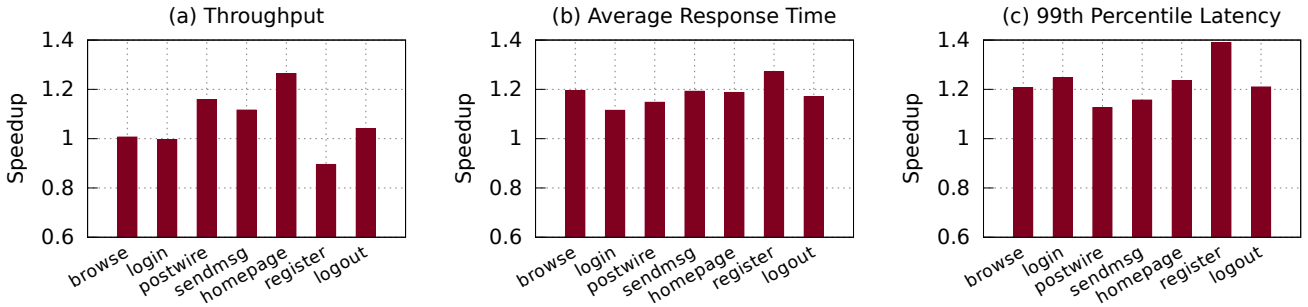

Figure 11: Performance of each operation with concurrent 110 users. All data are the speedup ratio normalized to the `glibc`, the higher the better.

machine, iFed reduces 13.04% TLB miss, lowers the branch miss by 1.85%, and improves the IPC by 7.33%, on average. The average speedup is 7% and the largest improvement is 33%. In most cases, iFed achieves a larger improvement on the physical machine than the virtual machine. This is because VMs have an extra address translation layer. Thus if the host OS allocates small pages to the guest OS, iFed will get less benefit by enabling hugepage in the guest OS.

5.3 Web Serving

Finally, we evaluate iFed in a system-wide scenario with a web serving benchmark from Clousuite [10]. This benchmark is a dynamic website hosting a production-quality social networking engine. Since the current Clousuite is not supported on ARM architecture, we port it to our ARM machine, and upgrade its components to newer versions. Particularly, we use nginx 1.16.1, mysql 8.0.17, PHP 7.2.10, and elgg 3.0.7. We run the client and server on two ARM machines under the same ToR switch. The client simulates multiple users who browse the website and issue different operations, such as register, login, and send messages to a friend. These operations are mixed in a distribution that favors common operations (*e.g.* send a message and post a tweet), while containing fewer login/logout operations. Each test case runs 5 minutes, and Clousuite collects the throughput and response time.

Figure 10 shows the normalized performance with various simulated concurrent users. The efficiency is seen in the improved throughput, reduced response time, and tail latency. The performance keeps increasing with more users until the system is saturated. For the peak performance, iFed has 13.3% higher throughput, 14.7% smaller average response, time and 12.5% lower 99th percentile latency. Figure 11 shows the detailed performance statistics of each operation with 110 concurrent users. iFed is better than `glibc` in most cases. For the throughput of `register` operation, iFed is lower because the client issues less `register` operation due to the probabilistic workload distribution. This is also confirmed by the reduced response time from Figure 11 (b) and (c). To summarize, these results demonstrate that optimizations in iFed are effective in the realistic multi-application environment.

6 Related Work

Loader modification and improvement. Many projects have to modify the loader to achieve their specific goals, even though the loader is not of their research contribu-

tion. However, the current dynamic loading infrastructure is neither flexible nor extensible to accommodate those modifications, causing their research to have limited applications in the industry. When utilizing MPK [14, 38, 50] or SGX [7,13,32,37,40,44,60] for stronger isolation or security, most works have to modify the loader to be aware of such isolation facility. Besides hardware-assistant isolation, software implementation also require to coordinate with loader, such as sandbox [5,6,24,55] and CFI [22,25,47,58]. It is necessary to change the loader to support program migration and execution on remote, heterogeneous, or smart devices [3, 8, 52]. Kard [2] leverages MPK for per-thread memory protection to implement a dynamic data race detector, which uses a custom loader to handle global variables. Shuffler [53] continuously re-randomizes code locations in a separate thread, but requires a small loader patch for bootstrap. With iFed, these modifications will be made easily and further reused across different projects.

Agrawal et al. propose a speculative hardware mechanism to avoid executing relocation trampolines [1], while we provide a pure software approach to eliminate relocation overhead in iFed. Stephen Kell et al. describe the formal semantics for static linking [19]. As iFed decouples a monolithic dynamic loader into smaller pieces, we expect a similar formal method can be applied to dynamic linking as well.

Load time technologies. There is a large body of research focusing on load time technology. Paschalis Mpeis et al. introduce a capture and replay mechanism [28] that detect and profile hot code regions, and optimize them offline. Instead of the original code from binary, these captured and optimized hot regions are fed into the loader to replay. Egalito [54] is a binary transformation framework that supports dynamic analyses or code-generation at load time. Load time binary stirring [51] randomly reorders some code sections and repairs code pointers accordingly. ASLR-Guard [26] contains a dynamic loader, which decouples code sections from data sections and encrypts some sensitive regions. Library debloating [33,35] is a type of load time optimization that loads only the set of library functions that will be used at each library call site within the application at runtime. iFed provides a platform to explore and integrate broader load time technologies. Wei Dong et al. propose a holistic dynamic linking and loading mechanism in networked embedded systems to generate minimal code size [9].

Loader on new system and architecture. Since dynamic loader is a basic toolkit, it has to be rewritten whenever a new system or hardware comes. For example, RedLeaf [29] is a rust-base OS with a new abstraction, called Domains, for lightweight isolation, and supports dynamically loaded Domains. CARAT [41] allows programs to run efficiently in a physical address space and needs a loader to collaborate properly. Different loaders are also implemented within different system architectures, such as microkernel [20,49], unikernel [43] or LibOS [4,34,45,59]. Similarly, the loader is always needed to be updated to explore new hardware features for isolation [39], security [31], communication [48], container [57], and embedded device [21]. With the help of iFed's modular design, we are able to extract the system agnostic or architecture independent parts and reduce the porting effort.

7 Conclusions

We introduce iFed, an infrastructure for dynamic library transformation. While iFed is compatible with the current dynamic loader, its function goes beyond the traditional dynamic linking and loading. By a pass-based architecture and RiMF, iFed can provide much richer functionalities over isolation, security, and optimizations in a flexible, extensible, and modular way. We demonstrate the extensibility of iFed by implementing two optimization passes. One pass reduces TLB miss and improves IPC because of the effective usage of hugepages. The other pass rewrites the call sites to eliminate function relocation overhead. Modularity and extensibility are crucial to reducing the development, deployment, and maintenance costs of today's complicated system software. We believe it is an open research area to investigate modular design in many other monolithic system software, not just in the loader.

Our evaluation shows optimizations in iFed improve performance and predictability for a wide range of applications on multiple architectures and platforms. On an ARM physical machine, iFed achieves up to 33% speedup, and on an Intel virtual machine, iFed gets a maximum improvement of 18%. In a complex dynamic website that requires collaboration among multiple applications, iFed improves the throughput by 13.3% and achieves a 12.5% reduction of end-to-end 99th percentile latency. More importantly, iFed boosts the performance transparently with no application changes. Building on both customers' demands from industry and load time technology advances from academia, the dynamic library manipulation infrastructure is a promising area of research. We believe that iFed paves the first example of a new generation of dynamic loaders for integrating research advancement of load-time transformations and technologies.

Abstract

Kernel synchronization primitives are the backbone of any OS design. Kernel locks, for instance, are crucial for both application performance and correctness. However, unlike application locks, kernel locks are far from the reach of application developers, who have minimal interpolation of the kernel's behavior and cannot control or influence the policies that govern kernel synchronization behavior. This disconnect between the kernel and applications can lead to pathological scenarios in which optimizing the kernel synchronization primitives under one context, such as high contention, leads to adversarial effects under a context with no lock contention. In addition, rapid-evolving heterogeneous hardware makes kernel lock development too slow for modern applications with stringent performance requirements and frequent deployment timelines.

This paper addresses the above issues with application-informed kernel synchronization primitives. We allow application developers to deploy workload-specific and hardware-aware kernel lock policies to boost application performance, resolve pathological usage of kernel locks, and even enable dynamic profiling of locks of interest. To showcase this idea, we design SYNCORD, a framework to modify kernel locks without recompiling or rebooting the kernel. SYNCORD abstracts key behaviors of kernel locks and exposes them as APIs for designing user-defined kernel locks. SYNCORD provides the mechanisms to customize kernel locks safely and correctly from the user space. We design five lock policies specialized for new heterogeneous hardware and specific software requirements. Our evaluation shows that SYNCORD incurs minimal runtime overhead and generates kernel locks with performance comparable to that of the state-of-the-art locks.

1 Introduction

With the ending of Moore's Law and Dennard scaling, the exponential growth of single-processor performance has come to a standstill. Hence, application developers now resort to customization, rather than generalization, to further squeeze out the performance from the hardware. For instance, different applications work best with changing underlying system mechanisms. Although a generic mechanism often provides acceptable performance, it rarely matches the performance of a specialized mechanism, whose performance difference often is an order of magnitude or more [10, 34, 59, 70].

Such a major improvement stems from the fact that specialization bridges the semantic gap between applications and the underlying system [23, 63]: It establishes the *context* under which an application requests functionality from the system. Thus, the underlying system can provide the most suitable implementation or even allow applications to provide their own implementation. The method of specialization is not new. For instance, prior works have targeted the widely used Linux OS that has become a major performance bottleneck for applications [29, 33, 47, 53, 61]. As a result, kernel customization has been extensively studied in the context of scheduling [34], networking [49], storage [70], and accelerators [10]. Although such works mostly focus on the scheduling aspect of the IO, they do not expose one of the basic building blocks of today's software design: concurrency control. Hence, this work takes a step in that direction by enabling the customization of the kernel synchronization primitives that have never been exposed to applications.

Kernel synchronization primitives, especially locks, are of paramount importance to ensuring correctness, achieving good performance, and scalability for applications [8, 9, 35, 37, 52]. Traditionally, kernel developers bake these primitives as a part of the OS implementation. Since it is difficult to change these primitives dynamically, the kernel developers favor supporting common scenarios and make all the decisions regarding their design and implementation. Thus, all these primitives are invisible and are out of reach of applications.

Given evolving hardware and changing software requirements, this static approach of lock design raises two issues: missing hardware and software contexts. From the hardware perspective, applications using kernel components, which rely on such generic primitives, suffer from regression issues in pathological cases [8, 37, 52]. In particular, these primitives

suffer from a high level of contention with increasing core count [8], which requires further optimization for the underlying hardware [11, 21, 51]. In addition, increasing hardware heterogeneity in modern systems further exacerbates this issue [4, 5, 16, 41]. Second, from the software perspective, these baked generic primitives lack application context. As a result, it can lead to pathological cases, such as missing readers-writer context [11], priority inversion [35, 38, 52], scheduler subversion [58], and lock-holder preemption [36].

The current practice of addressing these issues involves developing synchronization primitives for specific scenarios [12, 21, 26, 39, 42, 45, 46, 51]. However, designing, implementing, and verifying new synchronization primitives is challenging. In addition, developers need a huge amount of effort to upstream and maintain them. To satisfy fast-evolving scenarios and requirements, synchronization primitives should be easily changeable and even on the fly instead of providing point-solutions as in previous works.

This paper proposes the idea of *application-informed kernel synchronization primitives* that enables users to develop custom *lock policies* to maximize performance or resolve pathological cases. For example, with an asymmetric multicore processor machine, in which processors operate at a different speed [4, 5, 16], application developers may want to prioritize lock waiters on fast cores to maximize performance. To demonstrate this idea, we design and implement SynCord, a framework built to safely modify kernel locks on the fly without recompiling or rebooting the kernel. We abstract and modularize the semantics of the locking primitives and expose them in the form of APIs. A developer uses these APIs for implementing policies, such as NUMA-awareness, priority boosting, readers-writer preference [11, 21, 37] etc. SynCord then verifies these policies and safely patches the running kernel in the end. It provides the capability to deploy custom code for a wide range of lock instances: from a single lock instance to a set of locks, or every lock in the kernel. Besides deploying lock policies, SynCord further allows users to profile locks at fine granularity. Our approach departs from the conventional tools profiling a fixed set of statistics for all kernel locks [73]. Instead, a user can now collect any lock statistic on arbitrary locks.

The ultimate goal of SynCord is to completely realize the idea of contextual concurrency control [57], which enables users to modify any synchronization primitives from the user space in a safe manner. As a first step in kernel lock customization, our SynCord prototype currently supports non-blocking locks. In particular, SynCord allows users to write their own logic for reordering lock waiters, setting priorities between competing threads to acquire a lock. We support three existing non-blocking primitives: ShflLock [37], CNA [19], and the stock readers-writer lock in Linux. We further demonstrate the generality of SynCord by adapting four different locking algorithms to the kernel and optimizing them based on our evaluation platform. In addition, we provide a case study of lock profiling using SynCord and show how it simplifies the performance analysis of a lock algorithm. Our evaluation shows that the custom algorithms developed with SynCord increase the application performance by up to three orders of magnitude compared to the generic locks.

This paper makes the following contributions:

- **Application-defined concurrency.** We propose the idea of on-the-fly modification of lock design. To realize that, we design and implement the SynCord framework.
- **APIs for non-blocking locks.** We provide a set of APIs that exposes the key decisions of non-blocking locks to implement various lock algorithms.
- **Lock algorithms.** We implement four lock algorithms and optimize them based on the platform. The optimized versions outperform generic locks up to three orders of magnitude.
- **Custom fine-granularity profiling.** SynCord provides custom, fine-granularity lock profiling that simplifies locks' performance analysis with smaller overhead.

2 Background And Motivation

Modifying kernel locking primitives without recompiling and rebooting the OS spans various domains of concurrent OS design. We first discuss the evolution of locks, followed by various mechanisms for kernel customization and the specific need for dynamic patching for kernel locks.

2.1 Lock evolution

Locks are widely used and heavily influenced by hardware. For example, queue-based locks minimize cache-line contention [51] among CPUs by forming a queue of waiters who spin on private cache lines. Hierarchical locks [11, 17, 21] improve application throughput for non-uniform memory access (NUMA) architecture, in which local memory is faster than remote NUMA memory. Such locks exploit the NUMA characteristic by batching requests from the same NUMA node at the cost of higher memory use and lower throughput in non-contended scenarios. CNA [19] and ShflLock [37] address these limitations by dynamically reordering the queue. ShflLock enforces *policies* given by hardware characteristics and software behaviors through shuffling. Although both locks allow designing new lock algorithms by abstracting both hardware and software requirements in the form of policy, their approach is insufficient for changing kernel locks on the fly. A developer still needs to recompile and reboot the kernel to test a new policy. SynCord allows users to develop custom policies and safely deploy them to a live kernel.

2.2 Kernel customization

With the introduction of fast IO devices, hardware accelerators and hundreds of cores, customizing the kernel on the fly is the new norm for improving application performance. However, this idea is not new, as Exokernel [22] is

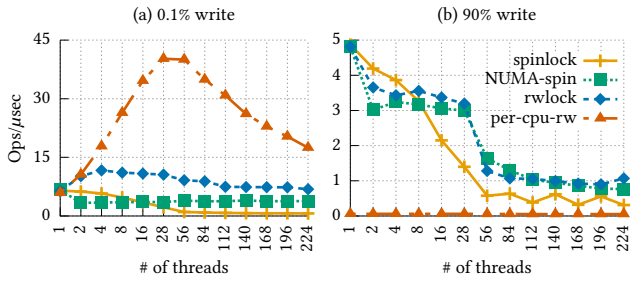

Figure 1: Impact of locks on throughput with different write ratios. The workload is a hashtable benchmark in the kernel [69] where a global lock guards the hashtable.

the first kernel design that enables customization by safely exporting hardware resources to untrusted library OSes and downloading application code to the kernel. Another prominent one that enables customization is the split-level I/O scheduling [70], which enables users to deploy custom I/O scheduling mechanisms across various layers of the storage stack.

Recently, Linux has been allowing user-level applications to customize the kernel by handling page faults in user space [14] or using the eBPF framework [23]. eBPF has seen wide deployment at various places in the kernel. For example, EXTFUSE speeds up user-level file systems with eBPF [6]. eXpress Data Path (XDP) [63] introduces a programmable network data path that allows a user-supplied eBPF program to control network packets. Moreover, recent work proposed delegating kernel operations to user space. For example, Syrup [34], ghOSt [28] and Scheduler BPF [15] allow users to specify scheduling policy and deploy it in the kernel networking stack and thread schedulers. Snap [49] enables the development of networking features in user space, while DPDK [61] and SPDK [29] provide libraries to accelerate packet processing and develop storage features. Compared to these works, SynCord takes a step further in customizing the kernel: it allows users to control the concurrency mechanisms in the underlying kernel.

2.3 Application-defined locking matters

Figure 1 illustrates the fact that one lock design cannot perform the best in all scenarios. For example, when the workload is read-dominant, rwlock outperforms spinlock because spinlock requires mutual exclusion even between read operations. In particular, per-CPU rwlock works better than a centralized one by avoiding cache traffic caused by a reader indicator across cores. However, with a write-dominant workload, the per-CPU rwlock performs the worst. In addition to the application semantics, underlying hardware also requires a different lock [17]. The NUMA-aware spinlock performs better than the MCS spinlock when threads execute across multiple sockets, but MCS can be a better choice on a single socket machine for the first few threads.

One might solve this problem by designing and implementing a special kernel lock. However, developing and maintaining kernel locks customized for each application and hardware is difficult, time-consuming, and costly. Meanwhile, SynCord eases the development of new lock algorithms. First, unlike other subsystems, synchronization primitives are not well isolated in the kernel. Hence, changes to synchronization primitives require understanding the surrounding details that impact a lot of other kernel codes. SynCord provides modularity for synchronization primitives. Second, SynCord APIs serve as an abstraction layer. These APIs hide the underlying tricky implementation details of lock, such as concurrency, memory model, and atomic instructions use. Instead, developers implement policies for scheduling waiters, such as what to do before and after acquiring a lock, and which type of waiters should be prioritized (§5). Moreover, locks designed with SynCord require no changes to the kernel's components and achieve similar speed up with only a few lines of code (Table 5).

2.4 The need for dynamic lock patching

Apart from the difficulty of designing and implementing new lock algorithms in the kernel, installing a modified kernel requires a system reboot. However, there are common scenarios where applications or underlying hardware change during execution, requiring live kernel lock changes. In terms of application changes, applications whose performance matters might change over runtime. This case is possible in a cloud environment, as multiple applications execute in a particular order. In addition to performance, applications try to maintain some form of service level agreements in the form of latency or fairness. Besides this, a scenario of runtime hardware modification is virtual machine (VM) live migration [2]. For example, if a cloud provider migrates a VM from a single socket machine to a multi-socket NUMA machine, users should modify their kernel locks' policies to handle the NUMA behavior. Moreover, with increasing hardware heterogeneity, applications require policies incorporating both hardware and software policies for better performance. One might argue that the traditional approach of kernel patching is sufficient. In this case, the conventional static kernel patching approach cannot efficiently handle such scenarios, motivating the need for the SynCord dynamic approach, which allows developers to implement specific APIs and patch a set of locks, while generally ensuring safety properties.

3 The SynCord Framework

SynCord is a framework for customizing kernel locks on the fly without recompiling or rebooting the kernel. To modify kernel locks, a user writes custom lock algorithms in user space, and SynCord safely deploys them in the kernel. SynCord can patch individual lock instances or every lock in the kernel. In addition, SynCord enables fine-grained profiling of kernel locks, helping users better understand the impact the kernel has on their application. We design

Type	Group	API	Description
Safe	General	① `void lock_to_acquire(lock)`	Invoked before acquiring the lock.
		② `void lock_acquired(lock)`	Invoked after acquiring the lock.
		③ `void lock_to_release(lock)`	Invoked before releasing the lock.
		④ `void lock_released(lock)`	Invoked after releasing the lock.
	Fast path	⑤ `void lock_to_enter_slowpath(lock, node)`	Invoked before entering the slow path.
		⑥ `bool lock_enable_fastpath(lock)`	If true, allow acquiring the lock by the fast path.
	Waiter reordering	⑦ `bool should_reorder(lock, anchor, curr)`	If true, move thread `curr` forward in the queue.
		⑧ `bool skip_reorder(lock, anchor)`	If true, skip the current reordering operation.
Unsafe	Lock bypass	⑨ `bool lock_bypass_acquire(lock)`	If true, bypass lock aquisition.
		⑩ `bool lock_bypass_release(lock)`	If true, bypass lock release.

Table 1: A summary of SynCord APIs. General APIs intercept the entry and exit points of the lock acquire and release phase. Today most of the lock algorithms have at least two paths to enter the critical section: fast path and slow path. Here, the fast path APIs intercept the fast path access to acquire the lock. Meanwhile, the slow path provides waiter reordering APIs that control the reordering of waiters for lock acquisition. Lock bypass APIs allow threads to bypass locks. The lock bypass APIs allow expert developers to design their algorithm, which comes at their own risk.

SynCord to modify kernel locks as a sandbox that adds new policies on top of existing locks.

Design goals. SynCord has three main design goals:

- *Correct lock patching.* SynCord must maintain the mutual exclusion of the lock instances being patched and should not introduce any correctness bugs through the process of patching.
- *Sandboxed user's code.* Users may provide unsafe code that leads to mutual exclusion violation. SynCord aims to prevent such code from corrupting the kernel as long as they use SynCord safe APIs, so that relieves users' concerns about the correctness of their lock design.
- *Usability and expressiveness.* SynCord aims to provide APIs expressive enough to tune kernel locks for various platforms or requirements.

To strike a balance between expressiveness and sandboxed impact, we design two sets of APIs. A set of *safe* APIs (①–⑧ in Table 1) guarantees mutual exclusion for general use, and the other set of *unsafe* APIs (⑨, ⑩) grant expert kernel developers full control of locks at their own risk.

Moreover, we envision that a single organization uses SynCord to modify kernel locking primitives. In particular, the sysadmins of that organization, with root privileges, handle the conflicting policies for various applications contending on the same lock or a set of locking instances. We follow this model because unlike other subsystems, locking primitives guard shared resources, which an unprivileged user should not change. In addition, we assume that such kernel changes do not occur frequently. Thus, a single policy optimized for underlying hardware or applications' usage patterns may last several minutes.

3.1 SynCord overview

Figure 2 illustrates SynCord's key components and workflow. SynCord exposes a set of APIs (Table 1) to abstract underlying lock implementation and allows users to write

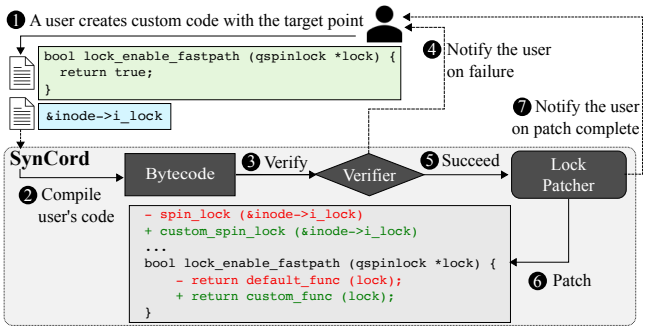

Figure 2: Overview of SynCord's key components and workflow. (1) A user writes custom lock code and specifies lock instances to patch; (2) SynCord compiles the user's lock code (*e.g.*, eBPF) and (3) verifies basic properties of the compiled bytecode. (4) SynCord notifies the user if the verification fails, (5) otherwise loads the program into the kernel and generates a patch. (6) The lock patching module patches the kernel to call compiled bytecode on predefined hook points.

custom kernel locks in the abstracted layer. These APIs are the pre-defined hooking points that developers use for inserting their custom code to control the logic of underlying locks. To use SynCord, a privileged user first specifies the lock instance they want to patch and writes the custom locking code in C with SynCord APIs in a separate file (❶). SynCord processes this file in a semi-interactive fashion. It first reads the file and compiles the custom code (❷). It then passes the compiled program to the verifier that performs static analysis to validate the safety requirements (❸). The verification process usually takes a few milliseconds. If the verification fails, SynCord notifies the user (❹). Otherwise, it loads the policy into the kernel and gets a unique ID of the policy (❺). With the ID, SynCord patches the locking func-

```
def spin_lock(lock):
  lock_to_acquire(lock) # ① Hook the start of lock acquire

  if lock_bypass_acquire(lock): # ⑨ bypass lock acquire
    # lock acquisition is bypassed: used by lock experts
    return

  # If fastpath is enabled, first try to acquire the lock
  # instead of going into the wait queue
  if lock_enable_fastpath(lock) and # ⑥ can steal lock?
                  CAS(&lock.state, UNLOCK, LOCKED):
    lock_acquired(lock) # ② lock is acquired
    return

  node = Node() # A node to join the queue
  lock_to_enter_slowpath(lock, node) # ⑤ Hook before enqueuing
  queued_spin_lock_slowpath(lock, node) # Time to join the queue
  lock_acquired(lock) # ② Hook the start of critical section

def spin_unlock(lock):
  lock_to_release(lock) # ③ Hook the end of critical section

  if lock_bypass_release(lock): # ⑩ bypass lock release
    # lock release is bypassed; used along with ⑨
    return

  lock.state = UNLOCK # Lock released; critical section ends
  lock_released(lock) # ④ Hook right after critical section
```

Figure 3: Pseudocode of `spin_lock` and `spin_unlock` with SynCord APIs. We place the waiter reordering APIs in the slow path of the existing `qspinlock` (`queued_spin_lock_slowpath`) function [13].

tions to execute the policy at pre-defined hooking points (❻). The patching process is time-consuming, as the patching module (`Livepatch`) has to find a quiescence period, *i.e.*, no task is executing the locking functions to patch. This period can last a few seconds. Finally, SynCord notifies the user after the patch completes (❼).

3.2 Programming with SynCord

To design a custom kernel lock with SynCord, a developer first specifies a set of lock instances to patch and implements a new policy by writing code blocks for each API. At a high level, there are two main purposes for developers to write code in the APIs: to enforce user-defined policies on scheduling waiters, and fine-grained profiling. From the scheduling perspective, a lock algorithm ensures the mutual exclusion property while scheduling a set of waiters based on user requirements *e.g.*, FIFO. Thus, SynCord exposes various means to schedule lock waiters, such as queue ordering and backoff schemes. In addition, both custom lock design and profiling often record extra information. Thus, we also provide auxiliary data structures (refer to §3.2.2) that serve as the extra storage space for the custom code.

3.2.1 SynCord APIs

Table 1 summarizes the APIs in the current SynCord prototype. The APIs expose several key behaviors of queue-based non-blocking locks, especially the ordering between lock waiters. We design SynCord APIs to be general across many existing lock designs and safe enough to use in user space. Most locks have well-known interfaces: acquire() and release(). Hence, the first category of our APIs (①–④) hooks these interfaces. Figure 3 shows the pseudo-code of `spin_lock` and `spin_unlock` with the hooking points for SynCord APIs. The *General* APIs allow users to intercept the entry and exit points of the acquire and release phase. These APIs are particularly useful for lock profiling as their hooking points are inspired by Linux's lockstat to profile every kernel lock. For example, users can use these APIs to record the time spent in acquiring the lock or the time spent in the critical section.

The second set of APIs—the *Fast path*—hooks the entry of a slow path (⑤) or controls the fast path of the lock (⑥). The fast path uses test-and-set-based lock for low contention scenarios [13, 19, 37]. For example, in `qspinlock`, CNA and ShflLock, a thread first tries to issue a test-and-set instruction to grab the lock, and only enqueues itself on failure. The fast path optimizes performance but may impact fairness, which now can be easily controlled with APIs. The slow path involves queue maintenance when the lock is in use, which applies to almost all queue-based lock algorithms [13, 44, 54, 55].

To design policies controlling the order to acquire a lock, we rely on a queue-based lock design that provides a powerful abstraction to reorder the waiting queue on the fly without using extra memory. Both CNA and ShflLock allow arbitrary dynamic queue ordering to achieve user-defined policies. Thus, we provide two *waiter reordering* APIs (⑦–⑧). `should_reorder()` moves a waiter in front of the queue by comparing the current node with an anchor node. `skip_reorder()` skips the reordering procedure. When the reordering is skipped, the waiting queue goes back to the first-in-first-out policy to maintain waiting threads. This is useful to enforce fairness for specific scenarios or purposes.

Although these APIs can implement several queue-based lock algorithms, they cannot change the basic mechanism of the underlying kernel locks. However, an experienced lock developer may want to redesign the kernel lock completely [17, 20, 21]. Thus, SynCord introduces a set of APIs that allow the custom code to bypass the lock acquire and release phase (⑨–⑩). These APIs grant users complete control of the kernel lock and thus allow users to design arbitrary lock algorithms. Since these APIs bypass underlying locks, it is the user's responsibility to correctly maintain the mutual exclusion property.

A point to note is that most of the APIs only introduce performance bugs with incorrect usage. Although the reordering API might affect the fairness, SynCord prevents threads from starvation with runtime checks. Meanwhile, our APIs are designed not to introduce correctness bugs (*e.g.*, infinite loops, mutual exclusion violations) except for the lock bypass APIs.

3.2.2 Auxiliary data structures

Sometimes, designing new lock algorithms or profiling existing locks might require extra information. For example, to implement a NUMA-aware lock scheduling algorithm (§5.1), each waiter needs to record its socket ID. Hence, we support auxiliary data structures to save some semantic information. In particular, we support three such types: per-node data, per-lock data, and global data. Per-node data is associated with a thread (node) that waits to acquire the lock. Its lifetime starts when a thread joins the waiting queue and ends when the thread acquires the lock. Per-lock data is associated with a lock instance, and global data plays the identical role as global variables in the kernel. Both per-lock and global data structures are created and destroyed explicitly by SynCord and follow the lifetime of the associated policy in most cases. The user, while implementing custom code, also defines the required types of auxiliary data structures, which get compiled along with the lock.

3.3 SynCord properties for lock design

Unlike current kernel customization approaches that localize resources within a process model, exposing dynamic lock modification requires reasoning about the mutual exclusion properties, minimizing the impact of starvation and ensuring that we patch the lock code correctly.

Sandboxed impact. If the user provides buggy code, SynCord should prevent such code from corrupting the kernel. SynCord guarantees code safety: memory safety (no access to illegal memory address), termination (no infinite loop), liveness (no deadlock) and mutual exclusion. The current verifier, which relies on the eBPF verifier, uses static analysis to enforce code safety. In particular, SynCord APIs pass a lock instance as a read-only argument to prevent arbitrary changes to the lock state during the lock acquisition and release phases. For instance, SynCord APIs (except the bypass ones) do not modify the functioning of the existing lock algorithm, such as atomic instruction, barriers, and concurrent executions. Because of this, SynCord does not introduce any new deadlock situation, meanwhile maintaining the liveness of the underlying lock even after adding the user logic. Our APIs only provide suggestions/hints to existing locks, as we do not change their underlying working. Hence, it is impossible to incur mutual exclusion violation. Meanwhile, we advise only lock experts to use the bypass APIs for complete access to the lock state.

Avoiding starvation. The reordering of waiters by SynCord introduces starvation that can severely affect the kernel response. We address this issue with bounded runtime checks. For example, if a custom lock uses backoff, we ensure that a waiter only waits for a maximum amount of time. To ensure this behavior, SynCord disables the custom logic for the respective APIs if the thread is suffering from starvation. We currently set the bounded time to 10 ms.

Correct lock patching. If a user provides the correct code, SynCord must address three issues: 1) only patch the required code, 2) apply the patch when the system is in a quiescence state to avoid any inconsistency, and 3) resolve the lock patch if multiple conflicting policies exist. We address these issues by using the mature patching service in Linux: `Livepatch` [32], which works as follows. `Livepatch` first generates a difference between the changed code. It then compiles the diff as a kernel module. Now, `Livepatch` inserts the module once the system reaches a quiescent state, *i.e.*, when a thread leaves the kernel space or CPUs are in idle mode.

In the case of SynCord, `Livepatch` can fail to insert the code if a user patches the same lock instances with multiple policies. We address this issue as follows: Before applying a patch, SynCord checks for an existing patch on the lock. If so, it aborts and reports the conflict to the system administrator. We also support re-patching the same locking call site by bypassing the previous check. Thus, SynCord provides the flexibility to resolve patch conflicts. For example, the user can completely override the old patch with the new one. Alternatively, they can develop and apply a new patch by manually merging those two patches.

4 SynCord Implementation

We now discuss the implementation of SynCord. First we present a summary of SynCord's implementation and then the two existing mature Linux kernel tools SynCord builds upon: eBPF (§4.1) and `Livepatch` (§4.2).

The current SynCord prototype targets non-blocking locks and supports both exclusive locks (*e.g.*, spinlocks) and readers-writer locks. For spinlocks, we implemented SynCord with the stock Linux spinlock, CNA [19] and ShflLock [37]. For readers-writer locks, we implemented SynCord with the readers-writer locks in ShflLock and the Linux kernel. Our current prototype uses Linux v5.4.

SynCord requires a one-time kernel modification to expose APIs (§3.2.1), extra eBPF helper functions, and runtime checks. Exposing the current SynCord APIs is relatively straightforward. Except for the waiter reordering APIs, we exposed all the other APIs by inserting a dummy function. We expose the waiter reordering for ShflLock and CNA in the form of a comparison function and also support the case for skipping the comparison with the `skip_reorder()` function. In total, we modify 143 lines of code in the Linux kernel. Our code is publicly available at https://github.com/rs3lab/SynCord.

4.1 eBPF for SynCord

eBPF allows applications to run custom code at specific points in the kernel (called hook points or target points). To use eBPF, a user first writes a program in C and compiles it into the eBPF bytecode. The kernel then loads the bytecode, verifies the memory safety, and then deploys it at the specified hook points. The eBPF verifier uses static analysis to check any illegal memory access in the program and also

verifies if the program terminates. To guarantee the termination of a program, the verifier only allows bounded loops [65] and rejects unreachable instructions or out-of-bound jumps. eBPF further tries to ensure safety by only whitelisting a set of safe functions (called helper functions), so that applications can obtain system state, such as the current time, CPU ID, etc. SynCord exploits the eBPF safety guarantees to enforce several safety requirements (§3.3).

Several lock algorithms require threads to spin until they satisfy a set of specific conditions. However, the eBPF verifier does not allow loops since it cannot guarantee termination. To address this issue, SynCord introduces a new eBPF helper function: `backoff()`. With this helper function, a thread terminates its spinning either by meeting the defined condition or the specified time is over. SynCord further sets an upper limit on the timeout value (10 ms) to avoid starvation. We designed `backoff()` as an eBPF helper function so users can use these functions in any SynCord APIs.

4.2 Kernel livepatching for SynCord

Kernel livepatch [32, 56, 60, 66] modifies the kernel on the fly without rebooting the system. While eBPF alone can deploy user-defined code into the kernel (§4.1), the effect is global and thus affects all the lock instances in the kernel. To support a finer deployment granularity (§3) and auxiliary data structures (§3.2.2), SynCord uses `Livepatch`, specifically `Kpatch` [60] to deploy the custom code.

Implementing auxiliary data structures. We expose three types of auxiliary data structures: per-node data, per-lock data, and global data. Per-node data stores additional information when a thread joins a waiting queue in a queue-based lock design. Currently, the per-node data is 16 bytes but it is aligned at a cache-line boundary (64 bytes) to avoid false sharing. Thus, SynCord uses the remaining 48 bytes to store extra information. Presently, the current spinlock size is fixed at 4 bytes, and modifying the lock itself increases the memory footprint of any lock instance. Hence, for per-lock data, we use shadow variables [40] to allocate extra memory only for the target lock instances. In particular, we store the auxiliary data inside an in-kernel key-value store created by Livepatch. The address of a target lock instance serves as the key, while the value is per-lock auxiliary data. In addition to the per-lock data, global data such as per-CPU data can be also stored in that key-value store. SynCord frees the extra memory allocated as shadow variables when it removes the corresponding policy. In other words, SynCord does not modify the structure of the lock itself, instead it stores the additional per-lock data separately from the parent lock object. Hence, our design choice does not increase the memory footprint of all locks in the kernel. SynCord only allocates memory for the target locks, thereby having no additional memory footprint without an installed policy.

Workload	Lock: Usage
MWRL [52]	**rename_lock:** Rename files within a directory
lock1 [7]	**files_struct.file_lock:** fcntl and fd allocation
page_fault1 [7]	**mmap_sem:** Anonymous memory page-fault
LevelDB [25]	**futex** contention on futex hash bucket
Metis (wrmem) [48]	reader side of **mmap_sem** on page-fault
SCL-Victim [58]	**rename_lock:** Rename files from/to an empty directory
SCL-Bully [58]	**rename_lock:** Rename files from an empty directory to a directory with 1M files

Table 2: Lock usage in each benchmark.

```
# per-node auxiliary data structures
class node:
  ...
+ int socket_id # Store socket ID for the thread

def lock_enable_fastpath(lock): # Allow lock stealing
  return True

def lock_to_enter_slowpath(lock, node):
  node.socket_id = get_numa_id() # Record socket ID for waiter

# Return true if anchor and curr are in the same socket
# Applicable to both ShflLock and CNA
def should_reorder(lock, anchor, curr):
  return anchor.socket_id == curr.socket_id

# randomly skip reordering to pass the lock to another socket
def skip_reorder(lock, anchor):
  return random() & 0xffff
```

5 Use Cases

We discuss the design and evaluation of various use cases enabled by SynCord. We first cover lock scheduling algorithms that manipulate the ordering of the lock acquisition. SynCord provides the means to define a custom lock acquisition order either by reordering the waiting queue or by blocking specific threads from joining the queue. We classify the lock scheduling algorithms into two types: (1) acquisition-aware scheduling, which considers the characteristics of lock waiters to enter the critical section, such as NUMA-awareness (§5.1) or biased readers-writer (§5.4); (2) occupancy-aware scheduling, which involves scheduling based on the time a thread spends in the critical section (§5.2, §5.3). The second use case focuses on customized fine-grained profiling (§5.5). Finally, we discuss our experience of using SynCord to implement these use cases (§5.6). Note that every lock implemented with SynCord is marked with "⋆" in figures. "-static" represents Linux kernel compiled with a static implementation of the equivalent locking strategy.

Experimental setup. We evaluate SynCord on an 8-socket, 224-core machine equipped with Intel Xeon Platinum 8276L CPUs. The machine runs Ubuntu 20.04 with Linux kernel 5.4.0 with disabled hyperthreading. Table 2 lists the benchmarks we use for the evaluation.

5.1 NUMA-aware spinlock

Motivation. Modern servers have non-uniform memory access (NUMA) architectures, with multiple sockets, multi-

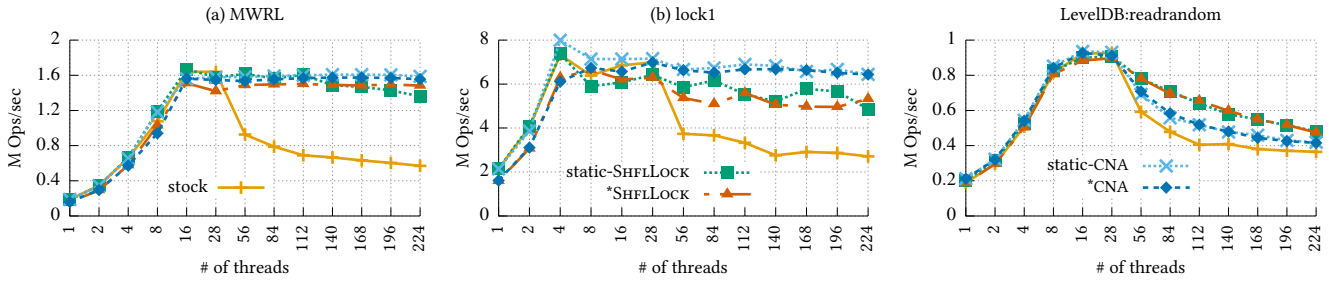

Figure 5: Comparison between kernel locks (stock, ShflLock, CNA) and their SynCord equivalent for NUMA-aware scenario.

ple cores, locally attached memories, and shared last-level caches. In such a server, accessing local memory is faster than accessing remote NUMA memory [21, 62]. NUMA-aware locks improve application throughput by batching lock acquisitions from the same socket together [19, 37].

Design. SynCord adopts the dynamic reordering mechanism for NUMA-aware locking from ShflLock and CNA, and batches requests from the same socket. NUMA locks ensure long-term fairness by periodically passing the lock to another socket. Figure 4 shows the implementation of this algorithm with SynCord. We add a per-node auxiliary integer: `socket_id` to record the socket ID of each waiting thread (line 4). The pseudocode denotes it inside `Class`, while the actual implementation is the `struct` of C code. We also enabled the fast path (lines 6–7) for lock stealing. If the fast path fails, the waiter enters the slow path after recording the socket ID (lines 9–10). The reordering process occurs in the slow path, and the underlying lock decides a reordering strategy. For example, in the case of ShflLock, the shuffler (`S`) first checks whether it should skip reordering by invoking the `skip_reorder` (lines 18–19) API. If not, `S` iterates the queue starting from itself; it invokes `should_reorder` (lines 14–15) with itself being the `anchor` and a waiting thread as `curr`. For all the waiting threads that make `should_reorder` return true, `S` moves that waiter forward, which groups waiters from the same socket. If `skip_reorder` returns true, `S` assigns the next waiter as the new shuffler, which ensures long-term fairness. The CNA lock also applies the same approach of grouping, but with a queue-splitting mechanism.

Evaluation. Figure 5 compares the stock version and two versions of ShflLock and CNA. The first is a static implementation requiring kernel re-install and reboot, while the other is the SynCord-based (marked $*$). Since ShflLock and CNA have a NUMA-aware policy on default, the evaluation shows how much overhead is introduced by SynCord's dynamic approach compared to the static implementation of the identical policy. We evaluate two microbenchmarks that contend on a single lock, and LevelDB's readrandom, which contends on the lock guarding the `futex` bucket. We find that the SynCord-based locks enforce a NUMA-aware policy on the fly without any significant overhead. Their performance is similar to their static counterparts and outperforms the stock version present in the Linux kernel, without having to compile or reboot the kernel. LevelDB's performance drops can be attributed to its use of a global database lock, which is not NUMA-aware.

5.2 Asymmetric multicore lock

Motivation. Asymmetric multicore processors (AMP) [4, 5, 16] consist of heterogeneous cores with different computing powers: energy-efficient slow cores and power-hungry fast cores. By combining both fast and slow cores in one processor, an AMP machine can adjust for dynamic usage patterns, for example, utilizing all cores to maximize the performance or using only slow cores for better energy-efficiency. Moreover, an AMP-aware scheduler can place low computation tasks on slow cores and place compute-intensive tasks on the fast ones. Unfortunately, current lock designs are unsuitable for the AMP architecture, as most lock designs assume homogeneous cores [41]. In particular, their performance significantly degrades when running on an AMP machine. This happens because slow cores execute critical sections up to 4× slower than faster cores [4], leading to lower throughput and higher latency [41]. Moreover, no lock design works efficiently for a multi-socket NUMA server, each has AMP.

Design. Our design is inspired by the LibASL [41], an AMP-aware user space lock without NUMA-awareness. Taking a step further, we extend LibASL's design for future AMP NUMA machines. LibASL works as follows: During a low contention scenario, it allows both slow cores and fast cores to acquire the lock to maximize performance. Meanwhile, during high contention, it penalizes slow cores so that fast cores can acquire the lock more aggressively for better performance. We slightly depart from LibASL with regards to penalty. In particular, we penalize slow core threads by forcing them to wait for a maximum of fixed time (10ms) before acquiring the lock. Providing appropriate wait time prevents starvation and ensures acceptable latency for workloads running on slow cores.

Figure 6 shows our version of the AMP-aware lock implemented using SynCord APIs. We use `MAX_WAIT_TIME` (line 2) as the maximum wait time for threads running on slow cores, and per-node socket ID (line 6) is used for NUMA-awareness.

```
1  class global_aux: # Global auxilary data structure
2  + int MAX_WAIT_TIME = 10ms # Max backoff for the slow core
3
4  class node: # Per-node auxiliary data structures
5    ...
6  + int socket_id # Store socket ID for the thread
7
8  def lock_enable_fastpath(lock): # Allow lock stealing
9    return True
10
11 def is_lock_unlocked(lock):
12   return lock.val == UNLOCK # Check if the lock is unlocked
13
14 def lock_to_enter_slowpath(lock, node):
15   node.socket_id = get_numa_id() # Record socket ID for waiter
16   cpu = get_processor_id() # Get the CPU ID of the thread
17
18   # Fast core thread directly enters; the slow one joins if:
19   #   1. the lock is not held or
20   #   2. it has been waiting for a predefined time
21   if is_slow_core(cpu):
22     backoff(lock, MAX_WAIT_TIME, is_lock_unlocked)
23
24 # Group same socket thread together
25 def should_reorder(lock, anchor, curr):
26   return anchor.socket_id == curr.socket_id
27
28 def skip_reorder(lock, anchor):
29   return rand() & 0xffff # Skip reordering to avoid starvation
```

Figure 6: AMP algorithm pseudocode with SynCord.

Similar to ShflLock, we allow lock stealing in the fast path (lines 8–9). On failing the fast path, the waiter assigns itself a socket ID (line 15) and checks its core type (line 21). If the waiter runs on a fast core, it immediately enters the slow path and joins the waiting queue. Otherwise, the waiter needs to wait before joining the waiting queue using the `backoff` function (lines 21-22). The thread on the slow core spins either until the `MAX_WAIT_TIME` has elapsed or if the lock has been released (lines 11–12). After returning from the `backoff` function, the waiter finally enters the slow path and joins the waiting queue. Once a thread enters the slow path, it follows a similar strategy as that of the NUMA lock for queue reordering and skipping. Thus, our NUMA-aware AMP lock prioritizes threads on fast cores before joining the queue, and further prefers the thread from the same socket after entering the queue. On the other hand, slow cores do acquire the lock after spinning for a predefined time (10ms). With the time-bound spinning, our approach prevents starvation while boosting application throughput.

Evaluation. Since there is no NUMA-AMP machine, we emulate the AMP environment by changing the CPU frequency. The fast cores are 4× faster than the slow cores and each socket has 14 fast and 14 slow cores, respectively. We use the same workloads as before (§5.1) and compare stock, ShflLock, and AMP. AMP is implemented statically (static-AMP) and using SynCord (*AMP) to compare the overhead coming from SynCord. Figure 7 shows that AMP outperforms both ShflLock and stock by 1.5x and 13.4x each and maintains the performance with increasing core count. To dig deeper, we measure the throughput of fast and slow cores separately. We find that all three locks have similar throughput under low contention (eight threads) for all workloads. This happens because all three locks are able to steal locks during the fast path. However, when the contention becomes high, both stock and ShflLock allow slow cores to acquire the lock, leading to lower throughput. On the other hand, AMP lets fast cores acquire the lock most of the time and thus achieves higher throughput.

5.3 Scheduler-cooperative lock

Motivation. Patel *et al.* [58] described the *scheduler subversion* problem, in which competitive threads hold the same lock for varying times, leading to a subversion of CPU scheduling goals. In particular, current CPU schedulers let each thread have an equal share of the CPU time. Suppose two threads are spending most of their CPU time executing in a critical section protected by the same lock; one thread (the bully thread) holds the lock for a much longer time (*e.g.*, orders of magnitude longer) than the other (the victim thread). In this case, the bully thread essentially receives a much longer CPU time than the victim thread, subverting the scheduling goal. This can lead to pathological cases of denial of service attacks, and lower application performance [58].

Design. To address this problem, we implement a new lock algorithm, that strives to achieve fair hold time across threads: SCL. SCL utilizes ShflLock as the underlying kernel lock and uses SynCord APIs. The algorithm assumes that all threads have the same priority and receive the same CPU time. The algorithm tracks the time spent in the critical section for each thread. If one thread holds the lock longer than its share, it cannot acquire the lock until other threads have received an equal chance to acquire the lock. On top of SCL, we also implement a NUMA-aware version: NUMA-SCL.

Figure 8 presents the implementation of SCL. We have not included the NUMA part for brevity, which is similar to §5.1. We introduce several auxiliary data structures to implement this algorithm: a per-thread lock hold time variable (line 3), a per-thread variable for recording the beginning of the critical section (line 5), a per-lock integer for counting contending thread (line 9), and total hold time for each lock (line 10). The algorithm works as follows: Before a thread (`t`) joins the waiting queue, it first computes the lock quota based on the number of threads and overall lock holding time (line 14). Based on the time `t` spent in the critical section (line 15), it waits until other threads get the equal opportunity (lines 15–20) by backing off for that approximated time (line 20). We track the per-lock total lock hold time and per-thread lock hold time by tracking when the thread enters the critical section (line 23) and update the overall lock usage in the release phase (lines 26–31).

Evaluation. We evaluate five locks with a workload proposed by Patel *et al.* [58]. The workload creates two types of threads: victim threads and bully threads that contend on the `rename_lock`. Table 2 shows the configuration of the work-

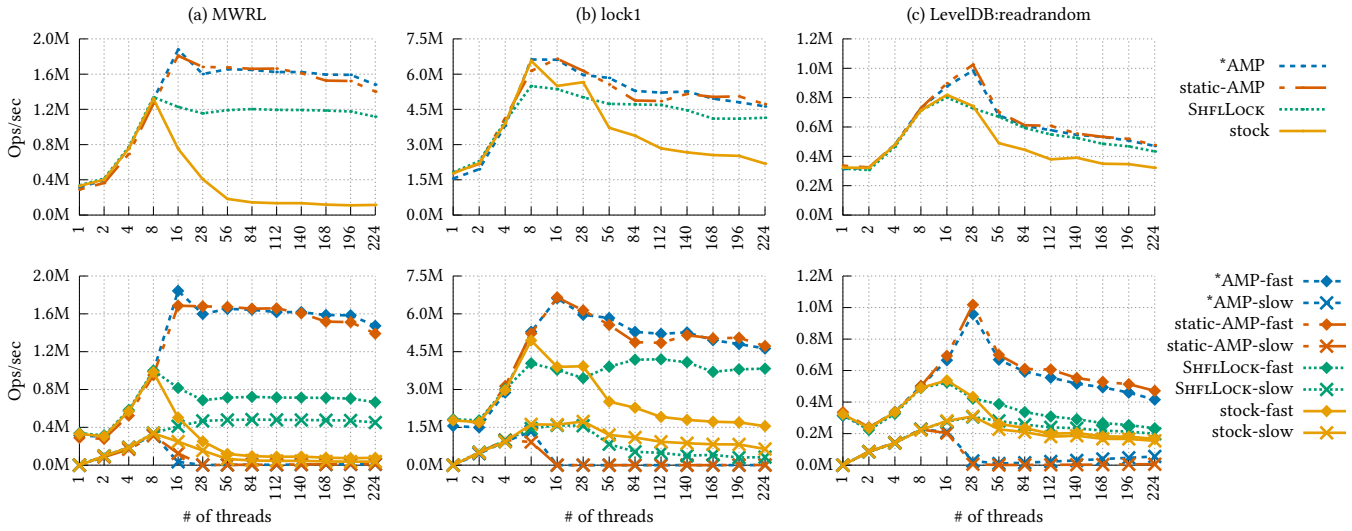

Figure 7: Overall throughput (up) and the throughput of fast and slow cores (down) for stock, ShflLock, and AMP implemented statically (static-AMP) and with SynCord (*AMP). Throughput of AMP-slow after 28 threads is very low but not zero. Refer to Table 4 for details.

```
class global_aux: # Global auxiliary data structures
    # Per-thread variable to record the lock hold time
+   int lock_hold_time<thread>
    # Per-thread variable to timestamp the beginning of CS
+   int cs_beg_ts<thread>

class lock: # Per-lock auxiliary data structures
    ...
+   int num_threads # Threads contending for the lock
+   int tot_lock_hold_time # Total lock hold time of all threads

def lock_to_enter_slowpath(lock, node):
    # Calculate the lock hold quota
    quota = lock.tot_lock_hold_time / lock.num_threads
    if lock_hold_time[curr_thread] > quota:
        # Exceeded local quota. Wait until threads
        # use same amount of quota
        wait = (lock_hold_time[curr_thread] * lock.num_threads)
        wait -= lock.tot_lock_hold_time
        backoff(lock, wait, None)

def lock_acquired(lock):
    cs_beg_ts[curr_thread] = get_time() # get timestamp after acq

def lock_to_release(lock):
    # Calculate the length of the critical section
    cs_len = get_time() - cs_beg_ts[curr_thread]

    # Update the lock usage for this thread and the lock
    lock_hold_time[curr_thread] += cs_len
    lock.tot_lock_hold_time += cs_len
```

Figure 8: Pseudocode of NUMA-SCL with SynCord. We omit the NUMA-awareness code (refer to Figure 4).

load, in which the bully holds the lock up to three orders of higher magnitude than the victim. These five locks include Linux's stock, ShflLock, static-SCL [58], *SCL (SCL without NUMA) and *NUMA-SCL. We implement the last two SCL locks with SynCord. Figure 9 shows the overall throughput and Jain's fairness index [31] of these locks. Jain's fairness

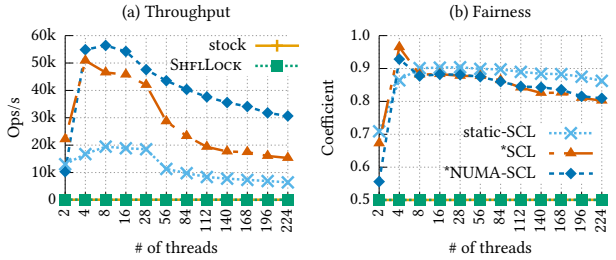

Figure 9: Impact of different lock designs on throughput and fairness. The workload is a rename program contending on rename lock where bully threads hold lock much longer than victim threads. Refer to Table 2 for more details.

index ranges from zero to one, where zero and one indicate completely unfair and fair, respectively. Since the SCL policy ensures that each thread holds the lock for the same length, all SCL versions allow the victim threads to hold the lock much more often than the bully threads. As a result, SCL implementations achieve orders of magnitudes higher throughput than both stock and ShflLock. Moreover, *NUMA-SCL outperforms the non-NUMA version (*SCL) by minimizing cache-line bouncing, thereby having the best overall throughput. The static implementation of SCL performs worse than SynCord versions, as it requires periodic scanning of the thread lists to remove inactive waiters. Such an approach is not required for SCL locks with SynCord because the user can dynamically decide the timeframe to enforce the lock hold time fairness.

We further confirm the aggregated lock hold time of bullies and victims. Figure 10 shows that a bully thread holds the lock

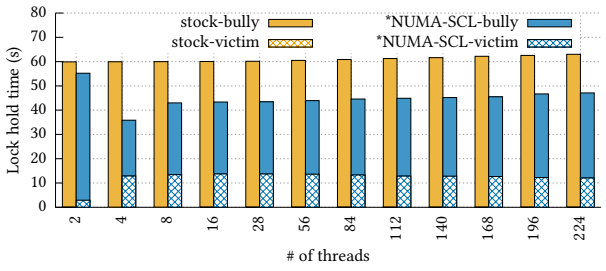

Figure 10: Total lock hold time of bully (B) and victim (V) threads.

for more than 99.9% in the stock version while *NUMA-SCL ensures a better share between bully and victim.

5.4 Biased per-cpu readers-writer lock

This section shows the use of SynCord lock bypass APIs.

Motivation. Readers-writer lock (`rwlock`) is one of the most widely used primitives in Linux [37]. This primitive allows either multiple readers or one writer to acquire a lock. Most `rwlock` designs track active readers with a centralized readers indicator. However, the centralized readers indicator has poor scalability (Figure 1) because frequent atomic instructions for readers result in cache-line invalidation and coherence traffic. Prior work addressed this issue using distributed counters, but with the cost of high memory usage and longer writer latency. Thus, it is a good candidate only for read-intensive workloads [18, 42].

Design. We design a distributed readers-writer lock using the SynCord bypass APIs. Our design is inspired by the `BRAVO` design [18]. With SynCord's dynamic approach, users can enable the distributed `rwlock` only when needed and disable it to avoid unnecessary overhead, such as memory footprint and writer latency. Note that SynCord cannot ensure the mutual exclusion property for the unsafe APIs, and it is up to the lock developers to ensure the correctness. Moreover, we also use another unsafe function (`backoff_unsafe`) that waits indefinitely until the condition is met. We forbid the user from using this unsafe function with our safe APIs, as we throw an error on detecting it.

Figure 11 shows the per-CPU `rwlock` implementation in SynCord. We add two more fields per lock: `rbias` to track the read bias mode, and `visible_readers` table with cache-line aligned entries. Before a reader (`R`) acquires a lock, it first checks the read-biased mode. If the read-biased mode is set, `R` marks itself as an active reader (lines 7–9) and checks the `rbias` again due to a possible race from the writer's side (line 33). If `rbias` is still set, `R` bypasses the underlying lock, else it falls back to the underlying implementation (lines 11–13). At the time of release, `R` checks whether it acquired the lock in the read-biased mode (lines 16–20), and bypasses the underlying lock release if so. `R` is also responsible for setting `rbias` once it acquires the underlying lock without

```
1  class lock: # Per-lock auxiliary data structures
2    ...
3  + int rbias # When set, the lock is on readers-biased mode
4  + int visible_readers[max_cpu] # Distributed read indicator
5  # === Reader ===
6  def lock_bypass_acquire(lock):
7    if lock.aux.rbias: # If in read biased
8      lock.aux.visible_readers[cpu] = 1 # Mark the reader
9      if lock.aux.rbias: # No writer is waiting
10       return True
11     else: # Writer is present
12       lock.aux.visible_readers[cpu] = 0
13   return False
14
15 def lock_bypass_release(lock):
16   # Bypass the lock if reader acquired in rbias mode
17   if lock.aux.visible_readers[cpu] == 1:
18         lock.aux.visible_readers[cpu] = 0
19       return True
20   return False
21
22 def lock_acquired(lock):
23   # Enter the read-biased mode
24   if not lock.aux.rbias:
25     lock.aux.rbias = True
26
27 # === Writer ===
28 def wait_for_reader(lock, cpu):
29   return lock.aux.visible_readers[cpu] == 0
30
31 def lock_acquired(lock):
32   if lock.aux.rbias:
33     lock.aux.rbias = False # Revoke bias
34     for i in range(0, NUM_CPU): # Wait for readers to leave
35       backoff_unsafe(lock, wait_for_reader(i))
```

Figure 11: Pseudocode of the `BRAVO` algorithm. We omit the code to get CPU ID for brevity.

bypassing it (lines 24-25) so that other readers can directly acquire the read lock by setting their respective indicators. In the case of writer acquisition, a writer (`W`) first acquires the underlying writer lock. `W` will only acquire the lock when there are no active readers that hold the underlying lock. After that, `W` further checks for the read-biased mode (line 32). If it is active, `W` first disables it and waits for all readers to exit the critical section that used the per-CPU indicator (lines 34–35).

Evaluation. Figure 12 compares the stock `rwlock` with our version using SynCord (*per-CPU `rwlock`). We evaluate these locks with a `page_fault1` microbenchmark from `will-it-scale` [7] and Metis [48], a MapReduce framework, contending on the reader side of `mmap_sem`. Figure 12 shows that *per-CPU `rwlock` outperforms stock by 2.2x and maintains the performance with increasing core count.

5.5 Dynamic lock profiling

Motivation. Several works [8, 19, 35, 37, 52] have shown that kernel locks mostly determine the scalability of applications. Hence, lock profiling tools are critical to understanding a lock's performance. Unfortunately, only few tools exist for kernel lock profiling, and even those have limited analysis capability. For example, developers often use Linux perf [1] to measure the aggregated CPU cycles in each code region. While this is useful to find lock contention, it does not pro-

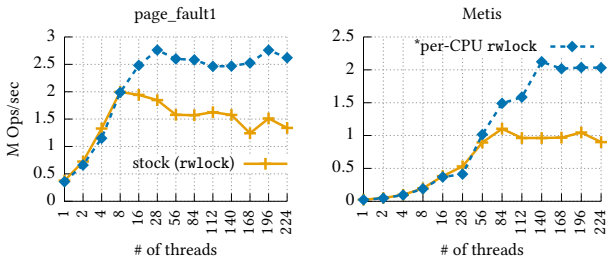

Figure 12: Comparison between Linux `rwlock` and our distributed per-CPU `rwlock` with SynCord. Refer to Table 2 for workload details.

policy	acquisitions	x-socket	avg-batch	violation
SCL+Reorder$_{Bully}$	4042	277	14.59	1659
SCL+Backoff$_{Bully}$	918765	8678	105.87	538

Table 3: Statistics collected by SynCord to analyze our two different implementations of NUMA-SCL: SCL+Reorder$_{Bully}$ and SCL+Backoff$_{Bully}$. We collect this result from the same benchmark used in §5.3 with 224 threads.

vide any lock-specific performance stats, such as the time spent in the critical section. As a result, Linux perf is not always the right tool for understanding lock performance. On the other hand, Linux provides another tool: `lockstat` [73] which exposes various statistics of kernel locks. However, it profiles all the kernel locks together and only shows the system-wide statistics. Moreover, a user can neither choose the lock instance nor specific lock data to profile. To make matter worse, `lockstat` requires a kernel to be compiled with a specific configuration, which significantly increases the size of every lock data structure and introduce performance overhead. For example, a kernel with `lockstat` uses 423MB of extra memory over the stock version even from the booting.

Design. SynCord can patch locks at various granularities, from an individual lock instance to a set of locks. In addition, SynCord provides the ability to profile any lock instance with arbitrary lock-specific performance stats. In particular, a user can now customize which set of lock instances to profile with specific statistics (even the algorithm-specific ones). For example, a user can profile only the rename lock and count the number of lock acquisitions across socket instead of collecting a set of statistics for all the locks in the kernel. We reproduce the statistics provided by `lockstat` using SynCord. Since the hooking points of SynCord General APIs (Table 1) have the same context as those of lockstat, the implementation is straightforward with simple updates of the counters and timestamp in each API.

Evaluation. We compare the overhead of lock profiling between `lockstat` and SynCord. `lockstat` keeps track of 10 counters for each lock. We implement two versions of SynCord-based `lockstat` having identical 10 counters and

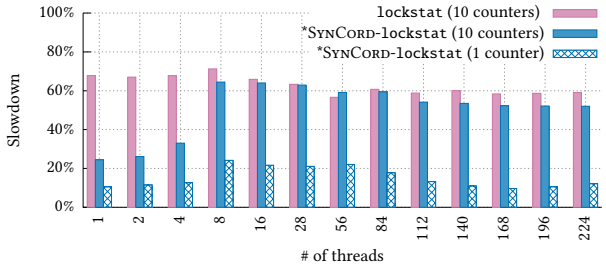

Figure 13: Performance overhead of lock profiling in MWRL for both `lockstat` and our custom implementation of `lockstat` with SynCord. The overhead increases with increasing counters.

policy	# threads	acqst-fast	acqst-slow
AMP+Reorder$_{Fast}$	8	20,340,943	8,192,987
AMP+Backoff$_{Slow}$	8	24,825,644	5,267,531
AMP+Reorder$_{Fast}$	224	571,712	571,354
AMP+Backoff$_{Slow}$	224	37,937,529	54,941

Table 4: Statistics collected by SynCord to analyze our two different implementations of AMP: AMP+Reorder$_{Fast}$ and AMP+Backoff$_{Slow}$. We collect the result for MWRL with the same environment as in §5.2.

one counter. Figure 13 shows that `lockstat` constantly incurs a 60% application slowdown. We observe that the overhead of SynCord profiling increases with an increased number of counters. With 10 counters, SynCord profiler incurs a similar overhead as that of conventional `lockstat`, while it is only 24% for one counter. Furthermore, unlike `lockstat`, SynCord opens the door for lock profiling even on production servers, as SynCord can dynamically turn on the profiling feature and does not introduce overhead when the profiling is uninstalled.

Simplifying performance analysis. We now illustrate an example of how SynCord's custom profiling can significantly simplify the performance analysis. Our initial implementation of the AMP (§5.2) and SCL (§5.3) algorithms only utilized the reordering mechanism of CNA and ShflLock (§5.1). In particular, we only used the `should_reorder` API to enforce both NUMA-awareness to handle hardware characteristics and SCL and AMP algorithms for software requirements. However, the reordering API alone has limitations in strictly enforcing the policy, thus it is difficult to have desired performance as the number of threads increases.

To understand the NUMA-SCL algorithm, we collect the following statistics for the reordering-based algorithm (SCL+Reorder$_{Bully}$), and the current algorithm-based on bully backoff with NUMA-aware reordering (SCL+Backoff$_{Bully}$): the total number of lock acquisitions, the number of lock acquisitions across socket, the average times of lock passing within a socket, and the number of policy violations (a bully

thread acquires the lock when it shouldn't). Table 3 shows that SCL+Reorder$_{Bully}$ fails to enforce the policy, leading to a high violation count. This happens because the reordering approach guarantees that a waiter will acquire the lock once it is part of the waiting queue. Thus, a bully can still grab the lock even though it is penalized, if a victim has not yet joined the waiting queue. Instead, the backoff-based approach (SCL+Backoff$_{Bully}$) avoids this problem by preventing the bully thread from joining the wait queue, thereby effectively enforcing the policy.

Table 4 shows the collected statistics for AMP locks using two variations: AMP+Reorder$_{Fast}$ which uses reordering only to enforce both fast-core preference and same-socket preferences, and AMP+Backoff$_{Slow}$ shown in §5.2. We collect the number of lock acquisitions separately on the fast and slow cores. Under low contention (eight threads), both algorithms have similar throughput. However, under a highly contended scenario (224 threads), the reordering approach cannot correctly enforce the fast-core preference anymore, leading to a performance drop. The same reasoning from SCL holds true here too.

5.6 Experience with SynCord

Policy	LoC	Time
NUMA-aware spinlocks (§5.1)	6	3 hours
Scheduler-cooperative locks (§5.3)	30	18 hours
Asymmetric multicore-aware locks (§5.2)	15	8 hours
Scalable reader-writer locks (§5.4)	36	5 hours
Lock profiling (§5.5)	36	1 hour

Table 5: Development effort of the use cases.

We now discuss the efforts and lessons we have learned in developing the use cases with SynCord.

Lock development effort. Table 5 summarizes the development effort of all use cases. We spent most of the development time understanding, debugging, and testing the lock algorithm. Implementing the algorithms in SynCord involves only tens of lines of code and is relatively straightforward. In addition, SynCord allows users to modify the lock without kernel installation and rebooting, which dramatically reduces the overall development effort.

Hardware is (still) the key factor of performance. We include the NUMA grouping policy even for SCL and AMP algorithms to make them perform well on a NUMA machine. Initially we did not plan to include the NUMA grouping algorithm since we thought the performance gain achieved by task-specific scheduling should dominate. For example, due to the big performance gap between fast and slow cores in AMP machines, scheduling fast cores should achieve good enough performance without NUMA grouping. However, this has proven to not be the case. LibASL performs even worse than ShflLock on our emulated AMP NUMA machine due to the cache-line bouncing among sockets. Hence, we believe that a lock developer still needs to consider and prioritize the underlying hardware when designing a lock.

Avoid overloading APIs. As discussed in §5.5, our initial implementation of the SCL and AMP algorithms only used reordering mechanisms to enforce both customized policy and the NUMA-grouping algorithm. However, the profiling results show that complex policy in the reordering API does not work at a high thread count. The root cause of this issue is that the node reordering mechanism in ShflLock and CNA cannot strictly prevent certain nodes from acquiring a lock once they join the queue. Specifically, the reordering mechanism makes the scheduling decision as soon as it encounters the first suitable candidate, without considering whether a better candidate exists in the entire waiting queue. With the current lock implementation, we believe the best way to address this issue is to avoid overloading APIs. Specifically, a lock developer should not specify too complicated policies in one API and, if possible, divide the policies into small pieces and enforce each one of them with the suitable APIs. For example, in our AMP implementation, we enforced the NUMA grouping policy through reordering and the fast core scheduling policy when cores enter the wait queue.

6 Discussion

6.1 Generality of SynCord

SynCord's current implementation focuses on non-blocking locks, but the fundamental concept can be applied to other synchronization primitives, such as blocking locks (mutex) [55], RCU [50], seqlocks [27], and wait events [68]. SynCord can similarly modularize key decisions and behaviors of these synchronization primitives and expose them as APIs. For example, SynCord may expose the condition to wake up or park a thread as APIs for a blocking lock. Moreover, with *lock bypass* APIs, which grant privileged users complete control of the kernel lock, the implementation of kernel locks can even be moved to user space.

6.2 Support for multi-tenancy

The current SynCord prototype targets an environment where one user or a set of users trust each other to share the machine. In this scenario, SynCord can resolve patch conflicts (i.e., a lock instance is patched by multiple patches) by allowing a privileged user to provide a final patch (§3.3). However, this approach no longer works in a multi-tenancy cloud environment.

To extend SynCord to a multi-tenancy environment, we plan to apply the widely used *cgroup* and *namespace* concepts to kernel synchronization primitives. For example, a synchronization cgroup controls the set of kernel synchronization primitives that an application can change. A synchronization namespace virtualizes the underlying synchronization primitives. For example, for a shared kernel lock, a corresponding virtual lock is created in every synchronization namespace. The kernel implements an arbitration mechanism, such as

time-sharing, to decide which virtual lock can hold the physical lock. Hence, the synchronization namespace enables applications to modify synchronization primitives while still enforcing performance isolation. With this change, we can drop privilege for SynCord to each namespace instead of limiting it to system administrators.

6.3 Easier programming of lock policy

In the current SynCord prototype, a user needs to provide the entire code for each policy. For example, both AMP (§5.2) and SCL (§5.3) policies include NUMA grouping code to achieve better scalability. We can extend SynCord to compose multiple policies into one (*i.e.*, merge NUMA-grouping and AMP to get NUMA-aware AMP) unless there is a duplicate use of the API between policies.

SynCord currently only supports C to write customized lock code, but it can be further extended to support more languages. With several toolchains [24, 30, 64] that allow writing eBPF programs in languages other than C, SynCord can support more expressive and memory-safe languages such as Python or Rust with better libraries and ecosystems.

6.4 Patching time

With our environment, the patching time is typically 10-40ms, and at a maximum of 5 seconds in an extreme case: patching every spinlock in the kernel. Livepatch applies the patch by checking each thread's stack whether the thread has invoked any patched functions. If so, Livepatch waits until all threads exit the patched function. One of the reasons for long patching time derives from a few tasks blocking the completion of a patching operation. The five-second patching time looks unreasonably long to us and further reducing the patching time is possible by sending a fake signal to the remaining blocking tasks.

7 Related Work

In section §2.2, we covered several works that customize kernel from user space. While SynCord is the first work to expose the concurrency control to user space, the need for different locking designs depending on hardware or software requirements has been also discussed in previous works.

Dice and Kogan [18] presented the `BRAVO` lock which can dynamically switch between a centralized reader-writer lock and a lock using distributed reader indicators. When the `BRAVO` algorithm detects a *read-biased* workload pattern, it improves scalability between readers by using distributed reader indicators, but at a cost of a potential slow down when released from the read-biased mode. This clear trade-off shows that the logic to turn on the read-biased mode is critical to performance, but `BRAVO` relies on heuristic parameters because it was impossible to change lock algorithms on the fly. Once ported to SynCord, when to turn on the read-biased mode can be an open problem for users.

Recently, Chehab *et al.* [17] proposed CLoF, which generates hundreds of possible combinations of spinlocks to create NUMA-aware hierarchy locks. CLoF first generates a set of locks and then selects the best performing lock for the target environment. The work emphasizes the need for different lock designs depending on the underlying hardware, which strengthens our motivation. Constructing and finding the best performing lock is an orthogonal topic to our work.

Lock profiling. Synchronization primitives play a significant role in application scalability, thus sophisticated lock profiling tools can help users understand the performance bottleneck. In addition to the `perf` [1] and `lockstat` [73] introduced in §5.5, there are several more works to improve lock profiling.

SyncPerf [3] hooks `pthread` related functions and provide a synchronization analysis tool with low overhead. Tallent *et al.* [67] used a sampling approach to quantify lock contention and SyncProf [71] collects profiling data through repetitive execution of an application to find the source of contention. Although these studies contributed to a better understanding of lock contention, all three works profile locks used in the user space, not the kernel locks.

LockDoc [43] traced the usage of kernel locks and automatically generates documentation describing the order in which each lock should be used. The work mainly focused on inferring locking rules instead of the performance aspect of each lock. wPerf [72] analyzes waiting events to find the source of a performance bottleneck, but does not provide lock-specific statistics.

8 Conclusion

Kernel synchronization primitives greatly impact application performance and scalability. However, the current kernel design prevents application developers from controlling the kernel synchronizations. This paper proposes *application-informed kernel synchronization primitives* which allow users to customize the kernel locks on the fly. To showcase the idea, we implemented SynCord, a framework for user-defined custom lock code. SynCord allows a privileged user to deploy custom code into the kernel lock safely and efficiently without recompiling or rebooting the kernel. We show that applications can leverage SynCord to achieve significant performance gains by developing hardware- or workload-specific lock algorithms. Furthermore, SynCord enables users to perform custom, fine-granularity lock profiling, which can greatly simplify the performance analysis of lock algorithms.

BlackBox: A Container Security Monitor for Protecting Containers on Untrusted Operating Systems

Alexander Van't Hof
Columbia University

Jason Nieh
Columbia University

Abstract

Containers are widely deployed to package, isolate, and multiplex applications on shared computing infrastructure, but rely on the operating system to enforce their security guarantees. This poses a significant security risk as large operating system codebases contain many vulnerabilities. We have created BlackBox, a new container architecture that provides fine-grain protection of application data confidentiality and integrity without trusting the operating system. BlackBox introduces a container security monitor, a small trusted computing base that creates protected physical address spaces (PPASes) for each container such that there is no direct information flow from container to operating system or other container PPASes. Indirect information flow can only happen through the monitor, which only copies data between container PPASes and the operating system as system call arguments, encrypting data as needed to protect interprocess communication through the operating system. Containerized applications do not need to be modified, can still make use of operating system services via system calls, yet their CPU and memory state are isolated and protected from other containers and the operating system. We have implemented BlackBox by leveraging Arm hardware virtualization support, using nested paging to enforce PPASes. The trusted computing base is a few thousand lines of code, many orders of magnitude less than Linux, yet supports widely-used Linux containers with only modest modifications to the Linux kernel. We show that BlackBox provides superior security guarantees over traditional hypervisor and container architectures with only modest performance overhead on real application workloads.

1 Introduction

Containers are widely deployed to package, isolate, and multiplex applications on shared computing infrastructure. They are increasingly used in lieu of hypervisor-based virtual machines (VMs) because of their faster startup time, lower resource footprint, and better I/O performance [6, 15, 26, 47]. Popular container mechanisms such as Linux containers rely on a commodity operating system (OS) to enforce their security guarantees. However, commodity OSes such as Linux are huge, complex, and imperfect pieces of software. Attackers that successfully exploit OS vulnerabilities may gain unfettered access to container data, compromising the confidentiality and integrity of containers—an undesirable outcome for both computing service providers and their users.

Modern systems incorporate hardware security mechanisms to protect applications from an untrusted OS, such as Intel Software Guard Extensions (SGX) [30] and Arm TrustZone [2], but they require rewriting applications and may impose high overhead to use OS services. Some approaches have built on these mechanisms to protect unmodified applications [7] or containers [3]. Unfortunately, they suffer from high overhead, incomplete and limited functionality, and massively increase the trusted computing base (TCB) through a library OS or runtime system, potentially trading one large vulnerable TCB for another.

As an alternative, hypervisors have been augmented with additional mechanisms to protect applications from an untrusted OS [11, 12, 27, 35, 67]. This incurs the performance overhead of hypervisor-based virtualization, which containers were designed to avoid. The TCB of these systems is significant, in some cases including an additional commodity host OS, providing additional vulnerabilities to exploit to compromise applications. Theoretically, these approaches could be applied to microhypervisors [10, 61] with smaller TCBs. Unfortunately, microhypervisors still inherit the complexity of hypervisor-based virtualization, including virtualizing and managing hardware resources. The reduction in TCB is achieved through a much reduced feature set and limited hardware support, making their deployment difficult in practice.

To address this problem, we have created BlackBox, a new container architecture that provides fine-grain protection of application data confidentiality and integrity without the need to trust the OS. BlackBox introduces a *container security monitor (CSM)*, a new mechanism that leverages existing hardware features to enforce container security guarantees in a small

trusted computing base (TCB) in lieu of the OS. The monitor creates protected physical address spaces (PPASes) for each container to enforce physical memory access controls, but provides no virtualization of hardware resources. Physical memory mapped to a container's PPAS is not accessible outside the PPAS, providing physical memory isolation among containers and the OS. Since container private data in physical memory only resides on pages in its own PPAS, its confidentiality and integrity is protected from the OS and other containers.

The CSM repurposes existing hardware virtualization support to run at a higher privilege level and create PPASes, but is itself not a hypervisor and does not virtualize hardware. Instead, the OS continues to access devices directly and remains responsible for allocating resources. This enables the CSM to be minimalistic and simple while remaining performant. By supporting containers directly without virtualization, no additional guest OS or complex runtime needs to run within the secured execution environment, minimizing the TCB within the container itself.

Applications running in BlackBox containers do not need to be modified and can make use of OS services via system calls, with the added benefit of their data being protected from the OS. The monitor interposes on all transitions between containers and the OS, clearing container private data in CPU registers and switching PPASes as needed. The only time in which any container data in memory is made available to the OS is as system call arguments, which only the monitor itself can provide by copying the arguments between container PPASes and the OS. The monitor is aware of system call semantics and encrypts system call arguments as needed before passing them to the OS, such as for interprocess communication between processes, protecting container private data in system call arguments from the OS. Given the growing use of end-to-end encryption for I/O security [55], in part due to the Snowden leaks [36], the monitor relies on applications to encrypt their own I/O data to simplify its design. Once a system call completes and before allowing a process to return to its container, the monitor checks the CPU state to authenticate the process before switching the CPU back to using the container's PPAS.

In addition to ensuring a container's CPU and memory state is not accessible outside the container, BlackBox protects against malicious code running inside containers. Only trusted binaries, which are signed and encrypted, can run in BlackBox containers. The monitor is required to decrypt the binaries, so they can only run within BlackBox containers with monitor supervision. The monitor authenticates the binaries before they can run, so untrusted binaries cannot run in BlackBox containers. It also guards against memory-related Iago attacks, attacks that maliciously manipulate virtual and physical memory mappings, that could induce arbitrary code execution in a process in a container by preventing virtual or physical memory allocations that could overwrite a process's stack.

We have implemented BlackBox on Arm hardware, given Arm's growing use in personal computers and cloud computing infrastructure along with its dominance on mobile and embedded systems. We leverage Arm hardware virtualization support by repurposing Arm's EL2 privilege level and nested paging, originally designed for running hypervisors, to enforce separation of PPASes. Unlike x86 root operation for running hypervisors, Arm EL2 has its own hardware system state. This minimizes the cost of trapping to the monitor running in EL2 when calling and returning from system calls because system state does not have to be saved and restored on each trap. We show that BlackBox can support widely-used Linux containers with only modest modifications to the Linux kernel, and inherits support for a broad range of Arm hardware from the OS. The implementation has a TCB of less than 5K lines of code plus a verified crypto library, orders of magnitude less than commodity OSes and hypervisors. With such a reduced size, the CSM is significantly easier for developers to maintain and ensure the correctness of than even just the core virtualization functionality of a hypervisor. We show that BlackBox can provide finer granularity and stronger security guarantees than traditional hypervisor and container architectures with only modest performance overhead for real application workloads.

2 Threat Model and Assumptions

Our threat model is primarily concerned with OS vulnerabilities that may be exploited to compromise the confidentiality or integrity of a container's private data. Attacks in scope include compromising the OS or any other software to read or modify private container memory or register state, including by controlling DMA-capable devices, or via memory remapping and aliasing attacks. We assume a container does not voluntarily reveal its own private data whether on purpose or by accident, but attacks from other compromised containers, including confidentiality and integrity attacks, are in scope. Availability attacks by a compromised OS are out of scope. Physical or side-channel attacks [5, 32, 43, 52, 68, 69] are beyond the scope of the paper. Opportunities for side-channel attacks are greater in BlackBox than in systems that isolate at a lower level, e.g. VMs. The trust boundary of BlackBox is that of the OS's system call API, enabling adversaries to see some details of OS interactions such as sizes and offsets.

We assume secure key storage is available, such as provided by a Trusted Platform Module (TPM) [31]. We assume the hardware is bug-free and the system is initially benign, allowing signatures and keys to be securely stored before the system is compromised. We assume containers use end-to-end encrypted channels to protect their I/O data [21, 37, 55]. We assume the CSM does not have any vulnerabilities and can thus be trusted; formally verifying its codebase is future work. We assume it is computationally infeasible to perform brute-force attacks on any encrypted container data, and any encrypted communication protocols are assumed to be designed to defend against replay attacks.

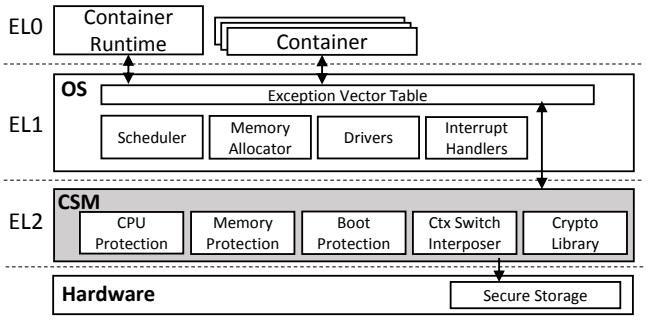

Figure 1: BlackBox Architecture

3 Design

BlackBox enclaves traditional Linux containers to protect the confidentiality and integrity of container data. We refer to a container as being enclaved if BlackBox protects it from the OS. From an application's perspective, using enclaved containers is little different from using traditional containers. Applications do not need to be modified to use enclaved containers and can make use of OS services via system calls. Container management solutions [48, 49] such as Docker [20] can be used to manage enclaved containers. BlackBox is designed to support commodity OSes, though minor OS modifications are needed to use its enclave mechanism, in much the same way that OS modifications are typically required to take advantage of new hardware features. However, BlackBox does not trust the OS and a compromised OS running enclaved containers cannot violate their data confidentiality and integrity.

BlackBox introduces a container security monitor (CSM), as depicted in Figure 1, which serves as its TCB. The CSM's only purpose is to protect the confidentiality and integrity of container data in use. It achieves this by performing two main functions, access control and validating OS operations. Its narrow purpose and functionality makes it possible to keep the CSM small and simple, avoiding the complexity of many other trusted system software components. For example, unlike a hypervisor, the CSM does not virtualize or manage hardware resources. It does not maintain virtual hardware such as virtual CPUs or devices, avoiding the need to emulate CPU instructions, interrupts, or devices. Instead, interrupts are delivered directly to the OS and devices are directly managed by the OS's existing drivers. It also does not do CPU scheduling or memory allocation, making no availability guarantees. The CSM can be kept small because it presumes the OS is CSM-aware and relies on the OS for complex functionality such as bootstrapping, CPU scheduling, memory management, file systems, and interrupt and device management.

To enclave containers, the CSM introduces the notion of a *protected physical address space (PPAS)*, an isolated set of physical memory pages accessible only to the assigned owner of the PPAS and the CSM. Each page of physical memory is mapped to at most one PPAS. The CSM uses this mechanism to provide memory access control by assigning a separate PPAS to each enclaved container, thereby isolating the physical memory of each container from the OS and any other container. The OS determines what memory is allocated to each PPAS, but cannot access the memory contents of a PPAS. Similarly, a container cannot access a PPAS that it does not own. Memory not assigned to a PPAS, or the CSM, is assigned to and accessible to the OS. The CSM itself can access any memory, including memory assigned to a PPAS. Within a PPAS, addresses for accessing memory are the same as the physical addresses on the machine; physical memory cannot be remapped to a different address in a PPAS. For example, if page number 5 of physical memory is assigned to a PPAS, it will be accessed as page number 5 from within the PPAS. Container private data in memory only resides on pages mapped to its own PPAS, therefore its confidentiality and integrity is protected from the OS and other containers. Section 4 describes how BlackBox uses nested page tables to enforce PPASes.

The CSM interposes on all transitions between containers and the OS, namely system calls, interrupts, and exceptions, so that it can ensure that processes and threads, which we collectively refer to as tasks, can only access the PPAS of the container to which they belong when executing within context of the container. The CSM ensures that when a task traps to the OS and switches to running OS kernel code, the task no longer has access to the container's PPAS. Otherwise, the OS could cause the task to access the container's private data, compromising its confidentiality or integrity. The CSM maintains an *enclaved task array*, an array with information for all tasks running in enclaved containers. When entering the OS, the CSM checks if the calling task is in an enclaved container, in which case it saves to the enclaved task array the CPU registers and the cause of the trap, switches out of the container's PPAS, and clears any CPU registers not needed by the OS. When exiting the OS, the CSM checks the enclaved task array if the running task belongs to an enclaved container, in which case it validates the current CPU context, namely the stack pointer and page table base register, match what was saved in the enclaved task array for the respective task. If they match, the CSM switches to the respective container's PPAS so the task can access its enclaved CPU and memory state. As a result, container private data in CPU registers or memory is not accessible to the OS.

To support OS functionality that traditionally requires access to a task's CPU state and memory, the CSM provides an application binary interface (ABI) for the OS to request services from the CSM. The CSM ABI is shown in Table 1. For example, `create_enclave` and `destroy_enclave` are called by the OS in response to requests from a container runtime, such as `runC` [29], to enclave and unenclave containers, respectively. For CSM calls that require dynamically allocated memory, the OS must allocate and pass in the physical address of a large enough region of contiguous memory to perform the respective operation. Otherwise, the call will fail and return the amount of memory required so that the OS can

CSM Call	Description
create_enclave	Create new enclave for a container.
destroy_enclave	Destroy enclave of a container.
protect_vectors	Validate OS exception vectors.
alloc_iopgtable	Allocate I/O device page table.
free_iopgtable	Free I/O device page table.
set_iopt	Update entry in I/O device page table.
get_ioaddr	Get physical address for I/O virtual address.
enter_os	Context switch CPU to OS.
exit_os	Context switch CPU from OS.
set_vma	Update virtual memory areas of a process/thread.
set_pt	Update page table entry of a process/thread.
copy_page	Copy contents of a page to a container.
task_clone	Run new process/thread in a container.
task_exec	Run in new address space in a container.
task_exit	Exit a process or thread in a container.
futex_read	Read the value of a futex in a container.

Table 1: BlackBox Container Security Monitor ABI

make the call again with the required allocation. For example, create_enclave requires the OS to allocate memory to be used for metadata for the enclaved container. Upon success, the allocated memory is assigned to the CSM and no longer accessible to the OS until destroy_enclave is called, at which point the memory is assigned back to the OS again.

3.1 System Boot and Initialization

BlackBox boots the CSM by relying on Unified Extensible Firmware Interface (UEFI) firmware and its signing infrastructure with a hardware root of trust. The CSM and OS kernel are linked as a single binary which is cryptographically signed, typically by a cloud provider running BlackBox containers; this is similar to how OS binaries are signed by vendors like Red Hat or Microsoft. The binary is first verified using keys already stored in secure storage, ensuring that only the signed binary can be loaded. To keep the CSM as simple as possible, BlackBox does not implement bootstrapping within the CSM itself, which can require thousands of lines of code to support many systems. Instead, it relies on the OS's bootstrapping code to install the CSM securely at boot time since the OS is initially benign. By relying on commodity OSes such as Linux that already boot on a wide range of systems, this makes it easier for the CSM to support many systems without the burden of manually maintaining and porting its own bootstrapping code for many systems.

At boot time, the OS initially has full control of the system to initialize hardware, and installs the CSM. CSM installation occurs before local storage, network and serial input services are available, so remote attackers cannot compromise its installation. Once installed, the CSM runs at a higher privilege level than the OS and subsequently enables PPASes as needed. A small amount of physical memory is statically assigned to the CSM, and the rest is assigned to the OS. Any attempt to access the CSM's memory except by the CSM itself will trap to the CSM and be rejected. Although the OS's memory is separate from the CSM's, the CSM can access the OS's memory and can restrict its from modifying its own memory if needed.

The CSM expects the hardware to include an IOMMU to protect against DMA attacks by devices managed by the OS [62]. The CSM retains control of the IOMMU and requires the OS to make CSM calls to update IOMMU page table mappings, which are typically configured by the OS during boot. This ensures that I/O devices can only access memory mapped into the IOMMU page tables managed by the CSM. The OS calls alloc_iopgtable during boot to allocate an IOMMU translation unit and its associated page table for a device, and set_iopt and to assign physical memory to the device to use for DMA. The CSM ensures that the OS can only assign its own physical memory to the IOMMU page tables, ensuring that DMA attacks cannot be used to compromise CSM or container memory.

3.2 Enclaved Container Initialization

To securely initialize an enclaved container, an image that is to be used for such a container must first be processed into a BlackBox container image, using a process similar to how Amazon enclaves are created using Docker images [1]. BlackBox provides a command line tool build_bb_image, which can be used by a cloud customer, that takes a Docker image, finds all executable binary files contained within the image, and encrypts the sections containing the code and data used by the code using the public key paired with a trusted private key stored in the secure storage of the host and accessible only by the CSM. These encrypted sections are then hashed and their hash values recorded along with the binaries they belong to. These values are then signed with the private key of the container image's creator whose paired public key is accessible in the secure storage of the host to ensure authenticity and bundled with the container image for later reference during process creation, as described in Section 3.3. This ensures the binaries cannot be modified without being detected, or run unless decrypted by the CSM. Other than additional hashes and using encrypted binaries, the BlackBox container image contains nothing different from a traditional Docker image.

To start a container using a BlackBox container image, the container runtime is modified to execute a simple shim process in place of the container's specified init process. The container runtime passes the shim the path of the init process used by the container along with any arguments and its environment. The shim is also given the signed binary hash information bundled with the container image. The shim process runs a tiny statically linked program that initiates a request to the OS to call the create_enclave CSM call before executing the original init process, passing the signed hash information to the CSM as part of the call. Other than the shim process, which exits upon executing the init process, there is no additional code that runs in a BlackBox container

beyond vanilla Linux containers. There are no additional libraries and no need for a library OS, avoiding the risks of bloating the TCB of the container itself.

`create_enclave` creates a new enclave using the BlackBox container image and returns with the calling process running in the enclaved container, the return value of the call being the new enclave's identifier. `create_enclave` performs the following steps. First, it creates a new PPAS for the container. Second, it freezes the userspace memory of the calling process so it, and its associated page tables, cannot be directly changed by the OS, then moves all of its pages of physical memory into the container's PPAS so that they are no longer accessible by the OS. Finally, it checks the contents of the loaded shim binary in memory against a known hash to validate the calling process is the expected shim process.

After returning from `create_enclave`, the shim executes the container's init process from within the container. Since the container's init process obtains its executable from the BlackBox container image whose code and data are encrypted, the OS may load it, but cannot actually execute it without the CSM using its private key to decrypt it. Further details on `exec` with encrypted binaries are described in Section 3.6. In this way, the OS is incapable of running a BlackBox container image without the CSM. Therefore, if it is running, the CSM must be involved and protecting it. Because the CSM itself is securely booted and enclave code is encrypted and only runnable by the CSM, an unbroken chain of trust is established enabling remote attestation similar to that of other security systems, such as Samsung Knox [56].

The container runtime calls `destroy_enclave` to remove the enclave of a container, which terminates all running processes and threads within the container to ensure that any container CPU state and memory is cleared and no longer accessible to the OS or any other container before removing the enclave. The container is effectively returned to the same state it was in before `create_enclave` was called.

3.3 Enclaved Task Execution

BlackBox supports the full lifecycle of tasks executing in enclaved containers, including their dynamic creation and termination via standard system calls such as `fork`, `clone`, `exec`, and `exit`. This includes tracking which tasks are allowed to execute in which containers. This is achieved by requiring the OS to call a set of CSM calls, `task_clone` on task creation via `fork` and `clone`, `task_exec` when loading a new address space via `exec`, and `task_exit` when a task exits via `exit`. These calls request the CSM to perform various functions related to task execution that the OS is not able to do because it does not have access to task CPU state and memory. If the OS does not make the respective CSM call, the created task and executed binary will simply not run in its enclave and therefore will not have access to its data. These calls update the enclaved task array, the index of which is used as the enclaved task identifier. Each entry in the array includes the enclave identifier of the container in which the task executes, as well as the address of the page table used by the task as discussed earlier.

When a task running in an enclaved container creates a child task via a system call, the OS calls `task_clone` with the enclaved task identifier of the calling task and a flag indicating whether the new task will share the same address space as the caller, as when creating a thread, or have its own copy of the address space of the caller, as when creating a process. In the latter case, new page tables will be allocated for the child task and the CSM will ensure that they match those of the caller's and cannot be directly modified by the OS. The CSM will also confirm that the calling task issued the task creation system call. If all checks pass, the CSM will create a new entry in the enclaved task array with the same enclave identifier as the calling process, and return the array index of the new entry as the identifier for the task. The entry will also contain the address of the task's page table, which will be the same as the caller's entry if it shares the same address space as the caller.

When the OS runs the child and the task returns from the OS, the OS provides the CSM with the enclaved task's identifier. The CSM then looks up the task in its enclaved task array using this identifier and confirms that the address of the page table stored in the entry matches the address stored in the page table base register of the CPU. If the checks pass, it will then restore CPU state and switch the CPU to the container's PPAS, thereby allowing the task to resume execution in the container. If the OS does not call `task_clone`, then upon exiting the OS, the task's PPAS would not be installed and it would fail to run.

On `exec`, the calling task will replace its existing address space with a new one. The OS calls `task_exec`, which, like `task_clone` for `fork`, creates a new enclaved task entry with a new address space. The difference is that the new address space is validated by ensuring that the new process' stack is set up as expected and the executable binary is signed and in the BlackBox container image, as described in Section 3.6. After creating the new enclaved task entry, the original address space is disassociated from the container, scrubbing any memory pages to be returned to the OS and removing them from the container's PPAS.

On `exit`, the OS will call `task_exit` so the CSM can remove the enclaved task entry from the enclaved task array. If an address space has no more tasks in the container, the CSM disassociates it in a similar manner to the `exec` case.

3.4 Memory

BlackBox prevents the OS from directly accessing a container's memory, but relies on the OS for memory management, including allocating memory to tasks in the container. This avoids introducing complex memory management code into BlackBox, keeping it small and simple, but means that BlackBox also needs to protect against memory-based Iago

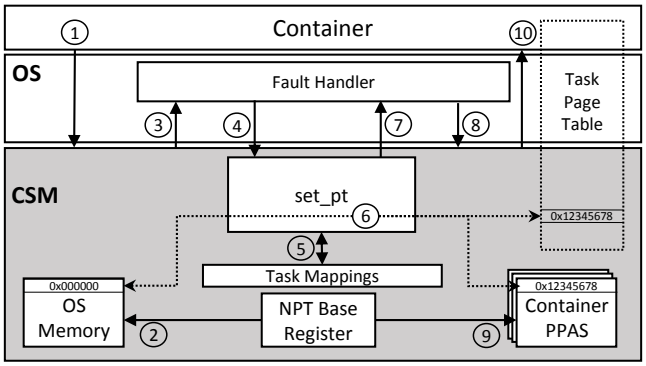

Figure 2: BlackBox Page Fault Workflow

attacks [9] by the untrusted OS through manipulation of system call return values. For example, if a process calls `mmap`, it expects to receive an address mapping that does not overlap with any of its existing mappings. If the OS were to return a value overlapping the process's stack, it could manipulate the process into overwriting a return address on its stack through a subsequent `read` with an attacker controlled address, opening the door for return-oriented-programming [53] and return-into-libc [58] attacks. Furthermore, the OS may return an innocuous looking non-overlapping virtual address from `mmap`, but still maliciously map the returned address to the physical page the stack is on.

To rely on the OS for memory management while preventing memory-based Iago attacks, BlackBox protects the container's memory at the application level by preventing the OS from directly updating per process page tables. It instead requires the OS to make requests to the CSM to update process page tables, allowing the CSM to reject updates if the OS behaves incorrectly. Figure 2 depicts how a container's page table is updated during a page fault. When a process in a container faults on a page, an exception causes control to transfer to the OS by way of the CSM (steps 1-3). The OS then allocates a page for the process, but instead of updating the process page table directly, it performs a `set_pt` CSM call (step 4). Upon receiving the `set_pt` call, the CSM verifies if the allocation is acceptable (step 5). To do so, the CSM maintains a list of valid mappings for each process. This list is maintained by interposing on system calls that adjust memory mappings. In Linux these calls include `mmap` and `brk`. Prior to writing the page table entry, the CSM first verifies that the virtual address specified belongs to a valid mapping. If it does not, the update is rejected. Second, the CSM checks if the physical page assigned is already in the container's PPAS and therefore already in use. This can commonly occur innocuously when, e.g., two processes in a container have the same file mapped in their address spaces. However, to prevent the risk of a malicious OS coercing an enclave to overwrite existing memory via a malicious memory allocation, the CSM marks any physical page mapped more than once read only in the container's PPAS, unless it was inherited from a parent as part of process creation in which case it can be trusted. While this is effective at preventing these attacks, the downside is that writes to such memory will trap and need to be handled by BlackBox; for simplicity, BlackBox disallows writable memory-mapped file I/O as it is uncommonly used. Finally, if the virtual address is valid and not mapped to an existing physical page in a container's PPAS, the CSM unmaps the assigned physical page from the OS and maps it into the container's PPAS. The CSM then updates the page table entry on the OS's behalf (step 6). Control is then returned back to the OS (step 7). When returning control back to the process that faulted, the process's container PPAS will be switched to (steps 8-10). Section 4 describes further details about this process. The CSM also invalidates TLB entries as needed when it performs page table updates, ensuring that a malicious OS cannot violate a container's PPAS through stale TLB entries.

BlackBox provides support for copy-on-write (CoW) memory, a key optimization commonly used in OSes. The OS traditionally expects to be able to share a page in memory among multiple processes and when a write is attempted, break the CoW by copying the contents of the page to a new page assigned to the process. With BlackBox, the OS does not have the ability to copy container memory though, so the OS instead makes a `copy_page` CSM call to have the CSM perform the CoW break on its behalf. The CSM will check that the source page belongs to the container's PPAS and the destination page is in the OS's memory. If so, it will move the destination page into the container's PPAS and perform the copy.

BlackBox supports the dynamic release of memory back to the OS as tasks adjust their heap, unmap memory regions, and exit, while preserving the privacy and integrity of a container's memory. As with memory allocation, system calls that can allow for returning of an application's memory, like `munmap` and `_exit` are tracked to maintain an accurate view of a container's memory mappings. During these calls, the OS may attempt to free pages allocated to the process. In doing so, as with memory allocation, it must make use of the `set_pt` CSM call since it cannot update page tables directly. The CSM will then check if the application has made a call to release the specified memory and reject the update if it has not. If the update is valid, the CSM will perform the page table update, and if no longer needed, scrub the page and remove it from the container's PPAS.

While BlackBox ensures that container memory is not accessible to the OS, many OS interactions via system calls expect to use memory buffers that are part of an application's memory to send data to, or receive data from, the OS. BlackBox treats the use of such memory buffers in system calls as implicit directives to declassify the buffers so they can be shared with the OS. To support this declassification while ensuring that a container's PPAS is not accessible to the OS, BlackBox provides a syscall buffer for each task running in an enclaved container that is outside of the container's PPAS and accessible to the OS. When interposing

on a system call exception, the CSM replaces references to memory buffers passed in as system call arguments with those to the task's syscall buffer. For buffers that are used to send data to the OS, the data in those buffers is copied to the syscall buffer as well. When returning to the container, the references to the syscall buffer are replaced with those to the original memory buffers. For buffers that are used to receive data from the OS, the data in the syscall buffer is copied to the original memory buffers as well.

Most system calls are interposed on by a single generic wrapper function in the CSM that uses a table of system call metadata to determine which arguments must be altered. System calls with more complex arguments, like those involving `iovec` structures are interposed on with more specific wrapper functions. On Linux, this interposing and altering of arguments works for most system calls with a few notable exceptions as discussed in Section 3.5.

As part of the copying of data from the OS to an enclaved container, BlackBox also does simple checks on system call return values to ensure they fall within predefined correct ranges. This has been shown to protect against many Iago attacks [14]. However, to keep its TCB simple and small, BlackBox only guarantees the correctness of system call semantics for memory management and inter-process communication (IPC), the latter discussed in Section 3.5. As a result, BlackBox protects against Iago attacks related to memory management and IPC, but is susceptible to some other Iago attacks. Augmenting BlackBox with a user-level runtime library in an enclaved container that guarantees the correctness of system call semantics could improve Iago attack protection, but at the cost of a larger TCB and potential additional limitations on system call functionality.

3.5 Inter-process Communucation

While BlackBox declassifies data to the OS passed in as system call arguments, it protects inter-process communication (IPC) among tasks running in the same enclaved container by encrypting the data passed into IPC-related system calls. This protects applications using IPC, which is transferred through and accessible to the OS. System calls that can create IPC-related file descriptors, such as `pipe`, and Unix Domain Sockets are interposed on and their returned file descriptors (FDs) recorded in per-process arrays marking them as related to IPC. When the CSM interposes on system calls that pass data through FDs, like `write` and `sendmsg`, it checks if the given FD is one related to IPC for that process. If it is, the CSM first uses authenticated encryption with a randomly generated symmetric key created during container initialization to encrypt the data before moving it into the task's syscall buffer. A record counter, incremented on each transaction, is included as additional authenticated data to prevent the host from replaying previous transactions. Similarly, data is decrypted and authenticated when interposing on system calls like `read` and `recvmsg` before copying it to the calling process's PPAS. With this mechanism, IPC communication is transparently encrypted and protected from the OS.

As mentioned in Section 3.4, to avoid trusting the OS's memory allocations, memory pages that are used by more than one process in a container are marked read-only in the container's PPAS unless the pages are known to belong to a shared memory mapping and are inherited during process creation. Shared memory regions created by a parent process through `mmap` with `MAP_SHARED` and faulted in prior to forking can be written to by both parent and child processes since the child's address space is validated after `fork`, as discussed in Section 3.3. However, for simplicity, BlackBox does not allow for writable IPC shared memory via XSI IPC methods such as `shmget` and `shm_open`, which are no longer widely-used. Modern applications instead favor thread-based approaches for performance or shared mappings between child worker processes via `mmap` compatible with BlackBox.

Futexes are used among threads and processes to synchronize access to shared regions of memory. As part of the design of `futex`, the OS is required to read the futex value, which is in the process's address space and included in the respective container's memory. This direct access to container memory is incompatible with BlackBox's memory isolation. To support `futex`, the OS makes a `futex_read` CSM call to obtain the value of a futex for container processes, rather than try and access the memory directly. The CSM ensures that only the futex address passed to `futex` can be read, and only if a `futex` call has been made.

Signals, used to notify processes of various events, present two issues for BlackBox. First, when delivering a signal to a process, a temporary stack for the signal handler is set up in the process's memory. With enclaved containers, this memory is not accessible to the OS. To remedy this, the OS is modified to setup this stack in a region of memory outside of the container's PPAS, which is then moved to the PPAS when the signal handler is executed and returned to the OS when the signal handler returns via `rt_sigreturn`. Second, the OS has to adjust the control flow of the process to execute the signal handler instead of returning to where it was previously executing. BlackBox cannot allow the OS to adjust the control flow of an enclaved process without validating it is doing so properly. To achieve this, as part of the CSM interposing on system calls, it tracks signal handler installation via system calls such as `rt_sigaction`. Upon handling a signal, the CSM ensures that the process will be correctly returning to a registered handler.

3.6 Container File System

Files within a container can only be accessed through an OS's I/O facilities making access to a container's files inherently untrustworthy without additional protection. A userspace encrypted file system could potentially be used to provide transparent protection of file I/O, but this would likely signif-

icantly increase the container's TCB. BlackBox relies on applications to use encryption to fully protect sensitive data files within a container, and provides a simple mechanism to allow the OS to load encrypted executable binaries for execution.

As discussed in Section 3.2, container images for BlackBox are pre-processed. For example, ELF binaries, widely-used on Linux, have `.text`, `.data`, and `.rodata` sections that contain the executable code and data used by the code. These sections are combined into various segments when loaded into memory. In a BlackBox container image, the ELF headers are left unencrypted, but the `.text`, `.data`, and `.rodata` sections are encrypted then hashed, and their hash values are recorded along with the binaries. This enables BlackBox to validate the integrity and authenticity of executable binaries.

An ELF binary is executed by the OS as a result of a process calling `exec`, upon which the OS loads the binary by mapping its ELF headers into memory, reading the ELF headers to determine how to process the rest of the binary, then mapping the segments of the binary to memory. As discussed in Section 3.3, the OS is required to call `task_exec`, which passes the virtual addresses of the binary's loaded segments containing the `.text`, `.data`, and `.rodata` sections to the CSM. During this call, the CSM moves the process's pages, corresponding to the loaded binary, into the container's PPAS, validates that the hashes of the encrypted `.text`, `.data`, and `.rodata` sections match the hashes for the given binary from the BlackBox container image to confirm the authenticity and integrity of the loaded segments, then decrypts the sections in memory. The virtual to physical address mappings of these binary segments are recorded for later use. Upon returning from `task_exec`, the OS will begin running the task whose binary is now decrypted within protected container memory. If checking the hashes or decryption fails, the CSM will refuse to run the binary within an enclaved container, ensuring only trusted binaries can run within.

For dynamically linked binaries, in addition to the binary segments the OS maps during `exec`, the OS also maps the segments of the loader in the process's address space. These segments are verified in the same manner as the binary's segments. Dynamically linked binaries load and execute external libraries that BlackBox must validate are as expected and trusted. During the container image creation process, as with executable binaries, library binaries are also encrypted preventing their use without the CSM. These libraries are loaded and linked at runtime in userspace by a loader that is part of the trusted container image. To do this, the loader, running as part of a process's address space, `mmap`s library segments into memory. The CSM intercepts these mmaps by interposing on FD-related system calls, such as `open`. If an FD is created for one of the libraries within a container, as recorded during container image creation, the CSM marks that FD as associated with the given library. If this FD is then used with `mmap`, the CSM intercepts it. Based on the size of the mmap request and the protection flags used, the CSM can infer which segment the loader is mapping. If it is a segment containing one of the encrypted sections, the CSM performs the same hashing, decryption, and memory map recording as it does with executable binaries.

4 Implementation

We have implemented a BlackBox prototype by repurposing existing hardware virtualization support available on modern architectures, including a higher privilege level, usually reserved for hypervisors, and nested page tables (NPTs). NPTs, also known as Arm's Stage 2 page tables and Intel's Extended Page Tables (EPT), is a hardware-assisted virtualization technology that introduces an additional level of virtual address translation [8]. When NPTs are used by hypervisors, the guest OS in a VM manages its own page table to translate a virtual address to what the VM perceives as its physical address, known as a guest physical address, but then the hypervisor manages an NPT to translate the guest physical address to an actual physical address on the host. Hypervisors can thereby use NPTs to control what physical memory is available to each VM.

BlackBox uses hardware virtualization support to run the CSM in lieu of a hypervisor to support PPASes. The CSM runs at the higher hypervisor privilege level, so that it is strictly more privileged than the OS and is able to control NPTs. The CSM introduces an NPT for each container and the OS, such that a container's PPAS is only mapped to its own NPT, isolating the physical memory of each container from the OS and each other. The CSM switches a CPU from one PPAS to another by simply updating its NPT base register to point to the respective container's NPT. Similarly, the CSM uses NPTs to protect its own memory from the OS and containers by simply not mapping its own memory into the NPTs. The memory for the NPTs is part of the CSM's protected memory and is itself not mapped into any NPTs so that only the CSM can update the NPTs. When the CSM runs, NPTs are disabled, so it has full access to physical memory.

Specifically, BlackBox uses Arm hardware virtualization extensions (VE) [16–19]. The CSM runs in Arm's hypervisor (EL2) mode, which is strictly more privileged than user (EL0) and kernel (EL1) modes. EL2 has its own execution context defined by register and control state, and switching the execution context of EL0 and EL1 are done in software. The CSM configures Stage 2 page tables in EL2, and the System Memory Management Unit (SMMU), Arm's IOMMU. The Linux kernel runs in EL1 and has no access to EL2 registers, so it cannot compromise the CSM. CSM calls are made using Arm's `hvc` instruction from EL1.

Before and after every transition to the OS, BlackBox traps to the CSM, which in turn switches between container and OS NPTs. One might think that imposing two context switches to the CSM to swap NPTs for every one call to the OS would be prohibitively expensive, but we show in Section 5

that this can be done on Arm without much overhead. The flexibility that Arm EL2 provides of allowing software to determine how execution context is switched between hypervisor and other modes turns out to be particularly advantageous for implementing the CSM because it does not lock its implementation into using heavyweight hardware virtualization mechanisms to save and restore hypervisor execution context that are not required for the CSM.

Trapping to the CSM before and after every transition to the OS requires that the CSM interpose on all system calls, interrupts, and exceptions. Hypervisors traditionally accomplish similar functionality by trapping interrupts and exceptions to itself, then injecting virtual interrupts and exceptions to a VM. BlackBox avoids the additional complexity of virtualizing interrupts and exceptions by taking a different approach. The CSM configures hardware so system calls, interrupts, and exceptions trap to the OS and modifies the OS's exception vector table for handling these events so that `enter_os` and `exit_os` CSM calls are always made before and after the actual OS event handler. To guarantee these handlers are installed and not modified by the OS at a later time, BlackBox requires the OS to make a `protect_vectors` CSM call with the address of the text section of the vector table during system initialization, before any container may be enclaved. The CSM then prevents the OS from tampering with the modified vector table by marking its backing physical memory read only in the OS's NPT. Similarly, the vDSO region of memory is marked read only to prevent malicious tampering of the region.

Figure 3 depicts the steps involved in interposing on transitions between the containers and OS when repurposing virtualization hardware. While running in a container, an exception occurs transferring control to the protected OS exception vector table (step 1). All entry points in the exception vector table invoke the `enter_os` CSM call (step 2). During this, the CSM switches to the OS's NPT (step 3). The OS will therefore not be able to access private physical memory mapped into container NPTs. For system call exceptions, system call arguments are copied to an OS accessible syscall buffer (step 4). Control is transferred back to the OS (step 5) to perform the required exception handling. When the OS has finished handling the exception, the `exit_os` CSM call is made as part of the return path of the exception vectors when returning to userspace (step 6). For system call exceptions, OS updated arguments are copied back to the original buffer (step 7). On `exit_os`, the CSM verifies the exception return address to ensure the call is from the trusted exception vectors, which the OS cannot change, rejecting any that are not. The CSM then checks if the running task belongs to an enclaved container, in which case the CSM switches to the respective container's NPT so the task can access its PPAS memory state (step 8). Control is restored to the container by returning from `exit_os` (step 9) and back to userspace (step 10). If `exit_os` is not called, the CSM will not switch the CPU to use the container's PPAS, so its state will remain inaccessible on that CPU.

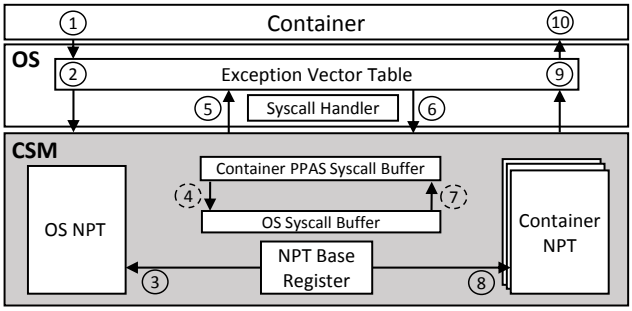

Figure 3: System Call from Enclaved Container

BlackBox protects a container's memory by using separate NPTs for the OS and each container, but still relies on the OS to perform all complex memory management functions, such as allocation and reclamation, to minimize the complexity and size of the CSM. This is straightforward because unlike hypervisors which virtualize physical memory using NPTs, the CSM merely uses NPTs for access control so that the identity mapping is used for all NPTs including the OS's NPT. The OS's view of memory is effectively the same as the actual physical memory for any physical memory mapped into the OS's NPT. Except for the CSM's physical memory, all physical memory is initially assigned to the OS and mapped to its NPT. When the OS allocates physical memory to processes in containers, the CSM can just unmap the physical memory from the OS's NPT and map it to the respective container's NPT at the same address. The CSM does not need its own complex allocation functionality. The CSM checks the OS's NPT to make sure that the OS has the right to allocate a given page of memory. For example, should the OS attempt to allocate a physical page belonging to the CSM, the CSM will reject the allocation and not update the OS's or container's NPT. The CSM also checks that any page allocation proposed by the OS for a container is not mapped into the IOMMU page tables and will therefore not be subject to DMA attacks, as discussed in Section 3.1.

Note that the OS is oblivious to the fact that its allocation decisions for process page tables, Arm's Stage 1 page tables, are also used for Stage 2 page tables. Furthermore, since Arm hardware first checks Stage 1 page tables before Stage 2 page tables, page faults due to the need to allocate physical memory to a process all appear as Stage 1 page faults, which are handled in the normal way by the OS's page fault handler. Since the CSM maps the physical memory to the respective Stage 1 and Stage 2 page table entries at the same time, there are no Stage 2 page faults for memory allocation.

As discussed in Section 3.4, BlackBox requires that process page tables cannot be directly modified by the OS. At the same time, commodity OSes like Linux perform many operations that involve walking and accessing process page tables. To minimize OS modifications required to use enclaved containers, BlackBox makes the process page tables readable but not writable by the OS by marking the corresponding entries in the OS's NPT read only. All existing OS code that walks

and reads process page tables can continue to function without modification, and only limited changes are required to the OS to use CSM calls for any updates to process page tables. A process's page tables are also mapped to its respective container's NPT, so they can be accessed by MMU hardware for virtual address translation while executing the process. BlackBox also maps tasks' syscall buffers, used for passing system call arguments to and from the OS, to their Stage 1 page tables. This allows OS functions designed to copy data to and from buffers in the calling process's address space to function correctly without modification. The tasks' syscall buffers themselves are only mapped to the OS's NPT, not the container's NPT, as they are shared directly only by the CSM and OS.

To optimize TLB usage, physically contiguous memory can be mapped to an NPT in blocks larger than the default 4 KB page size. The BlackBox implementation supports transparent 2 MB stage 2 block mappings by first fully populating the last-level stage 2 page table with 4 KB mappings, then folding all 512 entries into a single entry. BlackBox checks that all 512 entries are contiguous in physical memory and that the first entry is aligned to a 2 MB boundary. BlackBox will unfold a block mapping if one of the original 512 entries is unmapped, such that all 512 entries are no longer contiguous in physical memory. Similarly, BlackBox will unfold a block mapping if there is a need to change the attributes of one of the original 512 entries, such as marking it read only while other entries remain writable. This approach is advantageous over just supporting huge pages allocated by the OS because it improves TLB usage even when the OS does not use huge pages.

Although BlackBox is designed to work using existing hardware virtualization support, the upcoming Armv9 architecture with its inclusion of the Arm Confidential Compute Architecture (CCA) [41] offers alternative mechanisms that may be used for implementing BlackBox. CCA introduces secure execution environments called Realms. The memory and execution state of these Realms are inaccessible to existing privileged software like OSes and hypervisors guaranteeing their confidentiality and integrity from them. Realms are supported by a separate Realm World and managed by a Realm Management Monitor (RMM) running in EL2 within the Realm World giving it full access to Realm memory and CPU state as well as control over their execution. Although Realms are currently only designed to support VMs, it may be possible to use them to support enclaved containers by integrating the functionality of the CSM with the RMM and extending its ABI to encompass the CSM's ABI.

BlackBox's implementation is relatively small. The implementation is less than 10K lines of code (LOC), most of which is the 5K LOC for the implementation of Ed25519, ChaCha20, and Poly1305 from the verified HACL* crypto library [70]. Other than HACL*, BlackBox consisted of 4.9K LOC, all in C except for 0.4K LOC in Arm assembly. Table 2 shows a breakdown by feature. 0.3K LOC was for verifying the CSM was correctly booted and initialized. 1K LOC was for enclave management, including enclave creation and handling enclave metadata 0.1K LOC was for switching between enclaves and the OS. 0.2K LOC was for protecting data in CPU registers. 1K was for system call interposition, including marshaling of arguments. The table used for determining how to marshal system calls and check return values is dynamically generated as a single line of C code at compile time. 2.3K LOC was for memory protection, including NPT management of PPASes, Iago and DMA protection, and handling and validating page table update requests. BlackBox's CSM TCB implementation complexity is similar to other recently verified concurrent systems [39–41, 63], suggesting that it is small enough that it can be formally verified. Beyond the CSM itself, only 0.5K LOC were modified or added to the Linux kernel to support BlackBox.

Feature	BlackBox	Linux	KVM
Bootstrapping	0	8.5K	8.5K
Device Support	0	425K	425K
Filesystem Support	0	163K	163K
Process Management	0	110K	110K
Memory Management	0	60.7K	60.7K

DMA Protection	0.8K	0	9K
Total	9.9K	1.2M	862K

Table 2: LOC for BlackBox, Linux, and KVM

Table 2 also compares the code complexity of BlackBox versus the Linux kernel and KVM hypervisor. This is a conservative comparison as the LOC for Linux and KVM only include code compiled into the actual binaries for one specific Arm server used for the evaluation in Section 5. Even with this conservative comparison, BlackBox is orders of magnitude less code, in part because its functionality is largely orthogonal to both OSes and hypervisors, which have much more complex functionality requirements.

5 Experimental Results

We quantify the performance of BlackBox compared to widely-used Linux containers, and demonstrate BlackBox's ability to protect container confidentiality and integrity. Ex-

Name	Description
Lmbench	`lmbench` v3.0-a9 [46] latency microbenchmarks.
Hackbench	`hackbench` [54] using Unix domain sockets and 100 process groups running in 500 loops.
Apache	`Apache` v2.4.46 server handling 100 concurrent requests from remote `ApacheBench` [64] v2.3 client, serving the 12 KB default Debian `index.html`.
HAProxy	`HAProxy` v1.8.19 server proxying 100 concurrent requests from remote `ApacheBench` [64] v2.3 client to remote `Apache` v2.4.29, serving the 82 KB `index.html` of the GCC 13.0.0 manual.
Kernbench	Compilation of the Linux 5.4 kernel using `allnoconfig` for Arm with GCC 8.3.0.
Memcached	`memcached` v1.6.9 using the `memtier` [51] benchmark v1.3.0 with default parameters.
MySQL	`MariaDB` v10.3.27, a `MySQL` fork, handling requests from remote `YCSB` [13] v0.17.0 client running workload A with 200 parallel transactions, recordcount=500K, and opcount=100K.
Netperf	`netperf` v2.6.0 [33] running `netserver` on the server and the client with default parameters in three modes: TCP_STREAM (receive throughput), TCP_MAERTS (send throughput), and TCP_RR (latency).
Nginx	`Nginx` v1.18.0 server handling 100 concurrent requests from remote `ApacheBench` [64] v2.3 client, serving the 12 KB default Debian `index.html`.

Table 3: Microbenchmarks and Application Workloads

periments were run using both Arm multiprocessor embedded system and server hardware with VE support, specifically (1) a Raspberry Pi 4 Model B with a 4-core Cortex-A72 64-bit 1.5 GHz Broadcom BCM2711 SoC, 8 GB RAM, a 250 GB Samsung 860 EVO SSD connected via USB3.0, and Gigabit Ethernet, running Raspberry Pi OS Buster (2020-08-20 Debian), and (2) an AMD Seattle Rev.B0 server with an 8-core Cortex-A57 64-bit ARMv8-A 2 GHz AMD Opteron A1100 SoC, 16 GB of RAM, a 512 GB SATA3 HDD, and an AMD XGBE 10 GbE NIC, running Ubuntu 16.04. For client-server experiments, the clients ran on a Lenovo ThinkPad P52 with a quad-core Intel i7-8750H 64-bit 4.1 GHz CPU, 32 GB RAM, and a 1 TB PCIe SSD, running Linux Mint 20, connected to the Arm hardware via Gigabit Ethernet through an ASUS RT-N16. All machines used Linux kernel 5.4 LTS and for running in containers, the Docker 20.10.6 container runtime.

We ran the microbenchmarks and application workloads listed in Table 3 using the following five system configurations: (1) natively on the host without containers to provide a baseline measure of performance, (2) Docker with unmodified Linux containers (Docker), (3) BlackBox running Docker with traditional Linux containers, without the security guarantees of being enclaved (BlackBox NS, for Non-Secure), (4) BlackBox running Docker with enclaved Linux containers without encrypted IPC (BlackBox NE, for no encryption), and (5) BlackBox running Docker with enclaved Linux containers (BlackBox Enclaved). Three BlackBox configurations were used to quantify the cost of different protection mechanisms. BlackBox NS provides the same security as Docker, the only difference being that BlackBox NS runs the containers on BlackBox with the OS's NPT enabled, to quantify NPT overhead. BlackBox NE provides stronger security by enclaving the container but without enabling IPC encryption, thereby quantifying BlackBox overhead without IPC encryption. BlackBox Enclaved is the same as BlackBox NE but with IPC encryption enabled. When using BlackBox, its DMA protection is not available on the Raspberry Pi 4 because it has no SMMU. Docker's default `seccomp` policy is enabled for all configurations. Versions of `libseccomp` prior to v2.5 had a significant performance issue on policies like Docker's default [65]. The Docker version we use incorporates this performance fix.

5.1 Performance Measurements

Figure 4 shows performance measurements for each microbenchmark and application workload for each container configuration normalized to native execution; lower numbers are better. Solid bars indicate results run on the Raspberry Pi and the overlaid outlined bars indicate results run on the AMD Seattle Arm server. BlackBox has the highest overhead relative to native execution on the null system call measurement, but most of the overhead is from Docker, due to its use of `seccomp` to configure and limit the system calls available in a container to reduce the available attack surface area. Although `seccomp` is used for all system calls, its overhead is most apparent for the null system call as its base cost is the lowest since it does no work. In contrast, the overhead due to BlackBox, from the two CSM calls that BlackBox makes on every system call, is small relative to `seccomp`. Although CSM calls require switching to and from Arm's EL2 mode, it requires no more than EL2's system register state to execute, eliminating the need to save and restore system registers when switching between EL1 and EL2; only general-purpose registers need to be saved and restored. Taking advantage of Arm's architectural features makes CSM calls relatively inexpensive, enabling fine-grained container protection without significant overhead from system call interposition. The key aspect of Arm's design that is crucial for the CSM is that software determines what state needs to be saved and restored. Running the CSM in the equivalent x86 hypervisor root mode would be much more expensive as it provides a hardware instruction that must be used to context switch to root mode that requires saving and restoring the entire CPU system state [17]. The x86 mechanism works well for hypervisors since they already require this operation, but poorly for the CSM which makes minimal use of CPU system state, and therefore does not need the expensive save and restore.

For the `read`, `write`, `stat`, `open/close`, and `select` system call measurements, BlackBox Enclaved is less than two times the cost of Docker. The overhead for the

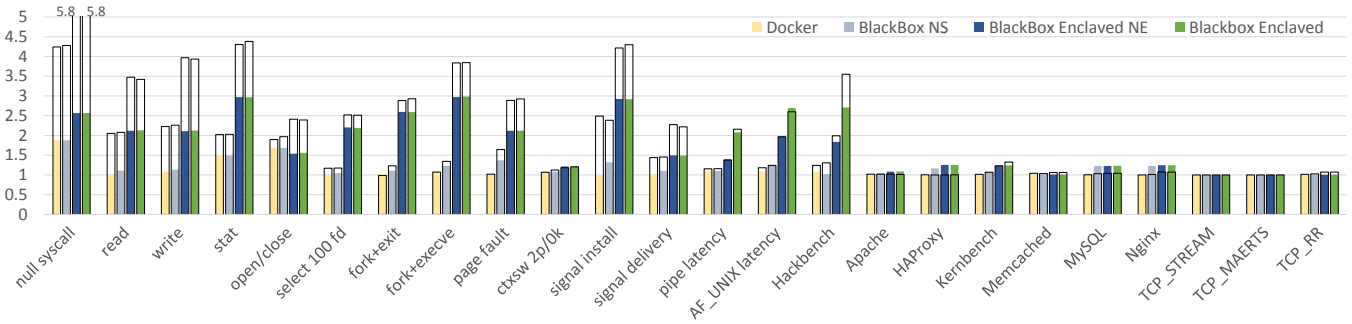

Figure 4: Container Performance for Microbenchmarks and Application Workloads.

enclaved configurations is due to the need to copy system call arguments back and forth between the container PPAS and OS, since enclaved container memory is not accessible to the OS. `open` additionally incurs overhead as part of checking the path being opened to identify FDs associated with shared libraries as part of BlackBox's binary decryption mechanism. For all system calls, the overhead on the AMD server, as indicated by the outlined bars, exceeds that of the Raspberry Pi's. In most cases, this is due to the server hardware performing the CPU bound system call operations more quickly than the Raspberry Pi while their memory performance remains similar, resulting in the similar costs for BlackBox's system call argument copying having relatively higher overhead.

`fork` and `exec` measurements show the highest overhead for BlackBox Enclaved versus Docker, less than three times the cost of Docker. This is due to validating that the new process's address space matches its parent's on `fork`, and additionally validating the address space against the new binary's mappings on `exec`. Although the binary must be decrypted for `exec` measurements, it is only decrypted once and all subsequent iterations just confirm the mappings match the first's, thereby amortizing the cost of the initial decryption.

Page fault measurements show the one microbenchmark for which there is noticeable overhead for BlackBox NS versus Docker. This is due to the added cost of using NPTs for the BlackBox NS configuration. This overhead then increases for enclaved containers due to needing to verify the fault resides within a known address mapping to protect the container from potential Iago attacks from the OS. Although a page fault results in several context switches to the CSM, the context switches themselves are not a significant cost because they are relatively inexpensive on Arm.

Protecting container IPC communication through encryption imposes little cost for most workloads, but this overhead is noticeable for pipe, UNIX domain sockets (AF_UNIX), and `hackbench` measurements. These benchmarks represent worst-case overheads for IPC encryption because they all use IPC to read and write a single byte to signal other processes. When encrypting, this single byte is padded and written along with authentication data, significantly increasing the relative write size and affecting read/write latency measurements. In contrast, the context switch microbenchmark, in which a parent process spawns two child processes that communicate between each other with pipes, has almost no overhead. In this case, 4 byte reads and writes are used so the extra data that encryption adds, and therefore the time to complete the calls, is relatively less, and context switching and rescheduling dominates IPC encryption costs. The signaling microbenchmarks do not involve any encryption. BlackBox Enclaved overhead for signal installation is due to copying the `sigaction` struct in and out, and for signal delivery is due to verifying the control flow.

Apache, HAProxy, Kernbench, memcached, MySQL, and Nginx measurements show that BlackBox overhead is much less on realistic application workloads than microbenchmarks. In most cases, BlackBox Enclaved overhead versus native execution is less than 15% on both the Raspberry Pi and AMD server, demonstrating modest overhead across both Arm embedded and server hardware. As indicated by the BlackBox NS measurements, NPT usage is a source of overhead, though more so on the Raspberry Pi than the AMD server. Apache, HAProxy, and Nginx workloads measure latency in addition to throughput. In terms of latency, the overhead for these workloads for BlackBox Enclaved versus native execution is less than 15% on both the Raspberry Pi and AMD server. Furthermore, Netperf measurements show that BlackBox provides fast networking performance as it involves no I/O virtualization, in contrast to using VMs. Applications are able to make full use of the host's networking capabilities. Although applications are expected to encrypt their network I/O to protect their data, we did not encrypt network connections for these measurements to avoid encryption costs obscuring BlackBox's overhead.

Figure 5 quantifies the CPU utilization when running the application workloads, as a measure of computational overhead. Solid bars indicate results run on the Raspberry Pi and the overlaid outlined bars indicate results run on the AMD server. CPU utilization is generally lower on the AMD server than the Raspberry Pi, since the AMD server is more powerful with more CPUs. On the Raspberry Pi, the difference in CPU utilization between BlackBox Enclaved and native execution is less than 15% across all workloads, and less than 5% for all workloads except Apache and Memcached. On the AMD server, the difference in CPU utilization between BlackBox

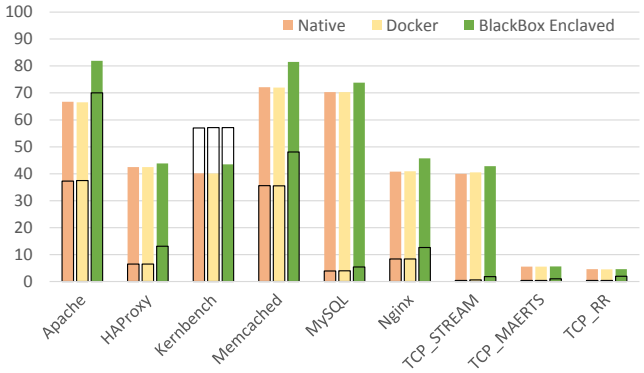

Figure 5: CPU Utilization for Application Workloads

Enclaved and native execution is less than 15% across all workloads, except Apache. Apache CPU utilization for BlackBox Enclaved is high because at higher throughput rates, the cost of extra copying to use syscall buffers, as discussed in Section 3.4, becomes dominant. The buffers are used to send data from a container's PPAS to the OS to perform network I/O. Other than Apache, the difference in CPU utilization between BlackBox Enclaved and native execution is quite modest across both Arm embedded and server hardware.

5.2 System Call Coverage

We evaluated the completeness of Linux system call support in the current BlackBox prototype implementation by running the Linux Test Project (LTP) [44] version 20210524 system call test suite. LTP consists of 1344 test cases designed to test for correct functionality across the entire Linux system call interface. We compared system call support results for running LTP in an enclaved container on BlackBox versus running it natively, in both cases using the Raspberry Pi. When running LTP natively, 1149 test cases pass and 195 fail. These failures are expected and are a combination of missing dependencies and unsupported features of the kernel and architecture used. For example, test cases for the 16-bit version of `fchown` are not supported on the platform. When running LTP using BlackBox, 1012 test cases pass and 332 fail, demonstrating support for almost 90% of test cases that passed when run natively. The additional 137 failed tests are due to the current prototype not yet supporting lesser used system calls like `process_vm_readv`.

5.3 Evaluation of Practical Attacks

We evaluated BlackBox's effectiveness against a compromised OS by analyzing CVEs related to the Linux kernel and various Linux container engines such as Docker. We considered 23 CVEs which could result in privilege escalation, code execution, and memory corruption in Linux capable of compromising the integrity and confidentiality of container data; we did not consider denial of service attacks, as BlackBox does not guarantee availability. Specifically, privilege escalation occurs if the exploit enables the attacker to gain root access or kernel privilege level, and code execution occurs if the exploit enables executing arbitrary code at the same privilege as the software with the bug.

Bug (CVE-*)	Description
2009-3234	Kernel buffer overflow enabling return-to-user attack.
2010-2959	Function pointer overwrite due to integer overflow.
2010-4258	Kernel memory overwrite due to improper handling of get_fs value.
2013-6441	Improper permissions when mounting /sbin/init.
2014-6407	Symbolic and hardlink issues during docker pull.
2014-9357	Mishandling untrusted archive extraction.
2015-1335	Directory traversal flaw in lxc-start.
2015-3627	Unchecked file descriptor opened prior to chroot.
2015-3629	Unchecked symlink when respawning container.
2015-3630	Weak permissions on /proc filesystem.
2016-1576	Improperly restricted mount namespace.
2016-5195	Race condition in handling CoW breakage.
2016-7117	Use after free in __sys_recvmmsg.
2016-9962	Improperly flushed file descriptors.
2017-7308	Improper validation of data size in packet_set_ring().
2017-1000112	Exploitable memory corruption due to UFO to non-UFO path switch.
2018-15664	TOCTOU vulnerability in symbolic link checking.
2018-18955	Mishandled nested user namespaces in map_write().
2019-5736	/proc/self/exe file descriptor mishandling
2019-10144	Container processes not isolated during 'rkt enter'.
2019-11247	Improper access to cluster-scoped custom resource.
2019-14271	Container contents loaded while privileged during container copy.
2020-14386	Kernel memory corruption due to arithmetic issue in tpacket_rcv().

Table 4: CVEs Used for Evaluation of Practical Attacks

Table 4 lists the CVEs considered. We considered both malicious containers and unprivileged host users who exploit bugs in the kernel and container engines to elevate privileges and compromise container data. In general, these CVEs exploit flaws in container runtime systems and the kernel that enable an attacker to obtain kernel-level or root-level access. Ordinarily, this level of access compromises all container data and integrity on the system. Linux and the relevant container engine do not fully protect against any of these compromises. In contrast, BlackBox protects against all of them.

6 Related Work

Various approaches have been explored to securing applications from untrusted OSes. Hardware-based trusted execution environments (TEEs) such as ARM TrustZone [2] and Intel Software Guard Extensions (SGX) [30] can protect application memory from higher privileged software, but require applications to be written or rewritten specifically for this purpose and may impose other functionality restrictions.

Some systems have built on TEEs. Haven [7] aims to en-

clave Windows applications by porting a Windows library OS to run inside SGX, avoiding Iago attacks by trusting the library OS at the cost of a significant TCB. Other systems also propose running library OSes enclaved by SGX [50,59,66]. CubicleOS [57] is a library OS designed to be runnable within containers that makes use of Intel MPK hardware extensions to isolate apps. Scone [3] uses SGX to enclave Linux containers, requiring its own custom threading model and a modified C library within SGX to provide system call support and shielded I/O interfaces for interacting with the OS. TZ-Container [28] leverages a shield layer and a container manager inside TrustZone to protect containers, but relies on the OS not modifying the memory mappings used to protect containers by scanning the OS image to ensure it does not contain instructions capable of updating page tables. TrustShadow [24] introduces a runtime system within TrustZone so that a limited number of security-critical legacy apps operate on TrustZone memory isolated from the OS. Unlike these approaches, BlackBox does not rely on TrustZone or SGX and does not rely on a library OS or other significant runtime system running inside an enclaved execution environment, avoiding increasing TCB complexity. Unlike Haven, its small TCB comes with potentially greater susceptibility to Iago attacks by allowing applications to use the system call interface of the untrusted OS.

Commodity hypervisors have been modified to secure applications from an untrusted OS by restricting a guest OS in a VM to an encrypted view of application memory [4,10,11,27,35,45,67]. For example, InkTag [27] uses two NPTs as part of its isolation mechanism, one for the OS and the other for all applications, separating the plaintext memory of isolated applications from encrypted memory, but relying on paravirtualized page table updates to isolate applications from each other. Appshield [12] uses virtualization techniques to protect and isolate critical applications against OS-level malware attacks. Appshield's memory protection model requirements are not compatible with Linux's copy-on-write semantics and its limited system call interface is insufficient to support significant workloads. In contrast, BlackBox does not rely on a hypervisor or traditional memory virtualization, but instead introduces a new concept of protected physical address spaces implemented as part of a container security monitor, enabling it to have a much smaller TCB.

Various approaches reduce the hypervisor's TCB. Microhypervisors [25,34,61] build new hypervisors from scratch with smaller TCBs, but at the cost of a significantly reduced feature set. BlackBox's approach allows for a small TCB while still maintaining a significant feature set and the full hardware support available in a commodity OS. SeKVM [38–40,63] retrofits KVM with a small verified TCB to provide VM data confidentiality and integrity. In contrast, BlackBox provides container-level isolation and does not require a hypervisor, introducing a new concept, the CSM, that avoids the cost and complexity of hypervisor-based virtualization.

X-Containers [60] targets securely isolating containers in the cloud. Its containers include an entire library OS based on Linux and run on top of a Xen hypervisor, providing a model more akin to nested virtualization. Unlike BlackBox, X-Containers have a large TCB from requiring both large library OSes and a commodity hypervisor.

Other approaches have looked at ways to harden traditional containers. gVisor [23] runs a limited userspace kernel within a container and beneath applications. System calls are intercepted to further isolate applications from the host OS through reduced interactions and potential attack surfaces. gVisor's increased isolation comes at the cost of a increased TCB size in the container. Distroless images [22] aim to limit the contents of a container to precisely what is necessary for the target app to run, reducing what must be trusted and maintained within a container. Linux Container Hardening [42] aims to improve the security of Linux containers through improving the kernel subsystems and primitives used by containers to be more secure. These approaches are complementary to BlackBox, and although they improve container security, unlike BlackBox, they all must still trust the OS and its large codebase.

7 Conclusions

BlackBox is a new container architecture providing fine-grain protection of application data confidentiality and integrity without trusting the OS. BlackBox achieves this by introducing a container security monitor, a new software component that creates protected physical address spaces for containers. The monitor enforces protected address spaces to isolate container memory and CPU state from the OS and other containers. It facilitates the use of OS facilities via system calls by passing required data between protected address spaces and the OS, implicitly declassifying such data. This narrow purpose keeps it small and simple. Unlike a hypervisor, the monitor performs no virtualization or resource management. Instead, it relies on the OS to provide complex functionality required to manage hardware resources, including CPU scheduling, memory management, file systems, and device management. We have implemented BlackBox by repurposing Arm hardware virtualization support. Our results demonstrate that BlackBox supports existing unmodified containerized application workloads with modest overhead while maintaining a trusted computing base orders of magnitude less than an OS or commodity hypervisor.

Blockaid: Data Access Policy Enforcement for Web Applications

Abstract

Modern web applications serve large amounts of sensitive user data, access to which is typically governed by data-access policies. Enforcing such policies is crucial to preventing improper data access, and prior work has proposed many enforcement mechanisms. However, these prior methods either alter application semantics or require adopting a new programming model; the former can result in unexpected application behavior, while the latter cannot be used with existing web frameworks.

Blockaid is an access-policy enforcement system that preserves application semantics and is compatible with existing web frameworks. It intercepts database queries from the application, attempts to verify that each query is policy-compliant, and blocks queries that are not. It verifies policy compliance using SMT solvers and generalizes and caches previous compliance decisions for better performance. We show that Blockaid supports existing web applications while requiring minimal code changes and adding only modest overheads.

1 Introduction

Many modern web applications use relational databases to store sensitive user data, access to which is governed by organizational or regulatory *data-access policies*. To enforce these policies, today's web developers wrap each database query within access checks that determine whether a user has access to the queried data. As an application can query the database at many call sites, getting access checks right at every call site is challenging, and erroneous or missing checks have exposed sensitive data in many production systems [4, 30, 37, 38, 47, 64].

Prior work has suggested a variety of languages, frameworks, and tools that simplify the enforcement of data-access policies. As we detail in §2, these approaches either (1) require applications be written using specialized web frameworks, hindering their adoption; or (2) transparently remove from query results any data that cannot be revealed, possibly resulting in unexpected application behavior (e.g., the user has no idea that there are missing results and reaches the wrong conclusion).

[*]Work done while at UC Berkeley.

This paper proposes an alternative approach to enforcing data-access policies that meets four goals:

1. **Backwards compatibility**: Applies to applications built using common existing web frameworks.
2. **Semantic transparency**: Fully answers queries that comply with the policy and blocks queries that do not (rather than providing partial, and potentially misleading, results).
3. **Policy expressiveness**: Supports a wide range of policies.
4. **Low overhead**: Has limited impact on page load time.

We implement this approach in Blockaid, a system that enforces a data-access policy at runtime by intercepting SQL queries issued by the application, verifying that they comply with the policy, and blocking those that do not. We assume non-compliant queries are rare in production (having been mostly eliminated in testing), and focus on efficiently checking compliant queries. Blockaid expects the developer to insert access checks as usual; it merely ensures that the checks are adequate.

A Blockaid policy consists of SQL view definitions that specify what information can be accessed by a given user, although the application still issues queries against the base tables as usual (rather than against the views). Under this setting, a query is compliant if it *never* reveals—for any underlying dataset—more information than the views do, a well-studied property in databases called *query determinacy* [51].

While determinacy characterizes the compliance of one query in isolation, it is too restrictive in the context of web applications, which typically issue multiple queries when serving a request. In this setting, what queries can be allowed often depends on the result of previous queries in the same web request. Thus, we extend determinacy to take a *trace* of previous queries and their responses, a novel extension we call *trace determinacy*, and use that as the criterion for compliance.

To verify compliance, Blockaid frames trace determinacy as an SMT formula and checks it using SMT solvers. As we later explain, a solver returns an unsatisfiability proof when a query is compliant, and a test demonstrating a violation otherwise.

This basic method, while correct, is impractically slow as it invokes solvers on every query. Thus, we use a *decision cache* to record compliant queries (with traces) so that future

occurrences need not be rechecked. But caching *exact* queries and traces would be ineffective: a query is usually specific to the user and page visited, and so is unlikely to occur many times.

Thus, to increase cache hit rate, we implement a novel generalization mechanism which, given a compliant query-trace pair, extracts a small set of assumptions on the query and trace that alone would guarantee compliance. These assumptions are cached in the form of a *decision template*, which will apply to all future query-trace pairs that meet those assumptions. Blockaid generates decision templates by progressively relaxing a query and trace while maintaining compliance, with the help of solver-generated unsat cores [8, § 11.8]. It does not cache noncompliance results, which we expect to be rare in production as they typically indicate application/policy bugs.

We applied Blockaid to three existing applications—diaspora* [25], Spree [63], and Autolab [5]—and found that it imposes an overhead of 2 % to 12 % to the median page load time when compliance decisions are cached.

Blockaid has some important limitations. It assumes that the application obtains all of its information through SQL queries visible to Blockaid or from a caching layer or file system mediated by Blockaid. It also supports only a subset of SQL and is at the mercy of solver performance and unsat-core size.

Blockaid is open source at `https://github.com/blockaid-project`, and further theoretical discussions can be found in the appendices of our extended technical report [73].

2 Related Work

The subject of data-access control has been studied by many. We compare our approach to prior ones along our goals (§1).

Static verification. Several systems have been proposed to statically verify that application code can only issue compliant queries; examples include Swift [17], SELINKS [22], UrFlow [15], and STORM [42]. These systems incur no run-time overhead and can be more precise than Blockaid as they analyze source code. However, they typically require using a specialized language or framework like Jif [50] or Ur/Web [16], sacrificing compatibility with common web frameworks.

Query modification. A popular run-time approach is query modification [65]: replacing secret values returned by a query with placeholders (or dropping any rows containing secrets). This is implemented in commercial databases [13, 49] and academic works like Hippocratic databases [3], Jacqueline [72], Qapla [48], and multiverse databases [46]. While this approach allows programmers to issue queries without regard to policies, it lacks semantic transparency as it can alter query semantics in unexpected ways and return misleading results [32, 58, 69].

Furthermore, many of the query modification mechanisms use row- and cell-level policies (e.g., SQL Server RLS and DDM, Oracle VPD). As we discuss in §9, this row/cell-level format is less expressive than Blockaid's view-based scheme.

View-based access control. Many databases allow creating views and granting access to views and tables. Although identical in expressiveness to Blockaid, this mechanism requires queries to explicitly use view names instead of table names (like `Users`). This marks a significant deviation from regular web programming, as programmers must now sort out which views to use for each query. In contrast, Blockaid allows queries to be issued against the base tables directly.

While some prior work has studied view-based compliance of queries issued against base tables [10, 11], they only check single queries, while Blockaid checks a query in the context of a trace, a crucial feature for supporting web applications.

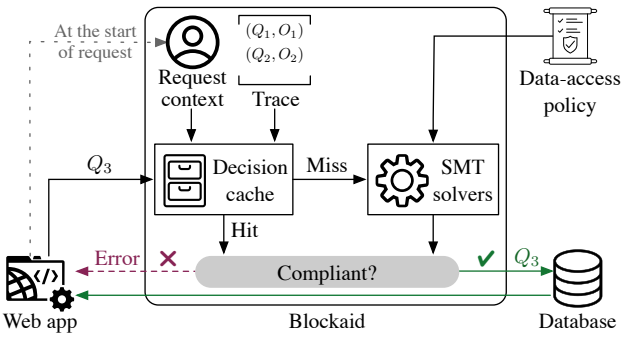

Figure 1: *An overview of Blockaid (for a single web request).*

3 System Design

3.1 Application Assumptions and Threat Model

Blockaid targets web applications that store data in a SQL database. We assume that a user is logged in and that the current user's identifier is stored in a *request context*. The application can access the database and the request context when serving a request; each request is handled independently from others. We assume that the application authenticates the user correctly, and that the correct request context is passed to Blockaid (§3.2).

A *data-access policy* dictates, for a given request context, what information in the database is *accessible* and what is *inaccessible*. We treat the database schema and the policy itself as public knowledge and assume that the user cannot use side channels to circumvent policies. We enforce policies on database *reads* only, as done in prior work [2, 10–12, 33, 41, 46, 58, 61, 65, 69]. Ensuring the integrity of updates, while important, is orthogonal to our goal and is left to future work.

3.2 System Overview

Blockaid is a SQL proxy that sits between the application and the database (Figure 1). It takes as input (1) a database schema (including constraints), and (2) a data-access policy specified as database views (§4), and checks query compliance for each web request separately. For each web request, it maintains a *trace* of queries issued so far and their results; the trace is cleared when the request ends. Blockaid assumes that the results returned by queries in the trace are not altered till the end of the request.

When a web request starts, the application sends its request context to Blockaid. Then, every SQL query from the application traverses Blockaid, which attempts to verify that the query

is *compliant*—i.e., it can be answered using accessible information only. To do so, Blockaid checks the decision cache for any similar query has been determined compliant previously. If not, it encodes noncompliance as an SMT formula (§5) and checks its satisfiability using several SMT solvers in parallel (§7).

If a query is compliant, Blockaid forwards it to the database unmodified. In case of a cache miss, Blockaid also extracts and caches a decision template (§6). Finally, it appends the query and its result to the trace. If verification fails, Blockaid blocks the query by raising an error to the application.

Although our core design assumes that all sensitive information is stored in the relational database, Blockaid supports limited compliance checking for two other common data sources:

1. If the application stores database-derived data in a **caching layer** (e.g., Redis), the programmer can annotate a cache key pattern with SQL queries from which the value can be derived. Blockaid can then intercept each cache read and verify the compliance of the queries associated with the key.
2. If the application stores sensitive data in the **file system**, it can generate hard-to-guess names for these files and store the file names in a database column protected by the policy.

Blockaid's basic requirement is soundness: preventing the revelation of inaccessible information (formalized in §4.3). However, it may reject certain behaviors that do not violate the policy (§9), although such false rejections never arose in our evaluation (§8).

We end by emphasizing two aspects of Blockaid's operation:

1. Blockaid has *no visibility into or control over* the application (except by blocking queries). So it must assume that *any* data fetched by the application will be shown to the user.
2. Blockaid has *no access* to the database except by observing query results—it cannot issue additional queries of its own.

3.3 Application Requirements

For use with Blockaid, an application must:

1. Send the request context to Blockaid at the start of a request and signal Blockaid to clear the trace at the end;
2. Handle rejected queries cleanly (although a web server's default behavior of returning HTTP 500 often suffices); and,
3. Not query data that it does not plan on revealing to the user.

Existing applications often violate the third requirement. For example, when a user views an order on a Spree e-commerce site, the order is fetched from the database, and only then does Spree check, in application code, that the user is allowed to view it. To avoid spurious errors from Blockaid, such applications must be modified to fetch only data known to be accessible.

4 View-based Policy and Compliance

Throughout the paper, we will use as a running example a calendar application with the following database schema:

$$Users(\underline{UId}, Name)$$
$$Events(\underline{EId}, Title, Duration)$$
$$Attendances(\underline{UId}, \underline{EId}, ConfirmedAt)$$

Listing 1: *Example policy view definitions V_1 to V_4 for the calendar application.* `?MyUId` *refers to the current user ID.*

1. `SELECT * FROM Users`
   Each user can view the information on all users.
2. `SELECT * FROM Attendances WHERE UId = ?MyUId`
   Each user can view their own attendance information.
3. `SELECT * FROM Events WHERE EId IN (SELECT EId FROM Attendances WHERE UId = ?MyUId)`
   Each user can view the information on events they attend.
4. `SELECT * FROM Attendances WHERE EId IN (SELECT EId FROM Attendances WHERE UId = ?MyUId)`
   Each user can view all attendees of the events they attend.

where primary keys are underlined. The request context consists of a parameter *MyUId* denoting the *UId* of the current user.

4.1 Specifying Policies as Views

A policy is a collection of SQL queries that, together, define what information a user is allowed to access. Each query is called a *view definition* and can refer to parameters from the request context. As an example, Listing 1 shows four view definitions, V_1–V_4; we denote this policy as $\mathcal{V} = \{V_1, V_2, V_3, V_4\}$.

Notationally, for a view V and a request context ctx, we write V^{ctx} to denote V with its parameters replaced with values in ctx. We often drop the superscript when the context is apparent.

4.2 Compliance to View-based Policy

Under a policy consisting of view definitions, Blockaid can allow an application query to go through *only if* it is certain that the query's result is *uniquely determined* by the views. In other words, an allowable query must be answerable using accessible information alone. If a query's output *might* depend on information outside the views, Blockaid must block the query.

Example 4.1. Let $MyUId = 2$. The following query selects the names of everyone whom the user attends an event with:

```
SELECT DISTINCT u.Name
FROM   Users u
       JOIN Attendances a_other
         ON a_other.UId = u.UId
       JOIN Attendances a_me
         ON a_me.EId = a_other.EId
WHERE a_me.UId = 2
```

Looking at Listing 1, this query can always be answered by combining V_4, which reveals the *UId* of everyone whom the user attends an event with, with V_1, which supplies the names associated with these *UId*'s. Hence, Blockaid allows it through.

This query above is allowed *unconditionally* because it is answerable using the views on *any* database instance. More commonly, queries are allowed *conditionally* based on what Blockaid has learned about the current database state, given the trace of prior queries and results in the same web request.

Example 4.2. Again, let $MyUId = 2$. Consider the following sequence of queries issued while handling one web request:

```
1. SELECT * FROM Attendances
   WHERE UId = 2 AND EId = 5
   ↪ (UId=2, EId=5, ConfirmedAt="05/04 1pm")
2. SELECT Title FROM Events WHERE EId = 5
```

The application first queries the user's attendance record for Event #5—an unconditionally allowed query—and receives one row, indicating the user is an attendee. It then queries the title of said event. This is allowed because V_3 reveals the information on all events attended by the user. More precisely, the trace limits our scope to only databases where the user attends Event #5. Because the second query is answerable using V_3 *on all such databases*, it is conditionally allowed given the trace.

Context is important here: the second query cannot be safely allowed if it were issued in isolation.

Example 4.3. Suppose instead that the application issues the following query by itself:

```
SELECT Title FROM Events WHERE EId = 5
```

Blockaid must block this query because it is not answerable using $\mathcal{V}$ on a database where the user does not attend Event #5. Whether or not the user *actually* is an attendee of the event is irrelevant: The application, not having queried the user's attendance records, cannot be certain that the query is answerable using accessible information alone. This differs from alternative security definitions [32, 39, 74] where a policy enforcer can allow a query after inspecting additional information in the database that has not been fetched by the application.

Definition 4.4. A *trace* $\mathcal{T}$ is a sequence $(Q_1, O_1), \ldots, (Q_n, O_n)$ where each Q_i is a query and each O_i is a collection of tuples.

Such a trace denotes that the application has issued queries $Q_1, \ldots, Q_n$ and received results $O_1, \ldots, O_n$ from the database.

We now motivate the formal definition of query compliance given a trace (using colors to show correspondence between text and equations). Consider any two databases that are:

- Equivalent in terms of accessible data (i.e., they differ only in information outside the views), and
- Consistent with the observed trace (i.e., we consider only databases that *could* be the one the application is querying).

Blockaid must ensure that such two databases are indistinguishable to the user—by allowing only queries that produce the same result on both databases.

Definition 4.5. Let *ctx* be a request context, $\mathcal{V}$ be a set of views, and $\mathcal{T} = \{(Q_i, O_i)\}_{i=1}^{n}$ be a trace. A query Q is *ctx-compliant* to $\mathcal{V}$ given $\mathcal{T}$ if for every pair of databases D_1, D_2 that conform to the database schema and constraints,[1] and satisfy:

$$V^{ctx}(D_1) = V^{ctx}(D_2), \qquad (\forall V \in \mathcal{V}) \tag{1}$$

$$Q_i(D_1) = O_i, \qquad (\forall 1 \le i \le n) \tag{2}$$

$$Q_i(D_2) = O_i, \qquad (\forall 1 \le i \le n) \tag{3}$$

we have $Q(D_1) = Q(D_2)$. We will simply say *compliant* if the context is clear.

We call Definition 4.5 *trace determinacy* because it extends the classic notion of query determinacy [51, 60] with the trace. Query determinacy is undecidable even for conjunctive views and queries [27, 28]; trace determinacy must also be undecidable in the same scenario. Although several decidable cases have been discovered for query determinacy [1, 51, 53], they are not expressive enough for our use case. A promising direction is to identify classes of views and queries that capture common web use cases and for which trace determinacy is decidable.

4.3 From Query Compliance to Noninterference

Blockaid's end goal is to ensure that an application's output depends only on information accessible to the user. In relation to this goal, query compliance (Definition 4.5) satisfies two properties, making it the right criterion for Blockaid to enforce:

1. **Sufficiency**: As long as *only compliant queries* from the application are let through, there is no way for an execution's outcome to be influenced by inaccessible information.
2. **Necessity**: Any enforcement system that makes per-query decisions based solely on the query and its preceding trace *cannot safely allow any non-compliant query* without the risk of the application revealing inaccessible information.

Before stating and proving these properties formally, let us first model our target applications, enforcement systems, and goals.

We model a web request handler as a program $\mathcal{P}(ctx, req, D)$ that maps a request context *ctx*, an HTTP request *req*, and a database D to an HTTP response.[2] A program that abides by a policy $\mathcal{V}$ satisfies a *noninterference* property [21, 29] stating that its output depends only on the inputs that the user has access to—namely, *ctx*, *req*, and $V^{ctx}(D)$ for each $V \in \mathcal{V}$. The formal definition follows from a similar intuition as Definition 4.5.

Definition 4.6. A program $\mathcal{P}$ satisfies *noninterference* under policy $\mathcal{V}$ if the following condition holds:

$$\mathrm{NI}_{\mathcal{V}}(\mathcal{P}) := \forall ctx, req, D_1, D_2.\ \big[\forall V \in \mathcal{V}.\, V^{ctx}(D_1) = V^{ctx}(D_2)\big] \implies \mathcal{P}(ctx, req, D_1) = \mathcal{P}(ctx, req, D_2).$$

An enforcement system must ensure that any program running under it satisfies noninterference. We now model such a system that operates under Blockaid's assumptions.

[1] We will henceforth use "schema" to mean both schema and constraints, and rely on the database and/or the web framework to enforce the constraints.

[2] For simplicity, we assume $\mathcal{P}$ is a pure function—deterministic, terminating, and side-effect free—although this assumption can be relaxed through standard means from information-flow control [34, § 2].

Definition 4.7. An *enforcement predicate* is a mapping from a request context, a query, and a trace to an allow/block decision:

$$E(ctx, Q, \mathcal{T}) \to \{\checkmark, \times\}.$$

Definition 4.8. Let $\mathcal{P}(ctx, req, D)$ be a program and E be an enforcement predicate. We define the program $\mathcal{P}$ *under enforcement using* E as a new program $\mathcal{P}^E(ctx, req, D)$ that simulates every step taken by the original program $\mathcal{P}$, except that it maintains a trace $\mathcal{T}$ and blocks any query Q issued by $\mathcal{P}$ where $E(ctx, Q, \mathcal{T}) = \times$ by immediately returning an error.

Note that $\mathcal{P}^E$ evaluates E only on traces in which every query has been previously allowed by E given its trace prefix.

Definition 4.9. Given a request context ctx, we say that a trace $\mathcal{T} = \{(Q_i, O_i)\}_{i=1}^n$ is *prefix* E*-allowed* if for all $1 \le i \le n$,

$$E(ctx, Q_i, \mathcal{T}[1..i-1]) = \checkmark.$$

Definition 4.10. A predicate E *correctly enforces* policy $\mathcal{V}$ if:

$$\forall \mathcal{P}.\ \mathrm{NI}_{\mathcal{V}}(\mathcal{P}^E).$$

We are ready to state the sufficiency-and-necessity theorem, whose proof is left to our extended paper [73, § B]. Like before, we use colors to link a statement to its explanation.

Theorem 4.11. *Let $\mathcal{V}$ be a set of views and E be a predicate.*

1. *Suppose $E(ctx, Q, \mathcal{T}) = \checkmark$ only when Q is ctx-compliant to $\mathcal{V}$ given $\mathcal{T}$. Then E correctly enforces $\mathcal{V}$.*
2. *Suppose E correctly enforces $\mathcal{V}$. Then for any request context ctx, query Q, and prefix E-allowed trace $\mathcal{T}$ such that $E(ctx, Q, \mathcal{T}) = \checkmark$, Q is ctx-compliant to $\mathcal{V}$ given $\mathcal{T}$.*

To unpack, Theorem 4.11 says: (1) as long as an enforcement predicate ensures query compliance, it correctly enforces the policy on applications (i.e., sufficiency); and (2) for a predicate to correctly enforce the policy, it must ensure query compliance (i.e., necessity). Thus, query compliance can be regarded as the "projection" of application noninterference onto Blockaid's lens, making it the ideal criterion to enforce.

5 Compliance Checking with SMT

Having defined view-based policy and compliance, we now introduce how Blockaid verifies compliance using SMT solvers.

5.1 Translating Noncompliance to SMT

Blockaid verifies query compliance by framing *noncompliance* (i.e, the negation of Definition 4.5) as an SMT formula and checking its satisfiability—a query is compliant if and only if the formula is *unsatisfiable*. We use a straightforward translation based on Codd's theorem [20], which states, informally, that relational algebra under set semantics is equivalent in expressiveness to first-order logic (FOL). Relational algebra has five operators—projection, selection, cross product, union, and difference—and tables are interpreted as *sets* of rows (i.e., no duplicates). Under this equivalence, tables are translated to predicates in FOL, and operators are implemented using existential quantifiers, conjunctions, disjunctions, and negations.

Example 5.1. Let us translate into FOL the following query Q executed on a database D:

```
SELECT e.EId, e.Title
FROM   Events e, Attendances a
WHERE  e.EId = a.EId AND a.UId = 2
```

Let $E^D(\cdot,\cdot,\cdot)$ and $A^D(\cdot,\cdot,\cdot)$ be FOL predicates representing the *Events* and *Attendances* table in the database D in:

$$\mathsf{Q}^D(\mathsf{x}_e, \mathsf{x}_t) := \exists x_d, x_u, x'_e, x_c.\, E^D(\mathsf{x}_e, \mathsf{x}_t, x_d) \wedge A^D(x_u, x'_e, x_c) \wedge \mathsf{x}_e = x'_e \wedge x_u = 2.$$

$\mathsf{Q}^D(\mathsf{x}_e, \mathsf{x}_t)$ encodes the statement $(\mathsf{x}_e, \mathsf{x}_t) \in Q(D)$, i.e., that the row $(\mathsf{x}_e, \mathsf{x}_t)$ is returned by Q on database D. Note that Q^D is not a logical symbol, but merely a shorthand for the right-hand side.

Example 5.2. We now present the noncompliance formula for a single query Q with respect to $\mathcal{V}$ from §4.1. Let $\mathsf{V}_1^{D_i}, \ldots, \mathsf{V}_4^{D_i}$ and Q^{D_i} encode the views and query on database D_i ($i = 1, 2$) in FOL. The desired formula would then be the conjunction of:

$$\begin{aligned}
&\forall \mathbf{x}.\, \mathsf{V}_1^{D_1}(\mathbf{x}) \leftrightarrow \mathsf{V}_1^{D_2}(\mathbf{x}), && (V_1(D_1) = V_1(D_2)) \\
&\qquad\vdots \\
&\forall \mathbf{x}.\, \mathsf{V}_4^{D_1}(\mathbf{x}) \leftrightarrow \mathsf{V}_4^{D_2}(\mathbf{x}), && (V_4(D_1) = V_4(D_2)) \\
&\exists \mathbf{x}.\, \mathsf{Q}^{D_1}(\mathbf{x}) \not\leftrightarrow \mathsf{Q}^{D_2}(\mathbf{x}), && (Q(D_1) \neq Q(D_2))
\end{aligned}$$

where $\mathbf{x}$ denotes a sequence of fresh variables. Database constraints and consistency with a trace can be encoded similarly.

5.2 Handling Practical SQL Queries

The encoding of relational algebra into logic, while straightforward, fails to cover real-world SQL due to two semantic gaps:

1. While the encoding assumes that relational algebra is evaluated under *set semantics*, in practice databases use a mix of set, bag, and other semantics when evaluating queries.[3]
2. SQL operations like aggregation and sorting have no corresponding operators in relational algebra.

For Blockaid to bridge these gaps, it must first assume that database tables contain no duplicate rows. This is generally the case for web applications as object-relational mapping libraries like Active Record [59] and Django [26] add a primary key for every table. Given this assumption, Blockaid rewrites complex SQL into *basic queries* that map directly to relational algebra.

5.2.1 Basic SQL Queries

Definition 5.3. A *basic* query is either a `SELECT-FROM-WHERE` query that never returns duplicate rows, or a `UNION` of `SELECT-FROM-WHERE` clauses (the `UNION` always removes duplicates).[4]

A basic query on duplicate-free tables maps to relational algebra under set semantics, and so can be directly translated to FOL. To ensure a `SELECT` query is basic, we check it against these sufficient conditions for returning no duplicate rows:

[3] For example, a SQL `SELECT` clause can return duplicate rows, but the `UNION` operator removes duplicates.

[4] The `MINUS` operator is not used in our applications and is omitted.

- It contains the `DISTINCT` keyword or ends in `LIMIT 1`; or
- It projects unique key column(s) from every table in `FROM`, e.g., **`SELECT`** `UId, Name` **`FROM`** `Users`; or
- It is constrained by uniqueness in its `WHERE` clause—e.g.:

```
SELECT e.EId
FROM   Events e, Attendances a
WHERE  e.EId = a.EId AND a.UId = 2
```

For this query to return multiple copies of x, the database must contain multiple rows of the form $Attendances(2, x, ?)$; this is ruled out by the uniqueness constraint on (UId, EId).

In our experience, policy views can typically be written as basic queries directly—e.g., for Listing 1 we can frame V_3 and V_4 as equivalent basic queries by replacing subqueries with joins and using the inner join transformation from §5.2.2.

5.2.2 Rewriting Into Basic Queries

When the application issues a query Q, Blockaid attempts to rewrite it into a basic query Q' and verify its compliance instead. Ideally, Q' would be equivalent to Q, but when this is not possible, Blockaid produces an *approximate* Q' that reveals *at least as much* information as Q does.[5] Such approximation preserves soundness but may sacrifice completeness, although it caused no false rejections in our evaluation. We now explain how to rewrite several types of queries encountered in practice.

Inner joins. A query of the form:

```
SELECT ... FROM R1
INNER JOIN R2 ON C1 WHERE C2
```

is equivalently rewritten as the basic query:

```
SELECT ... FROM R1, R2 WHERE C1 AND C2
```

Left joins on a foreign key. Consider a query of the form:

```
SELECT ... FROM R1
LEFT JOIN R2 ON R1.A = R2.B WHERE ...
```

If `R1.A` is a foreign key into `R2.B`, then every row in `R1` matches at least one row in `R2`. In this case, the left join can be equivalently written as an inner join, which is handled as above.

Order-by and limit. Blockaid adds any `ORDER BY` column as an output column and then discards the `ORDER BY` clause. It also discards any `LIMIT` clause but, when adding the query to the trace, uses a modified condition $O_i \subseteq D(Q_i)$ (instead of "=") to indicate that it may have observed a partial result.

Aggregations. Blockaid turns **`SELECT SUM`**`(A)` **`FROM`** `R` into **`SELECT`** `PK, A` **`FROM`** `R`, where `PK` is table `R`'s primary key. By projecting the primary key in addition to `A`, the rewritten query reveals the multiplicity of the values in `A`—necessary for computing **`SUM`**`(A)`—without returning duplicate rows.

Left joins that project one table. Left joins of the form:

```
SELECT DISTINCT A.* FROM A
LEFT JOIN B ON C1 WHERE C2
```

can be equivalently rewritten to the basic query:

```
(SELECT A.* FROM A
 INNER JOIN B ON C1 WHERE C2)
UNION
(SELECT * FROM A WHERE C3)
```

where `C3` is obtained by replacing each occurrence of `B.?` with `NULL` in `C2` and simplifying the resulting predicate.[6] The first subquery covers the rows in `A` with at least one match in `B`, and the second subquery covers those with no matches.

Feature not supported. The SQL features not supported include `GROUP BY`, `ANY`, `EXISTS`, etc., although they can also be formulated / approximated using basic queries. In the future we plan to leverage other formalisms [14, 18, 19, 66–68, 70] to model complex SQL semantics more precisely.

5.3 Optimizations and SMT Encoding

We end this section with several optimizations for compliance checking and some notes on the SMT encoding.

Strong compliance. We define a stronger notion of compliance, which we found SMT solvers can verify more efficiently.

Definition 5.4. A query Q is *strongly ctx-compliant* to policy $\mathcal{V}$ given trace $\{(Q_i, O_i)\}_{i=1}^{n}$ if for each pair of databases D_1, D_2 that conform to the schema and satisfy:

$$V^{ctx}(D_1) \subseteq V^{ctx}(D_2), \qquad (\forall V \in \mathcal{V}) \tag{4}$$

$$Q_i(D_1) \supseteq O_i, \qquad (\forall 1 \le i \le n) \tag{5}$$

we have $Q(D_1) \subseteq Q(D_2)$.

Theorem 5.5. *If Q is strongly compliant to $\mathcal{V}$ given trace $\mathcal{T}$, then Q is also compliant to $\mathcal{V}$ given $\mathcal{T}$.*

Proof. Let Q be strongly compliant to $\mathcal{V}$ given $\mathcal{T}$. To show that Q is also compliant, let D_1, D_2 be databases that satisfy Equations (1) to (3) from the compliance definition. These imply the strong compliance assumptions (Equations (4) and (5)), and so we have $Q(D_1) \subseteq Q(D_2)$. By symmetry, we also have $Q(D_2) \subseteq Q(D_1)$. Putting the two together, we conclude $Q(D_1) = Q(D_2)$, showing Q to be compliant to $\mathcal{V}$ given $\mathcal{T}$. □

For faster checking, Blockaid verifies strong compliance rather than compliance; by Theorem 5.5, soundness is preserved. However, there are scenarios where a query is compliant but *not* strongly compliant (see our extended paper [73, § C]); such queries will be falsely rejected by Blockaid. This did not pose a problem in practice as we found the two notions to coincide for every query encountered in our evaluation.

Fast accept. Given a view **`SELECT`** `C1, ..., Ck` **`FROM`** `R`, any query that references only columns `R.C1, ..., R.Ck` must be compliant and is accepted without SMT solving.

[5] It suffices to guarantee that Q can be computed from the result of Q'.

[6] As long as `C2` contains no negations, it is safe to treat a `NULL` literal as `FALSE` when propagating through or short-circuiting `AND` and `OR` operators.

Trace pruning. Queries that returns many rows can inflate the trace and slow down the solvers. Fortunately, often times only few of the rows matter to a later query's compliance. We thus adopt a trace-pruning heuristic: when checking a query Q, look for any previous query has returned over ten rows, and keep only those rows that contain the first occurrence of a primary-key value (e.g., user ID) appearing in Q. This heuristic is sound, but may need to be adapted for any application where our premise for pruning does not hold.

SQL types and predicates. To model SQL types, we use SMT's uninterpreted sorts, which we found to yield better performance than theories of integers, strings, etc. We support logical operators `AND` and `OR`, comparison operators <, <=, >, >=, and operators `IN`, `NOT IN`,[7] `IS NULL`, and `IS NOT NULL`. We model < as an uninterpreted relation with a transitivity axiom.

NULLs. We model `NULL` using a two-valued semantics of SQL [31, § 6] by (1) designating a constant in each sort as `NULL`, and (2) taking `NULL` into account when implementing SQL operators. For example, the SQL predicate `x=y` translates into the following SMT formula: $x = y \wedge x \neq null \wedge y \neq null$.

6 Decision Generalization and Caching

While SMT solvers can check a wide range of queries, doing so often takes 100s of milliseconds per query. As a page load can depend on tens of queries, this overhead can add up to *seconds*.

To alleviate this overhead, Blockaid aims to reduce solver calls by caching compliance decisions. Naively, once query Q is deemed compliant given trace $\mathcal{T}$, we could record $(Q, \mathcal{T})$ and allow future occurrences without re-invoking the solvers.

However, this proposal is unlikely to be effective because the number of distinct $(Q, \mathcal{T})$ pairs can be unbounded. For example, an application can issue as many queries of the form `SELECT * FROM Users WHERE UId = ?` as there are users in the system. Therefore, requiring an exact query-trace match for a cache hit would result in a low cache hit rate.

Fortunately, while an application can issue an unbounded number of distinct queries, it only exhibits a finite number of truly different behaviors. For example, the query sequences generated by requests for two different calendar events are likely identical in structure while differing only in parameters (e.g., event ID). If one sequence is compliant, we can *generalize* this knowledge to conclude that the other is also compliant.

This generalization problem is the central challenge we tackle in this section: Given a query's compliance with respect to a trace, how to abstract this knowledge into a *decision template* such that (1) any query (and its trace) that matches this template is compliant, and (2) the template is general enough to produce matches on similar requests. Such a template, once cached, will apply to an entire class of traces and queries.

Decision templates are designed to cache compliant queries only. Our techniques do not extend to non-compliant queries, which are expected to be rare in production as they typically indicate bugs in the application or the policy.

Let us start with an example of a decision template.

6.1 Example

Suppose a user with $UId = 1$ requests Event #42 in the calendar application, resulting in the application issuing a sequence of SQL queries. Consider the third query, shown in Listing 2a. As we explained in Example 4.2, Query #3 is compliant because Query #2 has established that the user attends the event.

Blockaid aims to abstract this query (with trace) into a decision template that applies to another user viewing a different event. Listing 2b shows such a template; the notation says: If each query-output pair above the line has a match in a trace $\mathcal{T}$, then any query of the form below the line is compliant given $\mathcal{T}$. This particular template states: after it is determined that user x attends event y, user x can view event y for any x and y.

Compared with the concrete query and trace, this template (1) omits Query #1, which is immaterial to the compliance decision; and (2) replaces the concrete values with parameters. Occurrences of `?0` here constrain the event ID fetched by the query to equal the previously checked event ID. We use `*` to denote a fresh parameter, i.e., any arbitrary value is allowed.

We now dive into how Blockaid extracts such a decision template from a concrete query and trace. But before we do so, let us first define what a decision template is, what it means for a template to have a match, and what makes a "good" template.

6.2 Definitions and Goals

For convenience, from now on we will denote a trace as a set of query-*tuple* pairs $\{(Q_i, t_i)\}_{i=1}^{n}$, where each t_i is *one* of the rows returned by Q_i. A query that returns multiple rows is represented as multiple such pairs. This change of notation is permissible because under strong compliance (Definition 5.4), we no longer take into account the *absence* of a returned row.

Definition 6.1. We say a trace $\mathcal{T} = \{(Q_i, t_i)\}_{i=1}^{n}$ is *feasible* if there exists a database D such that $t_i \in Q_i(D)$ for all $1 \leq i \leq n$.

Definition 6.2. A *decision template* $\mathcal{D}[\mathbf{x}, \mathbf{c}]$, where $\mathbf{c}$ denotes variables from the request context and $\mathbf{x}$ a sequence of variables disjoint from $\mathbf{c}$, is a triple $(Q_\mathcal{D}, \mathcal{T}_\mathcal{D}, \Phi_\mathcal{D})$ where:

- $Q_\mathcal{D}$ is the *parameterized query*, whose definition can refer to variables from $\mathbf{x} \cup \mathbf{c}$;
- $\mathcal{T}_\mathcal{D}$ is the *parameterized trace*, whose queries and tuples can refer to variables from $\mathbf{x} \cup \mathbf{c}$; and
- $\Phi_\mathcal{D}$, the *condition*, is a predicate over $\mathbf{x} \cup \mathbf{c}$.

We will often denote a template simply by $\mathcal{D}$ if the variables are either unimportant or clear from the context.

As we later explain, $\Phi_\mathcal{D}$ represents any extra constraints that a template imposes on its variables (e.g., `?0` < `?1`).

Definition 6.3. A *valuation* ν over a collection of variables $\mathbf{y}$ is a mapping from $\mathbf{y}$ to constants (including `NULL`), extended to objects that contain variables in $\mathbf{y}$. For example, given a parameterized query Q, $\nu(Q)$ denotes Q with each occurrence of variable $y \in \mathbf{y}$ substituted with $\nu(y)$.

[7] We only support `IN` and `NOT IN` with a list of values, not with a subquery.

Listing 2: *An example query with trace from the calendar application and a decision template generated from it.*

(a) *Example query with trace ($UId = 1$).*

```
1. SELECT * FROM Users WHERE UId = 1
   ↪ (UId=1, Name="John Doe")
2. SELECT * FROM Attendances
   WHERE UId = 1 AND EId = 42
   ↪ (UId=1, EId=42, ConfirmedAt="05/04 1pm")
---
3. SELECT * FROM Events WHERE EId = 42
```

(b) *The decision template generated by Blockaid.*

```
1. SELECT * FROM Attendances
   WHERE UId = ?MyUId AND EId = ?0
   ↪ (UId = ?MyUId, EId = ?0, ConfirmedAt = *)
---
✓ SELECT * FROM Events WHERE EId = ?0
```

Definition 6.4. Let $\mathcal{D}[\mathbf{x},\mathbf{c}] = (Q_\mathcal{D}, \mathcal{T}_\mathcal{D}, \Phi_\mathcal{D})$ be a decision template, *ctx* be a request context, $\mathcal{T}$ be a trace, and Q be a query. We say that $\mathcal{D}$ *matches* $(Q,\mathcal{T})$ *under ctx* if there exists a valuation ν over $\mathbf{x} \cup \mathbf{c}$ such that:

- $\nu(\mathbf{c}) = ctx$,
- $\nu(Q_\mathcal{D}) = Q$,
- $(\nu(Q_j), \nu(t_j)) \in \mathcal{T}$ for all $(Q_j, t_j) \in \mathcal{T}_\mathcal{D}$, and
- $\nu(\Phi_\mathcal{D})$ holds.

Example 6.5. Listing 2b can be seen as a stylized rendition of a decision template $\mathcal{D}[\mathbf{x},\mathbf{c}]$ where $\mathbf{x} = (x_0, x_1)$—x_0 denoting `?0` and x_1 denoting the occurrence of `*`—and $\mathbf{c} = (MyUId)$; $Q_\mathcal{D}$ and $\mathcal{T}_\mathcal{D}$ are as shown below and above the line; and $\Phi_\mathcal{D}$ is the constant $\top$, meaning the template imposes no additional constraints on the variables.[8] Under the request context $MyUId = 1$, this template matches the query and trace in Listing 2a via the valuation $\{x_0 \mapsto 42, x_1 \mapsto$ `"05/04 1pm"`$, MyUId \mapsto 1\}$.

We are interested only in templates that imply compliance.

Definition 6.6. A decision template $\mathcal{D}$ is *sound* with respect to a policy $\mathcal{V}$ if for every request context *ctx*, whenever $\mathcal{D}$ matches $(Q,\mathcal{T})$ under *ctx*, Q is strongly *ctx*-compliant to $\mathcal{V}$ given $\mathcal{T}$.

Blockaid can verify that a template is sound via the following theorem derived from strong compliance (Definition 5.4):

Theorem 6.7. *A decision template $\mathcal{D}[\mathbf{x},\mathbf{c}] = (Q_\mathcal{D}, \mathcal{T}_\mathcal{D}, \Phi_\mathcal{D})$ is sound with respect to a policy $\mathcal{V}$ if and only if:*

$$\forall \mathbf{x}, \mathbf{c}, D_1, D_2. \quad \left.\begin{array}{r} \Phi_\mathcal{D} \\ \forall V \in \mathcal{V}. V(D_1) \subseteq V(D_2) \\ \forall (Q_i, t_i) \in \mathcal{T}_\mathcal{D}. t_i \in Q_i(D_1) \end{array}\right\} \implies Q_\mathcal{D}(D_1) \subseteq Q_\mathcal{D}(D_2).$$

For a compliant query Q (with trace $\mathcal{T}$) that misses the cache, there often exist many sound templates that match $(Q,\mathcal{T})$. But all such templates are not equal—we prefer the more *general* ones, those that match a wider range of *other* queries and traces.

Definition 6.8. A template $\mathcal{D}_1$ is *at least as general as* a template D_2 if for every query Q and feasible trace $\mathcal{T}$, if $\mathcal{D}_2$ matches $(Q,\mathcal{T})$, $\mathcal{D}_1$ also matches $(Q,\mathcal{T})$.

[8] Technically, this template requires $MyUId \neq$ `NULL` $\wedge\, x_0 \neq$ `NULL`. We omitted this condition in Listing 2b because we assume the user ID parameter and the *Attendances* table's *EId* column are both non-NULL.

Thus, Blockaid aims to generate a decision template that (1) is sound, (2) matches $(Q,\mathcal{T})$, and (3) is general enough for practical purposes. We now explain how this is achieved.

6.3 Generating Decision Templates

Blockaid starts from the trivial template $D_0 = (Q, \mathcal{T}, \top)$, which is sound but not general, and generalizes it in two steps:

1. Minimize the trace $\mathcal{T}$ to retain only those (Q_i, t_i) pairs that are required for Q's compliance (§6.3.1).
2. Replace each constant in the trace and query with a fresh variable, and then generate a weak condition Φ over the variables that guarantees compliance (§6.3.3).

6.3.1 Step One: Trace Minimization

Blockaid begins by finding a minimal sub-trace of $\mathcal{T}$ that preserves compliance. It removes each $(Q_i, t_i) \in \mathcal{T}$ and, if Q is no longer compliant, adds the element back. For example, for Listing 2a this step removes Query #1. Denote the resulting minimal trace by $\mathcal{T}_\text{min}$ and let decision template $\mathcal{D}_1 = (Q, \mathcal{T}_\text{min}, \top)$.

Proposition 6.9. *$\mathcal{D}_1$ is sound, matches $(Q,\mathcal{T})$, and is at least as general as $\mathcal{D}_0$.*

As an optimization, Blockaid starts the minimization from the sub-trace that the solver has actually used to prove compliance. It extracts this information from a solver-generated *unsat core* [8, § 11.8]—a subset of clauses in the formula that remains unsatisfiable even with all other clauses removed. If we attach *labels* to the clauses we care about, a solver will identify all labels in the unsat core when it proves the formula unsatisfiable.

To get an unsat core, Blockaid uses the following formula:

$$[LQ_i] \quad \begin{array}{rr} V^{ctx}(D_1) \subseteq V^{ctx}(D_2), & (\forall V \in \mathcal{V}) \\ t_i \in Q_i(D_1), & (\forall (Q_i, t_i) \in \mathcal{T}) \\ Q(D_1) \not\subseteq Q(D_2), & \end{array}$$

where the clause asserting the i^{th} trace entry is labeled LQ_i. If Q is compliant, the solver returns as the unsat core a set S of labels. Blockaid ignores any $(Q_i, t_i) \in \mathcal{T}$ for which $LQ_i \notin S$.

6.3.2 Interlude: Model Finding for Satisfiable Formulas

A common operation in template generation is to remove parts of a formula and re-check satisfiability. A complication arises

when the formula turns satisfiable—while solvers are adept at proving unsatisfiability, they often fail on satisfiable formulas.[9]

To solve these formulas faster, we observe that they are typically satisfied by databases with small tables. We thus construct SMT formulas to directly seek such "small models" by representing each table not as an uninterpreted relation, but as a conditional table [35] whose size is bounded by a small constant.

A conditional table generalizes a regular table by (1) allowing variables in its entries, and (2) associating with each row with a *condition*, i.e., a Boolean predicate for whether the row exists. For example, a *Users* table with a bound of 2 appears as:

UId	*Name*	Exists?
$x_{u,1}$	$x_{n,1}$	b_1
$x_{u,2}$	$x_{n,2}$	b_2

where each entry and condition is a fresh variable, signifying that the table is not constrained in any way other than its size.

Queries on condition tables are evaluated via an extension of the relational algebra operators [35, § 7]. This allows queries to be encoded into SMT without using quantifiers or using relation symbols for tables.[10] For example, the query `SELECT Name FROM Users WHERE UId = 5` can be written as:

$$\mathsf{Q}(\mathsf{x}_n) := \bigvee_{i=1}^{2} (x_{u,i} = 5 \wedge x_{n,i} = \mathsf{x}_n \wedge b_i)\,.$$

We found that such formulas could be solved quickly by Z3.

After Blockaid generates an unsat core as described in §6.3.1, it switches to using bounded formulas (i.e., ones that use conditional tables instead of uninterpreted relations) for the remainder of template generation. Blockaid sets a table's bound to one plus the number of rows required to produce the sub-trace induced by the unsat core;[11] it relies on the solvers to produce small unsat cores to keep formula sizes manageable.

Care must be taken because using bounded formulas breaks soundness—a query compliant on small tables might not be on larger ones. Therefore, after a decision template is produced Blockaid verifies its soundness on the unbounded formula, and if this fails, increments the table bounds and retry.

6.3.3 Step Two: Find Value Constraints

Taking the template $\mathcal{D}_1 = (Q, \mathcal{T}_{\min}, \top)$ from Step 1, Blockaid generalizes it further by abstracting away the constants. To do so, Blockaid *parameterizes* $\mathcal{T}_{\min}$ and Q by replacing each occurrence of a constant with a fresh variable. We use a superscript "p" to denote the parameterized version of a query, tuple, or trace. Listing 3a shows $\mathcal{T}^{\mathrm{p}}_{\min}$ and Q^{p} from our example. As an optimization, Blockaid assigns the same variable (e.g., `x0`) to locations that are guaranteed by SQL semantics to be equal.

[9] For example, finite model finders in CVC4 [57] and Vampire [56] often time out or run out of memory on tables with only tens of columns.

[10] To avoid using quantifiers in these formulas, we drop the transitivity axiom for the uninterpreted less-than relation (§5.3).

[11] If the bounds are too small for a database to produce the trace, the resulting formula will be unsatisfiable regardless of compliance.

Listing 3: *Parameterization and candidate atoms for Listing 2a.*

(a) *Parameterized trace $\mathcal{T}^{p}_{min}$ and query q^{p}.*

```
2. SELECT * FROM Attendances
   WHERE UId = x0 AND EId = x1
   ↪ (UId = x0, EId = x1, ConfirmedAt = x2)
3. SELECT * FROM Events WHERE EId = x3
```

(b) *Candidate atoms (with symmetric duplicates removed).*

Form `x = v`:
- `MyUId = 1`
- `x0 = 1`
- `x1 = 42`
- `x2 = "05/04 1pm"`
- `x3 = 42`

Form `x = x'`:
- `MyUId = x0`
- `x1 = x3`

Form `x < x'`:
- `MyUId < x1`
- `MyUId < x3`
- `x0 < x1`
- `x0 < x3`

Blockaid must now generate a condition Φ such that the resulting template $\mathcal{D}_2 = (Q^{\mathrm{p}}, \mathcal{T}^{\mathrm{p}}_{\min}, \Phi)$ meets our goals. It picks as Φ a conjunction of atoms from a set of *candidate atoms*. Let $\mathbf{x}$ denote all variables generated from parameterization, and let ν map $\mathbf{x}$ to the replaced constants and $\mathbf{c}$ to the current context *ctx*.

Definition 6.10. The set of *candidate atoms* is defined as:

$$C = \bigcup \begin{cases} \{\texttt{x = v} & \mid x \in \mathbf{x} \cup \mathbf{c}, v = \nu(x) \neq \texttt{NULL}\} \\ \{\texttt{x IS NULL} & \mid x \in \mathbf{x} \cup \mathbf{c}, \nu(x) = \texttt{NULL}\} \\ \{\texttt{x = x'} & \mid x, x' \in \mathbf{x} \cup \mathbf{c}, \nu(x) = \nu(x') \neq \texttt{NULL}\} \\ \{\texttt{x < x'} & \mid x, x' \in \mathbf{x} \cup \mathbf{c}, \nu(x) < \nu(x')\} \end{cases}.$$

(We write atoms in `monospace font` to distinguish them from mathematical expressions. Following SQL, the "=" in an atom implies that both sides are non-`NULL`.)

Note that all candidate atoms hold on Q and $\mathcal{T}_{\min}$. Blockaid now selects a subset that not only guarantees compliance, but also imposes relatively few restrictions on the variables.

Definition 6.11. With respect to Q^{p} and $\mathcal{T}^{\mathrm{p}}_{\min}$, a subset of atoms $C_0 \subseteq C$ is *sound* if the decision template $(Q^{\mathrm{p}}, \mathcal{T}^{\mathrm{p}}_{\min}, \bigwedge C_0)$ is sound. ($\bigwedge C_0$ denotes the conjunction of atoms in C_0.)

Definition 6.12. Let $C_1, C_2 \subseteq C$. We say that C_2 is *at least as weak as* C_1 (denoted $C_1 \preceq C_2$) if $\bigwedge C_1 \implies \bigwedge C_2$, and that C_2 is *weaker* than C_1 if $C_1 \preceq C_2$ but $C_2 \not\preceq C_1$.

Example 6.13. Listing 3b shows all the candidate atoms from Listing 3a (after omitting symmetric ones in the `x = x'` group). Consider the following two subsets of atoms:

$$C_1 = \{\texttt{MyUId = x0},\ \texttt{x1 = 42},\ \texttt{x3 = 42}\},$$
$$C_2 = \{\texttt{MyUId = x0},\ \texttt{x1 = x3}\}.$$

While both are sound, C_2 is preferred over C_1 as it is weaker and thus applies in more scenarios. In fact, C_2 is *maximally* weak: there exists no subset that is both sound and weaker than C_2.

Ideally, Blockaid would produce a maximally weak sound subset of C to use as the template condition, but finding one can be expensive. It thus settles for finding a subset that is weak enough for practical generalization. It does so in three steps.

First, as a starting point, Blockaid generates a minimal unsat core of the formula:

$$\begin{aligned} & V^{ctx}(D_1) \subseteq V^{ctx}(D_2), && (\forall V \in \mathcal{V}) \\ & t_i^{\mathrm{p}} \in Q_i^{\mathrm{p}}(D_1), && (\forall (t_i^{\mathrm{p}}, Q_i^{\mathrm{p}}) \in \mathcal{T}_{\min}^{\mathrm{p}}) \\ [LC_i] \quad & c_i, && (\forall c_i \in C) \\ & Q^{\mathrm{p}}(D_1) \not\subseteq Q^{\mathrm{p}}(D_2). \end{aligned}$$

Let C_{core} denote the atoms whose label appears in the unsat core. For example, $C_{\text{core}} = \{\texttt{MyUId = x0}, \texttt{x1 = 42}, \texttt{x3 = 42}\}$.

Second, it augments C_{core} with other atoms that are implied by it: $C_{\text{aug}} = \{c \in C \mid \bigwedge C_{\text{core}} \implies c\}$. In our example,

$$\begin{aligned} C_{\text{aug}} &= C_{\text{core}} \cup \{\texttt{x1 = x3}\} \\ &= \{\texttt{MyUId = x0}, \quad \texttt{x1 = 42}, \quad \texttt{x3 = 42}, \quad \texttt{x1 = x3}\}. \end{aligned}$$

C_{aug} enjoys a closure property: if $C_0 \subseteq C_{\text{aug}}$ and $C_0 \preceq C_1$, then $C_1 \subseteq C_{\text{aug}}$. In particular, C_{aug} contains a maximally weak sound subset of C. Thus, Blockaid focuses its search within C_{aug}.

Finally, as a proxy for weakness, Blockaid finds a *smallest* sound subset of C_{aug}, denoted C_{small}, breaking ties arbitrarily. It does so using the MARCO algorithm [43, 44, 55] for minimal unsatisfiable subset enumeration, modified to enumerate from small to large and to stop after finding the first sound subset. In our example, the algorithm returns $C_{\text{small}} = \{\texttt{MyUId=x0}, \texttt{x1=x3}\}$ of cardinality two, which is also a maximally weak subset (even though this might not be the case in general).[12] Nevertheless, searching for a smallest sound subset has produced templates that generalize well in practice.

At the end, Blockaid produces the decision template:

$$\mathcal{D}_2[\mathbf{x}, \mathbf{c}] = \left(Q^{\mathrm{p}}, \mathcal{T}_{\min}^{\mathrm{p}}, \bigwedge C_{\text{small}}\right).$$

Proposition 6.14. *$\mathcal{D}_2$ is sound, matches $(Q, \mathcal{T})$, and is at least as general as $\mathcal{D}_1$.*

As an optimization, whenever $\bigwedge C_{\text{small}} \implies x = y$ for $x, y \in \mathbf{x} \cup \mathbf{c}$, Blockaid replaces x with y in the template. This is how, e.g., in Listing 2b `?0` appears in both the trace and the query.

6.3.4 Optimizations

We implement two optimizations that improve the performance of template generation and the generality of templates.

Omit irrelevant tables. Given trace $\mathcal{T}$ and query Q, we call a table *relevant* if (1) it appears in $\mathcal{T}$ or Q, or (2) the table appears on the right-hand side of a database constraint of the form $Q_1 \subseteq Q_2$, given that a relevant table appears on the left.[13] Blockaid sets the size bounds of irrelevant tables to zero, reducing formula size while preserving compliance.

Split `IN`. A query Q that contains "c `IN` $(x_1, x_2, \ldots, x_n)$" often produces a template with a long trace. If Q is a basic query that does not contain the `NOT` operator, it can be split into $q_1, \ldots, q_n$ where q_i denotes Q with the `IN`-construct substituted with $c = x_i$, such that $Q \equiv q_1 \cup \ldots \cup q_n$. If $q_1, \ldots, q_n$ are all compliant then so is Q, and so Blockaid checks the subqueries instead. This is usually fast because $q_2, \ldots, q_n$ typically match the decision template generated from q_1. If any q_i is not compliant, Blockaid reverts to checking Q as a whole.

This optimization also improves generalization. Suppose Q' has structure identical to Q but a different number of `IN` operands. It would not match a template generated from Q, but its split subqueries q_i' could match the template from q_1.

6.4 Decision Cache and Template Matching

Blockaid stores decision templates in its *decision cache*, indexing them by their parameterized query using a hash map. When checking a query Q, Blockaid lists all templates whose parameterized query matches Q; for each such template, it uses recursive backtracking (with pruning optimizations) to search for a valuation that results in a match. This simple method proves efficient in practice as the templates tend to be small.

7 Implementation

We implemented Blockaid as a Java Database Connectivity (JDBC) driver that interposes on an underlying connection. It thus supports only applications on the JVM and runs within the web server, although our design allows it to reside elsewhere (e.g., in the database). The JDBC driver accepts custom commands that (1) set the request context, (2) clear the context and the trace, and (3) check an application cache read.

Blockaid parses SQL using Apache Calcite [9] and caches parser outputs. To check compliance, it uses Z3's Java binding [23] to generate formulas in SMT-LIB 2 format [7] and invokes an ensemble of solvers in parallel. Our ensemble consists of Z3 [24] (v4.8.12) and CVC5 [6] (v0.3) using default configurations, and Vampire [40] (v4.6.1) using six configurations from its CASC portfolio.[14] The ensemble is killed as soon as any solver finishes. If a query is not compliant, or all solvers time out after 5 s, Blockaid throws a Java `SQLException`.

To generate decision templates, Blockaid uses the same ensemble to produce the initial unsat core (§6.3.1), but kills the ensemble only when a solver returns a small core of up to 3 labels (subject to timeout). It uses only Z3 on bounded formulas.

Our prototype does not verify that queries return no duplicate rows and does not look at any `ORDER BY` columns. We manually ensured that queries in our evaluation return no duplicates and do not reveal inaccessible information through `ORDER BY`.

[12] For example, $\{\texttt{x < y}, \texttt{x < z}\}$ is strictly weaker than $\{\texttt{x < y}, \texttt{y < z}\}$ even though the two sets have the same cardinality.

[13] Every constraint encountered in our evaluation can be written in the form $Q_1 \subseteq Q_2$, including primary-key, foreign-key, and integrity constraints.

SQL feature	1	3	5
Parameterize queries	0	18	32
File system checking	0	0	9
Total	19	64	96

8 Evaluation

We use Blockaid to enforce data-access policies on three existing open-source web applications written in Ruby on Rails:

- **diaspora*** [25]: a social network with 850 k users.
- **Spree** [63]: an e-commerce app used by 50+ businesses.
- **Autolab** [5]: a course management app used at 20 schools.

For each application, we devised a data-access policy, modified its code to work with Blockaid, and measured its performance.

In summary: Blockaid imposes overheads of 2 %–12 % to median page load time when compliance decisions are cached; the decision templates produced by Blockaid generalize to other entities (users, etc.); and no query was falsely rejected in our benchmark. Instructions for reproducing our experiments can be found in Appendix A.

8.1 Constraints, Policies, and Annotations

Table 1 summarizes the constraints and policies for database tables queried in our benchmark, including any necessary application-level constraints (e.g., a reshared post is always public in diaspora*). Spree and Autolab use the Rails cache, and we annotate their cache key patterns with queries (§3.2).

Once a policy is given, transcribing it into views was straightforward. The more arduous task lied in divining the intended policy for an application, by studying its source code and interacting with it on sample data. This effort was complicated by edge cases in policies—e.g., a Spree item at an inactive location is inaccessible *except* when filtering for backorderable variants. Such edge cases had to be covered using additional views.

To give a sense of the porting effort, writing the Spree policy took one of us roughly a month. However, this process would be easier for the developer of a new application, who has a good sense of what policies are suitable and can create policies while building the application, amortizing the effort over time.

When writing the Autolab policy, we uncovered two access-check bugs in the application: (1) a persistent announcement (one shown on all pages of a course) is displayed regardless of whether it is active on the current date, and (2) an unreleased handout is hidden on its course page but can be downloaded from its assignment page. This experience corroborates the difficulty of making every access check airtight, especially for code bases that enjoy fewer maintenance resources.

8.2 Code Modifications

Our changes to application code fall into five categories:

1. **Boilerplate**: We add code that sends the request context to Blockaid at request start and clears the trace at request end.
2. **Fetch less data**: We modify code to not fetch potentially sensitive data unless it will be revealed to the user; some of these changes use the `lazy_column` gem [45].
3. **SQL features**: We modify some queries to avoid SQL features not supported by Blockaid (e.g., general left joins) without altering application behavior.
4. **Parameterize queries**: We make some queries parameterized so that Blockaid can effectively cache their parsing results. Most changes are mechanical rewrites of queries with comparisons, as idiomatic ways of writing comparisons [54] cause query parameters to be filled within Rails.
5. **File system checking**: Autolab uses files to store submissions; the file name are always accessible but the content is inaccessible during an exam. We modify it to store the submission content under a randomly generated file name and restrict access to the file name in the database (§3.2).

The code changes are summarized also in Table 1, which omits configuration changes, adaptations for JRuby, and experiment code. The changes range from 19 to 96 lines of code.

8.3 Experiment Setup and Benchmark

We deploy each application on an Amazon EC2 c4.8xlarge instance running Ubuntu 18.04. Because our prototype only supports JVM applications (§7), we run the applications using JRuby [36] (v9.3.0.0), a Ruby implementation atop the JVM (we use OpenJDK 17). In Rails's database configuration, we turn on `prepared_statements` so that Rails issues parameterized queries in the common case.[15] The applications run atop the Puma web server over HTTPS behind NGINX (which serves static files directly), and stores data in MySQL (and, if applicable, Redis) on the same instance. To reduce variability, all measurements are taken from a client on the same instance.

For each application, we picked five page loads that exercise various behaviors (Table 2). Each page load can fetch multiple URLs, some common among many pages (e.g., D9, which is the notifications URL). All queries issued are compliant, and all experiments are performed with the Rails cache populated.

8.4 Page Load Times

We start by measuring page load times (PLTs) using a headless Chrome browser (v96) driven by Selenium [62]. PLTs are reported as the time elapsed between `navigationStart` and `loadEventEnd` as defined by the `PerformanceTiming` interface [71]. The one exception is the Autolab "Submission" page,

[15] In case a Rails query is not fully parameterized (e.g., due to the use of raw SQL), it gets parameterized by Blockaid as described in §6.3.3.

Table 2: *Application benchmark. For a page we list the page URL followed by other URLs fetched (URLs for assets are excluded). When compliance decisions are cached, Blockaid incurs up to* 12 % *overhead to the median PLT over the modified applications.*

a file download, for which we report Chrome's download time instead. Since the client is on the same VM as the server, these experiments reflect the best-case PLT, as clients outside the instance / cloud are likely to experience higher network latency.

We report PLTs under four settings: *original* (unmodified application), *modified* (modified à la §8.2), *cached* (modified application under Blockaid with every query hitting the decision cache), and *no cache* (decision caching disabled). For the first three, we perform 3000 warmup loads before measuring the PLT of another 3000 loads. For *no cache*, where each run takes longer, we use 100 warmup loads and 100 measurement loads.

Table 2 shows that when compliance decisions are cached, Blockaid incurs up to 12 % overhead to median PLT over the modified application (and up to 17 % overhead to P95). With caching disabled, Blockaid incurs up to 236× higher median PLT. Compared with the original applications, the modified versions result in up to 6 % overhead to median PLT for all pages but Autolab's "Submissions", which suffers a 19 % overhead. (The P95 overhead is up to 7 % for all but two pages with up to 26 % overhead.) We will comment on these overheads in the next subsection, where we break down the pages into URLs.

8.5 Fetch Latency

To better understand page load performance, we separate out the individual URLs fetched by each page (Table 2), omitting URLs for assets, and measure the latency of fetching each URL (not including rendering time). The median latencies are shown in Figure 2. In addition to the four settings from §8.4, it includes performance under a "cold cache", where the decision cache is enabled but cleared at the start of each load (100 warmup runs followed by 100 measurements). When all compliance decisions are cached, Blockaid incurs up to 10 % of overhead (median 7 %) over "modified". In contrast, it incurs 7×–422× overhead on a cold decision cache, and 7×–310× overhead if the decision cache is disabled altogether.

For most URLs, "cold cache" is slower than "no cache" due to the extra template-generation step. Two exceptions are D4 and A6, where many structurally identical queries are issued, and so the performance gain from cache hits *within each URL* offsets the performance hit from template generation.

Compared to the original, the modified diaspora* and Spree are up to 5 % slower (median 2 %), but Autolab is up to 21 % slower (median 8 %). Autolab routinely reveals partial data on objects that are not fully accessible. For example, a user can distinguish among the cases where (1) a course doesn't exist, (2) a course exists but the user is not enrolled, and (3) the user is enrolled but the course is disabled. The original Autolab fetches the course in one SQL query but we had to split it into multiple—checking whether the course exists, whether it is disabled, etc.—and return an error immediately if one of these checks fails.

In one instance (S2), the modified version is 11 % faster than the original because we were able to remove queries for potentially inaccessible data that is never used in rendering the URL.

8.6 Solver Comparison

When a query arrives, Blockaid invokes an ensemble of solvers to check compliance when decision caching is disabled, and to generate a decision template on a cache miss when caching is enabled. The *winner*, in the no-cache case, is the first solver to return a decision; and in the cache-miss case, the first to return a

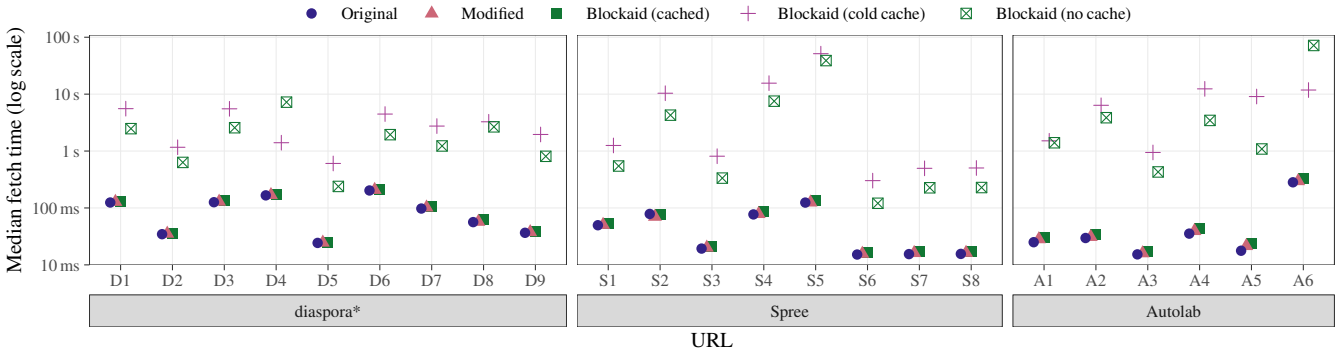

Figure 2: *URL fetch latency (median). With all compliance decisions cached, Blockaid incurs up to* 10 *% overhead over "modified".*

Listing 4: *Two (abridged) decision templates generated for the same parameterized query from Spree.* `Token` *is a Spree request context parameter identifying the current (possibly guest) user, and* `NOW` *is a built-in parameter storing the current time.*

(a) *This template doesn't fully generalize.*

```
SELECT * FROM products WHERE id IN (*, *, *)
↪ (id = ?1, available_on < ?NOW,
    discontinue_on IS NULL, deleted_at IS NULL, *)

SELECT * FROM variants WHERE id IN (*, *, *)
↪ (id = ?2, deleted_at IS NULL,
    discontinue_on IS NULL, product_id = ?1, *)
```

```
SELECT a.* FROM assets a
JOIN variants mv ON a.viewable_id = mv.id
JOIN variants ov ON mv.product_id = ov.product_id
WHERE mv.is_master AND mv.deleted_at IS NULL
  AND a.viewable_type = 'Variant' AND ov.id = ?2
```

(b) *This template does fully generalize.*

```
SELECT * FROM orders WHERE ...
↪ (id = ?0, token = ?Token, *)

SELECT * FROM line_items WHERE order_id = ?0
↪ (variant_id = ?1, *)
```

```
SELECT a.* FROM assets a
JOIN variants mv ON a.viewable_id = mv.id
JOIN variants ov ON mv.product_id = ov.product_id
WHERE mv.is_master AND mv.deleted_at IS NULL
  AND a.viewable_type = 'Variant' AND ov.id = ?1
```

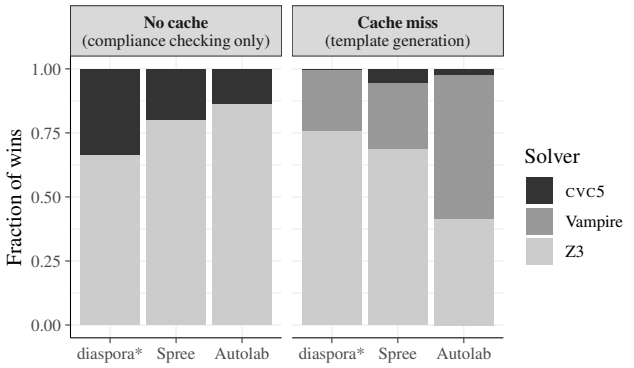

Figure 3: *Fraction of wins by each solver. "Vampire" covers a portfolio of six configurations (§7).*

small enough unsat core (§7), assuming the query is compliant.

Figure 3 shows, in the fetch latency experiments (§8.5), the fraction of wins by each solver in the two cases. In the no-cache case, the wins are dominated by Z3 followed by CVC5, with none for Vampire. In the cache-miss case, however, Vampire wins a significant portion of the time. This is because Z3 and CVC5 often finish quickly but with large unsat cores, causing Blockaid to wait till Vampire produces a smaller core.

8.7 Template Generalization

We found that the generated decision templates typically generalize to similar requests. The rest generalize in more restricted scenarios, and none is tied to a particular user ID, post ID, etc.

To illustrate how Blockaid might produce a template that fails to generalize fully, consider a query from Spree's cache key annotations (Listing 4). This query fetches assets for product variants in the user's order. (Here, the asset of a variant belongs to its product's "master variant".) Listing 4a shows a template that fails to generalize fully, for three reasons.

First, due to the queries with the `IN` operator in its premise (above the horizontal line), this template applies only when an order has exactly three variants. The `IN`-splitting optimization from §6.3.4 only applies to the query being checked, and we plan to handle such queries in the premise in future work.

Second, this template constrains the variant to be "not discontinued", which is defined as `discontinue_on IS NULL` or `discontinue_on >= NOW`. But because disjunctions are not supported in decision templates, Blockaid picked only the condition that matches the current variant (`IS NULL`).

Third, in this example there are multiple justifications for

this query's compliance, and Blockaid happened to pick one that does not always hold in a similar request. The policy states that a variant's asset can be viewed if it is not discontinued, or if it is part of the user's order.[16] This particular variant in the user's order happens to not be discontinued, and the template captures the former justification for viewing the asset. However, it does not apply to variants in the order that *are* discontinued; indeed, for such variants, Blockaid produces the template in Listing 4b, which generalizes fully. We could address this issue by finding multiple decision templates for every query.

Incidentally, inspecting decision templates has helped us expose overly permissive policies. When writing the Autolab policy, we missed a join condition in a view, a mistake that became apparent when Blockaid generated a template stating that an instructor for one course can view assignments for *all* courses. Although manual inspection of templates is not required for using Blockaid, doing so can help debug overly broad policies, whose undesirable consequences are often exposed by the general decision templates produced by Blockaid.

9 Additional Issues

Comparison to row- and cell-level policy. Several commercial databases (such as SQL Server [49] and Oracle [52]) implement *row- and/or cell-level* data-access policies, which specify accessible information at the granularity of rows or cells.

Such policies are less expressive than the view-based ones supported by Blockaid. For example, suppose we wish to allow each user to view everyone's timetables (i.e., the start and end times of the events they attend). Querying someone's timetable requires joining the *Events* and *Attendances* tables on the *EId* column, which must then be treated as visible by a cell-level policy. But this inevitably reveals meeting attendee information as well. Instead, we can implement this policy using a view:

```
SELECT UId, StartTime, EndTime
FROM   Events e
JOIN   Attendances a ON e.EId = a.EId
```

which lists the times of events attended without revealing *EId*.

False rejections. Even though false rejections of compliant queries never occurred in our evaluation, they remain a possibility for several reasons, including: (1) approximate rewriting into basic queries, which is incomplete; (2) our use of strong compliance; and (3) solver timeouts. Developers can reduce the chance of false rejections by running an application's end-to-end test suite under Blockaid before deployment, and manually examining any rejected query to determine whether it is due to a false positive, a bug in the code, or a misspecified policy.

Off-path deployment. If an operator is especially worried about false rejections affecting a website's availability, we can modify Blockaid to log potential violations instead of blocking any queries. We can even move Blockaid off-path by having the application stream its queries to Blockaid to be checked asynchronously, further reducing its performance impact.

[16] This is to allow users to view past purchases that are since discontinued.

What if Blockaid could issue its own queries? Suppose Blockaid can issue extra queries—but only ones answerable using the views, lest the decision itself reveal sensitive data—when checking compliance. Blockaid can now safely allow more queries from the application. For example, faced with the formerly non-compliant single query from Example 4.3:

```
SELECT Title FROM Events WHERE EId = 5
```

Blockaid can now *ask* whether the user attends Event #5 and if so, allow the query. In fact, under this setup the "necessary-and-sufficient" condition for application noninterference (in the sense of §4.3) becomes instance-based determinacy [39,58,74], a criterion less stringent than trace determinacy.

We decided against this design alternative for two reasons. First, it seems nontrivial to check instance-based determinacy efficiently: Blockaid must either figure out a small set of queries to ask, a difficult problem, or fetch all accessible information, an expensive task. Second, Blockaid is designed for conventional applications that do not *rely on* an enforcer for data-access compliance. These applications should not be issuing queries that fail trace determinacy but pass instance-based determinacy: Such queries can, in Blockaid's absence, reveal inaccessible information on *another* database and typically indicate application bugs. Thus, Blockaid is right to flag them.

Theoretically optimal templates. While decision templates produced by Blockaid are general enough in practice, they might not be *maximally general* among all sound templates that match the query and trace being checked. For one thing, the template condition might not be maximally weak (§6.3.3). For another, a maximally general template can have a *longer* trace than the concrete one, a possibility Blockaid never explores.

Fundamentally, our template generation algorithm is limited by its *black-box access* to the policy: It interacts with the policy solely by checking template soundness using a solver. Producing maximally general templates might require opening up this black box and having the policy guide template generation more directly, a path we plan to explore in future work.

10 Conclusion

Blockaid enforces view-based data-access policies on web applications in a semantically transparent and backwards compatible manner. It verifies policy compliance using SMT solvers and achieves low overhead using a novel caching and generalization technique. We hope that Blockaid's approach will help rule out data-access bugs in real-world applications.

Acknowledgments

We are grateful to Alin Deutsch and Victor Vianu for the many discussions about query determinacy, and to Nikolaj Bjørner, Alvin Cheung, Vivian Fang, and members of the Berkeley NetSys Lab for their help with the project. We also thank the anonymous reviewers and our shepherd Malte Schwarzkopf for their helpful comments. This research was funded in part by NSF grants 1817116 and 2145471, and gifts from Intel and VMware.

A Artifact Appendix

Abstract

Our artifact includes our Blockaid implementation, which is compatible with applications that can run atop the JVM and connect to a database via JDBC (§7). We also provide the three applications we used for our evaluation—modified according to §8.2—as well as the data-access policy we wrote for each. Finally, we provide a setup for reproducing the evaluation results from §8.

Table 3: *Where artifact contents are hosted.*

Content	Location	Branch / tag / release
Artifact README	https://github.com/blockaid-project/artifact-eval	`main` branch
Blockaid source	https://github.com/blockaid-project/blockaid	`main` branch (latest version) `osdi22ae` branch (AE version)[a]
Experiment launcher	https://hub.docker.com/repository/docker/blockaid/ae	`latest` tag
Launcher source	https://github.com/blockaid-project/ae-launcher	`main` branch
VM image	https://github.com/blockaid-project/ae-vm-image	`osdi22ae` release
Experiment scripts	https://github.com/blockaid-project/experiments	`osdi22ae` branch
Applications		
diaspora*	https://github.com/blockaid-project/diaspora	`blockaid` branch[b]
Spree	https://github.com/blockaid-project/spree	`bv4.3.0-orig` branch (original)[c] `bv4.3.0` branch (modified)[d]
Autolab	https://github.com/blockaid-project/Autolab	`bv2.7.0-orig` branch (original)[c] `bv2.7.0` branch (modified)[d]
Policies for applications	https://github.com/blockaid-project/app-policies	`main` branch

[a] The "AE version" is the version of Blockaid used in artifact evaluation.
[b] The same diaspora* branch is used for both baseline and Blockaid measurements. The code added for Blockaid is gated behind conditionals that check whether Blockaid is in use.
[c] "(original)" denotes the original application modified only to run on top of JRuby.
[d] "(modified)" denotes the "(original)" code additionally modified to work with Blockaid (§8.2).

Scope

This artifact can be used to run the main experiments from this paper: the page load time (PLT) measurements (§8.4) and the fetch latency measurements (§8.5 and §8.6) on the three applications. From these experiments, it generates Table 2 (with URLs and descriptions omitted), Figure 2, and Figure 3. Because the full experiment can be time- and resource-consuming (taking roughly 15 hours on six Amazon EC2 c4.8xlarge instances), the experiment launcher can be configured to take fewer measurement rounds at the expense of accuracy.

Our Blockaid implementation can also be used to enforce data-access policies on new applications, as long as they have been modified to satisfy our requirements (§3.3), run atop the JVM, and connect to the database using JDBC (§7).

Contents

This artifact consists of our Blockaid implementation, the three applications used in our evaluation (with modifications described in §8.2), the data-access policy we wrote for each, and scripts and virtual machine image for running the experiments.

Hosting

See Table 3.

Requirements

The experiment launcher, which relies on Docker, launches experiments on Amazon EC2 and so requires an AWS account. By default, it uses six c4.8xlarge instances—to run the PLT and fetch latency experiments for the three applications simultaneously. However, it can be configured to launch fewer instances at a time (e.g., to run the experiments serially, using one instance at a time).

SHORTSTACK: Distributed, Fault-tolerant, Oblivious Data Access

Midhul Vuppalapati* Cornell University
Kushal Babel* Cornell University
Anurag Khandelwal Yale University
Rachit Agarwal Cornell University

Abstract

Many applications that benefit from data offload to cloud services operate on private data. A now-long line of work has shown that, even when data is offloaded in an encrypted form, an adversary can learn sensitive information by analyzing data access patterns. Existing techniques for oblivious data access—that protect against access pattern attacks—require a centralized and stateful trusted proxy to orchestrate data accesses from applications to cloud services. We show that, in failure-prone deployments, such a centralized and stateful proxy results in violation of oblivious data access security guarantees and/or in system unavailability. We thus initiate the study of distributed, fault-tolerant, oblivious data access.

We present SHORTSTACK, a distributed proxy architecture for oblivious data access in failure-prone deployments. SHORTSTACK achieves the classical obliviousness guarantee—access patterns observed by the adversary being independent of the input—even under a powerful passive persistent adversary that can force failure of arbitrary (bounded-sized) subset of proxy servers at arbitrary times. We also introduce a security model that enables studying oblivious data access with distributed, failure-prone, servers. We provide a formal proof that SHORTSTACK enables oblivious data access under this model, and show empirically that SHORTSTACK performance scales near-linearly with number of distributed proxy servers.

1 Introduction

Cloud services offer applications scalable, fault-tolerant, and easy-to-manage systems for storing and querying data. Many applications that benefit from offloading data to these cloud services operate on private data that can reveal sensitive information even when stored in an encrypted form [1–6]. An example is that of medical practices offloading patient health data to the cloud [7–9]—charts accessed by oncologists can reveal not only whether a patient has cancer, but also depending on the frequency of accesses (*e.g.*, the frequency of chemotherapy appointments), indicate the cancer's type and severity. Several such applications are subject to severe security concerns.

*Equal contributions.

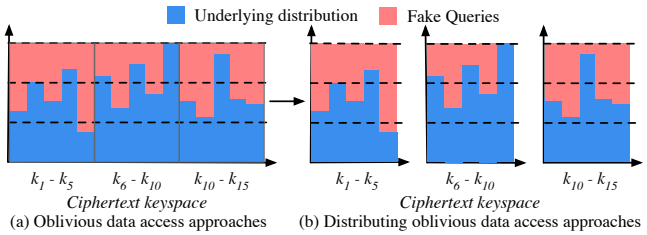
There is a large and active body of research on building systems for oblivious data access, that is, hiding not only the content of the data, but also data access patterns (*e.g.*, access frequency across data objects). These systems use one of the two techniques—Oblivious RAM [10–17] that enables oblivious data access against active adversaries but has bandwidth overheads that are logarithmic in the number of data objects, or Pancake [6, 18, 19] that enables oblivious data access against passive persistent adversaries with a small constant bandwidth overhead. Both of these techniques provide a powerful oblivious data access guarantee: an adversary observing all queries to and all responses from the cloud storage service observes uniform random accesses over the encrypted data objects. The challenge, however, is that both of these techniques require a centralized, *stateful*, proxy to orchestrate data access from applications to cloud services. Such a centralized and stateful proxy means that existing systems for oblivious data access suffer from two core issues (§3.1):

- *Security violation, or long periods of system unavailability during proxy failures:* The proxy being stateful means that, upon a failure, the proxy may lose state. We show in §3.1 that, if the proxy state is lost, naïvely restarting a new proxy and executing queries without restoring the state would lead to violation of oblivious data access security guarantees. To avoid such a security violation, upon restarting a new proxy, the state must be restored before executing any queries, *e.g.*, by downloading the entire data and metadata from the cloud, decrypting all the data, reconstructing the (ORAM or Pancake) data structure, re-encrypting all the data, and uploading all the data back to the storage service; this would lead to long periods of system unavailability.
- *Bandwidth and/or compute scalability bottlenecks:* Since the proxy receives multiple responses for each client query, it has bandwidth overheads ($\Omega(\log n)$ in ORAM [20–25] and $3\times$ in Pancake [6]); and, since the proxy is responsible for both data encryption/decryption and processing for each individual query and response, it has non-trivial compute overheads. Thus, the centralized proxy can become bandwidth or compute bottlenecked, limiting system throughput.

We present SHORTSTACK, a distributed, fault-tolerant, system for oblivious data access. SHORTSTACK achieves three desirable goals: (1) formal oblivious data access guarantee against passive persistent adversaries, even under failures; (2) system availability even when an arbitrary, bounded-sized, subset of distributed proxy servers may fail; and (3) near-linear throughput scalability with number of distributed proxy servers. In designing SHORTSTACK, we make three core contributions.

Our first contribution is to fundamentally establish security goals for oblivious data access in failure-prone deployments. Indeed, existing security models [6, 10–17, 26] do not capture failures. We introduce a formal security model and a security definition to study distributed, fault-tolerant, systems for oblivious data access under passive persistent adversaries. The model requires the classical oblivious data access guarantee [6, 10]—access patterns observed by the adversary must be independent of the input; in addition, to capture failures, the model requires this guarantee to hold under a powerful adversary that can fail an arbitrary (bounded-sized) subset of distributed proxy servers at arbitrary times. Informally, under our security definition, a scheme is considered secure if the access distribution over encrypted data objects is independent of the input distribution, even with adversarial choice and time of proxy server failures.

Our second contribution is design of a distributed, fault-tolerant, proxy architecture—SHORTSTACK—that enables oblivious data access against passive persistent adversaries, system availability (under a bounded number of failures), and near-linear throughput scalability with number of proxy servers. Simultaneously guaranteeing these three properties, especially when proxy servers can fail, turns out to be challenging: to avoid bandwidth and compute bottlenecks, multiple proxy servers must simultaneously process and send queries to the storage server; this makes it non-trivial, if not impossible, to ensure uniform random access over encrypted objects at all times (*e.g.*, right after one of the proxy server fails) without giving up on availability. The key insight in SHORTSTACK design is that obliviousness only necessitates that access patterns observed by the adversary are independent of the input; the requirement of uniform random access over all encrypted objects as in prior designs is one, but not the only, way to achieve such independence. SHORTSTACK design achieves such independence as follows. The security of oblivious data access techniques stems from "flattening" the access distribution over unencrypted (plaintext) objects to a uniform random one over encrypted (ciphertext) objects (Figure 1 (a)). As illustrated visually in Figure 1 (b), any uniform random distribution over ciphertext objects can be decomposed into multiple sub-distributions in a manner that (1) each sub-distribution is uniform random over its support; and (2) the set of objects in any sub-distribution is equal in size, disjoint, and random. Thus, if each proxy server that forwards queries to the storage server is responsible for one of the sub-distributions, even with failure of a subset of these



(a) Oblivious data access approaches (b) Distributing oblivious data access approaches

Figure 1: The flattened distribution over all ciphertext keys in oblivious data access schemes can be expressed as a sum of distributions over disjoint subsets of ciphertext keys.

proxy servers, the adversary observes nothing but a uniform distribution (using (1)) over a random subset (using (2)) of objects. Achieving independence, and not necessarily a uniform random access pattern, at all times is at the core of the SHORTSTACK design. In §4, we present a novel layered SHORTSTACK architecture that, using k physical proxy servers, maintains system availability with up to $(k-1)$ proxy server failures and achieves throughput a factor $\sim k$ higher than a single proxy, all while enabling oblivious data access.

Our third contribution is a formal proof that SHORTSTACK enables oblivious data access under the above security model, and empirical evidence that SHORTSTACK can achieve near-perfect scalability with number of proxy servers (assuming storage server is not the bottleneck). We also show that SHORTSTACK gracefully handles failures: in the worst-case, SHORTSTACK throughput reduces linearly with number of proxy server failures (as one would expect). For the current SHORTSTACK implementation, the cost of achieving oblivious data access, availability and scalability is a $\sim$7ms increase in latency, a tiny fraction of the usual wide-area network latency. An end-to-end implementation of SHORTSTACK is available at https://github.com/pancake-security/shortstack.

2 SHORTSTACK Background

We describe our system, failure, and threat models, followed by a brief primer on oblivious data access approaches.

2.1 System, Threat and Failure Models

System model. We consider settings where applications offload data to the cloud to benefit from the many properties enabled by cloud services, *e.g.*, strong data durability and persistence, geo-replication, lower cost than provisioning dedicated and replicated storage servers, transparent handling of devices wearing out, and others. Examples of such applications include cloud-based healthcare services [9, 27–29] as well as classical applications from access pattern attack literature [6, 11]. The cloud-based storage service implements a key-value (KV) store that stores a collection of KV pairs, and support the following single-key operations: get, put, and delete. SHORTSTACK design can be applied to any data store that supports single-key read/write/delete operations.

SHORTSTACK employs the standard encryption proxy model, commonly used in encrypted data stores [6, 15, 16,

30–35]: a trusted proxy orchestrates query execution from one or more client applications; the only difference compared to previous designs is that, in SHORTSTACK architecture, the proxy is logically-centralized but physically-distributed—that is, client queries may now be routed though multiple physical proxy servers within the same trusted domain.

All network channels are encrypted using TLS. Each key k in the KV store is encrypted using a pseudorandom function (PRF), denoted by $F(k)$; each value v is symmetrically encrypted, denoted by $E(v)$. The logically-centralized proxy stores secret cryptographic keys needed for F and E, and performs encryption. Since F is deterministic, the proxy can execute all queries related to key k by sending $F(k)$ to the cloud service. Similar to many existing commercial deployments [31–35], keys and values are padded to a fixed size to avoid any length-based leakage.

Threat model. SHORTSTACK builds upon the widely-used trusted proxy threat model [11–13, 15], where one or more mutually-trusting clients execute operations on an untrusted cloud storage service via a trusted proxy; as mentioned earlier, the only difference in SHORTSTACK is that the proxy is logically-centralized but comprises physically-distributed servers. As in many prior works [6, 11, 30], we consider scenarios where the clients and the proxy servers all belong to a trusted domain. The storage service is controlled by an honest-but-curious (or, a passive persistent) adversary that observes all encrypted accesses but does not actively perform its own accesses. Since network channels are encrypted using TLS, the adversary cannot observe communications within the trusted domain, that is, the adversary cannot observe traffic between the clients and proxy servers.

We model queries to the KV store using the Pancake model [6]: queries are generated as a sequence of accesses sampled from a (time-varying) distribution π over n KV pairs. While the encryption mechanism has an estimate of the distribution $\hat{\pi}$, the adversary knows both the distribution π and the transcript of encrypted queries and responses. We define a formal security model and definition in §5, but informally, the system is secure if the transcript is *independent* of the underlying distribution π, i.e., the adversary cannot identify an association between the two.

Failure model. We assume the cloud service provides data durability. However, proxy servers can fail. We consider the fail-stop model [36] for proxy server failures.

2.2 Oblivious Data Access Approaches

There are two approaches to oblivious data access today—the classical ORAM [10–17], and the more recent approach of frequency smoothing as in Pancake [6, 18, 19]. ORAMs are designed to prevent a broad range of attacks (*e.g.*, active adversaries); accordingly, they also suffer from high overheads, *e.g.*, recent results [20–25] have established strong lower bounds on ORAM overheads—for a data store with n KV pairs, any

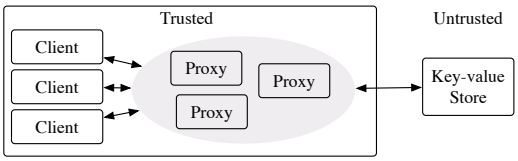


Figure 2: SHORTSTACK System and Threat model

ORAM design must incur bandwidth overheads of $\Omega(\log n)$ (for proxy storage sublinear in KV store size). For KV stores that store millions or billions of KV pairs, these overheads may amount to orders-of-magnitude of throughput loss [6, 37], making ORAMs impractical. Pancake enables oblivious data access against passive persistent adversaries, and incurs a small, constant, bandwidth overhead of $3\times$, independent of the number of objects in the KV store. Thus, we focus on building a distributed, fault-tolerant, proxy architecture within the Pancake context. To keep the paper self-contained, we summarize the Pancake mechanisms necessary to understand the SHORTSTACK architecture.

A brief primer to oblivious data access using Pancake. The Pancake approach combines the knowledge of the distribution estimate $\hat{\pi}$ with several techniques (selective replication, fake accesses, batching, etc.) to transform a sequence of queries into uniform accesses over encrypted KV pairs. Selective replication creates "replicas" of KV pairs that have high access probability relative to other KV pairs, which serves to partially smooth the distribution over (replicated) KV pairs, while also ensuring that the total number of keys to be stored in the KV store is exactly $2n$ (if needed, dummy replicas are added so that the number of replicas does not reveal any distribution-sensitive information). To hide the association between the original keys and their replicas, each replica (k,i) of an unencrypted key k is protected by applying the pseudorandom function F, discussed in §2.1, to the replica identifier to generate an encrypted label $F(k,i)$ for the replica. In the rest of the paper, we refer to the original unencrypted key as the plaintext key, and the encrypted label for each replica as the ciphertext key. To remove the remaining non-uniformity, "fake" queries are added: these queries are sampled from a carefully crafted fake access distribution π_f to boost the likelihood of accessing replicated KV pairs, until the resulting distribution is uniform.

Security requires ensuring that fake and real queries be indistinguishable; to achieve this, encrypted queries are issued in small batches of size B, where each query is either real or fake with equal probability. Since the adversary cannot observe traffic between the clients and the proxy server, it has no way to distinguish real and fake queries within any batch. To prevent an adversary from distinguishing between reads and writes, every access is performed as a read followed by write of a freshly encrypted value. Writes to keys with multiple replicas could reveal which replicas belong to the same key; thus, only one replica is updated at the time of the write query, and the write value is cached at the proxy in

a data structure called the UpdateCache, and the remaining replicas are opportunistically updated during subsequent fake or real queries to the replicas.

Dynamic adaptation to changes in the underlying access distribution is achieved by adjusting the fake-distribution (π_f), and by reassigning the number of replicas across keys. This can be done securely by exploiting the observation that the total number of replicas is exactly $2n$, regardless of the underlying distribution. As such, when the distribution changes, for every key that must lose a replica, another must gain a replica to ensure the distribution remains smooth. Thus, replicas can be reassigned opportunistically for all such key-pairs using a replica-swapping protocol.

In summary, to enable oblivious data access for the general case of read/write workloads and for time-varying distributions, Pancake uses a centralized, *stateful*, proxy that stores (1) the UpdateCache to buffer writes until they are opportunistically propagated to all the replicas; (2) distribution-related state; and (3) replica-related state, to execute the replica swapping process during distribution changes. Using this state, Pancake enables oblivious data access by performing three tasks at the proxy in failure-free scenarios: (1) generating "fake" queries for each real client query; (2) updating UpdateCache upon each query; and (3) issuing a batch of queries comprising real and fake queries to the server, and relaying the response for the real query back to the client.

3 Limitations of Strawman approaches

In this section, we describe subtle security vulnerabilities with strawman approaches to designing distributed, fault-tolerant, systems for oblivious data access.

3.1 Centralized proxy: Insecure and/or long periods of unavailability

The stateful nature of the centralized proxy makes it challenging to simultaneously achieve oblivious data access security guarantees, availability and scalability upon a failure. If achieving scalability were the only goal, the proxy server could be overprovisioned with large bandwidth and/or compute resources; however, achieving security and availability upon a failure is hard due to the proxy being stateful: the naïve solution of replacing the failed proxy server with a new one and having clients reissue failed queries results in violating security and correctness guarantees:

- Consider the (simplest) case of a read-only workload with a static access distribution. Replacing a failed proxy server with a new one, and having clients reissue the failed queries, results in the following subtle security issue. Consider a real query on key k; and consider the scenario where the proxy fails in the middle of sending out queries (both real and fake) in the batch to the KV store, that is, some of the queries in the batch have been sent out while others are lost. Since the proxy has failed, the client would receive no response for k; thus, upon restarting the proxy, the client will retry a real query on k. The retried queries will result in the same real accesses, but potentially new fake accesses. An adversary can thus exploit the transcript of queries at the server to identify real queries with high confidence by isolating repeated accesses right before and right after a failure, hence gaining sensitive information.
- Write queries make the problem significantly more challenging. Consider a write query to a key with two replicas; suppose the proxy fails when the write value has propagated to only one of the replicas (and thus, is buffered in the UpdateCache waiting to be propagated to the other replica). We now replace the failed proxy with a new one. Since the UpdateCache state is lost, when a read query for this key is received, the new proxy could end up reading the value from one of the stale replicas, violating the data correctness/consistency guarantee. Alternatively, if the new proxy reads all replicas of the key to determine which one has the latest value (*e.g.*, using timestamps), oblivious data access guarantees would be violated since an adversary can identify replica correlations (replicas being accessed belong to the same key) by analyzing queries right after a failure.

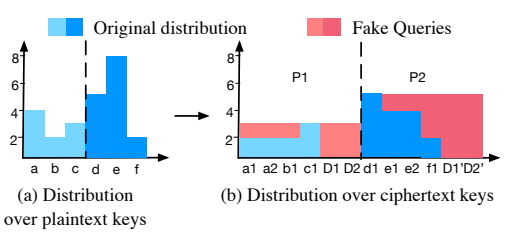
For a centralized stateful proxy design and for the general case of read/write workloads over time-varying distributions, to avoid the above security and correctness violations upon a failure, the proxy state must be reconstructed—*e.g.*, by downloading all the data from the cloud service, decrypting the data, reinitializing the data structures, re-encrypting the new data structures, and writing all the new data back to the server—before issuing new queries. Even for moderate-sized KV stores, this would incur extremely large bandwidth and compute overheads, as well as long unavailability periods.

In summary, replacing the centralized proxy server with a new one (upon a failure) and having clients reissue the queries either fails to ensure critical system properties (security and/or correctness), or results in large unavailability periods. This motivates the need for a distributed proxy architecture.

3.2 Challenges in Distributing Proxy Logic

We now describe security and correctness vulnerabilities with naïvely distributing the proxy state and logic across multiple physical servers.

Naïvely partitioning both the proxy state and the query execution responsibility leads to security violations. A straightforward approach to designing a distributed proxy for oblivious data access is to partition both the proxy state and the query execution responsibility across multiple physical servers—each proxy server stores the UpdateCache and access distribution for a subset of the plaintext keys (*e.g.*, using hash partitioning over the plaintext keys); clients forward their (real) query on key k to the proxy server responsible for k; and, upon receiving a real query, the proxy server generates fake queries based on distribution *corresponding to its own partition*, and executes these queries on the storage service.



(a) Distribution over plaintext keys

(b) Distribution over ciphertext keys

Figure 3: Security violation in one-layer approach.

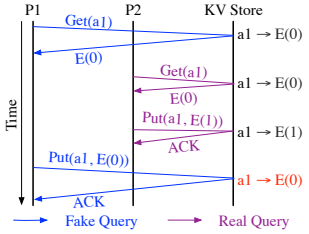


Figure 4: Correctness violation in one-layer approach.

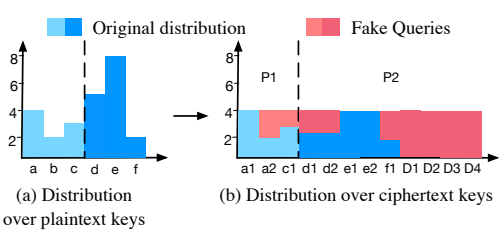

(a) Distribution over plaintext keys

(b) Distribution over ciphertext keys

Figure 5: Security violation in two-layer approach.

While this approach scales linearly with number of physical proxy servers, it suffers from security vulnerability. In particular, it does not guarantee that the resulting distribution observed by the adversary is independent of the input distribution. Consider the scenario shown in Figure 3 (a). Here, plaintext keys are partitioned across two proxy servers—P1 is responsible for keys $\{a, b, c\}$, and P2 is responsible for keys $\{d, e, f\}$. Since, each proxy server operates only on its local plaintext key partition, P1 selectively replicates key a into 2 replicas a_1, a_2, and introduces two dummy key replicas D_1, D_2, leading to a total of 6 ciphertext keys; it then adds fake queries to make the access distribution across these ciphertext keys uniform. Similarly, P2 selectively replicates key e into 2 replicas e_1, e_2, and introduces two dummy key replicas D'_1, D'_2, again leading to a total of 6 ciphertext keys; P2 then adds fake queries to make the access distribution across these ciphertext keys uniform. Figure 3 (b) shows the final output access distribution over ciphertext keys. Since P1 and P2 smooth the distribution over their sets of plaintext keys independently, and since the key set assigned to P2 has a higher average access frequency than the key set assigned to P1, the frequency of accesses over ciphertext keys for P2 is higher than the frequency of accesses over ciphertext keys for P1. In particular, the overall access distribution over all ciphertext keys is dependent on the input distribution over the two subset of keys, thus leaking sensitive information.

Replicating proxy state across all physical servers but naïvely partitioning query execution responsibility leads to security violations. To avoid the security vulnerability in the previous scenario, one possible approach is to replicate the entire proxy state (UpdateCache and access distribution) across all physical servers in the distributed proxy. We will need to keep the state consistent across all physical servers—various mechanisms exist for this; for instance, clients can broadcast each query to each physical server to keep the access distribution consistent, and servers could use a distributed protocol (*e.g.*, state machine replication) to keep the UpdateCache consistent. Let us ignore the scalability issues with maintaining such consistent state for a moment.

To avoid bandwidth and compute bottleneck, we still want each query to be executed at one (or a small number) of the physical proxy servers. Thus, each physical server will now be responsible for receiving real queries from the clients for a subset of the keys (again, *e.g.*, using hash partitioning over the plaintext keys), and generating fake queries for each real query (now on the entire distribution). One question remains: which physical server should send the (real and fake) queries to the storage service on the cloud? Unfortunately, both the obvious solutions—the server generating the batch executes all queries in the batch, and the server responsible for plaintext key k executes all (real and fake) queries for the key k (independent of which server generated the fake query)—suffer from security and/or correctness vulnerabilities.

To see the issue with the first solution, consider the example in Figure 4 with two proxy servers P1 and P2: to serve a client query to write value 1 to key a, P2 sends a get($F(a,1)$) followed by put($F(a,1)$, $E(1)$) query to the KV store, where $(a,1)$ is one of the ciphertext key, or replica, corresponding to a. At the same time, P1, unaware of P2 ongoing write query, sends a fake put query to the same ciphertext key $(a,1)$ in response to another client query. Based on the timeline of operations shown in Figure 4, the fake put from P1 overwrites the real put from P2, resulting in incorrect system behavior. Note that the incorrectness occurs since two different proxy servers issue queries for the same ciphertext key.

Unfortunately, the second solution also suffers from security vulnerabilities—partitioning the query execution across physical servers reveals not only which *plaintext* keys are managed by each server, but also their relative access frequencies. Figure 5 shows an example; the scenario is the same as Figure 3, but with selective replication and fake query generation done over the entire distribution across all plaintext keys—thus, as shown in Figure 5 (b), in addition to selective replication of keys d and e, 4 dummy key (D) replicas (D_1, D_2, D_3, D_4) were added, and the access distribution across ciphertext keys is uniform. We use the same partitioning of plaintext keys across P1 and P2 as in the example of Figure 3—P1 handles all real and fake queries for the three less popular plaintext keys, while P2 handles all queries for the three more popular plaintext keys and the dummy key. The challenge, however, is that although each server handles roughly equal number of plaintext keys, the number of ciphertext keys handled by P1 ($= 3$) and P2 ($= 9$) are very different. This leaks the subset of keys handled by each server and, by extension, their relative popularities to the adversary. Even if the volume of traffic issued by individual proxy servers is hidden (*e.g.*, via a trusted gateway/NAT so that all proxy servers have the same publicly visible IP address), failures of one of the physi-

cal proxy servers would reveal the same information. Even if clients were to retry their queries upon a failure, in-flight queries to the KV store from a failed server would be repeated, again revealing the same information.

Summary. The above discussion leads to three different design principles for distributed, fault-tolerant, oblivious data access systems. From the partitioning-based approach, we learn that, to achieve oblivious data access, each physical server in the distributed proxy should perform selective replication and (fake) query generation over the entire distribution across all plaintext keys (thus, each physical server should know the access distribution across the entire set of plaintext keys). The replication-based approach leads to two additional principles. First, even if proxy state can be replicated in a consistent and scalable manner, maintaining correctness requires that no two physical proxy servers should send the queries for the same ciphertext key; in other words, query execution should be partitioned by ciphertext keys across different physical servers. Second, to avoid security vulnerability, no single proxy server should be deterministically responsible for executing queries for all ciphertext keys corresponding to the same plaintext key; that is, query execution should be partitioned by ciphertext keys—randomly, and independent of plaintext keys—across physical proxy servers.

4 SHORTSTACK Design

We now present the SHORTSTACK distributed, fault-tolerant, proxy architecture.

4.1 Design Overview

SHORTSTACK uses a novel layered architecture, with three *logical* layers*, as shown in Figure 6. Each layer has multiple logical proxy servers for fault tolerance and/or scalability purposes, and embodies one of the three design principles outlined at the end of the previous subsection. In the first layer (L1), proxy servers are responsible for a random subset of client queries—upon receiving a real client query on a plaintext key, the server generates real and fake queries (over ciphertext keys); importantly, fake queries are generated using the *entire* access distribution across all plaintext keys. In the second layer, L2, proxy servers are responsible for maintaining a partition of the UpdateCache state; importantly, the UpdateCache is partitioned by *plaintext* keys across the L2 servers. Finally, in the third layer, L3, each proxy server is responsible to execute real and fake queries on the KV store for a random, distinct, subset of *ciphertext* keys.

We outline the lifetime of a query with the layered SHORTSTACK architecture in a *failure-free scenario*. The client sends the query to a randomly selected L1 proxy server; the L1 server generates the batch comprising real and fake queries (recall, these generated queries are on ciphertext keys). The L1 server then forwards each individual query within the batch to

*On a lighter note, our work seems to formally establish the widely-agreed belief that three is the right number for a SHORTSTACK [38]!

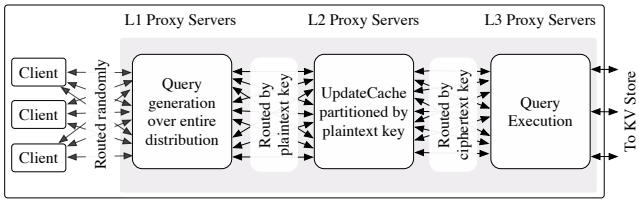

Figure 6: An overview of three-layer SHORTSTACK architecture

one of the L2 servers—the one that maintains UpdateCache state for the corresponding plaintext key in the query. Upon receiving a query, an L2 server updates its local partition of the UpdateCache, and forwards the query to one of the L3 servers—the one that is responsible for executing queries for that ciphertext key. The L3 server ultimately forwards the query to the KV store; upon receiving a response from the KV store, the L3 server sends a response for the real query back to the client, as well as an acknowledgement in the reverse direction of the original path taken by the query (from L3 to L2 to L1) to clear any buffered state associated with the query. We provide more details on the three-layer SHORTSTACK architecture and query execution in §4.2.

For fault-tolerance against f failures, each of the L1 and L2 proxy servers use $f+1$ replication along with the chain replication protocol [39]. Replicating L1 servers prevents the security vulnerabilities discussed in §3.1 that are caused by clients retrying queries upon failures. Specifically, as we discuss in §4.3, SHORTSTACK uses chain replication to guarantee that a batch of queries is never partially executed—either all the queries in a batch are (eventually) forwarded to the KV store or none of them are—thus preventing access pattern leakage even when failures happen. Replicating L2 servers prevents UpdateCache state from being lost due to failures. As we will show, L3 server failures do not have the same security vulnerability as L1 and L2 server failures. Thus, L3 layer is not chain replicated; however, it needs at least $f+1$ servers to maintain availability during failures—if one of the L3 server fails, the remaining L3 servers take over its load. Upon an L3 server failure, in-flight queries at the server will be dropped and L2 servers will reissue the dropped queries. While this results in duplicate queries being forwarded to the KV store, we will show that these duplicate queries do not reveal any sensitive information—the adversary would only observe duplication of queries to a random subset of labels independent of the input distribution. We provide more details on SHORTSTACK mechanisms for handling failures in §4.3.

SHORTSTACK design allows independently setting desired fault tolerance f and scalability factor k. Specifically, to achieve a factor k scalability—that is, achieving system throughput a factor of k higher than a centralized proxy—along with fault tolerance against f failures, SHORTSTACK creates k independent L1 and L2 chains that operate in parallel. The case of L3 is again different; if $f+1 > k$, SHORTSTACK will already have at least k L3 proxy servers to ensure fault tolerance (as described earlier). For $f+1 \leq k$, SHORTSTACK

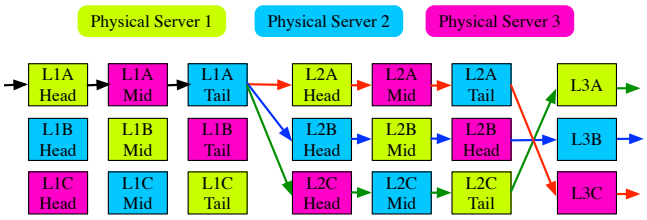

Figure 7: An instantiation of SHORTSTACK's three-layer architecture that guarantees system security and availability with $f = 2$ failures, and achieves $k = 3\times$ scalability (as defined in §4.1). Multiple logical layers in SHORTSTACK are colocated on the same physical server. The arrows depict the lifetime of a single query.

uses a total of k L3 proxy servers, thus guaranteeing both fault tolerance against f failures and a factor k scalability. Figure 7 shows an example for $f = 2$ and $k = 3$.

Colocating SHORTSTACK logical layers and their replicas on a small number of physical servers. Consider an instantiation of SHORTSTACK with fault-tolerance against up to $f = 2$ failures and $k = 3$ scalability. Then, given the above design, SHORTSTACK will require 3 L1 and 3 L2 chains, each having 3 logical replicas within the chain replication protocol. In addition, SHORTSTACK will require 3 logical servers in the L3 layer. Overall, for $f = 2$ and $k = 3$, SHORTSTACK requires 21 "logical" units. However, as shown in Figure 7, all these 21 logical units can be packed on 3 physical servers without compromising security, fault tolerance, availability and scalability. In particular, the replicas of each logical server in each layer are staggered across the physical servers such that no two replicas of the same logical server within the same layer are co-located on the same physical server. Hence, even upon failure of any two physical servers, one replica from each of the L1 servers, one replica from each of the L2 servers, and one L3 server will still be alive, ensuring security, availability and $f = 2$ fault tolerance. In general, using a technique from [40], SHORTSTACK achieves a factor k scalability and fault tolerance against $f \leq k-1$ failures, using only k physical servers. Since any system that tolerates f failures and achieves a factor k scalability must require at least $\max(f+1,k)$ physical servers, SHORTSTACK uses minimum resources to provide these properties.

We provide more details on design of each layer in the SHORTSTACK layered architecture, the mechanisms for fault tolerance, and the mechanisms for handling dynamic distributions in §4.2, §4.3 and §4.4, respectively.

4.2 SHORTSTACK Design Details

In this subsection, we describe SHORTSTACK's three-layer architecture in detail, for the case of no failures and static access distribution. We will extend this design to handle failures and dynamic distributions in §4.3 and §4.4, respectively.

In a failure-free scenario, the key challenge that SHORTSTACK addresses relative to a single proxy architecture is scalability. To achieve k-factor scalability in the failure-free scenario, SHORTSTACK uses k (logical) proxy servers in each layer. For example, in Figure 7, each layer would consist of three nodes, *e.g.*, L1A, L1B and L1C for the L1 layer, L2A, L2B and L2C for the L2 layer, and L3A, L3B and L3C for the L3 layer.

Details of three-layer operation. Figure 8 details the precise initialization and L1/L2/L3 server logic in SHORTSTACK. SHORTSTACK employs the following functionalities from PANCAKE ($\mathcal{P}$) [6] as a black-box:

- an Init function, which takes as input an estimate of the access distribution $\hat{\pi}$ and the unencrypted KV store KV of size n plaintext keys, and generates an encrypted KV store KV$'$ of size $2n$ ciphertext keys, along with a fake distribution π_f over KV$'$;
- a Batch function, which takes a query on a plaintext key k in KV as input, and generates (using $\hat{\pi}$ and π_f) a batch of B ($B = 3$ by default) ciphertext queries to KV$'$; and,
- an UpdateCache function that internally updates per-plaintext key state, and returns an encrypted (possibly updated) value to be written to the KV store.

We now outline how SHORTSTACK distributes the execution of PANCAKE across its three-layer design:

*Initialization (*Init() *in Figure 8):* SHORTSTACK first performs PANCAKE initialization (using $\mathcal{P}$.Init), transforming the unencrypted KV store KV with n plaintext keys to the encrypted KV store KV$'$ using $2n$ ciphertext keys, using an estimate of the underlying access distribution $\hat{\pi}$. During the process, the adversary just observes insert operations of $2n$ ciphertext keys, which does not reveal any information. SHORTSTACK then initializes and configures k logical proxy servers in each of the three layers on top of k physical servers. Finally, SHORTSTACK computes a weight vector δ, containing weights assigned to each L2 server (proportional to the volume of ciphertext traffic generated by it). As will be discussed, L3 servers use these weights to process L2 queries such that the queries issued by L3 servers appear uniform random (recall, this subsection focuses on failure-free scenario, where SHORTSTACK achieves uniform random distribution over ciphertext keys).

Query processing logic (s_{L1}.ProcessQuery(), s_{L2}.Process() *and* s_{L3}.Process() *in Figure 8):* Clients forward each query to a randomly chosen L1 proxy server. Upon receiving a query, the L1 server generates a batch of B queries (using $\mathcal{P}$.Batch) that comprises both real and fake queries to KV$'$. The L1 server then enqueues each query in the batch across different L2 servers based on the hash of the query's plaintext key.

Upon receiving a query, an L2 server calls $\mathcal{P}$.UpdateCache which leads to two sequential actions. First, the per-plaintext key state stored at the L2 server is updated; and second, if this query can be used to propagate outstanding write requests into the plaintext key replicas, the value to be written to the KV store is updated. It then forwards the query to the corresponding L3 server based on the hash of the query's ciphertext key (denoted as "Enqueue" in Figure 8).

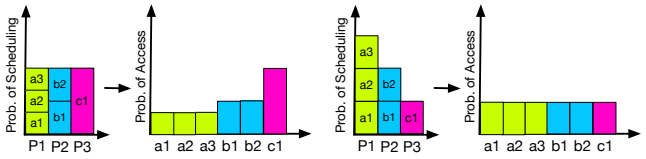
```
Init(π̂, KV, S, f):
  KV′, π_f ← P.Init(KV, π̂)
  S_L1, S_L2, S_L3 ← Configure(S)
  δ ← Weights(S_L2, KV′)
  return KV′, (S_L1, S_L2, S_L3), δ

s_L1.ProcessQuery(k, v):
  ℓ ← P.Batch(k)
  For ((k, j), v) ∈ ℓ:
    s_L2 ← S_L2[H(k)]
    s_L2.Enqueue((k, j, v))

s_L2.Process():
  k, j, v ← Dequeue()
  v ← P.UpdateCache(k, j, v)
  s_L3 ← S_L3[H(F(k, j))]
  s_L3.Enqueue(s_L2, (F(k, j), v))

s_L3.Process(δ):
  s_L2 ←δ S_L2
  k′, v ← Dequeue(s_L2)
  v ← ReadThenWrite(KV′, k′, v)
  return k′, v
```

Figure 8: **SHORTSTACK initialization and processing logic at L1, L2 and L3 servers.** S_{L1}, S_{L2}, S_{L3} are the sets of proxy servers in each layer, and S is the set of physical servers upon which they are initialized. (k, v) corresponds to the plaintext key-value pair, while j is the replica identifier for a given replica of the key. F is a secretly keyed pseudorandom function and $\mathcal{H}$ is a consistent hash function.



(a) Round robin scheduling of queires at L3 queues results in non-uniform distribution

(b) Weighted scheduling at L3 queues ensures uniform distribution

Figure 9: Query-scheduling at L3 layer should ensure uniform distribution over ciphertext keys for security. In each figure, (left) shows the probability of scheduling queries from each of the L2 servers, while (right) shows the resulting distribution across ciphertext keys.

Finally, each L3 server maintains a separate queue for each L2 server it receives queries from, and dequeues queries from the queues following a biased distribution determined by the weight vector δ. To hide whether the query is a read or a write, SHORTSTACK employs the standard approach from prior oblivious data access schemes of performing each queries as a read followed by a write to the KV store. Specifically, in Figure 8's ReadThenWrite() method, the L3 server first reads and decrypts the value associated with the query from the key-value store. If the value needs to be updated (i.e., write query), then the plaintext value is updated accordingly. Finally, the L3 server writes the (re)encrypted value for the query back to the KV store.

Query scheduling at L3 layer for security. The way in which queries from different L2 servers are scheduled at each L3 server has security implications. As a concrete example, consider a scenario where three plaintext keys a, b and c with 6, 4 and 2 replicas (or, ciphertext keys), respectively, are mapped to three different L2 servers P_1, P_2 and P_3. Suppose we have two L3 servers, and one of these handles half of the ciphertext keys for each plaintext key (Figure 9 illustrates the example, focusing only on one of the L3 servers and the ciphertext keys mapped to this server). If the L3 server processes queries from each server with equal likelihood (*e.g.*, using round-robin scheduling), then the distribution across ciphertext keys would no longer be uniform, since queries from the first server would be under-sampled while those from the third server would be over-sampled (Figure 9 (a)). To ensure L3 servers still issue queries that are uniform random, they maintain a separate query queue for each L2 server, and process the queues in proportion to the volume of traffic the corresponding L2 servers generate. In the above example, the L3 server would schedule queries from each of the L2 servers with probabilities $3/6$, $2/6$ and $1/6$, respectively, leading to a uniform distribution across ciphertext keys (Figure 9 (b)).

Accurately estimating the access distribution. SHORTSTACK employs a lightweight mechanism through which a single L1 proxy server can observe all client queries, enabling distribution estimation as accurately as a centralized proxy system [6]. One of the L1 proxy servers, designated as the leader, monitors the access distribution (handling failures will be discussed in the next subsection). Upon receiving a query, an L1 proxy server asynchronously forwards the corresponding plaintext key—and not the entire query—to the L1 leader, ensuring that the leader has a complete view of the access distribution. Sending the plaintext key and not the entire query to the leader is an useful optimization for both read and write queries—it reduces the additional network load (for write queries, values are not forwarded; for read queries, the responses are not forwarded) since the plaintext key is typically much smaller than the value itself (*e.g.*, 8B keys for 1KB value in [41]). As such, this has negligible impact on SHORTSTACK scalability and performance.

4.3 Handling Failures

We now describe how SHORTSTACK ensures fault-tolerance while preserving security and correctness under failures. We assume the standard *fail-stop* failure model [36, 39]. SHORTSTACK employs a separate centralized *coordinator* node which keeps track of the health of the proxy servers using heartbeats, detects failures, and notifies other proxy servers as needed to designate a fail-over node. The coordinator node is also replicated using ZooKeeper [42] for strong consistency. As such, a $(2r+1)$-replicated coordinator can tolerate up to r failures without any security or performance consequences.

Handling L1 and L2 failures. Failure of a single L1 server does not impact the availability of SHORTSTACK, as future client queries could potentially be load balanced across the remaining L1 servers. Such a failure, however, has security implications—consider the case where an L1 proxy server fails in the middle of forwarding a batch of queries, i.e., some of the queries in the batch have been forwarded, but others are lost due to the failure. Any real queries that are lost would need to be retried by clients. The retried queries would now result in the same real accesses, but with *new* fake accesses generated. This permits an adversary to identify real queries with high confidence by simply isolating the repeated accesses due to failures. To protect against such a vulnerability,

SHORTSTACK ensures the following invariant:

Invariant 1 (Batch atomicity)**.** *Either all of the queries in a batch are forwarded to the KV store, or none of them are.*

SHORTSTACK achieves this by replicating the state of the L1 proxy servers across multiple replicas ($f+1$ replicas to tolerate up to f failures) using chain replication protocol [39]. As shown in Figure 7, SHORTSTACK maintains staggered chains across a fixed pool of physical servers, such that each physical server hosts the head node of a single chain. Chain replication ensures that all L1 replicas in the chain buffer a batch of queries, before the queries are forwarded to L2 servers—the buffered batches are only cleared when all corresponding acknowledgements are received from the L2 servers. As such, as long as any L1 replica in the chain is online, the set of buffered batches is available and can be used to retry queries as required, ensuring Invariant 1.

Since L2 servers store UpdateCache partitions, ensuring fault-tolerance for them is crucial for availability, correctness and security. As such, SHORTSTACK replicates the UpdateCache state for any key across multiple L2 proxy replicas using chain replication, similar to L1 servers.

Within each chain of L1 and L2 servers, failures of replicas are handled as per the standard chain replication protocol [39]. Since the L1 server chains interact with the L2 server chains, additional failure handling is necessary in certain cases. Consider the interaction between an L1 tail and an L2 head: if the L1 tail fails, its predecessor in the chain becomes the new tail, and resends the queries in the buffered (unacknowledged) batches to the corresponding L2 head replicas. The L2 servers, on the other hand, discard the queries that they have already seen and forward the remaining down the chain. SHORTSTACK facilitates the detection of duplicate queries by assigning unique sequence numbers to each query. If an L2 head fails, on the other hand, its successor become the new head. All L1 tails then examine their buffered batches to resend queries that were destined to the failed L2 head. As before, the new L2 head simply discards any queries that it has already seen, forwarding the remaining down the chain.

Handling L3 failures. Unlike L1 and L2 servers, L3 servers are not replicated, and hence entail different failure handling. Since L3 servers are stateless, if an L3 server fails, the remaining L3 servers can assume the responsibility of the ciphertext labels that the failed server was handling. Since the system remains available as long as at least one of the L3 servers is online, we need at least $f+1$ L3 servers to tolerate f failures. However, there are two subtle issues that can arise due to L3 failures—we describe these next, along with how SHORTSTACK addresses them.

On an L3 server failure, queries that were in-flight at the failed L3 server would be lost, which can then be retried by the L2 servers. Note that such retries can cause duplicate queries being sent to the KV store. Since the duplicate queries are to uniformly accessed ciphertext keys, it may seem like they do not reveal any distribution-sensitive information. However, repeating the queries in exactly the same order (or a correlated order) introduces a subtle security vulnerability. Specifically, when an L3 server fails, L2 tail servers repeat buffered queries (which are uniform random) and redistribute them to different L3 servers. If the order of these queries is exactly the same as before, an adversary can identify the sequences of repeated queries and correlate them to the L2 server that generated those queries. Moreover, the adversary can also map the specific ciphertext keys corresponding to the plaintext keys managed by a particular L2 server, revealing distribution sensitive information. To prevent this leakage, SHORTSTACK *randomly shuffles* buffered queries before repeating them—we formally prove in [43] how this ensures security under L3 server failures.

Recall that the L3 server performs a read followed by a write for all queries. For read queries (fake or real), the write simply writes back the value read from the KV store, i.e., a *fake* write. This can lead to consistency issues during failure of L3 servers—fake in-flight write queries sent by a failed L3 server prior to failure could be delayed by the network and overwrite a real write query sent by the new L3 proxy server responsible for the same ciphertext key. To address this issue, after an L3 failure, the L2 servers delay repeating buffered queries for a fixed amount of time to allow potential in-flight queries from the failed L3 server to get delivered to the KV store. We select the wait time at L2 servers long enough to ensure *all* in-flight queries are propagated to the KV store.

4.4 Handling Dynamic Distributions

Designing distributed, fault-tolerant, oblivious data access systems is challenging when underlying distribution can change over time. We outline two reasons. First, the centralized proxy design (§2.2) relies on having a complete view of the underlying distribution to detect and to react to distribution changes. Detecting the change when queries are spread across multiple proxy servers, and informing other proxy servers about the same, introduces the first challenge. Second, if different proxy servers independently initiate and terminate the replica swapping phase at different times, the resulting distribution may not appear uniform random to an adversary. As such, the adversary may be able to leverage this information to identify the keys that may have changed in popularity. We next discuss how SHORTSTACK resolves these challenges.

To detect distribution changes, SHORTSTACK leverages the L1 leader, which has visibility of all client queries (§4.2). The L1 leader is responsible for monitoring the access distribution and employs standard statistical tests to check if there is a change in distribution (i.e., from $\hat{\pi}$ to $\hat{\pi}'$) similar to PANCAKE. Upon detecting a change in distribution, the L1 leader initiates the distribution change process. To ensure security and correctness during distribution change, the L1 leader employs a specialized protocol inspired by two-phase commit (2PC) [44] to facilitate an *atomic* transition from $\hat{\pi}$ to $\hat{\pi}'$ across all servers

in its three-layer design, both during the initiation and termination of the replica-swapping phase employed by PANCAKE. Our 2PC-based approach guarantees:

Invariant 2 (Distribution change atomicity)**.** *Once any L3 proxy server issues a query according to $\hat{\pi}'$, all subsequent queries issued by any L3 server must be according to $\hat{\pi}'$.*

In other words, there is an instant of time t_c in the protocol's execution, such that: (1) before t_c, all queries are processed according to the distribution $\hat{\pi}$, and (2) after t_c, all queries are processed using $\hat{\pi}'$. This allows us to ensure security for SHORTSTACK even under dynamic distributions, as we detail in §5. The invariant also ensures consistency during distribution change. In particular, since the change of distribution can result in a change in number of replicas for various plaintext keys, the invariant ensures queries from old and new distributions are not mixed together; this guarantees consistency by ensuring stale replicas from the old distribution are not updated incorrectly due to the new distribution by different L2 proxy servers. We show that our protocol guarantees the above invariant, with a precise specification in [43]. Failures during the above protocol are handled transparently by chain replication as L1, L2 servers are chain replicated. This ensures that even with failures during protocol execution, Invariant 2 is still preserved. As demonstrated in §6, SHORTSTACK can recover from such failures quickly enough so as to ensure that their effects are not perceptible to an adversary.

5 Security Analysis

This section presents a security model for access pattern attacks on a system with distributed, *fault-tolerant* proxy servers, and a proof that SHORTSTACK achieves security under this model.

5.1 Need for New Security Definitions

State-of-the-art ROR (real-or-random indistinguishability) based security definitions for access pattern attacks [6] are unable to capture the security implications of our distributed proxy setting due to two main reasons. First, ROR-based definitions focus on indistinguishability between a real and a uniform random distribution (over the entire support). However, as discussed in §3.2, we do not yet know whether it is possible to guarantee uniform random distribution over the entire support during failures for *any* distributed proxy architecture. Our IND-based security model and definitions capture the powerful intuition that uniform random distribution is not even necessary: even though the distribution is non-uniform under failures, the adversary does not gain any *usable* advantage as long as the final distribution is independent of the real distribution. More precisely, our IND-based security focuses on demonstrating indistinguishability between two arbitrary input distributions. As we will show, under our model, the only information revealed to the adversary is that a failure occurred, information the adversary already possess; it cannot, however, use this information in inferring any information about the underlying distribution itself. While it is not uncommon for IND security to reduce to ROR security in many settings, this is clearly not the case in our setting if (and, as we note later, only if) there are failures.

$\text{IND-CDFA}^{\mathbb{A}}_{b,q,S,f,\pi_0,\hat{\pi}_0,\pi_1,\hat{\pi}_1}$:
$\mathsf{KV}, \mathcal{T}, \mathsf{st}_A \leftarrow\$ \mathbb{A}_1(f, S)$
$(\mathsf{KV}', \mathcal{C}, \delta) \leftarrow\$ \mathsf{Init}(\hat{\pi}_b, \mathsf{KV}, S, f)$
For i in 1 to q:
  $w \leftarrow\$ \pi_b$
  $W \leftarrow W \cup \{w\}$
$\tau_1, \tau_2, \ldots \leftarrow \mathsf{Process}(W, \mathcal{C}, \mathcal{T}, \mathsf{KV}', \delta)$
$b' \leftarrow\$ \mathbb{A}_3(\mathsf{st}_A, \mathsf{KV}', \tau_1, \tau_2, \ldots)$
return b'

Figure 10: **IND-CDFA security game.**

The second reason for needing new security model and definitions is that ROR-based definitions fail to capture the impact of query reordering on the transcripts observed by an adversary due to (i) distributed query processing, and (ii) worst-case timings of proxy failures. Specifically, a key challenge in demonstrating security lies in precisely capturing the effect of the distributed and failure-prone execution of any scheme in a sequential game-based proof, which the ROR-based approach omits. We thus have to develop accurate *simulators* that transform distributed query processing to an equivalent sequential one. Our model and definitions are not specific to SHORTSTACK, and can be used as templates for any distributed, fault-tolerant, proxy design.

When there are no failures, our security definition captures the same security guarantees as prior work [6] — our extensions to the model are required to capture the effect of failures in the distributed proxy setting. In incorporating these extensions, we have only strengthened the adversary.

5.2 Security Definitions and Proof of Security

We call our security definition Indistinguishability under Chosen Distribution and Failure Attack, or IND-CDFA (Figure 10). The game IND-CDFA is parameterized by bit b (to pick one out of the two given distributions), number of queries q, the set of proxy servers S on which the distributed oblivious data access protocol runs, the maximum number of server failures f allowed (similar to classical distributed systems literature that provides fault tolerance up to a fixed number of failures), and two distributions (and their estimates) that the adversary tries to distinguish between.

The adversary first outputs KV pairs KV and a queue $\mathcal{T}$ of at most f failure events. Each failure event e is characterized by the tuple (n, t, γ, r), where n is the server in S that fails, t is the time at which the last query is issued by n before failure, $t - \gamma$ is the time at which the last query was acknowledged at n before failure, and r is the failure recovery time. Next, the distributed proxy scheme's Init function generates transformed KV pairs KV', a set of (potentially replicated) servers $\mathcal{C}$, and internal state δ specific to the scheme. For instance, in SHORTSTACK, $\mathcal{C}$ consists of two sets of replicated server

chains (with replication factor $f+1$) corresponding to L1 and L2 layers, and a set of $> f$ unreplicated servers for the L3 layer. The state δ corresponds to weights for L3 servers used in query scheduling, as outlined in §4.2.

After initialization, q queries are drawn from the distribution π_b and populated into the vector W. The proxy scheme's Process function takes W, $\mathcal{C}$, $\mathcal{T}$, KV′ and δ as input, and generates the output transcripts τ, which is fed to the adversary to try and guess the underlying distribution (i.e., the bit b). The adversary "wins" if it guesses b correctly. Intuitively, the security goal captured by the definition rules out access pattern attacks since the probability of accessing an encrypted label in KV′ is independent of the underlying distribution itself, and an adversary cannot determine which distribution was used to generate accesses to KV′.

Note that, IND-CDFA definition is independent of SHORTSTACK's design. Specifically, our definitions only assume the presence of multiple failure-prone proxy servers which are initialized using an Init function and process queries using a Process function, neither of which are specific to SHORTSTACK. Thus, our security model and definitions can be used to study oblivious data access properties of any distributed system that can factor its initialization and query processing logic along these two functions.

The following theorem establishes the security of SHORTSTACK under IND-CDDFA:

Theorem 1 (IND-CDFA Security)**.** *Let $q \geq 0$ and $Q = q \cdot B$. Let $\pi_0, \hat{\pi}_0, \pi_1, \hat{\pi}_1$ be query distributions. For any q-query* IND-CDFA *adversary $\mathbb{A}$ against* SHORTSTACK *there exist adversaries $\mathbb{B}$, $\mathbb{C}$, $\mathbb{D}_1$, $\mathbb{D}_2$ such that*

$$\mathbf{Adv}^{ind\text{-}cdfa}_{\text{SHORTSTACK}}[(\mathbb{A})] \leq \mathbf{Adv}^{prf}_{F}[(\mathbb{B})] + \mathbf{Adv}^{ror}_{E}[(\mathbb{C})] + \mathbf{Adv}^{dist}_{Q,\pi_0,\hat{\pi}_0}[(\mathbb{D}_1)] + \mathbf{Adv}^{dist}_{Q,\pi_1,\hat{\pi}_1}[(\mathbb{D}_2)]$$

where F, E are PRF, AE schemes used by SHORTSTACK*. Adversaries $\mathbb{B}, \mathbb{C}, \mathbb{D}_1, \mathbb{D}_2$ run in same time as $\mathbb{A}$ with Q queries.*

Our security proof stems from three key components:

- Security of E as a randomized authentication scheme applied over values and F as a pseudorandom function applied over keys; this is rigorously analyzed in prior work [45, 46].
- Our estimate $\hat{\pi}$ of the underlying distribution π is sufficiently accurate. While this estimate may not be perfect, our security model only requires that $\hat{\pi}$ and π be indistinguishable for a limited number of samples, which holds for estimators used in prior work [6] on real-world workloads [41]. Since our design employs a single leader L1 server to estimate the underlying distribution using the keys for all client queries (§4.2) and employs the same estimators as prior work, its estimation is just as accurate.
- Accesses issued to the KV store reveal nothing about the underlying distribution π.

To prove the third component, we introduce simulators to sequentialize the distributed execution of SHORTSTACK's query processing to make it compatible with our game-based definition (Figure 10). Specifically, we simulate Process function for SHORTSTACK by first generating the intermediate transcript, β, assuming no failures. We do so by (i) going layer by layer and executing processing logic at appropriate servers in SHORTSTACK, and (ii) incorporating the impact of network reordering across queries between layers. We then use a Transform simulator to capture the effect of failures and generate the final transcripts τ from β. We do so by recursively applying the effect of L3 server failure events in $\mathcal{T}$ on the intermediate transcripts β in the order that they occur.

Finally, we show that the final transcripts τ are independent of intermediate transcripts β, and then show that β are independent of the underlying distribution π. The first part holds since SHORTSTACK randomly shuffles buffered queries before replaying them post failure (§4.3) and failure recovery time in SHORTSTACK is short enough to not be visible to an external observer given our failure model (§4.3) and as shown empirically in (§6.2). The second part holds, since the underlying oblivious data access scheme [6] in SHORTSTACK generates uniform random queries (§4.2) and network reorderings between layers are independent of π.

Finally, to model dynamic distributions, we generalize the above definition to Indistinguishability under Chosen Dynamic Distribution and Failure Attack or IND-CDDFA. This definition, along with the proof of SHORTSTACK's security under it, formal descriptions of our simulators, and the proof for independence of τ and π are presented in [43].

6 Evaluation

SHORTSTACK is implemented in $\sim$ 6k lines of C++, using Thrift as the RPC library, AES-CBC-256 for encrypting values, HMAC-SHA-256 as our PRF, and Redis as the KV store.

Compared systems. We compare SHORTSTACK performance against two baselines. The first baseline is distributed, but encryption-only, that is, it encrypts data and client queries, but does not guarantee oblivious data access; here, client queries are randomly load balanced across stateless proxy servers that perform encryption/decryption and forward queries to the KV store. This baseline serves as an upper bound on the performance that can be achieved by any oblivious data access system (including SHORTSTACK). The second baseline is a centralized PANCAKE [6] proxy server. While this suffers from security and availability problems in the face of failures (§3.1), its performance serves as a reference point for understanding SHORTSTACK's scalability.

Experimental setup. We run our experiments on Amazon EC2. By default, we host the proxy instances across c5.4xlarge VMs with 16 vCPUs (8 cores with 2 threads per core), 32 GB RAM and 10Gbps network links. In order to emulate a cloud KV store with practically infinite bandwidth,

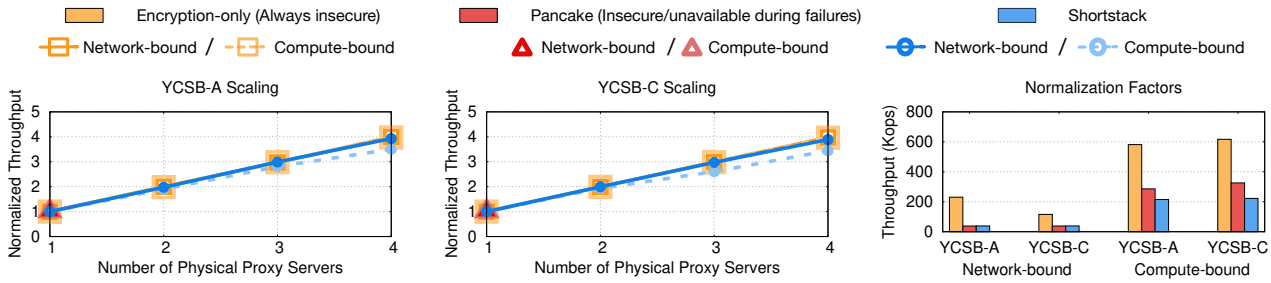


Figure 11: **Scalability properties of different systems when network bandwidth and compute are the bottleneck.** (left, middle) show system throughput normalized by throughput for a single physical proxy server, while (right) shows system throughput with a single physical proxy server. The Encryption-only lines for the network-bound and compute-bound cases overlap, since its throughput scales linearly in both cases. Since Pancake is centralized, it only has a single data point at $X = 1$ for each of the cases, and these points overlap. See §6.1 for details.

we use a single powerful VM, c5d.metal (96 vCPUs, 128 GB RAM) with large network bandwidth (25 Gbps). Similar to prior work [6], we emulate WAN access link bandwidth by throttling the bandwidth from each proxy server to the KV store server to 1Gbps. The clients run on lightweight t3.2xlarge VMs (8 vCPUs, 32GB RAM) in the same LAN. Both PANCAKE and SHORTSTACK use a batch size of $B = 3$.

Dataset and Workloads. We use the standard YCSB benchmark [41] to generate our dataset and workloads. The dataset comprises 1 million KV pairs, with 8B keys and 1KB values. We use workloads A (50% reads, 50% writes) and C (100% reads) for our experiments. YCSB workloads perform accesses distributed according to the Zipfian distribution [41]; unless otherwise stated, the skewness parameter for the Zipfian distribution in our experiments is set to the YCSB default of 0.99 (that is, heavily skewed), which is representative of many real world workloads. We also perform sensitivity analysis against distribution skew.

6.1 Scalability Analysis

We now analyze SHORTSTACK's scalability with varying number of physical proxy servers under different workloads.

Throughput scaling under bandwidth bottleneck. We study throughput scaling for SHORTSTACK by varying the number of physical proxy servers and comparing its performance against the baselines. For SHORTSTACK, k physical proxy servers constitute k chain-replicated L1 instances with $\min(k,3)$ replicas each, k chain-replicated L2 instances with $\min(k,3)$ replicas each, and k unreplicated L3 instances (i.e., the system can tolerate up to $\min(k,3)-1$ failures). For the encryption-only baseline, a separate proxy instance is run on each physical proxy server, and the PANCAKE baseline always uses only one physical proxy server.

Figure 11 shows the scalability results for two cases: one where the physical proxy servers are network-bound (solid lines), and another where they are compute-bound (broken lines). We begin with the former case; we see that SHORTSTACK throughput scales linearly with the number of physical proxy servers. Note that we normalize each system's throughput by its throughput with a single physical proxy server — Figure 11 (right) shows normalization factors for each system, i.e., throughput with single physical proxy server. The red cross shows the throughput of the PANCAKE baseline (38 KOps): SHORTSTACK's distributed design enables linear throughput gains relative to PANCAKE via scaling. The insecure baseline also scales linearly due to random load-balancing across its proxy instances. Since all proxy servers are network bound, SHORTSTACK incurs only a constant overhead (corresponding to the relative bandwidth increase due to the oblivious data access protocol) compared to the encryption-only baseline for all configurations as we scale the number of physical proxy servers. For the YCSB-C workload, the gap between SHORTSTACK and Encryption-only baseline throughput stems from the 3× overhead imposed by the PANCAKE protocol for a batch size of $B = 3$. For the YCSB-A workload, however, the encryption-only baseline throughput is 6× higher than SHORTSTACK since it can exploit the bidirectional bandwidth to the KV store for 50% reads and 50% writes. SHORTSTACK, however, already issues a read followed by a write for every query, so it is unable to similarly exploit the bidirectional bandwidth. Since YCSB-A has equal proportion of read and write queries, this situation corresponds to the worst-case bandwidth increase (6×) for SHORTSTACK relative to the encryption-only baseline.

Throughput scaling under compute bottleneck. We now analyze throughput scaling when the physical proxy servers are compute-bound: we re-run the same experiments as above, but using c5.metal EC2 VMs (96 vCPUs, 192GB RAM, 25Gbps network bandwidth) for all systems *without* throttling the access link bandwidth to the KV store server. As the broken lines corresponding to the compute-bound case in Figure 11 show, with a single physical proxy server SHORTSTACK achieves slightly lower throughput than PANCAKE for both workloads. This is because, under a compute bottleneck, SHORTSTACK incurs additional RPC processing overheads for communication between its layers. SHORTSTACK's throughput increases significantly with more physical proxy servers, achieving $3.4-3.6\times$ higher throughput with 4 physical proxy servers. The increase in throughput is not perfectly linear, since workload skew results in load imbalance at the L2 layer. This effect

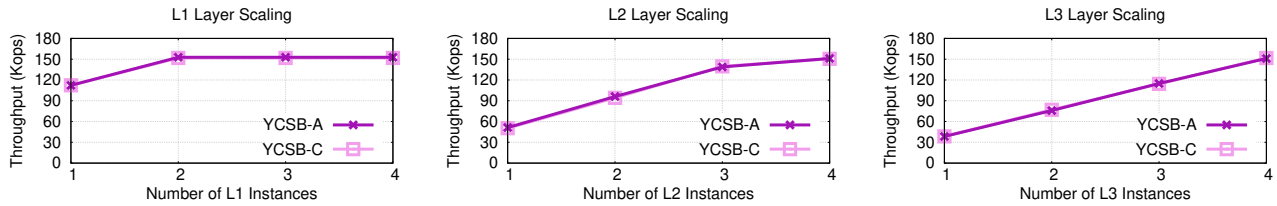

Figure 12: **SHORTSTACK layer-wise scaling for YCSB workloads A and C.** See §6.1 for details.

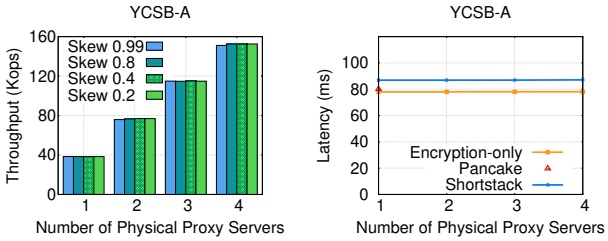

(a) SHORTSTACK throughput is unaffected by access skew.

(b) Query latency vs. number of physical proxy servers.

Figure 13: **SHORTSTACK throughput scaling with varying skew (a) and SHORTSTACK latency overheads (b).** See §6.1 for details.

is not observed for the network-bound case, since the network bandwidth between L3 instances and the KV store is bottlenecked before workload skew causes compute at the L2 layer to become bottlenecked. For the reminder of our evaluation, we use the network-bound setting as our default configuration.

Understanding per-layer scalability bottlenecks. Our experiments in Figure 11 scale up all layers of SHORTSTACK in equal proportions as the number of physical proxy servers are increased. To better understand SHORTSTACK's bottlenecks, we now study scalability on a per-layer basis. Since each layer performs a different component of PANCAKE logic (§4), varying the scale of each layer independently while keeping the scale of the other two layers fixed allows us to understand which step becomes a throughput bottleneck before the others. For this, we use a setup similar to Figure 11. To understand L1 layer scalability, we fix the number of physical proxy servers to 4, the number of replicated L2 instances and unreplicated L3 instances to the default (4), and vary the number of replicated L1 instances from $1-4$. We perform similar experiments for the L2 and L3 layers as well. Figure 12 shows the corresponding results for the YCSB-A and YCSB-C workloads. For the L1 layer, throughput increases slightly from $X = 1$ to 2, beyond which it saturates, since L1 is no longer the bottleneck. For the L2 layer, from $X = 1$ to 3 throughput increases, albeit non-linearly due to plaintext key-based partitioning — while the number of plaintext keys handled by each L2 server is roughly equal, the number of replicas handled by them is skewed due to the skew in the YCSB workload. At $X = 4$, the L2 layer is no longer the bottleneck. For the L3 layer, throughput scales linearly from $X = 1$ to $X = 4$ due to ciphertext key-based partitioning, with each L3 proxy handling roughly the same number of ciphertext keys.

As expected, the bottlenecks are different at different SHORTSTACK layers. When all layers are sufficiently provisioned, SHORTSTACK is able to saturate the access link bandwidth between the L3 layer and the KV store. Reducing the number of L1 and L2 proxy instances, however, leads to *compute* becoming the bottleneck at the respective layers. One of the key contributors of compute overheads are serialization/deserialization for network queries. Finally, layer-wise scaling characteristics are similar for YCSB-C and YCSB-A workloads, as UpdateCache processing in YCSB-A due to writes does not account for much of the compute overheads.

Throughput scaling with skew. We evaluate SHORTSTACK scaling for workloads with different skew for a setup similar to Figure 11. We vary the skew parameter for YCSB's Zipf distribution from 0.2 (close to uniform) to 0.99 (heavy skew) to consider both extremes. We only show our results for YCSB-A in Figure 13(a), since results for YCSB-C were similar. SHORTSTACK system throughput scales linearly regardless of skew, because the bottleneck in the end-to-end query execution is the access link bandwidth between the L3 layer and the KV store for all scales. Since the skew only affects processing at L2 layer (which is not the bottleneck), our throughput is independent of skew. While SHORTSTACK throughput scales linearly even for heavily skewed workloads, there could indeed be rare extreme-case scenarios where such would not be the case, *e.g.*, if all popular plaintext keys get consistently hashed to a single L2 instance, resulting in a compute bottleneck at that instance.

SHORTSTACK Latency overheads. To quantify SHORTSTACK's latency overheads, we evaluate end-to-end query latency for varying number of physical proxy servers for compared systems using a setup similar to Figure 11 with one change: we separate the KV store and physical proxy servers by the WAN. Figure 13(b) shows the results; again, we only show YCSB-A workload results, as YCSB-C results are similar. Independent of the scale, SHORTSTACK increases query latency by a modest 8% (additional 6.8ms) compared to PANCAKE. This increase in latency is due to additional processing and network hops introduced by SHORTSTACK's multiple layers and chain replication within the L1 and L2 layers. Nevertheless, these overheads are masked by the significantly larger WAN access latency.

6.2 Failure Recovery

We now evaluate SHORTSTACK's ability to recover from failures and also validate our assumptions in proving SHORTSTACK security. We fix the number of physical proxy servers

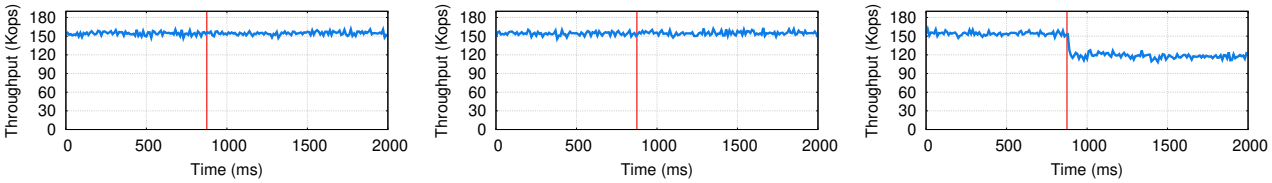

Figure 14: **SHORTSTACK failure recovery for (left) L1, (middle) L2, and (right) L3 failures.** See §6.2 for details.

to 4, the number of 3×-replicated L1, 3×-replicated L2, and unreplicated L3 instances to 4 each, and use the YCSB-A workload. To understand the impact of failures on each layer independently, we fail one proxy instance in a particular layer by killing its associated process; for L1 and L2, we kill an arbitrary replica from one of the instances. We measure the instantaneous throughput of our system during each experiment at 10ms granularity; when measured at finer-grained timescales, we found that the instantaneous throughput numbers were too noisy to discern any meaningful trends.

Figure 14 shows the effect of failure at each layer on SHORTSTACK throughput. We find that failures in L1 and L2 proxy chains do not cause any noticeable dip in the throughput, since SHORTSTACK can quickly recover from failures within 3–4 ms — much faster than the average query latency over WAN (∼ 90ms), and smaller than the typical variance in query latencies. Hence, an adversary cannot reliably distinguish between a failure event and variations in instantaneous throughput due to noise caused by network delays, independent of the timescale at which measurements are done. This validates our assumption for SHORTSTACK security under failures discussed in §5 — specifically, L1 and L2 failures have an imperceptible impact on an adversary's observed access pattern to the KV store. Upon an L3 proxy failure, the throughput reduces by 25% – commensurate with the reduction in the bandwidth to the KV store server; however, since L3 layer partitions queries by ciphertext keys, it does not reveal any information about the client access patterns.

7 Related Work

We now discuss the works most closely related to SHORTSTACK's goals of distributed, fault-tolerant, oblivious data access. ORAM [10] approaches have been adapted to real world cloud storage [12–17, 26], with recent efforts enabling *concurrency* and *asynchrony*. Oblivious Parallel RAM (OPRAM) [12, 14, 47–50] permits multiple concurrent clients to query the storage, but requires cross-client coordination per-query (*e.g.*, using oblivious aggregation [12]) to ensure no two clients concurrently issue a query for the same data. This severely limits throughput scaling under high query traffic due to compute bottlenecks.

CURIOUS [16] and TaoStore [15] employ a centralized proxy model, but permit client parallelism via *asynchrony*. Since each operation requires updates to per-plaintext key proxy state for multiple random KV pairs, extending their design to a distributed and secure one is challenging. The latest in this line of work, ConcurORAM [17] and Snoopy [26], permit multiple parallel clients to query a cloud-hosted ORAM *without* inter-client or proxy based coordination. ConcurORAM achieves this by offloading much of the synchronization to the cloud, which not only requires non-trivial changes to cloud storage, but also limits system throughput under high load. Concurrent to our work, Snoopy builds a distributed oblivious data access system (for ORAM-based designs); however, Snoopy does not prove security for scenarios where servers can fail. In any case, SHORTSTACK and Snoopy offer the same trade-offs as discussed in [6]—Snoopy can handle active adversaries, but also incurs significantly higher overheads relative to SHORTSTACK. Prior work [6] has empirically shown that state-of-the-art single proxy ORAM schemes achieve 220× lower throughput than PANCAKE for the same workloads as in our evaluation. Since SHORTSTACK can scale PANCAKE's throughput linearly (§6) with number of proxy servers, even if one could design a distributed ORAM system that scales near-perfectly with number of proxy servers, the maximum achievable throughput would still be orders of magnitude lower than SHORTSTACK.

8 Conclusion

Existing systems for oblivious data access rely on a centralized, stateful, proxy to coordinate queries between applications and the storage server. We have demonstrated that, in failure-prone deployment, such systems can suffer from security violations, long periods of unavailability and/or scalability limits. Our core contribution is SHORTSTACK, a distributed, fault-tolerant and scalable system for oblivious data access. Using a novel layered architecture, SHORTSTACK achieves the classical obliviousness guarantee—access patterns observed by the adversary being independent of the input—even under a powerful passive persistent adversary that can force failure of arbitrary (bounded-sized) subset of proxy servers at arbitrary times. We also introduce a security model to study oblivious data access with distributed, failure-prone, servers.

Abstract

Metadata-private messaging designs that scale to support millions of users are *rigid*: they limit users to a single device that is online all the time and transmits on short regular intervals, and require users to choose precisely when each of their buddies can message them. These requirements induce high network and energy costs for the clients, restricting users to communicate via one powerful device, like their desktop.

Groove is the first scalable metadata-private messaging system that gives users *flexibility*: it supports users with multiple devices, allows them to message buddies at any time, even when those buddies are offline, and conserves the user's device bandwidth and energy. Groove offers flexibility by introducing *oblivious delegation*, where users designate an untrusted service provider to participate in rigid mechanisms of metadata-private communication. It provides differential privacy guarantees on par with rigid systems like Stadium and Karaoke.

An evaluation of a Groove prototype on AWS with 100 servers, distributed across four data centers on two continents, demonstrates that it can achieve 32 s of latency for 1 million users with 50 buddies in their contact lists. Experiments with a client running on a Pixel 4 smartphone show that it uses about 100 MB/month of bandwidth and increases battery consumption by 50 mW (+16%) compared to an idle smartphone. These measurements show that Groove makes it realistic to hide messaging metadata on a mobile device.

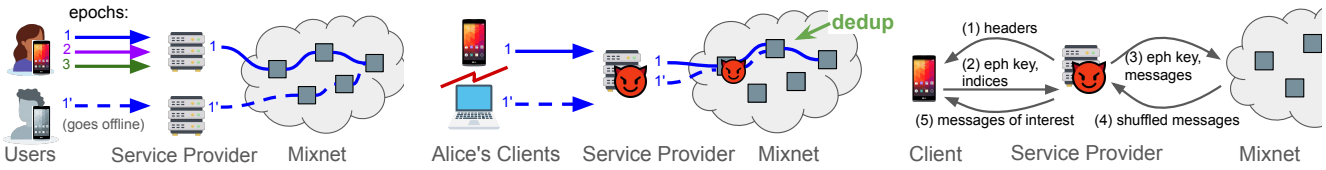
1 Introduction

There has been significant recent progress in scalable metadata-private messaging systems. These systems hide who communicates with whom and can support more users by deploying proportionally more servers (supporting a large user base is crucial for privacy [9]). However, systems that are scalable and provide strong privacy guarantees impose *rigid* requirements on users [16, 19, 20, 26, 27], like needing users to synchronize messaging into rounds and coordinate precisely in which rounds they will communicate with their buddy. If two buddies are not simultaneously online, they cannot communicate. Naively storing a message for a buddy to fetch later exposes the age of the message, which can be used to correlate the sender. Instead, this line of work has relied on expensive dialing protocols [21, 27] to coordinate conversations, which are impractical for mobile devices.

Rigidity in private messaging systems is inherently costly for clients. Since communicating users must be simultaneously online, an attacker monitoring the network can correlate buddies over time. To combat such attacks, clients submit and poll for messages at every round, leading to high bandwidth and energy overhead. This makes running a client on a phone prohibitively expensive and effectively requires the users to have an always-on desktop computer (e.g., at home). However, many users do not have such a computer, e.g., if they use a laptop that they carry with them. Finally, using metadata-private messengers from multiple devices poses a risk if the devices become partitioned and accidentally send multiple message to the same buddy in the same round (which reveals the sender). These limitations stand out compared to traditional messaging systems (without metadata privacy) and hinder adoption.

We present Groove, the first *flexible* messaging system that provides metadata privacy and scales well to support a large user base. Groove's users can send messages to any of their buddies from any device, and can go offline and retrieve messages sent to them later. Groove provides similar messaging latency to recent metadata-private communication systems under the same global active adversary model [15, 16, 19, 20, 26]. Groove builds on mixnets, where servers shuffle messages in batches, to unlink senders from their messages. However, mixnets are inherently rigid: they require all users to submit a message in every round to mix all conversations together, and for all users to receive messages from the mixnet at the same rate to avoid correlated traffic patterns between buddies. To handle this rigidity, Groove introduces *oblivious delegation* to an untrusted service provider. Groove clients interact with a service provider who participates in the rigid mixnet protocol on their behalf and synchronizes multiple devices. Oblivious delegation ensures that an adversary can not learn anything about users' communication metadata by compromising their service providers, even if the users' devices go offline or get partitioned. Achieving oblivious delegation involves three mechanisms, as follows.

Non-interactive setup (Figure 1a). Establishing a message channel between buddies requires them to submit just one setup message through the mixnet, without waiting for their peer's response. A non-interactive setup protocol is crucial since buddies might not be simultaneously online to run the



(a) *Non-interactive Setup*. Groove's async setup protocol enables metadata-private messaging between buddies, even if they are not simultaneously online. The service provider buffers setup messages and submits them to the mixnet at the right time.

(b) *Uncoordinated Replacement*. Groove allows multiple clients (on different devices) of the same user to interact with the system safely, even if they cannot coordinate. Clients can replace old messages buffered at the service provider to support new buddies.

(c) *Oblivious Fetch*. Groove's clients avoid retrieving cover traffic messages stored at the service provider, without revealing which messages they fetch. The servers only process a user's messages once per client, regardless of the number of messages stored.

Figure 1: The three mechanisms that allow oblivious delegation in Groove.

protocol. Groove hides communication metadata even if only one buddy attempts this setup (or their peer's provider discards the other setup message). Message channels persist for long epochs, and this protocol allows Alice to prepare setup messages at her service provider well in advance and for many epochs. Service providers, if they're honest, submit setup messages to the mixnet at the right time, allowing Alice's buddies to send her messages even she goes offline. If the service provider misbehaves, messages might be (noticeably) lost but privacy is preserved, and Alice can switch to a different provider.

Uncoordinated replacement (Figure 1b). The adversary may partition a user's devices and prevent them from deciding which device communicates at a given round. If several devices of the same user accidentally submit messages to the same buddy in the same round, they can expose the recipient, who receives extra messages. Groove solves the issue with a new message replacement technique: each device can independently refresh the messages queued at the service provider without coordinating with other devices. Crucially, the protocol ensures that no metadata is revealed to the adversary, even if the provider is rogue and submits all messages (old and new) to the mixnet. This is achieved through path selection and message-tagging mechanisms, which ensure that each buddy receives at most one message from all of the user's devices. The replacement protocol allows clients to update setup messages, and hence to add buddies after preparing message channels for future epochs. It also allows users to switch between their devices, like traditional messaging applications.

Efficient messaging with many buddies (Figure 1c). Groove avoids expensive dialing (as in [21, 27]) by keeping a message channel open for each of a user's buddies. To minimize client costs when having many message channels, Groove's clients use a submission protocol that avoids sending a cover message for each idle channel, and a fetch protocol that avoids retrieving cover messages from idle channels. Crucially, both protocols are oblivious and do not reveal sensitive information to the service provider (e.g., which channels were active and carried real messages from buddies). Finally, Groove minimizes the cost that each message channel induces on the mixnet, with the most crucial improvement over prior work being the memory footprint. Groove supports 75M parallel message exchanges with 100 servers (prior work supports 1M–10M parallel message exchanges in the same deployment [16, 19, 20, 26]).

We analyze Groove's design and show that it achieves differential privacy against an attacker who has complete control over the network and has the power to compromise many servers that make up the system (including all service providers). Through this analysis, we choose the system's parameters that would provide a strong degree of privacy.

To demonstrate that Groove can support a large user base, we built a prototype and evaluated its performance on AWS servers distributed across four data centers. We also implemented a mobile client, deployed it on a Pixel 4 phone, and measured Groove in terms of battery and network usage. We show that Groove scales well with the number of servers and using 100 servers, it supports 1–3 million users sending and receiving messages from 50 buddies every 32–80 seconds. The client uses 54 MB–106 MB of network bandwidth per month and its battery consumption increases by 16% compared to the idle phone (when using cellular data). We recognize that Groove's latency is high compared to traditional messaging apps; nonetheless, it removes the rigid client requirements of previous designs and enables large-scale metadata-private messaging for mobile users.

In summary, our contributions are the following:

- oblivious delegation, an approach for offloading rigid mixnet requirements to an untrusted service provider, which enables client flexibility;
- Groove, a scalable metadata-private messaging system, and an analysis proving Groove's privacy guarantee;
- an implementation of Groove and an experimental evaluation of its performance, showing that it can support mobile clients and scale well to handle a large user base.

2 Related Work

Differential privacy. Groove's approach of providing differentially-private communication using a mixnet is based on prior work [19, 26, 27]. However, these earlier designs impose rigid requirements on users. First, users must be simultaneously online, and their clients must send and receive messages at every round to communicate. Second, users can only run a client on a single device, which also sidesteps the problem of device partitions. When a user's devices cannot coordinate, a conversation (which normally has one message per round) might end up with multiple messages per round, revealing the recipient. Groove addresses these problems through oblivious delegation.

Private Information Retrieval (PIR). PIR protocols support storing and retrieving information asynchronously from a database, without revealing anything about which message is retrieved [7, 23]. These protocols could provide a good degree of flexibility to clients: they have low client bandwidth requirements and allow the recipient to read a message at any time after the sender deposits it in a database. However, as users' messages accumulate in the database, processing each client's PIR query requires more work from the database server, limiting scalability. For example, Pung [2, 4] supports up to 20k–60k fetches per minute with 1M messages in its database. Express [11] optimizes PIR retrievals at the cost of making writes more expensive, but still the system only supports sending tens of messages per second across all clients. In contrast, Groove clients induce the same amount of work independent of how many messages accumulate in the system, enabling millions of users to send and receive messages every minute.

Communicating with many buddies. Metadata-private messaging systems minimize the load on the servers and overhead for the client by limiting users to receive messages from one buddy at a time [2, 4, 16, 19, 26, 27]. They require buddies to run a hefty dialing protocol to agree on when to communicate. For PIR systems, such as Pung and Addra [1,4], relying on dialing is even more essential; since reading is expensive for the servers, clients cannot retrieve messages from each buddy all the time. Many systems [1, 2, 16, 19, 26] propose using Alpenhorn's differentially private dialing [21], which takes about 5 minutes to coordinate between buddies and requires 62 GB of client bandwidth per month [21, §8.2]. Groove mitigates the clients' costs through its oblivious message fetching protocol and minimizes the load each message channel induces on the system, so users can keep channels with many buddies (e.g., 50 buddies per user in our implementation). Dialing may also be seen as a limited form of asynchronous messaging between users. The Vuvuzela [27] and Alpenhorn [21] dialing protocols use at least 3000× more bandwidth on clients than Groove, when configured to provide 1-minute messaging latency like Groove.

Metadata-private communication over persistent channels. Groove's users communicate over persistent message channels, similar to Tor's circuits. However, Tor does not protect users from a strong adversary model. An adversary monitoring the network can infer the path of users' messages across relays by correlating incoming and outgoing packets. Hydra [25] uses circuits to connect two endpoints, like Tor's hidden services [5], but does not hide the number of active conversations to the adversary [25, §4.6¶1], which allows for intersection attacks. Yodel [20] uses a mixnet with persistent circuits but requires two communicating users to be online at the same time to coordinate their circuits. Both Hydra and Yodel support only one device per user and have clients send and receive messages every round, two rigid shortcomings that Groove addresses.

Flexible clients through trusted servers. Loopix [24] hides metadata by relaying messages through a mixnet. It addresses the client flexibility problem by storing messages for users at *trusted* service providers. The service providers sees when a user receives a message, and can thus perform intersection attacks with other users who were online in time to send this message. Thus, users must make a tricky decision about which service providers they trust. Furthermore, the service provider is a singular target for learning about the relationships of its users. Pond [17] requires users to run a trusted server themselves. This leads to a simpler design than Groove (e.g., partitioned devices are not a concern) but limits the system to savvy users who can securely operate their own servers.[1] This is problematic for metadata-private communication, which benefits from a large user base [9]. In Groove, users maintain privacy even if their service providers fall under the attacker's control, so they do not need to operate servers themselves.

3 Overview

Groove allows buddies that share a secret to secretly exchange short text messages (e.g., 100B). Each buddy can run clients on multiple devices and seamlessly switch between them. Service providers bridge between the rigid mixnet protocol and the flexible clients, that can send and receive messages asynchronously. Each user designates a service provider and runs Groove's oblivious protocols for setting up message channels (Figure 1a), replacing messages (Figure 1b), and fetching messages (Figure 1c). The service provider submits messages to the mixnet on the user's behalf and stores messages that the user receives from the mixnet. It also helps the user synchronize their clients across all devices. Users

[1] Running a personal server in the cloud undermines security against a strong adversary that may be able to compel the cloud operator to disclose data or exploit side channels by deploying a VM on the same machine, and operating a physical server requires significant effort and expertise.

need not trust their service provider for privacy. To anonymize messages, Groove uses a parallel mixnet [12]. Parallel mixnets scale well with the number of servers by offering many parallel routes for processing messages. Groove extends the servers' message processing logic to enable oblivious delegation, and it is otherwise agnostic to the mixnet's internal design choices, such as the server topology or verification protocol (that ensures servers process messages correctly).

3.1 Threat model

Groove aims to hide its users' communication metadata from a *global active attacker* that controls all network links. In particular, this attacker observes when clients (dis)connect from the network and may partition users' devices. The attacker may also control all service providers, and each mixnet server with some probability f, which is provided as an assumption in the system's configuration. A smaller f yields better performance at the expense of a stronger trust assumption. The attacker can also run arbitrarily many clients. Still, an attacker could learn about a user's communication by directly compromising their device or the devices of their buddies [3], although forward secrecy prevents them from learning about the user's communication in the past. Finally, Groove assumes that the attacker is computationally bounded, so standard cryptographic primitives, such as hash functions and encryption schemes, are secure.

3.2 Goals

Privacy. Groove achieves differential privacy [10]. Consider an attacker and their view of the system through all network links and service providers, and the mixnet servers and clients that they operate. Groove ensures that the attacker's view is likely to be the same whether two users, call them Alice and Bob, are buddies or not. More formally, consider the attacker's observations $\mathcal{O}$ and the following two scenarios. In one scenario, Alice and Bob are buddies and can chat (denoted by $\mathrm{A} \leftrightarrow \mathrm{B}$), and in the other, they are not buddies and cannot chat (denoted by $\mathrm{A} \not\leftrightarrow \mathrm{B}$). Groove ensures the following inequalities for small $\varepsilon, \delta \geq 0$:

$$Pr[\mathcal{O}|\mathrm{A} \leftrightarrow \mathrm{B}] \leq e^{\varepsilon} Pr[\mathcal{O}|\mathrm{A} \not\leftrightarrow \mathrm{B}] + \delta, \quad (1)$$
$$Pr[\mathcal{O}|\mathrm{A} \not\leftrightarrow \mathrm{B}] \leq e^{\varepsilon} Pr[\mathcal{O}|\mathrm{A} \leftrightarrow \mathrm{B}] + \delta$$

That is, the probability for any observations the attacker could make is close under both scenarios (up to small constants ε, δ). Informally, Alice being buddies with Bob appears to the adversary almost as likely as them not being buddies. Thus, Alice could plausibly deny being buddies with Bob or claim to be buddies with anyone else. This privacy guarantee holds even if Alice or Bob is the sole honest user of a rogue service provider, the attacker partitions their devices, and observes the system for a long time.

Client flexibility. Groove should not impose strong timing or resource requirements on clients. It should allow Bob to retrieve Alice's message at any time after it reaches Bob's service provider and accommodate clients with network and battery constraints (that need to minimize communication or that might go offline). In particular, Groove should support clients running on mobile devices. At the same time, Groove should allow other clients to connect more often and achieve lower message latency. Finally, Groove should enable users to run clients on multiple devices and switch between them.

Performance. Groove aims to support millions of users with dozens of buddies. Once Alice sends a message, Bob can retrieve it with a latency on the order of a minute. The system should scale, i.e., provide the same performance to a larger user base by deploying proportionally more servers.

Availability. Groove's availability guarantees in the face of failing servers should primarily come from the mixnet and not degrade by its oblivious delegation approach. An overloaded or downed service provider can prevent service to its users, but the system's availability for users of other service providers should not be affected. Since the service provider is untrusted, it can use replication for better availability guarantees without security implications for its users. Moreover, having untrusted service providers also allows users to change to another provider if they suspect their provider is preventing service without risking exposing sensitive information to more parties (the current and new provider). We describe how users can detect and combat such providers in Groove's design (§5).

4 Background

Groove's users send and receive messages over message channels called *circuits*. A circuit is a fixed route of servers in the mixnet that persists for an *epoch*, which consists of many communication rounds (e.g., an hour to a day's worth). Each circuit connects a user's service provider to a *dead drop*, an ephemeral address where users exchange messages. Two buddies coordinate pseudorandom dead drops using a shared secret. The mixnet ensures that an adversary cannot correlate which service provider connects to what dead drop using noise messages. Groove borrows this communication model from previous systems [5, 19, 20, 25] (see §2), but changes the way circuits establish to support oblivious delegation. We summarize below the existing techniques that Groove uses to simplify the exposition of its new mechanisms in §5.

Like other mixnets [15, 26, 27], Groove's mixnet servers have unique public keys per epoch. Clients know the servers' public keys, e.g., through a transparent public key infrastructure [18, 22]. The way rounds are kicked-off depends on the mixnet, which Groove abstracts; e.g., many designs use an untrusted coordinator that announces to all mix servers when to start new rounds [15, 16, 19, 20, 26, 27].

Messaging over circuits and dead drops. The circuit setup message is onion encrypted with the public keys of the servers on the route. Each onion layer includes the next

server's ID, an ephemeral Diffie-Hellman public key, and an authentication code that ensures no earlier server has modified the onion. Each server completes the Diffie-Hellman handshake to derive a shared symmetric key with the client, and uses this key to verify the authentication code. After receiving messages from all servers in the previous hop, the server deduplicates and shuffles messages, and forwards them to the next hop. Servers store their shuffle's permutation and the symmetric keys; later, they use these records to process messages over the circuit.

During a communication round, mixnet servers process one message on each circuit. Each message is onion encrypted with the symmetric keys registered at circuit setup. The mixnet's servers shuffle and decrypt messages they receive using the permutation and symmetric keys they stored earlier. Servers deduplicate messages on the same circuit. If a server does not receive a message on a circuit, it fills in a cover message to ensure all circuits have one message. The symmetric encryption ensures that any random message that a server fills in is indistinguishable from a real message to other servers along the route. When two circuits connect to the same dead drop, the server hosting its address swaps the messages on these circuits and sends them back through the circuits, which is how buddies exchange messages.

Noise. Previous work shows how mixnet servers can add noise messages to protect metadata [19, 27]. We apply this technique in the context of Groove's circuits. For each inter-server mixnet link, each server decides on the number of noise circuits to route over that link by drawing from the Poisson distribution. Servers generate two kinds of noise: "doubles" which is a pair of circuits bound to the same dead drop to obscure the number of buddy-relationships, and "singles" which is a circuit terminating at a dead drop without a pair, to obscure the case where one of the buddies does not create their circuit to the shared dead drop. Like Karaoke [19], Groove uses Bloom filters to ensure that malicious servers do not drop the noise circuits.

5 Design

Figure 1 illustrates the parties in Groove: users, clients running on different types of devices, service providers, and the mixnet. When Alice and Bob become buddies, they add each other to their address books, and their clients establish a fresh shared secret. This secret allows Alice and Bob's clients to authenticate and encrypt messages (end-to-end) and coordinate dead drops for exchanging messages. The clients might create this secret out-of-band (e.g., by scanning QR codes if users meet in person) or via a metadata-private "add-friend" protocol (like in Alpenhorn's protocol suite [21][2]).

Users designate a service provider that stores their messages and participates in the rigid mixnet protocol on their behalf. The mixnet operates in rounds, where messages are exchanged over circuits. We envision rounds being relatively frequent, e.g., starting every 30 seconds to a minute. Every round, service providers submit messages to the mixnet. The mix servers shuffle messages and ensure each circuit carries precisely one message per round (by deduplicating messages on the same circuit and filling in a cover message when one is missing, as §4 describes). Messages are exchanged between circuits at the end of the mixnet and then sent back through the mixnet towards the service providers, where users can fetch their messages.

[2]Alpenhorn's add-friend protocol differs from its *dialing* protocol, which precedes every conversation—a cost that Groove avoids.

```
while true {
   // Block, waiting for the next wakeup event.
   <-client.Schedule // §5.1

   if oncePerDay {
      client.RefreshCircuits() // §5.2, §5.3 and Fig. 4
      client.ForwardSecrecy()  // §5.5
   }

   buddy, msg := client.OutgoingMessageQueue.Pop()
   // If the user has nothing to say, send cover traffic.
   if buddy == nil {
      msg = random.Bytes(MessageSize)
   }
   client.SendMessage(buddy, msg) // §5.4 and Fig. 5
   client.CheckForMessages()      // §5.4 and Fig. 6
}
```

Figure 2: The client's main loop. The client refreshes circuits once per day, at that time it also evolves the multidevice and buddy keys for forward secrecy. It sends and receives messages according to the schedule, which can be configured to balance battery life with communication rate.

In the remainder of this section, we introduce the concept of client schedules, present the protocols for oblivious delegation from Figure 1, and the mechanism for forward secrecy. Our descriptions follow the client's operation, outlined in Figure 2, and its interactions with the service provider via the API depicted in Figure 3.

5.1 Client schedules

To achieve Groove's privacy goal, the network traffic pattern between a user's client and their service provider must not reveal information about the user's communication with their buddies. In particular, this pattern includes when the client initiates requests to the service provider, which we call the client's *schedule*. The adversary can potentially infer any information that goes into deciding the client's schedule, and hence it should be independent of the user's buddy-relationships, which Groove aims to hide. Groove gives flexibility for clients to operate on their own schedule, independent from other clients. In this manner, it can accommodate clients on low-power devices with lightweight schedules without impacting other clients. A simple and safe schedule is to communicate with the service provider at regular intervals. Clients can use different intervals to trade network and power consumption for communication latency. They can also piggyback on other device wake-

// RPCs to queue a message for a buddy.
rpc (t *Txn) GetRoundOutgoing(epoch int, round int) RoundData
rpc (t *Txn) SetRoundOutgoing(epoch int,round int,rd RoundData)

type RoundData struct {
   // Messages are split into two, one for each buddy circuit.
   Onion [2]Onion
   // Previously sent message for this round.
   OutboundMsg []byte
}
```

Figure 3: Service provider API. Clients use these RPCs asynchronously to setup circuits to their buddies and send/receive messages through them.

ups (like checking for software updates) to interact with the service provider at a relatively low cost.

Clients can change their communication patterns if this change is independent of the user's buddies. For instance, it is safe for Alice's client to skip transmissions due to a network outage or because Alice boards a flight and her phone disconnects from the internet. It is also safe for users to have correlated schedules, as long as the correlation is not caused by their relationship status (being buddies or not). For example, users in the same time zone may prefer their devices to be more conservative during the day when on battery, but less at night when near a power outlet. Such correlations do not leak new information to the attacker (who can already observe their IP addresses and deduce their geographic locations). However, changes in the client's network patterns that depend on a user's buddies are unsafe; e.g., if Bob's client stops sending messages whenever Alice's device goes offline, an adversary might infer that Bob is connected with Alice.

5.2 Non-interactive circuit setup

Groove splits time into epochs, which correspond to the circuits' lifetimes. Periodically, e.g., once a day, clients call `RefreshCircuits` to generate circuit setup messages and upload them to their service provider (see the client's main loop in Figure 2). The service provider queues these messages and sends them to the mixnet at the appropriate time (sending circuit setup messages for the next epoch when the preceding epoch nears its end), even if all of the user's clients go offline. Users exchange messages over circuits,

```
func (c *Client) RefreshCircuits() error {
  epochs := c.serviceProvider.UpcomingEpochs()
  txn := c.serviceProvider.BeginTransaction()

  // Get address book and epoch of last update.
  addressBook, epochUpdated := txn.GetAddressBook()
  addressBookKey := c.MultiDeviceKey[epochUpdated]

  // Merge address books (buddy lists) across devices.
  prevBuddies := Decrypt(addressBookKey, addressBook)
  c.buddies = MergeAddressBooks(prevBuddies, c.buddies)

  // Pad the buddy list so its size doesn't reveal anything
  // to the provider and so we generate noise onions below.
  if len(c.buddies) < MaxBuddies {
      c.buddies = append(c.buddies, GenerateFakeBuddies())
  }
  newBook:= Encrypt(c.MultiDeviceKey[c.currentEpoch],c.buddies)
  txn.SetAddressBook(newBook, c.currentEpoch)

  for epoch := range epochs {
   var onions [MaxBuddies][2][]byte
     for i, buddy := range c.buddies {
        // Devices use the same PRNG to choose circuit
        // routes & tags, enabling deduping setup messages.
        randRouteTag := PRNG(i, epoch, c.MultiDeviceKey[epoch])
        onions[i][0] = GenCircuitSetupMsg(randRouteTag,buddy,0)
        onions[i][1] = GenCircuitSetupMsg(randRouteTag,buddy,1)
     }
     txn.SetEpochOutgoing(epoch, onions)
  }
  return txn.Commit()
}
```

Figure 4: Pseudocode for updating a client's address book and corresponding circuit setup onions for upcoming epochs, which are stored on the service provider. It is safe for multiple devices to run this function concurrently.

so adding or removing buddies only takes effect on epoch boundaries, when circuits are established. The more epochs a client prepares for in advance (by uploading circuit setup messages for future epochs in `RefreshCircuits`), the longer the user can go offline and keep receiving messages from their buddies. If all of a user's clients remain offline beyond this number of epochs, Groove will eventually not be able to establish circuits with the user's buddies, preventing them from communicating. Differential privacy is still maintained, however, due to mixnet noise during circuit setup. The epoch's duration is a knob that allows Groove to trade less client communication for higher latency in setting up circuits with new buddies.

Figure 4 gives the pseudocode for `RefreshCircuits`. First, the client synchronizes the user's contacts through the service provider, since the user might have added or removed a buddy through another device. The service provider's `BeginTransaction` and `Commit` APIs allow each of the user's clients to retrieve and upload data atomically with respect to the user's other clients, which may simultaneously call `RefreshCircuits`. Rogue providers can break the transactional semantics or deliver different address books to different clients, leading clients to set up circuits for stale address books; Groove protects against such providers, as we prove in §6. The client retrieves the address book from the

service provider, appends new buddies to the first available slots, and pushes the new address book to the service provider. Clients pad the address book to `MaxBuddies` slots and encrypt it under the multidevice key, which hides when users add or remove buddies.

Next, the client prepares two circuit setup messages for each buddy and many upcoming epochs (e.g., for the next month) and uploads these messages to the service provider. The reason for creating two circuits per buddy, rather than one circuit, is to allow clients to fake connections to buddies when the user has less than `MaxBuddies` friends, hiding their number of friends. In this case, the client creates two "cover circuits" to one dead drop, so there are precisely two circuit setup messages to all dead drops a client uses (regardless of the number of buddies the user has). The client learns the epoch number from the service provider and relies on it to submit circuit setup messages at the right epoch; however, the provider can cheat. Thus, the client writes the epoch number in each onion layer, so the mixnet servers can discard circuit setup messages the provider sends at the wrong time. As one epoch nears the end, the mixnet runs circuit setup for the next epoch, so circuits are ready at all times to route messages between buddies. The mixnet's servers then process the setup messages as in previous works (§4).

One issue is that Groove must ensure privacy when one user establishes a circuit and their buddy does not. Groove handles this challenge by noising the circuit setup step with cover circuits generated by the mix servers. The cover circuits ensure that, regardless of whether Alice and Bob are buddies, the attacker observes the same traffic pattern (on the network and to dead drops). Groove applies Karaoke's noising technique [19], of creating "single" and "double" dead drop accesses, to circuit setup messages (summarized in §4).

Circuit setup messages in Groove are acknowledged to the clients, which then learn whether anyone dropped their circuit or the circuit from their buddy. This allows users to detect active attacks and, as in previous systems [19,20], provision a tighter privacy budget when choosing the system parameters (and thus, achieving better performance) compared to systems that do not detect active attacks (like [26, 27]). To achieve this in Groove, the content of circuit setup messages is a pseudorandom ID that each user derives from the secret they share with their buddy (or the multidevice key if the circuit is cover). When the circuit setup message reaches the dead drop, the server hosting that dead drop swaps the content of messages (see §4) and returns it through the mixnet to the user's service provider. The next time the client connects to the provider and learns the current epoch, it downloads the returned IDs of the circuits from previous epochs and checks they are correct by deriving the IDs the buddies would use. Correct IDs acknowledge to clients that the circuit setup message from them and their buddy had propagated to the dead drop, so all servers in the route shuffled these messages with the other setup messages.

5.3 Oblivious replacement

Preparing circuits for future epochs allows users to go offline for a long time. However, users might add buddies after submitting circuit setup messages. Groove clients can update the circuit setup messages stored at the service provider, so users can communicate with new buddies soon after adding them to their address books. Each client performs this replacement periodically, according to its schedule (Figure 2); if there are no changes in the address book, the client uploads fresh circuit setup messages pointing to the same dead drops. The key challenge in performing this replacement is that, without coordination across the user's devices, several of their clients might establish circuits to the same dead drop. This will create a distinct access pattern (i.e., not the single- or double- dead drop access patterns covered by the noise). An attacker controlling the dead drop's hosting server can then associate that dead drop with the user.

Groove introduces circuit tagging, which enables safe replacement of old setup messages without relying on communication between a user's devices, as illustrated in Figure 1b. When choosing the circuit's path, `RefreshCircuits` seeds a pseudorandom number generator (`randRouteTag` in Figure 4) for each epoch with the multidevice key and the buddy's slot number in the user's address book. This pseudorandom number generator is the same across all of the user's devices. The clients then use it to choose the route for each address book slot and include a pseudorandom tag derived from this generator in each layer of the circuit's setup message. Honest servers on the route deduplicate circuit setup messages according to this tag. Although the routes are the same, each client submits different-looking messages to the service provider since the onion encryption scheme is randomized.

This route and tag selection procedure ensures that Alice submits circuit setup messages with the same route and tags across all her devices for each buddy in her address book. If all of Alice's devices upload circuit setup messages and a malicious service provider submits all of them, the first honest server along each the (identical) routes of duplicate messages observes the duplicate tags and discards the redundant messages. This ensures the user's circuits do not access a dead drop an unusual number of times.

5.4 Efficient messaging

Groove uses oblivious protocols for efficiently submitting and fetching messages over many concurrent circuits.

Sending messages. During an epoch, there are $2 \times$ `MaxBuddies` circuits available to the client for messaging. Uploading a message to every circuit every time the client's schedule is triggered (Figure 2) incurs unnecessary bandwidth costs, especially since users do not typically talk to all of their buddies at once. Instead, the Groove client submits just one message (split into two parts, leveraging two circuits

```
func (c *Client) SendMessage(buddy, msg string) error {
   epoch := c.currentEpoch
   round := c.nextRound

   txn := c.serviceProvider.BeginTransaction()
   rd := txn.GetRoundOutgoing(epoch, round)

   prevMsg, prevBuddy :=
      Decrypt(c.MultiDeviceKey[epoch], rd.OutMsg)
   if IsRealMessage(prevMsg) {
      err = "refusing to overwrite user-typed message"
      // Re-encrypts previous content.
      msg, buddy := prevMsg, prevBuddy
   } else {
      msg = MsgHeader(epoch, round, buddy.key[epoch]) ++ msg
   }

   msg1, msg2 := SplitMessage(msg)
   ix := GetBuddyIndex(buddy)
   onion1:= EncryptSymOnion(epoch.circuits[ix][0].keys,msg1)
   onion2:= EncryptSymOnion(epoch.circuits[ix][1].keys,msg2)

   txn.SetRoundOutgoing(epoch, round, RoundData{
      Onion:  {onion1, onion2},
      OutMsg: Encrypt(c.MultiDeviceKey[epoch], {buddy, msg}),
   })

   return txn.Commit(), err
}
```

Figure 5: Client pseudocode for sending messages.

per buddy) and does not reveal the designated circuits to the service provider. The service provider then broadcasts the message on all of the user's circuits (i.e., the first half of the message on even circuits, and the second half on odd circuits). Messages are encrypted end-to-end, so only the intended recipient can decrypt them. If a rogue provider does not broadcast a message, the first honest mix server on each path will fill in a cover message, ensuring buddies keep receiving messages at the same rate (§4). Figure 5 gives the client's pseudocode for sending messages.

Fetching messages. The recipient's service provider receives messages from the mixnet (one message per circuit per round) and stores them for the clients to fetch later. Clients should avoid fetching cover messages to minimize their bandwidth and energy costs (e.g., messages that mixnet servers fill in or that are intended for another buddy), and at the same time, hide which circuits carry real messages to hide when someone messages the user. We could use PIR to fetch messages, but this comes at high cost and complexity clients and the service provider, especially as messages accumulate. Instead, Groove's fetch protocol relies on mixing messages, where a set of servers processes the messages from the provider just once regardless of the number of messages a client retrieves. We describe it following the illustration in Figure 1c and the pseudocode in Figure 6.

When Bob's client calls `CheckForMessages` from its main loop (Figure 2), it first retrieves from the service provider a short header for each stored message (e.g., two bytes per buddy). The header acts as a pseudorandom flag, shared between the two buddies: when Alice sends a message to

```
func (c *Client) CheckForMessages(epoch int) ([]int,[][]byte){
   round := c.GetNextRound()
   mixers := RandomMixnetPath(11) // Path of length 11

   hdrs := c.serviceProvider.GetHeaders(epoch, round)

   // Identify the indices of real messages from buddies
   indxs = []
   for i, buddy := range c.buddies {
      if hdrs[i] == MsgHeader(epoch, round, buddy.key[epoch]){
         indxs = append(indxs, i)
      }
   }

   // Shuffle user's inbox with a fresh key
   pk, sk := GenerateDHKeypair()
   nonces := c.serviceProvider.ShuffleInbox(ShuffleParams{
      Epoch:          epoch,
      Round:          round,
      PublicKey:      pk,
      Mixers:         mixers,
   })

   // Predict the indices after mixing step in ShuffleInbox
   shuffledIxs := PredictPositions(sk, mixers, nonces, indxs)

   // Ensure we fetch a constant number of messages
   PadWithFakeRequests(shuffledIxs)

   // Fetch messages at the (shuffled) indices
   onions := c.serviceProvider.FetchInbox(shuffledIxs)

   // Remove onion encryption from ShuffleInbox's mixing step
   msgs := DecryptOnions(onions, sk, mixers, nonces)

   // Map the messages back to the correct buddy
   Unshuffle(msgs, sk, mixers, nonces)

   return indxs, msgs
}
```

Figure 6: Client pseudocode for oblivious fetch. Clients first fetch headers from the service provider and identify indices of interest. Finally, they request the shuffled indexes corresponding to the result of the mixing step of the oblivious fetch.

Bob, her client derives the header's value from the current round and the key that Alice and Bob share, and sends it along with the content (inside the onion). Bob's client derives the same header and compares it against the header from Alice's circuit (users only need to check one of the circuits in the pair). If the header values match, his client knows to fetch the corresponding message next. To avoid revealing messaging rates between buddies, the service provider must not learn from which circuits Bob fetches messages. Groove hides this by mixing Bob's messages again, as follows.

`CheckForMessages` instructs the service provider to submit all messages pending for Bob to a "fetch mixchain," which is a sequence of mixnet servers chosen by the client. The client also supplies a new Diffie-Hellman public key, which the service provider relays to the first server in the sequence. The first server uses its secret key to complete the Diffie-Hellman handshake and derives a shared secret with the client; it then chooses a fresh nonce and hashes it with this shared secret to derive an ephemeral symmetric key. The server derives the shuffle permutation from this ephemeral

key and encrypts the messages. The server passes its nonce, the client's public key, and the list of the remaining servers to the next mixchain server, which continues in the same fashion. The nonces ensure that a mixchain server's output looks freshly random, even if a rogue service provider replays an old request. The last server passes the shuffled messages and the nonces to the recipient's service provider, who in turn forwards the nonces to the client. The client then derives the symmetric key for each server and computes the (shuffled) position of the messages it should fetch. Finally, it fetches messages at the shuffled indices directly from the service provider. The freshness of the client's Diffie-Hellman key ensures that it accesses random-looking locations each time it runs the protocol.

Clients download a small fixed number of messages in every round. For example, a client could always download six messages per round to support up to three buddies simultaneously messaging the user. This way, the number of messages clients retrieve does not reveal information about messaging rates to the attacker. The oblivious fetch mechanism also lets clients retrieve a different number of messages to quickly catch up after being offline for an extended time. Similarly, if there's a burst of real messages in some round (beyond the fixed fetch rate), the client can run a large daily fetch procedure (e.g., for 100 messages) to catch any missed messages at relatively low cost.

5.5 Forward secrecy

Groove achieves forward secrecy for both the message contents as well as metadata, meaning that an adversary that compromises a user's device cannot retroactively decrypt messages, determine who the user communicated with, or who was in the user's address book. Note, however, that an adversary that compromises a user's device does get to see the device's current address book and messages.

The challenge in achieving forward secrecy in Groove is that user devices may be partitioned from one another, and thus cannot refresh their keys by coordinating over the network. To achieve forward secrecy in this setting, Groove deterministically evolves secret keys based on the epoch: for each passing epoch, clients hash the keys (as described below) and erase the pre-image. Clients evolve the multidevice key, ensuring that an adversary compromising a device cannot track old circuit routes from the user to a dead drop, and cannot decrypt old copies of the user's address book. Clients also evolve shared secrets across buddies to ensure that the adversary cannot decrypt old messages.

Deterministically evolving keys could allow an adversary that obtains old keys (e.g., by compromising a user's old powered-off phone) to derive all future keys, thereby compromising data and metadata privacy for all epochs since the stale compromised key, a form of post-compromise insecurity [8]. To avoid this vulnerability, Groove involves the servers in computing the hash function for evolving keys, and honest servers refuse to compute this hash function for epochs in the past or that are more than T epochs in the future. This limits the vulnerability window by ensuring that an adversary with access to older keys cannot evolve them forward to decrypt newer user data or metadata.

Realizing this approach is challenging because it requires combining secrets from two parties, without either party learning the other's secret. The client wants to hash a key without giving it to the server, and the server must not reveal its secret that would allow hashing arbitrary values in the future. We address this by using an oblivious pseudorandom function (OPRF), specifically, the verifiable DH-OPRF construction from [13]. Groove's clients run the verifiable DH-OPRF protocol with each server (evolving their keys with each server in turn). This ensures that the keys are evolved with at least one honest server's secret key. Clients verify the DH-OPRF result against the server's public key for that epoch (§4). Verifying this result is critical here, since it ensures that an adversary cannot cause two of a user's devices to diverge in their multidevice key, which would cause them to create different circuit paths and thus leak metadata.

The client evolves keys every day (see Figure 2), deleting keys older than T epochs from the newest key. The client keeps keys for T epochs in the future, which allows circuit setup messages to be prepared in advance. If the device is off for longer than T, the client's newest key becomes stale, and the servers will refuse to roll it forward with their old keys. Thus, the duration T is a tradeoff between security and user convenience: after T epochs offline, a device must be set up again manually (e.g., by copying keys from another device). If the provider lies about committing the address book, then the evolved key on the device is also useless since it cannot decrypt the address book.

5.6 Provider availability and switching providers

Groove's service providers are *not* trusted for privacy (as we prove in §6), but a service provider can still block communication for its users. To address this, Groove clients can periodically send messages to themselves (on empty buddy circuits) and detect provider malfunction in case these messages often do not route back intact (the provider cannot tell which message is for a buddy and which would route back to the user). In this case, the client notifies the user to switch providers. Such self-addressed messages were proposed in prior work to detect attacks [24]. Keeping providers untrusted for privacy, however, simplifies dealing with such availability attacks compared to prior work since users can switch providers without risking exposing their communication metadata to more parties. Moreover, this property also protects against attacks that steer users towards corrupt providers and contrasted against systems with trusted providers (§2).

Users can also submit copies of messages to multiple providers to ensure availability when all but one provider

fail. This is safe since Groove ensures privacy even if rogue providers duplicate messages (by deduplicating messages in the mixnet, §5.3). One detail when using multiple providers is that Groove delivers only one message copy (to defend against malicious providers submitting multiple messages). Malicious providers can thus actively try to prevent service by submitting corrupt messages, hoping their copies will prevail. Users can detect this intervention and switch providers (as discussed above).

6 Privacy analysis

Clients send and receive messages through the user's service provider. They communicate according to a schedule that is independent of their buddy relationships (§5.1); thus, the clients' network pattern does not leak sensitive information about the user.

Since it places the users' trust in the mixnet's servers as a collective rather than their service provider, our analysis focuses on reducing the security of Groove to the security of the mixnet (§6.1). We analyze each oblivious protocol and show that a more restricted attacker, who controls the network and the same mixnet servers but not the service provider, can obtain the same information. Groove's design uses a parallel mixnet as a black box that hides the sender of messages. The dead drop-based message exchange provides differential privacy for every epoch (since users can change their communication patterns by setting up circuits on epoch boundaries), similar to prior work [19, 26, 27]. The advanced composition theorem [10, 3.20] allows to compute Groove's privacy guarantee after multiple epochs, as we do in §7.

6.1 Oblivious delegation

We now prove that the security of Groove reduces to the mixnet; controlling the service providers does not enable an attacker that already controls the network and some mixnet servers to learn new information. In particular, this implies that it is safe to be the sole user of a rogue service provider.

Theorem 1. Consider Groove's attacker, who controls the users' service providers, the network, and a portion of the mixnet servers, and his observations about the users' communication. A restricted attacker, who only controls the network and the same mixnet servers (but not the service providers), can obtain the same observations.

Proof. We consider all the ways a user's clients interact with their service provider. These interactions take part in three oblivious protocols (non-interactive circuit setup, oblivious replacement, and efficient messaging). We analyze each protocol in §6.1.1 – §6.1.3 and show that Groove's attacker cannot learn any information that the restricted attacker could not obtain (e.g., by dropping network packets). □

6.1.1 Non-interactive setup

The user's clients synchronize address books through one service provider. Clients always update the user's address book before preparing circuit setup messages (§5.2). On each update, the client uploads the address book under fresh encryption, padded to a fixed length (`MaxBuddies`), so the service provider cannot tell whether it has changed. The service provider may give stale address books to clients; this is our focus in §6.1.2.

Clients also retrieve the current epoch number from their service provider before preparing circuit setup messages. A malicious service provider can lie about the epoch number or submit the circuit setup messages to the mixnet at the wrong epoch. The client writes the epoch number in every onion layer of the setup message, and honest mix servers discard onions with the wrong epoch number. Thus, if an honest server exists en route, this service provider's attack is equivalent to a network attacker simply dropping the user's circuit setup messages. If there is no honest server on the route, then even the restricted attacker can learn everything about the circuit by observing the setup message going from one malicious mix server to the next. (Groove mitigates this risk by using sufficiently long mixnet routes, §7.1.)

6.1.2 Oblivious replacement & device partitions

A rogue service provider may interfere when clients replace circuit setup messages, or collect and submit setup messages from multiple devices. Since the attacker controls the network, it might partition devices and prevent them from communicating. The risk with partitioned devices is that a rogue service provider submits circuits from different devices and creates distinct dead drop access patterns (i.e., a dead drop getting more than two accesses, which is not obscured by the "single" and "double" noise). Groove solves this problem with its mechanism for choosing circuit routes and tagging circuit setup messages (§5.3), as we prove next.

Consider the user Alice with two partitioned devices, d and d', and a circuit they establish for the buddy at slot $i \in [1, \texttt{MaxBuddies}]$ in their respective address books for the same epoch. Both devices submit setup messages for circuits with the same route and tag: they derive them from the buddy's slot number i, the multidevice key, and the epoch number, which are all the same for both devices, even if their address book differs and have different buddies for the same slot (see Figure 4). (The multidevice key is identical on all devices for the same epoch. If two devices use different epochs, the mixnet will discard the circuit setup message from the device using the wrong epoch, as described above.) If there is no honest server on this route, then the attacker can trace Alice's messages through the malicious mixnet servers to the dead drop, regardless of controlling her provider.

Otherwise, an honest mix server exists on the circuits' route. It will de-duplicate the two circuit setup messages and ensure that only one circuit will be established. There

are two cases regarding the dead drops at the end of these circuits. First, the circuits from d, d' reach the same dead drop. In this case, since the honest server drops one message, the attacker's observations will be precisely the same as if the devices could coordinate and only one device submitted setup messages. The second case is that device d submits a circuit setup message to a different dead drop than device d'. A device-partitioning attacker can cause this, e.g., by giving one device an old address book where a now-occupied slot was free. In this case, one of the circuits' dead drops receives one less circuit, i.e., becomes a "single"-access dead drop, which is covered by Groove's noise. The attacker could obtain the same view by dropping one circuit setup message from Alice on the network (even if Alice had just one device).

6.1.3 Efficient messaging

The sender's client submits one fixed-length, onion-encrypted message to the service provider. However, it does not contain any information about the intended recipient and, therefore, cannot teach the provider about the user's communication (the service provider broadcasts it on all circuits, §5.4).

The service provider serves messages to the recipient's client by routing them through the fetch mixchain, which the client chooses when calling `CheckForMessages` (see §5.4). The choice of mixchain servers is independent of the user's buddy-relationships, so it leaks nothing about them. Since mixchain servers choose fresh nonces when shuffling messages, they uses different ephemeral keys for processing every fetch. Thus, the messages output from the fetch mixchain always appear random to the recipient's service provider. Furthermore, the client chooses a new ephemeral key each time it calls `CheckForMessages`, so it always fetches messages from random-looking locations (even if the service provider replays old headers). Therefore, having one honest server on the fetch mixchain ensures that the client's pattern of retrieving messages appears random every time.

7 Implementation

We implemented a prototype of Groove in Go on top of Yodel's mixnet framework [20] in 20k lines of code. The mixnet has a full-mesh server topology [19, 20], which allows Groove to scale with the number of servers. The prototype uses ChaCha20 for symmetric onion encryption, the NaCl box primitive to generate circuit setup onions, and the Blake2b hash function. To implement forward secrecy with DH-OPRF, we use BLS12-381 in the CIRCL library [6].

Communications between clients, service providers and mixnet servers all use gRPC over TLS 1.3 for transport security. The service provider uses BadgerDB to implement atomic transactions and manage user state.

Our implementation includes two types of clients, for desktop and mobile devices. The desktop client is a command-line program, and the mobile client is built for Android using the `gomobile` tool.

Memory usage. A prominent challenge in implementing Groove has been minimizing the circuits' memory footprint to allow users receive messages from any of their buddies in parallel. With 3M users, 100 circuits per user, 100 mix servers, and 14 mixnet hops, each server needs to keep track of at least 42 million pieces of cryptographic state per epoch:

$$100\,\text{circuits} \times 3\,000\,000\,\text{users} \times \frac{1}{100\,\text{servers}} \times 14\,\text{hops} = 42\text{M}.$$

Initially, we used AES-GCM to implement Groove's circuits, but its state is 512 B, resulting in at least 20 GB of memory usage per mixnet server. To reduce memory, we replaced AES-GCM with ChaCha20, which requires only 32 B per state, reducing this memory usage to 1.3 GB per server, but increasing CPU usage due to lack of hardware acceleration.

7.1 Parameter selection

We set Groove to resist $f = 20\%$ malicious mixnet servers, and the mixnet path length to be 14 hops (similar to prior work with the same mixnet topology [19, 20]). As shown in prior work, this topology requires two honest servers on a circuit's route, and the probability that this holds for all four circuits that two buddies use to communicate in Groove is $\geq 1 - 4 \cdot 10^{-8}$, assuming $f = 20\%$. The fetch mixchain requires only one honest server on its path, so we set its length to 11, which fails with even smaller probability. Users send 128-byte messages, split over the two circuits they create per buddy. Out of the 128 bytes, 2 bytes are reserved for the pseudorandom header indicating whether the message is real or cover traffic (§5.4), 12 bytes are reserved for the end-to-end authentication code, and 12 bytes are reserved for a nonce. Thus, recipients get a 102 byte encrypted text message per buddy per mixnet round.

Noise in practice. We configure Groove to tolerate 245 epochs of active attacks and 9600 epochs of passive observations. These parameters are comparable to the suggested configuration in Karaoke [19], which resists the same number of active attacks, and sustains passive attacks for a year (if epochs are at least 1 hour long, then 9600 epochs are over a year's worth).

Specifically, with 100 mixnet servers, each honest server creates 88 000 noise circuits on average in every epoch to provide $(\varepsilon = \ln 2, \delta = 10^{-4})$-differential privacy (the same ε, δ as Vuvuzela's implementation, and better than Karaoke's $\varepsilon = \ln 4, \delta = 10^{-4}$ and Stadium's $\varepsilon = \ln 10, \delta = 10^{-4}$ [19, 26, 27]). The more servers there are, the less noise each server contributes (e.g., a mixnet with 50 servers requires each of them to create 125k noise circuits for the same privacy level).

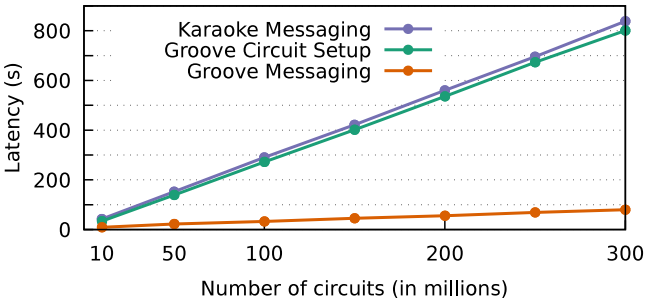

Figure 7: Latency of circuit setup and messaging rounds with respect to the number of circuits. The figure also compares with Karaoke's messaging round as a baseline (1 user relationship in Karaoke equals 2 Groove circuits) [19]. The mixnet has 100 servers.

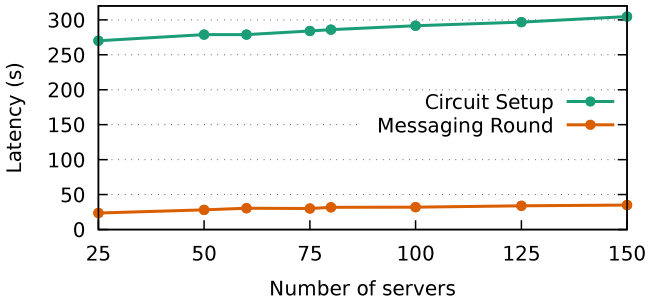

Figure 8: Scalability of the mix servers. The mixnet server load is constant (1 million circuits per server). This experiment shows that by having more mix servers, Groove can support more clients with the same communication latency.

8 Evaluation

We use the prototype to evaluate Groove's performance and costs. Our experiments answer the following questions:

1. What throughput and latency can Groove achieve?
2. How does Groove scale with the number of servers?
3. What are Groove's deployment costs?
4. What are the costs for a mobile client in terms of battery consumption and network usage?
5. What is the cost for a client catching up to old messages after having been offline?
6. How does Groove's performance compare to prior work?

First, we focus on the Groove's servers, i.e., the service providers and mixnet, and then on the mobile client.

8.1 Server performance and costs

Setup. We test Groove with 25–150 mixnet servers that we deploy evenly split across 3 EC2 regions across the US and one in Europe: `us-east-1`, `us-east-2`, `us-west-2`, `eu-west-1`. Each server is an `r5.8xlarge` VM with an Intel Platinum 8000 3.1 GHz CPU with 32 cores, 256 GB of memory, and a 10 Gbit/s network link. We evaluate with a single service provider on `us-east-1`: since service providers only buffer and relay messages, but do not participate in processing messages through the mixnet, the performance of Groove's mixnet does not depend on the number of service providers. Only clients connected through an overloaded service provider will experience performance issues.

We simulate hundreds of millions of circuits by having mix servers create extra circuits. Assuming each user has up to 50 buddies, and hence requires 100 circuits, the system load corresponds to relationships between millions of users. Although clients do not use these circuits, they correspond to real conversation load on the servers. We set Groove's system parameters as described in §7.

Throughput and latency. We measure messaging latency for a given circuit load in deployment of 100 mixnet servers. To measure the latency, we measure the time from when the service provider submits a message until the mixnet completes the round and returns the result to the service provider, plus the time needed for the fetch protocol (§5.4). Users will experience additional latency depending on their schedules and the network RTT to their service provider. Groove is not tied to one configuration of buddies per user, so we use the number of circuits to quantify Groove's load (each buddy requires two circuits). Since Groove ensures there is one message delivered on every circuit in every round §4, the number of circuits sets the load on its servers.

In Figure 7, we observe that the Groove's messaging round latency is 32.4 s, 55.9 s and 79.83 s for 100M, 200M and 300M circuits, respectively. The measured latencies have two components: The first, larger, component is mixing the users' messages and routing them from the source to the destination service provider; this represents the majority of the duration of Groove's messaging round (28.7 s, 50.8 s and 71.3 s for 100M, 200M and 300M circuits). The second, smaller, component ($\approx 11\%$ of the total duration) is the time spent on running Groove's fetch protocol (§5.4). For this second part, we model an average load of clients running the fetch protocol: we simulate fetches at the end of each round, and we wait for all messages of a round to be fetched before moving on to the next round. Thus, assuming the average user sets up 100 circuits (to communicate with up to 50 buddies), Groove could support 1M–3M users with these latencies.

The duration for setting up the circuits in Groove is 13.3 minutes for 300 million circuits (Figure 7). Since circuit setup is relatively infrequent (e.g., once a day), it can run in the background and stretch up to an epoch's duration. Groove's circuit setup is similar to a messaging round in Karaoke [19], which also offers differential privacy, though there is a difference in the payload size (Groove's payload is about 200 bytes smaller than Karaoke). For the same setup, where the system processes 300M messages per round, a communication round in Karaoke takes 14 minutes (Figure 7).

Scalability. We test how Groove scales with the number of users by measuring the latency for varying deployment sizes of 25–150 mixnet servers and keeping the number of circuits per server constant at 1M (so the load on the system increases proportionally to the number of servers). Figure 8 shows that

Groove scales well: it can support additional users at almost the same latency by proportionally increasing the number of servers. We attribute the slight latency increase to the fact that shuffling messages together requires each server, in every hop along the mixnet route, to wait for inputs from all other servers that processed messages at the previous hop.

Deployment costs. With 300 million circuits, each of the 100 mixnet servers sends at about 2 Gbps at peak usage, for a network usage of 13.4 GB per messaging round. In this deployment, setting up circuits for one epoch uses 47.5 GB of network data per mixnet server.

Service providers buffer messages for their users. For a user who generates circuit setup messages for the next 30 epochs (i.e., the next month if epochs last a day), the storage requirement for circuit setup is 2.1 MB. Further, if messaging rounds happen every minute, then storing a month's worth of received messages amounts to 264 MB per user.

Forward secrecy. On the server, computing OPRF incurs low overheads. A single server can answer 12k DH-OPRF requests per second, or 10^9 per day. A client evolves keys with all their buddies and the multidevice key every epoch (§5.5), creating 51 requests/day with day-long epochs. Servers can run the OPRF computations in the background and load-balance client requests throughout the day, allowing servers to easily support 1–3M users as in the earlier experiments. On the client-side, it takes 2.03 s to run `ForwardSecrecy` with 100 servers (primarily due to the network latency, then to the two pairing operations used in the verification), and the bandwidth usage is 150 kB/day.

8.2 Mobile clients

We evaluate Groove's mobile client, which represents an important class of clients enabled by its flexibility. We focus on two metrics: the impact on battery life and network usage. We run the mixnet with 32s messaging round time, which correspond to the latency with 100M circuits and 100 servers (Figure 7). We evaluate the mobile client on a Pixel 4 cellphone running the stock Android 10 OS. Our tests include cellular (3G with HSDPA) and WiFi networks.

Battery usage. We explore the impact of different schedules on battery life. To evaluate battery consumption, we connected the mobile device to a USB power meter (UM25C) and collected energy consumption roughly every 1 second.

We force-enable *doze mode* to reduce noise from apps running in the background; this is the battery-saving optimization that typically runs when the device's USB port is unplugged. Yet, running Groove's app in this mode implies that the client's transmissions may change without adhering to the schedule. Therefore, we excluded our app from doze mode (Android's `AlarmManager` provides APIs to avoid it).

First, we measure the baseline energy consumption when the phone is fully charged, idle, the screen is turned off, and Groove's client is not installed. We observe that after an hour, the idle phone consumes about 310 mWh of energy, both when the phone uses WiFi and cellular networks. Then, we run Groove's client with different schedules. At the beginning of the experiment, the client uploads circuit setup messages for the next 30 epochs. Then, the client sends a message and downloads pending messages according to its schedule (following Figure 2).

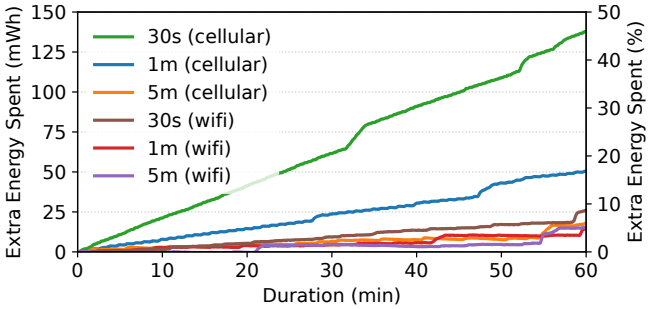

Figure 9: Client's energy consumption on a Pixel 4 phone for different schedules and network types. The graph shows how much more energy is spent running a schedule compared to leaving the phone idle. The bumps in some of the lines correspond to wake-ups to service other running apps (as we verified by reading device logs).

Figure 9 shows the energy consumption over an hour for different schedules compared to the baseline. It is apparent from the figure that as the schedule becomes more frequent, the energy consumption increases, especially when using cellular networks. A mobile client following the mixnet's $\approx$ 30s round-schedule would have increased battery usage by 47% over the idle phone, but flexibility allows the mobile client to use lighter schedules. On a 1-minute schedule, the client on the cellular network uses an extra 50 mWh compared to the baseline, a 16% increase. Moreover, the energy cost from running the client is substantially reduced further when the client runs on a 5-minute schedule (about 6% over idle). We hypothesize that this allows the phone to hibernate and save power. The energy consumption is more modest when using WiFi, which is more energy-efficient [14].

Network usage. We monitored the link between the client and service provider to quantify the client's network usage. It uploads one message to the service provider every time the schedule triggers and downloads a message per round (see Figure 2). Consequently, different schedules affect the message upload volume, which ranges from 33 kB/h with a 5-minute send schedule to 77 kB/h with a 1-minute schedule. The download volume is 39 kB/h on the 5-minute schedule and 69 kB/h on the 1-minute schedule. In addition, the client sends about 110 kB for the circuit setup per epoch; for a month's worth of prepared circuits, this phase costs 3.2 MB. These measurements show that Groove's client uses a total of 54 MB to 106 MB of bandwidth per month, depending on the schedule. We believe that Groove's moderate network usage is compatible with mobile data packages.

Catch-up. Groove's oblivious fetch protocol filters cover messages, allowing clients to quickly catch up on messages that buddies send their users after being offline for an extended time (§5.4). Consider a client that catches up on a month by downloading 500 messages per offline day (15k total); we evaluate it requires 11 MB of bandwidth.

8.3 Comparison with prior work

Groove provides asynchronous messaging with many buddies, whereas recent mixnet-based work, like Karaoke, Stadium, and Yodel [19, 20, 26], provide synchronous communication with one buddy. PIR-based approaches, like Pung [4], could allow asynchronous messaging but with a significant performance cost compared to [19, 20, 26] (owing to stronger privacy guarantees and weaker trust assumptions); see discussion in §2.

Thus, these prior systems rely on a hefty dialing protocol (Alpenhorn [21]) to synchronize between buddies before they can communicate. Groove outperforms prior designs when users talk with multiple buddies since dialing through Alpenhorn adds about 5 minutes of latency when users switch between buddies. On the other hand, if users communicate with just one buddy who is simultaneously online, they can avoid frequent dialing, and in this case, Yodel and Karaoke outperform Groove.

In more detail, Stadium, Karaoke, Yodel, Pung, and Groove were evaluated on a similar 100 server configuration, which we use to compare. We assume that users in Stadium, Karaoke, Yodel, and Pung only chat with one buddy that is simultaneously online. Karaoke supports 1M users with 7 s of latency (Figure 6 in the Karaoke paper [19]), while 1M Groove users can communicate with 50 buddies with a latency of 32 s. The increase in latency is only 4× that of Karaoke, despite Groove supporting all 50 buddies to message the user at the same time, since Groove establishes circuits through the mixnet (allowing for more efficient symmetric onion encryption rather than the public-key onion encryption used in Karaoke). Stadium induces latency on the order of minutes (see Figure 9 in the Stadium paper [26]) largely because of its use of zero-knowledge proofs to ensure that mixnet servers process messages correctly. Pung's latency increases quadratically with the number of users [2, 4]; with millions of users, latency is over 30 minutes (as we interpolate from Figure 8 in the Pung paper [2] assuming that a 100-server Pung cluster performs 100× better than one server). This performance gap grows with the size of the user base. Yodel builds on its interactive circuit establishment protocol to directly connect (not through the mixnet) each user to its buddy's dead drop. Groove avoids this direct connection to protect the user's communication metadata-privacy if the buddy is offline (hiding the user was trying to connect with an offline buddy). For 1M users, Yodel's latency is 750 ms (Figure 10 from the Yodel paper [20]), 42× better than 1M Groove users that can communicate with 50 buddies simultaneously (corresponding to the 100M circuits datapoint in Figure 8). If we limit Groove to allow one buddy per user, then it needs to support only 2M circuits per 1M users (as in Yodel), and Groove's latency shrinks to about 4× that of Yodel. This remaining performance gap is primarily due to Groove connecting both buddies to dead drops through the mixnet (above) and Groove's fetch protocol that conserves client bandwidth at the expense of routing the messages buffered at the recipient's service provider again through the mixnet.

Another significant difference is the client bandwidth. Dialing through Alpenhorn requires clients to receive 62 GB per month (§2), on top of the overlying system's bandwidth requirements (such as Karaoke, Stadium, etc.). In contrast, Groove's oblivious messaging protocols allow communication with many buddies while reducing clients' bandwidth costs by orders of magnitude (see §8.2).

9 Conclusion

Groove removes the rigid requirements that prior metadata-private messaging systems imposed on clients. Groove allows users to have asynchronous text message chats with multiple buddies, while seamlessly switching between resource-constrained mobile devices. It does so with similar scalability and privacy guarantees as prior rigid differentially-private messaging systems. Groove achieves this advancement by introducing protocols for oblivious delegation that allow users to have an untrusted service provider participate in the rigid messaging protocol on their behalf. Our evaluation of a prototype of Groove shows that it can support a large user base with latency on the order of a minute. Our experiments with a Pixel 4 smartphone demonstrate that Groove can accommodate the network and power constraints of a mobile device, unlike previous rigid systems. Groove's techniques narrow the gap between metadata-private messaging and standard messaging apps, allowing for broader adoption.

Abstract

Applications often have fast-paced release schedules, but adoption of software dependency updates can lag by years, leaving applications susceptible to security risks and unexpected breakage. To address this problem, we present UPGRADVISOR, a system that reduces developer effort in evaluating dependency updates and can, in many cases, automatically determine which updates are backward-compatible versus API-breaking. UPGRADVISOR introduces a novel co-designed static analysis and dynamic tracing mechanism to gauge the scope and effect of dependency updates on an application. Static analysis prunes changes irrelevant to an application and clusters relevant ones into *targets*. Dynamic tracing needs to focus only on whether targets affect an application, making it fast and accurate. UPGRADVISOR handles dynamic interpreted languages and introduces call graph over-approximation to account for their lack of type information and selective hardware tracing to capture program execution while ignoring interpreter machinery.

We have implemented UPGRADVISOR for Python and evaluated it on 172 dependency updates previously blocked from being adopted in widely-used open-source software, including `Django`, `aws-cli`, `tfx`, and `Celery`. UPGRADVISOR automatically determined that 56% of dependencies were safe to update and reduced by more than an order of magnitude the number of code changes that needed to be considered by dynamic tracing. Evaluating UPGRADVISOR's tracer in a production-like environment incurred only 3% overhead on average, making it fast enough to deploy in practice. We submitted safe updates that were previously blocked as pull requests for nine projects, and their developers have already merged most of them.

1 Introduction

Powered by agile development methodologies and supported by continuous integration and testing infrastructure, modern software companies achieve blazing fast release cycles, quickly pushing bug fixes and new features to production servers or client devices. For instance, Google's Chrome ships a new major version to the stable channel every four weeks [3], while Facebook publishes updates to their front-end three times a day and releases a new version for iOS and Android every week [7].

A key enabler to this fast development cycle is the large collection of preexisting frameworks and libraries to build on. One open source software (OSS) discovery service tracking popular libraries in leading package managers lists almost 5 million open-source libraries [40]. We surveyed OSS projects developed with prominent interpreted languages[1] (§2) and found that an application, on average, depends on tens to hundreds of frameworks and libraries; these are known as dependencies.

Unfortunately, our survey shows that despite the fast pace of application updates, the adoption of dependency updates is delayed by years, and this delay is getting worse (see Fig. 1 in §2). We believe a key reason behind this dichotomy is the knowledge gap between application and dependency developers. Although dependency developers invest significant effort in creating robust and often backward-compatible updates, they typically have no direct access to the dependent applications, hindering their ability to gauge potential update risks. Application developers want the security fixes and performance enhancements in dependency updates, but lack knowledge of the dependency internals and therefore fear that dependency updates may cause the application to malfunction.

The effect of dependency update delays aggregates across projects and even whole software ecosystems. For a given installation composed of an ensemble of software components, even if only one component requires an older version of a dependency, the entire installation is forced to use the same older version. This older version might accumulate unpatched vulnerabilities over time or break unexpectedly due to deprecation. Moreover, when many older dependency versions are involved, attempts to update subsets of the dependency graph become impossible due to dependency

[1]We surveyed Python, JavaScript, and Ruby projects from GitHub.

conflicts (a.k.a "dependency hell" [30]).

Ideally, an application's test suite should discover any malfunctions due to interactions with dependencies, but this is sadly not the reality. Application and dependency developers strive to make their unit, integration, and system tests have high coverage of their projects. However, state of the art tools for coverage metrics do not examine the difficult-to-measure interfaces between applications and their dependencies. Thus, it is dangerous to rely on application test suites to detect dependency update incompatibilities. The problem is worse for dynamic interpreted languages, as without compilation, API breaking changes not discovered during testing become runtime errors on production servers.

We present UPGRADVISOR, a system for maximizing the safety of and reducing developer efforts invested in dependency updates. UPGRADVISOR is based on the observation that changed dependency code that does not run cannot affect application semantics. UPGRADVISOR works by combining sound static analysis with efficient dynamic tracing to aid developers in the timely adoption of dependency updates. Given a dependency update that developers want to adopt, UPGRADVISOR computes the code difference between its old and new versions and then employs static analysis to discard semantically irrelevant differences and cluster potentially meaningful ones into tracing targets.

To enable this process for modern applications written in widely-used interpreted languages, UPGRADVISOR first builds an over-approximating call graph that accurately accounts for the lack of type information in variables and function arguments in these languages as well as handling implicit language-specific call-site creation features. It then creates a fused abstract syntax tree (AST) representing both the old and new versions of the dependency and tags all changes on a per statement basis. The change tags are propagated up the AST to the call graph, clustering code differences into *call targets* (Python functions or methods) for later tracing. UPGRADVISOR can then statically discard unreachable or semantically irrelevant code changes, such as backward-compatible changes to API signatures and changes in imports location (see §7). If there are no call targets tagged with change tags, the dependency update is safe because it has no changes that can possible affect application execution. Unlike test suites, the static analysis provides complete code coverage, allowing UPGRADVISOR to accurately determine if a dependency update is safe.

While static analysis may be sufficient in many cases to determine the safety of a dependency update, it is conservative, identifying calls not actually used in practice. UPGRADVISOR therefore performs dynamic tracing to determine if call targets with change tags remaining after static analysis actually influence application execution. Dynamic tracing is performed without applying the dependency update and is designed to incur little overhead. Both of these features allow it to be used in a production environment, giving a complete trace of a production server over a substantial amount of time to serve as the ground truth of application-dependency interactions. Running UPGRADVISOR on production servers allows mitigating the inherent unsoundness of dynamic analysis.

UPGRADVISOR achieves low-overhead tracing using two key mechanisms. First, UPGRADVISOR can select which parts of application execution to trace, tracing only the call targets with change tags identified through static analysis. Second, UPGRADVISOR leverages the hardware tracing module in modern CPUs using a novel coarse-grained tracing technique to collect data only for chosen bytecodes while ignoring unnecessary low-level interpreter instructions. In particular, using our technique, each bytecode branch executes exactly one native branch. Tracing only one branch creates one trace record, reducing tracing data size and runtime overhead. Combining the two allows lowering overhead while retaining precision: we only collect the minimal information required to fully capture control flow in the updated parts of the dependency.

We have built an UPGRADVISOR prototype that supports dependency updates for Python programs. It contains an analysis framework and a tracer implanted into our fork of the Python 3.7 interpreter. We evaluated UPGRADVISOR on 172 potential dependency updates that were previously blocked from being adopted by applications in top-starred OSS repositories on GitHub. The dependency updates include popular frameworks such as `Django`, `aws-cli`, `tfx` and `Celery`. Our results show that UPGRADVISOR is effective. UPGRADVISOR determines through static analysis that 98 (56%) dependencies can be automatically updated, meaning the majority of blocked dependency updates can be adopted without manual inspection. When static analysis cannot completely determine if an update is safe, the analysis reduces the code differences that must still be reviewed by an order of magnitude compared to the overall changes between old and new dependency versions. UPGRADVISOR determines through dynamic tracing that various dependencies not automatically deemed safe through static analysis can still be updated. (see §7.1)

We randomly sampled several dependency updates deemed safe: although we were not developers of either the applications or the dependencies, we were able to quickly submit pull request (PR)s, most of which were subsequently merged by the corresponding developers. The PRs that were merged included dependency updates deemed safe by just static analysis as well as by combining static and dynamic analysis, demonstrating that dynamic tracing can indeed provide additional upgrade opportunities beyond static analysis.

Finally, we performed an extensive performance evaluation, including running a production Django workload published by Instagram and Intel [8]. Our measurements show that our tracer incurs an average overhead of 3%, much lower than other tools.

UPGRADVISOR's code, evaluation datasets, and other resources are available at `http://upgradvisor.github.io`.

Figure 1: The average delay days for all the projects surveyed for each month between August 2019 and November 2021.

2 Survey of Dependency Usage in OSS

Modern applications declare their dependency requirements in metadata files as a list of `(package name, version specifier)` tuples. These direct dependencies also have their own dependencies, creating a graph of transitive dependencies for the application. The version specifier follows a common version structure, "MAJOR.MINOR.PATCH", where MAJOR increments signal API breakage, MINOR increments signal backwards-compatible feature additions, and PATCH increments signal backwards-compatible bug fixes. For example, if the old API is `foo(int a, int b)` and the new one is `foo(int a, int b, int c)` the API was broken. A version specifier in a metadata file can be expressed as conditions, which can directly point to a specific version, also called pinning, or use a combination of lower/upper-bounding terms to define a range of possible versions. Out of a range of allowed versions, the latest one is selected. A given dependency may be specified by the application and by any number of dependencies. All these specifiers must overlap to have a viable dependency set. Using range-defining conditions allow developers to block a version update if they deem it not compatible with their code, e.g., `<=2.5.1`.

		Dependencies					
Language	Projects	Direct			Transitive		
		max	avg	std	max	avg	std
Python	389	118	7.1	11.5	480	15.9	41.3
JS	462	130	17.1	23.3	>1000		
Ruby	501	91	12.3	17.3	548	28.1	103.9

Table 1: Dependency usage in OSS projects on GitHub.

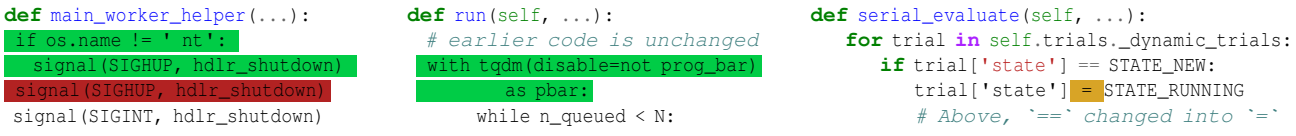
To better understand dependency usage patterns in the leading dynamic interpreted languages, Python, Ruby, and JavaScript (JS), we performed a survey of OSS projects using them. We randomly sampled top starred (>1k) project repositories on GitHub, for which Python, Ruby, or JS, was the primary programming language. Starting from 1,382 Python, 913 Ruby, and 1,144 JS projects, we examined the dependency requirement conditions of the latest version of each project and filtered those with no direct dependents as of November 2021.[2] Table 1 summarizes the results for projects with dependencies, showing the maximum, average, and standard deviation in the number of dependencies per project. Each project is considered an application. For example, Python applications averaged seven direct dependencies and 16 transitive ones for an average of 23 total dependencies per application, but the standard deviations (STDs) show significant differences among applications. The number of direct and transitive dependencies for a Python application was as high as 118 and 480, respectively.

For the 389 Python applications, we examined the dependency requirement conditions for not just the latest version of the application, but also earlier versions published from August 2019 to October 2021. 2% have no restrictions (latest), 29% are lower-bound only, 38% are double-bound (both lower- and upper-bound), and 31% are pinned version specifiers. In other words, more than two-thirds of the version specifiers, double-bound and pinned, may block available updates. A developer whose application may have dozens of dependencies, including transitive dependencies, cannot update dependency X unless every other dependency which depends on X also includes the new version in the specifier.

We measured the historical delay for Python, Ruby, and JS applications in updating their dependencies by examining all versions of the applications published from August 2019 to November 2021. For each released application version, we examine direct dependency requirements. Considering only the dependency versions which existed on the application version's release date, we check if the dependency offered an updated version. If an updated version exists, we consider the application to be delaying updates and measure the number of delay days. Delay days are counted from the dependency's new version release date up to the application's release date. If an application has multiple delayed dependencies, we consider only the most severely delayed dependency.

Fig. 1 shows the delay days for all applications as measured each month from August 2019 to November 2021. We show both the average delay days as well as the standard deviation. For example, Fig. 1a shows that Python applications start from

[2] Unlike JS and Ruby, Python projects declare dependencies implicitly in their setup scripts. We discarded projects when we could not extract dependency constraints.



(a) (b) (c)

Figure 2: Three code change snippets from `hyperopt`'s update from version 0.1.1 to version 0.1.2.

an average of roughly 20 delays days for August 2019 and balloon to reach roughly 200 delay days by August 2021, an order of magnitude increase in delay over two years. Fig. 1 shows that this pattern of increasing delay in adopting dependency updates persists across applications in all languages, indicating that the problem of timely adoption of dependency updates worsens over time. Digging into the data shows that while some projects invest consistently in dependency upkeep, other projects struggle. This difference leads to the significant variations as expressed by the standard deviation bars in Fig. 1. The standard deviation in delay days is so large for Ruby applications that they exceed the visible range in Fig. 1c for most months; the visible maximum was capped at 1,200 delay days to provide a consistent visual comparison across languages while keeping the graphs readable. Because dependency requirements cater to the lowest-common-denominator, having even one such struggling project as a dependency forces the use of an old version.

We designed UPGRADVISOR to address this problem.

3 UPGRADVISOR Overview

We use `Qlib`, a popular Python AI-oriented quantitative investment platform developed by Microsoft, as a motivating example of the dependency update problem and show how UPGRADVISOR solves it. `Qlib` version 0.7.1, released on 15-Sep-2021, relies on 30 direct dependencies. One of them is `hyperopt` 0.1.1, released on 27-Aug-2018, a distributed asynchronous hyper-parameter optimization library for Python.

3.1 An Example Dependency Update Problem

`hyperopt`'s developers changed 828 line of code (LOC) spanning 14 files to go from version 0.1.1 to 0.1.2. Because `Qlib` uses a pinned version specifier "hyperopt==0.1.1", it did not adopt version 0.1.2. Counting the days between `hyperopt`'s version 0.1.2 release on 21-Feb-2019 to `Qlib`'s 0.7.1 release on 15-Sep-2021, the number of delay days for `Qlib` due to not updating `hyperopt` is 937.

To update `Qlib` to use `hyperopt` version 0.1.2, `Qlib`'s developers need to ensure the update is safe. It should not cause `Qlib` to crash, experience other silent failures, or change `Qlib`'s API. A change in `hyperopt`'s output content or structure could propagate to `Qlib`'s output. An update solving a bug in `hyperopt` might benefit `Qlib`, yet still requires `Qlib`'s developers to check for unexpected side effects. Ideally, `Qlib`'s developers can use the opportunity of updating to a new `hyperopt` version to incorporate improvements in `hyperopt`'s functionality they already use or explore its new features.

This process offers the developers a tradeoff between short-term safety by not updating versus investing efforts towards gaining long-term safety and quality. We aim to maximize the safety of the update and its benefits while reducing the developer's efforts required to examine the dependency update.

The easiest way to evaluate the updated dependency is to run `Qlib`'s test suite with `hyperopt`'s new version. It turns out that all of `Qlib`'s tests pass. Sadly, this result is ambiguous as it can not differentiate between the tests not covering `hyperopt` and the update being safe. In fact, measuring the coverage of `hyperopt` when running `Qlib`'s test suites shows that no line in `hyperopt`'s code is covered.

Instead of using its test suite, `Qlib`'s developers can examine all code changes made to `hyperopt` to assess the safety of the update. Fig. 2 shows a few changed code snippets from `hyperopt`'s update. Fig. 2a shows a change in the way worker helpers initialize signal handlers. After the update, when the code runs in a Windows environment, the `SIGHUP` handler is no longer set. Fig. 2b shows a change in the `run` method in charge of running the trial's computations, adding an optional progress bar (controlled by the `disable` flag). Fig. 2c shows a change to the `serial_evaluation` method, turning the condition on `trial['state']`, which was never assigned (effectively redundant code), into an assignment.

Fig. 2a and Fig. 2c are bug fixes, which might benefit `Qlib`, but Fig. 2b constitutes a change to `Qlib`'s CLI, which might break other systems using the CLI output.

The changes in these procedures[3] require human review. Doing this for a few changes may be manageable, but is too difficult for all changes on each update; manual code examination is not scalable.

3.2 Using UPGRADVISOR to Update `Qlib`

UPGRADVISOR is based on the observation that changed dependency code that does not run cannot affect application semantics. If we can show such code is unreachable, we can ignore it. Fig. 3 shows UPGRADVISOR's process for analyzing the dependency update (steps 1-3), employing the tracer (steps 4-6), and gathering and summarising results towards update advice (steps 7-8).

[3] For brevity, we use procedure in place of "method or function".

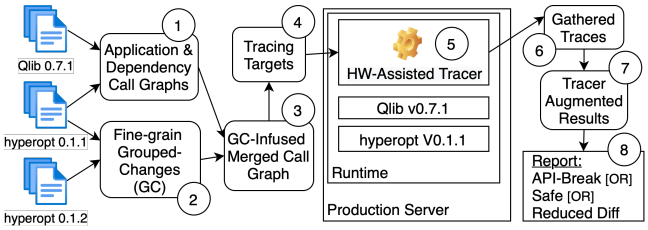


Figure 3: UPGRADVISOR's process of analyzing, tracing and providing update advice for our motivating example.

Analyzing the dependency update. Our analysis goal is to determine statically if the update is safe, or if not possible, reduce the number of changed procedures that need to be tracked by the tracer or examined by a developer. Static analysis involves the following steps.

Step 1: Build call graphs for `Qlib` (the application) and `hyperopt`'s old version (the dependency). Call graph nodes represent procedures, and directed edges represent call relations.

Step 2: Compare `hyperopt` versions to create a fused abstract syntax tree (AST) containing a set of fine-grain change tags. Change tags label the affected AST subtree with the type of change made and the change position in the source code. As we see later, specific change types and location combinations will be handled differently. A change can be a statement modification (e.g., Fig. 2c), an addition of several statements to an existing procedure (e.g., Fig. 2a), or the deletion of a method from a class, possibly breaking any code calling it. We group all change tags in the same procedure because UPGRADVISOR traces at procedural level.

All non-semantic changes, adding a space or changing comment text, are ignored by using an AST representation. Change tags are discarded by employing a language-specific analysis using the AST-subtrees content. For example, for Python, any changes involving type annotations and order changes between unrelated import statements are discarded.

Step 3: Merge the application and dependency graphs, connecting all interfaces between `Qlib` and `hyperopt` in the graph, and infuse the grouped changes into the relevant graph nodes. We discard `hyperopt` nodes that are not reachable from any of `Qlib`'s nodes, along with any change tags connected to these nodes. For example, the changes depicted in Fig. 2a are discarded as no graph path from `Qlib` into `hyperopt` leads to the `main_worker_helper` function.

Starting from 72 changed procedures in `hyperopt`, performing steps 1-3 leaves only four nodes with change tags in the merged graph. Fig. 4 shows part of the merged call graph containing these four nodes, which represent changed procedures. `Qlib`'s only procedure calling into a changed procedure in `hyperopt` is `contrib.tuner.(...)` (in green), calling `fmin`, a part of `hyperopt`'s API (in orange). The changed procedures, e.g., `FMinIter.init` are marked as red stars, while other non-changed `hyperopt` procedures connecting them, e.g., `(...).exhaust`, are shown as well (in red).

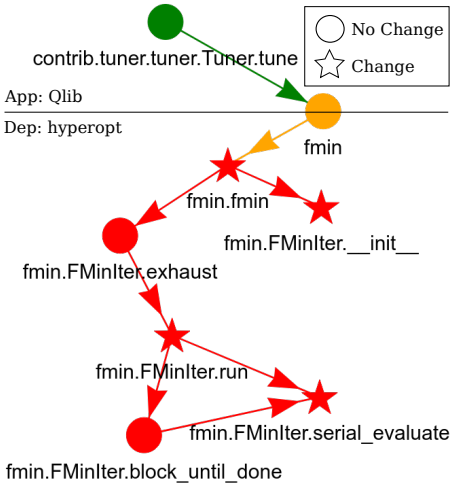

Figure 4: The graph of `hyperopt`'s code changes reduced to only show changes affecting `Qlib`.

Employing the tracer. UPGRADVISOR traces the existing dependency code, ideally running on a production server. These traces can then be used to simulate the dependency update, which can catch breaking changes and discard changes to unreached parts of the dependency.

Step 4: After statically determining the four changed `hyperopt` procedures which might be reachable from `Qlib`'s code, their names are sent on the fly to the tracer already running on the production server.

Step 5: The tracer then starts tracking them by logging every control-flow decision in the procedure, including conditional branches and exceptions. `Qlib`'s test suite did not cover any of `hyperopt`'s code and specifically did not exercise `contrib.tuner.(...)` which calls the changed part of `hyperopt` from `Qlib`. However, if a production environment is not available to trace, the static analysis provides insight on what kind of test cases should be created to provide better coverage. For this example, we manually created a production-like workload which covered calls to `hyperopt` and ran them on the traced system. Specifically, we made `Qlib` use `hyperopt`'s asynchronous computation mode. Tracing relevant methods in `hyperopt` incurs only ~5% runtime overhead on the system.

Step 6: The tracer's output is decoded offline to reconstruct execution traces for tracked procedures.

Gathering and summarizing results. Step 7: The graph created in step 3 is augmented with the collected traces. Any change tag is excluded if its code location is not present in the traces. If all tags in a group are excluded, the whole procedure is discarded. The changed statement in `serial_evaluate`, shown in Fig. 2c, does not exist in the traces, so it is discarded.

At this stage, only three changed procedures, including `run` shown in Fig. 2c, require manual examination. Taking a closer look at the changes in these three methods shows

that all changes relate to the addition of the progress bar in `run`. `fmin.fmin`'s signatures adds a new variable: `def fmin(... , prog_bar=True): ...`. Its value is then propagated to the `fmin.FminIter` class, which then uses it when calling `tqdm(disable=prog_bar)`.

Adding arguments to a function declaration might be a source for API breakage, as a change to required positional arguments might cause a runtime error. In this example, because the new argument has a default value ("True"), a runtime error will not occur. UPGRADVISOR still marks this update as a "possible API break" due to the change in `Qlib`'s output caused by the progress bar. Specifically, this can be avoided by changing `Qlib`'s code to assign "False" to `prog_bar` when calling `fmin.fmin`. Following this, developers can move forward with the updating `hyperopt` to version v0.1.2.

We submitted a PR to the `Qlib` project, recommending the changes described above. This PR was adopted quickly by the maintainers and merged into the `Qlib`'s main code branch within five hours, even though `hyperopt`'s version 0.1.2 had been available almost three years (released 21-Feb-2019) at the time of the PR.

4 Static Analysis of Dependency Updates

As shown in steps 1-3 from Fig. 3, UPGRADVISOR uses static analysis to determine if a dependency update is safe, or identify what procedures may be affected by the update so they can be further considered by dynamic tracing. The inputs are the application code, A, and dependency code D in two versions before and after the update, D_{Before} and D_{After}, respectively.

Throughout this section, we use Python terminology for methods and functions, where a method is a block of code associated with a class and a function is a block of code that can be called but is not associated with a class.

4.1 Application and Dependency Call Graphs

UPGRADVISOR first builds call graphs for A and D_{Before}, which are merged into one graph G. Building an accurate call graph requires: (1) mapping call sites and (2) detecting callees (call targets). However, dynamic interpreted languages such as Python typically do not require specifying types, causing callee uncertainty. Consider the following Python snippet:

```
def foo(a):
    return a.get_size()
```

The function `foo` has an untyped argument `a`, and it calls `a`'s method `get_size`. `a` can be any class that has a method `get_size`, and there is no type information to help narrow down the potential callees. We refer to `get_size` as a named method with an unknown class because the method name called is known but the class to which it belongs to is unknown. Alternatively, consider the following Python code snippet:

```
def foo(a):
    return a()
```

The function `foo` has an untyped argument `a`, and it calls `a`. `a` can resolve to any function in the code, and there is no type information to help narrow down the potential callees. We refer to `a` as an anonymous function. There are ways to explicitly specify types in Python using type annotations [36], as in the following code snippet:

```
def foo(a:arg_type) -> ret_type:
    return a.get_size()
```

However, this is optional in Python, so call graph construction must account for the absence of types.

We use call graphs to decide if an update is safe or identify tracing targets, so their soundness is crucial. While false edges can be tolerated (false positives), there cannot be missing edges (false negatives). We achieve this by over-approximating calls in the graph. The basic idea is to use type information when available to build a context-sensitive [15] call graph to pinpoint the exact method called, but then combine this with context-insensitive analysis for missing targets. We split missing targets into two types: (1) named methods with unknown class and (2) anonymous functions. To express the first type of missing targets in our call graph, we create an edge with a "magic" prefix followed by the callee name, e.g., `UNK.get_size`. To express the second type in the graph, we create a magic edge from the node to `ANON`.

Using the process described above, we construct call graphs for A and D_{Before}, and merge them into one graph $G = (V,E)$ with V nodes and E edges. We split V into two groups depicting M methods or F functions, respectively: $V = M \cup F$. To make G over-approximate for missing call targets we apply the following edge adding rules:

1. $(n,UNK.x) \in E, \exists y.x \in M \Rightarrow E = E \cup \{(n,y.x)\}$
2. $(n,ANON) \in E, x \in F \Rightarrow E = E \cup \{(n,x)\}$.

The first rule adds edges from the respective node to all methods with the same name as the named method with unknown class. The second rule adds edges from the respective node to all functions. These rules add all possible call targets for named and anonymous missing targets. Exploring the Python projects discussed in §2, we find a limited amount of named method missing targets exist in almost every project, while anonymous function missing targets were scarce.

Due to their scripting-oriented roots, most dynamic languages allow placing statements in the source-code file outside of procedures or classes. Running this file as a script or importing it from another file will execute these statements. For example, given a file named "h.py" including `print("Hello World")`, putting the import statement `from h import *` in another file will result in "Hello World" printed on the screen. To represent these statements in the call graph, we place them into a special `module_ctor` pseudo-procedure node and add an edge to relevant importing files.

A graph will contain an edge from a procedure to `module_ctor` if the procedure contains the relevant import statement.

Similarly, we place class fields and their optional initialization in a special pseudo-class-initializer `X_cinit` node, adding edges to and from it between every call site to any class constructor. For example, a statement creating a new class instance, `ClassA()`, placed inside a procedure named `foo` will create the following call path: `foo` → `ClassA_cinit` → `ClassA_ctor`.

We treat other language-specific container for representing code, such as Python's decorators (see §6), similarly.

4.2 Grouping Changes

UPGRADVISOR introduces a novel static approach for creating grouped fine-grain changes. We introduce *change tags*, used for tagging individual statements that have changed between D_{BEFORE} and D_{AFTER} as additions, deletions, or modifications. These fine-grain per statement tags are then grouped together by the lowest-level procedure that contains the respective tags.

UPGRADVISOR fuses the code in D_{BEFORE} and D_{AFTER} into one AST and marks changes with change tags. For example, for Python, we create one AST per Python module. Each module is contained in a file and has procedures, classes, and other statements. The fused AST contains all deleted and added statements, while modified statements contain the code from D_{BEFORE}. For modified code, the code in D_{BEFORE}'s copy is stored in the AST because UPGRADVISOR will later need to identify D_{BEFORE} code when combining it with collected traces generated by running D_{BEFORE}, as discussed in §5. Each change tag represents a change in a statement and contains a pointer and a type, the type being either addition, deletion, or modification. The pointer points to the affected statement, i.e., the lowest statement-tree-node containing the change. For example, in Fig. 2c, the modification tag is applied to AST node representing `trial['state'] = ...`, while in Fig. 2b an addition tag is applied to the node representing `with tqdm(...)`, and no tag is applied to the node representing `while n_queued`. Changes to procedure declarations, such as adding an argument or default value for one, are represented as a tag on the procedure's declaration node in the AST. If a file was deleted or added, we create an AST with all statements and procedure declarations containing deletion or addition tags to represent it. Change tags are then grouped by the lowest procedure, class, or module containing them by following each AST pointer and moving up the tree.

4.3 Clustering Changes Into Call Targets

UPGRADVISOR attaches the grouped changes to nodes in the call graph G, discussed in §4.1. As grouped changes are associated with the lowest procedure, class, or module containing them, it is straightforward to attach them to nodes in the call graph. Any node with at least one change tag attached to it is considered a changed node. Note that changed nodes exclusively appear in the part of G constructed from D_{BEFORE}.

UPGRADVISOR then performs the following two steps. First, it discards change tags that, in G's context, do not affect the semantics of the code. Examples include (1) called APIs adding unused default values, and (2) changes in import location or procedures moving between files. If all change tags in a specific group were discarded, the node associated with this group is no longer considered a changed node. Second, UPGRADVISOR discards any changed node not reachable from an application node. Any changed nodes remaining after this two-step process are marked as call targets, and their corresponding procedures will then be sent to the tracer. These call targets represent changes that can potentially affect the application. If there are no call targets, static analysis alone was successful in automatically determining that the update is safe.

Propagating the indirect effects of direct updates to data is currently out of scope for UPGRADVISOR. These include direct updates to external data used by the code, such as HTML templates, or changes to data in the code itself, such as data used for initialization. UPGRADVISOR can be configured to report on changes to external data. As changes to data in the code are necessarily a changes to the code, these will be detected statically through the call graph if it is reachable from the application, ensuring the correctness of the static analysis. However, any effects due to changed data on other non-changed parts of the code will not be propogated. For example, if a dependency's internal state, such as a global variable, is updated and an unchanged method reads this global variable, UPGRADVISOR will not identify the unchanged method as a call target. UPGRADVISOR can be expanded to propagate the effect of the changed state and mark these methods for tracing or report more methods for developer inspection, and we intend to explore this in future work. As discussed in §7, we find such transitive state changes in the code to be rare.

5 Dynamic Hardware Tracing

UPGRADVISOR uses dynamic tracing to determine what an application actually does in practice. By tracing application execution in a production environment, we can obtain the ground truth of application-dependency interactions and see which call targets are actually used. To allow dynamic tracing in production environments, it is crucial that tracing have minimal impact in production, including avoiding application changes and incurring minimal overhead. For the former, UPGRADVISOR traces the existing application without applying any dependency updates, so no application changes are required. For the latter, UPGRADVISOR introduces two key mechanisms, target-focused tracing and hardware-assisted coarse-grained tracing for interpreted languages.

```
// given a code block with a sequence of bytecode
for (each opcode in code block){
  switch (opcode) {
    case opcode_1:
      subroutine_1(); //interpretation logic for opcode_1
      break;
    case opcode_2:
      subroutine_2(); //interpretation logic for opcode_2
      break;
    ...
    case opcode_i:
      subroutine_i(); //interpretation logic for opcode_i
      break;
    ...
  }
}
```

Figure 5: Original interpretation loop inside an interpreter.

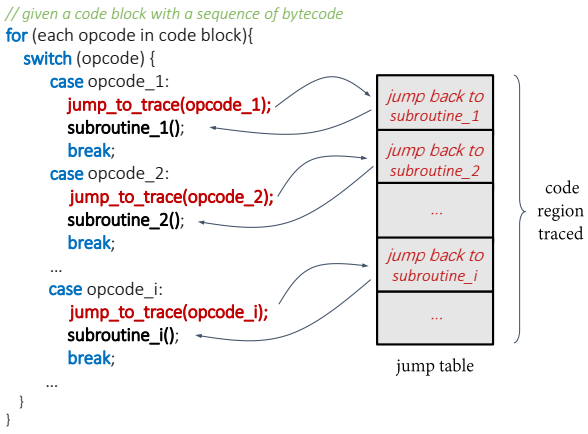

Figure 6: Traced interpretation loop inside an interpreter.

5.1 Target-focused Tracing

UPGRADVISOR does not need to trace the entire application execution, but needs only to trace call targets generated from the static analysis discussed in §4.3. This small handful of methods is not known in advance, and may change for different updates. For languages such as Python, a compiler compiles the program written in the interpreted language to a sequence of bytecode instructions, and the interpreter runs a loop that interprets bytecodes one by one at runtime, as shown in Figure 5. UPGRADVISOR enables on-the-fly selection of which methods are traced by interposing on the interpretation loop used to interpret the intermediate bytecode for dynamic interpreted languages. This logic is illustrated in Listing 1.

```
1 // given a code block with a sequence of bytecodes
2    maintain set of methods to be traced;
3    if(signature of code block is in the set)
4        { goto traced loop; }
5    else{ goto original loop; }
6    original loop:
7        loop code shown as Figure 5;
8    traced loop:
9        loop code shown as Figure 6;
```

Listing 1: UPGRADVISOR's target-focused tracing check logic.

We modify the interpreter to allow running a traced version of the loop on demand. UPGRADVISOR maintains a set, updatable during runtime, of signatures for all methods marked for tracing. Before running any method, the interpreted checks if it is part of this set, directing the execution to the traced or original version (where no tracing is enabled) of the loop accordingly. The traced loop is shown in Figure 6, which only differs from the original loop by adding a jump instruction before each call to a subroutine in the interpreter loop, which enables tracing as discussed further in §5.2.

5.2 Coarse-grained Hardware Tracing

To further reduce tracing overhead, UPGRADVISOR leverages hardware tracing mechanisms widely available in modern CPUs, specifically Intel Processor Trace (PT) [21]. Intel PT records dynamic control-flow information such as branch targets and branch taken indications, encoding them as trace packets. With the trace packets collected and the program's native code as input, a software decoder [20] can then be invoked to reconstruct the control flow of the program executed. Although hardware tracing has advantages in terms of low overhead and the absence of intrusiveness, a key challenge is how to leverage it to meaningfully trace interpreted languages since it can only profile native instructions directly running on physical CPUs [43]. For a native program, native instructions can be readily mapped back to the source code with the aid of compilation metadata. This is not the case for programs written in interpreted languages. For interpreted languages such as Python running in a virtual machine, the intermediate bytecode corresponds to the source code, but the native instructions executed by the CPU are those of the interpreter.

To leverage the efficiency of hardware tracing, we need to develop tracing support that can bridge the gap by relating hardware traces generated by CPU to bytecode instructions of interpreted languages that developers can understand. A naive way to obtain the execution trace at the bytecode level is to trace the execution of the entire interpreter code and then reconstruct the execution flow of high-level bytecode based on the mapping between bytecode types and their respective interpreter subroutines. For example, Intel PT generates trace packets with instruction pointers (IPs) to identify the address range for each instruction. In Figure 5, interpreter subroutines such as `subrountine_1` and `subrountine_2` have static address ranges for their instructions. Knowing that the executed instructions are within the address range of a particular function suggests which bytecode opcode is being interpreted.

Unfortunately, this approach may suffer from data loss as it can record a huge amount of unnecessary low-level trace data.

Intel PT uses a memory buffer to store trace data. Data loss occurs when there is more trace data generated than can be written into the buffer. It is extremely challenging to determine after the fact what data is lost and how to recover it [43]. However, what we are interested in is only the sequence of bytecode instructions executed, not the low-level control flow of the interpreter subroutines. What is needed is a *coarse-grained* tracing mechanism that focuses on the collection of the high-level bytecode sequences without capturing extraneous details of the subroutine implementations.

To this end, we developed a novel coarse-grained tracing mechanism that avoids capturing low-level interpretation instructions. We leverage a feature of Intel PT that allows trace packets to be filtered based on their IPs. An address range can be specified such that packets whose IPs are not in the range will be filtered out by the CPU. We create a trampoline (i.e., *jump table*) and use it as a special memory region that allows us to quickly filter out irrelevant instructions while retaining those that correspond to the bytecode. As shown in Figure 6, the jump table consists of a sequence of contiguously allocated *tablets*, each corresponding to a particular opcode. A tablet contains only one single jump instruction that jumps back to the call to the subroutine for the opcode. The traced interpretation loop has a jump instruction before each call to a subroutine in the interpreter. This instruction takes the control to its corresponding tablet; executing the instruction in the tablet takes the control back to the interpreter code. Essentially, the interpreter takes a "detour" to visit a specific (a priori known) address range defined by the jump table. We use this address range to allow Intel PT to filter out all instructions whose IPs are not in the range. As a result, the trace that PT ends up generating contains only the executed jump instructions in the tablets, and these instructions immediately reveal the bytecode opcodes due to their one-to-one mapping.

5.3 Gather Trace Results

Once hardware traces are collected, we decode them offline to reconstruct the dynamic control-flow of the program execution and deduce the code executed at runtime. The decoder decompresses the hardware trace data as a sequence of executed jump instructions, each corresponding to one tablet in the jump table. Using the one-to-one mapping between tablets and bytecodes, we reconstruct a partial sequence of bytecodes interpreted at runtime. Using the static control-flow graph for each traced method and partial bytecode sequence we project the sequence of bytecodes onto the graph so as to reconstruct the dynamic control flow executed. Once the concrete dynamic control-flow is determined at the bytecode level, we then leverage the available compilation metadata to obtain the exact lines of source code executed.

We then return to the call graph discussed in §4.3 and discard additional changed nodes based on the trace results. Specifically, UPGRADVISOR discards any change tag not associated with a statement present in the traces. Any remaining changed nodes are used to create a reduced diff file, containing differences between D_{BEFORE} and D_{AFTER} where only reachable changes appear. This reduced diff file is then made available to the developer for further examination to determine if the update is safe for adoption. If there are no changed nodes remaining, the update is considered safe.

The current version of UPGRADVISOR lacks support for exceptions. Once an exception is raised, the exception mechanism's unusual execution flow affects the control-flow reconstruction mentioned earlier. In future work, we would like to support exception handling. In brief, an exception redirects execution to a dedicated block inside the interpreter. This block is responsible for directing the execution flow back to the corresponding exception handling bytecode determined by the point where the exception occurs. Supporting hardware tracing of exceptions requires tracing that redirection block to bridge the exception control flow gap.

Apart from interpretation, certain language runtimes also enable just-in-time (JIT) compilation mode for the sake of performance. Our design focuses on interpreted mode. Adding a similar design to the one we proposed by [43] will allow for hardware tracing JITed code.

6 Implementation

We have implemented an UPGRADVISOR prototype for Python 3 applications. We built the static analyzer on top of Pyre-check [9], a type-checker for Python 3. Pyre infers missing types and generates a set of calling targets for each call site it soundly resolves. For non-resolved targets, we inserted the magic edges explained in §4.1. To perform an AST-based code comparison, we used `GumTreeDiff` [10], a state-of-the-art code differencing tool employing its JSON-edit scripts creation function to help generate fused and tagged AST.

UPGRADVISOR handles Python decorators [35] by defining them as procedures so they are represented as nodes in the call graph. For example, given a function `bar` decorated with `@dec`, a function `foo` calling `bar` will result in the following graph path: `foo` → `dec` → `bar`. We leave for future work a more subtle analysis allowing separation of the different parts of the decorator logic (i.e., set up, wrapper and cleanup) and subsequent graph edge creation. Any change (add, modify or delete) to a procedure's decorator or its arguments is handled similarly to a procedure declaration change.

We built the hardware tracer on top of CPython [12], the default and most widely used interpreter of Python. In CPython, the interpretation functionality is directly written as a loop in C code and Python code is compiled into executables once the interpretation starts. We modified the interpretation loop as explained in §5. Instead of allocating a buffer, we statically inserted a trampoline block (equivalent to a jump table) into the interpreter's codebase. As CPython does not feature any JIT-related optimizations, we only need to monitor bytecodes

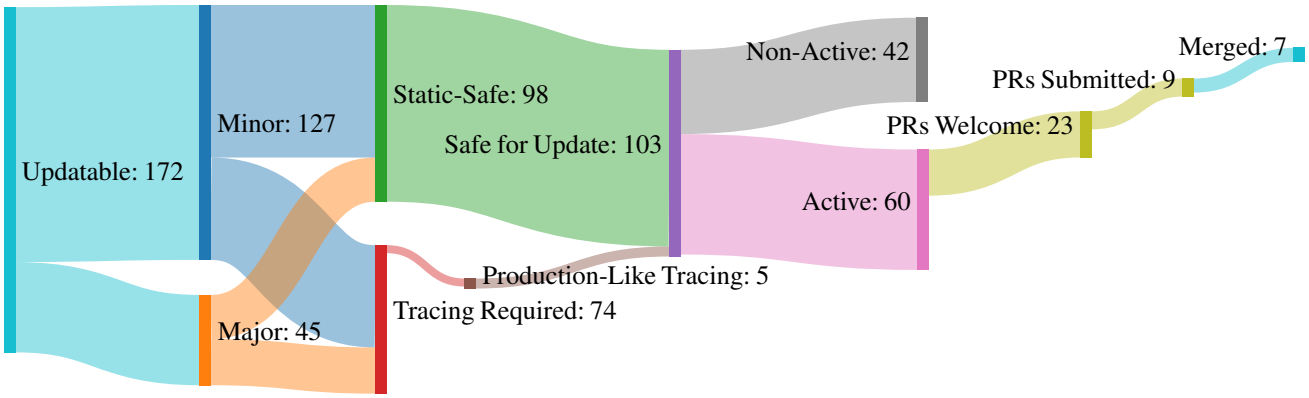

Figure 7: UPGRADVISOR's effectiveness on 172 dependency updates. Its hybrid static and dynamic analysis identified 102 updates as safe. A sample of safe updates were submitted as PRs, almost all of which have been merged.

resulting in control-flow divergence. Five kinds of Python bytecode are taken into account: *POP_JUMP_IF_FALSE*, *POP_JUMP_IF_TRUE*, *JUMP_IF_FALSE_OR_POP*, *JUMP_IF_TRUE_OR_POP*, and *FOR_ITER*. Each of them has two potential branches, true or false. Thus, the trampoline block has ten tablets.

The current prototype supports only applications written entirely in Python. Performance-minded Python projects may convert computation-heavy code into C. A prominent example is `numpy`, a scientific computing package. We leave extending UPGRADVISOR's approach to mixed language projects for future work, and currently UPGRADVISOR will alert and stop processing when C code is detected in the project. The prototype supports tracing only on bare-metal machines. To extend it to run in a virtualized environment (e.g., VMs or containers) will require OS support and further changes in memory mappings for tracing. We note that Intel already added initial support to KVM [19], and leave the rest for future work.

7 Evaluation

We evaluated the effectiveness of UPGRADVISOR in adopting blocked dependency updates and its performance overhead. We first used UPGRADVISOR to examine possible Python dependency updates from our survey discussed in §2. Although the vast majority of the 389 Python applications blocked dependency updates, we only considered those written entirely in Python 3. Altogether, we examined 50 applications with 172 possible dependency updates. We further tested UPGRADVISOR's ability to detect API breakage using known API changing updates. We then measured the performance overhead of UPGRADVISOR's tracer using a subset of the 50 applications with available performance test suites. Finally, we also measured UPGRADVISOR's tracer performance using Instagram's `django-workload` [8], based on a real-world large-scale production workload.

Static analysis was done on a machine with an AMD Opteron 6168 CPU (48 cores) and 62GB of RAM. Dynamic tracing was done on a machine with an Intel i7-10700 CPU (8 cores) with 16 GB of RAM. All machines ran Ubuntu 16.4.

7.1 Facilitating Dependency Updates

We evaluated UPGRADVISOR's ability to adopt 172 previously blocked dependency updates for 50 GitHub projects, including `Django`, `aws-cli`, `tfx` and `Celery`. Some of these projects were also dependencies for other projects. When the latest version of a project blocked a dependency update, by pinning or double-bounding dependency requirement conditions, we explored the possibility of removing the block and updating it to the next version of the dependency. For example, in our motivating example presented in §3, `Qlib` v0.7.1 pinned the dependency `hyperopt` to version v0.1.1, while version v0.1.2 exists. Out of these 172 possible updates, 45 were major version updates, and the other 127 were minor. Fig. 7 depicts the high-level view of this process.

UPGRADVISOR's static analysis was able to determine that the majority of dependency updates, 76 minor and 22 major, were safe and could be automatically updated without further dynamic tracing. These 98 updates are marked as "Static-Safe" in Fig. 7. Referring back to our survey for update delays in Python, Fig. 1a, performing all of these updates to the next available dependency version would save an aggregate of 11,310 delay days, averaging 115 delay days saved per dependency. We further confirmed the "Static-Safe" results by sampling roughly 10% of them, 11 to be exact, and manually validated that the code changes were safe.

We measured the reduction in code differences that still remained to be considered after static analysis versus the entire code differences of the updates. The total number of diff lines in all 172 updated versions we considered for this experiment was 667,604, with the average update constituting 3,881 diff lines (STD 9,078). While not a perfect metric, we use diff size as a proxy for manual developer effort required to study a de-

Project (Dependency)	Diff (LOC)	% Discarded		
		Static	Dynamic	Total
AutoML (distributed)	850	95	5	100
Electrum (qdarkstyle)	641	88	8	96
Flair (gdown)	1500	71	29	100
Qlib (Hyperopt)	828	90	9	99
Scylla (requests)	449	90	8	98

Table 2: Diff reduction for dependency updates, showing diff size in LOC and the percentage of lines discarded statically, using dynamic tracing, and in total.

pendency update. UPGRADVISOR's static analysis was able to reduce the diff sizes by an average of 91%. The reductions are consistently large across updates, with a standard deviation of 17.58%. These reductions also count cases in which UPGRADVISOR finds the update safe, eliminating the whole diff file.

We also quantified the prevalence of direct changes to data such as global variables that could potentially be used by unchanged methods. We found that only 10 out of the 172 updates contained such transitive state changes, indicating that they are infrequent. Furthermore, UPGRADVISOR was able to statically determine 5 of the 10 as safe, so only the remaining 5 still requiring dynamic tracing could be impacted by the current limitation of UPGRADVISOR not identifying unchanged methods using changed data.

Among the remaining 74 dependency updates that could not be resolved statically, denoted "Tracing required" in Fig. 7, we selected a representative sample to evaluate further using dynamic tracing. The specific projects and dependencies evaluated are listed in Table 2.

Unfortunately, we did not have access to actual production environments for these applications, so we used the results of the static analysis to help construct production-like workloads to cover application-dependency interactions for these applications. For `AutoML`, an automated machine learning framework, we ran selected sk-learn tutorials. For `Electrum`, a GUI-based Electrum Bitcoin wallet, we manually interacted with the GUI to try and trigger the relevant parts of the dependency code. For `Flair`, a framework for state-of-the-art (SOTA) Natural Language Processing (NLP), we used publicly available datasets for multiple supported languages (used for training), employed trained models, and ran tutorial examples. For `Qlib`, we set up a MongoDB instance to allow `hyperopt` to conduct asynchronous hyper-parameter optimization, and generated testing inputs for various optimization calculations, as discussed in §3.2. For `Scylla`, a proxy search and connection tool, we scanned for available proxies and used them to crawl major news sites. When applicable, to further increase coverage for possible program behaviors, we used inputs included by the project or created in our environment to drive the `atheris` fuzzer for Python [14].

Table 2 shows the results of running UPGRADVISOR end-to-end process on the project's production-like environments.

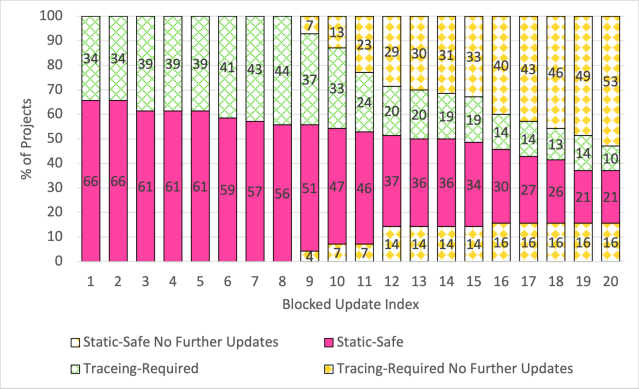

Figure 8: Using UPGRADVISOR on 75 application-dependency pairs with eight or more blocked updates.

On average, using the tracer further reduced diff sizes by 12%. Furthermore, the tracer allowed for classifying more updates as safe. For other updates, e.g., `Qlib`, additional manual inspection was required as not all code changes could be discarded from dynamic tracing, but only ~2% of the original code changes required manual inspection, significantly reducing developer effort in adopting the dependency update.

7.2 Analyzing Multiple Blocked Updates

When applications fail to perform their dependency's first update, subsequent updates are blocked as well. Among the 172 blocked dependency updates, the number of blocked updates per dependency is 12.5 on average, the median being 5, with a standard deviation of 43.67. For example, by pinning `hyperopt` to version 0.1.1, `Qlib` blocked eight updates, from 0.1.2 to 0.2.6. More generally, among the 172 blocked dependency updates, there are 75 dependencies with eight or more blocked updates.

Fig. 8 shows the result of using UPGRADVISOR on each of the eight or more blocked updates for the 75 dependencies. The blocked update index indicates how many versions after the adopted dependency is the update being considered. For example, the first bar shows the next version of the dependency, which is the subset of results from the study in §7.1 limited to just these 75 dependencies. For each blocked update index, we show the percentage of updates UPGRADVISOR requires tracing for as opposed to deeming safe statically. Starting from 34%, this percentage steadily increases to 44% in the eighth update, constituting a ~30% increase. If we count blocked updates as retaining their previous status (static-safe or tracing required) when no further updates are available, this trend continues as the blocked update index increases from 9 to 20.

To test UPGRADVISOR's hybrid approach contribution to the analysis of multiple blocked dependency updates, we employ our production-like testing environment to `Qlib`'s `hyperopt` dependency for all available updates. Fig. 9 shows diff sizes and UPGRADVISOR's ability to statically and dynamically

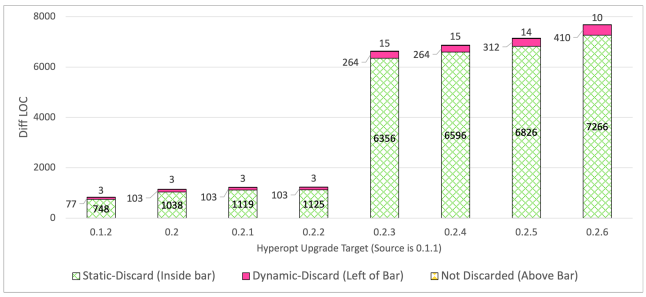

Figure 9: Diff sizes and static and dynamic discards for `hyperopt`'s eight updates.

discard changed code across `hyperopt`'s eight updates. Note that the first bar represents the same `Qlib` data as in Table 2.

7.3 Contributing to the OSS Community

To further validate our results, we selected a sample of dependency updates that UPGRADVISOR considered safe and submitted them to the respective project via a PR. Except `Qlib`, which was the first PR we submitted, all other dependencies were updated to their latest version. As submitting a PR requires manual effort, we focused on active projects welcoming PRs. We deem projects active if their latest commit was made in or after 2021, and PR-welcoming if they accepted a PR from an external developer in the last month and have less than 100 open PRs. Each PR clearly explained UPGRADVISOR's goals and affiliation, provided UPGRADVISOR outputs (e.g., graphs such as the one shown in Fig. 4), and any other relevant information (e.g., dependency change log) allowing the developers to examine the updates and validate our results. In some cases, our PR prompted discussions with the developers providing us with ideas for improving UPGRADVISOR's outputs. Out of nine PRs submitted, seven were merged and two received no response. Furthermore, five of the merged PRs were for dependencies listed in Table 2, validating the results of UPGRADVISOR's dynamic tracing.

7.4 Detecting API Breakage

We noticed that in OSS projects, API breakage is discovered by dependency users in a few days/weeks. The relevant version will quickly be "yanked" from the repositories, so that the API breaking version ends up not being visible in our experiments in §7.1. As a result, none of the dependency updates considered in §7.1 caused API breakage. While this shows the advantages of OSS, for the individual entities, this discovery might have been made at the price of production failures or even data corruption, and UPGRADVISOR's goal is to detect these before they happen.

To evaluate UPGRADVISOR's ability to detect API breakage, we conducted a small controlled experiment with two applications, `django-oscar` and `label-studio`, which were examined by UPGRADVISOR in §7.1. These applications have a dependency on `Django`, which has a well-documented deprecation timeline [4] allowing us to study API breakage. We consider the recent 7-Dec-2021 release of `Django 4.0`, which contains 28 API breaking changes including arguments losing default value, removed APIs, etc. Both `django-oscar` and `label-studio` are stuck on much earlier 3.x versions of `Django`. Instead of considering an update to the next available 3.x version of `Django`, we used UPGRADVISOR to statically analyze the difference between version 4.0 and the 3.x version specified by the application. In these cases, UPGRADVISOR correctly identified all API breaking changes with no false positives or negatives, which we manually confirmed by studying UPGRADVISOR's output and comparing it to the deprecation information. This experiment also showcases UPGRADVISOR ability to direct developers to the relevant portions of their code which will break and provide context for the fix.

7.5 Tracing Overhead

We evaluated UPGRADVISOR's tracer overhead using applications from our previous experiments in §7.1 with test suites that we could set up and execute without errors. Ironically, some test suites failed to run due to broken or conflicting dependencies. We selected a subset of qualifying projects to represent the Python open-source eco-system, including ML (`Qlib` and `Flair`), data-science (`Faust`), blockchain (`Electrum` and `Vyper`), administration tools (`aws-cli`), and website-building (`Django`). `Django` allowed us to experiment with multi-process code and control the number of processes used. We ran Django's test suite using 1, 8, and 16 logical CPUs. Each project had some dependency update among the 172 possible updates considered in §7.1. Specifically, the dependency updates for `Qlib`, `Flair`, `Faust`, `Electrum`, `Vyper`, `aws-cli`, and `Django` were `hyperopt`, `gdown`, `Croniter`, `qdarkstyle`, `asttokens`, `colorama`, and `pytz`, respectively.

We compared the performance of UPGRADVISOR to several other tools, including `cProfile`, `Coverage.py`, and `JPortal4Py`. `cProfile` is a de-facto standard tool for cPython that profiles executions at the method-level. `Coverage.py` is a de-facto standard tool for cPython that tracks statement-level test coverage. Neither of them provide the same functionality of UPGRADVISOR's tracer, but provide useful performance comparisons. `JPortal4Py` is a Python-compatible implementation of a hardware tracer that traces the whole interpreter [43]. We also compared against UPGRADVISOR-SW, an implementation of UPGRADVISOR's tracer that uses software tracing in lieu of Intel PT to trace all procedures. In evaluating UPGRADVISOR, we compared two configurations, UPGRADVISOR-ALL to trace all procedures, and UPGRADVISOR-Targeted to trace only procedures marked by UPGRADVISOR's static analysis. We ran each application on each tool five times and report the average and standard deviation of the overhead measurements.

Fig. 10 shows the performance overhead measurements

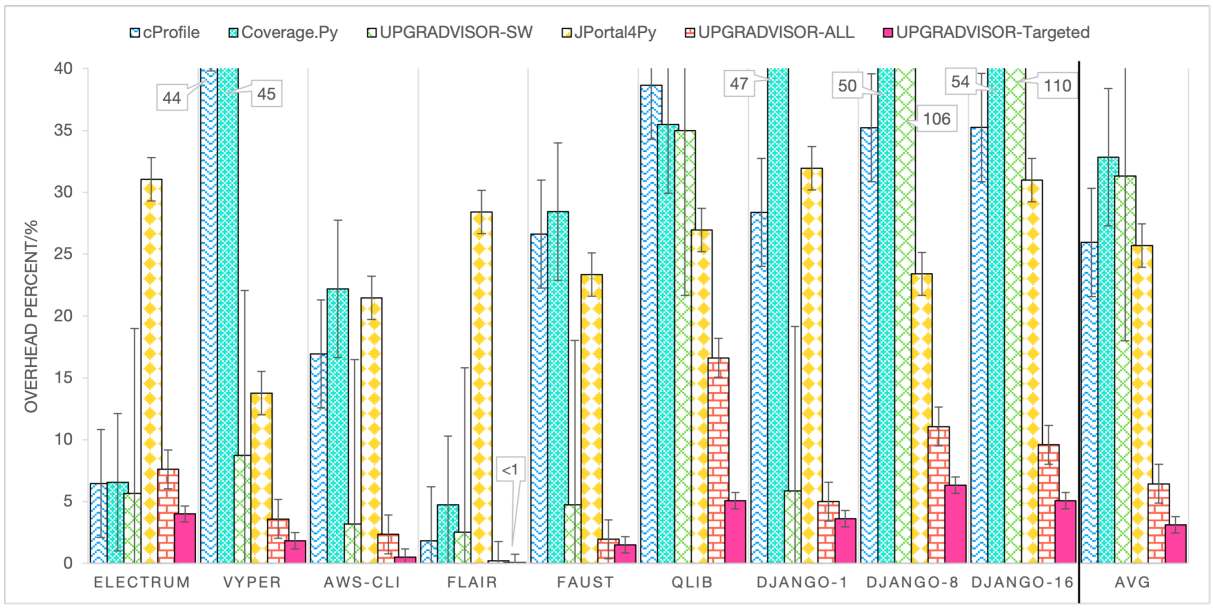

Figure 10: Comparing the performance of UPGRADVISOR's two modes, ALL and Targeted, with `cProfile`, `Coverage.py`, `JPortal4Py`, and UPGRADVISOR-SW, a software-only tracer.

normalized to native execution of the application without any tracing. UPGRADVISOR in targeted mode has the least overhead in all cases, averaging 3%, with a standard deviation of 2.15%. It is an order of magnitude faster than all other tools for some applications, except for UPGRADVISOR-ALL. Django's multiprocess test-suite measurements showcase the advantages of using hardware features for tracing, as all software-based approaches suffer from significant overhead trying to record all control operations made by the interpreter across several processes. Nevertheless hardware tracing is not a panacea as the `JPortal4Py` hardware tracer performs much worse than UPGRADVISOR-SW on most of the single process measurements. This is because `JPortal4Py` traces the whole interpreter as well, flooding the memory buffer with trace packets and causing significant disk I/O.

While tracing all methods, UPGRADVISOR-ALL manages to only incurs an average of 6.4%, over 60% worse than UPGRADVISOR-Targeted but still much better than all other tools. However, because it traces many more methods and fills up the memory buffer quickly, it suffers data loss, which can lead to misdiagnosing unsafe updates as safe. Data loss measures lost tracing events, those overwritten before they could be read from memory by the CPU and written to disk, as a percentage of all tracing events. We calculated data loss rates by comparing UPGRADVISOR-ALL versus UPGRADVISOR-SW, which also traces all methods but does not suffer the data loss of hardware tracing. UPGRADVISOR-ALL's data loss rates across the different applications rose as high as 16% for single process workloads and over 20% for Django running with 16 logical CPUs. In our experiments, we set a memory buffer size limit of 128MB per logical CPU. Increasing this limit or using faster disks/memory might help convert some data loss into overhead. In contrast, UPGRADVISOR-Targeted does not suffer from any data loss due to the reduced amount of trace records generated.

To further stress UPGRADVISOR's tracer, we used Instagram's `django-workload` [8]. This testing environment includes a Cassandra database [2], `memcached` [27] in-memory key-value instance, a Django installation and the Siege load generator [13]. We set up Django according to its recommended configuration for production systems [6] using the WSGI interface. Django depends on `pytz`, a frequently updated package dealing with time-zone related date manipulations, and supports thousands of plugins and sub-packages [5], including `django-cassandra-engine` used by `django-workload`. We measured the performance of UPGRADVISOR's tracer using `django-workload` when evaluating updates to both `pytz` and `django-cassandra-engine`. Running this workload using both UPGRADVISOR-ALL and UPGRADVISOR-Targeted, we found that UPGRADVISOR incurs an average overhead of only 7% and 3%, respectively. These results are consistent with those in Fig. 10, and indicate that our measurements of UPGRADVISOR's tracer overhead provide a good indication of its expected performance when running real-world production workloads.

8 Related Work

Dependency upgrade surveys. Other surveys also show that many projects suffer from dependency update delays [23, 38, 41]. For example, a survey of 7.3K Java projects

reports that 81.5% of projects display dependency update lag [23], and a survey of 610K JS projects in the NPM package repository between 09-11-2010 and 02-11-2017 reports a similar number of delay days as ours [41]. Our survey focuses on three modern dynamic languages and investigates historical dependency upgrade patterns.

AST differencing algorithms. AST differencing algorithms [10, 11, 16, 29] compute an edit script between two versions of an AST. GumTree [10] first finds isomorphic subtrees through a greedy top-down algorithm then executes a bottom-up algorithm to match sub-trees which share a large number of matching nodes. As discussed in §6, UPGRADVISOR uses GumTree's AST-diffing and builds upon its generated edit-script to generate a fused AST representing the dependency before and after the update.

Changeset and impact analysis. Given a set of code changes and test suite runs, change impact analysis tools generate a list of tests affected by the change and re-test them to verify if they pass after the change is adopted. Approaches can be classified based on the techniques used, the granularity of changes considered, and whether static or dynamic analysis is used [24]; only one approach explored statically studying changes at the code-snippet scope (below the method/class level) [32]. Chianti [33] introduced a change impact analysis tool for Java programs, incorporated in the Eclipse IDE. Prior techniques all rely on application test suites and do not scale to allow usage in production servers. UPGRADVISOR expands on these works, representing changes at the statement level and statically discarding them before using a dynamic tracer to validate them on production servers.

Call graph construction. PyCG [34] builds call graphs for Python code using assignment graphs. It prioritizes analysis speed and completeness and thus exhibits unsoundness in its evaluation. UPGRADVISOR prioritizes soundness, achieved by over-approximating call targets. Various approaches dynamically generate call graphs for JS code [17]. NodeProf [39] instruments the code under test and gather information in the face of code generation and other JS-born challenges. UPGRADVISOR records similar information via tracking jumps and calls online and then decoding this information offline to avoid high overhead. We plan to leverage these works to add JS support for UPGRADVISOR.

Hardware tracing. Modern CPUs provide hardware features for tracing, including Intel PT [21] and ARM embedded trace macrocell (ETM) [26, 37]). These have generally only been applicable to native programs. Our previous work, JPortal [43], showed how to enable hardware tracing for Java bytecode, but it suffers from high overhead and data loss from needing to trace the whole virtual machine. UPGRADVISOR improves on JPortal via novel coarse-grained and selective tracing mechanisms which achieve low overhead without data loss.

Statistical debugging. Statistical debugging [25, 42] reduces tracing overhead through randomized sampling and dispersing data collection among different users. UPGRADVISOR achieves low overhead through selective hardware tracing, which maintains completeness.

Multi variant execution (MVE). MVE methods [18, 28] split test suite execution at the point of change, then run the two versions (before and after upgrade) and merge them back to show compliance. MVE concepts have also been applied towards detecting exploitation attempts and test generation [22, 31]. To overcome lacking coverage in test-suites, UPGRADVISOR traces production servers focusing only on parts relevant to the dependency update.

Patch analysis in continuous integration. SubmitQueue [1] is a system for examining simultaneous application code updates. It combines a build dependency graph with a continuously trained statistical model to optimize the order of application code updates to maximize parallelism for integration tests. In contrast, UPGRADVISOR provides decision support for evaluating dependency updates using production traces.

9 Conclusions and Future Work

We have shown that many projects suffer from prolonged delays in adopting dependency updates. We have designed and built UPGRADVISOR, a system for reducing developer effort and error risk in adopting dependency updates. UPGRADVISOR features the co-design of a sound static analysis constructed to pinpoint a carefully selected target set of methods to trace and a low-overhead production-ready tracer to observe dependency usage. Using this hybrid analysis together with hardware tracing, UPGRADVISOR has analyzed 172 upgrade opportunities, determining that ~60% of them can be updated safely. For the rest, UPGRADVISOR benefits developers by reducing the manual effort of going over the changes in the dependency.

We plan to extend UPGRADVISOR to benefit more dynamic languages. Moreover, we wish to build upon UPGRADVISOR's analysis to alert about malicious updates and generate application tests for increasing dependency update coverage. We believe UPGRADVISOR's low-overhead tracing technique can become useful in other domains and intend to explore its use in debugging and fault isolation.

A Artifact Appendix

Abstract

The version of UPGRADVISOR used to perform the experiments described in the paper may be downloaded from figshare.com. The artifact contains the code for the package survey, the static analyzer, and the hardware tracer. It also contains scripts to compile the tracer, run the experiments described in the paper, and produce most of the figures. For the most up to date version of UPGRADVISOR and other resources please refer to may be accessed on Github at http://upgradvisor.github.io.

Requirements

We provide the analyzer pre-installed in a docker container. The tracer requires a bare-metal machine. It directly employs a tracing capability found in Intel 5th generation CPUs (Broadwell) and above. Installing the tracer software requires root access to the OS.

This artifact will run on a i7-10700 CPU workstation with 16GB RAM. A slower machine may result in reduced performance. We set up the docker container on the tracer machine and encourage you to do the same.

Scope

The artifact may be used to reproduce the experiments described in the paper, including Fig. 1, Fig. 4, Fig. 8, Fig. 9, Fig. 10, Table 1, and Table 2.

Contents

- AnalyzerDocker.tar.gz: A docker container for running the survey and static analysis portions of Upgradvisor.
- Cache[2].tar.gz: Cached intermediate results of Upgradvisor to serve as examples and troubleshooting aids.
- UpgradvisorArtifact-main.tar.gz: The code of the Upgradvisor analyzer and tracer.
- README.md: Instructions for setting up and running the Upgradvisor experiments.

We recommend following the README's instructions for running the survey, and static analysis, as well as for checking compatibility with, compiling, and running the hardware tracer.

Practically Correct, Just-in-Time Shell Script Parallelization

Abstract

Recent shell-script parallelization systems enjoy mostly automated speedups by parallelizing scripts ahead-of-time. Unfortunately, such static parallelization is hampered by dynamic behavior pervasive in shell scripts—*e.g.*, variable expansion and command substitution—which often requires reasoning about the current state of the shell and filesystem.

We present a just-in-time (JIT) shell-script compiler, PASH-JIT, that intermixes evaluation and parallelization during a script's run-time execution. JIT parallelization collects run-time information about the system's state, but must not alter the behavior of the original script and must maintain minimal overhead. PASH-JIT addresses these challenges by (1) using a dynamic interposition framework, guided by a static preprocessing pass, (2) developing runtime support for transparently pausing and resuming shell execution; and (3) operating as a stateful server, communicating with the current shell by passing messages—all without requiring modifications to the system's underlying shell interpreter.

When run on a wide variety of benchmarks, including the POSIX shell test suite, PASH-JIT (1) does not break scripts, even in cases that are likely to break shells in widespread use; and (2) offers significant speedups, whenever parallelization is possible. These results show that PASH-JIT can be used as a drop-in replacement for any non-interactive shell use, providing significant speedups without any risk of breakage.

1 Introduction

The UNIX shell is an environment for composing programs from components written in a variety of programming languages. Coupled with UNIX's toolbox philosophy [41], this language agnosticism makes the shell a popular choice for succinctly expressing tasks that involve data processing, system orchestration, and other automation. Recent systems [52, 55, 63] accelerate such tasks by exploiting data parallelism: using *ahead-of-time* (AOT) analysis and transformation, these systems parse, analyze, and transform shell scripts into new scripts that execute in parallel.

Unfortunately, AOT parallelization quickly becomes intractable due to the dynamic nature of the shell: dynamic features such as variable expansion and command substitution, pervasive in shell scripts, generate and consume values at run-time while depending on and interacting with the broader environment—*i.e.*, the filesystem, the environment variables, and the shell interpreter itself. Additionally, modern shells offer several different configurations and execution modes, leading to complex behaviors described in hundreds of pages of POSIX standardese [2]. The complexity of these interactions and their side-effects lead existing parallelization tools to an unavoidable trade-off between (1) being conservative, aborting on scripts that use dynamic features, or (2) being unsound, possibly breaking scripts during parallelization. Recent systems [52, 55, 63] tend to be conservative—operating only on fully expanded shell pipelines and having a hard time even on simple uses of variables (see §2).

This paper presents PASH-JIT, a production-grade just-in-time (JIT) shell-script compiler aimed at non-interactive parallelization: PASH-JIT focuses on three practical (but conflicting) goals: (G1) run-time-informed parallelization: PASH-JIT leverages run-time information to parallelize script fragments that depend on state that is statically indeterminable; (G2) full behavioral equivalence: PASH-JIT is aware of the full set of dynamic behaviors present in POSIX shells, producing results that are indistinguishable from the sequential execution on the system's shell interpreter; (G3) loose shell coupling: PASH-JIT avoids modifications to the system's underlying shell interpreter, eschewing practical problems (*e.g.*, maintaining two Bash implementations). PASH-JIT behaves as a drop-in shell shim enhancing any non-interactive shell use, providing significant speedups without any risk of breakage.

PASH-JIT's key insight is to parallelize scripts just-in-time: by intermixing evaluation and parallelization during a script's execution, PASH-JIT collects and uses the latest possible run-time information about the state of an expression's vari-

*The author is now at Google but the work was done while he was at MIT.

ables, the shell, and the filesystem. PASH-JIT parallelizes script fragments when it is safe to do so, resolving indeterminacies in the broader environment on the fly. Unfortunately, low-overhead run-time-informed parallelization (G1) is particularly challenging to implement in view of full behavioral equivalence (G2) and loose shell coupling (G3). PASH-JIT addresses this conundrum using: (1) a dynamic interposition framework, guided by an instrumentation preprocessing pass; (2) support for reentrance, transparently pausing and resuming the execution of the underlying shell interpreter at run-time; and (3) a stateful, long-lived compilation server that communicates with the current shell by exchanging messages. A 9K-LOC implementation and several run-time optimizations—*e.g.*, dynamic independence discovery, commutative-aware parallelization—complete the picture.

We apply PASH-JIT to a variety of benchmarks, ranging from scripts collected from the wild to the POSIX test suite. PASH-JIT behaves identically to Bash 4.4.20(1) on 406 out of 408 applicable POSIX tests; matching Bash is a significant achievement even for a non-parallelizing shell—shells in widespread use differ on much larger subsets of tests. PASH-JIT offers speedups up to 33.7× over Bash on a 64-core machine (improving the state of the art [63] by 2× on average), notably parallelizing scripts that prior work failed to parallelize due to dynamic behaviors.

The paper begins by exemplifying dynamic shell features and the application of PASH-JIT's techniques (§2). Sections 3–6 describe PASH-JIT's main contributions:

- *A dynamic interposition framework for the shell*: A just-in-time analysis and optimization subsystem enables safe and effective parallelization during the execution of a script, dealing with the challenges of dynamic shell-script behavior. A first pass determines where to insert calls to a parallelizing optimizer in a given input script (§3), which is then invoked on-the-fly while the script is executing (§4).
- *A stateful, parallelizing compilation server*: PASH-JIT queries a long-lived parallelization server at run-time to compile script fragments. This model improves run-time efficiency by avoiding startup costs on every JIT invocation, and enables additional run-time optimizations for (1) executing independent regions in parallel, and (2) pipelining compilation and execution. The core of the server has been modelled and formally verified using SPIN [29] (§5).
- *Commutativity-aware optimization*: Additional compilation optimizations target commands that are commutative with respect to their input, along with parallelizing transformations and run-time primitives that improve the run-time performance of scripts that contain such commands (§6).

The paper then presents PASH-JIT's evaluation (§7) and related work (§8), before concluding (§9). PASH-JIT is MIT-licensed open-source software supported by the Linux Foundation at https://github.com/binpash/.

2 Example & Overview

Below is a shell program that downloads a compressed archive of text files (books from Project Gutenberg), extracts them in a directory, and then performs an analysis to find the frequencies of all words of a specific form.

```
IN=${IN:-$TOP/pg}
mkdir "$IN"
cd "$IN"
echo "Download will take some time, be patient..."
wget "$SOURCE/data/pg.tar.xz"
if [ $? -ne 0 ]; then
  echo "Download failed!"
  exit 1
fi
cat pg.tar.xz | tar -xJ

cd "$TOP"
OUT=${OUT:-$TOP/output}
mkdir -p "$OUT"
for input in $(ls "$IN"); do
  cat "$IN/$input" | tr -sc '[A-Z][a-z]' '[\012*]' |
    grep '^....$' | sort | uniq -c > "$OUT/$input.out"
done
```

The program makes pervasive use of the shell's dynamic features. For example, it uses environment variables such as `$TOP`, variable expansion like `${OUT:-$TOP/output}` to assign default values, command substitution `$(...)` as part of the loop condition, and state reflection on the file system by running `ls` on `$IN` (itself resolved dynamically).

None of the values of these variables can be known ahead of time just by analyzing the program's source code. They become known only at run-time, when the shell interpreter reaches these points in the program's execution. A sound AOT compiler such as PASH-AOT [63] or POSH [52] would fail to parallelize—foregoing all the performance benefits of data-parallel execution spread across many files in `$IN`.

PASH-JIT instead takes a JIT approach that interjects parallelization opportunities during and throughout the script's execution (Fig. 1).

Dynamic interposition (§3): PASH-JIT first uses a preprocessing step to instrument all potentially optimizable program regions with calls to the JIT engine. PASH-JIT chooses regions to maximize the potential benefits of parallelizing them: intuitively, commands and pipelines can yield significant benefits, whereas word expansion, control flow, and variable assignments are operations that do not perform heavy computation and can therefore be left as they are. PASH-JIT's preprocesor and compiler both make extensive use of parsing/unparsing of shell source code, implemented as a new parsing library. After PASH-JIT has inserted calls to the JIT engine, it invokes the user's shell interpreter to execute this transformed script. During this execution, the JIT engine calls the parallelizing compiler at run-time—right before the execution of each fragment, when the state of the shell and the file system have already been resolved. The transformed program

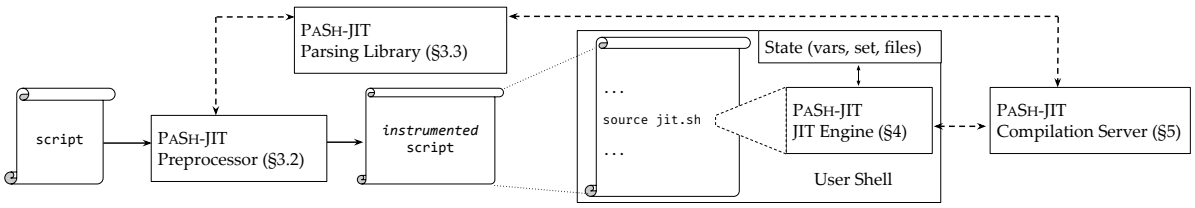

Fig. 1: PASH-JIT overview. PASH-JIT instruments scripts with calls to the JIT engine, which passes program fragments to the compilation server at run-time.

maps original commands to *regions*—for example, `region8` corresponds to the `cd` call and `region10` corresponds to the pipeline in the **`for`** loop.

```
source jit.sh "$region8"                    # cd $TOP
OUT=${OUT:-$TOP/output}
source jit.sh "$region9"              # mkdir -p "$OUT"
for input in $(ls "$IN"); do
  source jit.sh "$region10" # cat "$IN/$input" | ...
done
```

The command `source jit.sh "$regionN"` invokes the JIT engine passing as argument the corresponding fragment. The `source` built-in retains the same shell environment, reflecting any effects directly into the current environment.

JIT engine (§4): Internally, the JIT engine first saves the state of the shell at that point in the script's execution to isolate it from compilation—protecting the shell from the JIT engine and protecting the JIT engine from obscure shell configurations. PASH-JIT then invokes the compiler to attempt to parallelize the fragment. If the compiler succeeds, PASH-JIT runs the resulting parallel fragment; if not, it runs the original, unmodified region. In both cases, PASH-JIT will first restore the state of the shell before executing the fragment. Whether the compiler succeeds or not depends on the properties of the fragment's code—*e.g.*, PASH-JIT will reject `region8` due to the side-effectful `cd` command, but will accept `region10` compiling `grep` and `sort` into the parallel fragment below:

```
c_split /tmp/fifo8 /tmp/fifo9 /tmp/fifo10 &
c_wrap 'grep "^....$"' </tmp/fifo9 >/tmp/fifo11 &
c_wrap 'grep "^....$"' </tmp/fifo10 >/tmp/fifo12 &
c_strip </tmp/fifo11 >/tmp/fifo13 &
c_strip </tmp/fifo12 >/tmp/fifo14 &
sort </tmp/fifo13 >/tmp/fifo15 &
sort </tmp/fifo14 >/tmp/fifo16 &
eager.sh </tmp/fifo15 >/tmp/fifo17 &
eager.sh </tmp/fifo16 >/tmp/fifo18 &
sort -m /tmp/fifo17 /tmp/fifo18 >/tmp/fifo19 &
```

The resulting compiled fragment executes in a data-parallel fashion: data is split by PASH-JIT primitives, then fed to multiple instances of `grep` and `sort` runnning in parallel, and finally merged at the end of the parallel execution.

Dependency untangling (§5): While the JIT engine operates as if invoked on every region, PASH-JIT is engineered to spawn a long-running stateful compilation server just once, feeding it compilation requests until the execution of the script completes. This design has two benefits: (1) it reduces run-time overhead by avoiding reinitializing the compiler for each compilation request; and (2) it allows maintaining and querying past compilation results when compiling a new fragment. The latter allows PASH-JIT to untangle dependencies *across* regions, finding and exploiting opportunities for cross-region parallel execution. For example, the server's first invocation on `region10` (the body of the loop) determines that all prior successfully compiled regions have finished executing. PASH-JIT can thus simply run the loop in the background and continue with the second iteration in a task-parallel fashion, without waiting for the first iteration to complete executing. During the second invocation on `region10`, PASH-JIT will use the dependency state to determine that while the previously compiled fragment is still running, the input and output files of the two regions are completely independent and can thus be executed in parallel: our loop is now pipelined! PASH-JIT goes beyond intra-region data parallelism: the JIT enables inter-region task parallelism by resolving dependencies and confirming they are independent.

Commutativity analysis & compilation (§6): The first goal when compiling fragments such as `region10` is to identify command sequencies that are parallelizable using a divide-and-conquer strategy. Due to the shell's order-aware nature [28], naive divide-and-conquer would need to (1) read the entire input before splitting it, to determine the exact size of each batch, leading to stalled pipeline parallelism; and (2) wait until all of its predecessors have consumed their batch, storing data after split on disk, to ensure that all parallel nodes will not wait for their input.

While these overheads are unavoidable in the general case, and are indeed incurred by prior systems [55, 63], they can fortunately be alleviated for subsets of parallelizable commands. Two such subsets include (1) stateless commands such as `grep -c '^....$'` that operate in a line-oriented fashion, meaning that data-parallel copies of these commands can combine their partial output using a reordering operation, and (2) commutative commands such as `sort -u` that produce equivalent output regardless of the order of the input lines. PASH-JIT leverages this insight to achieve more effective parallelization by splitting into streaming micro-batches (using `c_split`) in a round-robin fashion—avoiding the overheads of reading all the input before splitting and of unnecessary storage to disk. It also wraps stateless commands to strip and re-add the microbatch headers (using `c_wrap`) and removes these headers completely before commutative commands (using `c_strip`).

Zooming back out: Fundamentally, PASH-JIT is neither a shell nor requires modifications to a user's shell. Rather, it is an interposition shim located between a user and their shell, deciding whether to optimize parts of the user script on the fly, using information about the execution state of the shell interpreter. PASH-JIT combines several techniques that allow harnessing speedups not attainable by ahead-of-time parallelization on both dataflow-only scripts and larger scripts with dynamic components and complex control flow; all of this, without modifying the behavior of the original script.

3 Interfacing With the Shell

PASH-JIT works by interposing on the shell, effectively rewriting invocations to external commands. Challenges arise due to the shell's complex semantics and its intricate internal state, both of which complicate side-effect-free interposition. The shell uses a string-based, bi-modal semantics: commands undergo *expansion*, a string rewriting phase where variables, tildes, and globs are processed before the commands undergo *evaluation*. Both modes have complex semantics heavily involved with the shell's state [24]; any rewriting must be careful to leave the shell's state unaltered.

3.1 Dynamic Interposition

To understand PASH-JIT's interposition, we must first understand the simpler structure of ahead-of-time (AOT) parallelization. While preserving a script's original behavior, AOT parallelization rewrites calls to external commands to exploit parallelism. External commands consume substantially more time and resources than shell language features (like expansion or loops) during the execution of typical shell scripts.

AOT parallelization centers around the identification of *parallelizable regions*—script fragments that may be safely parallelized to yield performance gains. Semantically, parallelizable regions only contain a set of command invocations that satisfy the following conditions: (1) they have no file dependencies (*interference-free*), *i.e.*, all commands can execute concurrently without affecting each other, (2) they communicate with each other using explicit UNIX channels (fifos/pipes); (3) they are *pure*, only affecting the environment by reading and writing to files, *i.e.*, they do not modify environment variables; and, (4) they are fully expanded. An AOT compiler parses and transforms these regions to an intermediate representation such as directed-acyclic [52] or dataflow [63] graphs, abstracted as functions that take a set of input files and produce a set of output files [28]. It then applies transformations on these graphs to perform the original computation in parallel.

PASH-JIT works similarly, but applies these steps at a much finer granularity and in a dynamic, online fashion. PASH-JIT's dynamic interposition mechanism pauses execution right before each parallelizable region, compiling it to an efficient and equivalent parallel script fragment, and executing that instead. Working dynamically means PASH-JIT has up-to-date information and can achieve increased parallelism.

3.2 Preprocessor

Dynamic script interposition without any shell-interpreter modifications is hard. To achieve this, PASH-JIT opts for a light-weight script instrumentation pre-processing step: it marks *possible* parallelizable regions with code that dynamically determines whether or not to invoke the compiler.

The intuition behind PASH-JIT's preprocessor is that a syntactic analysis of a shell script is enough to suggest potential parallelizable regions. This analysis is imprecise: there is no way to determine whether a command invocation will be pure ahead of time. Its goal however, is not to find parallelizable regions exactly, but rather to find potential compilation sites—PASH-JIT sorts out the details at run-time, using up-to-date information about the system's state.

There is a trade-off when choosing the right size for these regions: the larger the region, the more opportunities exist for analysis and optimization but the less likely it is for the entire region to be parallelizable. PASH-JIT targets a middle-ground: maximal syntactic schedule-free regions—*i.e.*, command sequences composed using shell primitives that do not impose scheduling restrictions. By focusing on maximal schedule-free regions, PASH-JIT minimizes the number of compiler invocations and maximizes the cross-command parallelization opportunities for the compiler. Note that schedule-free regions underapproximate interference-free regions (§3.1), *e.g.*, two commands composed in sequence `;` that write to different files do not interfere but are not syntactically schedule-free.

The preprocessor finds these maximal regions by searching the AST bottom-up, combining schedule-free subtrees when they are composed using constructs that do not introduce scheduling constraints (*e.g.*, `&`, `|`). When a region cannot outgrow a certain subtree, it is replaced with a call to the JIT engine. If successfully compiled, a region is transformed to a dataflow graph—a convenient and well-studied computation model amenable to transformation-based optimizations [28]. The instrumented AST resulting from the compilation is finally translated (unparsed) back to shell code and sent over to the underlying shell for execution.

3.3 Parsing Library

Parsing and unparsing are key operations in PASH-JIT and must address several challenges.

PASH-JIT parses lines of shell script as they come in, and unparses lines in order to execute them in the user's shell; it also uses parsing and unparsing during compilation, when the compilation server emits an optimized string or passes

strings to the shell for expansion. PASH-JIT initially used `libdash`—an OCaml library built using the dash parser and part of Smoosh [23, 24]—that caused two main issues. First, `libdash`'s unparsing introduced several bugs, as at the time it was used by the libdash project primiarly for testing and diagnostics—had much of its was functionality untested. Second, `libdash` parsing introduced significant run-time overhead due to (1) the cost of forking and executing the OCaml binary, (2) overheads due to serialization and deserialization during communication, and (3) suboptimal implementation. Run-time overheads were a significant concern due to PASH-JIT's online JIT parallelization, which intermixes calls to the compiler during the program's execution—bringing parsing and unparsing into the critical path of program execution.

To address these issues, PASH-JIT reimplements its own version of `libdash` in Python called Pylibdash. The Pylibdash implementation develops Python bindings for the dash parser and completely reimplements unparsing—adding 0.9k LOC of Python over libdash, structured as a separate library usable by other projects. The Pylibdash implementation contains several optimizations such as caching, inlining, and careful array appending to avoid some accidentally quadratic costs in the original implementation. As a side benefit, using a custom implementation reduces the number of dependencies required by PASH-JIT's installation.

4 The JIT Engine

The PASH-JIT preprocessor identifies possible parallelizable regions and instruments the shell script to dynamically determine whether they can be optimized by invoking the JIT engine. The JIT engine faces two key challenges: it must not change the original script behavior, and it must run with low overhead as it is invoked multiple times per script.

The JIT engine is a reflective shell script: by inspecting the state of the shell and that of the broader system, it can transparently work with the compiler to determine whether or not to parallelize a script (Fig. 2). When running scripts with PASH-JIT, it is helpful to think of the shell as having two modes: (1) conventional shell mode, where scripts execute in the original shell context, and (2) PASH-JIT mode, where the runtime reflects on shell state and invokes a compiler to determine whether to execute the original or an optimized version of the target region. To switch from shell mode to PASH-JIT mode, the JIT engine must carefully save the state of the user's shell; to switch back, it must carefully put things back just the way they were. A shell's state is quite complex: beyond saving and restoring variables, the runtime must account for various shell flags along with other internal shell state (*e.g.*, the previous exit status, working directory).

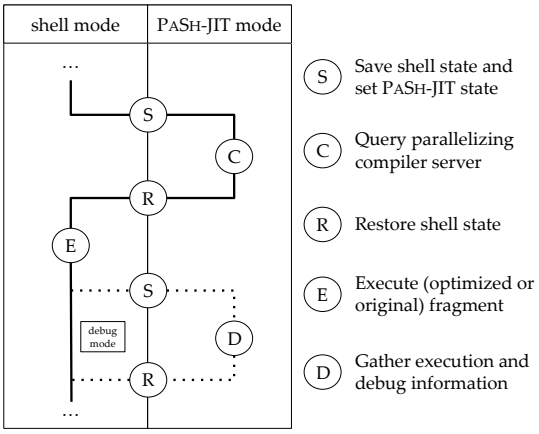

Fig. 2: Overview of JIT engine stages.

4.1 JIT Stages

When running normally, the JIT engine transitions into and out of PASH-JIT mode once per possible parallelizable region (Fig. 2): the JIT engine saves the shell state and switches into PASH-JIT mode (S); then it tries to compile the current fragment (C); whether successful or not, the JIT engine restores the state and switches back to shell mode (R); and, finally, either the original fragment or the optimized parallel version is executed (E). With debugging enabled, the JIT engine switches back into PASH-JIT mode (S) to collect debugging information (D), restoring again afterwards (R).

Saving (S): When entering a possible parallelizable region, the first step is to save the shell state—recording the previous command's exit status, the values of environment variables, and the configuration of the shell—essentially, a continuation that can later be restored to execute the target fragment. Once the state is saved, PASH-JIT mode reconfigures the user's shell to avoid changing script behavior. For example, if the user's shell has the `-e` "exit on error" flag set, the shell should exit immediately when a command (or a pipeline) returns a non-zero exit status, unless that command is in a checked position (*e.g.*, after `!`, or in the condition of an **`if`** or **`while`**) [2]. However, failing commands should not stop the JIT itself, so `-e` is unset (and will be restored later in (R)).

Compilation (C): With the state saved and shell reconfigured, PASH-JIT tries to compile the script fragment: the JIT engine queries the compilation server (§5) with the script fragment (already parsed during preprocessing) along with the saved shell state, so that the compilation server can try to expand all of the words in the fragment. The server responds to indicate whether it managed to optimize the fragment.

Restoring (R): Whether or not compilation was successful, the JIT engine exits PASH-JIT mode, restoring the continuation saved earlier (S) to prepare to execute the fragment. One particular challenge in this mode is to restore state while

accommodating different shell modes. Suppose PASH-JIT is in `-e` mode, trying to run some possible parallelizable region, and the command *before* this region exited with status 47 in a checked position, *i.e.*, without forcing the shell to exit. The JIT engine saves the exit status so as to not overwrite it. The fragment may depend on the exit status, so PASH-JIT needs to restore it before running the fragment. But it must be careful—simply running `(exit 47)` would force the shell to exit. Thus PASH-JIT runs the subshell in a checked position:

```
if (exit "$pash_previous_exit_code"); then
    source "$fragment"; ...
else
    source "$fragment"; ...
fi
```

This odd code ensures that the fragment (in identical branches) has access to the previous exit status (in the checked, conditional position of the **`if`**) without exiting when `-e` is set.

Execution (E): Back in shell mode, the JIT engine executes the fragment. If the compiler was successful, then the JIT engine selects the optimized script fragment. If the compiler failed, the JIT engine falls back to the original fragment. Either way, control flows back to the original shell.

Debug mode (S) (D) (R): When PASH-JIT is in debugging mode, the JIT engine will re-enter PASH-JIT mode after execution (E) in order to log information about the script, such as execution time and exit status. Standard execution skips this extra save/restore cycle.

5 Parallelizing Compilation Server

For each possible parallelizable region, the JIT engine queries the compiler: can this region actually be optimized? To answer this question, PASH-JIT builds on ideas from the PASH-AOT [63] dataflow compiler (§5.1). As ever, it focuses on preserving behavior and minimizing overhead.

To preserve correct behavior in the face of the shell's dynamism, PASH-JIT expands each script region prior to compilation (§5.2). To minimize overhead due to fixed startup costs—*e.g.*, initialization, dependency loading, logging setup, and output file arrangement—PASH-JIT packages the new compiler as a stateful compilation server communicating via UNIX domain sockets.[1]

The compilation server is also augmented to support a larger set of optimization opportunities, by storing and using information from one compilation to help another. PASH-JIT's long-lived compilation server achieves these additional optimizations by allowing parallelizable regions that work on independent inputs and outputs to be run in parallel (§5.3) and by learning to improve its parallelism configuration from past compilations (§5.4).

[1] We experimented with both socket and FIFO-based communication, but we saw no significant performance differences.

5.1 Command Annotations

PASH-JIT uses the command annotation and specification framework introduced by PASH-AOT [28, 63], extended to also indicate whether a command invocation is commutative (§6.1). This framework provides information about a command invocation's parallelizability class, inputs, and outputs. A command annotation can be used to extract high-level information about a specific command invocation, *i.e.*, a precise instantiation of its flags, options, and arguments. For example, annotations determine whether a given command invocation is pure and what its inputs and outputs are.

PASH-JIT uses this annotation framework to extract information for commands that are not shell builtins—that is, commands like `sort` and `grep`. Annotations enable analyses and transformations over command invocations by lifting them to pure dataflow nodes in a dataflow intermediate representation (IR) [28]. For example, `grep -f dict.txt src.txt > out.txt` is a dataflow node with two input files (`dict.txt` and `src.txt`) and one output file (`out.txt`), which are all extracted from the annotation of the `grep` command. Annotations also describe parallelization opportunities, *e.g.*, `grep "pattern" src.txt` processes each line of `src.txt` independently, and so it can be parallelized.

5.2 Early, Pure Expansion

PASH-AOT can only attempt to compile script fragments where all words are completely expanded. Running dynamically, PASH-JIT goes beyond PASH-AOT by expanding words according to the current state of the system (shell, file system, *etc.*).

One way to achieve expansion would be for PASH-JIT to maintain a "mirror" Bash process when initializing, which it could then query with any word to expand using `echo`. Every time PASH-JIT would query the compilation server with a fragment, it would also provide the latest state of the shell, which would in turn be passed to the mirror process to ensure it reflects the latest state. This expansion method would be correct, as it would leverage the underlying shell. It would, however, be expensive, since each fragment contains many unexpanded words and each unexpanded word would have to be expanded using its own `echo` command—leading to unnecessary run-time costs.

PASH-JIT avoids the overhead of a mirror shell by performing its own expansion, relying on the optimistic nature of the JIT engine (§4): if most common forms can be expanded in the compiler itself, the compiler will succeed often without incurring interprocess communication overheads; if expansion fails, PASH-JIT will just run the original fragment. Armed with this insight, PASH-JIT implements a subset of expansion in the compilation server itself. PASH-JIT's custom expansion is *purely* functional, in that it does not affect shell state by setting variables or running command substi-

tutions. The expansion routine is implemented in less than 300 LOC of Python, and reduces the compilation overhead significantly (§7). Expansion takes the host shell's configuration and expands common, safe expansions in as many positions as possible—in simple commands, pipelines, and other parallelizable regions.

PASH-JIT's expansion routine implements most parameter formats, plain tildes, and appropriate quoting. Currently, it does not cover impure expansion (*e.g.*, parameter formats that have side-effects like `${x=foo}`, which will set `x` to `foo` if `x` is unset), since impurity violates the parallelizable region requirements. It also does not implement a few expansion cases—*e.g.*, arithmetic expansions of the form `$((x + 1))`—that were not seen in the corpus of parallelizable scripts used to evaluate PASH-JIT (§7). Adding support for unimplemented forms would require engineering effort, but not a fundamental change to PASH-JIT's expansion. If the expansion encounters a term it cannot expand—because it is unimplemented or because it would be impure—the compilation process aborts and PASH-JIT runs the original fragment.

5.3 Dependency Untangling

PASH-JIT's compilation server makes it easy to detect when parallelizable regions are independent—including, for example, independent program fragments that are sequentially composed with `;` or different iterations of a `for` loop. A key insight here is the semantics of PASH-JIT's successful compilation: if the PASH-JIT compiler succeeds on a given region, that region's original script fragment must only affect its input and output streams (files). That is, successful fragment compilation means that the fragment is *pure*, reading from and writing to a well-defined set of streams without modifying any other global system state such as non-temporary streams or environment variables.

The PASH-JIT compiler thus tracks each parallelizable region in terms of its read and write sets, which suffice to detect read-write and write-write dependencies between fragments. If two fragments (a) compile successfully and (b) have no dependencies, they can be executed in parallel. This optimization improves performance not only because of the parallel speedup, but also because it overlaps (*i.e.*, pipelines) compilation and execution, reducing net run-time overhead.

To discover independent fragments, the compilation server (Fig. 3) and JIT engine (Fig. 4) are extended to communicate about successfully compiled fragments. Coordinating using `exit` requests, the compilation server maintains a map of running fragments. When it receives a compilation request that succeeds, the server waits for all prior fragments with dependencies to finish executing; only then does it send the compiled fragment to the JIT engine for execution in the background. While the compiled fragment executes in the background, the JIT engine can exit PASH-JIT mode, and execution proceeds with the rest of the input script. When

```
# State contains a map from ids to
#   inputs and outputs.
while True:
  req = receive_request()
  if reached_script_end(req):
    wait_all()
    exit()
  else if is_exit_request(req):
    state.remove_id(req.id)
  else if is_compile_request(req):
    compile_res = compile(region)
    if not compile_res.success:
      wait_all()
      respond(compile_res)
    else if compile_res.success:
      # Wait until all ids with dependencies
      #   finish executing.
      wait_for_dependencies(compile_res.inputs,
                            compile_res.outputs)
      request_id = fresh_id()
      state.add_request(request_id, compile_res)
      respond(compile_res, request_id)
```

Fig. 3: Compilation server algorithm (pseudocode) extended for dependency untangling (*Cf.*§5.3).

```
# Blocking query
res = query_server(compile_request(region))

if res.success:
  # Run the compiled code in parallel
  fork({
    run(compiled)
    send_exit(res.id)
  })
else:
  run(original)
...
```

Fig. 4: JIT engine algorithm (pseudocode) extended for dependency untangling (*Cf.*§5.3).

execution reaches another fragment and the JIT engine returns to PASH-JIT mode, the JIT engine will block again until the compilation server responds. Even if the compilation server encounters a fragment that fails to compile, the server blocks on dependencies: the uncompilable fragment might have arbitrary side-effects.

To ensure that our algorithm is correct, we modeled it using the SPIN Model Checker [29] and we verified (i) that it does not lead to deadlocks, (ii) that no failed compiled region is running simultaneously with any other region, and (iii) that two regions with dependencies never run at the same time.

5.4 Profile-driven Compiler Configuration

The long-lived PASH-JIT compilation server can additionally use dynamic information to improve compilation. One particularly effective optimization is to dynamically determine maximum parallelism degree. As scripts might already fea-

ture task-based parallelism, spawning too many data-parallel processes can overload the system—leading to higher overheads that cut into the speedup or even result in a slowdown. These slowdowns tend to occur when there are many computationally light commands with small inputs, *i.e.*, when the overhead of managing parallelism is higher relative to the actual work to be done. The PASH-JIT compiler can reflect on prior fragments to determine an appropriate parallelism degree.

The compilation server is often queried to compile the *same* fragment many times—*e.g.*, in each iteration of a loop. At run-time, the compiler collects and maintains execution-time information. As program fragments are recompiled, PASH-JIT tries progressively narrower parallelization degrees in an attempt to minimize overall execution time.

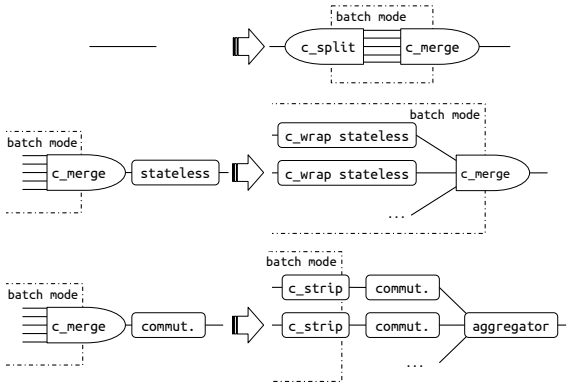

Fig. 5: Overview of commutativity-aware transformations.

6 Commutativity Awareness

Commutative commands can improve parallelization gains by allowing PASH-JIT to split and process data-parallel partial inputs in small and order-independent batches. Splitting input into many small batches improves expected CPU utilization and allows for additional pipeline parallelism. CPU utilization is improved due to an increase in partial input batches: the more work items, the more uniform the work each parallel copy does. Additional pipeline parallelism is achieved by overlapping input splitting and processing: rather than reading the entire input before deciding how to split it into batches, input can be split via small incremental steps that are immediately handed off to data-parallel commands for processing.

The PASH-JIT compiler uses these insights to produce more efficient parallel implementations of scripts that contain commutative commands. It introduces a few auxiliary nodes in its intermediate representation (IR) that orchestrate parallel execution for stateless and commutative commands, and compiler transformations that insert these nodes in a dataflow graph. It also provides efficient primitives implementing these nodes when instantiating in the parallel target script.

6.1 Compilation: Dataflow Model

The PASH-JIT compiler operates on a dataflow IR that builds on PASH-AOT, where commands correspond to nodes and communication channels correspond to edges between nodes. To enable commutativity-aware transformations, PASH-JIT extends PASH-AOT's annotation framework (§5.1) to indicate whether a command invocation is commutative (in addition to its parallelizability characteristics).

Command nodes: PASH-JIT introduces the following four dataflow nodes, which correspond to PASH-JIT-provided binary commands available in the `PATH`: `c_split`, `c_wrap`, `c_strip`, and `c_merge`. The `c_split` node takes a single input stream and N output streams. It splits its input into small batches, prepends a header on each batch identifying its sequence number, and then forwards it to one of the N outputs depending on a load-balancing strategy. Currently, PASH-JIT implements a round-robin strategy. The `c_merge` node performs the inverse operation: it merges N input streams into one and removes any headers. The `c_wrap` command is used to wrap stateless commands. It removes the header, forwards the input to the command, and then adds the header back to the command output. Finally, `c_strip` is a single-input-single-output header-removal node that often precedes commutative commands.

Transformations: To expose commutativity-aware parallelism, PASH-JIT transforms the dataflow graph; see §2 for an example. The transformations are visualized in Figure 5. The first transformation introduces a pair of `c_split` and `c_merge` before any commutative (*e.g.*, `sort`) or stateless (*e.g.*, `grep`) command. Another transformation then tries to eliminate unnecessary splits and merges, delaying `c_merge` as late as possible (*i.e.*, enclosing the biggest possible part of the graph). If a stateless command follows a `c_merge`, the command is wrapped with `c_wrap` and the `c_merge` is commuted after it. If a commutative command follows a `c_merge`, the command is parallelized and `c_merge` is transformed to a set of `c_strip` commands. Finally, if a `c_split` follows a `c_merge`, then the two are fused together to the identity function, connecting the inputs of `c_merge` with the outputs of `c_split`.

An important execution invariant is that `c_split` and `c_merge` (or `c_strip`) satisfy the requirements of well-formed parentheses, *i.e.*, a `c_split` must always be followed by a `c_merge` or a set of `c_strip` commands. PASH-JIT's dataflow graphs are essentially bimodal, since subgraphs that are between a `c_split` and a `c_merge` will execute with batches, requiring all commands in them to be wrapped with `c_wrap`, while the rest of the dataflow graph executes like the original.

Tab. 1: Benchmark summary. Summary of all the benchmarks used to evaluate PASH-JIT and their characteristics.

	Benchmark Set	Short Label	Sections	Scripts	LOC	Input	Source

6.2 Runtime: Commutativity Implementation

The runtime splits the source in small batches (that contain complete lines) in a round-robin fashion.

Protocol: To reconstruct the order of different outputs while merging, PASH-JIT needs to keep track of ordering as input batches are sent to different command copies for processing and, more generally, as input-output batches flow throughout the parallelized script. To achieve this, PASH-JIT wraps all input batches with a header that contains the three following fields: `block_id`, for ordering blocks; `block_size`, the size of the block in bytes; and `is_last`, a boolean value true only for the last block with a given `block_id`.

Utilization and deadlocks: PASH-JIT must avoid deadlocks during write operations between the wrapper commands and the commands they wrap—*i.e.*, the two should never be blocked trying to write at the same time. Additionally, the wrappers must maximize utilization of the command they wrap, *i.e.*, they should never wait on input unnecessarily. To avoid deadlocks, PASH-JIT wrappers use non-blocking read and write; and to increase utilization and reduce waiting time, they write in small chunks of 32KB.

Handling inputs with long lines: An input may contain lines that are longer than the `c_split` block size. Such an event leads to non-uniform block sizes and high memory consumption, because each block must be read and sized completely before splitting and adding to the header. PASH-JIT addresses this issue by introducing the `is_last` header field in `c_split`: if a block exceeds the specified size (due to containing large lines) the block is split into multiple blocks; all blocks share the same `block_id` but only the last sets `is_last` to true. Sub-blocks with the same `block_id` are sent downstream in-order, and therefore downstream commands can use the `is_last` information to correctly reconstruct the output and know when a block ends. Block splitting reduces memory requirements and improves performance, as it allows for higher utilization regardless of the frequency of newlines. And blocks maintain a constant size throughout the flow, despite the presence of commands with high output-to-input ratio such as `curl`.

Handling small inputs: Inputs that are smaller than `c_split`'s block size lead to a single block and thus sequential execution. PASH-JIT's `c_split` addresses this issue by first attempting to read an input size s equal to `downstream_count * block_size` bytes before forwarding any blocks. If the total input is larger than s, this buffering ensures that all parallel instances will get at least one block; if the total input is smaller than s, then the input read is re-split into blocks fairly and forwarded downstream. The size s is configurable and defaults to 1MB, which we empirically determined avoids both high overhead and low utilization.

7 Evaluation

The PASH-JIT implementation comprises 6784 lines of Python (preprocessor, compilation server, expansion, compiler, and parser), 1011 lines of shell code (JIT engine and various utilities), and 1174 lines of C (commutativity primitives, and other runtime components). All line counts are of semantically meaningful lines only.

To evaluate PASH-JIT, we use three experiments on benchmarks (Tab. 1). The first experiment focuses on PASH-JIT's compatibility and uses the entire POSIX test suite as well as additional scripts (§7.1). The second experiment focuses on the performance gains achieved by PASH-JIT's parallelization, evaluated using a variety of benchmarks and workloads (§7.2). The last experiment zooms into PASH-JIT-internal overheads and associated optimizations (§7.3).

Hardware & software setup: PASH-JIT was run on 64 physical × 2.1GHz Intel Xeon E5-2683 cores with 512GB of RAM, Debian 4.9.144-3.1, GNU Coreutils 8.30-3, GNU Bash 4.4.20(1), and Python 3.7.3. There is no special configuration in hardware or software. We use Dash v.0.5.8-2.10 and Ksh v.93u+ 2012-08-01. All scripts were executed completely unmodified, using environment variables, loops, and other shell

Tab. 2: Correctness results. Running the POSIX test suite on Bash and PASH-JIT. Tests are grouped in rows by theme. Columns contain the group name, total tests, non-applicable tests, and passing tests for PASH-JIT and Bash.

	Test Suite	Tests	Untested	PASH-JIT	Bash
1	Parsing	38	5	33/33	33/33
2	Expansion	83	8	71/75	71/75
3	Errors	38	3	26/35	27/35
4	Commands and redirects	99	2	96/97	96/97
5	Subshells and pipelines	56	7	46/49	46/49
6	Builtins	113	40	60/73	61/73
7	Special cases	67	21	42/46	42/46

constructs. To minimize statistical non-determinism, we host our experimental infrastructure on our own premises, avoid sharing with other research groups, and repeat the experiments several times noting imperceptible variance.

7.1 Correctness

We evaluate the correctness of PASH-JIT across all benchmarks from Tab. 1 by checking that PASH-JIT's stdout and exit status are equivalent to the ones produced from Bash. The output is over 650 million lines (18GB), taken from 82 scripts, in all of which PASH-JIT's output and exit status are correct. To increase our confidence on correctness, we use the POSIX shell test suite with both Bash and PASH-JIT.

Benchmarks: The POSIX test suite is a thorough evaluation of shell behavior, comprising 1007 'assertions' evaluated using 494 distinct, assertion-numbered test cases over 29k LOC of shell scripts (plus library support). We exclude (a) 78 test cases because they test the platform (*e.g.*, locales) rather than the shell, and (b) 8 cases because they test interactivity, which is out of scope for PASH-JIT (§1). These leave a total of 408 runnable test cases. The test cases use a mix of shell language features (*e.g.*, redirection, pipes), builtin commands (*e.g.*, `set`, `echo`), and standard UNIX utilities (*e.g.*, `printf`, `grep`). The POSIX suite tests many corner cases of shell behavior—*e.g.*, that aliases ending in space continue alias expansion (Assertion no. 284), that pipelines take precedence over redirections in their constituent commands (no. 454), or that **`return`** in a `trap` action restores the previous command's exit status (no. 651)—totaling several thousand behaviors. The exact number of 'tests' is hard to quantify: some test cases check a single behavior (*e.g.*, expanding an unset variable under `set -u`); others check hundreds (*e.g.*, many different characters escape properly; many different arithmetic expressions evaluate correctly).

Results: PASH-JIT overwhelmingly agrees with Bash (Tab. 2). PASH-JIT passes 374 and fails 34 POSIX tests, while Bash passes 376 and fails 32 POSIX tests. PASH-JIT diverges from Bash on the test cases for a mere 2 tests (no. 430 and 691) where Bash passes but PASH-JIT fails. These two failures concern the ranges of non-zero exit status and are in fact due to an unusual inconsistency in Bash itself (see "Discussion", below).

When running the test suite, PASH-JIT invokes the compiler a total of 3304 times, each for a different potentially optimizable fragment; 713 (20%) of those invocations successfully compile, *i.e.*, PASH-JIT generates and runs parallel code. Successful compilation does not necessarily translate to a speedup on individual tests, though: the POSIX suite tends to test with small scripts, so the compiled fragments contain very little computation—not much for PASH-JIT to optimize.

Discussion: PASH-JIT diverges from Bash in two cases only in the exit status returned. Both PASH-JIT and Bash exit with an error: Bash returns 1, and PASH-JIT returns 127. For the two failing cases, POSIX mandates (since 2008) that the exit status be between 1–125, making PASH-JIT's behavior incorrect. Why does PASH-JIT produce a different status?

Bash is inconsistent when called with the `-c` flag. Contrary to most other shells (*i.e.*, dash, ksh, mksh, posh, sash, Smoosh, yash, zsh), Bash is the only shell that, when failing during `-c` invocations, exits with 127—*i.e.*, outside the POSIX-mandated range. When PASH-JIT invokes the underlying Bash interpreter using `-c` in order to set `$0`, it receives and propagates an exit status that does not comply with POSIX. The rest of the Bash failing tests are caused by various subtleties; it is not clear which failures are 'true bugs' and which are considered desirable divergences from the spec. Greenberg and Blatt [24] discuss how implementations diverge from the POSIX spec. PASH-JIT mirrors the behavior of Bash in all those cases.

To put the number of diverging tests of PASH-JIT and Bash into perspective, we note that other production shells fail in significantly greater numbers: dash passes 3 tests that Bash fails and fails 20 that Bash passes; ksh passes 2 tests that Bash fails and fails 20 that Bash passes; and zsh cannot run the test suite at all. These results combined show that, in practice, PASH-JIT is virtually indistinguishable from its underlying shell interpreter on POSIX features.

7.2 Performance

We evaluate PASH-JIT's performance on 12 sets of real-world shell scripts taken from a variety of sources (Tab. 1, rows 2–13), totalling 82 shell scripts and 1015 LOC.

Benchmarks: Classics and Unix50 contain classic and recent (c. 2019) scripts making heavy use of UNIX and Linux built-in commands. COVID-mts contains four scripts used to analyze real telemetry data from mass-transit schedules during a large metropolitan area's COVID-19 response. NLP contains several scripts from UNIX-for-poets, a tutorial for developing programs for natural-language processing out of UNIX and Linux utilities. AvgTemp contains a large script downloading and processing multi-year temperature data across the US. WebIndex is a large multi-stage script for web crawling and

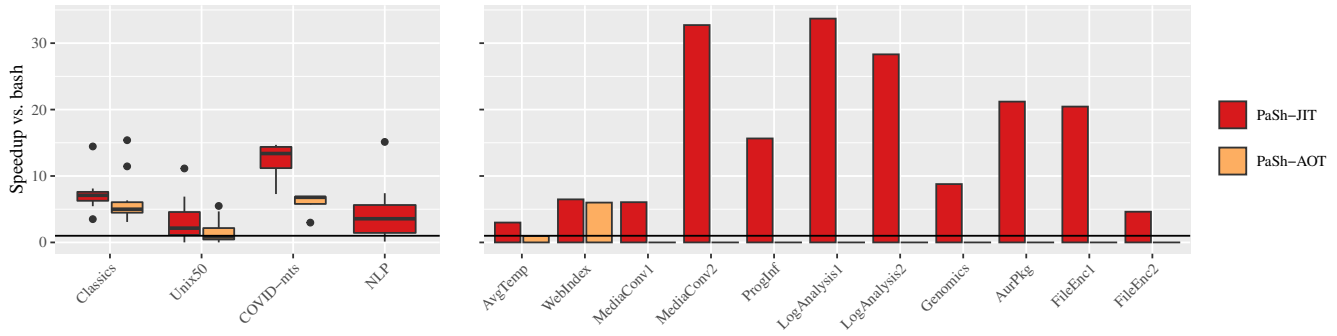

Fig. 6: PASH-JIT Performance. PASH-JIT speedup (*vs.* PASH-AOT whenever possible) over Bash for Tab. 1 rows 2–5 (left, box) and 6–13 (right, bar) (*Cf.*§7.2).

indexing, using a variety of third-party and built-in utilities. MediaConv contains two scripts that process, transform, and compress video and audio files. ProgInf contains a script that downloads JavaScript packages from the npm registry and applies a security-oriented static program analysis. LogAnalysis contains two scripts that apply typical system-administration and network-traffic analyses over log files. Genomics contains a script that processes next-generation sequencing data for the purposes of diagnostic virology. AurPkg contains the main script that compiles, builds, and packages software for the AUR Linux distribution. Finally, FileEnc contains long aliases that encrypt and compress files.

Results: PASH-JIT surpasses PASH-AOT's speedups (*vs.* Bash) on existing benchmarks and extends speedups to new ones (Fig. 6). Box-plots show results for multi-benchmark suites (Tab. 1, rows 2–5) and bars for individual scripts (Tab. 1, rows 5–13). PASH-JIT can run several more scripts than PASH-AOT (for which performance bars are set to 0). Across all benchmarks, PASH-JIT achieves an average speedup of 5.86× (*vs.* 2.9× for PASH-AOT) and a maximum speedup of 33.7× (*vs.* 15.38× for PASH-AOT).

A few scripts exhibit slowdowns when compiler startup, runtime, and parallelization overheads (splitting, merging) start dominating. PASH-JIT decelerates 14 scripts; PASH-AOT decelerates 20 scripts—and cannot run 30 additional scripts that PASH-JIT parallelizes. The scripts that PASH-JIT decelerates either have short sequential running times (8ms–10s) or have very short-running fragments in tight loops (*e.g.*, 1K iterations, 14ms per iteration). For example, PASH-JIT decelerates Unix50's `20.sh` (Bash: 8ms; PASH-JIT: 1.3s) and NLP's `no-vowel.sh` (Bash: 14s; PASH-JIT: 0.24×), on which PASH-AOT cannot operate.

Discussion: PASH-JIT is faster than PASH-AOT on all suites 2–5 (w.r.t. average) and on all individual benchmarks 5–13, often by a significant margin (3.1×).

PASH-JIT speeds up many scripts PASH-AOT cannot, as PASH-AOT's ahead-of-time parallelization cannot reason about the shell's dynamic features. PASH-AOT offers no speedup on the NLP suite, nor on any individual scripts except for AvgTemp and WebIndex.

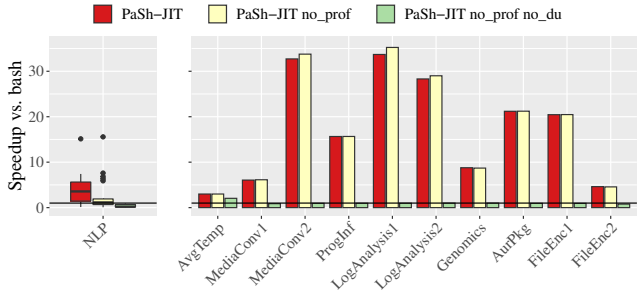

Fig. 7: PASH-JIT Dynamic Optimizations. PASH-JIT speedup over Bash when toggling profile-driven compiler configuration and dependency untangling for Tab. 1 row 5 (left, box) and 6, 8–13 (right, bar) (*Cf.*§7.3).

Compared to Bash, PASH-JIT is faster (or at least as good) in all cases, except when the given script is very short-running (*e.g.*, `unix50-20.sh`), or with a tight loop with a very short-running body (*e.g.*, `nlp-no-vowel.sh`).

7.3 Further Microbenchmarks

This section zooms into the benefits of PASH-JIT's optimizations targeting dependency untangling, profile-driven compiler configuration, commutativity analysis, and JIT engine overheads.

Dynamic optimizations: To better understand the benefits of dependency untangling and profile-driven compiler configuration (CC), we use benchmarks that have sequences of statements—*e.g.*, some form of sequential composition or `for`-loops: rows 5, 6, 8–13 from Tab. 1. One-line scripts such as Unix50 and WebIndex feature single pipelines and thus cannot benefit from any inter-region optimizations.

Across all scripts and compared to Bash, PASH-JIT achieves a speedup of 8.17×. PASH-JIT without profile-driven CC achieves 7.58×, and additionally without dependency untangling 0.55× (Fig. 7). The 0.55× slowdown is due to limited intra-region parallelization in these benchmarks.

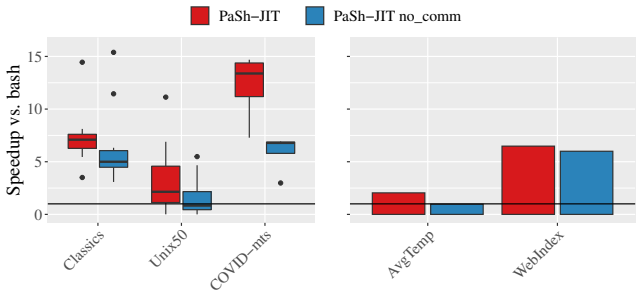

Fig. 8: PASH-JIT Commutativity Awareness. PASH-JIT speedup over Bash when toggling commutativity awareness for Tab. 1 rows 2–4 (left, box) and 6, 7 (right, bar) (*Cf.*§7.3).

Profile-driven CC may slightly reduce speedup in highly parallelizable scripts, because it explores lower parallelization degrees.

Commutativity awareness: To evaluate the benefits of commutativity-related optimizations, we focus on all scripts with intra-region parallelization potential: Classics, Unix50, COVID-mts, AvgTemp, and WebIndex; the performance of the rest is affected negligibly by changes to single-region transformations. We disable all dynamic optimizations to isolate the benefits of commutativity, and compare with the sequential Bash baseline.

Commutativity-aware PASH-JIT achieves an average speedup of 4.52× and a maximum of 14.68× (Fig. 8). Without commutativity-related optimizations, PASH-JIT achieves an average speedup of 3.72× and a maximum of 15.38×. Commutativity improves the average case but not cases that already see high speedups, as these (1) have negligible overheads coming from input reading—most overheads come due to line processing—and (2) commutativity extensions add some overhead due to the `c_wrap` primitive.

JIT engine overhead: To evaluate the benefits of PASH-JIT's runtime optimizations, we design a worst-case parallelization benchmark: a script that contains a **`for`** loop that performs 100 iterations of `echo hi`. A tight loop with a minimal-overhead body emphasizes the JIT engine overheads by allowing no parallelization gains. The table on the right shows the run-time performance of four PASH-JIT configurations compared to Bash: (1) PASH-JIT without custom expansion, compilation server, and dynamic optimizations, (2) PASH-JIT without compilation server, and dynamic optimizations, (3) PASH-JIT without the dynamic optimizations, and (4) the complete PASH-JIT. PASH-JIT's runtime optimizations (custom expansion, compilation server, and dependence untangling) improve performance by 12× (over the `-esd` configuration without them). As `echo hi` writes to stdout, dependence untangling does not manage to run it in parallel, and thus its benefit is only due to pipelining. Even then, PASH-JIT's JIT engine overhead is not negligible (about 47ms per JIT invocation), as it needs to save the state and invoke the compiler for every iteration of the loop body.

Config.	Time (s)
Bash	0.008
PASH-JIT -esd	59.334
PASH-JIT -sd	15.376
PASH-JIT -d	6.124
PASH-JIT	4.708

8 Related Work

Parallel shell scripting: Recent work addresses significant challenges related to automatic shell script parallelization. POSH [52] and PASH-AOT [63] are mostly-automated ahead-of-time shell-script parallelization systems; as described earlier, these systems focus on fully expanded shell pipelines that do not make use of dynamic features. Recent work explored an order-aware dataflow model as a foundation for modeling the transformations these systems perform and proving them correct [28]. To enable divide-and-conquer parallelism, KumQuat [55] proposes a program-synthesis technique for generating aggregators for black-box commands.

PASH-JIT builds on all this prior work, addressing fundamental limitations in static, ahead-of-time parallelization: AOT approaches apply to a very small subset of real shell scripts. By opting for just-in-time parallelization, PASH-JIT achieves parallel script behavior that is practically indistinguishable from the sequential execution—and ample opportunities for additional acceleration.

Other work on shell script parallelization either requires manual effort or is applicable to a smaller subset of scripts than our work. Such work includes: utilities like `qsub` [19], SLURM [66], and `parallel` [58]; shells with non-linear pipe topologies [17, 40, 56]; and using the shell itself as a DSL for concurrency [22].

Unix-related parallelization: There has been a significant body of work on parallel (and distributed) UNIX and UNIX-like environments [4, 44, 47], including shell-oriented efforts such as Plan9's `rc` [49]. Contrary to PASH-JIT, these systems did not (aim to) offer full compatibility with the sequential UNIX shell. They also focused on systems-level and program-runtime support, rather than automated program analyses and transformations.

Just-in-time compilation: Just-in-time compilation has been studied for long time [3], mainly in two contexts: (1) as a compilation technique for interpreted languages such as JavaScript [20], where critical type information is unavailable prior to execution; and (2) as a performance optimization over ahead-of-time compilation, allowing for specialization [30, 60], loop unrolling and function inlining [9, 50], and other profile-guided optimizations [34, 46]. PASH-JIT draws inspiration from work in both contexts—resolving unavailable dynamic information at run-time and performing additional optimizations. It also leverages the optimistic compilation technique employed commonly by just-in-time compilers: when it fails to compile (parallelize), it simply runs the original fragment using the shell interpreter as a fallback option.

PASH-JIT differs from most JITs, dealing with different challenges: it operates at a higher level of abstraction, in a unique programming environment with no single unified runtime.

PASH-JIT also draws inspiration from staged compilation [14] and partial evaluation [32]. These techniques perform some compilation ahead-of-time, waiting for the runtime to specialize and further optimize when there is more information about the environment of the target program and how it is used.

Parallelization in other contexts: More general parallelization support can be grouped into two categories: languages and tools. One approach to parallelization support is to use tools that requires writing in a new higher-level programming language [18, 21, 36] or a dataflow-based model embedded in an existing language [5, 12, 16, 45, 57, 67]. These tools usually offer automation, but require re-expressing existing computations in domain-specific programming models; PASH-JIT operates on completely unmodified POSIX shell scripts that use unusual features and obscure corner cases.

Another approach to parallelization support uses tools that provide automatic parallelization for standard sequential code, requiring no program modifications but often posing limitations with respect to the granularity of the parallelism that they can extract. The general approach started with explicit `DOALL` and `DOACROSS` annotations [10, 38], continuing with analysis-based compilers [27, 48, 54], and more recent work using profiling-guided speculation [1, 31, 35, 42, 61]. PASH-JIT draws inspiration from this line of work: it does not require manual modification to user code, and it leverages run-time information to optimize and parallelize user scripts. Existing tools work on imperative code with memory accesses, but PASH-JIT works at a higher level of abstraction: commands that affect the file system and the broader executing environment.

Shell correctness and POSIX compliance: Smoosh [24] offers a formalized, executable reference semantics for the POSIX shell, aiming to address subtleties in the standard [2]. PASH-JIT leverages Smoosh to identify and resolve issues in its JIT engine (§4) and to guide its early expansion routine (§5.2). It also builds on Smoosh's analysis to leverage the POSIX test suite for characterizing shell behavior.

PASH-JIT reimplements Smoosh's `libdash` [23], which presents dash's parser as a library (§3.3). We chose `libdash` over Morbig [53] because (1) `libdash` reuses dash's production-grade parser, and (2) `libdash` supports line-oriented input, but Morbig is strictly ahead-of-time.

Resurgence of shell research: Recent shell research [24, 25, 39, 43, 52, 55, 56, 63] highlights renewed interest in shell scripting both as a vehicle for impactful research and as a target worthy of scientific attention. We see PASH-JIT as a natural continuation of the insights and research behind recent shell-script parallelization systems [25, 28, 52, 63], allowing other researchers to leverage PASH-JIT's POSIX-compliant high-performance just-in-time compilation in their future work.

9 Discussion & Conclusion

The shell provides a dynamic programming language with complex evaluation-and-expansion semantics and ubiquitous side-effects—effects that interact with the entire UNIX system similar to how a conventional programming language interacts with its runtime environment. The benefits of just-in-time compilation for dynamic languages are clear, and PASH-JIT is the first JIT compiler that targets challenges unique in the UNIX shell ecosystem. PASH-JIT forms a promising drop-in shebang replacement: its POSIX compliance rivals shells in widespread use; and its performance benefits go well beyond the state of the art.

Interactivity: PASH-JIT's design goals (§1) do not include interactivity; an interactive shell switches between consuming its input (shell commands) and redirecting it to its executing commands—challenging for PASH-JIT's loose coupling. Furthermore, avoiding shell modifications leads to additional runtime overhead (since the state of the shell has to be reflected upon and is not accessible with a single dereference). Adding robust support for interactivity and improving runtime overhead would likely require a more intrusive design, *e.g.*, altering Bash's source and interposing directly. However, such a design would make PASH-JIT Bash-specific, requiring users to install a new shell, and would significantly complicate the engineering and maintenance effort involved.

Expansion: Some of PASH-JIT's expansion behaves in a way not exactly as specified by POSIX, although we conjecture (and our evaluation confirms, §7) it is safe. For example, pipelines are supposed to expand each component in its own subshell (though the last component may run in the outer shell, depending on a shell's implementation choices). PASH-JIT's expansion operates on each component of the pipeline early; each component uses its own copy of the shell environment, to simulate the subshells. We haven not proved these early expansions sound, and it would be interesting future work to pursue that, *e.g.*, by using Smoosh's semantics.

Command annotations: PASH-JIT's performance benefits depend on the existence of command parallelizability annotations. The annotations used by PASH-JIT depend on the PASH-AOT annotation library [63], which includes many commands in the POSIX and GNU Coreutils sets. Apart from commands in these sets, a script may contain other commands—for which PASH-JIT will lack annotations and thus will not attempt to parallelize to maintain soundness (§1). To better harness PASH-JIT parallelization in their scripts, users can: (1) opt for more restricted, rather than more general, utilities with more constrained and thus parallelizable behaviors (*e.g.*, use `cut` rather than `awk` when projecting columns, as `awk` programs are not parallelizable in general); or (2) add

their own annotations for custom commands to inform PASH-JIT on how to parallelize them.

Enabling other analyses: Even though PASH-JIT is mainly focused on parallelization, its just-in-time structure is not limited to it. By slightly modifying the preprocessor and by replacing the compilation server logic, PASH-JIT can be made to perform different types of analyses and transformations, while maintaining its benefits—compliance with the underlying shell, loose coupling, and low runtime overheads. This enables exciting avenues of future tooling and support for the shell, like incremental execution, automatic distribution, and safety monitoring.

Conclusion: Fundamentally, PASH-JIT shows that it is possible to build a just-in-time shell-script parallelization infrastructure that is substantially faster and more applicable than prior work, is loosely coupled, and addresses critical challenges associated with the shell ecosystem's polyglot runtime environment. But also, PASH-JIT is not a toy: it enables other researchers to use a production-grade POSIX-compliant shell compiler for impactful future work.

A Artifact Appendix

The structure of this section mirrors the artifact evaluation process. It is a shorter version of the README available in the frozen `osdi22-ae` branch of PaSh's GitHub repository. At a glance:

- Artifact available: Relevant links pointing to online resources.
- Artifact functional: Documentation, completeness with respect to the claims in paper, and exercisability.
- Results reproducible: Instructions for reproducing correctness (§7.1), performance (§7.2), and microbenchmark (§7.3) results.

A.1 Artifact available

The implementation described in this paper has been incorporated into PaSh, an MIT-licensed open-source software available by the Linux Foundation. Below are some relevant links:

- PaSh is permanently hosted on the GitHub binpash organization.
- The PaSh website is available at binpa.sh and https://binpash.github.io/web/.
- PaSh has joined the Linux Foundation and is available via Dockerhub.
- PaSh developers hang out on the pash-discuss mailing list and discord.

PaSh is developed actively, forms the foundation of further research on the shell, and has received open-source contributions from developers outside the core development team.

A.2 Artifact functional

Fig. 1 gives an overview of the interaction between different components and the correspondence of system components to sections. Below we provide links to the source code implementing them. Note that at the time of writing the terminology in the code is somewhat different from the one presented in the paper; we hope to align the code with the paper soon.

- Preprocessor (§3.1 and 3.2): The preprocessor uses the parser (below) to instrument the script AST with calls to the JIT Engine.
- Parsing library (§3.3): The parsing library contains Python bindings for the dash parser and a complete unparser implementation.
- JIT engine (§4): The JIT engine transitions between shell and PaSh mode and interacts with the parallelizing compilation server (below).
- Parallelizing compilation server (§5): The parallelizing compilation server handles compilation requests for parallelizing regions of the script. The server contains the following subcomponents: (i) the early expansion component (§5.2); (ii) the dependency untangling component (§5.3), enabled with `--parallel_pipelines`; and (iii) the profile-driven configuration component (§5.4), enabled with `--profile-driven`.
- Commutativity awareness (§6): It consists of (i) annotations indicating whether a command is commutative (*e.g.*, `sort`) and (ii) dataflow nodes for orchestrating commutativity-aware parallelization—*e.g.*, `c-split`, `c-wrap`, `c-strip`, and `c-merge`.
- The paper also claims that the core of the server has been modeled and verified using SPIN. The modeling of the dependency untangling algorithm in Promela (SPIN's language) can be found in algorithm.pml. The model captures compilation requests of regions with non-deterministic read/write dependencies, and ensures that no two regions with dependencies are running together, while also ensuring that both the server and the engine eventually terminate.

A.3 Results reproducible

The paper contains three classes of experiments, focusing on:

- correctness/compatibility, using the entire POSIX test suite as well as additional scripts (§7.1).
- performance gains achieved by PaSh-JIT's parallelization, evaluated using a variety of benchmarks and workloads (§7.2).
- PaSh-JIT-internal overheads and associated optimizations (§7.3).

Links to these can be found in the relevant section of the artifact README. The POSIX test suite is from the Open Standards Group and thus cannot be shared outside the Docker container on the machine shared with the AEC reviewers. These tests run via CI on every commit on the PaSh project. Instructions to verify the dependency untangling algorithm can be found here.

Hubble: Performance Debugging with In-Production, Just-In-Time Method Tracing on Android

Abstract

Hubble is a method-tracing system shipped on all supported and upcoming Android devices manufactured by Huawei, in order to aid in debugging performance problems. Hubble instruments every non-inlined bytecode method's entry and exit to record the method's name and a timestamp. Instead of persisting all data, trace points are recorded into an in-memory ring buffer where older data is constantly overwritten. This data is only persisted when a performance problem is detected, giving engineers access to invaluable, detailed runtime data Just-In-Time before the detected anomaly. Hubble is highly efficient, with its tracing inducing negligible overhead in real-world usage and each trace point taking less than one nanosecond in our microbenchmark. Hubble significantly eases the debugging of user-experienced performance problems and has enabled engineers to quickly resolve many bug tickets that were open for months before Hubble was available.

1 Introduction

Today, Android devices are pervasive and tightly integrated into people's daily lives, yet users still experience performance problems when using these devices. Unlike Apple's iOS and iPhone, the Android platform is far from a tightly-coupled monolithic ecosystem—the hardware (manufactured by OEMs), infrastructure system software (maintained by Google and customized by OEMs), and applications are provided by different parties, and all layers are released in a rapid yet uncoordinated development cycle. This open platform makes testing enough combinations of hardware, systems software, and applications particularly challenging. Thus, many of the performance bugs that escape current testing practices are intermittent, manifesting across multiple components maintained by different entities.

When end users experience an issue, it is often *systems* vendors that shoulder the blame, before the root cause is exposed [49]. This is particularly true for Android given its huge user base, many of whom are not tech-savvy. When such users experience an intermittent performance problem, they quickly assume that their device is at fault, simply because they could not immediately reproduce the issue on another device. However, the root cause could be in the application itself, only triggered under specific conditions or inputs. To combat these assumptions, device vendors are forced to devote ample engineering and support resources to these issues.

Yet, diagnosing performance problems that occur on a user's device is extremely challenging, owing to a lack of sufficient runtime information. While approaches like Windows Error Reporting (WER) [21] are widely adopted, they can only record runtime information *after* a problem is detected. Oftentimes this is too late, as it misses crucial information just before and during the problem. This is exacerbated for performance problems, especially intermittent ones, because the issue may vanish after being detected, before recording starts. Indeed, the primary use of WER is not to record enough information to debug an issue, but to collect error statistics that are then used to prioritize debugging effort.

Recording debugging information *before* the problem occurs is challenging. We cannot accurately predict when a problem will occur, so the only option is to continuously trace the system during *normal* execution. However, overhead is a concern. Unlike servers, mobile devices are heavily resource-constrained and their workloads are overwhelmingly interactive. Sampling-based profiling tools are available, but their trade-off between informativeness and performance is poor. Non-sampling-based profiling tools, on the other hand, are too heavyweight for continuous tracing. For example, existing profiling tools on Android like Systrace [25] and Android Studio's CPU Profiler [24] can trace every method call of an application. However, enabling this type of tracing noticeably slows down an application, sometimes by more than 10×, which is unsuitable for continuous use in production. Individual applications may implement their own in-app tracing [18,23,46], but such traces are typically only available to those applications themselves.

As a result, problems reported to Android device vendors typically only include system logs, sampled statistical metrics,

Design	Unnoticeable	No src.	Maintain	big. LITTLE
Instrumentation via JIT	✓	✓		
Ring-buffer & encoding	✓			
Hand-optimized asm	✓		✓	✓
Lock-free control	✓			

Table 1: Hubble's designs and the requirements they satisfy. The headings for the requirements are truncated as follows: "Unnoticeable" refers to having unnoticeable overhead. "No src." refers to not requiring source code. "Maintain" refers to being maintainable. "big.LITTLE" refers to supporting both big and little cores.

sparse Systrace traces, and details recorded *after* a problem has occurred, like the device model, application name, and symptom. Most times, this is not enough to be useful in debugging intermittent performance problems, and engineers are left "debugging in the dark." Consequently, many bug tickets are left open for months without any hope of resolution. Worse yet, many bugs cannot even be properly *triaged*, and after rounds of finger-pointing, it is often the low-level system engineers that bite the bullet.

1.1 Challenges and Opportunities

Therefore, a *production* tracing system that can provide fine-grained observability is desperately needed. However, continuous tracing in production is challenging; it needs to satisfy a number of stringent requirements. First, the *worst-case* overhead must be unnoticeable (it cannot exceed 3% or increase the number of performance regressions throughout the deployment cycle), regardless of whether the application is running on the powerful (big) or weaker (little) cores in ARM's big.LITTLE architecture. In addition, the tool should trace applications without access to their source. Finally, it needs to be easy to maintain, and easy to merge with every new (and often feature-breaking) Android release.

These goals and constraints are stricter than what is offered by existing solutions. For instance, while record and replay (R&R) can faithfully replay the entire execution, we are not aware of any R&R system that can achieve *worst-case* overhead below 3%. In fact, most literature [30,33,35,57] emphasizes the *average* overhead; for *production* tracing tools on Android devices, engineers are primarily concerned with the worst-case instead of the average. In addition, R&R techniques typically require deep integration with the Android runtime which means that they cannot be easily maintained.

Another challenge offered by the Android runtime environment is the semantic gap between an application written in a high-level language (Java) and its native execution, which renders a rich set of system profiling tools such as gprof [27] ineffective without the runtime's support. When applied to runtime workloads, these profilers only profile the runtime's execution instead of the applications running on top of it. For example, applying gprof to a runtime workload only provides the call graph of the runtime itself (including the interpreter, GC, and JIT-compiled code), instead of the call graph of the Java application.

Android [26] and other runtimes [7] can output symbol information during execution so that system profiling tools can be applied to profile language-level executions. This approach does not completely close the semantic gap for a few reasons. First, each profiling tool must support using these symbols; currently only the sampling-based perf [39] tool supports using the symbols, and only for JIT-compiled code. Android extended and integrated perf such that it can also profile the interpreter's execution at the language-level [26]. In addition, perf expects every symbol to have a unique memory address, which is not always true; for instance, the runtime may update JIT-compiled code with application hot-patching or recompilation based on new profiling information, thus unloading old mapped code and reusing the page [26].

Yet, the runtime environment also presents a unique opportunity: trace points can be embedded and removed transparently by the runtime without modifying the application's source. This opportunity remains under-exploited despite the popularity of managed languages (the five most popular languages on GitHub in 2021 were runtime languages). To the best of our knowledge, none of the existing language runtimes offer detailed tracing tools that can be used continuously in production. For example, the OpenJDK JVM provides a powerful JVMTI debugging interface that can embed breakpoints in applications. However, this means that execution has to be deoptimized and run in the interpreter (rather than JIT compiled). Therefore, it is mostly suitable for use in development environments. Many runtimes also provide sampling-based profiling features that show "hot" code paths, but none provide continuous method-level tracing suitable for production.

1.2 Contributions

This paper presents the design and implementation of Hubble that satisfies the aforementioned goals. Hubble can capture most method entry and exit points of any application's threads, just-in-time before a failure. We designed Hubble by combining several well-known techniques in a novel way that takes advantage of the Android platform. Table 1 shows Hubble's major designs and the requirements they satisfy.

First, Android applications are typically downloaded as bytecode and then either compiled or interpreted on the device; Hubble leverages this runtime environment to automatically embed its tracing logic into the compiled binary or interpreted logic. This enables efficient tracing, as the tracing logic can be inlined into the application, avoiding more expensive trampolines (i.e., jumps in control flow) that are common in other tracing tools. In addition, this means that Hubble is a purely black-box approach that does not depend on the application's source code.

In addition, Hubble writes trace points to an in-memory ring buffer that is only flushed when a problem is detected. This allows it to run continuously and capture information just-in-time leading up to a failure. By designing a concise, variable-length encoding, such that most trace points occupy eight bytes, a small (32MB) ring buffer is enough to capture sufficient debugging information.

Third, Hubble's performance-sensitive instrumentation logic is written in assembly. This ensures that performance is optimal even on a device's low-power (little) cores, which cannot perform out-of-order execution or have small instruction reordering buffers. In addition, this decouples Hubble from the Android compiler's compilation flow, so it avoids having the compiler affect the correctness of the tracing logic, and eases maintainability.

Finally, Hubble avoids using expensive synchronization primitives [14] in two ways: threads write trace points to thread-local buffers, avoiding inter-thread synchronization; and, Hubble communicates with these threads by using a purpose-built lock-free synchronization protocol.

The end result is a highly efficient method-tracing system sufficient for debugging intermittent performance bugs. In our microbenchmarks, each trace point costs less than one nanosecond for nearly empty methods, and tracing overheads are quickly amortized when methods perform meaningful operations. Hubble's tracing overhead is also unnoticeable in Huawei's continuous-integration performance testing infrastructure, which includes a variety of workloads and devices. Hubble's memory overhead is approximately 64 MB by default, accounting for two 32 MB ring buffers. As of 2021, Huawei's lower-end smartphones have at least 4 GB of RAM, while higher-end ones can have up to 12 GB. Therefore, Hubble's memory overhead is less than 2%.

Hubble also strives to protect user privacy. Similar to existing error reporting systems such as WER [21], MacOS [2] and Mozilla [34] crash reports, Hubble's traces are only collected with user consent. However, these other systems collect a minidump of the memory image, whereas Hubble's traces are far less sensitive: they only consist of method names and timestamps and do not contain any variable values.

Hubble has been integrated into Huawei's core Android OS codebase, deployed across a wide range of smartphone and tablet product lines, since August, 2020. Older devices may receive Hubble's functionalities via an over-the-air OS update. Since deployment, Hubble has significantly eased the debugging of intermittent performance problems. In fact, engineers were able to quickly resolve many performance problems that remained unresolved for months.

This paper makes the following contributions:

- The design and implementation of Hubble, a highly efficient method tracing subsystem for Android, that satisfies a set of unique, practical constraints, some of which are rarely mentioned by existing literature.
- Integration of Hubble's traces with existing debugging tools, like Perfetto [40] which can show call charts. This significantly improved the trace's utility, where developers can cross-examine Hubble traces with other runtime data.
- Case studies on how Hubble diagnoses real-world performance bugs which cannot be resolved without it.

Hubble also has the following limitations. First, it can only embed tracing logic into executions that go through the Android compiler or interpreter (from bytecode); Hubble cannot trace native libraries like those invoked through the Java Native Interface (JNI). In addition, Hubble's trace buffer could pollute the CPU cache and slow down cache-optimized workloads (e.g., loop tiling [8]). However, while cache-optimization is commonplace in server workloads, it is uncommon on smartphones, especially in the interactive UI-thread. Nonetheless, we evaluate this effect in §8.

2 Related Work

Record and replay (R&R) tools [10,15,16,29,30,35,36,38,50,57] work by recording a user's input and all non-deterministic events (e.g., scheduling), so that the execution can be faithfully replayed. R&R tools do not meet our requirements for a few fundamental reasons. The first is overhead. Among all R&R tools, Reverb [35] reported the best performance, yet its overhead is still 5.5% *on average* (the worst-case is not reported). It works only on JavaScript web applications, where threads communicate using a message-passing interface. When threads share memory, R&R incurs even higher overhead. For instance, DoublePlay [57] reported a worst-case overhead of 11% for network-bound workloads (Apache webserver), 19% for disk-bound workloads (MySQL), and 278% for CPU-bound workloads (SPLASH-2 ocean). To achieve low overhead, some tools [33, 38, 45] do not record all non-determinism which prevents accurate replay. Second, since intermittent performance bugs may take days to occur, R&R traces will grow untenably large. While checkpointing could allow replay from a partial trace, the checkpointing operation itself is expensive [50]. Compared to a call chart, an R&R trace also imposes much larger privacy concerns. Finally, R&R tools require deep integration with the Android runtime and compiler. For instance, applying DoublePlay's approach to Android would require the runtime to run a parallel execution of the application, checkpoint and compare state between the two processes, and so on. Hence, R&R tools would be difficult to maintain within Android.

An attractive alternative is to use hardware-support, like Intel PT or ARM ETM, to record branch-level traces [12,28,60]. These tools have a *worst-case* runtime overhead of 1–2%. However, there are two challenges on ARM devices. First, the semantic gap on Android's runtime complicates the decoding of the branch-level trace, as it only provides the traces of the runtime's execution instead of the application. Second,

hardware support for tracing is restricted to development platforms (most ARM processors on production Android devices do not support the feature) [4].

Only a limited set of bytecode method tracing tools are available on the Android platform. Android Studio's CPU Profiler can trace every method call, but its overhead is incredibly high (a worst-case of 921× in our evaluation), because instead of embedding the tracing logic into the compiled binary, it jumps into the Android runtime after every method call. Internal tracing utilities within Android mostly leverage Java Agent, JVMTI, or equivalent ART instrumentation interfaces to perform method tracing. These mechanisms are also expensive as they force applications to be interpreted only. Aspect-oriented frameworks such as Tai Chi [53] and Logan [55] are also available to intercept method calls at runtime to execute arbitrary tracing code. However, they either require modifications to the application's source code or root access. The fastest available method tracing utility that we are aware of, Nanoscope [54], primarily targets method tracing inside an x86 Android emulator, costing up to 10× higher memory usage and performance overhead, so it is mostly useful in an application development environment.

Some tools are able to perform in-application tracing with low overhead in production. For instance, Firebase performance monitoring [23] collects various metrics (e.g., startup time) and allows developers to insert additional trace points. AppInsight [41] instruments Windows Phone application binaries to log whenever the runtime calls into and returns from application methods. The instrumentation has sufficient detail to allow a server to reconstruct how a user request was processed across different application threads and what the critical path is. These tools typically trace the entire run of an application, but at a low enough granularity that the trace does not grow untenably large. As a result, they are useful for application developers to locate bottlenecks in their application; but the coarseness of the trace may necessitate additional debugging information to locate the exact root cause, especially if the bug is in the underlying systems which are not traced. Timecard [42] goes beyond tracing by using AppInsight's traces to adjust the server's computation quality (in real-time) to meet an end-to-end response deadline.

There are also a few high-performance logging solutions like NanoLog [58] and Log20 [59] that can provide nanosecond-level logging. Both write data to thread-local ring buffers and NanoLog uses a specialized encoding to save space. NanoLog uses only the existing log statements in the application while Log20 can be used to determine where best to place log statements based on profiling the application's usage pattern.[1] In any case, the generated trace is only as detailed as the developers' instrumentation.

Outside of the Android platform, there are many call profiling tools like gprof [27], Fay [17], ftrace [51], perf [39], DTrace [9], and SystemTap [52]. These tools support various degrees of tracing from periodically sampling the call stack to calling user-defined methods using dynamic instrumentation. However, to capture traces that are detailed enough to diagnose intermittent bugs, these tools incur overhead that prevents them from tracing continuously in production systems. These tools typically require calling a method in their instrumentation, whereas Hubble directly inlines the tracing code into each method.

There are a large number of tools designed to trace each request in a distributed system. Examples include Project5 [1], MagPie [5], X-Trace [20], Dapper [47], ÜberTrace [11], and Pivot Tracing [31], as well as commercial tools like Datadog [13] and New Relic [44]. These tools typically embed trace points in critical system or network events, such as RPCs, and record an ID that is unique to each request.

3 Case Studies

We present two case studies to showcase how Hubble helped in diagnosing real-world intermittent performance problems. The first issue was within AppX, a third-party multipurpose messaging, social media, and mobile payment application with over a billion monthly active users. Occasionally, AppX users experienced intermittent UI freezes (janks) of up to two seconds. Engineers detected this problem by monitoring the traces that Systrace continuously collects—namely, performance alerts, sparse trace points, and metrics sampled at low frequencies. Figure 1 (A) shows the available trace points rendered as a method call chart in the Perfetto trace-visualization tool. For the UI thread, this consists of only a few high-level methods within the Android framework. The only conclusion engineers can infer from this data is that the UI thread was blocked for about two seconds during which it was supposed to prepare the layout and content for rendering.

In contrast, the call chart based on Hubble's trace, shown in Figure 1 (B), accurately captures every method call in both the application and the Android runtime. From the canonical method names displayed in the chart, engineers were able to quickly reconstruct the events that occurred before, during, and after the UI jank. First, the user swiped back on the device's screen within AppX (①). Then, AppX initialized a software keyboard to respond to the user's action (②). However, to display the keyboard, the scrollable chat component must be resized (③), and this became the bottleneck. Drilling down further, we can observe the series of method calls responsible for generating the list of on-screen content (④). Specifically, we can see that the UI thread is primarily blocked by various long-running methods belonging to AppX. Now with concrete evidence, our engineers concluded that the root cause was within AppX, and initiated a meaningful collaboration with AppX's developers.

The second issue was a longstanding performance bug

[1] In fact, the initial goal of this project was to integrate Log20 into Huawei's Android platforms.

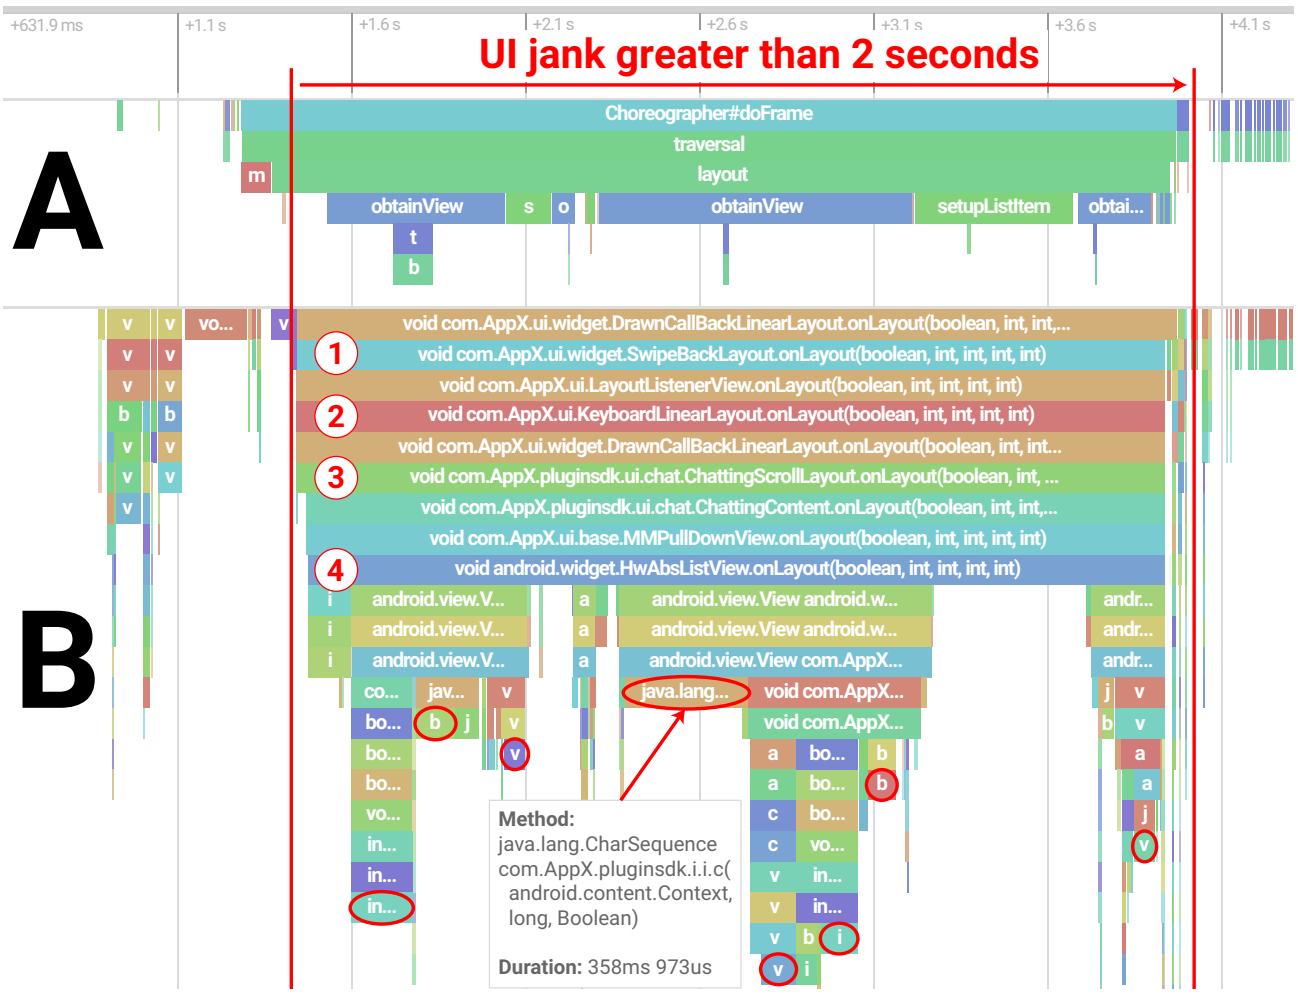

Figure 1: Screenshot of method call charts in Perfetto for the UI thread, which performs all UI and Android framework operations. (A) Traces generated by Systrace, (B) Traces with Hubble. Circled in red are 3rd-party application methods with long execution time. (A) includes *all* of Systrace's trace points recorded during this time period, whereas (B) is filtered to render only approximately 10% of all available methods.

within an internal business teleconferencing application. After the end of a teleconference, the application occasionally froze for up to a second on a small number of user devices. This annoyed users but it was not until months later that a particularly vocal employee reported the issue to management, who then opened a support ticket requesting that the issue be resolved. Our device support engineers attempted to reproduce the problem on their own, but all attempts were unsuccessful. The only method call captured by Systrace was `binder_transaction()`, which does not explain why the issue occurred. Further efforts to collaborate with the disgruntled users were also ineffective as most users were either too busy or otherwise unable to provide more detailed reproduction instructions. A few users were even invited to collaborate with an engineer to reproduce the problem, but the intermittent issue could not be reproduced after multiple attempts.

Several months later, Hubble, in pre-beta at the time, was available for internal use. The disgruntled employees happily consented to deploying Hubble onto their mobile device via an over-the-air Android OS update. Within a few days, performance anomalies were detected and their associated trace data was automatically collected. After a quick glance at Hubble's call chart, the support engineers identified that the teleconferencing software was calling `Thread.sleep()` from the UI thread after sending an Android Binder (IPC) system service call. Closer inspection revealed that immediately after a conference call ended, a series of method calls related to the Audio Manager were performed, prior to the `Thread.sleep()`. This behavior was unexpected and if not for the complete method call trace, which contained both the application and Android framework layers, we would still be stuck with many of our initial theories; e.g., the application could be collecting and sending meeting summary data back to the teleconference service or an unexplained scheduling issue.

With this new information, we brought in a developer with expertise in the Android audio stack. After examining Hub-

ble's call chart, the developer immediately identified the root cause. The problem can only be reproduced under very specific conditions where users must be connected to Bluetooth headsets using a special mode prior to ending the meeting. After the meeting ended, the application immediately rerouted audio to Bluetooth devices connected over the A2DP streaming protocol. This rerouting process requires re-initialization of Bluetooth's SCO (synchronous connection-oriented) link where the `Thread.sleep()` was invoked to wait for the link to be established. We were unfamiliar with these details, but with the help of a developer with the necessary domain knowledge, the issue was promptly fixed by moving the connection and rerouting logic into an asynchronous event handler.

4 Background and Overview

This section first discusses Hubble's design goals and the role it plays in the failure diagnosis process, which helps to understand Hubble's design. We then provide an overview of Hubble, leaving the details to the subsequent sections.

4.1 Goals and Requirements

Hubble's performance overhead and resource usage must be *undetectable* in all real-world usage scenarios. In practice, this translates to two requirements: Hubble's worst-case overhead in real-world scenarios, in terms of both latency and memory usage, should be less than 3%. This target was set by our quality assurance team since they cannot reliably measure overhead below 2–3% on mobile platforms, even under ideal conditions. Nonetheless, this is similar to the target set by other practitioners; Google, for example, reported a 2% overhead budget to deploy tracing tools in production server workloads [32, 48]. The second requirement is that the overhead budget should be respected regardless of whether Hubble is tracing workloads on big or little cores. Besides not being as fast as big cores, little cores also tend to lack advanced features like out-of-order execution. Thus, they enforce stricter restrictions on the tolerable overhead for Hubble. In any case, satisfying the target overhead only allows a tool to pass the deployment planning review. To be deployed in production, the tool needs to go through a systematic procedure consisting of three phases:

1. **Internal testing**. We simulate users using our devices by sending a stream of pseudo-random inputs to a large fleet of physical devices. Each device collects various metrics like application startup times, the number of dropped frames, and so on. Each metric forms a statistical distribution over a large number of trials. We compare the distribution before Hubble was added with the one after. If the differences are statistically insignificant, Hubble has not caused a noticeable change, and we move to phase 2.

2. **Internal beta release**. We push engineering builds to a small group of internal beta testers on their daily-use devices. We ask these users to report any performance regressions they notice and any new performance issues will need to be resolved before moving to the next phase.

3. **Public beta release**. A build is pushed to all beta users (tens of thousands of users), and we monitor all new performance anomaly reports. We only consider Hubble's overhead as undetectable when the beta build does not show a statistically significant increase in reports. Only then can the tool be further released to the entire public.

Android applications are typically distributed as bytecode compiled from high-level languages like Java. Once downloaded, this bytecode is either ahead-of-time (AOT) compiled, or executed within the Android runtime (similar to the Java Virtual Machine). The Android runtime compiles frequently executed code Just-in-Time (JIT), using the same AOT compiler. An already-compiled application could also be re-compiled, if runtime profiling reveals new optimization opportunities. Applications could also contain native libraries, i.e., code that was already compiled into native instructions. Thus, Hubble must be able to operate with only access to the downloaded or generated bytecode or native instructions.

Easy maintainability across Android versions is required. Android is typically updated every six to twelve months, with each new release potentially breaking features or making large-scale changes internally. Thus, Hubble should be modularized and decoupled from the upstream source.

Finally, as the case studies highlight, Hubble needs to be able to trace both the executions of the application and the Android framework to be useful. Ideally, device vendors would only be responsible for analyzing and debugging bugs within Android, and application developers would only be responsible for bugs within the application. The reality, however, is that bugs in the Android framework may manifest themselves in the application and vice versa. Furthermore, system traces are not available to application developers (in order to maintain users' security) and in-application traces may not be available to or easily understandable by device vendors. Exacerbating the issue, application developers and even internal developers at Huawei are reluctant to investigate bug reports without clear evidence that the bug is in their code. Whole-system method traces allow engineers to infer roughly what the application and framework are doing, together, so that the problem scope can be narrowed down to specific call chains and system services. Essentially, Hubble needs to bridge the gap between system and application developers, which in turn, will significantly ease triaging and debugging for both parties.

Overall, these requirements highlight the practical challenges of designing and deploying tracing tools onto a complex user-device platform such as Android.

4.2 The Failure Diagnosis Process

To understand Hubble's utility, we first need to overview the failure diagnosis process. Android devices ship with a set of anomaly detectors to detect common issues like lags in the UI. When an anomaly detector fires, the system saves several pieces of data such as logs, metrics, and traces. At an appropriate time, these data will be uploaded to the device vendor for analysis.

4.2.1 Anomaly Detection

Since Hubble's utility depends on an anomaly detector firing, we first provide background on the detectors available in the Android Open Source Project (AOSP) and our version of Android. There are two branches of anomaly detection mechanisms that device vendors can use in the production environment: Those implemented by Android itself and those implemented by in-house engineering teams. Both branches use information gathered either from the Android runtime layer or from the Linux kernel. In addition, both branches are generally tuned to be conservative to reduce the number of false positives. However, if a severe performance issue occurs, a signal will most likely be raised.

The anomaly detectors implemented in the AOSP have been continuously developed for over a decade. For example, the most frequently used anomaly detector is the UI jank (lag) detector, which has an extremely close correlation to user-observable performance issues. It will alert if a number of consecutive display frames are delayed longer than a predefined threshold. Android officially groups all its tracing, profiling, and anomaly detectors under one umbrella term known as systrace. In production environments, most of these anomaly detection signals and alerts are continuously captured and analyzed in real time.

Internally, we utilize a number of additional black-box anomaly detectors which monitor for a number of kernel level indicators and hardware events. For example, we implemented a system-level, HCI-based detector: Studies show users start to perceive a delay after 400-600ms. So by instrumenting the runtime where (1) a touch is detected by the screen, (2) when the signal is delivered to the application, and (3) the application generates a response, we can accurately measure the delay between (1) and (3) and fire an alert when the delay is longer than 400ms. Furthermore, we can attribute the delay to either signal delivery in the runtime or within the application.

Other black-box anomaly detectors could be as simple as monitoring whether the device has entered the thermal throttling mode. Most detectors, however, don't rely on a single metric. Instead, they correlate multiple metrics. For example, if a detector detects that the current GPU memory bandwidth utilization is high, it then checks other metrics such as the rendering queue backlog length; only if multiple of them suggest an anomaly does the detector fire a warning. Experimental anomaly detectors may further leverage real-time machine-learning monitoring Android runtime metrics like the number of locks held, memory allocation and garbage collection frequency, and so on.

4.2.2 The Utility of Hubble

When Hubble's traces are collected, they are integrated into systrace and Perfetto when presented to engineers with other runtime data. Perfetto and systrace are powerful debugging tools that can visualize a variety of runtime data, including visualizing the method trace as a call chart or flame graph. The tools also have search and analytics (e.g., using SQL) capabilities that allow developers to correlate data from different sources. For instance, developers can cross-examine traces with logs and hardware metrics. Developers can also alert based on traces. For example, one use case of Hubble is to search for the call stack that matches a specific method invocation order, get an average runtime, and alert when it exceeds a threshold. As a result, Hubble is not a standalone tool, nor the only debugging tool. Instead, developers usually start debugging by first examining the data from existing logs and metrics, and some bugs can be resolved with these alone. However, the remaining bugs—typically hard-to-diagnose, intermittent issues—require more insight, which is where Hubble excels.[2]

Key to Hubble's success is the visibility it provides into application and framework-level behaviour, without which engineers cannot triage issues. Hubble's detailed method traces also allow developers to better understand how a bug can be reproduced; with a reproduction, developers can repeatedly reproduce the bug in a development environment (with heavyweight tracing) until the issue is understood.

Nonetheless, there are some limitations to Hubble's utility. We have found Hubble's traces are not as useful in the following cases: (1) if the bug is in the system's native code (which is not traced), (2) if the method-level trace is not fine-grained enough (e.g., an infinite loop without making any function calls), or (3) if a bug is caused by incorrect data-flow (i.e., an incorrect variable value) that does not affect the call path (otherwise it could be inferred by Hubble's trace). However, Hubble's traces can still help developers to significantly narrow down the problem scope (e.g., they can locate the method that contains the infinite loop). In theory, if the distance between the root cause and the symptom is too long, Hubble could miss the cause due to the ring buffer size. However, we have not yet encountered such a case in practice.

[2] We do not have an exact number of issues exclusively resolved by Hubble, because Hubble's traces are integrated into existing debugging tools with other traces. However, we noticed the number of bug tickets containing intermittent and difficult to reproduce bugs quickly dropped after Hubble was first made available.

4.3 Overview of Hubble

Hubble modifies the compiler and interpreter to instrument tracing logic at the entry and exit of every non-inlined bytecode method, whether it is interpreted, ahead-of-time compiled, JIT compiled, or recompiled. Portions of the Android framework itself and factory installed apps, i.e., the apps that are packaged by the OEM vendor, could be already in compiled form instead of bytecode; for these cases, the trace points are embedded at the vendor's site. Hubble can also trace calls made using the JNI (when applications calls into the native libraries and the returns). However, function calls made within native libraries cannot be traced by Hubble.

Hubble adds one system thread, the trace control thread, to each application's process that can turn tracing on or off for any thread in the same process. Although Hubble instruments all bytecode methods, by default, the control thread only turns on tracing for the UI thread, which performs all UI and Android framework operations. At every method entry and exit, Hubble's tracing code writes an entry to a fixed size in-memory ring buffer. When the buffer is full, the buffer pointer will wrap around so the oldest data will be overwritten.

When a performance anomaly detector detects a performance problem, the control thread will be notified. It then notifies the UI thread to stop tracing, preventing useful debugging data prior to the problem from being overwritten. Once tracing has stopped, the control thread flushes the ring buffer to disk, before restarting tracing. The saved trace file could be sent back to Huawei to aid postmortem debugging, or post-processed and analyzed on the device, off the critical path, if a summary needs to be sent.

Each traced thread writes to a private ring buffer local to itself. Hubble keeps at most N buffers in the system, from the N threads that most recently executed in the foreground. Older buffers will be reclaimed by the system. N is configurable and the method trace logic can be programmatically enabled and disabled for individual threads, either via the runtime or by the user application itself. This means that any background threads from almost any process, even short lived ones, can be traced. However, if there are too many concurrent threads being traced, Hubble will run into memory usage issues. To solve this, we could have a ring buffer per core rather than per thread; to differentiate trace points from different threads, we could record the thread's ID (available from a register in the runtime) in each trace point. By default, N is set to 2. This is sufficient to capture both the current foreground and most recent background application's UI threads.

5 In-memory Tracing

This section describes the design and implementation of Hubble's tracing logic. We first explain the information recorded in each trace point and its encoding. We then discuss how we integrated the tracing code into Android's optimizing compiler so that compiler optimizations do not affect our instrumentation.

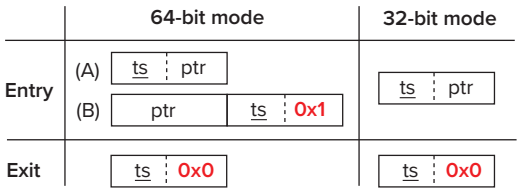

Figure 2: **Format and encoding of trace points** at method entry and exit, and in 64-bit and 32-bit execution modes. "`ts`" and "`ptr`" are timestamp (generic timer count) and method pointer. A solid bordered box represents a 64-bit slot. Underscores represent lossy encodings of timestamps.

5.1 Data Format and Encoding

Figure 2 shows the format of each trace point. As shown, method entry points have a varying encoding depending on the CPU's execution mode and other factors explained later. The CPU will change mode when executing a 32-bit or 64-bit application. Method entry trace points contain a timestamp and a method pointer, while exit points contain a timestamp and the constant `0x0`.

For timestamps, Hubble uses the Generic Timer [3] count instead of the standard system clock. A Generic Timer is a high resolution clock (nanosecond precision) and its tick value can be directly read from a register on modern ARM SoCs. It ticks at a constant frequency regardless of the CPU operation speed and the counter value starts at 0 when reset. When the trace is persisted, Hubble records the current time, which can be used to reconstruct the absolute timestamp of each trace point from the Generic Timer count.

The method pointer is the memory address of a metadata object, ArtMethod, that describes each loaded class-method and can be used to decode a method's canonical name. As part of the ClassLoader initialization process in Android's runtime (ART), an array of ArtMethods is allocated in a memory region outside the managed heap (ignored by garbage collection). ArtMethods can only be added to this array and never be modified nor removed. ART ensures that immediately after entering a method, the address of its ArtMethod is stored in register r0. Since the lifecycle of the main ClassLoader, which is responsible for loading all of the executed bytecode methods, spans the entire duration of the application, we can safely store the ArtMethod pointer in the trace buffer and reconstruct the method name after the trace data is persisted, so long as this happens before the application exits. Note that applications could use additional custom ClassLoaders with shorter lifecycles. If we persist the trace data *after* the custom ClassLoader exits, we could dereference pointers that are no longer valid. To avoid this, we install a cleanup hook for custom ClassLoaders to invalidate the trace buffer (or optionally persist the trace data).

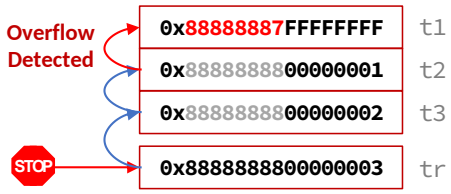

Figure 3: Iteratively Recover Truncated Timestamps.

For each thread that is traced, the control thread allocates storage for the trace in the traced thread's local storage (Java ThreadLocal [37]). This includes a ring buffer and metadata such as where content in the buffer begins and ends. The ring buffer is carved into an array of 64-bit wide integers in both 64-bit and 32-bit mode.

For the timestamp in each trace point, Hubble only stores the lower 32 bits of the Generic Timer counter, regardless of execution mode. (Even in 32-bit mode, the Generic Timer counter is 64 bits wide because the value is fetched from a co-processor that is not subject to the mode change.) Thus, the recorded timestamp may wrap around, which we handle during decoding.

Figure 3 shows how Hubble reconstructs the accurate timestamp from truncated ones. The last timestamp is a reference timestamp (`tr`), which is the complete 64-bit Generic Timer counter value recorded when the trace is persisted. Using `tr`, we can iteratively reconstruct the upper 32 bits of the previous three timestamps: if a previous timestamp has a lower value than the current one (e.g., `t3` versus `tr`), we assume it has the same upper 32 bits; if it has a higher value (e.g., `t1` versus `t2`), we assume a wrap around occurred and the upper 32 bits should be decremented by one.

Theoretically, this could lead to an error: if between two consecutive trace points more than 2^{32} ticks occur, the reconstructed timestamp will be inaccurate. However, this is unlikely to happen in reality. It takes 223.7 seconds on a Qualcomm ARM SoC and a little over 37 minutes on a Huawei-designed SoC for the lower 32-bit Generic Timer counter to tick 2^{32} times. So only if a method executes for more than 223.7 seconds, without calling another method or returning, will an inaccuracy occur.

5.1.1 Format under 64-bit Mode

Hubble uses a variable-width encoding for the ArtMethod pointer when executing in 64-bit mode. In this mode, the pointer is 64 bits; but for real-world applications, the vast majority of the pointers' upper 32 bits have the value `0x0`. We exploited this observation to increase encoding efficiency. When the upper 32 bits are `0x0`, Hubble only records the lower 32 bits of the pointer (Figure 2 (A)). Together with the lower 32 bits of the timer count, a method entry trace point occupies a single 64-bit buffer slot. If the upper 32 bits of the method pointer are not `0x0`, a method entry trace point occupies two buffer slots (Figure 2 (B)). The first 64-bit slot is used to save the complete 64-bit method pointer; in the second slot, the upper 32 bits store the timer count and the lower 32 bits store the constant `0x1`.

The method exit trace point occupies a single 64-bit slot. The upper 32 bits store the timer count, and the lower 32-bit stores `0x0`, indicating it is a method exit trace point.

Traces in this format can always be **unambiguously decoded** in reverse. To decode each trace point, Hubble first checks the lower 32 bits of the previous slot. Depending on whether its value is `0x0`, `0x1`, or another value, Hubble knows that this trace point is either a method exit, a method entry that is two slots wide (Figure 2 (B)), or a method entry that is one slot wide (Figure 2 (A)). `0x0` and `0x1` cannot be method pointers since they are invalid method pointer memory addresses. A method exit point is matched with the corresponding method entry point in a LIFO manner (implemented using a stack). Note that the decoding occurs server-side, after the persisted trace has been sent back.

5.1.2 Format under 32-bit Mode

In 32-bit mode, both method entry and exit trace points use a single buffer slot. The upper 32 bits are always the lower 32 bits of the timer count, like in 64-bit mode. For method entry points, the lower 32 bits store the method pointer, and for method exit points, the lower 32 bits store `0x0`.

5.1.3 Efficient Recording

The tracing logic can be efficiently implemented by a few assembly instructions. For example, Hubble uses only two assembly instructions to store the method entry trace point under 32-bit execution mode:

```
1 MRRC(al, scratch1, scratch0, 0b0001, 0b1111, 0b1110);
2 STRD(r0, scratch1, MemOperand(buffer, 8, PostIndex));
```

The first `MRRC` instruction is used to fetch the 64-bit Generic Timer counter value into two 32-bit CPU registers: `scratch1` and `scratch0` (readers can ignore the other operands). Then a `STRD` instruction is used to (1) store `scratch1`, which contains the lower 32-bits of the Generic Timer counter, and `r0`, which contains the ArtMethod pointer, to the memory address stored in `buffer` register, and (2) increment `buffer` by 8 bytes after the memory operation completes. So after this store instruction, `buffer` will point to the next buffer slot.

Hubble's tracing assembly is directly inlined in the basic block at each method entry and exit. Comparatively, in other profilers that use compiler instrumentations, the instrumented code will call a special tracing function. For example, `gcc -pg` instruments a call to the special function `mcount()`, which is required for tools like `gprof`. While easier to maintain and more portable, the added function call introduces overhead.

When tracing is stopped, the valid portion of the ring buffer is flushed to disk using an *fwrite* call. Three metadata files are generated. First, a complete 64-bit Generic Timer counter value (i.e., the reference timestamp) and the absolute system timestamp are collected at the same time; this facilitates the reconstruction of the actual, non-relative timestamp of each trace point if needed. Then the current buffer position and size are recorded. Finally, Hubble computes a symbol table, mapping each unique ArtMethod pointer value to the method's canonical name.

5.1.4 Alignment

Each trace point is always eight-byte (a word on 64-bit devices) aligned. Eight-byte aligned memory accesses are crucial to achieving the highest performance in both 32-bit and 64-bit mode on modern ARM SoCs. Unaligned accesses take at least one more cycle than a properly aligned memory access. In the worst case, a single unaligned access can cross a cache-line boundary and generate two cache misses or even two consecutive page faults. Worse yet, unaligned memory accesses are an unsupported operation on low-power or older ARM processors, so additional memory accesses and massaging logic are required. Accordingly, we use 32 bits to represent the constants `0x0` and `0x1`, since the performance gains of aligned accesses outweigh encoding inefficiency.

5.2 Hand-optimized Assembly

There are a few reasons to write the tracing logic in assembly. First, it decouples Hubble from the Android compiler's compilation flow. If written in C++, the compiler could move, reorder, or even remove the tracing logic (e.g., the tracing logic accesses global variables without a memory barrier (§6), which is an undefined behavior). By writing the logic in assembly, we can insert it after the compilation stage, bypassing any optimizations that are at odds with the tracing. To do so, early in the compilation stage, instead of generating the actual tracing code, we simply insert a special placeholder instruction at every method entry and exit (including exits due to exceptions); we then configure the Android compiler to exempt this instruction from its later optimization stages. After all the optimizations are performed, we replace this placeholder instruction with the actual tracing instructions. This also makes Hubble easy to maintain, as it is decoupled from any compiler changes that are not backward compatible.

Using assembly also allows us to optimize for both big and little cores. The Android compiler's optimization is heavily biased toward the big core. For example, the compiler skips the architecture-specific optimizations when they are unnecessary on big cores that support out-of-order execution. However, the little cores do not support out-of-order execution, so running the compiled code will result in poor performance. For instance, each trace point needs to check if we are at the end

```
// Initialization
start=0x0;  stop=0x0;

Control thread:                 Trace point:
1  start=buffer;                 7  if (start)
2  wait(signal);                 8    trace...
3  stop = 0x1;                   9    if (stop) {
4  while(stop==0x1)             10      stop=buffer;
5    sleep(..);                 11      start=0x0;
6  persist(..);                 12    }
```

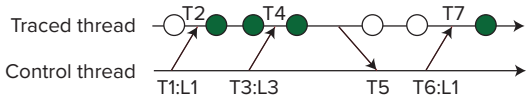

Figure 4: Lock-free Synchronization Protocol.

of the ring buffer (and if so, we need to wrap around). This check requires fetching the value of the ring buffer pointer from memory. If we manually prefetch this pointer (in assembly), it results in an approximate speedup of 35% on the little core. The compiler, however, did not perform this prefetching, because it expects the big core will perform the prefetching automatically.

Finally, because we have domain knowledge of the tracing logic and processor microarchitecture, we can perform better optimizations than the compiler, regardless of whether it is on the big or little core.

6 Tracing Control

Recall a system thread is responsible for notifying the traced thread to turn tracing on or off. The traced thread (e.g., the UI thread) is only responsible for (1) checking whether tracing is turned on, and if so, (2) writing the trace points into the trace buffer, and (3) turning tracing off if necessary. The rest of this section describes how the two threads communicate efficiently without synchronization primitives.

Figure 4 shows the communication between the control thread and the traced thread. Lines 1–6 are the control thread's logic, whereas lines 7–12 are executed at every trace point in the traced thread. Hubble uses two eventually-consistent, shared variables, `start` and `stop`. `start` is unidirectional, i.e., it is set by the control thread and read by the traced thread, and `stop` is bidirectional, as it can be set and read by both threads. Initially, both variables are set to `0x0`. To start tracing, the control thread sets `start` to the *address of the next buffer slot* (line 1 in Figure 4), and waits for a signal to stop tracing. Therefore, the value of `start` indicates two things: whether tracing is on or off, or the buffer position. At each trace point, the traced thread first checks if `start` is `0x0`, and only proceeds with tracing if it is not (line 7).

To turn tracing off, the control thread sets `stop` to `0x1` (line 3 in Figure 4), and then enters a polling loop until `stop` is changed to a value *greater than* `0x1` (lines 4–5). In the meantime, the traced thread performs tracing and evaluates

the value of `stop` at the end of every trace point (line 9). Once the traced thread detects that `stop` was changed to a non-zero value, it enters the logic to stop tracing. The traced thread first sets `stop` to the address of the current buffer pointer, i.e., the end position of the buffer, at line 10. So `stop` also serves dual purposes: whether tracing should stop (with value 0 or 1), or the buffer end position. (Note that `0x0` and `0x1` are invalid buffer memory addresses, so after line 10, `stop` will be greater than `0x1`.) Then the traced thread sets `start` to `0x0` at line 11, to guarantee that tracing will be disabled immediately. Finally, the control thread detects that the traced thread has stopped tracing, so it can persist the trace or clean up the ring buffer.

Figure 4 also shows an example trace control-flow. Each circle represents a trace point, with filled and blank shading indicating whether trace data is written or not. At the beginning, tracing is off. At T1, the control thread turns tracing on at line 1 (L1) by setting `start` to a non-zero value. This new value is propagated to the traced thread at time T2, as the result of eventual consistency in the memory cache coherence protocol. Then, the following three trace points are written to buffer. At T3, the control thread turns tracing off by setting `stop` to `0x1`, which is propagated to the traced thread at T4. The traced thread then executes lines 10–11, and at T5, the control thread detects that `stop` was changed to a value greater than `0x1`; so it breaks out of the polling loop and persists the trace. After the trace is persisted, the control thread restarts tracing at time T6 (line 1).

This design is highly efficient. Each trace point needs to check the values of `start` and `stop` only if the trace has been started. `start` and `stop` are regular shared variables that are almost always cached. In comparison, any alternative design that uses synchronization primitives or atomic variables would introduce much higher overhead in each trace point, which is on the critical path.

Since tracing is stopped and the current ring buffer location is written to the `stop` variable by the traced thread itself, no additional trace point will be written to the buffer afterwards and the buffer metadata will be consistent. For example, if the last trace point is a 64-bit method entry occupying two slots, it is guaranteed that both slots are written with the buffer pointer correctly incremented before tracing is stopped.

If the traced thread is executing native code, either through the JNI or a custom ClassLoader, it cannot respond to the control thread's stop tracing request, because the logic to stop tracing is only instrumented in bytecode methods. Therefore, the control thread further checks whether the traced thread is in native execution when it attempts to stop tracing. If so, the control thread will first obtain ART's state transition lock that prevents the traced thread's execution from changing state, i.e., from native execution back to the bytecode world (either the interpreter or compiled code). Then the control thread forcibly copies the buffer position to `stop`, and sets `start` to `0x0`, followed by a memory fence. Finally, the control thread can release the state transition lock. A subtle data race could occur during state transition where just before the lock is obtained, the traced thread transitions back to the bytecode world. Debugging this unfortunately took weeks, but we fixed it by rechecking the traced thread's execution state after obtaining the lock.

7 Privacy and Security

Security and privacy are some of our top priorities. Hubble does not collect personally identifying information, such as phone numbers or user IDs. Hubble's traces only contain method names and timestamps, there are no actual *data values*, not even parameter values. Widely-adopted error reporting systems like Windows Error Reporting (WER) [21], MacOS' crash report [2], or the Mozilla Crash Reporter [34], record a subset of the memory state or often collect system logs. In comparison, Hubble's traces are far less sensitive. Similar to WER and other widely-adopted error reporting systems, Hubble uses an informed consent policy.

Even when user consent is given, Hubble further strives to minimize the amount of data that leaves the device. Hubble has the capability to perform the same analyses that are performed server-side, locally on a user's device, with only a summary being sent back to the vendor. For example, Hubble can quickly scan the trace files and compute the top methods with the longest "self-execution-time", or it can automatically isolate and extract the longest method call chains from when a performance anomaly occurred. Performance bug models could be distributed to client devices, containing "signatures" of problematic method names or method call chains, and if there is a match, statistics could be sent back instead of the complete trace.

Hubble also exploits many built-in data security features in Android and the Linux kernel to protect trace data. The traces are stored inside an application-private storage area that is protected by the kernel-level application sandbox. Only the application itself with matching its UID, device vendors, and application developers—when they configure their mobile device in debug mode—have access to the trace files.

8 Evaluation

Hubble has been repeatedly tested on Huawei's performance testing framework, which included the top 100 popular applications, with workloads including startup, stress testing (simulated random screen touches at a high rate), and normal usage simulations, on all supported devices. Overall, we have found Hubble's overhead is statistically insignificant in real-world use-cases. Hubble tracing is now enabled by default in all Huawei testing frameworks.

We have designed a few experiments to stress test and study Hubble's runtime characteristics, aiming to answer four questions: (1) What is the runtime cost of Hubble's tracing?

(2) What is Hubble's effect on cache behavior and memory bandwidth? (3) What is Hubble's overhead in the most demanding real-world scenarios? (4) How long of an execution trace can be stored in the ring buffer? We did not evaluate power consumption. Despite best-effort attempts, we could not reliably observe battery overhead in any experiments. Huawei's devices are shipped with aggressively tuned power-saving profiles and thus far, we have not observed an increase in reports of battery drain.

Unless otherwise specified, experiments were performed on a Google Pixel 1 phone that is well-supported by the open-source version of Android (AOSP). The phone contains a Qualcomm Snapdragon 821 processor with two high-performance cores each with a 64 KB L1 (divided equally for instructions and data) and 1.5 MB L2 cache, and two low-power cores each with a 64 KB L1 and 512 KB L2 cache.

We compared three execution modes: (1) baseline – the phone running *unmodified* Android; (2) tracing off – Hubble is enabled and applications are instrumented, but tracing is turned off; and (3) tracing on. Baseline experiments were performed on AOSP's android-10.0.0_r2 [56] branch. We recompiled the same branch with Hubble enabled.

Hubble's overhead could only be measured reliably in CPU-intensive and unrealistic microbenchmarks. Repeatedly running the two microbenchmarks in §8.1 and §8.2 causes the CPU to quickly reduce its clock speed due to severe thermal throttling. To improve the validity and reproducibility of the experiments, we placed the phone on bags of ice water.

8.1 Trace Point Overhead

Hubble's tracing overhead is amortized by the amount of work performed by the traced method. Since Hubble's tracing logic does not impose any dependencies on the traced method, nor does it use synchronization primitives on the critical path, the amortization effect will be enlarged by the deeper CPU pipeline. We evaluated both the cost of an individual trace point as well as the overall runtime overhead as the method performs more work. For comparison, we also evaluated Android's built-in method tracing utility, typically invoked via Android Studio's CPU profiler, henceforth referred to ASMT.

Listing 1 shows the method used. The amount of work done can be controlled through the `work` parameter. To prevent the method from being inlined by the JIT compiler, we added tail-recursion on line 5. In addition, we executed the method with a `depth` of `10` since the compiler still performs inlining at lower depths. `sum` is carried across calls to ensure that the loop is not optimized away by dead code elimination.

We ran the method with `work` values of 0, 1, 10, 100, and 1,000. We measured the runtime of two billion iterations. The cost of a trace point is calculated as the overhead of the 0-work experiment divided by two, since each method call contains a method-entry and method-exit trace point. To ensure the method is compiled by the JIT compiler before evaluation, we ran the experiment until its runtime stabilized to a maximum variance of five percent. The method is then executed ten times for each experiment.

		Average Cost (ns)	Standard Deviation (ns)	Performance Overhead (%)
ASMT	**32-bit**	3,911.575	59.2450	920,587%
Tracing ON	**64-bit**	3,366.050	57.8026	748,510%
Hubble Method	**32-bit**	0.725	0.0551	171%
Tracing ON	**64-bit**	0.650	0.0023	145%
Hubble Method	**32-bit**	0.001	0.0030	0%
Tracing OFF	**64-bit**	0.008	0.0027	2%

Table 2: Cost of a Single Trace Point

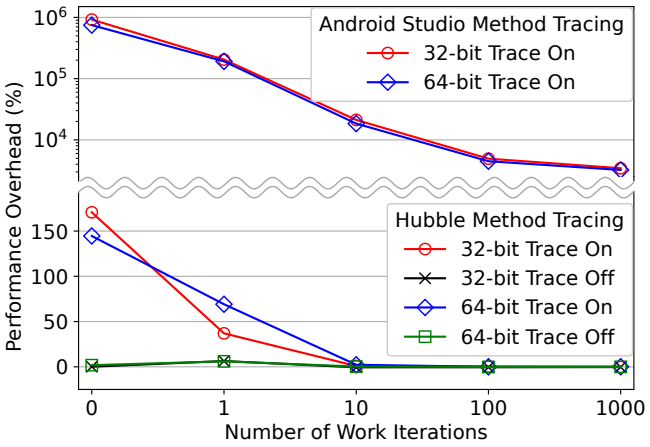

Figure 5: Performance Overhead Over Work Iterations

```
1 public long Test(int depth, int work, long sum) {
2   for (int i = 0; i < work; i++) {
3     sum *= i - 1; sum /= i + 2;
4   }
5   if (depth > 1) return Test(depth - 1, work, sum);
6   return sum;
7 }
```

Listing 1: Program used for measurement.

Table 2 shows the results of the 0-work experiment, with the other work values in Figure 5. The 0-work experiment shows that on average, each Hubble trace point costs less than one nanosecond when tracing is on, and less than 10 picoseconds when tracing is off. This is far less than ASMT's overhead which is on the order of microseconds. Figure 5 shows the amortization effect: as the amount of work done by the method is increased, Hubble's tracing overhead percentage decreases quickly. Note that in reality, small methods like this would likely be inlined, excluding them from being traced.

8.2 Cache Effects Microbenchmark

We used matrix-multiplication (MM) to measure Hubble's effects on the cache. MM is a classic workload that can either benefit heavily from caching or suffer ample cache misses [8]. When multiplying large matrices, a naïve implementation

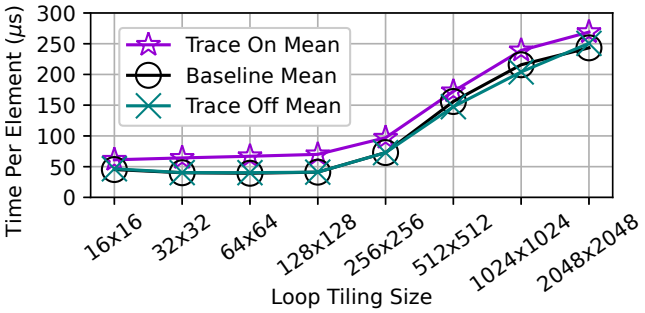

Figure 6: Cache and Memory Effects

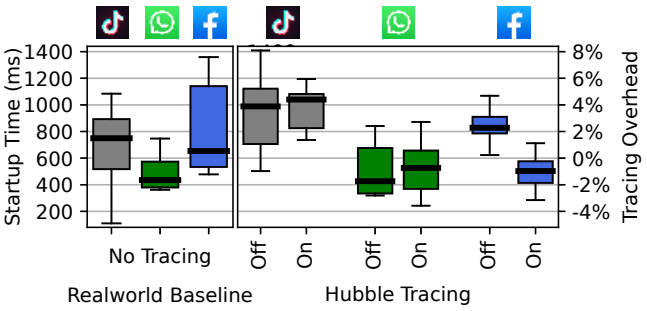

Figure 7: Application Startup Time

causes many unnecessary cache misses. However, the majority of these cache misses can be avoided using loop-tiling, i.e., partition each matrix into many small tiles, where each fits in the cache, and perform all accesses on one tile before moving on to the next. We examined Hubble's effect on each level of the cache by gradually increasing the tile size.

We evaluated Hubble's effect on MM with eight different tile sizes: 16×16, .., 2048×2048. The input matrices are 2048×2048, and each element is a four-byte integer. This means tile sizes 64×64 and below fit within the L1 cache; tile sizes 256×256 and below fit within L2; and all remaining tile sizes exceed both cache levels. To evaluate the highest amount of interleaved memory-contention that Hubble may have with MM, we performed each multiply and add operation inside a method such that two trace points are produced for each step of MM. We also inserted a dummy tail recursion call so that the JIT compiler does not inline the method. For each tile size, we ran the experiment five times. We did not compare with ASMT because it was too slow.

Figure 6 shows the results. With Hubble's tracing turned off, we could not reliably observe any overhead. With Hubble's tracing turned on, for the smallest tile size that fits within the L1 cache, Hubble has a min / max / mean overhead of 41% / 70% / 54%. When the tile size still fits within the L2 cache at 128×128, the overhead increased slightly to a min / max / mean of 64% / 83% / 70%. Finally, when the tile size is much larger than the L2 cache, caching is no longer effective. In this region, the increased execution time when tracing is turned on did not deviate significantly from smaller tile sizes, but the amortized overhead decreased.

Thus, in the absolute worst case scenarios, Hubble indeed affects programs heavily optimized for caching and, to some extent, memory-bound programs. However, in practice, similar small methods invoked in a tight loop would be inlined and excluded from tracing, not to mention that such loop-tiling is unlikely to be used in an application's UI thread.

8.3 Startup Overhead Macrobenchmark

We measured Hubble's overhead on application startup, one of the most demanding but realistic workloads for a method tracing tool since it comprises hundreds of thousands of method calls in a short period of time. These methods perform data loading and processing to prepare the application's UI and are often optimized to ensure the application loads quickly [22].

Since the performance of the application startup process varies significantly in practice, we took additional measures to minimize variation across benchmark runs. Specifically, we ran all experiments while disconnected from the network, eliminating variance introduced by network connections. We launched the target application repeatedly until its startup time stabilized to within a maximum variance of 5% (without these measures, the normal variance can be as much as 100% as shown on the left hand side of Figure 7). Each application was launched programmatically, avoiding any extraneous touch input that would occur with manual interactions. The startup time was obtained from a syslog message that indicates the duration from when the application process launched to the time after the application's UI has been drawn on the screen. To force cold starts (where the application starts completely unloaded), we manually killed each application before starting it again. Furthermore, we performed tests in quick succession to encourage the scheduler to place the application process on the performance-oriented CPU core operating at the maximum clock speed.

We ran the benchmark on the three applications that had the most downloads in 2020 [6]: TikTok, WhatsApp, and Facebook. The results are presented as a box and whisker chart on the right hand size in Figure 7. As the figure shows, the measured startup times vary considerably. To determine if Hubble causes a statistically significant difference in application startup time in our tightly controlled test environment, we performed two single-tailed dependent (paired sample) t-tests with a significance level of 5%. The t-test on the results of tracing turned off produced a p-value of 14.25% and the t-test of tracing turned on produced a p-value of 33.18%, both of which exceed the 5% threshold. Thus, we cannot conclude that Hubble causes a statistically significant difference in application startup time. In contrast, ASMT increased the average startup time of the three applications by approximately 10 times.

Although application startup overhead fluctuates significantly under real world scenarios, the number of methods executed remains nearly constant. When disconnected from

the network, TikTok, WhatsApp, and Facebook filled 6.0 MB, 3.8 MB, 6.4 MB of Hubble's ring buffer respectively; this corresponds to roughly 400,000, 250,000, and 420,000 methods invocations. When connected to the internet, the ring buffer content increased to 14 MB, 5.1 MB, and 11 MB because the applications loaded the user's content. In all three applications, the 32 MB of ring buffer proved to be more than sufficient to capture the entire application startup sequence. In Huawei's Hubble deployment, the 32 MB trace buffer is able to store the duration of almost all application startup and intermittent performance anomalies that our support engineers have encountered.

The results of the macrobenchmark were also in-line with results from our automated performance-regression testing, as well as feedback from support engineers and application developers. Recall that in part one of Huawei's three-phase deployment process (§4.1), we ran automated tests across a large fleet of devices and any significant statistical deviation in the results will prevent a new build from being deployed. In the automated performance-regression tests, we measured the application startup-time (both cold and warm startup) of the 100 most-downloaded third-party applications in addition to all our own applications. We categorized startup times into increments of 500 ms and count the number of applications that fall in each increment. After Hubble's deployment, we have not recorded any statistically-significant changes in the number of applications in each bucket for both cold and warm startup times.

The choice of 500 ms may seem high; however, Farrer *et al.* showed that users do not feel any loss of control (i.e., that an application is not responding to their action) until the response times reach approximately 350 ms [19], and users feel like they have completely lost control when response times exceed approximately 750 ms. Thus, our QA teams (and others [43]) have found that 500 ms increments are a good categorization to qualitatively evaluate loading speed—response times below 500 ms are considered excellent, 500–1000 ms is considered good, and above one second is considered slow.

9 Experiences

Hubble was shipped in the production branch of Huawei's Android system in August, 2020. An early prototype was merged into the main development branch in 2019, and engineers have been using it since. Huawei also runs a beta program where users can receive new features before public release. There are currently tens of thousands of beta users, and Hubble is enabled on their daily-use devices. For other end users, Hubble can only be enabled with their express consent.

The trace collection frequencies and retention policies vary depending on the type of users, the level of consent granted, operating region and local regulations, and device model. Internal beta users may not have any data upload restrictions. However, there are often additional restrictions on public users (including those beta users that are outside of Huawei). A common policy is that each user device can upload at most three traces per week. Which three traces to upload is configurable. For instance, sometimes there is a targeted campaign to improve specific applications, so in that case, only traces of anomalies for those applications are uploaded; other times we collect traces for anomalies whose symptoms are extremely severe; or, in the default case, we collect the first three anomalies detected. Although three traces is a low threshold, with a large user base, we are usually able to collect one or a few traces for each important issue.

Besides debugging production issues, Hubble is equally useful for debugging problems discovered during automated testing. Before Hubble, developers used ASMT to debug performance regressions, but due to its overhead it could only be enabled when debugging. This is cumbersome, and many problems simply could not be reproduced while debugging or worse, new issues would appear with ASMT enabled. Now, whenever a performance regression is detected, Hubble's traces are automatically collected, helping developers quickly narrow down the root cause without reproducing the issue.

A happy accident of implementing the tracing in assembly was that we discovered a bug in ARM's reference design on an older CPU model. While optimizing and testing the tracing assembly on a large number of devices, we found that when a specific permutation of 32-bit assembly instructions is used together with the Generic Timer counter, a segmentation fault could occur on the out-of-order performance cores. The bug was confirmed by the chip design team and fixed in later CPU models. On the buggy CPU model, we work around the issue by using an `ISB` instruction to flush the CPU pipeline after fetching the Generic Timer counter.

10 Concluding Remarks

Call profilers are known to be useful in debugging, however, their use has been limited to the development environment as a result of their overhead. Hubble shows that by leveraging Android's on-device compilation process, a just-in-time flushing strategy, and together with careful system-level design and engineering, we can achieve a highly efficient tool that can collect fine-grained call traces even in production environments. Hubble has proved its usefulness by significantly easing engineers' postmortem debugging processes.

Jawa: Web Archival in the Era of JavaScript

Ayush Goel[1], Jingyuan Zhu[1], Ravi Netravali[2], Harsha V. Madhyastha[1]
[1]*University of Michigan*, [2]*Princeton University*

Abstract—**By repeatedly crawling and saving web pages over time, web archives (such as the Internet Archive) enable users to visit historical versions of any page. In this paper, we point out that existing web archives are not well designed to cope with the widespread presence of JavaScript on the web. Some archives store petabytes of JavaScript code, and yet many pages render incorrectly when users load them. Other archives which store the end-state of page loads (e.g., screen captures) break post-load interactions implemented in JavaScript.**

To address these problems, we present Jawa, a new design for web archives which significantly reduces the storage necessary to save modern web pages while also improving the fidelity with which archived pages are served. Key to enabling Jawa's use at scale are our observations on a) the forms of non-determinism which impair the execution of JavaScript on archived pages, and b) the ways in which JavaScript's execution fundamentally differs between live web pages and their archived copies. On a corpus of 1 million archived pages, Jawa reduces overall storage needs by 41%, when compared to the techniques currently used by the Internet Archive.

1 Introduction

URLs are brittle pointers to information on the web. Over time, a page may cease to exist at the URL where it was originally available [44, 62] or the content available at that URL might change due to the page being modified [58, 36].

Therefore, web archives play a key role in the web ecosystem, enabling users to lookup the content that existed at any particular URL at various times in the past. Web archives are used for a wide variety of use cases, such as web-data analytics, genealogical analysis, and even as legal evidence [40]. To support these uses, a number of organizations—cultural heritage institutions, national libraries, and public museums—operate web archives to ensure long-term preservation of content on the web. A recent survey estimates that there are 119 web archives in the United States alone [35].

The largest and most popular of these archives, Internet Archive (IA), has archived over 600 billion web pages to date, storing data in excess of 100 petabytes [13]. It repeatedly crawls web pages over time and saves many snapshots of every page. For every page snapshot, IA first downloads all resources (e.g., HTMLs, CSS stylesheets, JavaScripts, images) on the page). It stores these resources after rewriting all URL references to point to the copy hosted by the archive. When a user wants to later view any stored snapshot of a page, the user's browser loads the snapshot from IA in the same manner as it would load any page on the live web.

In this paper, we argue that this modus operandi no longer suffices due to the preponderance of JavaScript on modern web pages [18, 38, 53]. Specifically, the widespread use of JavaScript hinders web archives from satisfying two of their primary objectives: 1) to capture and save as much of the web as feasible, and 2) to ensure that archived page snapshots faithfully mimic the original page.

- **Higher operational costs:** First, the total number of bytes on the median web page has more than tripled over the last decade [10]. A significant contributor to this increase has been the increased usage of JavaScript. For example, across Internet Archive's copies of the home pages of 300 randomly sampled sites, we see that JavaScript accounts for 44% of the bytes on the median page in 2020, as compared to 20% in 2000 (§2). Since web archives are typically run by non-profit institutions with limited budgets, needing to store more bytes per page reduces the number of pages they can crawl and archive.
- **Poor page fidelity:** The archived copies of many JavaScript-heavy pages render with missing images and improperly laid out content (§2.1). This occurs due to the non-deterministic execution of JavaScript; when a user loads an archived copy of a page, the resource URLs requested by the user's browser can differ from those saved by the archive when it crawled the page. Consequently, the web archive returns errors for some of the requested resources. Due to the complex dependencies between the resources on a page [65, 34, 54], one failed resource fetch often has a cascading effect on the rest of the page load.

The challenge in holistically addressing both problems is that trying to reduce storage overheads by not saving some of the JavaScript found on crawled pages risks further degrading fidelity. A web archive could statically or symbolically analyze the JavaScript code on every page to identify what subset is necessary to preserve correctness in *all* potential loads of the page. However, the computational overheads of such methods [42, 48] render them impractical at the scale of a web archive, e.g., the Internet Archive crawls roughly 5000 pages per second [64]. To jointly address JavaScript's adverse impacts on storage and fidelity using computationally lightweight methods, we observe and leverage three fundamental ways in which JavaScript's execution on archived pages differs from that on the live web.

First, a significant fraction of JavaScript is dedicated to either sending user data to a page's origin servers or processing dynamically constructed server responses, e.g., to enable

users to post comments or to push notifications. Any such functionality cannot work on archived pages, and therefore, the associated code need not be stored by web archives. Fortunately, the JavaScript code on any page is typically partitioned into several files, and we find that most of the code that will be non-functional in the context of a web archive is cleanly compartmentalized into a subset of these files that exhibit identifiable patterns in their URLs. Consequently, we show that web archives can efficiently, and safely, prune unnecessary JavaScripts by relying on URL-based filters to identify and discard JavaScript source files.

Second, many lines of JavaScript code are executed only in certain control flows, e.g., when a page is loaded on a smartphone, and not on a desktop. But, among the various sources of non-determinism that dictate whether or not a specific line might get executed, some sources are absent in loads of archived page snapshots; clients maintain no state across loads and server responses for the same request URL do not vary. Moreover, a web archive should actively eliminate those sources of non-determinism which can cause clients to request different resource URLs than those crawled. Thanks to the resulting reduction in non-determinism, we find that much of the JavaScript code on an archived page will never be exercised in any load of that page, making it moot for a web archive to store such code.

Lastly, a critical use of JavaScript is to enable users to interact with a page after the page's load has completed. On live pages, identifying *all* the code used to support such interactions is generally challenging because the code that is exercised varies based on how users interact with the page. For example, the input given to a search bar determines the server's response; based on the number of search results, JavaScript for paginating the results may or may not get executed. In contrast, we find that the subset of interactions that do work on archived pages (e.g., navigational menus and image carousels) distinctly differ from those that do not with respect to the properties of the page state they access. This greatly simplifies the task of identifying the code necessary to preserve post-load interactions.

Based on our three observations, we design and implement Jawa (JavaScript-aware web archive), a system for crawling and saving web pages. Jawa enables web archives to save many more pages than they could today for the same cost, e.g., it reduces the total amount of storage necessary to store a corpus of 1 million web pages by 41%. Importantly, Jawa enables this reduction both while increasing the rate at which pages can be crawled by 39% and significantly improving the fidelity of archived pages: for the vast majority of archived pages, Jawa ensures that the page is rendered in a manner identical to how it was when the page was crawled, and all page functionality that can possibly work on an archived page does work. Source code for Jawa, including scripts to reproduce the key results in the paper, are available at https://github.com/goelayu/Jawa.

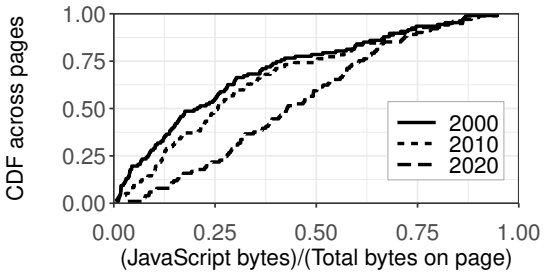

Figure 1: **Across the landing pages of 300 sites, distribution of fraction of bytes on the page accounted for by JavaScript.**

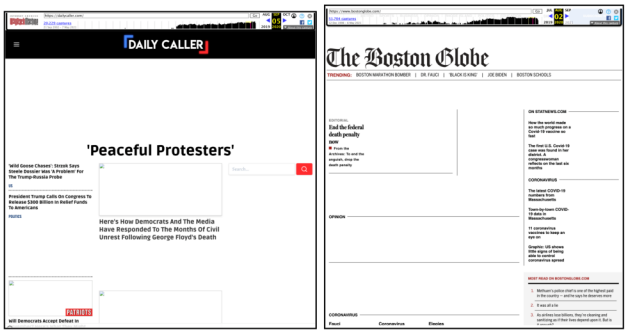
2 Background and Motivation

As mentioned earlier, the Internet Archive (IA) is the largest and most popular web archive in the world today. For every page that it crawls, IA stores all the individual resources on that page (such as HTMLs, CSS stylesheets, JavaScript files, and images) in the Web ARChival format (also known as the WARC format [22]). Client browsers can load archived pages from IA's Wayback Machine [24] in a manner identical to how they do on the live web. When the Wayback Machine receives a request for any resource, it looks up an internal index to locate the WARC record for this resource and then responds along with relevant HTTP headers. IA rewrites all resource files so that all statically embedded URLs point to IA's web servers. For URLs which are dynamically generated via JavaScript, IA rewrites them on the fly using client-side API shims.

This architecture sufficed when IA began operating two decades ago. However, the web today is very different. In particular, JavaScript (JS) has become significantly more common. For example, Figure 1 shows that JS accounts for 44% of the bytes on the median page today; up from 20% in 2000. In this section, we show that this increase in JS hinders the ability of web archives to meet their two primary objectives: 1) to crawl and capture as much of the web as possible, and 2) to preserve page fidelity, i.e., when an archived page is loaded by a user, it should ideally match the page as it was crawled, both in visual (how the page looks) and functional (user interactions supported on the page) aspects.

To support our claims, in this section (and in the rest of the paper), we consider pages from 300 sites, comprising 100 randomly chosen sites from each of three ranges from Alexa's site rankings: [1, 1000], [1000, 100K], and [100K, 1M]. Using these 300 sites, we construct two corpuses. $Corpus_{3K}$ contains one of IA's copies from September 2021 for 1 landing and 9 internal pages per site. $Corpus_{1M}$ contains 3500 page snapshots for each site out of all of IA's page snapshots from September 2020. Note that both corpuses contain a mix of old and new pages. Though both corpuses contain page snapshots which were archived in the last couple of years, many of these pages were created before then. This is because IA recrawls pages over time to track changes to page content.



(a) dailycaller.com [21] (b) bostonglobe.com [20]

Figure 2: **Examples of page snapshots loaded from IA.**

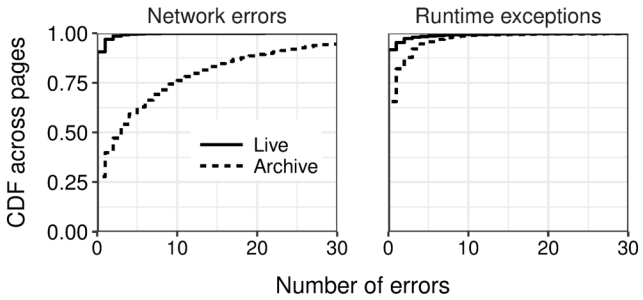


Figure 3: **Comparison of errors thrown during page loads from the web and from IA.**

2.1 Poor fidelity due to JS non-determinism

When a user loads a web page, scripts on the page often dynamically construct the URLs for many of the resources on the page. In doing so, JS execution can leverage various sources of non-determinism: client-side state (e.g., cookies, local-storage), client-characteristics (e.g., user-agent), random number generators, etc. When a user loads an archived page, these sources of non-determinism can potentially lead to a different set of resource URLs being requested compared to what was crawled by the archive. This, in turn, leads to two significant problems.

Failed fetches. First, IA returns a resource not found error (HTTP status code 404) for all resource URLs not stored at the archive, resulting in many archived pages rendering incorrectly. Figure 2 shows two examples of screenshots of page snapshots loaded from IA. In both cases, JS code on the page dynamically constructs the URLs of images to fetch by taking into account the screen size of the client loading the page. Since our client appears to differ from IA's crawler,[1] these pages end up being rendered incorrectly.

Runtime errors. Second, the execution of many scripts halts prematurely with runtime errors, which in turn leads to more resources going unfetched. We inspect the runtime logs generated by Chrome when loading the pages in $Corpus_{3K}$; specifically, the JavaScript console log and the network log. Figure 3 compares the number of errors seen in these logs during page loads from the web and when loading snapshots of these pages archived by the IA on the same day. Loading pages from IA results in more errors of both types. The total number of bytes that went unfetched because of these failed network requests cumulated to 5% and 45% of bytes on the median and 95th percentile page respectively.

2.2 High storage overhead

The more obvious downside of more JavaScript on web pages is that it increases a web archive's storage needs. To quantify this impact, we compute the total amount of storage required to store all the pages in $Corpus_{1M}$. Across all pages, we account for storing a single copy for every unique (resource URL, SHA-256 content hash) combination; IA applies similar deduplication to reduce storage overheads [23]. Despite the fact that scripts are often shared across pages (e.g., JavaScript libraries like jQuery are used by many sites and pages on the same site include a common set of scripts), JS accounts for 49% of all the bytes stored; resources of all other types (HTML, CSS, images, etc.) account for the remaining 51%.

Note that these numbers account for the size of textual resources such as HTML, CSS, and JS after compression. Also note that our corpus of a million pages appears to be large enough to approximate the utility of deduplication at scale because the fraction of total bytes accounted for by JavaScript plateaus after 750K pages.

Overall, the fact that scripts roughly double the amount of storage that a web archive needs to deploy is concerning because web archives are largely reliant on donations to cover their operational expenses [7]. For example, IA spends around $18 million dollars each year in operational expenses and attributes over 60% of its earnings to donations [14]. Needing to store more bytes per page means that an archive can store fewer pages for the same cost.

2.3 Downsides of alternate archival formats

To sidestep the shortcomings of IA that we have discussed thus far, a web archive could instead store and serve the end result of any page load, thereby preempting the need for clients to execute JavaScript.

Preserving post-load interactions. One such alternate archival format is to store a screenshot of the rendered page in the PNG or PDF format, as employed by private archiving institutions like Stillio [19] and PageVault [16]. However, many pages today enable users to interact with the content on the page, and storing screenshots of pages fails to preserve these post-load interactions [56]. Web developers enable such interactions by registering event handlers while a page is being loaded; these event handlers are triggered and executed when the user later interacts with the page. For example, modern pages often include carousels or sliders to display images and tabs to group information in separate categories; see, for example, the infographics on https://www.nytimes.com/interactive/2021/world/

[1] We look at the HTTP response headers of the archived resources to gather information about the client used by IA.

india-covid-cases.html. Event handlers are also used to enable users to navigate to other pages on the same site, e.g., the menu under the "Explore" button on https://www.coursera.org. Prior studies have shown that it is important to preserve such informational and navigational interactions even on archived pages [40].

We analyze the pages in *Corpus$_{3K}$* to determine how many contain interactions that should work on archived copies. Specifically, we load every page after instrumenting all scripts so that we can track all event handler registrations. We identify all event handlers which are associated with page elements whose attributes contain keywords such as menu, navbar, slider, carousel, dropdown, etc.; we consider 13 such keywords commonly associated with informational and navigational interactions. We find that 91% of the pages contained at least one such event handler.

Overhead of capturing JavaScript heap. Alternatively, client-local interactions enabled by event handlers could be preserved by storing a) every page's final rendered HTML, b) all resources referenced from this HTML (such as CSS and images), and c) the JavaScript heap, which stores custom, page-defined JavaScript state as well as native JavaScript objects [55]. However, modern browsers do not expose the entire JavaScript heap [43]; only the global scope of the heap is accessible using the "window" object. The closure scope, which is a non-global scope that is defined by any function and is accessible only by the nested functions that execute in that function's enclosed scope [51], is not accessible. This is a key roadblock because event handlers often access closure state; 47% of the pages in *Corpus$_{3K}$* contain at least one such handler (we describe how we perform the state tracking necessary to obtain this result in §4).

To access closure state, a web archive's crawler could statically analyze and rewrite the scripts on every page prior to executing them. However, we find that the combined overhead of performing the static analysis necessary to identify different scopes and running instrumented scripts inflates the time to crawl the median page in *Corpus$_{3K}$* by 2x; this overhead increases to 6x at the 99th percentile. Such computational overhead will significantly increase costs for a web archive crawling thousands of pages every second [64].

3 Overview

To overcome the adverse impacts of JavaScript on web archival, our high-level insights stem from two key differences between the loads of live and archived pages. In this section, we describe these differences and outline the challenges entailed in leveraging these differences.

3.1 Distinguishing properties of archived pages

No back-end origin server. Modern web pages include a range of functionalities which require communication with the page's origin servers, e.g., enabling users to post comments and having servers push updates to users while they are on a page. However, when a user loads an archived page snapshot, only that functionality on the page will work which can be served using the resources crawled when this snapshot was captured.

Limited sources of non-determinism. To deliver a dynamic user experience, many pages on the web adapt how they are rendered based on ① server-side state, ② client-side state (e.g., cookies, local storage), ③ client characteristics (e.g., user-agent, screen dimensions), and ④ "Date", "Random", and "Performance" APIs (we refer to these as *DRP* APIs for the sake of brevity). For example, after a script on a page fetches a JSON from the origin server, its subsequent control flow might depend on the contents of that JSON, which itself might be influenced by the contents of a client-side cookie. In loads of archived pages, the first two sources of non-determinism are absent: in response to the request for a particular resource in a specific page snapshot, a web archive will always serve the copy it fetched when crawling that snapshot; whereas, client browsers do not maintain any state across loads of archived pages.

3.2 Challenges

In order to leverage the above-mentioned differences to both improve page fidelity and reduce storage overhead in web archives, we need to answer several questions.

What are the causes of poor page fidelity? While some sources of non-determinism are absent in the loads of archived pages, the remaining sources – client characteristics, *DRP* APIs, and asynchronous execution of timer handlers and script fetches – still result in non-deterministic JS execution. Determining which of these factors is responsible for clients requesting different resource URLs than those crawled is key to eliminating failed resource fetches and the resultant runtime errors.

How to efficiently prune non-functional and unreachable code? In any page that it crawls, a web archive need not save any JS code that either relies on interactions with the page's origin servers or would never be executed in any load of the page (due to the absence of certain sources of non-determinism). One could potentially use methods like symbolic or concolic execution to perform reachability analysis and identify both unreachable code and non-functional code; the latter comprises code that is reachable from RPCs to origin servers. However, as reported in prior work [42, 49, 48], these methods for analyzing JS code are computationally expensive, requiring tens of minutes per page. Increasing the compute overheads of crawling to such a large extent would nullify any storage savings.

How to ensure code pruning does not hamper fidelity? While eliminating non-functional code reduces storage cost, doing so comes at the risk of inadvertently hurting fidelity. In particular, the code that is retained must function as it would if no code were discarded. Checking that any method identified for code elimination does preserve this property is

Goal	Observations	Section
Improve fidelity	APIs for client characteristics are the key cause for failed resource fetches	§4.1
	Differences in URLs due to *DRP* APIs can be resolved using server-side URL matching algorithms	
Prune non-functional code	Most of JS code which will not function on archived pages is in third-party source files, which can be identified based on their URLs	§4.2
	First-party scripts typically use third-party code cautiously, so that reliability of former is not dependent on availability of latter	
Prune unreachable code	*DRP* APIs typically have no impact on control flow	§4.3
	For event handlers associated with post-load interactions which work on archived pages, page state accessed is disjoint across handlers and user input does not influence control flow	

Table 1: **Overview of the main insights that influence our design of Jawa.**

non-trivial because browsers do not offer any APIs to extract runtime information that can be used to identify state dependencies between different scripts on any page.

3.3 Requirements

Based on all the considerations discussed thus far, we focus on three objectives.

- **High fidelity.** First, we seek to ensure that any archived page faithfully mimics the original page in two respects: 1) how the page is rendered, and 2) all functionality on the page which does not require communicating with the page's back-end servers works.
- **Low cost.** Second, we aim to enable a web archive to improve its coverage by reducing the amount of storage needed for any collection of page snapshots. In doing so, we seek computationally lightweight methods so as to minimize the cost overheads associated with maintaining the same rate of crawling pages as today.
- **Simplicity.** Lastly, our solutions must be simple to implement. In our discussions with the Internet Archive, they have emphasized that simplicity is key for any proposed changes to be viable in practice.

4 DESIGN

We describe our design of Jawa in three parts. We begin by describing how Jawa improves page fidelity by eliminating the sources of non-determinism which result in failed resource fetches while loading archived pages. Thereafter, we present the methods used by Jawa to identify what subset of crawled JS files need not be saved: first to eliminate non-functional code, and second to prune unreachable code while preserving post-load interactions. To enable Jawa's use at scale, the overriding principle that guides all aspects of our design is to minimize computational overheads by leveraging properties of JS typically found on the web; Table 1 provides an overview of our observations. Later (§7), we describe how a web archive which uses Jawa could potentially handle pages which do not satisfy these properties.

Analysis framework. Throughout this section, we use our custom JavaScript analysis framework (4.5K LOC) to study the properties of JavaScript found on pages in $Corpus_{3K}$. As in prior program analysis tools for JavaScript [49, 55, 38], our analysis framework first performs offline, static analysis of the JS in a page, converting each JS file into an abstract syntax tree (AST) representation. It then parses this AST to identify the different JS scope levels – local, block, closure, and global – and leverages this information to associate each JS variable to its corresponding scope. The framework also uses the AST to detect JS function invocations.

Building on these insights, our framework instruments pages with code that is triggered in each function invocation, and records the arguments to the function, all the closure and global scope variables read and written inside the function body, and the return value. Special care is taken to (1) record all accesses to the DOM, (2) track accesses of any global variable's properties via an alias, e.g., *"var a = window"* followed by a read of *"a.innerHeight"*, (3) identify DOM elements with registered event handlers and the corresponding handler functions, and (4) monitor and control the return values of browser APIs such as *"navigator.userAgent"*.

4.1 Improve fidelity by eliminating failed fetches

To ensure that users do not encounter failed resource fetches when they load archived pages, a web archive could rewrite every stored page to ensure that, when the page is loaded, the flow of execution and the return values of all browser APIs match those seen when the page was crawled.[2] If a web archive were to eliminate sources of non-determinism in this manner, we observe that fixing the schedule of execution cannot result in any loss of functionality; after all, developers of pages have no control over the client-side schedule of execution of asynchronous scripts. However, a page's developer can indeed ensure that code on the page behaves differently based on the results from browser APIs. Therefore, we seek to understand the impact of these APIs on resource URLs and eliminate only those sources of non-determinism which result in failed fetches during loads of archived pages.

Impact of different sources of non-determinism. We measure the impact of each source of non-determinism as follows. We first load our locally stored copies of all pages in $Corpus_{3K}$ with a desktop client. We then reload these pages mimicking a different client ("iPhone 6"). Mimicking a different client allows us to exercise different values of most

[2] Alternatively, a web archive could crawl every page under all possible combinations of non-determinism. Doing so is not only impractical, but would dramatically inflate compute and storage overheads.

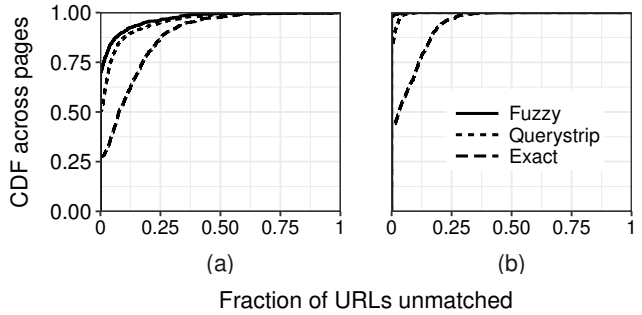

Figure 4: **For every page in *Corpus$_{3K}$*, fraction of resource requests which cannot be matched with any crawled resource. The impact of different URL matching algorithms is shown when the sources of non-determinism are (a) APIs for client characteristics as well as *DRP* APIs, and (b) only *DRP* APIs.**

client characteristics, such as user-agent, screen dimensions, and OS. We reload all pages once more, this time matching the client characteristics used in the original load.

On 72% of pages, at least one different resource URL was requested in the second load compared to the first load; these two loads differ in the values for both APIs for client characteristics and *DRP* APIs. Whereas, when comparing the third load to the first, which differ only with respect to *DRP* API values, the corresponding fraction was 52%. Note that, in both cases, even one failed resource fetch can have a cascading effect, resulting in many other resources going unfetched.

Variance in resource URLs due to non-determinism results in failed network fetches only if a web archive (like IA) expects requests from clients to specify URLs which are identical to the ones crawled. However, across loads of a page, if the same resources are being requested using different URLs, it might suffice for the web archive to employ a better algorithm to match URLs requested to those crawled.

To check if this is the case, we consider two URL matching algorithms used in prior work: ① *querystrip*, where the query string in any URL (i.e., the portion of the URL beyond the delimiter '?') is stripped before initiating a match [57], and ② *fuzzy matching*, which leverages Levenshtein distance [45] to find the best match for any given URL [26]. Querystrip relies on the fact that query strings are typically used for updating server-side state, and they do not influence the content of the response. Fuzzy matching accounts for cases where non-determinism across loads results in simple string transformations of the URLs for the same resources. In any page load, we match URLs in the order they are requested, and we match any requested URL against those crawled URLs that have not already been matched.

Figure 4(a) shows that, on many pages, a significant fraction of URLs were unmatched with both algorithms, when APIs for client characteristics were a source for diverging URLs. This is because, when client characteristics differ, often the *number* of resources fetched on the same page changes. For example, www.nytimes.com fetches the JavaScript file *player-embedded.js* on mobile clients to enable video players, whereas it fetches no such scripts on desktop clients.

Digging deeper into *DRP* APIs. In contrast, when *DRP* APIs are the only source of non-determinism, Figure 4(b) shows that either URL matching algorithm suffices to eliminate almost all failed resource fetches. However, this might be the case only because we compare two loads of every page, and the return values of *DRP* API invocations did not sufficiently differ to have an impact.

To capture the effects of all possible return values of *DRP* APIs, we turn to concolic execution [37, 61, 42], a variant of symbolic execution which executes programs concretely (rather than symbolically) while ensuring complete coverage of all control flows. We modify a prior concolic execution tool [42] to only track control flows influenced by *DRP* APIs. We then randomly sample 300 pages from *Corpus$_{3K}$* because it takes around 20 minutes per page with this tool. On all pages, *DRP* APIs had no impact on control flow. Thus, comparing any two loads of a page suffices to examine the divergence in URLs across loads due to these APIs.

Takeaways. These results influence our design of Jawa in two ways. First, we instrument all scripts on any page so that, when clients execute these scripts, all APIs for client characteristics return the same values as when the page was crawled. Compared to a thin-client model where a web archive serves requests for pages by executing page loads on behalf of users [26], our approach of letting users execute page loads on their devices reduces server-side overheads. Second, we do not need to account for any differences across loads in *DRP* APIs because the impact of these differences can be accounted for with server-side matching of requested URLs to crawled URLs.

Note that we choose to patch all invocations of client characteristic APIs, and not just the ones which influence the URLs fetched. This is because, even if a particular invocation of an API does not impact which URLs are fetched, it can impact the reachability of code which assumes that state dependent on the client's type has been setup earlier in the page load. Hence, if different API invocations return inconsistent values, this could exercise code which accesses uninitialized state, resulting in runtime errors.

4.2 Pruning non-functional code

We now turn our attention to reducing the storage overhead of JavaScript on web archives. Jawa's crawler uses two complementary approaches to take advantage of the two previously mentioned properties which distinguish archived page snapshots from pages on the web. The key consideration in both cases is to ensure that pruning any JavaScript code does not affect the execution of the remaining code.

Characteristics of non-functional code. Our first approach for pruning JavaScript code is based on two observations about the code which will not work on archived copies of pages, i.e., code which relies on clients interacting with

origin servers. First, on a typical page, we find that most of such code is compartmentalized into a few files, rather than being evenly spread across all JavaScript source files on the page. As we will show later, these files do not contain any code that is worth preserving. Second, functionality which will not work on archived pages is largely implemented by third-party scripts. Even though some of the functionality which relies on communication with origin servers (e.g., intra-site search, login) is implemented by the first-party origin, we only focus on discarding third-party files, for reasons discussed shortly.

The implication of these observations is that, to identify most of the non-functional JavaScript code in archived pages, it is unnecessary to perform any complex code analysis. Instead, it suffices to assemble and use a "filter list" which captures the features distinctive to the URLs of scripts containing non-functional code; when crawling pages, a web archive would simply have to discard (and not even fetch) any script whose URL matches the filter list.

For example, via manual analysis of the URLs of all scripts seen in $Corpus_{1M}$, we assemble a filter list comprising 45 rules. We consider those script URLs which are included on many pages. For each such popular script, we first visit the domain on which the script is hosted to understand the services offered by that domain. In cases where a domain hosts scripts of many kinds, some of which are important to retain even on archived pages, we examine the script's content to determine its utility.

Every rule in our list matches URLs at one of three granularities: 1) domain, i.e., filter any file hosted on that domain (e.g., *"zephr.com"* enables support for user subscriptions), 2) file name, i.e., filter scripts if the file name matches, regardless of the domain hosting the script (e.g., *"jquery.cookie.js"* is used for cookie management), and 3) URL token, i.e., filter scripts if a specific keyword appears anywhere in their URL (e.g., *"pagesocial-sdk"* and *"recaptcha"*).

Recall that $Corpus_{1M}$ comprises page snapshots crawled from the Internet Archive, which already discards resources that users often block on the live web, e.g., ads. In contrast, our filter list aims to prune scripts which implement functionality that is important to preserve on the live web, but will not work on archived copies. Moreover, since a few popular third-party service providers are used by the vast majority of websites [46], we find that we only need to add 6 rules to our filter list to account for pages on 300 additional sites beyond the 300 sites included in $Corpus_{1M}$.

Filtering has no impact on fidelity. Discarding a subset of the JS files on a page might, however, break the execution of code in files that are retained. Therefore, we study the impact of filtering along two dimensions: 1) visual (i.e, does the page look the same?), and 2) functional (i.e, are post-load interactions that will work on archived pages unaffected?)

We load every page in $Corpus_{3K}$ with and without filtering enabled. We take a screenshot after every page load.

```
<script src="https://js.sentry-cdn.com/7bc8b.min.js" </script>
<script>
        if (window.Sentry) {
            window.Sentry.onLoad(function() {
                window.Sentry.init({
                    maxBreadcrumbs: 30,
                environment: 'prd', });
            });
        }
</script>
```

Figure 5: **Code snippet from www.nytimes.com where the main frame first fetches a third-party JavaScript file hosted on www.js.sentry-cdn.com and then cautiously invokes a function from it inside an if condition.**

Leveraging our JavaScript instrumentation described earlier, we also 1) identify all event handlers registered during each page load, 2) trigger all event handlers after the page load completes, and 3) track all values read or written from the JavaScript heap and DOM by these handlers.

First, when we compare the screenshots for every page with and without filtering, we observe that these screenshots differ in the value of at least one pixel for 109 of the 3000 pages in $Corpus_{3K}$. Upon manual examination of these 109 pages, we find that all differences are either due to animations or because *DRP* APIs result in a different timestamp on the page. Second, for all event handlers registered by the unfiltered files, we find 35 pages on which at least one value accessed by at least one of these event handlers differed across loads with and without filtering. Again, these differences were not consequential: they were due to differences in timing information, e.g., some event handlers log the times at which their execution starts and ends.

A key reason for these positive results, which show that Jawa's filtering has no impact on the fidelity of the code retained, is our explicit choice to only consider third-party source files for filtering. On the one hand, most third party scripts are self-encapsulated, i.e., the code in these files only interacts with itself or the files it subsequently fetches. On the other hand, as shown in Figure 5, first-party scripts typically invoke third-party code cautiously, so that the former is unaffected in the off chance that the latter fails to be fetched.

Note that one cannot simply eliminate *all* third-party scripts; that would render dysfunctional many post-load interactions which do work, and are important to preserve, on archived pages. As we show later in our evaluation (§6), while discarding files which match our carefully curated filter list enables significant storage savings, doing so preserves all navigational and informational interactions.

4.3 Prune unreachable code

In the Javascript files which do not match Jawa's filter list, many lines of code will never be executed in *any* page load. This is because 1) some sources of non-determinism are absent in loads of archived pages (§3.1), and 2) Jawa elim-

inates non-determinism caused by asynchronous execution and APIs for client characteristics (§4.1). Furthermore, we found that *DRP* APIs have no impact on control flow. Yet, identifying all reachable code remains challenging: beyond the code executed while crawling the page, we also need to retain the code for users' post-load interactions.

Challenges in preserving interactions. Post-load interactions are enabled via event handlers which are registered while a page is being loaded. Every event handler is associated with a specific DOM node on the page, and is bound to a specific action that would trigger the handler, such as a click, scroll, mouse hover, etc.

The code that is exercised when an event handler on a page is invoked can vary as a function of a) the order in which the user interacts with different elements on the page, b) the inputs that the user provides to these events [30], and c) the return values of browser APIs. It is easy to see how the latter two can impact code reachability, e.g., in response to a search query, the number of search results can influence certain client type-specific UI features, such as the option of splitting the results across multiple pages. The order in which events are triggered can impact the execution of some handlers if the state read (from the DOM or JavaScript heap) by one handler could have been written to in a prior invocation of this or another handler. In particular, since we only care about identifying reachable code, only read-write dependencies which impact branch conditions are of interest.

We analyze the impact of these sources of non-determinism on the event handlers found on pages in $Corpus_{3K}$. We capture the state accessed by event handlers as described earlier in §4.2. For each event handler on a page, we check whether there is a read-write state overlap with itself or with any other event handler on the page, and if there was an overlap, whether this state is used in a branch condition. We also identify all handlers which accept user inputs; these include mouse events (e.g., click, mouseover, mouseon), keyboard inputs (e.g., keyup, keydown), and text inputs (e.g., "INPUT" or "FORM" DOM nodes). When we invoke each such handler, if a branch statement is executed, we conservatively conclude that the handler's inputs could impact the control flow of the handler.

On each page, we compare two sets of event handlers: those which work on the live version of these pages, and the subset which will work on archived copies. The former set comprises all handlers registered when we load the page without filtering. We identify the latter set of handlers by loading every page with Jawa's filtering enabled, and ignoring handlers which interact with origin servers (i.e., they are registered on either "INPUT" or "FORM" DOM nodes with a corresponding "action" attribute). On the median page, 14 event handlers work on the live page and 7 on the archived copy. At the 90th percentile, the corresponding numbers are 170 and 44.

Impact of order. On 40 of the 3000 pages in $Corpus_{3K}$, at least one pair of handlers that work on the live page had a read-write dependency which could affect the control flow of one of these handlers. In contrast, we found no such case when focusing on the handlers which work on archived pages. This stark difference is because dependencies between handlers arise on live pages predominantly due to analytics, e.g., handlers registered with certain DOM nodes update locally maintained state to track if the user interacted with those nodes; when the user navigates away from the page, another handler reads this state and sends this information to back-end servers if the user did interact with those DOM nodes.

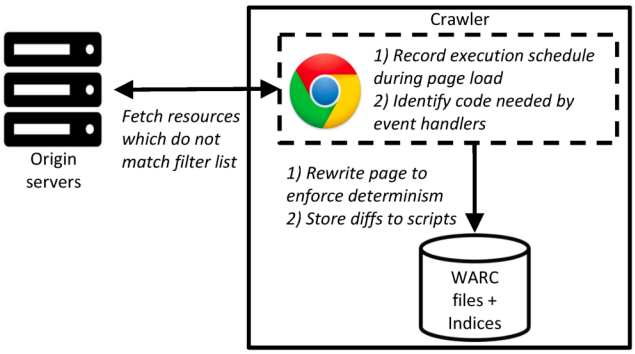

Figure 6: **High-level overview of Jawa.**

Impact of user input. Across all pages, none of the event handlers which work on archived copies read inputs which influenced branch predicates. Whereas, when we loaded all pages without filtering, 1134 of the 3000 pages had at least one handler which interacted with back-end servers. In such cases, the responses from servers could potentially impact what code gets executed on the client.

Impact of browser APIs. As discussed earlier (§4.1), Jawa eliminates non-determinism caused by APIs for client characteristics. That leaves *DRP* APIs. Among the handlers that work in an archived context, 449 of the 3000 pages had at least one handler which invoked an API from either "Date" or "Math.random". All the invocations of "Math.random" APIs were due to the jQuery library assigning unique identifiers to elements inside its `ElementSelector` function [15]. Whereas, the "Date" API was used only for logging the start and end time of handler executions. Thus, in all of these cases, *DRP* APIs did not impact the reachable code for any event handler.

Takeaways. These results demonstrate why prior work which aims to identify code reachable by event handlers performs complex JavaScript program analysis [30, 59]. In contrast, we find that no source of non-determinism impacts the code executed by handlers which work on archived pages. Therefore, on any page, to identify the code necessary to retain for post-load interactions to work, it suffices for Jawa to invoke every handler once and save the code that is executed.

4.4 Summary

Put together, our observations on the differences between loads of archived and live pages enable Jawa to use a fairly simple methodology to crawl and save pages, as shown in Figure 6. For every page that it crawls, Jawa fetches all those resources which do not match its filter list. For the remaining files, it ① injects code to identify what code was executed during the page load and in what order, and ② triggers every registered event handler using default input values (e.g., the default x and y coordinates for a mouse click event is 0,0) and identifies the code executed. Finally, it stores those portions of the page that are exercised in either step above. It instruments the retained code so that, when users load the page, their browser follows the same execution schedule and uses the same client characteristics.

5 IMPLEMENTATION

Implementing a web archive involves several considerations which are outside the scope of this paper, e.g., distributing data across servers, detecting and coping with hardware failures, etc. Our implementation focuses on the aspects of a web archive addressed by Jawa (Figure 6), namely crawling and storing page snapshots. We also describe the impact of Jawa's design on serving page snapshots to users.

5.1 Crawling pages

When crawling a page, Jawa's crawler (1.2K LOC) uses a Node.js based man-in-the-middle proxy to interpose on all requests/responses. The proxy uses the Esprima [9] and BeautifulSoup [4] libraries to instrument JavaScript and HTML files as they are fetched. Jawa references the filter list for every outgoing request and, using regular expression matching, blocks the request for any resource whose URL matches any of the rules in the filter list. For all the remaining resources fetched, Jawa selectively instruments JS files prior to their execution. This instrumented code, upon execution, enables Jawa to 1) interpose on all browser APIs, 2) track the subset of JS code executed (in terms of JS functions), and 3) helps enumerate all event handlers registered on the page. The instrumentation overhead incurred by the crawler is significantly lower compared to when tracking all state accesses (§4).

5.2 Storing page snapshots

For every page that it crawls, Jawa saves only a subset of the JavaScript code on that page. Consequently, when the same JavaScript file (e.g., a library) is included on many pages, it is often the case that different subsets of this file need to be stored as part of different page snapshots, thereby preempting simple file-level deduplication, as used by the Internet Archive today [23].

Our solution is to store every unique file as a set of partitions; each partition represents a different disjoint subset of the file: from a specific start byte offset to an end byte offset. When Jawa crawls a new page snapshot, for every JavaScript file crawled that is not filtered, it identifies the subset of code in this file relevant for this snapshot. It then looks up the crawl index (Table 2) to determine if this subset is already covered by the byte ranges in this file that have previously been stored. The crawler creates new WARC records for portions of the file that have not been previously stored and appends new entries to the crawl index. The crawl index is processed asynchronously to produce the serving index (like is the case today with Internet Archive).

Crawl index		
	Key	*Value*
IA	URL	List of (content hash, WARC file ID) tuples
Jawa	(URL, content hash)	List of (start byte offset, end byte offset, WARC file ID) tuples

Serving index		
	Key	*Value*
IA	(URL, timestamp)	(WARC file ID, byte offset)
Jawa	(URL, timestamp)	List of (WARC file ID, byte offset) tuples

Table 2: **Comparison of indices maintained by IA and Jawa.**

5.3 Serving page snapshots

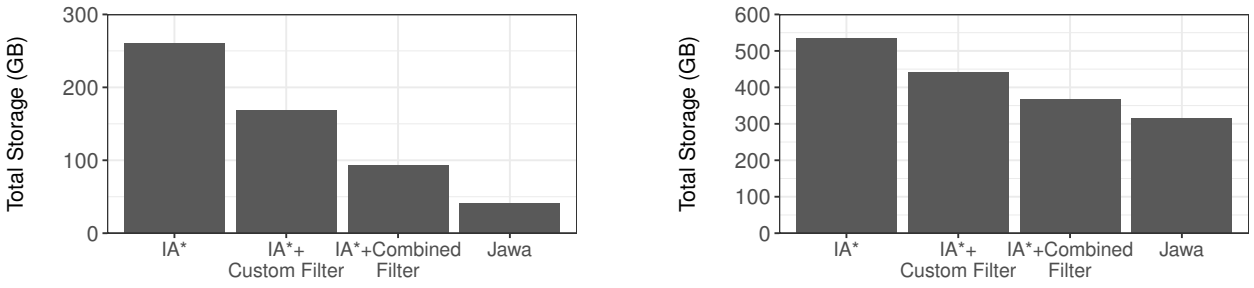
The implication of storing any JavaScript file's contents as above is that, when a client requests for a file while loading a page snapshot, one does not know which of the partitions stored for this file are relevant for this particular snapshot. Instead, a web archive which uses Jawa can return the union of all stored partitions for the requested JavaScript file; after all, the portion of the file needed for any snapshot is a subset of the stored partitions. Since the size of this union is at most equal to the size of the original file, clients will have to fetch no more bytes than they do today.

6 EVALUATION

We evaluate Jawa with three metrics: storage (to store crawled resources and to store indices), fidelity (similarity of archived page snapshots to the corresponding original pages) and performance (both for crawling and serving). In all cases, we compare against the corresponding techniques currently in use by the Internet Archive (§2), which we refer to as IA*.[3] In some cases, we also break down the utility/overhead of each of Jawa's components. The key findings from our evaluation are as follows:

- Jawa reduces the storage needed for our corpus of 1 million page snapshots by 41%. This reduction stems from Jawa discarding 84% of JavaScript bytes.
- Despite this significant reduction in storage, on a random sample of pages, all event handlers that one would expect to function on archived pages continue to work.
- When we mimic loads of archived pages from IA, at least a quarter of resource fetches fail on more than 10% of pages.

[3] IA* refers to us mimicking the techniques used by IA.



(a) JavaScript resources (b) All resources

Figure 7: **Total storage necessary to store corpus of 1 million page snapshots.**

Whereas, on over 99% of pages, Jawa eliminates all failed network fetches and ensures that the set of resources requested from the archive match those crawled.

- Crawling throughput with Jawa improves by 39%, thanks to our use of lightweight techniques for code analysis and filtering of JavaScript files.

6.1 Storage

6.1.1 Storage for resources.

To begin, we consider the total amount of storage needed to store the resources in our $Corpus_{1m}$ corpus. We crawl all of these page snapshots from IA using our crawler (§5). On each page, Jawa's crawler only fetches third-party JavaScripts which do not match its filter list. Apart from our manually curated filter list for pruning code which will not function on archived pages, we also leverage the open-source filter list from EasyList [8], which is widely used by many browser extensions to identify ads and analytics. In every script that it does fetch when crawling a page snapshot, Jawa's crawler identifies the subset of code necessary for this snapshot and stores the portion of this subset that is not covered by the subsets of this file previously stored.

Figure 7(a) shows that Jawa stores 40 GB of JavaScript across the 1 million pages, a reduction of 84% compared to IA*. Of course, to store the entire corpus, all resources on every page snapshot need to be saved, not only JavaScripts. For resources other than scripts (images, CSS, HTML, fonts), Jawa offers no storage benefits; it stores them exactly as IA*. Yet, we see a 41% reduction in total storage: 535GB with IA* to 314GB with Jawa (Figure 7(b)). This is because, as seen earlier in §2.2, JavaScript files account for 49% of all the bytes across all pages, even after file-level deduplication. Since 63% of the more than 140 PB of data stored by IA is devoted to web page snapshots [12, 13], we estimate that Jawa can reduce IA's storage needs by 35 PB.

Sources of storage benefits. Storage savings enabled by Jawa stem from a combination of not storing filtered files and pruning unreachable code. When we break down the impact of the filter lists we use, Figure 7(a) shows that our custom filter list alone reduces the total amount of JavaScript saved by 36%, and EasyList's rules result in a further reduction of 28%. Jawa also significantly reduces storage needs by eliminating unused code: the difference between the two right most bars in Figure 7.

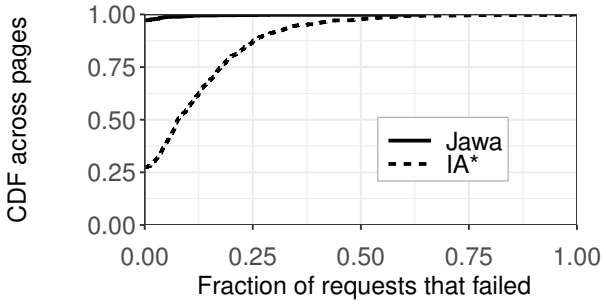
6.1.2 Storage for indices

In addition to storing crawled resources, both IA* and Jawa also need to store the crawling and serving indices (Table 2). The former enables the crawler to not store duplicate content, whereas the latter enables lookups of requested resources when serving page snapshots. For our corpus of 1 million page snapshots, we find that size of both indices is marginally smaller (15%) with Jawa than with IA*. First, for most script files, Jawa ends up having to store a single WARC record; for such files, after the first time a subset of the file's code is stored, all subsequent page snapshots which include the same file end up needing the same subset. Second, the increase in index entries for other files (for which multiple subsets end up being stored) is offset by the elimination from the index of filtered files.

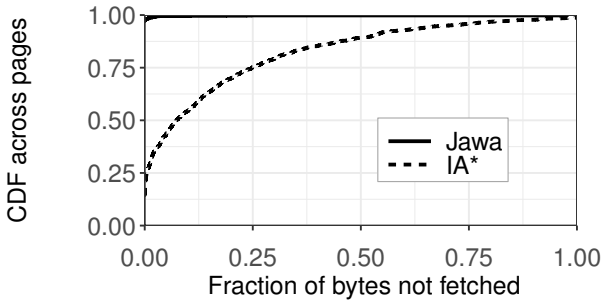
6.2 Fidelity

To evaluate Jawa's preservation of page fidelity, we crawl all 3000 pages in $Corpus_{3K}$ from the live web. We perform these crawls on a desktop, once with Jawa's crawler, and once without using any of its methods. We then load these pages from the two local copies, mimicking a different client ("iPhone 6"). When using page snapshots saved by Jawa, we match requested URLs to crawled URLs after stripping query strings.

Resource fetches. We first evaluate Jawa's impact on fidelity by examining the discrepancy between the set of resources stored for any snapshot and the set of resources fetched by a client when it loads that snapshot. Figure 8(a) shows that, while 7% of network requests return a 404 on the median page in loads of IA*, this fraction drops to 0% with Jawa. On the 95th percentile page, the corresponding fractions are 36% with IA* and 0% with Jawa. Consequently, Figure 8(b) shows that, while 10% of stored resources are not fetched on the median page when mimicking loads from IA, this fraction drops to 0% with Jawa. On the 95th percentile page, the corresponding fractions are 75% with IA* and 0% with Jawa.



(a)



(b)

Figure 8: **When snapshots of 3K pages are served, (a) number of resources requested by client which are not stored, and (b) fraction of resources stored for a snapshot which are not fetched by the client.**

Visual analysis. To check if the pages served by Jawa are identical to the ones it crawled, we take a screenshot of every page both when crawling it and when we reload it from our local copy. We then compare every pair of screenshots to check if the value of every pixel matches. Apart from the visual differences accounted for by animations and non-determinism in 54 pages, both screenshots matched exactly for every other page when using Jawa. Since loads of IA* do not patch APIs for client characteristics, differences in screen dimensions between clients make it moot to compare screenshots.

Interactions. Finally, to evaluate Jawa's impact on post-load interactions, we randomly sample 150 pages. For each page, we load the versions that would be served by IA* and by Jawa. To isolate the impact of Jawa's techniques, we also consider an intermediate design point (Only filter) where we only use Jawa's filtering but do not prune unreachable code.

We categorize all event handlers on every page into three types: 1) navigational, i.e., they help in navigating either to a different page (e.g., a navigational bar) or within the page (e.g., a scroll-to-bottom button), 2) informational, i.e., they help make more information available (e.g., carousels or tabs), and 3) transactional (e.g., login or post buttons). On archived pages, transactional event handlers will not function. So, on each of the 150 sampled pages, we manually trigger all event handlers that belong to the first two categories. All 124 navigational interactions and 100 informational interactions worked as expected in all three loads: IA*, Only filter, and Jawa. Key to preserving these post-load interactions are Jawa's carefully curated filter list for discarding non-functional code, and its methods for identifying and retaining all reachable code. In contrast, if we discard all third-party files or if we use Jawa's filter list but save only the functions registered as handlers, then only 42% of these interactions work in the former case and 10% in the latter.

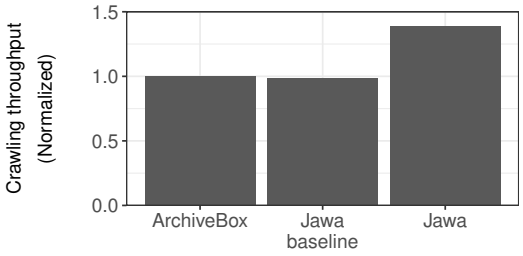


Figure 9: **Comparison of crawling throughput, normalized to that offered by ArchiveBox.**

6.3 Performance

Crawling throughput. IA's production crawler is not public to the best of our knowledge. Therefore, we turn to two open-source crawlers: Brozzler [5] and ArchiveBox [3]. Brozzler is operated by IA, and used alongside their production crawler. Whereas, ArchiveBox is a very active and commonly used crawler by individual archivists (over 12K stars on GitHub). We find that Brozzler is 20% slower than ArchiveBox because of the latter's more efficient implementation of their headless Chrome interface. We also note, that on a server with 32 cores and 128 GB RAM, we were able to crawl 5000 URLs in 15 minutes with ArchiveBox. With this crawling throughput, IA would need to dedicate 900 such servers for crawling pages, which is comparable to the number of servers they currently claim to use [11]. Therefore, we evaluate Jawa against ArchiveBox.

Figure 9 shows that Jawa's crawler offers throughput comparable to Archivebox when all of Jawa's techniques are disabled (Jawa baseline). Enabling all the methods in Jawa's design increases our crawler's throughput by 39%.

To breakdown the overheads, we measure the latency of each of the techniques used by Jawa's crawler in isolation, namely 1) filter: filtering JavaScript files, 2) code injection (CI): instrumenting the code in fetched scripts, 3) dynamic tracking (DT): dynamically tracking code execution and event handler registration, and finally 4) event triggering (ET): invoking event handlers and capturing the code executed. Figure 10 shows that not having to fetch filtered scripts completely offsets the overheads of all other techniques. Not only does Jawa's crawler not fetch any scripts which match its filter list, but all the resources that would have been fetched by the filtered files also go unfetched; this latter set of files often do not match the filter list.

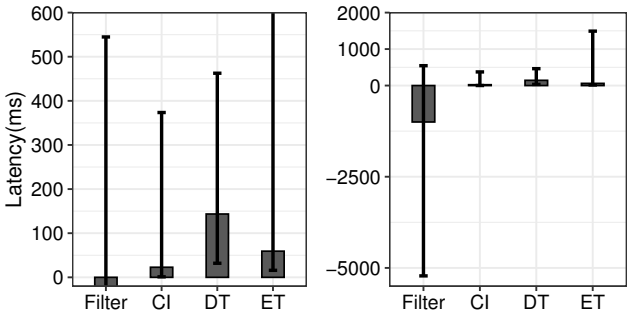

Figure 10: **Benchmarking the overhead of techniques used in Jawa's crawler. Bars plot median across pages, and whiskers plot 10^{th} and 90^{th} percentiles. Graph on the left zooms in on the yrange 0 to 500ms in the graph on the right.**

Index	I/Os per page with IA*		Reduction in I/Os per page with Jawa	
	50^{th} %ile	90^{th} %ile	50^{th} %ile	90^{th} %ile
Crawling	3	15	1	5
Serving	41	107	1	3

Table 3: **Writes on crawling index and reads on serving index; values shown for 50th and 90th percentile page on median site.**

Jawa also impacts crawling throughput by requiring more writes to the crawling index because, unlike IA*, it spreads the code in some script files across multiple WARC records. We cannot quantify the performance impact of doing so since our setup does not match a production archive like IA. However, we can quantify the number of additional writes that Jawa performs to the crawl index, compared to IA*. Table 3 shows that the number of writes to the crawl index *decrease* with Jawa; due to filtering, fewer files are crawled.

Serving performance. When serving page snapshots, Jawa's only overhead is in needing to potentially lookup multiple WARC records in order to respond to a request for a JavaScript file. We find that page load times on IA's Wayback Machine are proportional to the number of resources on the requested page snapshot, or equivalently, the number of WARC records that IA needs to lookup to serve the snapshot. Therefore, as a proxy for estimating Jawa's impact on user-perceived performance, we examine the increase due to Jawa in the number of WARC records read when serving page snapshots. Table 3 shows that the number of index lookups decrease with Jawa; again, thanks to filtering, a client has to fetch fewer files per snapshot.

7 Verifying Page Properties

Jawa's methods for pruning non-functional and unreachable code are based on three properties that we found to be true on archived web pages:

- *DRP* APIs have no impact on control flow
- Discarding third-party JavaScript files which match a manually curated filter list has no impact on fidelity
- For post-load interactions which work on archived pages, the event handlers which power them do not have read-write dependencies that influence branch conditions

All of these observations are rooted in our empirical analysis of a variety of web pages in *Corpus$_{3K}$*: 9 internal pages and 1 landing page in each of 300 sites, which span a wide range of rankings among Alexa's top million sites. However, we recognize that not all pages may abide by these properties. For example, consider a page which shows the time until a deadline and switches the font color when the time remaining is below a threshold; such a page would violate the first property listed above.

To handle such cases, we observe that web archives do not crawl every page just once; they repeatedly recrawl pages over time in order to capture changes to every page's content. For any given page, in some crawls of the page, a web archive can disable all of Jawa's methods and check if the properties expected to be true indeed hold on this page. For example, like the analysis we performed (§4), the web archive can instrument scripts to track state accesses, and then examine dependencies between event handlers and between files which do or do not match the filter list. It can also perform concolic execution to verify that *DRP* APIs have no impact on control flow.

The key to restricting the compute overheads of these heavyweight analyses is to run them on a sample of snapshots. To determine the sampling rate, a web archive can leverage properties that are stable across a page's snapshots. For example, upon analyzing all of IA's snapshots for 300 randomly chosen pages, we observe that the median page has the same number of runtime errors for an average of 53 snapshots. Therefore, once in every 53 crawls of any of these pages, a web archive can disable filtering and check if the number of runtime errors matches prior crawls where filtering had been used. If there is a mismatch, the web archive can disable the use of filtering for this page going forward. Since Jawa serves any JavaScript file to users as the union of all partitions of this file stored across crawls (§5), disabling filtering in one crawl of the page will also benefit all prior crawls of that page.

8 Discussion

How future proof is Jawa? In the immediate future, recent trends [18] indicate that the amount of JS on pages will continue to increase, making it important for web archives to adopt Jawa's techniques for pruning JS and for eliminating fidelity issues due to the non-determinism introduced by JS. In the long term, we expect that the principles that dictate Jawa's design will continue to hold: to serve pages with high fidelity, 1) archives must account for non-determinism, and 2) a large fraction of JS can be discarded with no risk.

Optimize already archived pages. Jawa's simple techniques make it highly amenable to be used with pages that have already been archived. First, a web archive can sig-

nificantly reduce its storage needs by discarding all JS files that match Jawa's filter list. Second, the web archive can rewrite the HTML of every archived page to include a custom script which will enforce the same client characteristics as the crawler when users load the page. The only aspect of Jawa that would be hard to use on already archived pages is the elimination of unreachable code, as that requires invoking all event handlers on every page.

9 Related work

Impact of JavaScript on web crawlers. Prior work has shown that it is important for web crawlers to execute JavaScript when crawling pages, both in the context of web archives [31, 32, 33] and web search engines [1], else many important resources on a page will often go uncrawled. Our work highlights that, due to the non-deterministic execution of JavaScripts, archived pages often have poor fidelity even when pages are crawled using a browser which executes all scripts on every page.

Beyond executing JavaScripts while crawling a page, systems like Conifer [6] also save all resources on the page that are fetched while the user is interacting with the page. However, such systems are designed for private web archival, i.e., a user saves a page and its constituent resources for the user's own personal use later. If users load a page archived by a different user using a different device/browser, they will face the same fidelity issues seen on the Internet Archive.

Coverage of web archives. Many measurement studies [27, 28] have demonstrated that web archives are far from comprehensive in archiving all pages on the web. Prior work [50, 41] has attempted to address the incompleteness caused due to large portions of the web not being openly available (e.g., behind paywalls) and requiring user logins (e.g., social media). In contrast, we seek to enable web archives to improve their coverage by reducing the costs associated with archiving any corpus of pages; thereby, for the same budget, a web archive can crawl and save more pages.

Supporting bulk processing of archives. Jawa focuses on enabling web archives to support the use case where users load individual page snapshots and interact with them. Alternatively, web archives are used by researchers to perform large scale analyses of historical information. Xinyue et al. [64] demonstrate the performance penalties of the WARC format for such batch processing workloads, and many systems [47, 2, 39] have been developed to enable programmatic analysis of large corpuses without needing to access each individual resource on every page.

JavaScript record and replay systems. A number of prior systems [29, 52, 60] enable users to record and replay JavaScript execution, both in the context of browsers [29] and independent JavaScript programs [60]. These record and replay tools are critical for debugging JavaScript based errors. Therefore, to ensure high fidelity replay, all of these systems identify and patch all sources of non-determinism to match the recorded version. In contrast, we analyze the individual impact of each source of non-determinism on the URLs fetched and patch them accordingly.

Code reachable through event handlers. JavaScript testing tools automate the process of testing by dynamically constructing test cases to achieve maximum code coverage. A key part of this process is identifying all code that can be potentially executed by event handlers. Doing so requires heavyweight symbolic execution analysis [42], or exhaustively going through all possible orders and inputs [30]. Jawa leverages the differences between archived and live web pages to simplify this analysis by only needing to use the trace from a single execution.

Program analysis on the web. JavaScript on the web has been notorious for various kinds of security, privacy and performance issues. A large body of prior work focuses on addressing such issues by relying on sophisticated program analysis techniques [63, 66]. Such techniques, however, incur a high computation cost. This is why, in solutions for optimizing web performance [42, 54, 49] which use computationally expensive JavaScript analysis techniques, web servers perform such analysis in the background to mitigate the impact of their overheads. For archival systems, even if crawled JavaScript resources are processed offline, the cost for computationally heavyweight processing is not sustainable. Hence, Jawa employs lightweight approaches, rooted in properties of JavaScript on the web.

Dead code elimination on the web. One way to optimize web performance is to eliminate dead code (i.e., code that is never reachable) from resources such as JavaScript and CSS. Tools [17, 25] which do so using static analysis are widely used. We observe that, in archived pages, a significantly greater fraction of code is potentially unreachable, since many sources of non-determinism (e.g., variation in client state and server responses) are absent. Jawa exploits this property to provide significant storage savings.

10 Conclusion

Since when the Internet Archive began operating in the late 1990s, a marked change on the web has been the increased use of JavaScript. In this paper, we shined light on two significant problems caused by this change: broken rendering of archived pages, and petabytes of storage wasted on JavaScript which will either be non-functional or never be used. Our design of Jawa addresses these problems while emphasizing low overhead on both crawling and serving pages. As a result of our work, web archives will be able to archive many more pages than they can today for the same cost and ensure that archived pages more closely approximate their original versions.

A Artifact Appendix

A.1 Abstract

Our open-source artifact contains the scripts and the data necessary to produce the key results from this paper. It also contains the code for the analysis framework which informed Jawa's design.

A.2 Scope

The artifact can be used to confirm the three main benefits of Jawa: a) reduced storage overhead, b) improved fidelity by eliminating almost all failed network requests, and c) improved crawling throughput.

A.3 Contents

The artifact contains all the code required to generate the key results with respect to three metrics: storage, fidelity and throughput. This includes a) Jawa's filter list and a NodeJS based crawler that leverages this filter list while loading web pages; b) a NodeJS based analyzer that injests JS files and instruments them to track all the JS functions executed at runtime, the set of event handlers registered, and the return values of browser APIs; and c) a set of scripts to automatically run the above code on a given corpus of pages. These scripts will produce the following results:

- **E1**: Reduced storage overhead using Jawa's two techniques: eliminating non-functional code using the filter list, and eliminating unused code by tracking the set of functions executed during the page load plus those required for enabling user interactions. This result will mimic the trend shown in Figure 7.

- **E2**: Improved page fidelity by eliminating almost all failed network requests. This result will reproduce the number of failed requests and the corresponding number of bytes not fetched, as shown in Figure 8.

- **E2**: Improved crawling throughput by reducing the number of IOs on the crawling index. This result will mimic the trend shown in the *"Crawling"* column of Table 3.

Apart from the scripts, the artifact contains a corpus of 3000 pages which is pre-recorded using the Mahimahi [57] tool. All scripts are run on this corpus of pages. Finally, the artifact also contains the JS analysis framework which was used to inform Jawa's design choices (§3).

A.4 Hosting

The source code of the artifact is hosted on https://github.com/goelayu/Jawa with the corresponding commit ID: *"07e358eeed7cc054747271b19070b5563f3ff189"*. The corpus of pages is hosted on Google Drive.

A.5 Requirements

Software dependencies

The artifact has been tested on Ubuntu 16.04.7 LTS. It requires installing the following dependencies, in addition to the NodeJS dependencies included in the github repo (§A.6):

```
$ sudo apt-get install mahimahi google-chrome-
    stable parallel r-base r-base-core
$ sudo sysctl -w net.ipv4.ip_forward=1
```

A.6 Installations

Setting up the artifact involves three steps: a) downloading the source code and installing the NodeJS dependencies, b) patching the NodeJS dependencies to use the modified versions included in the github repo, and c) fetching and extracting the corpus of pages to run the analysis on.

Install the code

```
$ git clone https://github.com/goelayu/Jawa
$ cd Jawa
$ npm install
$ export NODE_PATH=${PWD}
```

Patch the dependencies

```
$ vim node_modules/puppeteer-extra-plugin-
    adblocker/dist/index.cjs.js
# add to line 73:
  return adblockerPuppeteer.PuppeteerBlocker.parse
    (fs.readFileSync('../filter-lists/combined-
    alexa-3k.txt', 'utf-8'));
```

Fetch the data

```
$ cd data
# download tarball from https://drive.google.com/
    file/d/17j6AYgaaXMhmV0VKWUmU_kMcHibMryVV/view?
    usp=sharing
$ tar -xf corpus.tar
```

A.7 Experiments workflow

As listed in §A.3, the artifact scripts will produce results corresponding to three metrics: storage, fidelity and crawling throughput.

A.7.1 Fidelity

We provide scripts and data to exactly reproduce Figure 8 (both a and b). The corpus used for this experiment contained 3000 pages. On a single core machine, it takes roughly 20–30 seconds for each page to load and, therefore, takes about 20 hours to load all 3000 pages once. We recommend to either run this experiment on a smaller corpus of pages (more details below) or to use a multi-core (16–32 cores) machine to speed up the overall execution time.

```
$ cd ../ae
# Usage: ./fidelity.sh <corpus_size> <num of
    parallel processes>
$ ./fidelity.sh 3000 1 # depending on the number
    of available cores on your machine, provide
    the 2nd argument
```

The output graphs will be generated in the same directory: *"count_fidelity.pdf"* and *"size_fidelity.pdf"*, corresponding to Figures 8(a) and 8(b), respectively.

A.7.2 Storage

Reproducing Figure 7 requires processing 1 million pages, which would take around a week (even with 128 CPU cores). We instead provide scripts to process 3000 pages, and demonstrate storage savings derived from both of Jawa's techniques. We provide preprocessed web pages, i.e., injected with instrumentation code to detect which functions are executed at runtime, and code to track event handlers. You can fetch the the instrumented pages as follows:

```
$ cd ../data
# download tarball from https://drive.google.com/
    file/d/16Pt4a2l1CNxC8UBwjalgEki-UlGAnFUm/view?
    usp=sharing
$ tar -xf processed.tar
```

You can now run the end-to-end storage analysis script:

```
$ cd ../ae
# Usage: ./storage.sh <corpus_size> <num of
    parallel processes>
$ ./storage.sh 3000 1 # depending on the number of
     available cores on your machine, provide the
    2nd argument
```

The above script will print three storage numbers (in bytes) to the console. a) Total JS storage after deduplication (as incurred by Internet Archive); this mimics the *"IA*"* bar in Figure 7(a). b) Total JS storage after applying Jawa's filter; this mimics the *"IA*+Combined Filter"* bar in Figure 7(a). c) Total JS storage after removing unused JS functions; this mimics the *"Jawa"* bar in Figure 7(a).

A.7.3 Crawling throughput

We reproduce the throughput results from Table 3's *"Crawling"* column. The storage script above outputs the crawling index IOs as well. It prints the following two numbers: a) reductions in crawling IOs for the 50th percentile page, and b) reductions in crawling IOs for the 95th percentile page.

Ekko: A Large-Scale Deep Learning Recommender System with Low-Latency Model Update

Abstract

Deep Learning Recommender Systems (DLRSs) need to update models at low latency, thus promptly serving new users and content. Existing DLRSs, however, fail to do so. They train/validate models offline and broadcast entire models to global inference clusters. They thus incur significant model update latency (e.g. dozens of minutes), which adversely affects Service-Level Objectives (SLOs).

This paper describes Ekko, a novel DLRS that enables low-latency model updates. Its design idea is to allow model updates to be immediately disseminated to all inference clusters, thus bypassing long-latency model checkpoint, validation and broadcast. To realise this idea, we first design an *efficient peer-to-peer model update dissemination algorithm*. This algorithm exploits the sparsity and temporal locality in updating DLRS models to improve the throughput and latency of updating models. Further, Ekko has a *model update scheduler* that can prioritise, over busy networks, the sending of model updates that can largely affect SLOs. Finally, Ekko has an *inference model state manager* which monitors the SLOs of inference models and rollbacks the models if SLO-detrimental biased updates are detected. Evaluation results show that Ekko is orders of magnitude faster than state-of-the-art DLRS systems. Ekko has been deployed in production for more than one year, serves over a billion users daily and reduces the model update latency compared to state-of-the-art systems from dozens of minutes to 2.4 seconds.

1 Introduction

Deep Learning Recommender Systems (DLRSs) are a key infrastructure in large technology organisations such as Meta [54], ByteDance [23], Google [15] and NVIDIA [56]. A DLRS often contains a large group of *parameter servers* that host numerous Machine Learning (ML) models (i.e. embedding tables [10, 26, 54] and deep neural networks [18]). The parameter servers are replicated in geo-distributed data centres for fault-tolerance and low-latency communication with clients. Each data centre has a group of *inference servers* which pull models from local parameter servers and serve clients with recommendation results. To ensure new users and content can be served promptly, a DLRS must update ML models continuously: it first uses *training servers* to collect new training data and compute model gradients. It then uses parameter servers to disseminate model updates to model replicas, usually through a Wide-Area Network (WAN).

Large-scale DLRSs need to serve billions of users [15, 23, 54] and they must achieve latency-related Service-Level Objectives (SLOs) [49], e.g. the latency of making a newly created content available to users. To best achieve SLOs, the operators of DLRSs have emerging requirements for achieving low latency in updating models. There are several reasons for this: (i) recent DLRS applications (e.g. YouTube [24] or TikTok [8]) have enabled users to create massive short videos, articles and images. All these contents need to be made available for clients as soon as possible, usually in minutes if not seconds; (ii) data protection laws (e.g. GDPR [60]) allow DLRS users to become anonymous. The behaviours of anonymous users need to be learnt online; (iii) numerous online ML models (e.g. reinforcement learning [74]) have been adopted in production to improve recommendation quality. These models must be continuously updated online to achieve the best possible performance.

Unfortunately, achieving low-latency model updates is extremely difficult in existing DLRSs. Existing systems such as Merlin [56], TFRA [66], Check-N-Run [21] and BigGraph [39] follow an *offline* approach to updating models: after having collected new training data, these systems compute gradients for models offline, validate model checkpoints, and broadcast the checkpoints to all data centres. Such a model update process can take minutes and even hours [21]. An alternative approach is to use WAN-optimised ML systems [28] or federated learning systems [37]. These systems update replicated models using locally collected data and lazily synchronise replicas. The lazy synchronisation, however, introduces a non-trivial level of asynchrony, which often

*Chijun and Yao are co-primary authors.

adversely affects the achievement of SLOs [28, 42].

We want to explore a DLRS design that can achieve low-latency model updates without compromising SLOs. Our key idea is to allow training servers to update models (using gradients) online and immediately disseminate model updates to all inference clusters. This design allows us to bypass long-latency update steps, including offline training, model checkpoint, validation and broadcast, thereby reducing model update latency. To make this design feasible, we need to address several challenges: (i) how to efficiently disseminate massive model updates over WANs which have limited bandwidths and heterogeneous network paths [28]; (ii) how to protect SLOs from network congestion that can delay critical updates; and (iii) how to protect SLOs from biased model updates that are detrimental to model accuracy.

This paper introduces Ekko, a novel large-scale DLRS that updates globally replicated models at low latency. The design of Ekko makes several key contributions:

(1) Efficient peer-to-peer model updates dissemination. Existing parameter servers often adopt primary-backup data replication protocols [11, 41, 67] to realise model updates. With massive model updates, however, primary-backup protocols exhibit insufficient scalability due to long update latency [67] and leader bottlenecks [2].

To address these issues, we explore how to enable Peer-to-Peer (P2P) [20] model update dissemination. We design an efficient *log-less state-based synchronisation algorithm* for geo-distributed DLRSs (see §4). This algorithm is effective in DLRSs because model updates often hit hot parameters [21], and it only transfers the latest version of a model parameter (i.e. state). Ekko must allow parameter servers to efficiently discover the differences of model states in a P2P manner. To this end, we design (i) *model update caches* that allow parameter servers to efficiently track and compare model states, (ii) *shard versions* that can significantly reduce network bandwidth consumption when comparing model states, and (iii) *WAN-optimised dissemination topologies* that allow parameter servers to prioritise bandwidth-affluent intra-DC network paths over bandwidth-limited inter-DC network paths.

(2) SLO protection mechanisms. Ekko allows model updates to reach inference clusters without offline model validation. Such a design can make SLOs (particularly those related to the freshness and quality of recommendation results) vulnerable to network congestion and biased updates, both possible in production environments.

To handle network congestion, we design an *SLO-aware model update scheduler* (see §5). This scheduler computes metrics, including the update freshness priority, the update significance priority and the model priority. These metrics predict the impact of model updates on the inference SLOs. The scheduler computes a priority for each model update online based on these metrics. We integrate the scheduler into parameter servers without changing the decentralised architecture of the P2P model update dissemination in Ekko.

Ekko handles biased updates using a novel *inference model state manager*. This manager creates a *baseline* model for each group of inference models. This baseline model receives a small amount of user traffic and serves as the ground truth to the inference model. The manager continuously monitors the quality-related SLOs for baseline and inference models. When biased model updates corrupt the state of the inference model, the manager notifies *witness servers* to roll back the model to a healthy state.

We evaluate Ekko using both test-bed and large-scale production clusters (see §6). Test-bed experimental results show that Ekko reduces the model update latency by up to 7× compared to state-of-the-art parameter servers, namely Adam [11]. We further run large-scale production experiments with 40 TB models and over 4,600 servers spread across geo-distributed regions. Experimental results show that Ekko disseminates updates in 2.4 seconds while executing 1 billion updates per second (i.e. 212 GB/s). Ekko only uses 3.0% of the total network bandwidth for synchronisation, leaving the rest for training and inference. This second-level latency performance is orders of magnitude faster than the minute-level latency (i.e. 5 minutes [69]) achieved by state-of-the-art DLRS infrastructures (e.g. TFRA [66] and Check-N-Run [21]).

2 Low-Latency Model Updates in DLRSs

In this section, we introduce DLRSs and their algorithms for updating models. We then describe their Service-Level Objectives (SLOs) that can benefit from reducing the latency of updating models. Finally, we discuss the system challenges associated with realising low-latency model updates.

2.1 DLRSs and model updates

Most technology organisations adopt DLRSs following a system architecture shown in Figure 1. A DLRS often serves clients distributed across the globe (❶). To minimise serving latency, DLRS models (i.e. embedding tables [10, 26, 54] and deep neural networks [18]) are geo-replicated in multiple data centres. When a client's request arrives, an *inference server* pulls the model parameters from local parameter servers and infers over this model to answer the request.

Data pipelines collect training data (e.g. new content and user activities) from clients at run-time. The collected data reach training servers in a data centre (❷). The training servers use optimisers [33] to compute gradients that correct corresponding models. All updated models (usually 100s - 1,000s) are persisted as checkpoints (❸). The checkpoints are first validated, and only those that can improve SLOs are disseminated to the parameter servers in inference-oriented data centres over a WAN (❹), finishing the model update process.

In practice, the latency of updating a DLRS model comprises the time of computing model updates and disseminat-

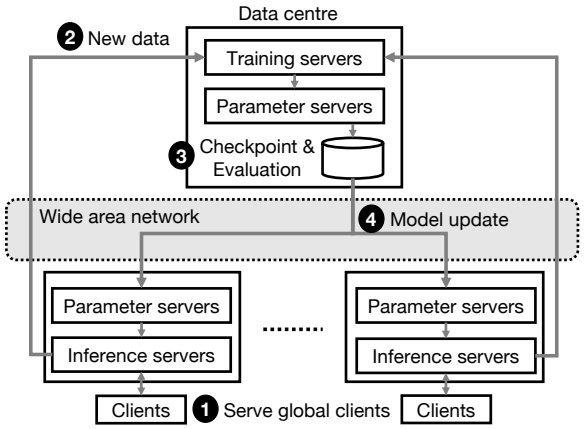

Figure 1: A typical DLRS architecture.

ing the updates to global data centres. This latency definition presumes that we have used low-latency message queues, e.g. Kafka [36], to accelerate the training data ingestion. Recent DLRSs, e.g. NVIDIA Merlin [56] and Meta Check-N-Run [21], report minute-level and hour-level latencies in updating models. Suppose we want to update a DLRS model with a large embedding table (often several TB in size). In this case, it can take tens of minutes to persist this model as a checkpoint and validate the model. It takes another dozen minutes to disseminate this model over a WAN (assuming this WAN provides several Gbps bandwidth [72]).

2.2 Reasons for low-latency model updates

DLRSs need to achieve numerous SLOs (usually related to the freshness and quality of recommendation results). Take a short-video recommendation service (e.g. TikTok) as an example. The DLRS model accuracy determines this service's quality SLOs. The time of making freshly made videos accessible to users decides this service's freshness SLOs.

In real-world DLRSs, we observe that SLOs often depend on the latency of finishing model updates, making low-latency model updates a critical system requirement. There are several reasons for this:

(1) Massive new content created in a short time. Global DLRSs, e.g. YouTube [24], TikTok [8] and Instagram [22], often serve billions of users, and they allow users to create massive content quickly. The DLRSs need to quickly incorporate the created content into recommendation results — by updating their models at low latency — otherwise affecting user engagement.

(2) Increasing anonymous users. Data protection laws (e.g. GDPR [60]) have forbidden many DLRSs from tracking user activities. As a result, such a DLRS can have anonymous users yet unknown to the recommendation models, even though these users have used the same service before. A DLRS thus must quickly react to the online activities of anonymous users, thus meeting their recommendation requirements. Such a quick reaction depends on low-latency model updates.

(3) Increasing online recommendation models. DLRSs have increasing online ML models, e.g. those using reinforcement learning [74] and continual learning [69]. These models improve recommendation quality. They need to collect training data from online user activities, and they thus must continuously update model parameters at low latency.

2.3 Our key idea and associated challenges

We want to explore how to achieve low latency in updating DLRS models. Our observation is that the update latency is accumulated mainly due to several offline steps: model training, validation and broadcast. Suppose we bypass these offline steps and allow updated models to be disseminated to the inference clusters directly. In that case, we can vastly reduce the steps for updating models, thus achieving low latency. To realise such a design, however, we must address several challenges:

(1) Lack of efficient algorithms for disseminating massive model updates. A real-world DLRS often has a large number of models (e.g. usually 100s - 1,000s). It needs to update many of these models online. These models comprise those on a multi-stage recommendation pipeline [10, 15] and those for A/B tests [69]. These models often cost 10s of TB memory. They have the requirement to complete massive model updates online (e.g. 100s of GB per second).

Suppose we use conventional data replication protocols, e.g. chain replication [41] and two-phase commit [11]. These protocols target generic data replication. They lack mechanisms to coordinate ML model updates (which may exhibit different impacts on inference SLOs) over a bandwidth-limited network (i.e. WAN). Furthermore, these conventional protocols suffer from leader bottlenecks. They also incur long update latency caused by the heterogeneous WAN paths and network stragglers. As a result, these protocols are ill-suited to meet our high-throughput, low-latency requirements. Alternatively, we could use geo-replication protocols [72]. These protocols, however, cannot handle the failures of servers in the training data centres, making them unable to meet our system availability requirement.

We also considered network-efficient distributed ML systems, e.g. Gaia [28] and Google Federated [35]. These systems [7, 28, 35, 37, 46] allow models to be trained independently in each data centre, thus improving the throughput and latency of updating models. They, however, lazily synchronise their states and therefore incur stale model states [47], which can adversely affect recommendation quality. As a result, the loosely synchronised distributed ML systems cannot meet our model accuracy requirement.

(2) Lack of mechanisms for protecting SLOs. Enabling online model updates in a DLRS poses challenges to SLOs. Such a DLRS can have model updates competing for network

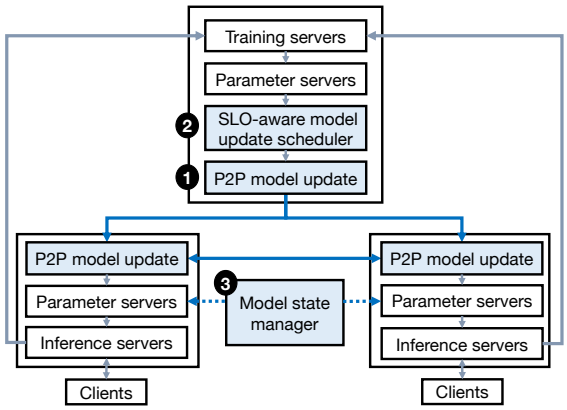

Figure 2: Ekko architecture overview.

bandwidth, delaying critical updates (e.g. those that significantly affect model accuracy or bring new items online). Even though there are systems that schedule the sending of model gradients [6], these systems target training clusters. As a result, they prioritise model updates based on gradients [6, 28] and lack awareness of how those updates will affect the SLOs of inference models.

Online model updates can be even detrimental. Since online updates are often computed based on a small batch of data (collected in a short time window: seconds or minutes), they often contain noise [34]. When updates become particularly noisy, they become detrimental to inference SLOs (i.e. decrease the accuracy of inference models). To handle this, existing model serving systems, e.g. Clipper [16] and Clockwork [25], use offline model validation, which averages model updates accumulated for an extended period (e.g. hours). Other model serving systems, e.g. Google TFRA [66], track the SLO metrics of inference models, and they reload checkpoints when SLOs are deteriorating. Such a design, however, is challenging to implement in DLRSs. Giant DLRS models (e.g. recommendation-oriented transformers [18]) are increasingly common. Reloading these models affect the availability of services.

3 Ekko System Architecture

This paper introduces Ekko, a novel DLRS system that enables low-latency model updates. In this section, we describe the system model of Ekko and present an overview that highlights the novel components in Ekko.

3.1 System model

Ekko is a geo-distributed DLRS. It updates models in a central data centre. It then disseminates updated models to geo-distributed data centres close to global users (i.e. clients). Ekko represents models as key-value pairs, and it partitions the models into shards (e.g. 100,000 in our production environment). It stores model shards in key-value stores (named as a parameter store in Ekko). The parameter stores assign key-value pairs to shards through hashing. The model size can change over time since the model often incorporates new items and feature expiration online [32].

Ekko directs parameter requests to model shards using software-based *routers*. The routers designate parameter servers in the training DC as the primaries for model shards. They also ensure that the choice of primaries can balance the workload of parameter requests. The implementation of the routers follows typical key-value stores and databases [38]. We omit the details of the router implementation in this paper.

In the routers, there are shard managers which can handle resource overload, fault domains [55] and copyset issues [12]. Different from conventional shard managers, Ekko's shard managers realise several DLRS-specific optimisations: (i) To amortise request processing overhead, Ekko batches concurrent inference requests for the same model [16]. Batched requests, however, can query a large number (e.g. 1000s) of parameters on different parameter servers, resulting in long-tail query latency [19]. To prevent long-tail latency, Ekko limits the number of servers assigned to a model's shards; (ii) Ekko supports multiple DLRS applications which require performance isolation. It maps the shards of different applications to different servers. Therefore, the spike of requesting the shards of an application will not affect the shards of other applications.

3.2 Architecture overview

We highlight the novel designs in Ekko in Figure 2. As we can see, Ekko enables parameter servers to achieve efficient *peer-to-peer model updates* (❶) (see §4). The P2P model update algorithm prevents the central training data centre from broadcasting updated models. Instead, it uses all network paths inside and across data centres (those solid lines in the figure), thus achieving high throughput in disseminating model updates. Without using a central coordinator, each data centre can independently choose optimised intervals that synchronise model updates.

Ekko supports concurrent dissemination of massive model updates. These updates can compete for network resources, delaying the updates that largely benefit SLOs. To handle this, Ekko relies on *an SLO-aware model update scheduler* (❷) (see §5.2). This scheduler predicts how each model update will affect inference results. The prediction results facilitate the computation of the priority of each model update. Based on the priority, Ekko coordinates which model updates to disseminate first at the training data centre, thus improving the overall satisfaction of the SLOs on inference servers.

Ekko can protect inference servers from being affected by detrimental model updates. To achieve this, it has a *model state manager* (❸) (see §5.3) running in the inference clusters.

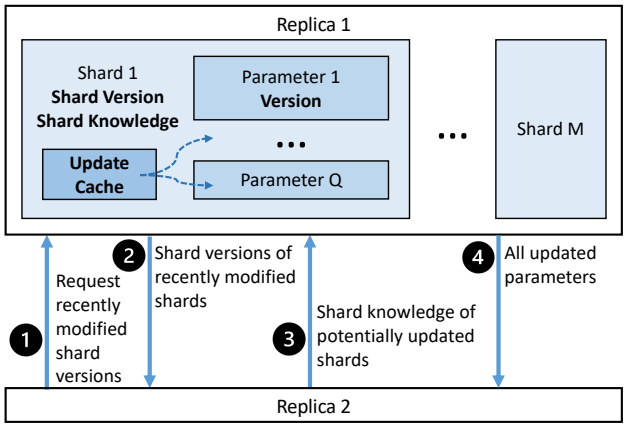

Figure 3: Ekko P2P model update overview.

This model state manager monitors SLO-related metrics of inference models. Suppose an inference model shows downgraded performance (caused by online updates). In that case, the manager rollbacks the model's state to a better-performing one, thus recovering the performance of the inference model.

4 Efficient Peer-to-Peer Model Update

This section introduces the efficient P2P model update mechanism in Ekko. To enable P2P model update in parameter servers, the design of Ekko achieves the following goals:

- Ekko needs to coordinate a large number (e.g. thousands) of parameter servers (deployed across the globe) to finish model updates. To avoid stragglers (which can be caused by slow networks), we design log-less synchronisation for the parameter servers in Ekko (§4.3).
- As a shared DLRS, Ekko needs to host thousands of models. These models can generate massive (e.g. billions per second) updates online. To support this, Ekko enables parameter servers to efficiently discover model updates through peers and pull updates without using excessive computation and network resources (§4.4).
- Ekko needs to support geo-distributed deployments, which often involve heterogeneous network paths across WANs and server/network failures. To support this, Ekko has system designs that improve the throughput/latency of sending model updates over a WAN and tolerate server/network failures (§4.5).

In the following, we give an overview of the P2P model update mechanism and describe its implementation in detail.

4.1 Model update overview

Figure 3 highlights the components and steps involved in a model update in Ekko. Suppose that we want to synchronise a shard (denoted by shard 1) between two replicas (denoted by replica 1 and replica 2). Similar to all other shards, shard 1 has a (i) *shard knowledge* which summarises parameter updates, and (ii) an *update cache* that tracks recent model updates based on *parameter versions*. Each shard also associates a *shard version* which tells if this shard potentially has parameters to synchronise. The shard knowledge, update cache and shard version together accelerate parameter synchronisation among parameter servers.

To finish a model update, replica 2 requests the recently modified shard versions from replica 1 (❶). Once receiving the request, replica 1 returns a list of recently modified shard versions (❷). Replica 2 then compares all shard versions of replica 1 with its local shard versions and then sends related shard knowledge to replica 1 (❸). Finally, replica 1 sends all updated parameters to replica 2 (❹). Following these steps, Ekko can ensure that model updates are eventually disseminated to all replicas at low latency (i.e. eventual consistency).

We find eventual consistency acceptable in real-world DLRSs. Even though DNN replicas may diverge in a small time window, they often exhibit close (even often identical) inference results [11]. This is because DNNs often use floating-point numbers to represent model parameters, and therefore, DNN replicas make close predictions even though there is a slight difference in the values of their local parameters.

4.2 Parameter versions in DLRSs

To track the state of model parameters, Ekko assigns each key-value pair (i.e. the storage format of a model parameter) with a parameter version defined below:

Definition 1 (Parameter Version)**.** A Parameter Version v is a pair (t, id) that consists of a timestamp t and an id uniquely identifying a replica. The timestamp t is generated based on the time range provided by modern physical time sources [14, 43]. Ekko makes sure t increases monotonically in each replica and pads the physical timestamp with a counter to make sure any two updates that originate from a single replica do not share the same timestamp. We define the total order of Parameter Versions:

$$v_1 \geq v_2 \iff (t_1 > t_2) \mid ((t_1 = t_2) \wedge (id_1 \geq id_2))$$

A parameter with a larger Parameter Version supersedes another during conflict resolution [62].

In Ekko, it is worth noting that the timestamp is based on a real-time clock instead of a logical clock (which is often used in key-value stores and storage services). We find such a design effective in distributed DLRSs for a reason: a DLRS has embedding tables where parameters are sparsely updated. Suppose there is an embedding's parameter in a primary replica and this parameter has a significant update count, but the primary does not disseminate this parameter

before it fails. When this primary recovers, the counter can overwrite the current primary with a small update count. Such an overwrite can adversely affect recommendation quality because the overwritten primary can have a newer parameter (updated by recently collected training data), leading to better recommendation results. Hence a logical counter is not sufficient to resolve conflicts in distributed DLRSs.

4.3 Log-less parameter synchronisation

Once version numbers have been assigned to parameters, Ekko needs to decide how to synchronise the different replicas. We observe that a DLRS often overwrites parameters and only the last write decides the state of a parameter. We therefore decide to send the last version of parameters.

Ekko needs to decide the interval of synchronising replicas. We could use log-based synchronisation algorithms [9, 11]: these algorithms choose synchronisation intervals so that model updates can be sent at the rates that do not exceed the bandwidth on the *slowest* links in a network. These algorithms, however, cause the under-utilisation of many network links. More importantly, it results in stragglers which can significantly increase the latency of synchronisation, making parameter servers more likely to have stale states when they recover from failures. Hence, we want to realise log-less parameter synchronisation in parameter servers so that these servers can dynamically choose synchronisation intervals with their peers according to the bandwidth on each link.

Shard knowledge in parameter servers. We propose to use shard knowledge [50, 51] to realise log-less parameter synchronisation. More formally, in each replica, all its shards maintain a corresponding shard knowledge. The shard knowledge, implemented using version vectors [58], summarises the parameter updates they have learnt. Shard data (associated with the shard knowledge VV_{shard}) reflect the state of an empty shard applying all historical parameter updates originating from each replica r, where the update corresponding parameter version $v \leq VV_{shard}[r]$. Suppose there is an update for the parameter p to be processed in replica r. To maintain shard knowledge, this replica generates a new parameter version $v_p = (t, id)$ and sets $VV_{shard}[id] = v_p$.

Shard synchronisation process. To synchronise a shard, replica r sends its shard knowledge VV_{r_1} to a selected replica s. Replica s *records* its current shard knowledge VV_s — that is, it atomically reads out VV_s and selects from its store all parameters p whose parameter version $v_p = (t_p, id_p) > VV_{r_1}[id_p]$ — and responds to r with VV_s. Then, r atomically applies all parameter updates based on the response from s, and further merges VV_s with its current shard knowledge VV_{r_2}.

There are several considerations to note in the synchronisation process: (i) When replica r synchronises with replica s, r could have concurrent synchronisation operations with another replica (denoted as replica k). These operations can complete before r finishes processing the response from s. As a result, VV_{r_2} (which is the result of $VV_r \bigsqcup VV_k$) does not necessarily equal VV_{r_1}. (ii) The synchronisation process omits all superseded versions of an updated parameter in failure-free scenarios where the requests for updating a parameter are always routed to the same primary. We find these failure-free scenarios common in our production environments.

4.4 Making synchronisation efficient

Ekko must ensure parameter synchronisation have negligible performance overheads on parameter servers. Otherwise, synchronisation can consume excessive computation and communication resources, affecting parameter servers' performance in serving model inference and training requests. In the following, we discuss how to make parameter synchronisation efficient through parameter update caches (which reduce computation costs) and shard versions (which reduce communication costs).

4.4.1 Parameter update caches

Since a shard can have a large number of parameters, naively iterating all parameters to answer a synchronisation request incurs substantial computation costs. Even though we could use an index to accelerate the parameter iteration, maintaining such an index costs tremendous memory resources, which are difficult to provision on parameter servers.

We design parameter update caches to reduce the computation cost of parameter synchronisation. The design of such caches exploits the *sparsity* and *temporal locality* we often observe in DLRSs [21]. Unlike dense DNN training systems where the entire models are updated every iteration, a DLRS updates a subset of its parameters (i.e. sparsity). For example, in our production DLRSs, 3.08% of its parameters are updated per hour. Further, model updates are often overwriting certain parameters (i.e. temporal locality) in a time window. This is because a DLRS often has trendy items and users, and their parameter updates dominate in a short period.

More specifically, a parameter update cache contains pointers to recently updated parameters. It exploits a Dominator Version Vector (denoted as DVV) to judge whether to hit the cache when a synchronisation request arrives.

Cache maintenance algorithm. The maintenance of the cache guarantees two invariants: (i) for all parameters $p_{uncached}$ existing in a shard but not in the cache, $DVV[id_{p_{uncached}}] \geq v_{p_{uncached}}$; (ii) for all cached parameters p_{cached}, $DVV[id_{p_{cached}}] < v_{p_{cached}}$.

Algorithm 1 describes the maintenance of the parameter update cache in Ekko. The maintenance relies on the estimated update propagation time D_{prop}. Consider the function of updating the cache: `UpdateCache` (line 1). $t_{pruneto}$ is a timestamp that describes $DVV_{proposed}$ – a version vector that judges whether a parameter should be pruned. For every modification request, the cache records a pointer to that parameter

Algorithm 1: Update Cache Maintenance using D_{prop}

```
1  Function UpdateCache(p):
2      if v_p.t ≤ t_pruneto then
3          DVV.Merge(v_p);
4      else
5          cache.Add(p);
6      end
7  Function PruneCache():
8      t_pruneto ← max(t_pruneto, t_now − D_prop);
9      for p ∈ cache do
10         if v_p.t ≤ t_pruneto then
11             cache.Erase(p);
12             DVV.Merge(v_p);
13         end
14     end
```

if the parameter version $v_p = (t_p, id_p)$ of the modified parameter p is larger than $DVV_{proposed}[id_p]$ (line 5). Otherwise, the cache merges the parameter version with DVV (line 3).

Consider the function of pruning a parameter pointer: `PruneCache` (line 7). This function takes D_{prop}, which essentially allows Ekko to exploit online observations towards cache hit rates to guide cache pruning operations. Suppose we want to prune parameter pointers when the cache size has grown beyond a limit. In that case, the cache first determines $DVV'_{proposed}$, which strictly dominates $DVV_{proposed}$ (line 8). It then removes parameter pointers dominated by $DVV'_{proposed}$ (line 11). Eventually, the cache updates DVV by merging it with parameter versions of pruned parameters (line 12). By doing so, Ekko achieves adaptive management of the cache size, reducing its memory footprint.

Cache hit analysis. We analyse when parameter updates hit the cache. Suppose replica s receives the synchronisation request from replica r which holds the shard knowledge VV_r. If VV_r dominates DVV_s, the request hits the cache and its subsequent operations (e.g. selecting a parameter) only touch the parameters in the cache.

Ekko ensures that the use of the update cache does not affect the eventual consistency property of log-less parameter synchronisation: the synchronisation process needs to select out parameters p in s where $v_p > VV_r[id_p]$. Because the update cache holds the invariant that $DVV_s[id_{p_{uncached}}] \geq v_{p_{uncached}}$ and VV_r dominates DVV_s, the process selects out the same set of parameters as the previous algorithm.

The parameter update caches are particularly effective in reducing the cost of selecting parameters. According to the traces of the caches deployed in our production environments, 99.4% of the synchronisation requests can hit the caches, leading to a 99% reduction in the cost of selecting parameters.

4.4.2 Shard versions

We introduce *shard versions* to reduce network costs in synchronising replicas. Shard versions capture partial causality relationships of shard data on replicas, and they are much smaller than version vectors. We can allow the replicas to book-keep shard version lists where each list is associated with a neighbour replica. By doing this, replicas can identify potentially updated shards by exchanging and comparing shard version lists. Formally, we define shard versions as:

Definition 2 (Shard Version)**.** A *shard version* $sv = (c, id)$ is a pair consisting of a counter c, which is monotonically incremented in each shard of each replica, and an id identifying the replica that generates this version. $sv_1 \succeq sv_2$ of a same shard s if and only if $id_1 = id_2$ and $c_1 \geq c_2$.

Shard version maintenance. On initialisation, each replica generates shard versions for its shards. It later generates a new shard version when a training worker issues a parameter update. Since each shard has a primary replica, there is a single replica generating shard versions in normal cases.

Once receiving a synchronisation request, the responder replica, denoted as s, replies its shard version: sv_s together with VV_s and updated parameters. Once having this reply, the requester replica, denoted as r, finishes the following operations in an atomic manner: it (1) merges its shard knowledge VV_r with the received VV_s (The merging result is denoted as VV'_r), and (2) it updates its shard version sv'_r to be sv_s when $VV'_r = VV_s$; Otherwise, replica r generates a new shard version if $VV'_r \neq VV_r$. Note that: when VV_r equals VV_s, to avoid livelock, Ekko will choose a shard version from s and r following deterministic rules (e.g. choosing the shard version which exhibits a larger numerical value).

We implement book-keeping techniques [51] which maintain the shard version lists associated with different replicas. By applying both shard versions and book-keeping, Ekko can effectively reduce synchronisation-oriented network traffic. For example, in one of our production DLRSs, Ekko filters out 98% of shards in synchronisation.

Synchronisation with shard versions. We discuss how shard versions facilitate synchronisation. Ekko maintains the invariant $sv_1 \succeq sv_2$ only if shard knowledge VV_1 dominates VV_2 for the same shard s. Thus replica r needs to synchronise a shard with replica s only if $sv_r \not\succeq sv_s$. Furthermore, consider different replicas which have comparable shard versions for the same shard. Ekko prefers to synchronise with the one with the largest shard version because larger shard versions indicate a more refreshed version of parameters.

4.5 Implementation details

WAN optimisation. Ekko targets geo-distributed deployments, which comprise multiple intra-DC networks and an

inter-DC WAN. To improve its performance with such deployments, Ekko uses a *WAN-optimised model update dissemination strategy*. This strategy constructs a flexible communication topology for P2P synchronisation. It lets each DC elect a local leader for each shard using Zookeeper [31]. The leaders pull model updates from other DCs while other replicas pull updates from this leader. By doing so, Ekko allows a large proportion of synchronisation traffic to go through bandwidth affluent intra-DC networks and only a small of synchronisation traffic to go over WANs. Note that the implementation of the parameter synchronisation does not require a specific communication topology. Ekko can use other overlay topologies to improve synchronisation performance.

Failure tolerance. Ekko uses the request routers to tolerate failures. The routers decide the routes of client requests, and they detect the healthiness of replicas using heartbeats. Suppose a router speculates a replica failure (either fail-stop or fail-slow [30]). In that case, it prevents clients (inference servers and training servers) from requesting that replica. It also tracks the shard knowledge of replicas in the cluster. If a previously suspected failed replica recovers and sends heartbeats to the router, the router will instruct that replica to catch up with a sufficiently updated replica in the cluster. When the catching-up finishes, the router directs client requests to that replica. If a replica loses its state, it re-joins the cluster with a new id. Training servers stop sending parameter updates if they cannot contact the router for a given period, which achieves best-effort protection of model parameters from divergence in the case of having network partitions [5].

5 SLO Protection Mechanisms

Ekko allows model updates to reach parameter servers in inference clusters directly. This, however, raises two challenges for the SLOs of recommendation services: (i) network congestion can cause critical model updates to be delayed, and (ii) model updates based on a small batch of biased data can have detrimental impacts on inference results.

This section introduces mechanisms that protect inference SLOs from network congestion and biased updates. We first define the SLOs (see §5.1), describe an SLO-aware model update scheduler (see §5.2), and discuss an inference model state manager that handles biased updates (see §5.3).

5.1 SLOs in a DLRS

A DLRS has two major types of SLOs:

- **Freshness SLOs** measure the latency of including new content and users in model inference. They are vital for recommendation services, especially those interacting with users in real-time, e.g. TikTok and YouTube. For example, such services often need to capture the interests of new users in a timely manner so that they are sufficiently engaged; otherwise, they leave the recommendation applications due to the loss of interest. Improving the freshness SLOs usually leads to a better user experience. Also, new content will have better exposure, securing the prosperity of DLRSs.
- **Quality SLOs** measure user experience and engagement. They have immediate impacts on the profitability of a DLRS. Examples of such objectives include the number of viewed videos and user watching time.

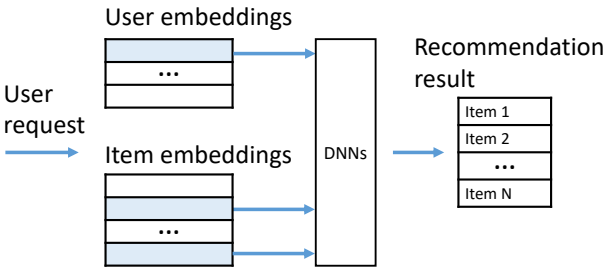

Figure 4: Overview of the inference process in Ekko.

Figure 4 describes how an inference server affects the freshness and quality SLOs. Once receiving a request, the inference server selects related user and item embeddings. It then aggregates the embeddings and sends an aggregated embedding to a DNN that returns the scores for recommendation items. The DLRS finally returns a list of items sorted by the scores. In this case, the freshness SLO is measured based on the latest timestamp of the recommended items (Ideally, this timestamp should be as close to the current time as possible). The quality SLO can be measured based on the viewing time of the items and how many items are clicked. In practice, Ekko maintains a large number of freshness and quality SLOs online. The implementations of such SLOs are contributed by DLRS application developers.

5.2 SLO-aware model update scheduler

Ekko prevents both freshness and quality SLOs from being affected by network congestion. This is achieved by an SLO-aware model update scheduler and an integration of this scheduler into P2P model update dissemination.

5.2.1 SLO-aware priorities for model updates

Ekko computes a set of priorities in scheduling model updates:

Update freshness priority. Ekko computes an update freshness priority p_u. This priority is designed based on the following observation. If a parameter has been created recently, it has a high priority; otherwise, it has a relatively lower priority. The reason for this is that newly created parameters have more significant impacts on inference results than those served for

an extended period. Suppose a user's embedding is unavailable in the inference server, but her request has arrived. In this case, the DLRS cannot answer this request, compromising quality SLOs. Another case is that if the embedding table does not include an item on the inference servers, the DLRS will not recommend this item, compromising freshness SLOs.

Update significance priority. Ekko computes an update significance priority p_g for each model update based on its gradient g. This priority is initially inspired by studies which showed how the gradient magnitude $|g|$ affects the inference results of a DNN [6, 28]. However, naively adopting the gradient magnitude is insufficient in Ekko. As a shared DLRS, Ekko multiplexes the updates from different models on a shared network. As a result, Ekko must have ways to compare gradient magnitudes that have different distributions. Therefore, we define $p_g = |g|/\overline{|g|}$, where $|g|$ denotes the 1-norm of g and $\overline{|g|}$ denotes the average gradient magnitude of recent model updates. Intuitively, this definition normalises gradient magnitudes, thus making them comparable.

Model priority. In a DLRS, models often receive inference requests at different rates, indicating their varied importance in measuring the overall satisfaction of SLOs. To consider this, Ekko allows the models that handle the majority of requests to be assigned with higher priorities compared to those that rarely receive requests. To this end, we define the model priority as $p_m = c_m / \sum_{i=1}^{M} c_i$, where c_m is the request count of model m and $\sum_{i=1}^{M} c_i$ denotes the total request count of all M models.

Combining priorities. We combine all the above priorities to compute the overall priority p of a model update as below:

$$p = (p_g + p_u)\, p_m$$

where the significance priority p_g and the freshness priority p_u have both been normalised so that they can be summed up. The sum is multiplied by the model priority p_m.

Note that Ekko does not require its users only to use the above priorities. Some Ekko users have custom priority definitions, including update count, update interval and the positions of parameters in embedding tables. These custom priorities are specific to certain DLRS workloads [69], and they are not generic enough to be included in a default setting. Ekko accommodates these custom priorities by supporting User-Defined-Functions (UDFs) in defining priorities.

5.2.2 Scheduler implementation

The model update scheduler computes the priority for each update once it is produced. It needs to ensure the cost of priority computation is negligible; otherwise, it can become a bottleneck in model updates. To achieve this, the scheduler offloads the maintenance of priority-related statistics (e.g. $\overline{|g|}$ and p_m for each model m) to a background thread. Moreover, to bound memory cost, it uses a quantile sketch (e.g. DDSketch [52]) that computes the k percentile priority p_k in a time window, where k is a ratio set by algorithm managers. Ekko executes user-defined priority computation using WebAssembly [27] to achieve efficient isolation among UDFs.

Algorithm 2: Priority-based synchronisation

```
1  Function UpdateSVV(SVV_other):
2      SVV.Merge(SVV_other);
3      TSVV.Merge(SVV);
4  Function WriteStoreParameter(p):
5      WriteIfVersionLarger(store, p);
6      EraseIfVersionNotSmaller(store_significant, p);
7  Function OnRecvPrioritisedSync(TSVV_other):
8      reply.TSVV ← TSVV;
9      for p ∈ (store ⋃ store_significant) do
10         if not TSVV_other.Dominate(p.sigv) then
11             reply.parameters.Add(p);

Integrating schedulers into parameter servers. To achieve the promise of priority scheduling, we must have ways of integrating the schedulers into the parameter servers which have enabled log-less P2P synchronisation. To this end, we propose the *significant version*, denoted as *sigv*, for each parameter and the *significant knowledge SVV* for each shard. Moreover, Ekko assigns each shard with a *transient significant parameter store* $store_{significant}$ and a corresponding *transient significant knowledge TSVV* to enable P2P synchronisation with priority scheduling.

Algorithm 2 describes the log-less P2P synchronisation augmented with priority schedulers. Suppose we have a model update from a replica. In this case, Ekko calculates p. If $p \geq p_k$, Ekko sets $sigv = v$, where v is the parameter version of this update; otherwise, *sigv* remains unchanged. Then, Ekko uses *sigv* to construct SVV_{other} and call the UPDATESVV function (line 1). In the case that Ekko does not apply priorities in synchronisation, replicas exchange *SVV* and execute the UPDATESVV function. On writing parameters into the persistent parameter store, Ekko prunes superseded parameters by executing the WRITESTOREPARAMETER function (line 4). Note that replicas estimate how long the model updates to reach themselves. Hence, when network congestion occurs, servers will have update time-outs. In this case, Ekko

uses the PRIORITISEDSYNC function (line 15) that triggers priority schedulers in synchronisation. Once receiving requests, replicas prefer to return parameters in significant parameter stores.

5.3 Inference model state manager

Ekko uses an inference model state manager to protect SLOs from detrimental model updates. This manager monitors inference models' healthiness (i.e. quality SLOs) and conducts low-latency model state rollback on demand.

5.3.1 Monitoring model healthiness

Ekko monitors model healthiness based on the following idea: for a DLRS application, it creates *baseline models* for its inference models. Baseline models process a small amount of user traffic (usually $< 1\%$). They are different from the online inference models because they carry delayed states. In other words, they are trained with previous training samples, usually several minutes earlier than the samples training the current inference model.

Ekko measures model healthiness based on metrics collected from inference servers and clients (e.g. user devices). To compute these metrics, Ekko defines a custom watermark and trigger [3]. Its state manager emits anomaly detection events only if confident (i.e. observing monitoring data for an extended period). Note that Ekko is not constrained to use specific anomaly detection algorithms. It supports custom anomaly detection algorithms, such as those often used with time-series data [61].

We model the transition of model states (i.e. healthy or not) as a replicated state machine [63], implemented within the model state manager. This manager evaluates and records model healthiness at a timestamp t by inspecting the healthiness-related metrics and the model update latency. The timestamp t monotonically increases. The manager makes judgements if the model state is *healthy*, *corrupted* or *uncertain*. When the manager is confident that changes have occurred in the model state (i.e. healthy or corrupted), it records this information in its replicated state. If the model state has corrupted, the manager re-directs client requests to alternative inference models (still healthy) and then launches a model state rollback.

5.3.2 Low-latency model state rollback

Ekko uses *witness servers* to roll back corrupted model states at low latency. The witness servers join replica synchronisation but they do not participate in model training. Unlike parameter servers, the witness servers (i) do not immediately flush updated parameters into parameter stores and (ii) do not run priority scheduling in synchronisation. More specifically, Ekko inserts the parameter updates that are not flushed yet into the logs. The logs are attached with the physical timestamp of synchronisation (denoted as t). If there are multiple synchronisation operations in a small time window, Ekko merges their logs to save space.

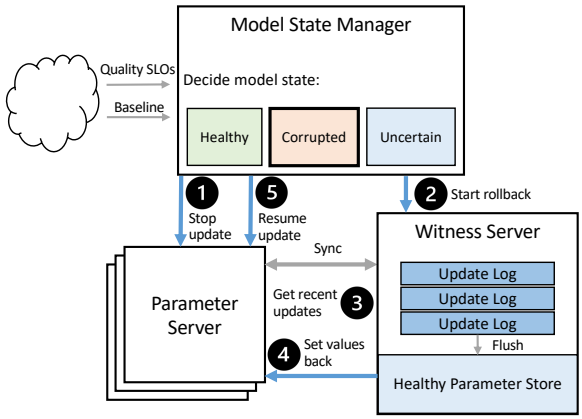

Figure 5: Inference model state manager.

The model state manager controls witness servers to launch state rollbacks. Suppose a model state is regarded as $t_{healthy}$ at the time t. In that case, witness servers find a timestamp t_{max} that meets two conditions: (i) it is $\leq t_{healthy}$ and (ii) it is not within any time interval where corrupted states have occurred. The witness servers then flush the logs which have the timestamps $\leq t_{max}$. The model state manager records this t_{max}, and t_{max} will be later used in witness servers for recovering a healthy model state. Following this way, we can ensure the parameter store $store_{healthy}$ always keep healthy model states on witness servers.

Rollback process. Figure 5 illustrates the process of rolling back a model state. Suppose a model is found to be corrupted. The model state manager first informs parameter servers to stop accepting training requests of this model (❶). It then instructs parameter servers to stop priority-based synchronisation, clears their $store_{significant}$, and resets $TSVV = SVV$. The manager then waits for the model shards on parameter servers and witness servers to converge. Later, the manager selects witness servers to initiate the state rollback (❷). We need to ensure recovered model shards can be used together. Hence, the manager selects shards from the $store_{healthy}$ on witness servers only if t_{max} of these shards are in a small time window.

A key design is that the witness servers will compare $store_{healthy}$ and its current state to find a state difference (❸). This difference is often small because of the locality in updated parameters. We thus only write the difference into the parameter servers to recover a state. We need to ensure the write operations can succeed. Hence, the written parameters are assigned with parameter versions that are larger than those currently on parameter servers (❹). After that, the man-

ager waits for the model shards to converge on parameter servers and witness servers. Finally, Ekko will recover a small amount of traffic on the recovered model. When this model's healthiness metrics go back to normal, the manager informs parameter servers to resume accepting requests (❺).

Note that if a witness server fails, its non-flushed update logs are discarded. This helps Ekko prevent potentially corrupted updates from being flushed. If a parameter server or a witness server fails (or re-joins the cluster), the rollback process will be re-executed.

6 Evaluation

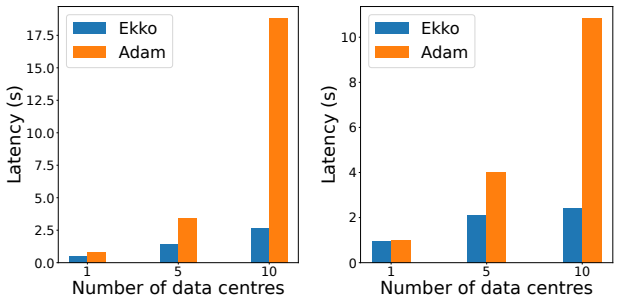
In this section, we evaluate the following aspects of Ekko through test-bed and in-production experiments: (i) The update latency of Ekko and its scalability with the number of data centres (§6.1.1); (ii) The update latency of Ekko in a heterogeneous-WAN (§6.1.1); (iii) The performance breakdown of optimisations implemented in Ekko (§6.1.2); (iv) The real-world latency and availability of Ekko in a large-scale production DLRS (§6.2.1); (v) The benefits of low-latency model updates in online services (§6.2.1); (vi) The effectiveness of using model update schedulers with a busy network (§6.2.2); and (vii) The latency of rolling back a model upon model corruption (§6.2.2).

Unless otherwise specified, the update latency is the maximum time difference between the time an update commits and the time this update becomes visible [68] in all replicas (failure-free scenarios). In all experiments, we measure the update latency and report its average across all updates.

6.1 Test-bed experiments

We conduct test-bed experiments in a 30-server cluster. Each server has a 24-core CPU, 64 GB RAM and a 5 Gbps network link. We group every three servers as a DC to emulate a multi-DC scenario, forming up to 10 DCs. We choose one of the DCs as the training-oriented DC, which receives model updates from a server (which acts as a DLRS client). We let other DCs be inference-oriented and connect them with the training-oriented DC. The inter-DC bandwidth is 4,800 Mbps (unless otherwise specified), emulating a WAN.

Our test-bed experiments comprise two workloads. The first workload trains a large ranking model typically used in our production environments. In this workload, we choose the shard size as 0.4 MB. The second workload trains the Wide & Deep model [10] using the Criteo Terabyte Click Logs [17] sorted chronologically. We initialise embedding tables using 21-day data logs. To ensure experiments are reproducible, we record model update traces and replay them during the experiments.



(a) Production workload (b) Criteo workload

Figure 6: Average model update latency.

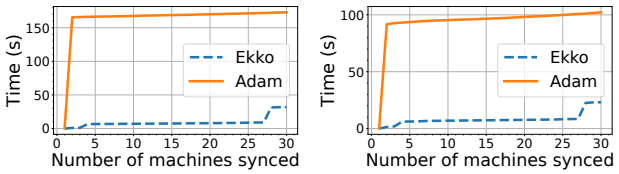
6.1.1 Update latency

We evaluate Ekko's update latency in a homogeneous WAN and a heterogeneous WAN. Both of these WANs are common in the real world. The first baseline is Adam [11] which is often used in parameter servers to synchronise model updates using the two-phase commit protocol. Our Adam implementation removes the waiting time between update broadcasts, thus improving network utilisation. The second baseline is Checkpoint-Broadcast which is the de-facto approach that applies model updates in DLRSs [1, 21]. We omit the experiments with general key-value stores, e.g. PaxosStore [73] and TiKV [29], which provide linearisability in writing operations. Our early adoption results show that these key-value stores achieve low writing throughput, orders of magnitude lower than what a production DLRS requires.

To make a fair comparison, Ekko and baselines all use DRAM for storage [57] and adopt the same primary-assignment and load-balancing schemes. We further ensure their dissemination are all network-bound and use the same numbers of shards.

Homogeneous WAN results. We first compare Ekko against Adam in the homogeneous WAN. We measure their latency with 1 DC (3 replicas), 5 DCs (15 replicas), and 10 DCs (30 replicas), respectively. Figures 6a and 6b show the results. As we can see, Ekko achieves significantly lower latency than Adam in both the production and Criteo workloads. More specifically, with the 10 DCs that run the production workload, Ekko achieves a 2.6-second latency, 7× lower than the 18.8-second latency achieved by Adam. We also observe that the performance gap between Ekko and Adam increases with more DCs. The reason is that Ekko has a scalable P2P synchronisation architecture. It also optimises its dissemination topology for a WAN. In contrast, Adam relies on the primary replica to send updates, constraining itself with the limited bandwidth available in the training DC.

We also compare Ekko against Checkpoint-Broadcast. According to our experimental results, Checkpoint-Broadcast takes more than 7 seconds to synchronise 4 GB of parameters in the WAN. The total parameters are 113 GB. With



(a) Production workload (b) Criteo workload

Figure 7: Update latency in a heterogeneous WAN.

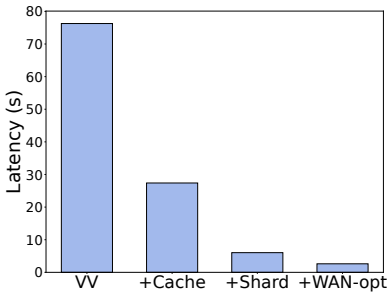


Figure 8: Performance breakdown.

10 DCs, the training DC needs to send $113 \times 9 = 1{,}017$ GB parameters to all other inference DCs. The training DC thus has to spend more than 29 minutes finishing the parameter broadcast (since the WAN has a 4,800 Mbps network link). This broadcast latency is orders of magnitude longer than the second-level latency (e.g. 2.6 seconds) achieved by Ekko.

Heterogeneous WAN results. We then evaluate Ekko and baselines in the heterogeneous WAN. In this WAN, we set inter-DC bandwidth to 256 Mbps by default. To introduce heterogeneity, we choose one link in between the training DC and another inference DC, and we set this link to 128 Mbps. The experiments run with 3 replicas per DC, for a total of 10 DCs. As shown in Figures 7a and 7b, Ekko is effective in mitigating slow heterogeneous links in both production and Criteo workloads. It allows replicas to synchronise at independent rates, preserving second-level synchronisation latency. Such low-latency performance shows the effectiveness of Ekko's log-less P2P synchronisation in alleviating the adverse effects of having heterogeneous network paths. On the contrary, Adam suffers from the slow paths in the WAN. As a result, it spends more than 150 seconds synchronising replicas in the production workload and 100 seconds in the Criteo workload.

Apart from Adam, we also considered other log-based synchronisation approaches, e.g. Multi-Paxos [9]. We could let these approaches aggregate updates (which arrive in a time interval) into a log entry to save bandwidth in using a WAN. These approaches, however, still suffer from the existence of heterogeneous links. This is because they choose the aggregation interval based on the slowest links in the network, under-utilising many other links.

6.1.2 Performance breakdown

We want to know the effectiveness of individual components in Ekko's synchronisation. We thus conduct a performance breakdown analysis for the production workload with 10 DCs. We first configure Ekko to only use shard knowledge (see §4.3) in synchronisation. This configuration is the baseline in this experiment, and it is equivalent to the Version Vector (VV) [50, 51] which is the state-of-the-art of P2P synchronisation.

Figure 8 shows the results. With only VV, Ekko needs 76.3 seconds to synchronise all parameters. After enabling update caches (§4.4.1), Ekko reduces the latency to 27.4 seconds (i.e. 2.8× speed-up). Diving into the update caches traces, we find out the caches achieve a 100% hit ratio in our production workload. Note that the total memories of a replica on our testbed servers are smaller (i.e. 10×) than those on our production servers, which means there are fewer parameters in a shard than in practical scenarios. With more parameters in a shard, VV will spend more time on synchronisation, while update caches can keep latency low.

Figure 8 also shows the effects of shard versions (§4.4.2). By further enabling shard versions, Ekko reduces the latency from 27.4 seconds to 6.0 seconds (i.e. 4.6× speed-up). This shows the effects of skipping non-updated shards to reduce network consumption incurred by synchronisation.

Finally, after enabling WAN optimisations (§4.5), Ekko further reduces the latency from 6.0 seconds to 2.6 seconds (i.e. 2.3× speed-up). This shows that P2P synchronisation must account for the bandwidth available on each link in a WAN. Otherwise, P2P synchronisation cannot deliver its full promise. In summary, enabling all components in Ekko leads to a total of 29.3× (i.e. 2.6 seconds vs. 76.3 seconds) speed-up in P2P synchronisation.

6.2 Production cluster experiments

We have deployed Ekko into production for over one year. The production environment comprises 4,600 servers spread across 6 geo-distributed DCs. By 2022, we have used Ekko to support a wide range of recommendation services, including short video recommendations, searching and advertisement. More than one billion users are using these services daily. In this section, we report Ekko's performance in this production environment.

6.2.1 Model updates

We collect traces from the production environment to analyse Ekko's performance in updating models. The production environment has hundreds of DLRS models (40 TB parameters or 250 billion key-value pairs in total). Each parameter shard ranges from 0.1 MB to 20 MB depending on model size. Ekko can execute 1 billion updates per second (i.e. 212 GB/s).

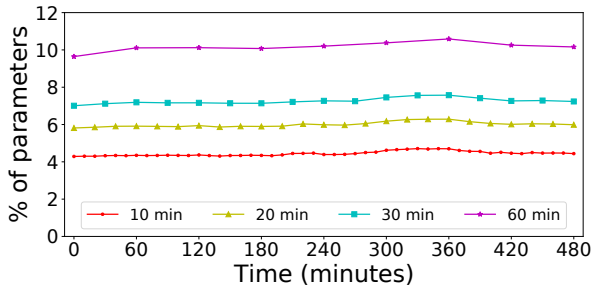

Figure 9: The proportions of updated parameters over time in different time intervals.

Regarding latency performance, Ekko spends 2.4 seconds synchronising the parameters in all DCs and 0.7 seconds in the training DC only. The synchronisation traffic accounts for only 3.0% of the total network traffic, reflecting the effectiveness of Ekko used as a background synchronisation service on parameter servers. Ekko's low-latency, high-throughput performance does not compromise system availability. Since its deployment, Ekko has achieved >99.999% availability for parameter reading and writing operations.

Update cache analysis. We are particularly interested in the performance of the update caches with various real-world recommendation services. Our traces show that: the update cache only needs to keep 0.13%-0.2% parameters in caches, and they can already achieve >99.4% hit ratios. These performance results verify that the update locality widely exists. In fact, our production recommendation services update 3.08% of the parameters per hour on average.

We choose an update-intensive DLRS model to demystify the update locality in the worse case. Figure 9 shows the proportions of updated parameters in a 480-minute window. This time window covers the busiest time of our production DLRSs in a day. We report the proportions with different time intervals. In a 10-minute interval, only 4.3% of parameters are updated, and this proportion is stable in the 480-minute time window. In a 60-minute interval, we observe a similar pattern, and the proportion only slightly increases to around 10%. In practice, many other models have fewer update workloads, and their proportions of updated parameters are lower than this model.

Benefits of low-latency model updates. We want to know if the low-latency model updates can actually improve the quality of recommendation services. To this end, we conduct a 15-day online A/B test [64] in a short video recommender service [65]. This service comprises a multi-stage pipeline [10, 15]. We conduct the experiment only in the ranking stage. We fork the ranking model: one as the experimental group and the other as the control group. Each group receives 1% of the total traffic for training and inference. We delay the data (i.e. event logs) used to train the model in the control group by 20 minutes through caching real-time logs in a distributed file system.

Our A/B-test results show that: compared to the control group, the experimental group exhibits a 3.82% increase in the proportion of fresh videos (posted within one hour) among all recommended videos. This means that the system recommends more fresh videos to users in the experimental group.

Moreover, the experimental group exhibits a 1.30% decrease in the proportion of users swiping through the video list as well as a 1.68% increase in the total time of browsing videos. These mean that users in the experimental group spend more time watching videos and are more interested in the recommended videos.

Finally, the experimental group exhibits a 2.17% increase in the percentage of users who clicked on comments. This means that user interaction in the experimental group increases. It is worth noting that the improvements in the range of 1%-3% are regarded as significant in a real-world multi-stage DLRS [10, 21, 71]. In fact, since enabling low-latency model updates in more stages in DLRSs, we have observed more significant improvements in recommendation quality.

6.2.2 SLO protection mechanisms

We also run A/B tests to evaluate the effectiveness of Ekko's SLO protection mechanisms.

SLO-aware model update scheduler. We fork the ranking model into an experimental group (where priority schedulers are enabled) and a control group. Each group has 1% of the training and inference traffic, and they are deployed into dedicated servers to avoid traffic interference. We monitor metrics that reflect freshness SLOs: the count of fresh videos (i.e. posted in the last one hour) in recommendation results. To emulate network congestion, we reduce the bandwidth available for model updates by 92%. The model update scheduler (i) uses the default priority computation rule (defined in §5.2.1) and (ii) sets the percentile priority k to 99 (k is defined in §5.2.2).

The A/B-test results show that, in the experimental group, Ekko reduces synchronisation traffic by 92% and keeps the latency of updating significant updates low. In contrast, the control group cannot distinguish model updates when sending them over a busy network. As a result, the control group delays SLO-critical updates, and it suffers from a 2.32% drop in its SLO metric. Such a drop is significant in practice because this SLO metric is a key factor that decides the profit of a DLRS.

Online model state rollback. We evaluate the latency of rolling back a model state online. We compare Ekko with the checkpoint-recovery approach. To make a fair comparison, we let the rollback latency exclude (i) the time of collecting SLO metrics in Ekko and (ii) the time of waiting for diverged parameters to converge. We deploy 5 witness servers. For each witness server, we allocate 113 GB parameters and 800 Mbps network bandwidth.

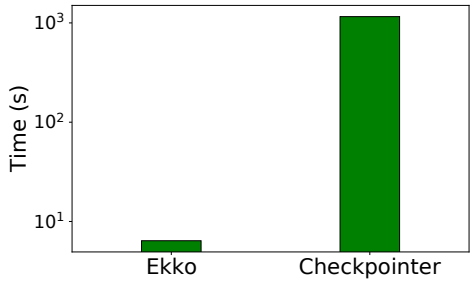

Figure 10: Model state rollback time.

During the experiment, we notify Ekko's model state manager to roll back the state of a DLRS model to a version that is 1 minute earlier. The manager then notifies all witness servers to identify the parameters updated in the last 1 minute. The witness servers thus only reload the difference between the current state and the earlier state. Hence, the entire rollback operation takes only 6.4 seconds to complete. In contrast, the checkpoint-recovery approach is agnostic to the recent updates to the model state. As a result, it has to reload the entire state, taking 1,157 seconds to complete (180× slower than Ekko).

7 Related Work

Data replication systems. The parameter synchronisation problem explored in Ekko is related to prior work on data replication. Existing data replication systems often explore how to leverage the characteristics of applications to improve their latency performance in replicating data [13, 40, 45, 53]. For example, Egalitarian Paxos [53] exploits the low interference rate of state machine commands, Gemini [40] leverages mixed consistency operations, and COPS [45] and PNUTS [13] exploit the tolerance of relaxed consistency in Internet services. Unlike these systems, Ekko leverages the DLRS-specific model update locality and the eventual consistency model to speed up the synchronisation of model parameters (instead of generic data), making Ekko unique in the design space.

Bandwidth saving techniques in ML systems. The problem of prioritising model updates relates to bandwidth saving techniques in distributed ML systems. Such techniques often involve gradient compression [4, 6, 28, 44] which prioritises large gradients in a busy network, with an anticipation that these large gradients have significant impacts on the final accuracy of a trained model. Unlike these techniques, Ekko targets model inference scenarios where people care about numerous inference SLO metrics instead of the model's accuracy only. Hence, Ekko does not rely on gradient magnitude solely. It further considers model freshness and priority in scheduling model updates.

SLO-aware scheduling in ML systems. Being aware of SLOs in scheduling has been explored in prior ML systems. Model serving systems often treat inference latency as the primary SLO to guide the scheduling of inference-related computation tasks [16, 25, 70]. Model training systems, e.g. Pollux [59] and KungFu [48], use ML-specific SLOs, e.g. training goodput and gradient statistics, to decide how to schedule training workers. Compared to these systems, Ekko sheds light on freshness and quality SLOs. It enables the use of these SLOs in scheduling model updates.

8 Conclusion

This paper proposes Ekko, a novel DLRS that enables massive model parameters to be updated at the second-level latency. Ekko has an efficient P2P model update algorithm which can coordinate billions of model updates to be efficiently disseminated to replicas in geo-distributed data centres. It further has SLO protection mechanisms that protect model states from being affected by network congestion and detrimental model updates online. Experimental results show that Ekko is orders of magnitudes faster than state-of-the-art DLRSs, indicating the effectiveness of its novel designs.

Abstract

Embedding-based retrieval (EBR) is widely used in recommendation systems to retrieve thousands of relevant candidates from a large corpus with millions or more items. A good EBR system needs to achieve both high throughput and low latency, as high throughput usually means cost saving and low latency improves user experience. Unfortunately, the performance of existing CPU- and GPU-based EBR are far from optimal due to their inherent architectural limitations.

In this paper, we first study how an ideal yet practical EBR system works, and then design FAERY, an FPGA-accelerated EBR, which achieves the optimal performance of the practically ideal EBR system. FAERY is composed of three key components: It uses a high bandwidth HBM for memory bandwidth-intensive corpus scanning, a data parallelism approach for similarity calculation, and a pipeline-based approach for K-selection. To further reduce hardware resources, FAERY introduces a filter to early drop the non-Top-K items. Experiments show that the degraded FAERY with the same memory bandwidth of GPU still achieves 1.21×-12.27× lower latency and up to 4.29× higher throughput under a latency target of 10 ms than GPU-based EBR.

1 Introduction

Recommendation systems have gained significant adoption in many online services [11, 12, 18, 38]. To make a recommendation from a large corpus containing millions of candidate items, industrial large-scale recommendation systems are usually divided into two layers, namely retrieval and ranking, as shown in Figure 1. Retrieval quickly selects thousands of relevant items from the large corpus with simple algorithms, while ranking utilizes sophisticated algorithms to sort the retrieval results more precisely, and then chooses dozens out of the sorted items.

Real-world retrieval systems conduct multi-channel retrieval [26, 39, 43]: It leverages different strategies in separate channels to retrieve different candidates, which are then merged and filtered to generate the final retrieval result. Among the multi-channel retrieval strategies, embedding-based retrieval (EBR) gains increasing popularity [12, 18, 20, 25, 38, 42]. EBR represents user queries and candidate items with semantic embedding vectors (embedding for short) using representation learning [9], and converts the retrieval problem into a similarity search problem in the embedding space. In particular, an EBR algorithm, as shown in Listing 1, involves *scoring*, which scans the corpus to get all items and calculates a similarity score (e.g., via inner product) between every item embedding and the given query embedding, and *K-selection*, which returns the Top-K items based on their similarity scores. The returned Top-K items of EBR are usually sorted [25, 42], to simplify merging and filtering retrieval candidates from multiple channels.

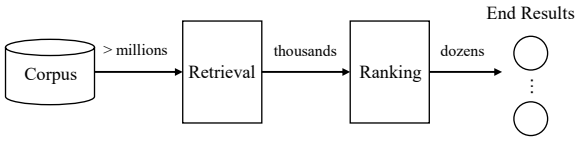

Figure 1: A typical recommendation system. Retrieval selects thousands of candidate items from a large corpus, and ranking further chooses dozens from the retrieval results.

The performance of such EBR systems is important. On the one hand, increasing the throughput of every EBR server reduces the overall server cost, as fewer servers are required to serve a target number of queries per second (QPS). On the other hand, decreasing the latency of each EBR server reduces the retrieval time, which can either shorten user's overall waiting time or leave more time for ranking computation to get better recommendation results [11]. Therefore, *latency-bounded throughput* becomes a critical metric for EBR systems.

To achieve high latency-bounded throughput, we characterize the EBR algorithm shown in Listing 1 and derive a practically ideal EBR hardware architecture (§2.2). Specifically, corpus scanning (line 3) is a memory-intensive operator which requires both large external memory capacity and high memory bandwidth. Similarity calculation (line 4) and K-selection (line 6) are both compute-intensive. They should match the memory bandwidth with a data-parallel architecture across multiple operator instances. Moreover, to overlap communications with computations among steps or operators, both inside K-selection and the entire EBR data flow require pipeline parallelism. Then, we extend the ideal architecture to support batch queries, by sharing corpus scanning among queries in a batch and providing separate compute pipelines

[*] This work is done while Chaoliang Zeng, Ding Tang, and Zilong Wang are interns in ByteDance.

```
# Scoring
for i in corpus_size:
    item_emb = corpus[i] # corpus scanning
    scores[i] = sim_calc(user_emb, item_emb) # similarity calc
# K-selection
ret_items = topk(scores) # returns the sorted top_k items
```

Listing 1: Simplified EBR algorithm for a single user query.

to serve different queries in the batch in parallel. As a result, the ideal architecture achieves the optimal query latency, and scales the latency-bounded throughput linearly with the batch size.

By comparing existing CPU- and GPU-based EBR with the ideal architecture, we realize that, unfortunately, none of the existing approaches achieve the optimal performance due to their inherent architectural limitations (§2.3). First, despite large memory capacity, CPU does not perform well in corpus scanning due to low memory bandwidth, and fails to well support the desired parallelism paradigms simultaneously due to the limited number of cores. Second, although GPU provides higher memory bandwidth and massive compute cores for data parallelism, GPU is not optimized for pipeline parallelism required by K-selection and the entire EBR data flow due to explicit resource boundaries.

We observe that FPGA, a programmable hardware device readily available in some hyper-scale cloud providers [10, 14, 41, 45], has all the desired properties of the practically ideal EBR architecture. Some modern FPGAs are equipped with large high bandwidth memory (HBM), ideal for corpus scanning. Moreover, FPGAs provide sufficient on-chip memories and fully programmable compute elements to enable appropriate parallelism paradigms for various operators (§2.4).

We exploit the above observations to design FAERY (§3), an **F**PGA-**A**ccelerated **E**mbedding-based **R**etrieval s**Y**stem, which is an embodiment of the ideal EBR architecture and achieves high performance. Specifically, FAERY stores the corpus in FPGA's HBM, which provides high bandwidth for the memory bandwidth-intensive corpus scanning. FAERY leverages a corpus manager to maximize the HBM bandwidth utilization in runtime while preserving memory-efficient storage and enabling online corpus update. FAERY follows the ideal architecture to design similarity calculation with data parallelism and K-selection with pipeline parallelism. Different from the ideal architecture, FAERY needs only a single K-selection pipeline, and adds a filter in front of it to significantly lower its throughput requirement, based on a unique property observed in the K-selection pipeline. The filter optimization lowers the resource requirements of FAERY compared with the ideal architecture by eliminating multiple K-selection pipelines.

The above ideas make a single FPGA-based EBR accelerator perform well. To further enhance its capabilities, multiple such accelerator cards can be inserted into a FAERY server (§4) and work together. When a corpus can fit into a single card, we can scale the aggregate query throughput by replicating the corpus among multiple cards. When the corpus is too large to fit into a single card, we can shard it evenly among multiple cards. FAERY supports both the *replication* and *sharding* modes and leverages a software front-end to dispatch queries and to merge retrieval results for multiple accelerator cards.

We have implemented a fully functional FAERY prototype with Xilinx FPGA cards (§5). Experiments (§6) show that the degraded FAERY with the same memory bandwidth of GPU achieves 1.21×-12.27× lower latency and up to 4.29× higher throughput under a latency target of 10 ms than an EBR system accelerated by Nvidia T4 GPU.

This paper makes the following contributions:

- We study the EBR algorithm from the first principles and derive a practically ideal EBR architecture to achieve the optimal query latency and to scale the latency-bounded throughput linearly with the batch size, constrained by hardware resources. We further identify the performance bottlenecks of CPU- and GPU-based EBR using the ideal EBR architecture as a reference (§2).
- We design FAERY, a domain specific accelerator (DSA) for EBR. FAERY arranges its key components: corpus scanning, similarity calculation, and K-selection in a perfect pipeline, and accelerates these components using appropriate data and/or pipeline parallelisms. FAERY is an embodiment of the ideal EBR architecture, with balanced filtering and buffering which matches the capability of parallel similarity score calculations with a single K-selection pipeline, based on a thorough analysis (§3 and §4).
- We implement FAERY using FPGA, evaluate its performance, and quantify its advantages over CPU- and GPU-based EBR systems, respectively (§5 and §6).

2 Background & Motivation

2.1 EBR Algorithms: KNN vs. ANN

EBR represents user queries and candidate items with embeddings, and converts the retrieval problem into a K-Nearest Neighbor (KNN) or an Approximate Nearest Neighbor (ANN) search problem in the vector space [20]. KNN-based EBR searches the **accurate** k-nearest item embeddings from the corpus, while ANN-based EBR retrieves the **approximate** k-nearest item embeddings, by sacrificing accuracy for efficiency using techniques such as indexing (e.g., IVF [34] and HNSW [28]) and quantization (e.g., PQ [21]). The tradeoff between accuracy and efficiency in various ANN algorithms is well studied in [8].

CPU provides limited memory bandwidth and computing power, so that it is challenging for CPU to perform KNN search on a large corpus due to the tremendous costs of memory accesses and computations. As a result, ANN search is

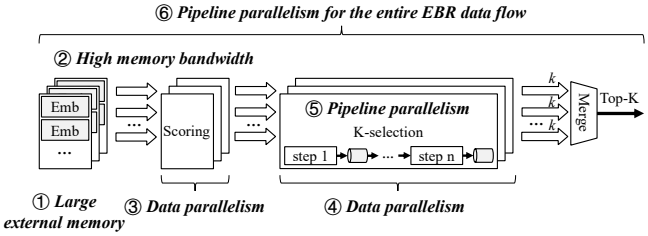

Figure 2: A practically ideal EBR architecture with the batch size of 1. It has the following properties: ① large external memory for corpus store, ② high memory bandwidth for corpus scanning, ③ data parallelism for similarity calculation, ④ data parallelism among multiple K-selection instances, ⑤ pipeline parallelism within a K-selection instance, and ⑥ pipeline parallelism for the entire EBR data flow.

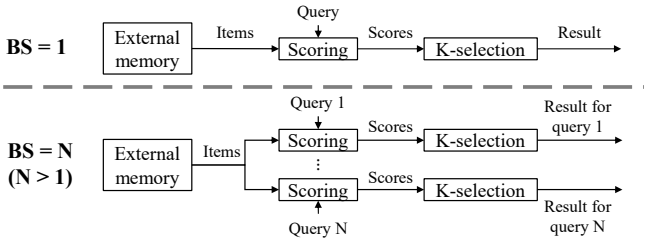

Figure 3: A practically ideal EBR architecture with the batch size of N, where the throughput scales linearly with the batch size N, while the latency remains the same as shown in Equation 1.

widely applied in CPU-based EBR in the industry. In contrast, accelerators, e.g., GPU and FPGA, provide much higher memory bandwidth and computing power, so that KNN search is usually adopted by these accelerators to trade memory bandwidth and computing power for higher accuracy and thus better recommendation quality.

To simplify discussion and comparison, we use the same KNN search (shown in Listing 1) for EBR on all platforms (CPU, GPU, and FPGA) in this paper, but our analysis results and acceleration ideas apply to ANN as well, as ANN shares similar characteristics and bottlenecks with KNN, just to different extents.

2.2 Practically Ideal EBR Architecture

To maximize latency-bounded throughput, an ideal architecture should first achieve minimal latency for each individual query (equivalent to maximal throughput with the batch size of 1), and then scale the throughput linearly with increasing batch sizes while preserving the consistent minimal latency.

In a theoretically ideal architecture, for each query, we do similarity calculation with ALL item embeddings in parallel and finish this operator in $O(1)$ time, followed by a perfect K-selection to match the parallelism. This is obviously impractical, as it requires millions of item accesses and millions of similarity calculation (e.g., inner product) operators in parallel, not to mention the design challenge of K-selection to match that extreme parallelism. A practically ideal EBR should take into account both realistic hardware constraints and the EBR characteristics which we discuss below.

Corpus scanning (line 3) is a memory-intensive operator. The size of an industrial corpus is up to several GBs [19], and scanning such a large corpus incurs millions of memory accesses for a single query. Thus, corpus store and scanning require large external memory and high memory bandwidth.

Similarity calculation (line 4) is a compute-intensive operator, which calculates similarity scores between the user query and all item embeddings. As the calculations for different item embeddings are independent, an ideal architecture should perform similarity calculation with data parallelism to match the throughput of corpus scanning.

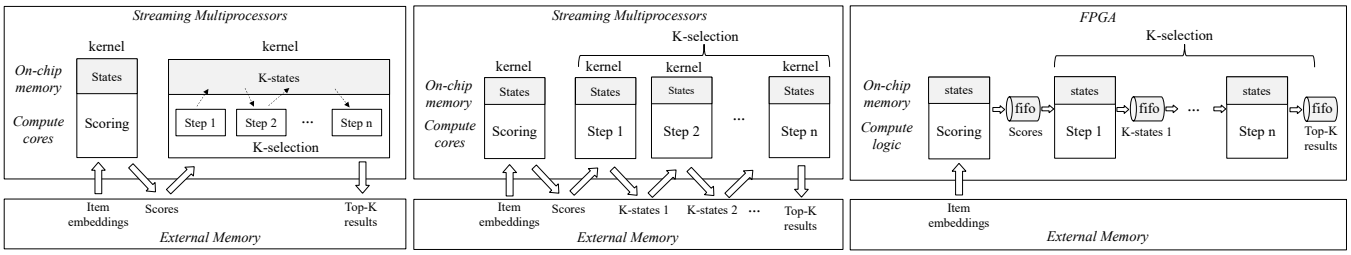
K-selection (line 6) is another compute-intensive operator. To match the throughput of multiple similarity calculation instances, K-selection requires data parallelism with multiple instances as well. Inside a single instance, K-selection can be realized by various algorithms [23, 33], among which a common practice is to partition this complex task into multiple steps, and organizes them in a pipelined manner.

Based on these characteristics, a practically ideal EBR architecture for optimal latency should have a large and high-bandwidth memory for corpus store and scanning, appropriate parallelisms for EBR operators to match their throughput to the memory bandwidth, and a perfect overlap among communications and computations of operators in the entire pipeline to minimize latency. Figure 2 describes a practically ideal EBR architecture with the batch size of 1 and its desired properties. The minimal query latency of this architecture is:

$$latency = \frac{S}{B} + C, \tag{1}$$

where S is the corpus size, B is the external memory bandwidth, and C is a constant delay, i.e., the pipeline latency, which is the time it takes for the last embedding going throughout the pipeline. Thus, the maximal throughput is $1/latency$ queries per second (QPS) with the batch size of 1.

The ideal architecture can be extended to support batch queries to increase latency-bounded throughput linearly, as shown in Figure 3. The key is to share corpus scanning among multiple queries in a batch (i.e., scan the corpus only once in each batch), and process multiple queries with separate compute pipelines in a data-parallel manner. In this way, the latency remains constant as shown in Equation 1, and the latency-bounded throughput scales linearly with the number of batched queries. In practice, the batch size cannot be increased unlimitedly due to resource constraints, and hence the maximum latency-bounded throughput will be bounded by the available hardware resource of the chosen platform.



(a) GPU-based EBR (GPU-o, K-selection with on-chip memory)

(b) GPU-based EBR (GPU-e, K-selection with external memory)

(c) FPGA-baesd EBR

Figure 4: Comparison between GPU- and FPGA-based EBR architectures. (a) GPU-o is a GPU-based EBR that stores intermediate states of K-selection in on-chip memory [23] and maintains corpus and scores in external memory. It suffers from heavy state maintenance cost and small k values; (b) GPU-e is a GPU-based EBR that moves all intermediate states of K-selection to external memory [33, 36], requiring multiple passes over the external memory; (c) is an FPGA-based EBR which stores only corpus in external memory, traverses external memory only once, and keeps the computation and communication of other operators fully on chip and in a streaming pipeline.

2.3 Existing EBR Architectures

Using the ideal EBR architecture as a reference, we analyze existing CPU- and GPU-based EBR architectures, and show that their performance are both sub-optimal due to inherent architectural limitations.

2.3.1 CPU-based EBR

Datacenter CPUs are equipped with large DDR memory (hundreds of GBs), able to store a very large corpus with millions or more item embeddings. However, CPU-based EBR does not perform well due to the following reasons.

Low memory bandwidth violates ② in Figure 2. The theoretical DDR memory bandwidth of a CPU is proportional to the limited number (typically 2∼8) of DDR channels [3], and the memory bandwidth utilization driven by a CPU is not high. Taking the server used in our evaluations (§6) as an example, a CPU with six DDR channels provides a theoretical maximum bandwidth of 140.8 GB/s, and an empirical upper bound of only 78 GB/s measured with Intel MLC [1]. The low memory bandwidth (B) significantly increases the first part (S/B) of Equation 1.

Limited number of CPU cores cannot support ③-⑥ and batch queries, simultaneously. A CPU contains dozens of processor cores that can be flexibly used for data parallelism, pipeline parallelism, and/or batch processing. However, due to the limited number of cores, CPU-based EBR fails to support all the above features well simultaneously, where the number of cores desired is the product of the number of memory channels, the number of pipeline stages, and the batch size as shown in Figure 2 and Figure 3. The poor support of data parallelism and pipeline parallelism results in throughput mismatch and imperfect overlapping among operators, leading to an increase on the second part (C) of Equation 1 as well as a sub-linear throughput increase with batch queries.

2.3.2 GPU-accelerated EBR

Compared with CPU, GPU provides high external memory bandwidth (e.g., Nvidia T4 [2] provides 300 GB/s bandwidth with GDDR6), and massive lightweight SIMT (Single Instruction Multiple Threads) cores optimized for data parallelism. Although GPU provides a smaller memory capacity (e.g., $16-80$ GB in a typical GPU and $128-640$ GB in a holistic server with 8 GPU cards), the size is still large enough to store the corpora in most recommendation services. For example, given a typical embedding size of 256 bytes, 128 GB memory can store more than 500M items that can meet the requirements of most recommendation systems [11,12,16,40]. These strengths inspire the design of GPU-accelerated EBR [23, 46] to achieve higher performance.

However, the performance of these GPU-based EBR systems are still sub-optimal, as GPU is not optimized for pipeline parallelism. GPU consists of a large number of *streaming multiprocessors* (SM), each of which contains exclusive on-chip memory and compute cores. Communication between SMs or kernels[1] is only possible via external memory, and the available on-chip memories for a single SM are very limited (e.g, 304 KB in Nvidia T4). These restrictions make GPU-based EBR not perfectly pipelined, leading to an increase on the second part (C) of Equation 1.

Inter-operator communication via external memory violates ⑥. Different EBR operators are organized as separate kernels. The similarity scores generated by scoring kernels are transmitted to the K-selection kernels via the external memory, as shown in Figure 4a and Figure 4b. The explicit kernel boundaries make it difficult to exploit pipeline parallelism

[1] A kernel is a function executed on GPU, which realizes a data-parallel portion of an application. An operator may consist of one or multiple kernels.

across EBR operators to overlap perfectly communication and computation [24, 47].

Existing K-selection pipelines violate ⑤. Existing GPU-based K-selection algorithms can be classified into the following two categories.

K-selection with on-chip memory (e.g., `WarpSelect` [23]), denoted as GPU-o, as shown in Figure 4a, fuses all K-selection sub-steps into a single kernel to avoid cross-kernel overhead, and keeps all K-states in on-chip memory. However, maintaining all K-states on chip and executing these steps in the SIMT cores introduce non-trivial computation overhead (e.g., per-thread queue sorting, sorted queues merging, and thread synchronization [23]), resulting in poor latency. To show this overhead, we measure Faiss [23], which adopts `WarpSelect`, with a 4M corpus and the same setting as §6. The result shows that the K-selection operator consumes up to 80.4% of the total time. Moreover, given the limited on-chip memory size of each SM, it fails to support a large k value, i.e., at most 2048 in this setting.

K-selection with external memory (e.g., `RadixSelect` [33, 36]), denoted as GPU-e, as shown in Figure 4b, implements different K-selection sub-steps as separate kernels, and transmits intermediate data among kernels via the external memory. As a result, the K-selection operator has to access the external memory multiple passes (well studied in [33]), leading to sub-optimal K-selection performance, which will become worse with a larger batch size due to heavy bandwidth contention on external memory. With the same setting mentioned above, the query latency of `RadixSelect` is increased by 12.36× when the batch size is increased from 1 to 16.

2.4 FPGA Opportunities

We observe that FPGA has the following properties that meet the requirements of the ideal EBR architecture.

- Similar to GPU, high-end FPGAs are equipped with HBM of large capacity (typically 8 to 32 GB). A typical HBM is a stack of 32 parallel DRAM channels (versus up to 8 DDR channels in a CPU), providing parallel memory accesses and thus high bandwidth (460 GB/s), which fundamentally eliminates the biggest memory bandwidth bottleneck in CPU-based EBR.
- Unlike GPU with exclusive and small on-chip memories for each SM, FPGA provides sufficient on-chip memories (dozens of MB in total), which are accessible to all compute elements. This could be leveraged to overcome the problems of GPU-based EBR as discussed in §2.3.2. Unlike GPU with SIMT cores optimized only for data parallelism, the massive compute elements and interconnects among them in FPGA are fully programmable, so that they can be orchestrated in any parallelism strategy (data parallelism or pipeline parallelism).

Desired features in ideal arch.	CPU	GPU	FPGA
large memory capacity	✔	✔	✔
high memory bandwidth		✔	✔
data parallelism	△	✔	✔
pipeline parallelism	△		✔
batch queries with low latency	△	△	✔

Table 1: EBR architecture comparison among CPU, GPU, and FPGA. ✔ means perfect support, while △ means limited support.

Table 1 summarizes the architecture comparison of CPU, GPU, and FPGA for EBR. Based on FPGA's advantages, we can design an FPGA-based EBR pipeline similar to that in Figure 4c: It traverses the HBM only once, passes intermediate data between operators via on-chip memory, and overlaps communications with computations of operators via careful pipeline designs. In this way, FPGA-based EBR has the potential to approach the optimal performance (Equation 1). The design details of such a system, named FAERY, are presented in the following sections.

3 FAERY Accelerator

We design the FAERY accelerator by following the most desired properties of the ideal EBR architecture, with some additional optimizations. Figure 5 presents the architecture of the FAERY accelerator, with a few major components including HBM, corpus manager, similarity calculation, filter, and K-selection. FAERY stores the corpus in HBM and uses the corpus manager (§3.1) for corpus scanning and update. FAERY applies data parallelism across multiple similarity calculation units (§3.2), and pipeline parallelism within K-selection (§3.3). Different from the ideal EBR architecture, FAERY does not need multiple K-selection pipelines with data parallelism, thanks to a new filter operator (§3.4) inserted before the K-selection pipeline to lower its throughput requirement. This optimization lowers the resource overhead compared with the ideal architecture. The above operators are perfectly pipelined and overlapped, and the resulting data streams are shown in §3.5.

3.1 Corpus Manager

FAERY stores the corpus in HBM and uses the corpus manager to perform corpus scanning and update. The corpus manager is designed to meet two objectives toward high bandwidth utilization of HBM: maximizing *single-channel performance* and maximizing *multi-channel parallelism*.

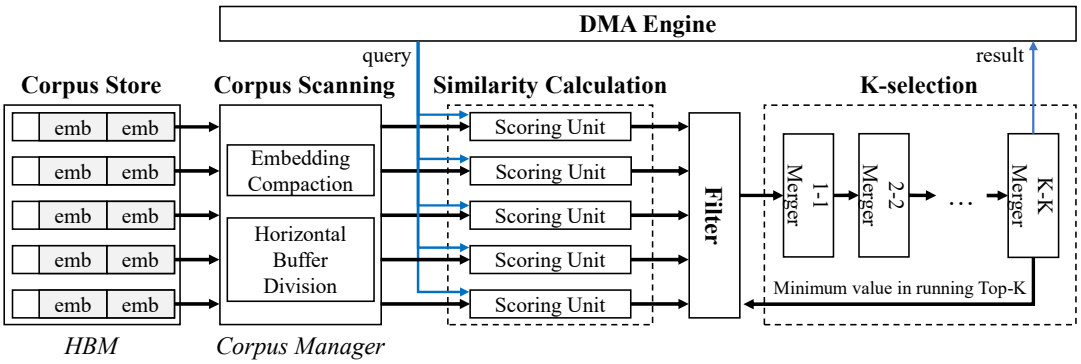


Figure 5: FAERY accelerator architecture with the batch size of 1. It stores item embeddings in high bandwidth memory (HBM), uses a corpus manager for corpus scanning and update, and applies appropriate parallelism paradigms for different key operators: data parallelism for similarity calculation and pipeline parallelism for K-selection. A filter is added between the above two operators to bridge their throughput mismatch and lower the resource requirement. The overall architecture is fully pipelined, with computations and communications perfectly overlapped to minimize latency and maximize throughput.

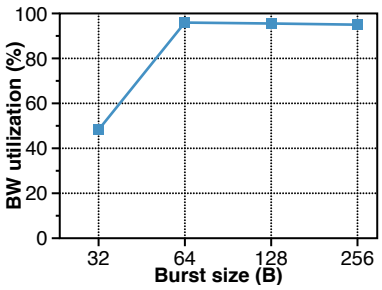

Figure 6: Bandwidth utilization of a single HBM channel with different burst sizes. The utilization is over 90% when the burst size is not smaller than 64 bytes.

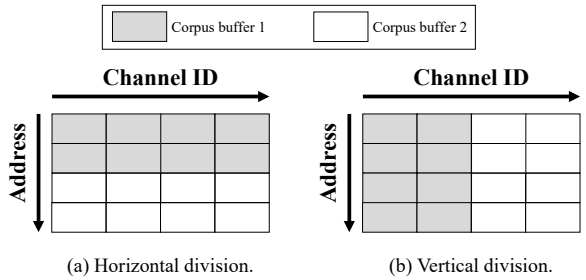

Figure 7: HBM can be divided into two buffers in two ways. (a) Horizontal division: divide buffers based on address, which preserves all memory channels and maximum memory bandwidth for each buffer. (b) Vertical division: divide buffers based on channel ID, which halves the number of available channels and the memory bandwidth for each buffer.

3.1.1 Embedding Compaction to Maximize Single-channel Performance

The bandwidth utilization of a single HBM channel is affected by two factors: *access pattern* (sequential or random access) and *burst size* (the number of bytes in a memory transaction). Given the nature of brute-force KNN search, both corpus scanning and corpus update perform sequential access, which is more efficient than random access. We show in Figure 6 the bandwidth utilization of a single HBM channel in sequential access over various burst sizes. The result reveals that, to achieve bandwidth utilization of over 90%, an ideal burst size should be not smaller than 64 bytes and be a multiple of the channel width of 32 bytes.

However, the size of embeddings could be smaller than 64 bytes, especially for those generated by quantization-aware training [30, 31, 37]. It could also be not a multiple of the channel width. To bridge the mismatch between the ideal burst size requirement and the realistic embedding size, we compact one or multiple embeddings into a burst, whose size might not be exactly a multiple of the embedding size, leaving some unused bytes in a burst. To minimize the waste, we choose an ideal burst size with minimal unused bytes.

3.1.2 Horizontal HBM Division to Maximize Multi-channel Parallelism

To support the online corpus update, the corpus manager partitions HBM into two corpus buffers: a runtime buffer to store the latest corpus and serve queries, and an update buffer reserved for update. Upon receiving a new corpus from the host, the corpus manager stores it into the update buffer, and then switches the EBR pipeline to scan corpus from that buffer for new queries. In this way, the runtime buffer and update buffer switch roles after each update.

HBM can be partitioned into two corpus buffers in two ways, horizontally or vertically, as shown in Figure 7. The horizontal division is chosen, as it keeps all the available HBM channels and thus the maximum memory bandwidth

for each buffer, while the vertical division loses half channels and thus half memory bandwidth for each buffer.

During corpus update, the HBM write caused by update and HBM read caused by query, may contend for HBM memory bandwidth with horizontal division. Such contention is negligible. Considering that the realistic HBM bandwidth is 414 GB/s (90% utilization of a typical 460 GB/s HBM), and corpus update is bounded by the PCIe Gen3 x16 bandwidth (16 GB/s), the update (HBM write) throughput over the total HBM throughput is less than 4%. Moreover, given that corpus update happens much less frequently than query, update can be further throttled to minimize its impact to query. Other update methods will be discussed in §7.

3.2 Similarity Calculation

Similarity calculation receives multiple item embeddings from multiple HBM channels simultaneously. In order to match the bandwidth of HBM, we apply data parallelism in similarity calculation, where multiple scoring units (SU) are instantiated to work in parallel, and each performs similarity calculation, e.g., inner product, between a separate item embedding and the given query embedding. The number of parallel SUs required is the product of the total number of HBM channels and the maximum number of item embeddings inside a channel width, which may contain more than one item embedding due to the embedding compaction (§3.1.1).

3.3 K-selection

There exist multiple different K-selection architectures [27,29, 44], suitable for different scenarios. In the context of recommendation systems, the value of k is from a few thousand to dozens of thousands in realistic EBR [16,25], so K-selection in FAERY aims to achieve both high performance and high scalability in supporting a large value of k. To this end, we choose an existing K-selection pipeline [29] based on bottom-up merge sort for the following two reasons.

First, the bottom-up merge sort allows processing input scores in a streaming manner to avoid storing the entire scores before computing. In contrast, some algorithms incapable of streaming processing, e.g., `RadixSelect` [36], inevitably need external memory to store the entire scores of a large size. Leveraging external memory to cache the scores should be avoided, as it will not only reduce the available storage space for the corpus, but also interfere with the performance of corpus scanning due to bandwidth contention.

Second, pipeline parallelism within K-selection is compute-efficient and scalable, e.g., the chosen K-selection pipeline [29] requires only $O(logk)$ comparators. In contrast, some data-parallel K-selection architectures [27, 44] use a large number of parallel comparators to process a batch of input scores at a time. The number of parallel comparators required by this method is $O(p*k)$, where p is the batch size

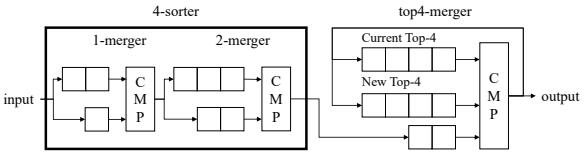

Figure 8: An example of the 4-selection pipeline in [29].

of input scores. Such design is not scalable, especially for k in the order of thousands.

Pipeline parallelism within K-selection. Figure 8 illustrates a K-selection pipeline where $k = 4$. The K-selection pipeline in [29] contains a series of *i-mergers* and a final *topk-merger*. An *i-merger* merges two sorted lists with length i into a sorted list with length $2i$, followed by a *2i-merger* in the pipeline. The pipeline starts at a *1-merger*, and log_2k sequential *i-mergers* form a *k-sorter*. At the end of the pipeline, a *topk-merger* merges the output of the *k-sorter* with the current sorted Top-K to generate a new running Top-K. All modules process data in a streaming manner, and the latency of such a pipeline is $k + log_2k$ clock cycles [29].

The above K-selection pipeline processes one score every clock cycle, which is slower than the throughput of scores generated by similarity calculation with data parallelism. According to the ideal architecture shown in Figure 2, K-selection can simply match the throughput with multiple K-selection pipelines, i.e., instantiating multiple K-selection pipelines in parallel, each processing different scores, followed by a merger at the end to get the final Top-K from multi-channel sorted Top-K. However, a single K-selection pipeline is much more resource-hungry than a single scoring unit. Instantiating multiple K-selection pipelines to match the throughput of the multi-channel similarity calculation is not resource-efficient, especially when supporting a large k and a large batch size. Based on an important observation on the K-selection pipeline, we address the throughput mismatch problem in a resource-efficient way by introducing a new operator: filter (§3.4).

3.4 Filter

The K-selection pipeline maintains inside a **running Top-K** (e.g., the *current Top-4* in Figure 8), which continuously updates the Top-K for all the past scores until the current point. We observe that, if the input score to K-selection is not greater than the minimum score of the running Top-K, the input won't change the internal running Top-K and thus can be dropped. Based on this observation, we design a filter to early drop non-Top-K scores, which significantly reduces the number of scores sent to K-selection. Figure 9 shows the throughput model of FAERY, where corpus scanning and similarity calculation are designed with data parallelism to match the HBM throughput, K-selection only provides a single pipeline to save resources, and the filter bridges the throughput mis-

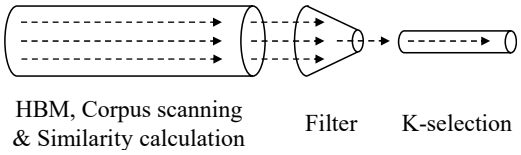

Figure 9: Throughput model of FAERY. Corpus scanning and similarity calculation are designed to fully match the HBM bandwidth, followed by a filter to early drop most of scores generated by similarity calculation, thus significantly lowering the throughput requirement of K-selection.

match between the multi-channel similarity calculation and the single-channel K-selection.

Let x ($x > 1$) denote the number of scores generated by similarity calculation per clock cycle. The throughput of similarity calculation is x scores per clock cycle, and the throughput of K-selection is one score per clock cycle, so that the throughput mismatch is $(x-1)/x$. We define filtering efficiency as the number of scores (m) dropped by the filter over the total number of scores (n), i.e., m/n. As long as $m/n \geq (x-1)/x$, the design will work well without performance degradation.

In practice, the recall ratio of EBR (the ratio of the retrieved items to the total items, i.e., $k:n$) is usually very low, e.g., $1:1000$. The majority of scores will be early dropped by the filter, and the filtering efficiency will be high enough to bridge the throughput gap. We analyze the average filtering efficiency as follows.

Filtering efficiency. Given that $n >> k$ in practice, we can derive the filtering efficiency using a simplified model. Assuming the input scores follow a random distribution, and the running Top-K values are already generated from all the previous scores when the dropping decision for a score is made, the probability of the i^{th} ($i > k$) score dropped by the filter follows

$$p(i) = \frac{i-k}{i}. \tag{2}$$

The expected number of scores dropped by the filter follows

$$m = \sum_{i=k+1}^{n} p(i) = \sum_{i=k+1}^{n} \frac{i-k}{i}. \tag{3}$$

As a result, the average filtering efficiency is

$$\begin{aligned} e &= \frac{m}{n} = \frac{\sum_{i=k+1}^{n} \frac{i-k}{i}}{n} \\ &= 1 - \frac{k}{n} - \frac{k}{n} \sum_{i=k+1}^{n} \frac{1}{i} \\ &> 1 - \frac{k}{n} - \frac{k}{n} ln(n). \end{aligned} \tag{4}$$

Given a typical setting in practice where $k = 1024$, $n = 10^6$, the filtering efficiency is larger than 98%. In our implementation (§5), x is 4, and the throughput mismatch is $3/4 = 75\%$. This shows that the filtering efficiency is much higher than the throughput mismatch in practice, and thus the filter enables K-selection to match the throughput of similarity calculation with just one pipeline, reducing resource consumption.

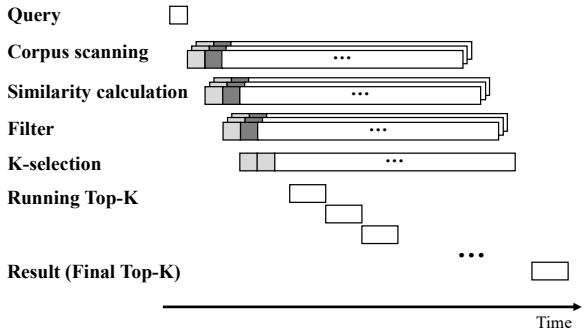

Figure 10: The perfect overlap of data streams in FAERY.

Buffer to absorb bursts. Although the filter balances good performance and low resource cost in practice, it can fail to drop any scores in the worst case when all the input scores are sorted ascendingly. Since the item embeddings are stored randomly in HBM, the probability that such worst case happens is very low. However, we do have a buffer in the filter to absorb two types of temporal bursts. The initial burst is built up while the filter is processing the first y scores of every new query, when the drop probability ($p(i)$, $i < y$) of score i is lower than the throughput mismatch $(x-1)/x$ between similarity calculation and K-selection. Based on Equation 2, y is $(k*x)$. The other type of burst is occasional score sequences in which all scores are larger than the minimum of the running Top-K. The size of this burst is variable but should be small given the increasing drop probability shown in Equation 2.

3.5 Perfect Overlap of FAERY Data Streams

As described in the above sections, all operators work in a streaming manner, i.e., all operators start processing as soon as the data begin to stream in, and the communications between operators are perfectly overlapped with computations. As a result, the data streams in this architecture exhibit a perfect overlap, as shown in Figure 10. Upon receiving a query, the corpus manager starts corpus scanning and gets a multi-stream of embeddings from 32 HBM channels, followed by similarity calculation and filter streams in the subsequent cycles. The filter operator early drops most of scores, so that a single stream of scores is sent to K-selection. As scores begin to stream into K-selection, the running Top-K is updated, and it is output as the final Top-K result soon after the last score is injected into the K-selection pipeline.

Batch is supported in FAERY in the same way as the ideal architecture (Figure 3). The data streams of multiple queries start at the same point. Therefore, the latency remains the same, and the throughput scales linearly with the batch size.

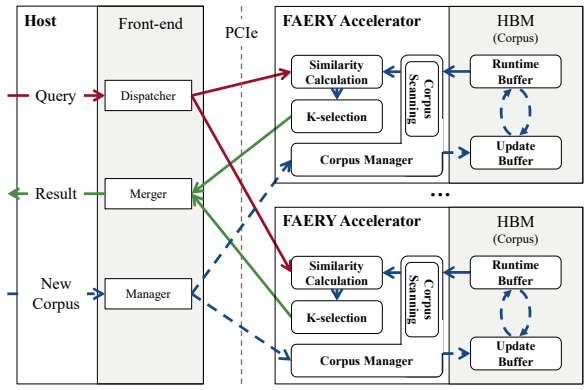

Figure 11: FAERY server architecture. A FAERY server hosts multiple FAERY accelerators to increase either the query throughput or the supported corpus size. A software front-end on the host CPU dispatches user queries to multiple accelerators, merges retrieval results from them, and updates the corpus on the fly.

4 FAERY Server

Figure 11 presents the FAERY server architecture, which includes a software front-end on the host CPU and multiple FAERY accelerators inserted in server PCIe slots.

Multiple FAERY accelerators can work together to enhance the capabilities of a single accelerator in two modes: *replication* and *sharding*. In the *replication* mode, these accelerators store separate replicas of the same corpus and serve different queries simultaneously to increase the query throughput. In the *sharding* mode, multiple accelerators store different shards of the same corpus and serve the same query simultaneously to increase the supported corpus size. The front-end running in the host CPU is responsible for query dispatching via a dispatcher module and result merging via a merger module in the above two modes.

When there is a new corpus received by the server, a manager module in the software front-end handles this update request. It determines whether corpus replicating or sharding is needed based on the working mode listed above, and then sends the corpus replicas (or shards) to the corresponding accelerators via PCIe. The corpus manager in each FAERY accelerator stores the update corpus in the update buffer and switch buffer roles as described in §3.1.2.

5 Implementation

We build a fully functional prototype of FAERY using FPGAs. The FPGA accelerator is built with Xilinx VU35P FPGA [4], which contains an HBM of 8 GB capacity, 32 memory channels, and 460 GB/s bandwidth. We implement the FAERY pipeline described in Figure 5 using the hardware programming language SystemVerilog. In the following part, we discuss several implementation details using this FPGA with a typical setting: One embedding contains 128 elements of 2 bytes each (i.e., the embedding size is 256 bytes), k is 1024, and the prototype runs at a clock frequency of 400 MHz, which matches the HBM bandwidth. An ASIC implementation of FAERY with the same HBM bandwidth but higher clock frequency (e.g., 1 GHz), could not provide significant performance improvement, as the end-to-end performance is mainly determined by the HBM bandwidth.

Corpus manager. Since the embedding size is 256 bytes, the burst size can be set to 256 bytes based on the embedding compaction strategy, resulting in no waste on both storage space and read bandwidth. Based on the measurement, the achievable HBM bandwidth is 414 GB/s, with 90% utilization of the theoretical upper bound of 460 GB/s. Given that the HBM has 32 memory channels of 32-byte width, the corpus scanning reads 1024 ($32*32=1024$) bytes from HBM every clock cycle, almost catching up with the HBM bandwidth at 400 MHz ($1024*400/1000=409.6$ GB/s), and outputs 4 ($1024/256=4$) embeddings per clock cycle on average. To support online corpus update, horizontal division keeps half of the 8 GB HBM space (i.e., 4 GB) for the runtime corpus, which supports up to 16M item embeddings in a single FPGA.

Similarity calculation. To match the throughput of 32 parallel HBM channels, similarity calculation is implemented with 32-channel SUs in parallel. Each SU performs inner product calculation, which consists of three stages. The first stage performs element-wise multiplications between the item and the query. Given that an HBM channel width (32 bytes) contains 16 elements (each 2 bytes) of an embedding, it requires 16 parallel multipliers in this stage to sustain the HBM channel bandwidth. In the second stage, it conducts a summation of the results in the first stage with an accumulation tree, which has $log_2 16=4$ layers. The summation result is finally added to the computing score in the last stage. Therefore, the latency of similarity calculation is 6 ($1+4+1=6$) cycles, and the throughput of similarity calculation with 32 parallel SUs (i.e., 4 scores per clock cycle) matches exactly the throughput of corpus scanning (i.e., 4 item embeddings per clock cycle).

K-selection. K-selection is implemented based on an existing pipeline [29], whose latency is $k+log_2 k$ clock cycles. For $k=1024$, the latency is 1034 cycles. This fully pipelined K-selection can process one score per clock cycle. Different from the ideal architecture, a single K-selection pipeline is required in FAERY, with the filter to bridge the throughput mismatch between similarity calculation and K-selection.

Filter. Since similarity calculation generates four scores per cycle, while K-selection only processes one score per cycle, the filter must drop at least 3/4 of the scores on average to bridge their speed gap. Based on the analysis in §3.4, the filtering efficiency in this setting is higher than 98% and thus greater than 3/4. To absorb bursts, the filter buffer is set to store at most 8192 ($2*k*x$, where $x=4$ and $k=1024$) scores,

	Per-query resources	Common resources
LUT	7.31%	11.05%
FF	6.98%	14.78%
BRAM	13.05%	10.66%
DSP	8.6%	0.07%

Table 2: Breakdown of FAERY resource consumption (batch size = 1). Per-query resources increase linearly with the batch size, while common resources remain unchanged.

slightly larger than the initial burst size ($k * x$) derived in §3.4 to reduce approximation error in the analysis. This buffer is implemented with only 8 Block RAMs (BRAMs), consuming less than 0.2% of the total FPGA memory resources. With both the high filtering efficiency and the sufficient buffer, the filter works well to bridge the throughput mismatch and to absorb temporal bursts, and we observe no performance loss with the above setting. Compared with the ideal architecture shown in Figure 2, FAERY with the filter and a single K-selection pipeline, can save 32% on-chip memories and 27% compute resources by eliminating the other three K-selection pipelines and a four-port merger [35] per query compute pipeline.

Batch support. FAERY supports batch queries as described in Figure 3. Despite the performance advantages, the resource requirements of batch queries increase with the batch size. As a result, the maximum batch size supported in our prototype is determined by the available resources in the Xilinx VU35P FPGA. The resources are consumed by two types of components: per-query compute pipelines (similarity calculation, K-selection, and filter) exclusive for each query, and common modules (corpus manager and PCIe DMA) shared among batch queries. Table 2 breaks down the resource consumption of a FAERY accelerator with the batch size of 1 into per-query resources and common resources. Based on this result, the upper bound of the batch size is 6 in the Xilinx VU35P FPGA. However, this FPGA chip is composed of multiple dies, so that timing closure is challenging when the resource utilization is high or cross-die routing is congested. We end up with an implementation with a batch size of 3, to balance good batch performance and easy timing closure.

6 Evaluation

We evaluate the performance of the FAERY implementation, and compare it with CPU- and GPU-based EBR, respectively. Our results reveal that:

- FAERY approaches the optimal query latency, and achieves 98.09×-118.99× and 1.85×-18.81× lower latency than CPU- and GPU-based EBR, respectively. The degraded FAERY with the same memory bandwidth of GPU still achieves 1.21×-12.27× lower latency than GPU-based EBR.
- In terms of latency-bounded ($\leq$ 10 ms) throughput, FAERY and the degraded FAERY outperform GPU-based EBR by 1.33×-6.58× and 0.87×-4.29×, respectively, while CPU-based EBR fails to meet the 10 ms latency target.
- FAERY achieves 1.66×-8.20× higher energy efficiency and 1.31×-6.46× higher cost efficiency than GPU-based EBR.
- A FAERY server with two accelerators provides 2× higher query throughput in the replication mode, and 2× higher corpus capacity in the sharding mode with less than 1.1% increase in latency.

6.1 Experiment Setup

Baseline. We compare FAERY with Faiss [23], an open-source similarity search library that supports both CPU and GPU. The K-selection implementation in Faiss GPU is `WarpSelect`, a heap-based algorithm using on-chip memory, as shown in Figure 4a, denoted as GPU-o. We further replace the Faiss K-selection implementation with an algorithm using external memory, as shown in Figure 4b, denoted as GPU-e. We choose `RadixSelect` implemented in [33], which reports the best performance when k is greater than 512, compared to other algorithms. Both GPU-o and GPU-e use `fp16` for embeddings and `fp32` for scores.

Platforms. FAERY is evaluated on a server with two 8-core Intel Xeon Silver 4110 CPUs. CPU-based EBR is evaluated on a server with two 16-core Xeon Gold 5218 CPUs and 192 GB memory. We choose Nvidia Tesla T4 GPU [2] in GPU-based EBR, as the T4 GPU shares a similar cost to the Xilinx VU35P FPGA (cost comparison will be discussed in §6.2.4). The CUDA version is 11.2 and the Tensor Core acceleration is enabled. T4 GPU is equipped with 16 GB GDDR6 of 300 GB/s bandwidth. To bridge the difference of memory bandwidth between FPGA (460 GB/s) and GPU (300 GB/s), we also evaluate a degraded FAERY, denoted as FAERY-d, by throttling its HBM bandwidth to 300 GB/s.

Corpus. We use the synthetic corpus, with randomly generated 128-dimensional item embeddings of 2 bytes each dimension, and retrieve $k = 1024$ items for each query. We use synthetic random corpora to verify the generality of FAERY, which by design, is not sensitive to any specific workload.

In the following, we first evaluate the performance of a single accelerator (§6.2). Many important applications contain a moderate corpus. For example, the YouTube video corpus contains tens of millions of items [40], and the Google play application corpus contains one million items [11]. The corpus of these applications could fit into the HBM of a single card based on the current FAERY implementation (§5). Then, we show the performance of a FAERY server with two accelerators (§6.3) to demonstrate FAERY's capability in supporting either higher query throughput or a larger corpus by adding cards.

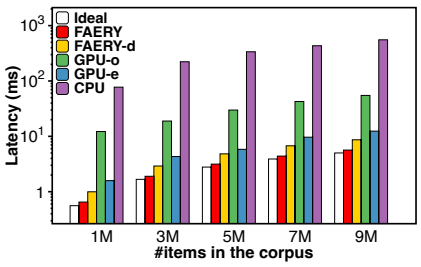

Figure 12: Query latency comparison among different EBR architectures (batch size = 1, latency is in log scale).

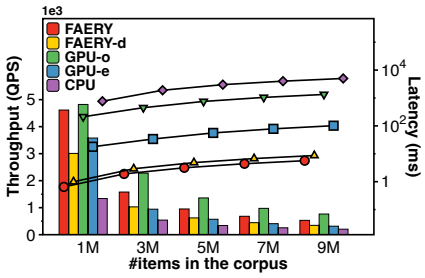

Figure 13: Query throughput comparison among different EBR architectures (Corresponding latency is also shown).

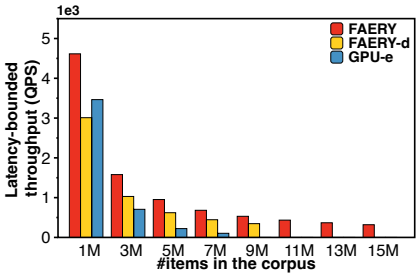

Figure 14: Comparison of latency-bounded throughput, where CPU and GPU-o fail to meet the latency target ($\leq$ 10 ms), and thus are not shown.

6.2 Single-accelerator Performance

6.2.1 Latency

We compare the query latency among different EBR architectures in Figure 12. Average latency is used as the metric, as latency distribution in each of these architectures doesn't show significant variance due to the deterministic execution flow of KNN. The query latency of the ideal architecture is calculated based on Equation 1, where S is $N * 256$ bytes, N is the number of items in the corpus, B is the maximum HBM bandwidth 460 GB/s, and C is the FAERY pipeline latency 2.6 us. The query latency of FAERY approaches the optimal latency of the ideal architecture, with only 1.13×-1.16× increases, which results from non-full ($\sim$ 90%) memory bandwidth utilization as measured in Figure 6. Both FAERY and FAERY-d consistently outperform CPU and GPU in query latency with different corpus sizes. Compared with CPU, FAERY significantly reduces the average latency (98.09×-118.99× lower) due to its high memory bandwidth and appropriate parallelism paradigms for different operators. Compared with GPU, FAERY achieves 9.48×-18.81× and 1.85×-2.44× lower latency than GPU-o and GPU-e, respectively. Even if we degrade the FAERY memory bandwidth to that of GPU T4 (300 GB/s), FAERY-d also achieves 6.18×-12.27× and 1.21×-1.59× lower latency than GPU-o and GPU-e, respectively. This verifies that even with the same memory bandwidth, FAERY-d still outperforms GPU-based EBR, because the poor pipeline support of GPU leads to a significant increase of the second part (C) in Equation 1, as detailed in §2.3.2.

6.2.2 Throughput

We compare the maximum throughput and its corresponding latency among different EBR architectures in Figure 13. Batch queries are used in all architectures to achieve the maximum throughput. Both FAERY and FAERY-d are evaluated with the batch size of 3, the same as that in the implementation. Although the throughput of CPU- and GPU-based EBR systems can be improved by increasing the batch size, we only show the results with the batch size up to 1024, because further increasing the batch size leads to marginal improvement. GPU-o consistently outperforms FAERY in throughput by 1.04×-1.44×, and FAERY-d by 1.60×-2.21×, with a large batch size but a much higher query latency (ranging from 212 ms to 1339 ms with different corpus sizes). In contrast, both FAERY and FAERY-d keep low query latency as that of batch size 1 when increasing the batch size. The throughput of GPU-e does not increase significantly with larger batch sizes, due to heavy contention on external memory bandwidth in K-selection among multiple queries. As a result, GPU-e achieves only 59%-78% (91%-119%) of the FAERY (FAERY-d) throughput, but has a much higher latency (ranging from 18 ms to 102 ms). FAERY outperforms CPU in throughput by 2.60×-3.45× even when the CPU-based EBR runs with a large batch size. Moreover, CPU suffers form the worst latency.

6.2.3 Latency-bounded Throughput

Latency-bounded throughput is a critical metric for EBR, as retrieval is a typical real-time service with strict requirements on the response time. For example, the response time is within 10 ms in the Taobao production retrieval [15, 25], and the query serving time of the entire recommendation pipeline (retrieval + ranking) is on the order of 10 ms in the Google application recommendation [11]. In this paper, we set the upper bound of the retrieval latency to 10 ms, and compare the latency-bounded throughput among different EBR architectures.

Since CPU and GPU-o fail to meet the latency target in any condition, we only compare FAERY and GPU-e in Figure 14. The latency target prevents GPU-e from using a large batch size, which increases per-query latency significantly due to the contention on memory bandwidth. In contrast, FAERY follows the ideal architecture for batch queries, maintaining constantly low latency when increasing the batch size, as discussed in §2.2. When the number of items in the corpus ranges from 1M to 7M, FAERY achieves 1.33×-6.58×

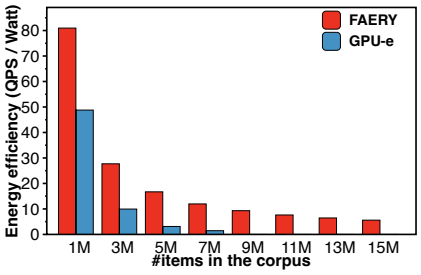

Figure 15: Comparison of energy efficiency among different EBR accelerators.

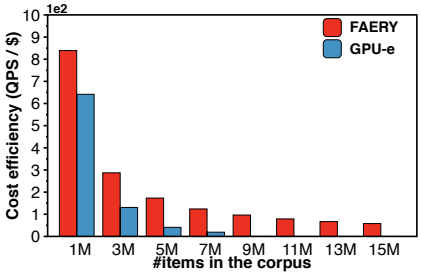

Figure 16: Comparison of cost efficiency among different EBR accelerators.

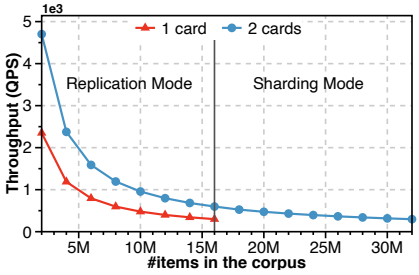

Figure 17: Throughput of a FAERY server with two cards.

higher latency-bounded throughput than GPU-e. However, FAERY-d achieves only 87% of the GPU-e latency-bounded throughput with the small corpus size of 1M, as GPU-e can leverage a large batch size (64 in GPU-e vs. 3 in FAERY-d) to boost the throughput with moderate memory bandwidth contention when the corpus size is small. As the corpus size increases from 3M to 7M items, FAERY-d exhibits its advantages in latency-bounded throughput and achieves 1.46×-4.29× higher latency-bounded throughput than GPU-e. When the number of items is larger than 7M, GPU-e fails to meet the latency target in any batch size, while FAERY-d can increase the corpus size until 9M items under latency target, and FAERY supports up to 15M items.

6.2.4 Energy & Cost Efficiency

The GPU and FPGA used in the evaluation have different architectural advantages and disadvantages, e.g., the GPU has lower memory bandwidth (300 GB/s vs. 460 GB/s), but much higher computing power (130 TOPS vs. 18.6 TOPS for INT8) than the FPGA. In addition to using the degraded FAERY with 300 GB/s memory bandwidth in a direct comparison between FPGA and GPU in terms of latency and throughput, we consider both energy efficiency (performance per watt) and cost efficiency (performance per dollar), as yet another fair metrics to compare the efficiency between totally different hardware architectures. We use the latency-bounded throughput measured in Figure 14 as the performance reference.

Energy efficiency. Based on the measurement, FAERY is 57 Watt and GPU-e is 71 Watt during serving. The above power consumption does not vary significantly with different corpus sizes. Given these power consumption and throughput data, Figure 15 shows the result of energy efficiency (QPS/Watt), where FAERY consistently outperforms GPU-e with 1.66×-8.20× higher energy efficiency.

Cost efficiency. As the concrete cost numbers are confidential, we normalize the costs of GPU, FPGA, and server used in the evaluation to 1, 1.1, and 4.4, respectively. With these cost units, the normalized costs of the FAERY and GPU servers are 5.5 (=1.1+4.4) and 5.4 (=1+4.4), respectively. Based on these normalized costs and the latency-bounded throughput data, Figure 16 shows the result of cost efficiency (i.e., QPS/(cost unit)), where FAERY provides 1.31×-6.46× higher cost efficiency than GPU-e.

6.2.5 Summary

Table 3 summarizes the EBR performance comparison among different processors, and reveals that each processor has its unique advantages for EBR. FAERY, an FPGA-based EBR, achieves the lowest latency, the highest latency-bounded throughput, and the highest energy and cost efficiency compared with CPU and GPU. Compared with CPU, FPGA's performance gain results from the high memory bandwidth provided by HBM and massive programmable compute elements to enable appropriate parallelism paradigms and batch processing. FPGA outperforms GPU due to the fully pipelined design with perfectly overlapping communications with computations of operators, and a programmable architecture that supports efficient K-selection. All these advantages make FAERY not only approach the optimal latency, but also achieve linear-scaling throughput when increasing the batch size. CPU-based EBR supports the largest corpus size, thanks to the large capacity of CPU DDR memory. GPU-based EBR achieves the highest raw throughput without latency bound with a very large batch size, thanks to its massive compute cores.

6.3 Multi-accelerator Performance

We evaluate a FAERY server with two accelerators. Figure 17 shows the aggregate query throughput with different corpus sizes. When the corpus can fit into a single card (i.e., the number of items is not larger than 16M), we replicate the corpus in the two cards to double the query throughput, as shown in the left part of Figure 17. When the corpus size is larger than the memory capacity of a single card, we evenly shard the corpus between the two cards, and thus the supported corpus size is extended up to 32M items, i.e., 2× the HBM capacity of a single card, as shown in the right part of Figure 17. In the

	Corpus size in bytes	Normalized latency	Normalized throughput	Normalized latency-bounded throughput (< 10 ms)	Normalized energy efficiency	Normalized cost efficiency
CPU	> 100 GB	98.09-118.99	0.290-0.385	-	-	-
GPU	16-80 GB	1.85-18.81	0.593-1.440	0.152-0.752	0.122-0.602	0.155-0.763
FPGA (FAERY-d)	8-32 GB	1.53	0.652	0.652	-	-
FPGA (FAERY)	8-32 GB	1	1	1	1	1

Table 3: Summary of performance comparison among different EBR processors.

sharding mode, the software front-end in CPU has to merge the two Top-K results from the two cards and yield the final Top-K, introducing an extra latency of less than 15 us, i.e., 1.1% of the total query latency.

7 Discussion

System lessons. While we focus on FPGA-accelerated EBR in this paper, we believe FPGA is a promising choice for not only EBR acceleration in specific, but also domain specific accelerator (DSA) in general. First, FPGAs are readily available for DSA in several hyper-scale cloud providers [10,14,41,45]. Second, FPGAs are inherently capable of faithfully implementing DSA systems such as FAERY, MicroRec [22], and Tiara [41]. These systems are memory and compute bounded, so they can benefit from customized parallelism and pipelining with optimized memory accesses provided by FPGAs.

Most FPGA-based architectures can be baked into custom ASICs for higher performance and efficiency. In FAERY, the query latency and throughput are mainly limited by the memory bandwidth, so an ASIC implementation with the same memory bandwidth would not significantly improve the performance. However, an ASIC version of FAERY can achieve higher energy efficiency. Nonetheless, it will require a significant volume to amortize the high non-recurring engineering (NRE) cost for higher cost efficiency.

Online update. The online update approach described in §3.1 minimizes the degradation of the total query throughput (QPS) during the update, by taking half of the HBM memory in each card as update buffer. We further note that there are other ways for online update from a distributed system perspective. In a typical production EBR system, there are multiple corpus replicas distributed across multiple FAERY servers for reliability and load balancing purposes. The online update in this case can be performed by taking off one replica at a time for updating while keeping the others online. This approach may achieve higher memory utilization, but experience higher update time and lower QPS than our update approach during the update process.

Support new models. In addition to the online corpus update, FAERY is able to change the pipeline structure on the fly to adapt to new models. Given the relatively stable EBR pipeline structure, including corpus scanning, similarity calculation, and K-selection, we are able to use the same hardware code to support different EBR pipeline variants with just different parameters (e.g., embedding size, data type, k). When a new model requires a change of the pipeline structure, we can simply change parameters in the code, generate a hardware image, and then load the image into FPGA on the fly.

Accelerate ANN-based EBR. Although FAERY is designed to accelerate KNN-based EBR, it can be extended to accelerate ANN to achieve higher throughput by sacrificing retrieval accuracy. Indexing-based ANN algorithms, e.g., IVF [34] and HNSW [28], leverage an index layer before corpus scanning to reduce the number of accessed items per query. Quantization-based ANN algorithms, e.g., PQ [21] and OPQ [17], leverage a codebook to compact the corpus. FAERY can support both ANN variants by maintaining the index layer or the cookbook in FPGA on-chip memory. Most of the other operators are the same, and their designs can be shared among KNN- and ANN-based FAERY.

Use FAERY for other services. Although FAERY is a DSA for retrieval in recommendation systems, we believe a similar idea can be applied to vector search in general, which is a fundamental part of many applications [13, 20, 25] that use semantic embedding vectors to represent contents (articles, images, audios, videos, etc.) and perform searches. These applications share a similar data flow to that described in this paper, but their characteristics vary. Interesting future work is to extend FAERY to accelerate a generic vector search service (such as Microsoft Vector search [5] and Google Vertex AI Matching Engine [6]).

8 Related Work

CPU- and GPU-based EBR systems have been discussed in §2. Existing FPGA-based similarity searches [27,44] were not designed for EBR, and thus not suitable. They leveraged massive parallel comparators to perform K-selection, whose resource consumption is unbearable for k being a few thousand in EBR. Moreover, they did not optimize the efficiency of corpus scanning, as they either did not leverage the high bandwidth of HBM [44] or failed to achieve high bandwidth utilization [27]. There are other kinds of work that accelerated specific ANN

algorithms, e.g., HPQ [7] for quantization-based ANN and QuickNN [32] for indexing-based ANN. They are orthogonal to FAERY that focuses on optimizing the entire EBR pipeline as a whole, including corpus scanning, similarity calculation, and K-selection.

9 Conclusion

FAERY is a domain specific accelerator (DSA) for embedding-based retrieval (EBR). The components of FAERY: corpus scanning, similarity calculation, and K-selection are arranged using the appropriate parallel techniques as required by an ideal EBR architecture. As a result, FAERY does not have the shortcomings and performance penalties of existing CPU- and GPU-based EBR approaches. FAERY not only provides both low latency and high throughput compared with CPU-based EBR, but also outperforms GPU-based EBR in terms of latency-bounded throughput.

Efficient and Scalable Graph Pattern Mining on GPUs

Xuhao Chen
MIT CSAIL

Arvind
MIT CSAIL

Abstract

Graph Pattern Mining (GPM) extracts higher-order information in a large graph by searching for small patterns of interest. GPM applications are computationally expensive, and thus attractive for GPU acceleration. Unfortunately, due to the complexity of GPM algorithms and parallel hardware, hand optimizing GPM applications suffers programming complexity, while existing GPM frameworks sacrifice efficiency for programmability. Moreover, little work has been done on GPU to scale GPM computation to large problem sizes.

We describe G^{2}Miner, the first GPM framework that runs efficiently on multiple GPUs. G^{2}Miner uses *pattern-aware*, *input-aware* and *architecture-aware* search strategies to achieve high efficiency on GPUs. To simplify programming, it provides a code generator that automatically generates pattern-aware CUDA code. G^{2}Miner flexibly supports both breadth-first search (BFS) and depth-first search (DFS) to maximize memory utilization and generate sufficient parallelism for GPUs. For the scalability of G^{2}Miner, we propose a customized scheduling policy to balance workload among multiple GPUs. Experiments on a V100 GPU show that G^{2}Miner is 5.4× and 7.2× faster than the two state-of-the-art single-GPU systems, Pangolin and PBE, respectively. In the multi-GPU setting, G^{2}Miner achieves linear speedups from 1 to 8 GPUs, for various patterns and data graphs. We also show that G^{2}Miner on a V100 GPU is 48.3× and 15.2× faster than the state-of-the-art CPU-based systems, Peregrine and GraphZero, on a 56-core CPU machine.

1 Introduction

Graph Pattern Mining (GPM) finds subgraphs in a given data graph which match the given pattern(s) (Fig. 1). GPM is a key building block in many domains, e.g., protein function prediction [6, 29, 83], network alignment [62, 76], spam detection [9, 34, 37], chemoinformatics [31, 57, 84], sociometric studies [36, 48], image segmentation [119]. Graph machine learning tasks can also benefit from GPM, including anomaly detection [4, 78], entity resolution [12], community detection [90], role discovery [88] and relational classification [61].

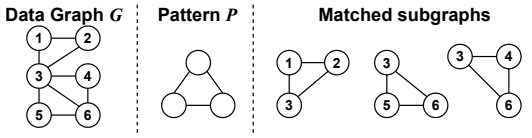

Figure 1: Graph Pattern Mining example. The pattern $\mathcal{P}$ is a triangle, and 3 triangles are found in the data graph $\mathcal{G}$.

GPM is extremely compute intensive, since it searches a space that is exponential in the pattern size. For example, Peregrine [53], a state-of-the-art GPM system on CPU, takes 9 hours to mine the `4-cycle` pattern (see Fig. 3) in the `Friendster` graph on a 56-core CPU machine. GPUs provide much higher compute throughput and memory bandwidth than CPUs, and thus are attractive for GPM acceleration.

However, implementing GPM on GPU efficiently is challenging. This is because it requires sophisticated optimizations by leveraging information in the GPU hardware architecture, the pattern(s) of interest, and the input data graph.

- *Architecture Awareness*: A GPU usually has smaller memory capacity than a CPU and requires more fine-grain data parallelism to be fully utilized. More threads, however, require more memory to accommodate intermediate data! The search order, BFS or DFS, offers a similar tradeoff between memory and parallelism and therefore, GPM on GPU requires careful orchestration of parallelism and memory usage to maximize efficiency. GPUs are also much more sensitive to thread divergence and workload imbalance [18] than CPUs. This necessitates a more sophisticated task-to-hardware mapping for GPU than that for CPU.
- *Pattern Awareness*: State-of-the-art GPM systems on CPU use *pattern aware* search plans that prune the search space using pattern information. This has been shown to be orders-of-magnitude faster than the pattern-oblivious search [53]. This pattern-aware approach has worked well for CPU, but it has not been well explored on GPU. For example, many

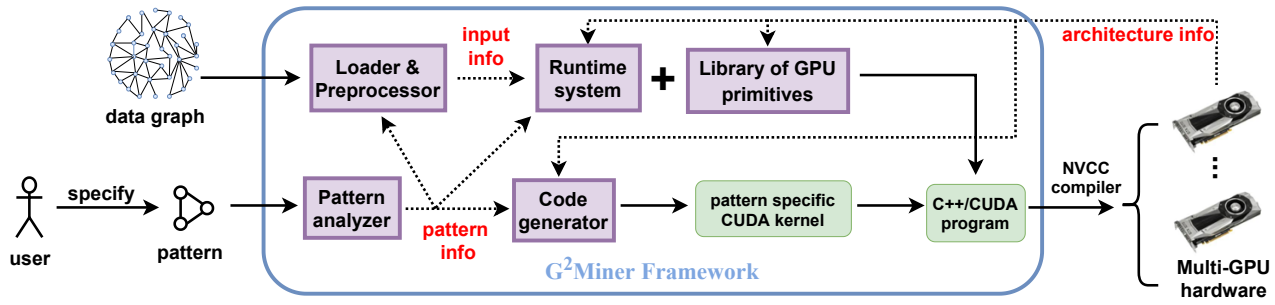

Figure 2: G^{2}Miner system overview. It contains a graph loader, a pattern analyzer, a runtime, a library of GPU primitives and a code generator.

pattern-aware pruning schemes are only effective under DFS exploration, but existing GPU-based systems use BFS, and thus loss these opportunities for pruning.

- *Input Awareness*: Dynamic memory allocation is expensive in GPU [110] and we can avoid it if we can estimate the worst-case memory usage. This can be done by using some meta information such as the maximum degree of the input graph. For labelled graphs, we can use the vertex label distribution of the input graph to get the maximum number of possible patterns, which helps save memory space. In general, input information helps make better tradeoff among work efficiency, parallelism and memory consumption.

Given this complexity, the design goal of our GPM framework on GPUs involves the following considerations:

- **Efficiency:** To achieve high efficiency on GPU, a GPM system must be highly optimized with awareness of the pattern, the input and the hardware architecture. There is no prior system, neither on CPUs nor on GPUs, that considers all three aspects together. This asks for a holistic solution that incorporates sophisticated optimizations systematically.
- **Ease of programming:** Writing efficient GPM code on GPUs is particularly difficult for domain users, who may not be parallel programming experts. Thus, hiding GPU programming complexity is essential for system usability.
- **Scalability:** The skewness in power-law graphs causes load imbalance. This problem is exacerbated for DFS-based GPM algorithms, because accesses to neighbors are multiple hops away. Hence, we need effective task scheduling and distribution policies to scale to multiple GPUs.

	General	CPU	GPU	Multi-GPU	Order	Code Gen
EmptyHeaded [2]		✓			DFS	✓

Pangolin [25,26]	✓	✓	✓		BFS	
PBE [42,43]			✓		BFS	
G^{2}Miner	✓		✓	✓	both	✓

Table 1: Comparison of state-of-the-art GPM systems, in terms of support for generality of the programming model, hardware platforms (CPU/GPU/multi-GPU), search orders, and code generation.

We propose G^{2}Miner to overcome these challenges. Table 1 compares G^{2}Miner to the state-of-the-art systems, including those that solve only the *subgraph matching* problem, which is a subset of the GPM problem. In Table 1, subgraph matching systems include EmptyHeaded, Graphflow, GraphZero, GraphPi and PBE, while Peregrine, Pangolin and G^{2}Miner are general GPM systems. Much of the prior work focuses on CPU, and uses DFS to reduce the memory footprint. GPU-based systems (Pangolin and PBE), on the other hand, use BFS because straightforward DFS implementations on GPU suffer from thread divergence and load imbalance. This, however, limits their efficiency and/or the problem size they can solve. Additionally, G^{2}Miner simplifies GPU programming with automated CUDA code generation, while Pangolin requires users to write CUDA code manually, and PBE is not programmable at all. Last but not least, G^{2}Miner is the only system that scales to multiple GPUs.

Fig. 2 shows the overview of G^{2}Miner. It consists of a graph loader, a pattern analyzer, a runtime system, a library of CUDA primitives and a code generator. The user is only responsible for specifying the pattern(s) of interest using our API (§4). The pattern analyzer does analysis on the pattern and generates a *pattern-specific* search plan, based on which, the code generator (§5) automatically generates pattern-specific CUDA kernels for GPUs. The kernels contain invocations to the device functions defined in the GPU primitive library (§6) which includes efficiently implemented set operations. The generated kernels, the GPU primitive library, and the runtime are compiled together by the NVCC compiler to generate the executable that runs on multi-GPU.

At runtime, the graph loader reads in the data graph, extracts input information (e,g., maximum degree and label distribution) and performs pattern-specific preprocessing on the data graph. The pattern, input and architecture information is fed to the runtime (§7) which heuristically handles GPU memory allocation, data transfer, and multi-GPU scheduling.

This paper makes the following contributions:

- G^{2}Miner is the first pattern-aware, input data-graph-aware and architecture-aware framework for GPM, and it is the first GPM system that automates CUDA code generation for arbitrary patterns to simplify programming.

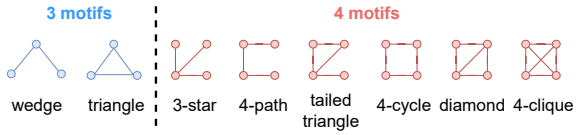

Figure 3: 3-vertex (left) and 4-vertex (right) motifs [26].

- G^{2}Miner is the first multi-GPU framework for GPM and the first GPU-based GPM framework that flexibly supports both BFS and DFS. It uses a novel task scheduling policy to balance workload among GPUs and we show G^{2}Miner performance increases linearly from 1 to 8 V100 GPUs.
- On a V100 GPU, G^{2}Miner is 5.4× faster than *Pangolin*, the only existing GPM system on GPU, and 7.2× faster than *PBE*, the state-of-the-art subgraph matching solver on GPU, thanks to the optimizations enabled in G^{2}Miner (Table 2).
- G^{2}Miner on a V100 GPU is 48.3× and 15.2× faster than state-of-the-art CPU-based GPM system *Peregrine* and subgraph matching system *GraphZero* on a 56-core CPU.

2 Background and Related Work

2.1 Graph Pattern Mining Problems

Let $\mathcal{G}(\mathcal{V}, \mathcal{E})$ be an undirected graph with $\mathcal{V}$ as the vertex and $\mathcal{E}$ as the edge set. Given a vertex $v \in \mathcal{V}$, the neighbor set of v is $\mathcal{N}(v)$, the degree d_v of v is $|\mathcal{N}(v)|$ and Δ is the maximum degree in $\mathcal{G}$. A graph $G'(W,F)$ is said to be a subgraph of $\mathcal{G}$ if $W \subseteq \mathcal{V}$ and $F \subseteq \mathcal{E}$. G' is a *vertex-induced subgraph* of $\mathcal{G}$ if F contains all the edges in E whose endpoints are in W. G' is an *edge-induced subgraph* of $\mathcal{G}$ if W contains all the vertices in $\mathcal{V}$ which are the endpoints of edges in F.

Definition of GPM. Given an undirected graph $\mathcal{G}$ and a set of patterns S_p={P_1, P_2, ...} by the user, GPM finds vertex-induced or edge-induced subgraphs in $\mathcal{G}$ that are isomorphic to any $\mathcal{P}$ in S_p. If the cardinality of S_p is 1, we call it a single-pattern problem. Otherwise, it is a multi-pattern problem. The output of GPM varies in different problems, e.g., the pattern frequency (a.k.a, *support*) or listing all matched subgraphs. The definition of support also varies, e.g., the count of matches or the *domain support* [26] used in FSM. Note that *listing* requires enumerating every subgraph, but *counting* does not. Thus, counting allows more aggressive search-space pruning.

A pattern $\mathcal{P}$ is a small graph that can be defined explicitly or implicitly. An explicit definition specifies the vertices and edges of $\mathcal{P}$, whereas an implicit definition specifies the desired properties of $\mathcal{P}$. For explicit-pattern problems, the solver finds matches of $\mathcal{P}$ in S_p. For implicit-pattern problems, S_p is not known in advance. Therefore, the solver must find the patterns as well as their matches during the search.

GPM requires guarantee for *completeness*, i.e., every match of $\mathcal{P}$ in $\mathcal{G}$ should be found, and often *uniqueness*, i.e., every distinct match should be reported only once [101]. To avoid confusion, we call a vertex in the pattern $\mathcal{P}$ as a *pattern vertex* and denote it as u_i, and a vertex in the data graph $\mathcal{G}$ as a *data vertex* and denote it as v_i. Our work covers the following GPM problems from the literature [26, 33, 101]:

- *Triangle counting* (TC): It counts the number of triangles (Fig. 1), i.e., 3-cliques, in $\mathcal{G}$.
- *k-clique listing* (k-CL): It lists all the k-cliques in $\mathcal{G}$ ($k \geq 3$). A k-clique is a k-vertex graph whose every pair of vertices are connected by an edge.
- *Subgraph listing* (SL). It lists all edge-induced subgraphs of $\mathcal{G}$ that are isomorphic to a pattern $\mathcal{P}$.
- *k-motif counting* (k-MC): It counts the number of occurrences of all possible k-vertex patterns. Each pattern is called a *motif* [11, 77]. Fig. 3 shows all 3-motifs and 4-motifs. This is also an example of a multi-pattern problem because we have to find all the subgraphs that are isomorphic to *any* pattern in a given set of patterns.
- *k-frequent subgraph mining* (k-FSM): Given k and a threshold σ_{min}, this problem considers all patterns with fewer than k edges and lists a pattern $\mathcal{P}$ if the support σ of $\mathcal{P}$ is greater than σ_{min}. This is called a *frequent* pattern. If k is not specified, it is set to ∞, meaning that it is necessary to consider all possible values of k. In k-FSM, vertices in $\mathcal{G}$ have application-specific labels.

For TC and k-CL, vertex-induced and edge-induced subgraphs are the same. SL and FSM find edge-induced subgraphs, while k-MC looks for vertex-induced subgraphs. All problems seek to find explicit pattern(s) except FSM which finds implicit patterns. k-MC and FSM are multi-pattern problems, while the others are single-pattern problems.

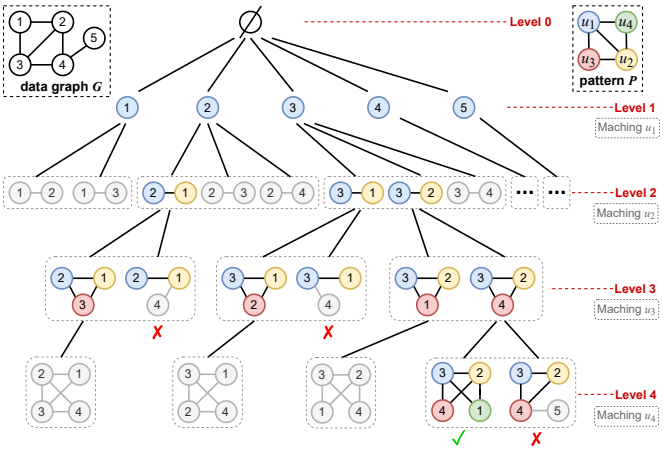

Figure 4: A search tree using vertex extension. Vertex colors (not vertex labels) show the matching between data vertices and pattern vertices. The matching order is $\{u_1 \rightarrow u_2 \rightarrow u_3 \rightarrow u_4\}$. The symmetry order is $\{v_a > v_b, v_c > v_d\}$. Subgraphs in grey are ruled out by symmetry breaking. × shows the unnecessary extensions that are pruned by the matching order. ✓ shows the matched subgraph.

Algorithm 1 Pseudo code for finding `diamond` in DFS order

```
1: for each vertex v1 ∈ V in parallel do                    ▷ match v1 to u1
2:     for each vertex v2 ∈ N(v1) do                        ▷ match v2 to u2
3:         if v2 ≥ v1 then break;                           ▷ symmetry breaking
4:         W ← N(v1) ∩ N(v2);                               ▷ set intersection: buffered in W
5:         for each vertex v3 ∈ W do                        ▷ match v3 to u3
6:             for each vertex v4 ∈ W do                    ▷ match v4 to u4; W is reused
7:                 if v4 ≥ v3 then break;                   ▷ symmetry breaking
8:                 else count ++;                           ▷ do the counting
```

Algorithm 2 Pseudo code for finding Pattern $\mathcal{P}$ in BFS order

```
1: for each level i ∈ [1, P.size] do          ▷ level i from 1 to the pattern size
2:     for each subgraph sg ∈ SL_i in parallel do          ▷ SL_i: subgraph list
3:         for each vertex u ∈ sg do
4:             for each vertex v ∈ N(u) do
5:                 sg' ← sg ∪ v                ▷ vertex extension: add vertex v
6:                 if sg' satisfy P.constraints(i) then
7:                     if i = P.size then count ++;      ▷ leaf: a match found
8:                     else SL_{i+1}.insert(sg')         ▷ go to the next level
```

2.2 Pattern-Aware GPM Algorithms

A GPM problem is a search problem, whose search space is a *subgraph tree* [25, 27] (Fig. 4). Each node in the tree is a subgraph of the data graph $\mathcal{G}$. Subgraphs in level l of the tree have l vertices. The root of the tree (level 0) is an empty subgraph, while the leaves of the tree are potential candidates of matches. A GPM problem can be solved by building this search tree, and checking each leaf if it is isomorphic to the pattern $\mathcal{P}$ using the typical *graph isomorphism test*.

The search tree is built by *vertex extension*: subgraph S_1=(W_1, E_1) can be extended by a single vertex $v \notin W_1$ to obtain subgraph S_2=(W_2, E_2), if v is connected to some vertex in W_1 (i.e., v is in the *neighborhood* of subgraph S_1). When two subgraphs are related in this way, we say that S_2 is a child of S_1. Formally, this can be expressed as W_2=$W_1 \cup \{v\}$ where $v \notin W_1$ and there is an edge $(v,u) \in \mathcal{E}$ for some $u \in W_1$. Similarly, *edge extension* extends a subgraph S_1 with a single edge (u,v), with at least one of the endpoints of the edge is in S_1.

The efficiency of a GPM algorithm depends heavily on how much we can prue the search tree. State-of-the-art GPM frameworks [53, 74] use *pattern-aware* search plans that leverage the properties of the pattern to prune the tree. A pattern-aware search plan consists of a *matching order* and *symmetry order*.

Matching order is a total order that defines how the data vertices are matched to pattern vertices. This order is used to eliminate irrelevant subgraphs on-the-fly. As shown in Fig. 4, to find the `diamond` pattern, we use a matching order among pattern vertices: $\{u_1 \rightarrow u_2 \rightarrow u_3 \rightarrow u_4\}$, meaning that each vertex v_1 added at level 1 is matched to u_1; each vertex v_2 added at level 2 are matched to u_2, and so on. To search for matching candidates, there are connectivity constraints for the data vertices. For example, in `diamond`, since u_3 is connected to both u_1 and u_2, candidate vertices of v_3 must be found in the intersection of v_1 and v_2's neighborhoods, i.e., $v_3 \in \mathcal{N}(v_1) \cap \mathcal{N}(v_2)$. The same constraint should also be applied to v_4. For a given pattern $\mathcal{P}$, there exist multiple valid matching orders. To choose the best performing matching order, prior works [7, 21, 22, 53, 59, 73, 74, 93] have proposed various cost models to predict the performance of matching orders, and choose the one with the highest expected performance.

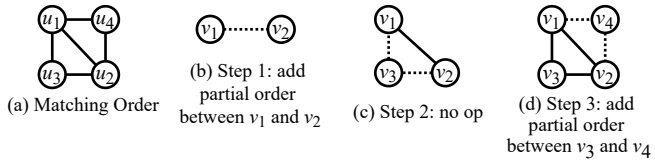
Symmetry order is a partial order enforced among data vertices for *symmetry breaking*, which removes redundant subgraph enumerations (a.k.a *automorphism* [26]), and thus guarantees that any match of $\mathcal{P}$ in $\mathcal{G}$ is found only once. For example, for `diamond`, we enforce that vertices added at level 1 must have larger ids than vertices added at level 2, i.e., $v_1 > v_2$. Thus, in level 2 of the tree in Fig. 4, the subgraph $\{2, 1\}$ is selected to be extended further, but subgraph $\{1, 2\}$ is pruned. Similarly we add a constraint that $v_3 > v_4$. So the symmetry order for `diamond` is $\{v_1 > v_2, v_3 > v_4\}$.

2.3 DFS vs. BFS

Any search order (e.g., BFS, DFS) can be used to explore the search tree, but different search orders come with different work efficiency, parallelism and memory consumption.

Algorithm 1 shows a DFS algorithm to mine the pattern `diamond`. It contains 4 nested `for` loops (Line 1, 2, 5, 6). Each loop corresponds to a data vertex (v_1, v_2, v_3, v_4) that is mapped to a pattern vertex (u_1, u_2, u_3, u_4) in Fig. 5 (a). A buffer W in Line 4 holds intermediate data that is reused multiple times, which avoids redundant computation and thus improves *work efficiency*. The memory footprint contains only four vertices $(v_i, i = 1, 2, 3, 4)$ and W in Line 4 whose size is bounded by Δ. In DFS, every parallel *task* does a DFS walk on the entire subtree rooted at v_1 (Line 1). This is known as *vertex parallelism*. The amount of parallelism is $|\mathcal{V}|$. Another way to parallelize it is *edge parallelism*, in which every task contains the subtree rooted at each edge (say, if we make Line 2 in parallel). The amount of parallelism then is $|\mathcal{E}|$.

The BFS algorithm in Algorithm 2 explores the tree level by level. In each level, it maintains a *subgraph list* that is shared globally among all threads. Each thread takes a subgraph from the subgraph list (Line 2), and extends it to generate its child subgraphs (Line 5). The child subgraphs are inserted into the next-level subgraph list (Line 8). In BFS, each parallel task is a subgraph in the subgraph list of the current level. Since the size of the subgraph list increases exponentially level by level, the amount of parallelism increases rapidly.



(a) Matching Order (b) Step 1: add partial order between v_1 and v_2 (c) Step 2: no op (d) Step 3: add partial order between v_3 and v_4

Figure 5: Generating symmetry order for `diamond` [27].

Although it provides more parallelism than DFS, BFS needs much more memory to accommodate the subgraph list. For example, the BFS-based GPM system Pangolin [26] needs more than 40GB memory to mine the 5-`clique` pattern in a moderate size graph `livejournal`, making it impossible to run in most of off-the-shelf GPUs.

2.4 GPM Systems and Applications

Many existing GPM systems [20, 26, 101, 107, 120] use the BFS order. As they do level-by-level subgraph extension, they generate massive intermediate data and thus are limited to small graphs and patterns. Recently, a few DFS-based GPM systems [25, 33, 53, 74] have been proposed to support larger datasets, but they are all CPU-based. Among all, Pangolin is *the only existing GPM system that supports GPU*. However, limited by the BFS order, Pangolin can only handle small graphs, and it lacks pattern and input awareness.

There also exist subgraph matching systems on CPU [2, 55, 73, 93, 104] and GPU [42, 43, 117]. But they only support a subset of GPM problems and are usually not programmable.

Numerous hand-optimized GPM applications have been developed, including triangle counting [32, 39, 47, 50, 80, 81, 94, 98, 109, 111, 116] , k-clique listing [30] and counting [5, 19, 52, 92], motif counting [3, 67, 70, 82, 89, 95], subgraph listing/matching [13, 14, 17, 46, 54, 59, 60, 65, 68, 72, 85, 86, 91, 96, 97, 103, 105, 108], and FSM [1, 35, 58, 99, 100, 102, 106, 114]. All of them are manually optimized with significant programming effort to achieve high efficiency, which is quite a lot of burden for the domain programmers.

3 Challenges of Efficient GPM on GPU

3.1 GPM vs. Graph Analytics

Similar to graph analytics, GPM algorithms are *irregular* [18] because the control flow and memory accesses are input-data dependent and thus, cannot be predicted statically. This irregularity causes random memory accesses and load imbalance, making it difficult to be efficiently parallelized. Unlike graph analytics that only accesses 1-hop neighbors, GPM requires accessing multi-hop neighbors, which exacerbates the irregularity problem. For example, load imbalance is much worse for DFS-based GPM than graph analytics because each parallel *task* (a DFS walk on the entire sub-tree) is more coarse-grain in GPM. In addition, GPM generates intermediate data during the search (buffer W in DFS or subgraph list in BFS), which consumes extra memory than graph analytics.

3.2 GPM on GPU vs. GPM on CPU

Since the tasks are independent of each other, they are fairly easy to parallelize on CPU, as shown in Algorithm 1 Line 1. But it is not as straightforward on GPU due to GPU's massively parallel model and limited memory capacity.

A GPU often consists of multiple *streaming multiprocessors* (SM). Each SM accommodates multiple vector units. This hardware organization results in a hierarchical parallel model: each CUDA *kernel* includes groups of threads called *cooperative thread arrays* (CTAs) or *thread blocks*. Within each CTA, subgroups of threads called *warps* are executed simultaneously. Thus GPUs, to be fully utilized, require much more hierarchical parallelism than CPUs.

GPUs generally have less memory than CPUs, while BFS-based GPM algorithms consume memory exponential in the pattern size. Using DFS can reduce memory consumption, and also improve work efficiency. Hence, state-of-the-art CPU-targeted GPM frameworks [25, 53, 73, 74, 93] all adopt DFS. However, naively porting the DFS-based CPU algorithms to GPU is not efficient because of the following reasons:

(1) Branch Divergence. In Algorithm 1, each thread takes a vertex v_1 from $\mathcal{V}$ and starts DFS walk rooted by v_1. Since different vertices have different neighborhoods, the threads in a warp may take different paths at the branches, leading to inefficiency on GPU [87]. Branch divergence is much more severe for DFS than BFS due to the multiple nested loops for DFS backtracking that access multi-hop neighborhoods.

(2) Memory Divergence. DFS walk also makes memory accesses more irregular. This causes memory divergence in GPU, i.e., threads in a warp access non-consecutive memory locations. In this case, each load instruction generates multiple (up to the warp size, i.e., 32) memory requests to the memory subsystem, which wastes memory bandwidth, congests on-chip data path [24], and thus results in poor GPU performance.

(3) Load Imbalance. Variance of neighborhood sizes in power-law graphs causes load imbalance. In CPU it is less significant because there are limited number of cores/threads and each core is very powerful. However, GPUs have thousands of lightweight cores and more than ten times the number of active threads. If unbalanced, it would be much more costly since the slowest thread is running on a low-frequency core and thousands of cores are waiting. Load imbalance is also less concerned for BFS, since it does level-by-level extension and at each level the tasks are lightweight, i.e., fine-grained.

Therefore, existing GPU-based GPM systems [26] and subgraph matching systems [42, 43] all use BFS order. This severely limits the graph sizes that they can handle. PBE [42] partitions the data graph to support large graphs, but partitioning introduces cross-partition communication. Note that using *beam search* [71] or bounded DFS does not fully resolve these issues, but loses the benefit of work efficiency of using DFS.

4 G^{2}Miner System Overview and Interface

We propose G^{2}Miner (Fig. 2) to address the challenges in §3. It hides away GPU programming complexity, and takes into

Listing 1: k-Clique Listing (k-CL) user code in G^{2}Miner

```
1 Graph G = loadDataGraph("graph.csr");
2 Pattern p = generateClique(k);
3 list(G, p); // count(G, p) for counting
```

Listing 2: Subgraph Listing (SL) user code in G^{2}Miner

```
4 Pattern p("pattern.el", EdgeInduced);
5 list(G, p);
```

Listing 3: k-Motif Counting (k-MC) user code in G^{2}Miner

```
6 Set<Pattern> patterns = generateAll(k);
7 Map<Pattern,int> result = count(G, patterns);
```

Listing 4: Frequent Subgraph Mining (k-FSM) user code in G^{2}Miner

```
8  Void updateSupport(Subgraph s) {
9    map(s.getPattern(), s.getDomain());
10 }
11 bool patternFilter(Pattern p) {
12   return p.getDomainSupport() >= threshold;
13 }
14 Set<Pattern> patterns = generateAll(k,
15                  EdgeInduced, patternFilter);
16 list(G, patterns, PATTERN_ONLY);
```

account the properties of the pattern, input data graph and hardware architecture to achieve high efficiency on GPU. We first describe how to program in G^{2}Miner in §4.1, and then introduce the system interface for extracting information out of the input, pattern and architecture (§4.2). Lastly we give an overview of the optimizations in §4.3.

4.1 Making Programming Easy

G^{2}Miner provides the same API as state-of-the-art CPU-based systems, e.g., Peregrine and Sandslash, making it friendly to users of CPU frameworks. As shown in Listing 1, to program a k-CL solver in G^{2}Miner, the user specifies the pattern using an utility function `generateClique()` (Line 2), and then call `list()` to do listing or `count()` to do counting. If `count()` is used, it allows the system enable counting-only optimizations (details in §5). To list an arbitrary pattern $\mathcal{P}$ (Listing 2), the user can specify $\mathcal{P}$ using its edgelist (`pattern.el` at Line 4). By default G^{2}Miner finds vertex-induced subgraphs. Since SL requires listing edge-induced subgraphs by definition, the user needs to specify it (`EdgeInduced` at Line 4).

For multi-pattern problems, the user is interested in a set of patterns instead of just one. For k-MC in Listing 3, the patterns can be generated by calling an utility function `generateAll()` (Line 6) or parsing the patterns' edgelists.

Programmability is particularly important for implicit-pattern problems. The user must implement API functions to specify the patterns. For example, for k-FSM in Listing 4, the user chooses to use `domain support` by implementing `updateSupport` (Line 8). To specify the properties that differentiate the interesting patterns with irrelevant patterns, the user must define `patternFilter` (Line 11). As FSM asks for only listing the patterns, we can specify a `PATTERN_ONLY` keyword in `list` to avoid listing the subgraphs (Line 16). If the user wants to customize the output, one can define a `output()` function and pass it to `list`, instead of using `PATTERN_ONLY`. This function defines custom operations on each subgraph of interest, which can also be used to do *early termination* [53] by checking a user-defined condition.

4.2 System Interface

The pattern specified by user API is fed to a *pattern analyzer* to extract useful pattern information. Meanwhile, the GPU hardware information is taken by G^{2}Miner to enable optimizations in the runtime, code generator and GPU primitives. At runtime, the data graph is loaded by a *graph loader* which collects input information and also performs preprocessing.

Pattern Analyzer. The *pattern analyzer* generates: (1) a search plan with a matching order and a symmetry order, which is used by the code generator; (2) reuse opportunities using buffers (e.g., W in Algorithm 1), used by the code generator and the runtime; (3) other important properties of the pattern, e.g., whether the pattern is a clique or `hub-pattern` (§5.4 (2)), used by the runtime and code generator.

The pattern analyzer enumerates all the possible matching orders of $\mathcal{P}$, and uses a cost model to pick the best one. We use the same cost model as GraphZero [73] for fair comparison, but any cost model can be employed by G^{2}Miner. We also use the algorithm in GraphZero to generate a symmetry order: it takes the generated matching order $\mathcal{MO}$ and builds a subgraph incrementally in the order specified by $\mathcal{MO}$. At each step it detects symmetric vertex pairs and adds orders accordingly. For example, for `diamond`, the matching order in Fig. 5 (a) results in the three steps shown in (b), (c) and (d), during which we add partial order $v_2 < v_1$ and $v_4 < v_3$.

Graph Loader and Preprocessor. The data graph $\mathcal{G}$ is loaded by the *graph loader* into the memory in the compressed sparse row (CSR) format. As $\mathcal{G}$ is being loaded, useful input information of the data graph is extracted, e.g., $|\mathcal{V}|$, $|\mathcal{E}|$ and Δ of $\mathcal{G}$. In addition, if the graph is labelled, the vertex frequency of each label is computed (see usage for FSM in §7.2). After $\mathcal{G}$ is loaded into memory, some preprocessing is performed on $\mathcal{G}$. First, the neighbor list of each vertex is sorted by ascending order of vertex IDs, so that we can apply early exit when we search the list with an upper bound (i.e., symmetry breaking). Second, if a pattern of `clique` is detected, G^{2}Miner enables a typical optimization called *orien-*

Optimizations		Effect					Used in Pangolin?	Used in hand written apps?	Conditions to apply
		mitigate divergence	load balance	mem. saving	algorithm pruning	extra GPU efficiency

Table 2: Optimizations in G2Miner. Among them, optimizations A, B, D, E, F, I, J, K, M, N are pattern-aware; optimizations B, C, G, H, I, K, M are architecture-aware; and optimizations B, E, F, K, N are input-aware. Pattern-aware optimizations are applied based on the pattern analysis, while input-aware and architecture-aware optimizations are enabled according to the input and architecture information, respectively. TC: triangle counting. CL/CC: clique listing/counting. MC: motif counting.

tation [26] . It gives every edge a direction in the undirected data graph $\mathcal{G}$, which in turn converts $\mathcal{G}$ into a directed graph. This halves the edge count in $\mathcal{G}$, significantly reduces Δ, and completely eliminates on-the-fly checking. Third, our preprocessor also supports sorting (e.g., by degree) and renaming the vertices in $\mathcal{G}$ to improve load balance [53, 73]. Note that all these preprocessing operations need to be done only once.

4.3 Overview of Optimizations

Table 2 lists all the optimizations enabled in G^{2}Miner. We classify them into three categories. Optimizations in Category-(1) are those exist in prior GPM systems. Optimizations in Category-(2) do not exist in prior GPM systems (e.g., Pangolin) but have been used in some hand-written GPM applications. For example, optimization `D: data graph partitioning` has only been used for triangle counting, while in G^{2}Miner we generalize it for all the clique patterns. These optimizations are missing in prior GPM systems because prior systems are oblivious to the required pattern, input or architecture information. Optimizations in Category-(3) are novel as they have never been used for GPM, though some of them are known for GPU computing in general.

As shown in column 3 to 7 of Table 2, these optimizations have different kinds of effect on GPM applications: (1) mitigating thread divergence; (2) improving load balancing; (3) reducing memory consumption; (4) pruning search space; and (5) improving efficiency based on GPU hardware features.

The last column of Table 2 shows the conditions for each optimization to be applied. All the optimizations in Table 2 are automated in G^{2}Miner based on detecting the conditions, except for M and N (the last two rows). M and N are particularly used for implicit-pattern problems like FSM, for which the system cannot infer the conditions automatically. Thus, M and N are user-activated by specifying a flag.

Next, we describe these optimizations in detail, in the three major components of G^{2}Miner: the code generator (§5), the device function library (§6) and the runtime scheduler (§7).

5 Pattern-specific GPU Code Generation

G^{2}Miner includes a *pattern-aware* code generator that automatically generate CUDA code specific to the pattern. Prior work [73, 74] has explored how to generate pattern-specific CPU code based on the matching order and symmetry order, but code generation is more challenging for GPU.

Generating pattern-specific CPU code is relatively straightforward. For example, to generate Algorithm 1 for `diamond`, the matching order in Fig. 5 (a) is used to generate the 4 nested `for` loops, and the symmetry order is then used to insert breaks at Line 3 and 7. Whenever a set operation is needed, a function call to the set operation primitive (imple-

mented in a library) is inserted (Line 4). Since v_3 and v_4 are both from $\mathcal{N}(v_1) \cap \mathcal{N}(v_2)$, a buffer W is created for data reuse. Finally, *task parallelism* is used to parallelize the program, i.e., each thread processes one task at a time (Line 1).

However, generating efficient GPU code is more challenging, because (1) DFS-based GPM suffers from the thread divergence and load imbalance issues (§5.1); (2) hybrid search orders are needed in some cases (§5.2); and (3) extra support is needed for multi-pattern problems (§5.3) and advanced pruning schemes (§5.4).

5.1 Parallel Strategies for DFS on GPU

To maximize GPU efficiency for the DFS algorithm, we employ a *two-level parallelism* strategy in G^{2}Miner to exploit both inter-warp task parallelism and intra-warp *data parallelism*. This is motivated by our key observation that in GPM algorithms *most of execution time is spent on set operations*. For example, when we executed Peregrine on a multicore CPU, set operations for each benchmark took 75% to 92% of the total execution time. This motivated us to parallelize set operations by exploiting the data parallelism within each warp. It alleviates divergence and also provides more parallelism to fully utilize GPUs. To reduce load imbalance and further increase parallelism, we use edge parallelism for GPU instead of the vertex parallelism used for CPU.

(1) Reduce divergence with warp-centric parallelism. We could map each task to a thread, a warp or a CTA in a GPU. As DFS has much more coarse-grained tasks than BFS, mapping a task to a thread would be highly divergent and unbalanced for GPUs. However, if we map a task to a CTA, all (e.g., 256) threads in the CTA will be used to process the same set operations. If the two input neighbor-lists of a set operation are small, many threads in the CTA will be idle, leading to low utilization. Moreover, all threads in the CTA will do the same DFS walk, which is a lot of redundant computation.

In G^{2}Miner we use *warp-centric data parallelism*. Each task is assigned to a warp. All threads in a warp synchronously perform the same DFS walk of the task. During the DFS walk, whenever a set operation is encountered, all threads in the warp work cooperatively to compute the set operation in parallel. It has several benefits. First it achieves higher throughput than CPU since set operations are parallelized. Second, it alleviates thread divergence within each warp as all threads in a warp are progressing synchronously. Third, it causes less redundancy than using CTA. Our evaluation shows it is on average 2× faster than CTA-centric parallelism.

(2) Reduce task granularity for load balance. GPM systems on CPU use vertex parallelism [25, 53, 73, 74], i.e., each task is a DFS walk rootedin a vertex, as shown in Fig. 6 (a). This can already provide enough parallelism for CPU, needs no auxiliary data, and potentially enjoys data reuse within the sub-tree. But the coarse-grain tasks lead to load imbalance which can not be well tolerated by GPUs. To reduce task granularity, we use edge-parallelism, i.e., each task explores the subtree rooted by an edge. As shown in Fig. 6 (b), apparently more work is required to search the subtree below a vertex on average compared to searching the subtree below an edge. In addition to better load balance, edge parallelism can provide more parallelism ($|\mathcal{E}| > |\mathcal{V}|$) for GPU than vertex parallelism.

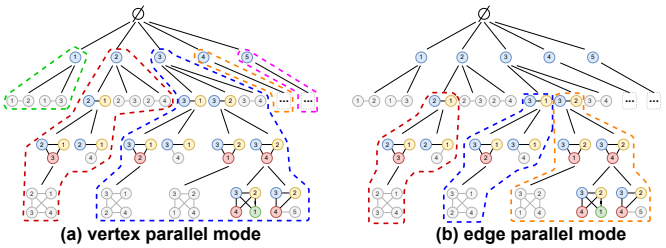

Figure 6: (a) vertex-parallel vs. (b) edge-parallel execution. Each dashed circle is a parallel task. A task is mapped to one thread on CPU, but in G^{2}Miner it is mapped to one warp on GPU.

- By default, our code generator generates edge-parallel kernels. Our evaluation shows they are mostly (1.5× on average) faster than vertex parallel ones. But some GPM algorithms must use vertex parallelism. For example, the 3-MC algorithm in [25] can only be done in vertex parallelism. G^{2}Miner supports both vertex and edge parallelism. The user can set a compiler flag to use vertex parallelism, in which case Ω is not generated to save memory.

Discussion. *Two-level parallelism* has been only used for triangle counting [50], and it is challenging to extend it for all GPM problems. First, triangle counting does subgraph extension only once, which needs no DFS traversal. Thus, G^{2}Miner is the first to support DFS for GPM on GPU. Second, naive GPU implementations for complex patterns can easily run out of memory for intermediate data. This is not a concern for triangle counting. Third, during the DFS traversal, it requires extension to support high-performance generic set operations and multi-pattern, which triangle counting does not require. In the following, we show that these challenges can be resolved by applying optimizations H, I, J, K, M, N in Table 2.

5.2 Support for Hybrid Search Orders

With the two-level parallelism in §5.1, for many GPM problems, DFS is faster than BFS in G^{2}Miner. However, this is not the case for problems like FSM. FSM computes the `domain support` and thus requires aggregating all the subgraphs for each pattern to compute its support. In the DFS-based FSM algorithm [99, 114], each task is a single-edge pattern (instead of subgraph) and the entire subtree of that pattern. This is *pattern-parallel*, instead of vertex-parallel or edge-parallel. Since the number of patterns is much smaller than the number of vertices or edges, the parallelism in FSM is not sufficient for GPU. Moreover, the task granularity in pattern-parallelism is much larger than that in vertex- or edge-parallelism, making

Algorithm 3 Pseudo code for counting `diamond`

```
1: for each vertex v1 ∈ V in parallel do                ▷ match v1 to u1
2:     for each vertex v2 ∈ N(v1) do                    ▷ match v2 to u2
3:         if v2 ≥ v1 then break;                       ▷ symmetry breaking
4:         n = |N(v1) ∩ N(v2)|;                         ▷ # triangles incident to (v1, v2)
5:         count += n*(n-1)/2                           ▷ choose 2 from n to form a diamond
```

the problem even more unbalanced.

In G^{2}Miner we use a hybrid of BFS and DFS, or *bounded BFS* search for problems that use `domain support` (e.g., FSM). At the single-edge level (i.e., level-2), we start with BFS search to aggregate edges by their patterns in parallel, which provides abundant parallelism. As the search goes deeper, the number of subgraphs increases exponentially. To fit the intermediate data in memory, we divide the subgraphs into blocks. Each block has a size that can resides in GPU memory, but also contains enough amount of subgraphs that can fully utilize the GPU. Once the current block is processed, it moves to the next block. Using this bounded BFS search, G^{2}Miner can support larger graphs than Pangolin.

5.3 Support for Multi-pattern Problems

Multiple patterns may have a common sub-pattern, which can be shared if they are searched in the same CUDA kernel. On the other hand, mining multiple patterns simultaneously would need a significant amount of intermediate resources, e.g., registers, which results in low hardware utilization (occupancy) on GPU.

Instead of generating a single gigantic kernel for all patterns, we employ *kernel fission* to reduce register pressure. Given multiple patterns, we leverage pattern analysis to find which patterns share the same sub-pattern, so that they should be merged into the same kernel to enjoy sharing. For those patterns do not share the same sub-patterns, we generate different kernels for them, so that each kernel is lightweight enough to avoid high register pressure. For example, in 4-motifs (Fig. 3), `tailed-triangle`, `diamond` and `4-clique` share the same sub-pattern `triangle`. So we generate a single CUDA kernel for the three patterns, in which they share the same workflow that enumerates triangles. However, for the other patterns, since there is no sharing opportunity, we generate one kernel for each. These separated kernels use fewer registers than a combined kernel, so that each SM in GPU can accommodate more co-running warps to maximize utilization. This improves performance by 15% for mining 4-motifs.

5.4 Support for Advanced Pruning Schemes

(1) Counting-only Pruning. If the user is interested in *counting* instead of *listing* subgraphs, there may exist an advanced pruning opportunity to further reduce the search space. For example, to count edge-induced `diamond` (Algorithm 3), because a `diamond` consists of two triangles, we first compute the triangle count n for each edge (v_1, v_2) using set intersection (Line 4), and then use the formula $\binom{n}{2} = n \times (n-1)/2$ to get the `diamond` count (Line 5). Note that this pruning opportunity is pattern specific and is not always available. For example, there is no such opportunity for `4-cycle`. Our pattern analyzer detects the opportunities by using automatic pattern decomposition [21,82], and based on the detection, our code generator can accordingly generate the CUDA kernel.

(2) Local Graph Search (LGS). This is a pruning scheme used for `hub-patterns`. A hub-pattern contains at least one `hub` vertex that is connected to all other vertices. For example, any vertex in a `clique` is a hub vertex. The key idea of LGS is, instead of searching a massive data graph $\mathcal{G}$, we can construct a small local graph for each vertex in $\mathcal{G}$ and search in the local graphs. For a hub pattern with a hub vertex u_1, we match the first data vertex v_1 to u_1, and the entire sub-tree rooted by v_1 is confined within v_1's 1-hop neighborhood. Fig. 7 shows an example of constructing a local graph. Search in the local graph is faster because the vertex degrees in the local graph are smaller than those in the global data graph. When the pattern analyzer detects a hub-pattern, the code generator inserts a call to construct local graphs, and generates code to search in the local graphs, instead of the original data graph.

- Previously, LGS has only been used for clique patterns [30], while G^{2}Miner generalizes and automates it for all hub patterns. Moreover, unlike CPUs, naive implementation on GPUs is not beneficial. We combine LGS with the `bitmap` format (see §6.2) to achieve significant speedups.
- *Input Awareness*. LGS is not always beneficial [25]. The key indicator is the maximum degree Δ of the data graph. For example, if Δ is too large, it is not beneficial due to high overhead of local graph construction. Therefore, we generate CUDA kernels for both cases: LGS enabled and disabled. The runtime system checks if Δ is above a threshold and decides accordingly which kernel to use. LGS brings us 1.2 $\sim$ 3.7$\times$ speedup on GPU for various data graphs.

6 Device Primitives for Set Operations

As G^{2}Miner assigns each task to a warp, whenever there is a set operation, all the thread in a warp work cooperatively to compute it. For example, in Algorithm 1, there is a set intersection at Line 4. In G^{2}Miner, set operations are done by invoking the corresponding device functions predefined in the GPU primitive library. We leverage GPU hardware SIMD support to implement efficient set operations (§6.1) and flexibly support various data formats for vertex sets (§6.2).

6.1 SIMD-aware Primitives

Given two sets A and B, we need two major set operations in GPM: (1) set intersection: $C = A \cap B$; (2) set difference: $C = A - B$, where C is the output set. Besides, another operation

set bounding is also often needed: given a set A and an upper bound y, set bounding computes $\{x|x < y \& x \in A\}$. We discuss set intersection in detail, and the other operations are similar.

In Algorithm 1 Line 4, the result of set intersection is stored in a buffer W for reuse. Buffering is widely used in GPM algorithms to avoid repetitive computation [74]. To support buffering in G^{2}Miner, each warp is allocated a private buffer in the GPU memory. In the primitive functions, threads in a warp write outputs to the buffer in parallel. To do this efficiently, we use CUDA warp-level primitives [69] which are supported by the GPU hardware (special instructions). For each vertex v in set A, we use a boolean flag to indicate whether it exists in set B. Using the flag, we compute a mask using `__ballot_sync` primitive. The mask is then used to compute the index and the total size of the buffer using `__popc` primitive.

Implementation details. Previous work has explored set intersection for SIMD [10, 15, 45, 51, 118] or GPU [8, 38, 40, 41, 49, 50, 79, 80, 112, 113]. We classify their algorithms into 3 categories: *Merge-path* [40, 41], *Binary-search* [38, 50] and *Hash-indexing* [80]. We have extensively evaluated these methods on GPU, and we find that binary search works the best since it is less divergent. In our library, we implement a high-performance binary search [50]: to exploit temporal locality, we leverage the scratchpad in GPU to pre-load the first five layers of the binary search tree, which further mitigates memory divergence. We extend this method to also support set difference, set bounding, and local graph construction.

6.2 Flexible Data Representation

Vertex set is a key data structure in GPM, which is used for the neighbor list in $\mathcal{G}$ and the buffer W in Algorithm 1. Its representation on GPU has a major impact on performance. For the set operations particularly, using a dense representation makes set operations easy to compute, but it requires more storage space. If using a sparse representation, it saves space but complicates the computation of set operations.

We support two types of formats for vertex set on GPU: `sorted-list` (sparse) and `bitmap` (dense). `sorted-list` is a list (i.e. array) of vertices sorted in ascending order. `bitmap` is a sequence of bits (length=$|\mathcal{V}|$), each of which indicates the connectivity to a vertex in $\mathcal{V}$. Set operations on `bitmap` are very simple and efficient, but `bitmap` consumes more space when $\mathcal{V}$ is large. Thus, by default we use `sorted-list`, and we only enable `bitmap` for hub-patterns since the `bitmap` size can be reduced significantly (Δ instead of $|\mathcal{V}|$).

7 Runtime Scheduling and Management

Our runtime system is aware of the pattern, input data graph and GPU architecture to balance workload among multiple GPUs (§7.1) and make full use of the GPU memory (§7.2).

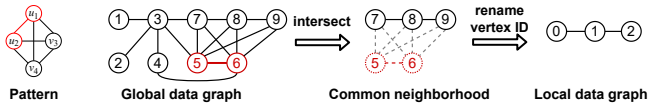

Figure 7: Local graph constructed for v_1=5 and v_2=6 which are matched to hub vertices u_1 and u_2 in the pattern respectively. We first compute set intersection of vertex 5 and 6, to get their common neighbors (vertex 7, 8, 9). The common neighbors are renamed to form a local graph. Renaming can reduce `bitmap` storage.

7.1 Task Scheduling for Multi-GPU

Given n as the number of GPUs[1] available in the system and a data graph $\mathcal{G}$ with an edgelist $\Omega = \{e_1, e_2, ..., e_m\}$ where $m = |\mathcal{E}|$ (in the case of symmetry breaking at level 2, $m = |\mathcal{E}|/2$), the task scheduler aims to divide GPM computation onto the n GPUs, by dividing Ω into n segments, each of which has the same amount of work, such that the execution time of the last completed GPU is minimized.

BFS-based GPM systems, e.g., Arabesque, RStream, and Pangolin, balance workload by reassigning tasks at every level. But this does not work for the DFS algorithm because DFS does not work in the level-by-level way as BFS. Existing DFS-based GPM systems target only CPUs, and thus can use sophisticated work stealing techniques [33]. But this will incur non-trivial runtime overhead on multi-GPU ($\sim$20%) [23, 50].

Policy 1: Even-split Scheduling. Ω is to evenly split into n consecutive ranges, each of which contains m/n tasks. This is used in existing triangle counting solvers on multi-GPU [80]. This policy is simple and has no scheduling overhead, but it results in severe load imbalance for skewed graphs. Fig. 8 shows the time spent on each GPU to finish its work under the even-split scheme. Due to the skewness of the workload assigned to each GPU, under the 2-GPU setting we observe that GPU_0 takes much more time to finish its work than GPU_1. The same time variance is observed for the 3-GPU and 4-GPU setting. Worse still, in the 4-GPU setting, since most of the heavy tasks are assigned to GPU_1, it makes the 4-GPU setting even slower than the 3-GPU setting. This means the even-split scheme does not scale beyond 3-GPU for this benchmark. The reason of poor scalability is two-folds: (1) the granularity of splitting workload is too coarse-grain; (2) it is unaware to the skewness of task workload by assuming every task has the same amount of work.

Policy 2: Round-robin Scheduling. Each GPU has a task queue, denoted as Q_i for the i-th GPU, $i \in [0, n)$. The tasks in Ω are assigned to each queue in a round-robin fashion, i.e., e_j is assigned to Q_i, where $i = j \bmod n$, $j \in [0, m)$. This is a fine-grained scheduling policy that has been used in existing motif counting solvers on multi-GPU [89]. The policy comes with some overhead, i.e., copying tasks into task queues. This copy is needed only once for a specific data graph and n, i.e., once

[1]We assume that every GPU has the same compute power for simplicity, otherwise it is not difficult to scale the workload by a factor accordingly.

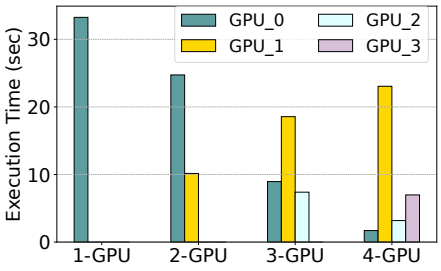

Figure 8: Running time of each GPU using even-split: 3-MC on Tw2.

done, the queues can be reused for mining different patterns.

Policy 3: Chunked Round-robin Scheduling. Ω is first split into lots of small chunks, and then we assign chunks to the task queues in a round-robin way. This is a generalization of the previous two policies. When the chunk size $c = m/n$, it becomes the same as policy 1. When $c = 1$, it becomes the same as policy 2. Thus if c is too small the data copying overhead will be high, but if c is too large, we see load imbalance as in policy 1. We use $c = \alpha \times y$, where y is the total number of warps and α is a constant (set to 2 empirically). Our chunking is also pattern aware, as described in §7.2.

Implementation details. To further reduce data copy overhead, we parallelize it as the location to copy to is fixed for each queue if the chunk size is fixed. Note that this overhead is constant to the pattern size k, which is trivial (< 1%) when $k > 3$, since the GPM computation is exponential to k. For small pattern like triangle, we overlap the scheduling overhead with the GPU computation, by first assigning a few chunks to each GPU and launch the kernel. During the GPU computation, we continue sending the remaining chunks from the CPU to feed the GPUs. Orthogonal work on ordering tasks in Ω [89] or grouping tasks by community may help further improve load balance and locality.

7.2 GPU Memory Management

GPU memory is a scarce resource. In GPM algorithms, the major memory usage involves the data graph $\mathcal{G}$, the edgelist Ω and the buffers (e.g., W in Algorithm 1)). For FSM, the subgraph list of each pattern requires additional space.

(1) Preprocessing the data graph. We have discussed *orientation* in §4.2. In the multi-GPU setting, for any hub-pattern, since the search is confined in the root vertex v_1's neighborhood, we partition $\mathcal{V}$ into n subsets (n is the number of GPUs). For each i-th subset we generate its vertex induced subgraph of $\mathcal{G}$, and copy it to the i-th GPU. This partitioning reduces memory usage and guarantees that there is no communication needed between GPUs. This technique has been used in [47] only for triangle counting. We generalize it for all hub-pattern problems. The scheduling policy is then adjusted by chunking vertices and assigning incident edges in Ω to the corresponding GPUs. For non-hub patterns, we do not partition $\mathcal{G}$ if it can fit in the single-GPU memory. This is because GPM algorithms access multi-hop neighbors, which leads to non-trivial communication overhead [99], especially for small-diameter graphs. When $\mathcal{G}$ is too large to fit in memory, we leverage community-aware partition [56] to minimize communication.

(2) Reducing the size of edgelist. For Ω, we apply an important optimization by considering symmetry at the edge level (level-2). Since $\mathcal{G}$ is an undirected graph, for each undirected edge in $\mathcal{G}$, the edgelist contains two instances, each for one of the two directions of the edge. However, when there is a partial order between v_1 and v_2 for symmetry breaking, we generate the edgelist that contains only one instance. More specifically, if $v_1 > v_2$ is included in the symmetry order (e.g., in Fig. 5 (b)), the edgelist includes only the edges whose source vertex id is larger than its destination vertex id. In this way, we can reduce half of the edges before execution. It not only saves memory but also reduces checking on-the-fly. Note that there is a similar optimization [96] to split the neighbor list of each vertex v into two sets, with one holding all neighbors whose IDs are larger than v, and the other holding the rest which have smaller IDs than v. This reduces on-the-fly checking, but it is not used to reduce memory usage.

(3) Adaptive buffering. In G^{2}Miner's warp-centric DFS walk, each warp is allocated with X buffers. The value of X is pattern specific and the pattern analyzer can decide it when generating the search plan. For a pattern of size k, $X \leq k-3$ because the first two levels and the last level do not need buffers. So the worst case memory consumption for buffering is $O(\Delta \times (k-3))$. This is linear to k for a given specific data graph. In comparison, the intermediate data generated in Pangolin is exponential to k, which can be easily over the GPU memory capacity (see in §8.1). Although Δ is much smaller than $\mathcal{E}$ (see Table 3), given the large number of warps in GPU, the memory space for buffers can still be very large. Therefore, the runtime limits the total number of warps to save memory usage, so that all tasks assigned to the same warp share the buffer usage. In this way, given different data graphs, we can adaptively tune the number of warps to make full use of memory and maximize parallelism. More specifically, we subtract the size of $\mathcal{G}$ and Ω from the total GPU memory size, to get the remaining memory size, denoted as Y. Then we can get the maximum number of warps $Y/(X \times \Delta)$. Finally we launch $\texttt{min}(Y/(X \times \Delta), |\Omega|)$ warps.

(4) Reducing memory allocation using label frequency. This optimization is particularly useful for problems that find *frequent patterns*, such as FSM. The graph loader in G^{2}Miner computes the vertex frequency for each label. This information can be leveraged to find *frequent labels*, i.e., labels with vertex frequency above the user-defined support threshold σ_{min}. Since infrequent labels can not be part of frequent patterns, the total number of possible frequent patterns N can be significantly reduced, if there are many infrequent labels. Note that in FSM we allocate a *subgraph list* for each possible pattern to store subgraphs for aggregation, and the memory consumption of these subgraph lists is proportional to N. With

this awareness of the input (i.e., label frequency), we can drastically reduce this memory consumption in many cases.

8 Evaluation

We compare G^{2}Miner[2] with state-of-the-art systems: (1) GPM system on GPU, Pangolin [26], (2) subgraph matching solver on GPU, PBE [42, 43], (3) CPU-based GPM system Peregrine [53] and (4) CPU-based subgraph matching system GraphZero [73, 74]. Note that Pangolin also provides a CPU implementation, but it is slower than GraphZero.

Table 3 lists the data graphs. The first 3 graphs (`Mi`, `Pa`, `Yo`) are vertex-labeled graphs which are used for FSM. We use all the GPM applications listed in §2.1 for evaluation, i.e., TC, k-CL, SL, k-MC. For SL, we use two patterns `4-cycle` and `diamond`. Note that GraphZero does not support FSM, Pangolin does not support SL, and PBE does not support k-MC and FSM. For FSM, we include DistGraph [99] in Table 8 as the state-of-the-art hand-written FSM solver.

CPU-based systems and solvers are evaluated on a 4 socket machine with Intel Xeon Gold 5120 2.2GHz CPUs (56 cores in total) and 190GB RAM, while GPU-based solutions are evaluated on NVIDIA V100 GPUs (each with 32GB device memory). We exclude preprocessing (e.g., DAG construction in Pangolin and vertex reordering in Peregrine) time in all systems. We use a time-out of 30 hours for CPU and 8 hours for GPU, and report all results as an average of three runs. We show single-GPU performance in §8.1 and compare with CPU solutions in §8.2. Multi-GPU performance of G^{2}Miner is shown in §8.3. Impact of optimizations is analyzed in §8.4.

8.1 Single-GPU Performance

We compare with Pangolin and PBE on a V100 GPU. Table 4 lists the GPU running time for triangle counting (TC). We

Table 6: SL running time (sec). 'G': GPU; 'C': CPU.

observe that Pangolin runs out of memory for `Tw4`[3] and `Uk`, while G^{2}Miner can run with all the data graphs. We also observe that G^{2}Miner is constantly faster than Pangolin, due to optimized set operations in our library. On average, G^{2}Miner is 1.8× faster than Pangolin on V100 GPU.

The speedups are more significant for k-CL and k-MC. As shown in Table 5, G^{2}Miner outperforms Pangolin by 4.6× and 7.6× for 4-clique listing on `Lj` and `Or` respectively. The speedups mainly come from data reuse enabled in DFS (i.e., buffering W in Algorithm 1) and optimized set operations[4]. Meanwhile, for all the rest of graphs and the larger pattern 5-clique, Pangolin runs out of memory. Similar trend is found in Table 7, where we observe an average of 21.3× speedup over Pangolin on 3-MC, and Pangolin also runs out of memory for most of the cases. G^{2}Miner managed to run all cases, which demonstrates that its DFS order and optimization J and K in Table 2 can effectively reduce memory consumption.

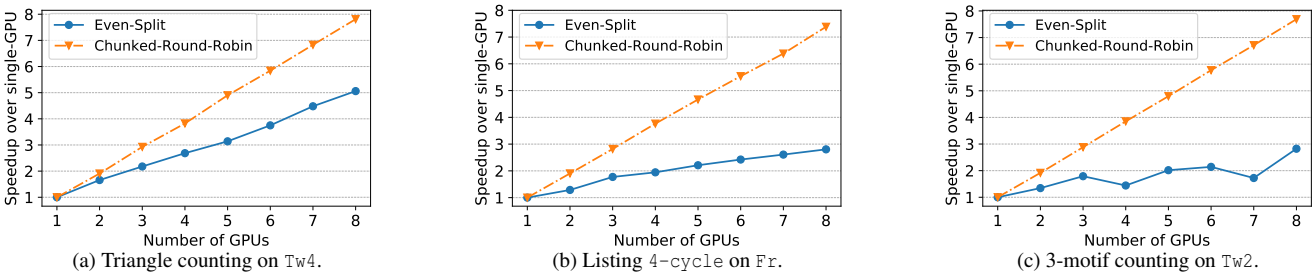
For FSM in Table 8, G^{2}Miner is competitive with Pangolin for the small graphs, since we use bounded BFS (optimization M in Table 2) that provides enough parallelism. For the largest graph `Yo`, Pangolin runs out of memory again, while G^{2}Miner succeeds to run it, thanks to both optimization M and N in Table 2 which help reduce memory consumption.

Overall, G^{2}Miner achieves an average speedup of **5.4**× over Pangolin, and the speedup is more significant for larger patterns. Moreover, G^{2}Miner can run much larger graphs.

We also compare with PBE [42, 43] on the V100 GPU. PBE partitions the data graph when it gets large, which allows it run all the single-pattern workloads. However, its performance is even worse (3.8× slower) than Pangolin, due to the cross-partition communication overhead and lack of data graph orientation. Particularly, for subgraph listing, as `diamond` contains a sub-pattern `triangle` but `4-cycle` does not, searching `diamond` generates much less intermediate data than searching `4-cycle`. Thus in Table 6 we observe that PBE's `4-cycle` performance is much worse than G^{2}Miner as

[3]Since data graphs are oriented in TC, `Fr` takes less memory than `Tw4`

[4]It can not be directly used for Pangolin, as Pangolin maps *connectivity checks* [26] to threads, but G^{2}Miner maps set operations to warps.



(a) Triangle counting on `Tw4`. (b) Listing `4-cycle` on `Fr`. (c) 3-motif counting on `Tw2`.

Figure 9: G^{2}Miner multi-GPU scalability using two task scheduling policies: even-split vs. chunked-split.

Pattern	3-Motif					4-Motif		
Data Graph	Lj	Or	Tw2	Tw4	Fr	Lj	Or	Fr
G^{2}Miner (G)	0.17	0.97	33.3	1703.6	22.0	138.1	2068.4	15475.4

Table 8: 3-FSM running time (sec). OoM: out of memory.

it has to do partitioning and suffers from the overhead. Overall, G^{2}Miner achieves a **7.2**× speedup over PBE on average.

8.2 Mining on GPU vs. on CPU

To evaluate how much speedup we can get from GPU over CPU, we compare G^{2}Miner (on V100 GPU) with GraphZero (on 56-core CPU). Note that for each specific GPM application, G^{2}Miner and GraphZero use exactly the same matching order and symmetry order, making it a fair comparison to show the benefit from the difference of hardware architectures. As listed in Table 4, G^{2}Miner is significantly faster than GraphZero on TC, with an average speedup of 38.0×. The same trend is observed for *k*-CL in Table 5, where G^{2}Miner outperforms GraphZero by 18.2×. This tremendous performance improvement is due to three parts: (1) the orientation optimization, (2) higher throughput (i.e. more parallelism) on GPU, and (3) our high-performance set operations on GPU.

For SL, orientation can not be applied. Thus it can be used to evaluate the benefit of the other two parts. As shown in Table 6, G^{2}Miner still achieves overwhelmingly better performance than GraphZero, with an average speedup of 10.5×. The speedup would be marginal if we use the BFS strategy in Pangolin and PBE or implement our DFS scheme naively.

While TC, *k*-CL and SL uses only set intersection, *k*-MC includes both set intersection and set difference. As G^{2}Miner optimizes both operations, we also observe dramatic performance boost for *k*-MC. In Table 7, it constantly outperforms GraphZero for all benchmarks. On average G^{2}Miner is 8.5× faster than GraphZero.

Overall, G^{2}Miner on GPU achieves **15.2**× speedup over GraphZero on CPU, which demonstrates the significant benefit of using GPU to accelerate GPM applications.

As GraphZero does not support FSM, we also compared to Peregrine. G^{2}Miner on GPU is **48.3**× faster than Peregrine on CPU. Note that Peregrine does not mine multiple patterns simultaneously for multi-pattern problems. Instead, for *k*-MC and FSM, it enumerates every pattern one by one, making it impossible to reuse data across similar patterns. Thus it is mostly even slower than GraphZero.

8.3 Multi-GPU Scalability

We evaluate multi-GPU performance by varying the number of GPUs from 1 to 8 in a single machine. Since PBE and Pangolin do not support multi-GPU, we only evaluate G^{2}Miner in this section. We compare two task scheduling policies in Fig. 9. As illustrated, the chunked round-robin scheme constantly works much better than the even-split scheme. More importantly, the chunked scheme scales linearly for all cases, while the even-split scheme fails to scale beyond 3-GPU for 3-MC on `Tw2`. The poor scalability of even-split is dues to the load imbalance. As shown in Fig. 10, in the 4-GPU setting, the execution time of each GPU varies dramatically for the even-split setting. In contrast, for the chunked scheme, each GPU finishes its work roughly at the same time.

8.4 Impact of Optimizations

Different optimizations in Table 2 contribute differently to the performance improvement. First, architecture-aware optimizations are crucial for all workloads on GPU. G^{2}Miner is 5.4× faster then Pangolin, where *two-level parallelism* (C in Table 2) and *SIMD-aware primitives* (H in Table 2) contribute 3.1× and 1.7× respectively. Second, for a pattern-aware optimization, it is beneficial only for the target pattern(s), and the speedups vary a lot depending on how much the search space is pruned. For example, *local-graph search* (E+F in Table 2) brings 1.2× ∼ 3.7× speedup for `hub-patterns` (2.1× on av-

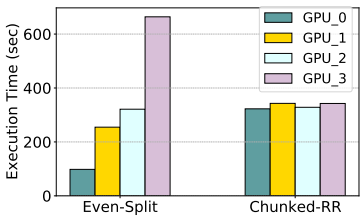

Figure 10: Running time of each GPU in the 4-GPU setting: `4-cycle` on `Fr`.

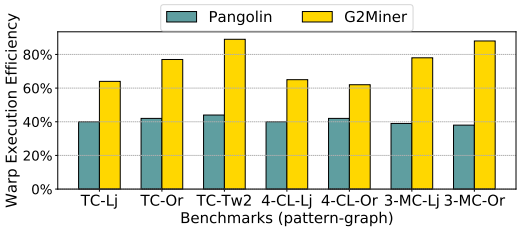

Figure 12: Warp execution efficiency.

Pattern	Diamond					3-Motif					4-Motif		
Time (sec)	Lj	Or	Tw2	Tw4	Fr	Lj	Or	Tw2	Tw4	Fr	Lj	Or	Fr
G^{2}Miner (GPU)	0.09	0.47	9.9	66.9	10.4	0.06	0.27	6.8	21.4	5.2	2.6	34.2	1307.2
Peregrine (CPU)	2.20	8.66	245.8	16312.6	158.8	2.51	4.90	116.0	8447.4	165.3	163.6	1701.4	TO

Table 9: Running time of G^{2}Miner vs. Peregrine, both with counting-only pruning enabled. TO: timed out.

erage), while *counting-only pruning* (D in Table 2) achieves 1.2× (`diamond`, `Fr`) to 79.7× (`3-motif`, `Tw40`), with 6.2× on average. Other optimizations in Table 2 are for memory saving, which is crucial for enabling larger datasets.

Large Pattern and Large Graph. A major advantage of G^{2}Miner over Pangolin is that G^{2}Miner can support much larger graphs and patterns. Fig. 11 shows that G^{2}Miner can run up to 8-clique listing on a billion-edge graph `Fr`. In contrast, Pangolin can not even run 4-clique due to out-of-memory, as shown in Table 5. Fig. 11 also shows that, from 4-clique to 8-clique, G^{2}Miner on GPU consistently achieves an order of magnitude speedup over GraphZero on the CPU, although the GPU has much less memory than the CPU. This trend implies that GPUs can be not only capable but also highly efficient for processing large graphs and patterns, thanks to G^{2}Miner's memory management and optimizations for the GPU architecture.

GPU Efficiency. To evaluate GPU utilization, we measure *warp execution efficiency*, which is the average percentage of active threads in each executed warp. As shown in Fig. 12, the warp execution efficiency in Pangolin is around 40%. This is relatively low since more than half of the compute horse power is wasted. In comparison, G^{2}Miner significantly improves the warp execution efficiency. This is mainly due to the highly efficient implementation of our warp-centric set operations. Besides, we also measure *branch efficiency*, i.e., the ratio of non-divergent branches to total branches. Although G^{2}Miner uses DFS, We find that Pangolin and G^{2}Miner have almost the same branch efficiency, thanks to the two-level parallelism scheme. Since we assign each task to a warp, all threads in a warp does the same DFS walk synchronously, which avoids most of the branch divergence. This creates some redundancy, but since most of execution time is spent on set operations, it is still a good tradeoff.

Counting-only pruning. In §8.1, we do not enable optimization D in Table 2, because GraphZero and Pangolin do not support it. We observe that for those patterns (e.g., `diamond`) enabling this pruning in G^{2}Miner further improve performance by 6.2× on average. Enabling this optimization in Peregrine also improves its performance, as shown in Table 9. However, due to our high efficiency on GPU, G^{2}Miner still outperforms Peregrine by 41.1× when both enable it. This again demonstrates the performance superiority of GPU over CPU, no matter what algorithm optimizations are applied.

Sorting and renaming vertices. For fair comparison, this optimization done by the preprocessor is also not enabled in §8.1. Our evaluation shows that this can futher improve G^{2}Miner performance by 5% (up to 90%). Applying this to GraphZero also helps, but G^{2}Miner is still 12× faster.

9 Conclusion

We present G^{2}Miner, the first multi-GPU GPM framework that supports efficiently mining large graphs and patterns. For high efficiency, G^{2}Miner is aware of the input, pattern and architecture to fully unlock the potential of GPM computing on GPUs, which results in a 5× speedup over the state-of-the-art GPU-based GPM system, Pangolin, on a single GPU. For scalability, G^{2}Miner employs a custom task scheduler that can scale GPM computation to multiple GPUs linearly. For programmability, it automatically enables applicable optimizations and generates CUDA code, which hides away GPU programming complexity, and in turn provides the same easy-to-use programming interface as the state-of-the-art CPU-based GPM frameworks (e.g., Peregrine). We also show that G^{2}Miner on a single V100 GPU is 48× faster than Peregrine on a 56-core Intel CPU, a free lunch for GPM users.

A Artifact Appendix

Abstract

This artifact appendix helps the readers reproduce the main evaluation results of the OSDI' 22 paper: Efficient and Scalable Graph Pattern Mining on GPUs.

Scope

The artifact can be used for evaluating and reproducing the main results of the paper, including Table 4, Table 5, Table 6, Table 7, Table 8 and Fig. 9, Fig. 10, Fig. 11, Fig. 12 in §8.

Contents

The artifact evaluation includes all the experiments in the paper. Details of the experiments are listed here: https://github.com/chenxuhao/GraphMiner/blob/master/OSDI-experiments-guide.md

Hosting

The source code of this artifact can be found on GitHub: https://github.com/chenxuhao/GraphMiner, master branch.

Requirements

Hardware dependencies

This artifact depends on an NVIDIA V100 GPU.

Software dependencies

This artifact requires CUDA toolkit 11.1.1 or greater and GCC 8 or greater.

Details of the dependencies are listed here: https://github.com/chenxuhao/GraphMiner/blob/master/OSDI-experiments-guide.md
