Semantic matching is the key to KARMA's adaptability. It uses symbolic execution to abstract away syntactic differences in function binaries, such as register allocation, instruction selection, and data offset. To evaluate its effectiveness, we cluster the collected 1,139 Android kernels [5] by syntactic and semantic features for 13 popular vulnerabilities. Specifically, the opcode-based clustering classifies kernel functions by types and frequencies of instruction opcodes; the syntax-based clustering classifies kernel functions by function calls and conditional branches; and the semantic-based clustering classifies kernel functions according to KARMA's semantic matching results. Table 5 lists the number of clusters and the percentage of kernels in the largest cluster for each clustering method. This table shows that the semantic-based method is the most precise one because it has the smallest number of clusters. Technically, each cluster may need a different adaptation of the reference patch. Therefore, fewer clusters mean a better chance for adaptation to succeed and less manual efforts if automated adaptation fails. Moreover, the largest clusters in the semantic matching often contain the majority of the vulnerable kernels. For example, a single reference patch for the largest cluster of `perf_swevent_init` can be applied to 96.3% of the vulnerable kernels.

We randomly picked some functions to manually verify the outcome of semantic matching. For example, the source code of `sock_diag_rcv_msg` (the function related to CVE-2013-1763) is exactly the same in Samsung Galaxy Note Edge (Android 5.0.1, Linux kernel 3.10.40) and Huawei Honor 6 Plus (Android 4.4, Linux kernel 3.10.30) [6]. However, its binaries are very different between these two devices because of the different compilers and kernel configurations. Figure 9a and 9b show a part of the disassembly code for these two binaries, respectively. The syntactic differences are highlighted. There are changes to the order of instructions (`BB8` on the left vs `BB8'` on the right), register

[5] Only kernels sharing symbols are considered in the clustering.
[6] Both vendors have released the source code for their devices.

Kernel Function	CVE ID	# of Opcode Clusters	% of the Largest Opcode Cluster	# of Syntax Clusters	% of the Largest Syntax Cluster	# of Semantic Clusters	% of Largest Semantic Cluster	Semantic Matching Time Cost	# of Instructions	# of Basic Blocks

Table 5: Clustering 1,139 kernels for each function by syntax and semantics. The last-but-two column lists the time of semantic matching to compare Nexus 5 (Android 4.4.2, kernel 3.4.0) and Samsung Note Edge (Android 6.0.1, kernel 3.10.40). The experiment was conducted on an Intel E5-2650 CPU with 16GB of memory, and the results are the average over 10 repeats. The last two columns list the number of instructions and basic blocks for each function in Nexus 5.

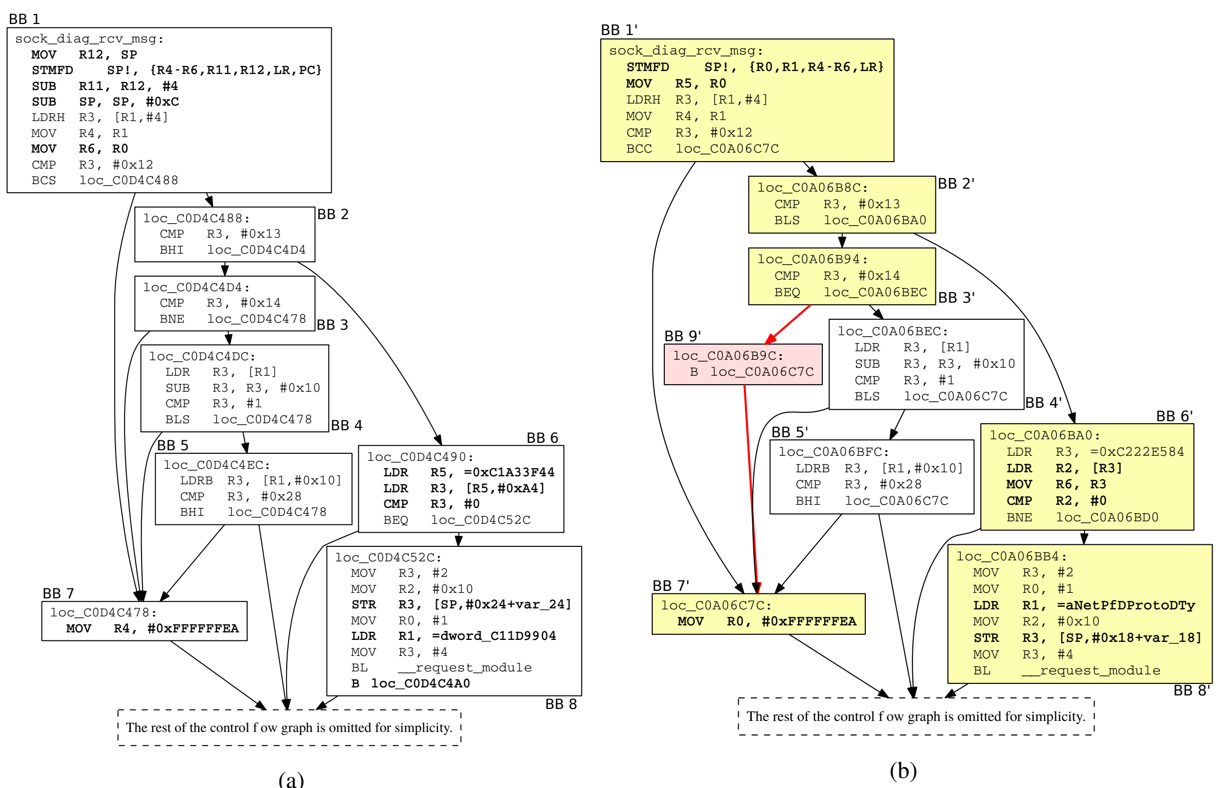

Figure 9: `sock_diag_rcv_msg` of (a) Huawei Honor 6 Plus (PE-TL10) with Android 4.4 and Linux kernel 3.10.30, compiled by GCC 4.7, and (b) Samsung Galaxy Note Edge (N915R4) with Android 5.0.1 and Linux kernel 3.10.40, compiled by GCC 4.8. Basic blocks and control flows with different syntax are highlighted.

allocation (`BB7` vs `BB7'`), instruction selection (`BB2` vs `BB2'`), and control flow (additional `BB9'` in the Samsung kernel). KARMA's semantic matching can abstract these syntactic differences and put these two binaries of `sock_diag_rcv_msg` into the same cluster. That is, both can be patched by the same CVE-2013-1763 patch discussed in Section 2.4.

Semantic matching can also separate kernel functions that are incorrectly classified together by the syntax matching. For example, the control flow and most instructions of function `msm_cci_validate_queue` (the function related to CVE-2014-9890) are identical in the

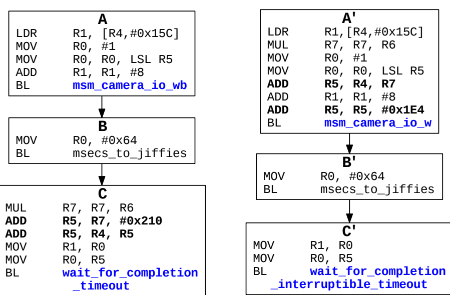

Figure 10: Three semantically different basic blocks of `msm_cci_validate_queue` in Oppo 3007 (left) and Samsung N910G (right). They have different callees and arguments, and thus different semantics.

kernel of Oppo 3007 (Android 4.4.4, kernel 3.10.28) and Samsung N910G (Android 6.0.1, kernel 3.10.40). A simple syntactic matching algorithm would consider them similar. These functions are shown in Fig. 10 (only basic blocks with different semantics are shown). However, KARMA's semantic matching algorithm considers basic block A and A', C and C' to be different because their last instructions call different functions with different arguments. Consequently, KARMA needs to use two patches to fix this vulnerability in these devices. A further investigation shows that KARMA can actually use the same patch for CVE-2014-9890 to fix both kernels because it only needs to validate the arguments, which are the same for both functions.

Finally, KARMA's semantic matching is quite efficient. It simplifies symbolic execution by considering most functions remain unchanged. The last-but-two column of Table 5 lists the time used by semantic matching to compare each listed function in two kernels. The analysis time increases with the complexity of the function, but they are all less than 36 seconds with an average of 12.5 seconds. Without this heuristics, it will take much longer and may never finish in some cases.

3.3 Evaluation of Performance

To evaluate the performance overhead of KARMA, we experimented with both a standard Android benchmark (CF-Bench [9]) and a syscall-based micro-benchmark. Both benchmarks were run on Google Nexus 5 with Android 4.4. Each reported result is the average over 20 measurements. The standard deviation of the results is negligible. Overall, we find that KARMA does not introduce noticeable time lag to regular operations of the test device. Considering the fact that most critical kernel vulnerabilities exist in less-hot code paths (e.g., device drivers' `ioctl` interfaces as shown in Table 6), we consider KARMA's performance is sufficient for real-world deployment.

The first benchmark measures the whole system performance with CF-Bench. We tested the performance of the following four configurations: the original kernel without any patches, the kernel with the patch for Towelroot, the kernel with the patch for PingPong root, and the kernel with both patches. The results are shown in Fig. 11. The measured performance is virtually the same for all four configurations. This benchmark shows that KARMA's kernel engine has minimal impact on the performance if patches are not frequently executed.

To further quantify the overhead of KARMA, we measured the execution time of a syscall with several different patches executed by a single Lua engine. We inserted a hook point in the execution path of a selected syscall (i.e., the patch was always executed for this syscall) and measured the execution time of the syscall under the following conditions:

- The patch simply returns 0. This reflects the run-time cost of the trampoline for function hooking. It takes about $0.42\mu s$ to execute.
- The patch contains a set of `if/elseif/else` conditional statements. This simulates patches that validate input arguments. It takes about $0.98\mu s$ to execute.
- The patch consists of a single read of the kernel memory. This measures the overhead of the Lua APIs provided by KARMA. It takes about $0.82\mu s$ to execution.
- To simulate more complex patches, we created a patch with a mixture of assignments, memory reads, and conditional statements. It takes about $3.74\mu s$ to execute.

The results are shown in Figure 12. In each test, the syscall was invoked in a tight loop for a thousand times, and each result is the average of 20 runs. To put this into context, we counted all the syscalls made by Google Chrome for Android during one minute of browsing. The most frequently made syscall was `gettimeofday` for about 110,000 times. This translates to about 0.55 seconds (0.9%) of extra time even if we assume the patch takes $5\mu s$ for each invocation. In summary, KARMA only incurs negligible performance overhead and performs sufficiently well for real-world deployment.

4 Discussion and Future Work

In this section, we discuss potential improvements to KARMA and the future work. First, KARMA aims at protecting the Android kernel from exploits because the kernel has a high privilege and its compromise has serious consequences on user security and privacy. An approach similar to KARMA can be applied to the Android framework and user-space apps. In addition, Android O formalizes the interface between the Android framework

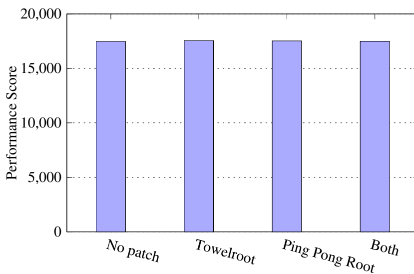

Figure 11: Performance scores by CF-Bench.

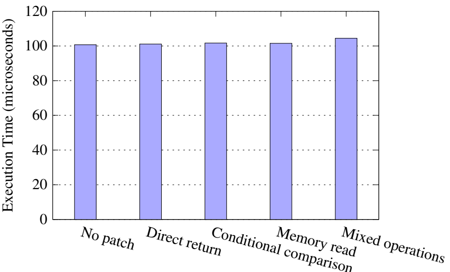

Figure 12: Execution time of `chmod` with different patches.

and the vendor implementation so that, eventually, the Android framework can be updated independent of the vendor implementation (aka. project Treble [20]). This will at least partially address the user-space update problem. However, project Treble does not address the kernel update problem. Android kernels are still fragmented and out-of-date. A system like KARMA is still necessary.

Second, KARMA's patches are written in the Lua programming language. It relies on the Lua engine to strictly confine patches' run-time behaviors. However, this approach increases the kernel's trusted computing base despite the fact that the Lua engine is relatively mature and secure. Executing patches on the Lua engine also negatively impacts the performance, especially if the system is under heavy load (in reality, this is not a concern because most Android kernel vulnerabilities are on the kernel's cold paths, such as device drivers' `ioctl` functions, as shown in Table 6). We are investigating alternative designs that can achieve similar security guarantees, such as BPF [8] and sandboxed binary patches.

Third, KARMA leverages the existing error handling code in the kernel to handle filtered malicious inputs, in order to keep the kernel as stable as possible. However, error handling code has been shown to contain vulnerabilities [36], and this design may leak resources and even cause deadlocks (KARMA does not allow patches themselves to release resource because that requires writing to the kernel). We did not find this to be a constraint during our experiment with *all* the critical Android kernel vulnerabilities. KARMA's reference patch is often a direct translation of the official source-code patch, which should have properly released the resources. If an official patch cannot be translated to a level-1 or level-2 patch, we can fall back to the level-3 (binary) patch. Level-3 patches are more flexible but require careful vetting.

Fourth, KARMA uses symbolic execution to semantically match two vulnerable functions. The approach is sufficient for our purpose in practice because many kernel functions are rather stable across devices and Android releases. In theory, the approach is not sound. It is a trade-off between soundness and scalability. Many systems make a similar trade-off because symbolic execution itself is neither very scalable nor very precise (e.g., how to handle loops). We are improving our method to better identify vulnerable functions and adapt patches. If KARMA's automated adaption cannot find a proper function to patch, we can fall back to the binary patch for this particular vulnerability.

Lastly, KARMA is a third-party kernel live patching system. Patches can be promptly delivered to user devices without the long wait caused by vendors and carriers. However, without testing performed by vendors and carries, its patches could cause stability issues in the user devices. Our implementation allows users to selectively disable a problematic patch. With KARMA's cloud service, we can automatically blacklist such patches from specific device models. We can also work with device vendors so patches can be quickly tested before release.

5 Related Work

Kernel live patching: the first category of the related work consists of a number of kernel live patching systems, such as kpatch [23], kGraft [22], Ksplice [27], and KUP [37]. They assume that the kernel source code is available (a reasonable assumption for their purpose) and create live patches from source code patches. Their patches are however in the binary form. This design does not fit the threat model of KARMA. First, although Android kernel is licensed in GPL, many Android vendors, small and large alike [19], do not (promptly) release their kernel source code. Second, these systems lack a mechanism to automatically adapt a kernel patch to different Android devices. An important design goal of KARMA is adaptiveness so that it can scale to the Android ecosystem. Third, binary patches are prone to misuse because they are hard to understand and vet, and these systems have no strong confinement of patches' run-time behaviors. KARMA has been designed specifically to address all these challenges in a live kernel patching system for Android.

Among these systems, kpatch [23] and kGraft [22] replace a whole vulnerable function with the patched version. They differ in how patches are applied: kpatch

stops all the running processes and ensures that none of these processes are running inside the function to be patched (similar to KARMA). kGraft instead maintains two copies of each patched function at the same time and dynamically decides which copy to execute. Specifically, the kernel code active at the time of patching (e.g., system calls, kernel threads, and interrupt handlers) is dispatched to the original version until it reaches a completion point; all other code is dispatched to the patched version. Like kpatch, Ksplice [27] also stops the machine to apply patches. However, Ksplice can patch individual instructions instead of replacing whole functions. These systems share the same limitation that they cannot support patches that "change the semantics of persistent data structures [27]". To address that, KUP [37] employs the process checkpoint-and-restart to implement kernel hot patching. Specifically, it checkpoints all the user processes, replaces the running kernel with the patched version, and then restores these user processes. Because it replaces the whole kernel, KUP can support all kinds of patches. However, restoring external resources (e.g., sockets) is often problematic for checkpoint-and-restore systems, including KUP.

Semantic matching: the second category of the related work includes systems that compare semantics or similarity of two functions [31, 32, 39, 40]. BinHunt [32] first uses symbolic execution to compute semantic similarity of basic blocks and uses a graph isomorphism algorithm to further compare the similarity of CFGs (control-flow graphs). Their follow-up work, iBinHunt [40], extends BinHunt with the inter-procedural control-flow graph comparison. However, whole-program comparison could be very time-consuming. To solve that, iBinHunt runs the program with taint tracking and only compares basic blocks within the same data flows. This approach is not suitable for KARMA because none of the commercial Android devices support kernel dynamic taint tracking or whole-kernel instrumentation. CoP [39] also uses symbolic execution to compute the semantic similarity of basic blocks and uses the longest common sub-sequence of linearly independent paths to measure the similarity of programs. KARMA uses symbolic execution to solve syntax differences in semantically-equivalent functions. In addition, it leverages the fact that most kernel functions remain semantically similar across different kernel versions to significantly speed-up the comparison. DiscovRE [31] takes a different approach by using the syntactic information (i.e., structural and numeric features) to compare function similarities. This can significantly improve the analysis efficiency. KARMA requires a more precise comparison than that can be provided by syntax-based approaches.

Automatic patch/filter generation: the third category of the related work includes systems that aim at automatically generating patches or input filters. For example, Talos [34] is a vulnerability rapid response system. It inserts SWRRs (Security Workarounds for Rapid Response) into the kernel source code in order to temporarily protect kernel vulnerabilities from being exploited. Talos shares a similar goal as KARMA, and both rely on the kernel's error handling code to gracefully neutralize attacks. Talos' source code based approach cannot be applied to the fragmented Android ecosystem. To address the fragmentation problem, KARMA can automatically adapt a patch to other devices and strictly confine the run-time behaviors of its patches. ClearView [41] learns invariants of a program during a dynamic training phase. When program failure happens, it identifies the failure-related invariants and uses them to generate patches for the program. PAR [38] proposes a pattern-based automatic program repair framework. Its generated patches resemble the patterns learned from human-written patches. ASSURE introduces rescue points that can recover software from unknown exploits while maintaining system integrity and availability [45]. ShieldGen [29] is a system for automatically generating vulnerability signatures (i.e., data patches). Signature-based filtering can only block known attacks. To address that, ShieldGen leverages protocol specifications to generate more exploits from an initial sample. Bouncer [28] uses static analysis and dynamic symbolic execution to create comprehensive input filters to protect software from bad inputs. Compared to these systems, KARMA aims at protecting kernel vulnerabilities for many Android systems and have a different design.

6 Summary

We have presented the design, implementation, and evaluation of KARMA, an adaptive live patching system for Android kernel vulnerabilities. By filtering malicious user inputs, KARMA can protect most Android kernel vulnerabilities from exploits. Compared to existing kernel live patching systems, the unique features of KARMA are that it can automatically adapt a reference patch for many Android devices, and it strictly confines the run-time behaviors of its patches. These two features allow KARMA to scale to a large, fragmented Android ecosystem. Our evaluation results demonstrated that KARMA can protect most critical Android kernel vulnerabilities in many devices with negligible performance overhead.

A Evaluation of Applicability: Additional Case Studies

A.1 CVE-2014-3153 (Towelroot)

this vulnerability is the second most-used one to root Android devices, known as "Towelroot". It lies in the `futex_requeue` function, which takes the addresses of two futexes as arguments. By design, the function should only re-queue from a non-PI (priority inheritance [46]) futex to a PI futex. However, this condition is violated if these two addresses point to the same futex. This leads to an exploitable dangling pointer condition. To fix this bug, Linux simply adds a check to ensure that these two futex addresses are different [13]. This vulnerability can be similarly fixed in KARMA by hooking the `futex_requeue` function, obtaining its arguments, and compare their equality. The patch returns `-EINVAL` if an attack is detected (Figure 4).

A.2 CVE-2015-3636 (PingPong Root)

This is another popular vulnerability used to root Android devices, known as "PingPong Root". It originates in the interaction between the socket and `hlist` functions. Specifically, when `hlist_nulls_del(&sk->sk_nulls_node)` is called, it assigns `LIST_POISON2` to `sk->sk_nulls_node.pprev`. `LIST_POISON2` is defined as the constant of `0x200200`. If interpreted as an address, address `LIST_POISON2` can be mapped by a malicious app in the user space without any permissions. A second call to `connect` by the attacker will result in a use-after-free on this attacker-controlled address, compromising the kernel. The Linux patch sets the pointer to `NULL` in the `ping_unhash` function [16]. However, this method cannot be applied by KARMA because its patch is prohibited from writing to the kernel memory. Instead, the patch checks if `sk->sk_nulls_node.pprev` equals to `LIST_POISON2`. If so, it returns an error code without freeing the associated memory. This blocks the exploit but leaves the socket object on the list. This patch is not clean, but it works and does not impact the kernel's functionalities. Alternatively, KARMA can hook `connect` in the kernel to prevent reusing the freed socket.

Vulnerability	Hotpatching Using KARMA	Adaptable?
CVE-2016-7117	Hook __sys_recvmmsg and its invocation of fput. On returning of fput, check if __sys_recvmmsg's err is not equal to 0 and not equal to -EAGAIN. If so, return err and skip the rest execution.	✓
CVE-2016-5340	Hook is_ashmem_file and check the full path of the input file. Only return True if the full path is /dev/ashmem. Otherwise return False.	✓
CVE-2016-4470	Hook key_reject_and_link and its invocation of __key_link_end. Check if link_ret is 0 before calling into __key_link_end. If so, simply return. key_reject_and_link is void typed so any return value is fine.	✓
CVE-2016-3951	It requires writing to kernel memory, violating KARMA's basic constraint.	Level-3
CVE-2016-3841	Hook do_ipv6_setsockopt to avoid concurrent access to the socket options of the same socket fd.	✓
CVE-2016-3775	Hook aio_setup_single_vector and check if the input kiocb->ki_nbytes exceeds MAX_RW_COUNT. If so, return -EFAULT.	✓
CVE-2016-3768	It requires to skip some instructions and continue execution afterwards, which is not an allowed operation by KARMA.	Level-3
CVE-2016-3767	Hook mtk_p2p_wext_discovery_results etc. functions of which the bodies are deleted by the official patch, and simply return 0.	✓
CVE-2016-3134	Android does not enable CONFIG_USER_NS so this should not be a direct threat to Android devices. But KARMA can still fix it by iterating newpos = pos + e->next_offset to check if there is a out-of-bound access.	✓
CVE-2016-2503	It requires to reorder the instructions (to change when to take the lock). This is not an allowed operation by KARMA.	Level-3
CVE-2016-2474	Hook hdd_parse_ese_beacon_req and check the tempInt read from the argument pValue. If it exceeds SIR_ESE_MAX_MEAS_IE_REQS, return -EINVAL.	✓
CVE-2016-2468	Hook _kgsl_sharedmem_page_alloc and validate the input size.	✓
CVE-2016-2467	Hook msm_compr_ioctl and its invocation of __copy_from_user. Check if the params_length passed into __copy_from_user exceeds MAX_AC3_PARAM_SIZE. If so, return error code from __copy_from_user without executing into it.	✓
CVE-2016-2466	Hook adm_get_params and check if adm_get_parameters[0] exceeds ADM_GET_PARAMETER_LENGTH-1 and params_length/sizeof(int). If so, return -EINVAL.	✓
CVE-2016-2465	Hook the concerned functions in drivers/video/msm/mdss/mdss_debug.c patched in the original patch, and their invocations of __copy_to_user. Validate len and count, and return -EFAULT in case of exploit conditions.	✓
CVE-2016-2067	Hook check_vma and return -EFAULT if vma->vm_flags & memdesc->flags != memdesc->flags.	✓
CVE-2016-2062	Hook adreno_perfcounter_query_group and its invocation of kmalloc. On the entry of kmalloc, check if t is larger than count.	✓
CVE-2016-0844	Hook ipa_wwan_ioctl and its invocation of find_mux_channel_index. On entry of find_mux_channel_index, if the value of rmnet_index exceeds MAX_NUM_OF_MUX_CHANNEL, return -EFAULT directly.	✓
CVE-2016-0843	Hook msm_l2_test_set_ev_constraint and check if shift_idx >= PMU_CODES_SIZE. Return -EINVAL in case of that.	✓
CVE-2016-0820	Hook priv_get_struct and its invocation of __copy_from_user, check if prIwReqData->data.length>u4CopyDataMax and return -EFAULT if so.	✓
CVE-2016-0806	Hook iw_softap_set_channel_range and check if the caller has the capability CAP_NET_ADMIN, return -EPERM if not.	✓
CVE-2016-0805	Hook get_krait_evtinfo and check if reg exceeds krait_max_l1_reg, return -EINVAL if so.	✓
CVE-2016-0801	Hook wl_validate_wps_ie and check if subelt_len exceeds the size of devname (100). Hook wl_notify_sched_scan_results and its invocation of memcpy and check if the buffer length passed in exceeds DOT11_MAX_SSID_LEN.	✓
CVE-2016-0758	Hook asn1_find_indefinite_length and check if dp is larger than datalen. Return -1 if so.	✓
CVE-2016-0728	Hook join_session_keyring and iterate the keyring. Return error if keyring->usage reaches the overflow boundary (0xFFFFFFFF).	✓

Vulnerability	Hotpatching Using KARMA	Adaptable?
CVE-2015-8942	Hook msm_cpp_subdev_ioctl, if the argument cmd equals to VIDIOC_MSM_CPP_IOMMU_DETACH, from its argument sd obtain cpp_dev->stream_cnt and check if it equals to 0.	✓
CVE-2015-8941	Hook msm_isp_axi_check_stream_state and iterate over the input stream_cfg_cmd->stream_handle to see if one exceeds MAX_NUM_STREAM. The other vulnerable functions can be fixed in the same way.	✓
CVE-2015-8940	Hook q6lsm_snd_model_buf_alloc and check if the integer argument len is out of range.	✓
CVE-2015-8939	Hook mdp4_argc_process_write_req and check if the input pgc_ptr->num_r/g/b_stages are out of range.	✓
CVE-2015-8938	Hook msm_isp_send_hw_cmd and check if the ioctl input arguments satisfy the constraints updated by the official patch. The constraint list is long so omitted here.	✓
CVE-2015-8816	Fixing the problem requires locking and increasing the reference of the usb_hub structure, thus the patch needs to write to kernel memory.	Level-3
CVE-2015-6640	Hook the system call prctl and check if the corresponding argument as the end passed to prctl_set_vma_anon_name is out of range.	✓
CVE-2015-6638	Hook PVRSRVSyncPrimSetKM and check if the input psSyncBlk->ui32BlockSize is smaller than another input ui32Index * sizeof(IMG_UINT32).	✓
CVE-2015-6619	The official patch is to remove all .tmpfile handlers. So we can simply hook such handlers and always return -EINVAL.	✓
CVE-2015-2686	Hook sys_sendto/sys_recvfrom and check if the input buff and len/size are out of range.	✓
CVE-2015-0570	Hook __iw_softap_setwpsie and check if ioctl arguments have improper length, same as the official patch. The check list is long so omitted here.	✓
CVE-2014-9902	Hook dot11fUnpackIeCountry and dot11fUnpackIeSuppChannels to validate the value of the input ielen.	✓
CVE-2014-9891	Hook __qseecom_process_rpmb_svc_cmd and validate if the input req_ptr fields passed in from user space are out of range.	✓
CVE-2014-9890	Hook msm_cci_validate_queue and validate if cmd_size extracted from the inputs is larger than 10.	✓
CVE-2014-9887	Hook qseecom_send_modfd_cmd and its invocation of __copy_from_user. Validate req.cmd_req_len obtained from user space.	✓
CVE-2014-9884	Hook qseecom_register_listener etc. handlers to validate pointers passed in from user space, same as the official patch.	✓
CVE-2014-9883	Hook extract_dci_log and check for the integer overflow condition of the input log_length.	✓
CVE-2014-9882	Hook iris_vidioc_s_ctrl. If the input ctrl->id is V4L2_CID_PRIVATE_IRIS_RIVA_ACCS_LEN/_POKE, validate if the copied data length exceeds MAX_RIVA_PEEK_RSP_SIZE.	✓
CVE-2014-9881	Hook iris_vidioc_s_ext_ctrls and perform range/overflow check on the input ctrl.	✓
CVE-2014-9880	Hook vid_enc_ioctl and its invocation of __copy_from_user. Validate seq_header fetched from user space.	✓
CVE-2014-9879	Hook mdp3_histogram_start and validate its input req; hook mdp3_pp_ioctl and validate mdp_pp obtained from user space.	✓
CVE-2014-9878	Hook send_write_packing_test_read and validate its input buffer and count.	✓
CVE-2014-9869	Hook msm_isp_ functions as specified in the official patch, and validate if stats_idx from input exceeds MSM_ISP_STATS_MAX.	✓
CVE-2014-9868	Hook msm_csiphy_release and validate the value of input csi_lane_params->csi_lane_mask.	✓
CVE-2014-9529	Fixing the issue requires to change the instruction order (delay the reference put). This is not a secure operation permitted by KARMA.	Level-3

Table 6: A partial list of recent critical Android kernel vulnerabilities and KARMA's effectiveness to create adaptable patches for them. Some adaptable vulnerabilities are omitted due to the space constraint.

CHAINIAC: Proactive Software-Update Transparency via Collectively Signed Skipchains and Verified Builds

Abstract

Software-update mechanisms are critical to the security of modern systems, but their typically centralized design presents a lucrative and frequently attacked target. In this work, we propose CHAINIAC, a decentralized software-update framework that eliminates single points of failure, enforces transparency, and provides efficient verifiability of integrity and authenticity for software-release processes. Independent *witness servers* collectively verify conformance of software updates to release policies, *build verifiers* validate the source-to-binary correspondence, and a tamper-proof release log stores collectively signed updates, thus ensuring that no release is accepted by clients before being widely disclosed and validated. The release log embodies a *skipchain*, a novel data structure, enabling arbitrarily out-of-date clients to efficiently validate updates and signing keys. Evaluation of our CHAINIAC prototype on reproducible Debian packages shows that the automated update process takes the average of 5 minutes per release for individual packages, and only 20 seconds for the aggregate timeline. We further evaluate the framework using real-world data from the PyPI package repository and show that it offers clients security comparable to verifying every single update themselves while consuming only one-fifth of the bandwidth and having a minimal computational overhead.

1 Introduction

Software updates are essential to the security of computerized systems as they enable the addition of new security features, the minimization of the delay to patch disclosed vulnerabilities and, in general, the improvement of their security posture. As software-update systems [17, 24, 34, 35, 48] are responsible for managing, distributing, and installing code that is eventually executed on end systems, they constitute valuable targets for attackers who might, *e.g.*, try to subvert the update infrastructure to inject malware. Furthermore, powerful adversaries might be able to compromise a fraction of the developers' machines or tamper with software-update centers. Therefore, securing update infrastructure requires addressing four main challenges:

First, the integrity and authenticity of updates traditionally depends on a single signing key, prone to loss [53] or theft [29, 32, 70]. Having proper protection for signing keys to defend against such single points of failure is therefore a top priority. Second, the lack of transparency mechanisms in the current infrastructure of software distribution leaves room for equivocation and stealthy backdooring of updates by compromised [15,46], coerced [11, 28, 66], or malicious [36] software vendors and distributors. Recent work on reproducible software builds [49,59] attempts to counteract this deficit by improving on the source-to-binary correspondence. However, it is unsuitable for widespread deployment in its current form, as rebuilding packages puts a high burden on end users (*e.g.*, building the Tor Browser bundle takes 32 hours on a modern laptop [60]). Third, attackers might execute a man-in-the-middle attack on the connections between users and update providers (*e.g.*, with DNS cache poisoning [67] or BGP hijacking [6]), thus enabling themselves to mount replay and freeze attacks [15] against their targets. To prevent attackers from exploiting unpatched security vulnerabilities as a consequence of being targeted by one of the above attacks [72], clients must be able to verify timeliness of updates. Finally, revoking and renewing signing keys (*e.g.*, in reaction to a compromise) and informing all their clients about these changes is usually cumbersome. Hence, modern software-update systems should provide efficient and secure means to evolve signing keys and should enable client notification in a timely manner.

To address these challenges, we propose CHAINIAC, a decentralized software-update framework that removes

single points of failure, increases transparency, ensures integrity and authenticity, and retains efficient verifiability of the software-release process.

First, CHAINIAC introduces a decentralized release sign-off model for developers which retains efficient signature verifiability by using a multi-signature scheme. To propose a software release, a threshold of the developers has to sanity-check[1] and sign off on it to express their approval. Third-party witness servers then validate the proposal against a release policy. These witnesses are chosen by the developers and are trusted collectively but not individually. If the proposed release is valid, the witnesses produce a collective signature [69], which is almost as compact and inexpensive to verify as a conventional digital signature. Although improving security, this approach does not place a burden on clients who otherwise would have to verify multiple signatures per updated package.

Second, CHAINIAC introduces *collectively verified builds* to validate source-to-binary correspondence. CHAINIAC's verified builds are an improvement over reproducible builds, in that they ensure that binaries are not only reproducible in principle, but have indeed been identically reproduced by multiple independent verifiers from the corresponding source release. Concretely, this task is handled by a subset of the witness servers, or *build verifiers*, that reproducibly build the source code of a release, compare the result with the binary provided by the developers, and attest this validation to clients upon success. An additional advantage of this approach is that companies, in order to provide the source-to-binary guarantee to customers, can reveal source code only to third-party build verifiers who sign appropriate non-disclosure agreements.

Third, CHAINIAC increases transparency and ensures the accountability of the update process by implementing a public update-timeline that comprises a release log, freshness proofs, and key records. The timeline is maintained collectively by the witness servers such that each new entry can only be added – and clients will only accept it – if appropriate thresholds of the witnesses and build verifiers approve it. This mechanism ensures the source-to-binary binding to protect clients from compile-time backdoors or malware, and it guarantees that all users have a consistent view of the update history, preventing adversaries from stealthily attacking targeted clients with compromised updates. Even if an attacker manages to slip a backdoor into the source code, the corresponding signed binary stays publicly available for scrutiny, thereby preventing secret deployment against targeted users.

[1] Precise details of this review process depend on the developers' engineering disciplines, which are also security-critical but are beyond the scope of this paper.

Finally, to achieve tamper evidence, consistency, and search efficiency of the timeline, and to enable a secure rotation of signing keys, CHAINIAC employs *skipchains*, novel authenticated data structures inspired by skip lists [55, 61] and blockchains [41, 56]. The skipchains enable clients to efficiently navigate arbitrarily long update timelines, both forward (*e.g.*, to validate a new software release) and backward (*e.g.*, to downgrade or verify the validity of older package-dependencies needed for compatibility). Back-pointers in skipchains are cryptographic hashes, whereas forward-pointers are collective signatures. Due to skipchains, even resource-constrained clients (*e.g.*, IoT devices) can obtain and efficiently validate binary updates, using a hard-coded initial software version as a trust anchor. Such clients do not need to continuously track a release chain, like a Bitcoin full-node does, but can privately exchange, gossip, and independently validate on-demand newer or older blocks due to the skipchain's forward and backward links being offline-verifiable. Although blockchains are well-known tools, to our knowledge the skipchain structure is novel and can be useful in other contexts, besides software updates.

The evaluation of our prototype implementation of CHAINIAC on reproducible Debian packages shows that, in a group of more than a hundred verifiers, the end-to-end cost per witness of release attestation is on average five minutes per package, with the verified builds dominating this overhead. Furthermore, skipchains can increase the security of PyPI updates with minimal overhead, whereas a strawman approach would incur the increase of 500%. Finally, creating a skipblock of the aggregate update timeline for the full Debian repository of about 52,000 packages requires only 20 seconds of CPU time for a witness server, whereas receiving the latest skipblock on a client introduces only 16% of overhead to the usual communication cost of the APT manager [23].

In summary, our main contributions are as follows:

- We propose CHAINIAC (Sections 3 and 5), a software-update framework that enhances security and transparency of the update process via system-wide decentralization and efficiently verifiable logging.
- We introduce skipchains (Section 4), a novel authenticated data structure that enables secure trust delegation and efficient bi-directional timeline traversal, and we discuss their application in the context of CHAINIAC.
- We conduct an informal security analysis (Section 6) of CHAINIAC, justifying its resilience in common attack scenarios.
- We implement CHAINIAC (Section 7) and evaluate (Section 8) a prototype on real-world data from the Debian and PyPI package repositories.

2 Background

In this section, we give an overview of the concepts and notions CHAINIAC builds on, this includes scalable collective signing, reproducible builds, software-update systems, blockchains, and decentralized consensus.

2.1 Collective Signing and Timestamping

CoSi [69] is a protocol for large-scale collective signing. Aggregation techniques and communication trees [25,73] enable CoSi to efficiently produce compact Schnorr multi-signatures [64] and to scale to thousands of participants. A complete group of signers, or *witnesses*, is called a collective authority or *cothority*. CoSi assumes that signature verifiers know the public keys of the witnesses, all of which are combined to form an aggregate public key of the cothority. If witnesses are offline during the collective signing process or refuse to sign a statement, the resulting signature includes metadata that documents the event.

In CHAINIAC, we rely on CoSi for efficient collective signing among a large number of witnesses. Furthermore, we use the witness-cosigned timestamp service [69] as a building block in our design for the protection of clients against replay and freeze attacks [15] (where clients are blocked from learning about the availability of new software updates by an adversary). We describe the design of the protection mechanism in Section 5.6.

2.2 Reproducible Builds

Ensuring that source code verifiably compiles to a certain binary is difficult in practice, as there are often non-deterministic properties in the build environment [49,59], which can influence the compilation process. This issue poses a variety of attack vectors for backdoor insertion and false security-claims [36]. Reproducible builds are software development techniques that enable users to compile deterministically a given source code into one same binary, independent of factors such as system time or build machines. An ongoing collaboration of projects [62] is dedicated to improving these techniques, *e.g.*, Debian claims that 90% of its packages in the testing suite are reproducible [22], amounting to ∼21,000 packages. To provide a source-to-binary attestation as one of the guarantees, CHAINIAC relies on software projects to adopt the practices of reproducible builds.

2.3 Roles in Software-Update Systems

The separation of roles and responsibilities is one of the key concepts in security systems. TUF [63] and its successor, Diplomat [44], are software-update frameworks that make update systems more resilient to key compromise by exploiting this concept. In comparison to classic systems, these frameworks categorize the tasks that are commonly involved in software-update processes and specify a responsible role for every category. Each of these roles is then assigned a specific set of capabilities and receives its own set of signing keys, which enables TUF and Diplomat to realize different trade-offs between security and usability. For example, frequently used keys with low-security risks are kept online, whereas rarely needed keys with a high-security risk are kept offline, making it harder for attackers to subvert them. To achieve, for each role, the sweet-spot between security and usability, we follow a similar delegation model in our multi-layered architecture in Section 5.6. However, we decentralize all these roles, use a larger number of keys, and log their usage and evolution to further enhance security and add transparency.

2.4 Blockchains and Consensus

Introduced by Nakamoto [56], blockchains are a form of a distributed append-only log that is used in cryptocurrencies [56, 75] as well as in other domains [41, 74]. Blockchains are composed of *blocks*, each typically containing a timestamp, a nonce, a hash of the previous block, and application-specific data such as cryptocurrency transactions. As each block includes a hash of the prior block, it depends on the entire prior history, thus forming a tamper-evident log.

CHAINIAC uses *BFT-CoSi*, introduced in ByzCoin [42], as a consensus algorithm to ensure a single consistent timeline, *e.g.*, while rotating signing keys. BFT-CoSi implements PBFT [16] by using collective signing [69] with two CoSi-rounds to realize PBFT's prepare and commit phases. CHAINIAC's skipchain structure is partly inspired by blockchains [41]: Whereas ByzCoin also uses collective signatures to enable light-client verification, skipchains extend this functionality with skiplinks to enable clients to efficiently track and validate update timelines, instead of downloading and validating every signature. As a result skipchains can be used for more efficient offline verification of transactions in distributed ledger systems that work with consensus committees [2,42,43].

3 System Overview

In this section, we state high-level security goals that a hardened software-update system should achieve, we introduce a system and threat model, and we present an architectural overview of our proposed framework.

3.1 Security Goals

To address the challenges listed in Section 1, we formulate the following security goals for CHAINIAC:

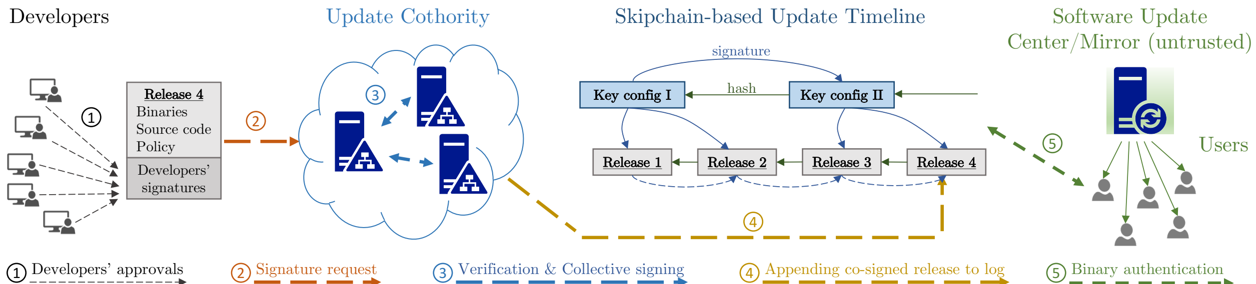

Figure 1: Architectural overview of CHAINIAC

1. **No single point of failure:** The software-update system should retain its security guarantees in case any single one of its components fails (or gets compromised), whether it is a device or a human.
2. **Source-to-binary affirmation:** The software-update system should provide a high assurance-level to its clients that the deployed binaries have been built from trustworthy and untampered source code.
3. **Efficient release-search and verifiability:** The software-update system should provide means to its clients to find software release (the latest or older ones) and verify its validity in an efficient manner.
4. **Linear immutable public release history:** The software-update system should provide a globally consistent tamper-evident public log where each software release corresponds to a unique log entry that, once created, cannot be modified or deleted.
5. **Evolution of signing keys:** The software-update system should enable the rotation of authoritative keys, even when a (non-majority) subset of the keys is compromised.
6. **Timeliness of updates:** Clients should be able to verify that the software indeed corresponds to the latest one available.

3.2 System and Threat Model

In the system model, we introduce terminology and basic assumptions; and, in the threat model, potential attack scenarios against CHAINIAC.

System model. *Developers* write the source code of a software project and are responsible for approving and announcing new project *releases*. Each release includes source code, binaries (potentially, for multiple target architectures), and metadata such as release description. A *snapshot* refers to a set of releases of different software projects at a certain point in time. Projects can have single or multiple packages. *Witnesses* are servers that can validate and attest statements. They are chosen by the developers and should be operated ideally by both developers and independent trusted third parties. Witnesses are trusted as a group but not individually. *Build verifiers* are a subset of the witnesses who execute, in addition to their regular witness tasks, reproducible building of new software releases and compare them to the release binaries. Witnesses and build verifiers jointly form an *update cothority* (collective authority). The *update timeline* refers to a public log that keeps track of the authoritative signing keys, as well as the software releases. *Users* are clients of the system; they receive software releases through an (untrusted) *software-update center*.

Threat model. We assume that a threshold t_d of n_d developers are honest, meaning that less than t_d are compromised and want to tamper with the update process. We further assume that a threshold t_w of n_w witness servers is required for signing, whereas at most $f_w = n_w - t_w$ witnesses can potentially be faulty or compromised. To ensure consistency and resistance to fork attacks, CHAINIAC requires $n_w \geq 3f_w + 1$, hence, $t_w >= 2f_w + 1$. If this property is violated, CHAINIAC does not guarantee single history of the update timeline, however, even then, each history will individually be valid and satisfy the other correctness and validation properties, provided fewer than t_w witnesses are compromised. Furthermore, a threshold t_v of n_v build verifiers is honest and uses a trustworthy compiler [71] such that malicious and legitimate versions of a given source-code release are compiled into different binaries. Software-update centers and mirrors might be partially or fully compromised. Moreover, a powerful (*e.g.*, state-level) adversary might try to target a specific group of users by coercing developers or an update center to present to his targets a malicious version of a release. Finally, we assume that users of CHAINIAC are able to securely bootstrap, *i.e.*, receive the first version of a software package with a hard-coded initial public key of the system via some secure means, *e.g.*, pre-installed on a hard drive, on a read-only media, or via a secure connection.

An attack on the system is successful if an attacker manages to accomplish at least one of the following:

- Make developers sign the source code that they do not approve.
- Substitute a release binary with its tampered version such that the update cothority signs it.
- Trick the update cothority into signing a release that is not approved by the developers.
- Create a valid fork of the public release history or modify/revoke its entries; or present different users with different views of the history.
- Trick an outdated client into accepting a bogus public key as a new signing key of the update cothority.
- Get a client to load and run a release binary that is not approved by the developers or validated by the update cothority.

3.3 Architecture Overview

An illustration of CHAINIAC, showing how its various components interact with each other, is given in Figure 1. To introduce CHAINIAC, we begin with a simple strawman design that most of today's software-update systems use, and we present a roadmap for evolving this design into our target layout. Initially, we assume that only a single, static, uncompromisable cryptographic key pair is used to sign/verify software releases. The private key might be shared among a group of developers, and the public key is installed on client devices, *e.g.*, during a bootstrap. To distribute software, one of the developers builds the source code and pushes the binary to a trusted software-update center from where users can download and install it. This strawman system guarantees that users receive authenticated releases with a minimal verification overhead.

This design, though common, is rife with precarious assumptions. Expecting the signing key to be uncompromisable is unrealistic, especially if shared among multiple parties, as attackers need to subvert only a single developer's machine to retrieve the secret key or to coerce only one of the key owners. For similar reasons, it is utopian to assume that the software-update center is trustworthy. Moreover, without special measures, it is hard to verify that the binaries were built from the given (unmodified) source code, as the compilation process is often influenced by variations in the building-environment, hence non-deterministic. If an attacker manages to replace a compiled binary with its backdoored version, before it is signed, the developers might not detect the substitution and unknowingly sign the subverted software.

Eliminating these assumptions creates the need to track a potentially large number of dynamically changing signing keys; furthermore, checking a multitude of signatures would incur large overheads to end users who rarely update their software. To address these restrictions, we transform the strawman design into CHAINIAC in six steps:

1. To protect against a single compromised developer, CHAINIAC requires that developers have individual signing keys and that a threshold of the developers sign each release, see step ① in Figure 1.
2. To be able to distribute verified binaries to end users, we introduce developer-signed reproducible builds. Although users still need to verify multiple signatures, they no longer need to build the source code.
3. To further unburden users and developers, we use a cothority to validate software releases (check developer signatures and reproducible binaries) and collectively sign them, once validated: steps ② and ③ in Figure 1.
4. To protect against release-history tampering or stealthy developer-equivocation, we adopt a public log for software releases in the form of collectively signed decentralized hash chains, see step ④ in Figure 1.
5. To enable efficient key rotation, we replace hash chains with skipchains, blockchain-like data structures that enable forward linking and decrease verification overhead by multi-hop links.
6. To ensure update timeliness and further harden the system against key compromise, we introduce a multi-layer skipchain-based architecture that, in particular, implements a decentralized timestamp role.

Before presenting CHAINIAC in detail in Section 5, we introduce skipchains, one of CHAINIAC's core building blocks, in Section 4.

4 Skipchains

Skipchains are authenticated data structures that combine ideas from blockchains [41] and skiplists [55, 61]. Skipchains enable clients (1) to securely traverse the timeline in both forward and backward directions and (2) to efficiently traverse short or long distances by employing multi-hop links. Backward links are cryptographic hashes of past blocks, as in regular blockchains. Forward links are cryptographic signatures of future blocks, which are added retroactively when the target block appears.

We distinguish *randomized* and *deterministic* skipchains, which differ in the way the lengths of multi-hop links are determined. The link length is tied to the height parameter of a block that is computed during block creation, either randomly in randomized skipchains or via a fixed formula in deterministic skipchains. In both approaches, skipchains enable logarithmic-cost timeline traversal, both forward and backward.

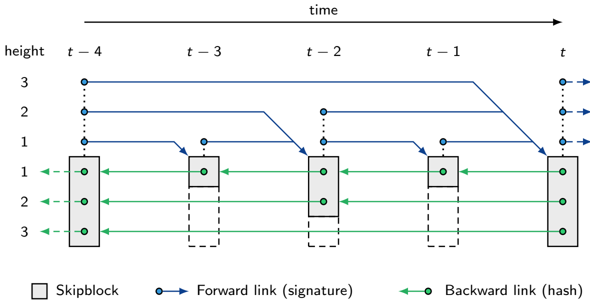

Figure 2: A deterministic skipchain $\mathcal{S}_2^3$

4.1 Design

We denote a skipchain by $\mathcal{S}_b^h$ where $h \geq 1$ and $b > 0$ are called *skipheight* and *skipbasis*, respectively. If $0 < b < 1$ we call the skipchain randomized; and if $b \geq 1$ (b integer), we call it deterministic. The elements of a skipchain are *skipblocks* $\mathcal{B}_t = (\mathsf{id}_t, h_t, D_t, B_t, F_t)$ where $t \geq 0$ is the block index. The variables id_t, h_t, D_t, B_t, and F_t denote block identifier, block height, payload data, list of backward links, and list of forward links, respectively. Both B_t and F_t can store exactly h_t links and a reference at index $0 \leq i \leq h_t - 1$ in B_t (F_t) points to the last (next) block in the timeline having at least height $i+1$. For deterministic skipchains this block is $\mathcal{B}_{t-j}$ ($\mathcal{B}_{t+j}$) where $j = b^i$.

The concrete value of h_t is determined by the dependency of the skipchain's type: if $\mathcal{S}_b^h$ is randomized, then a coin, with probability b to land on heads, is repeatedly flipped. Once it lands on tails, we set $h_t = \min\{m, h\}$ where m denotes the number of times it landed on heads up to this point. If $\mathcal{S}_b^h$ is deterministic, we set

$$h_t = \max\{i : 0 \leq i \leq h \wedge 0 \equiv t \bmod b^{i-1}\} .$$

Fig. 2 illustrates a simple deterministic skipchain.

During the creation of a block, its identifier is set to the (cryptographic) hash of D_t and B_t, both known at this point, *i.e.*, $\mathsf{id}_t = \mathsf{H}(D_t, B_t)$. For a backward link from $\mathcal{B}_t$ to $\mathcal{B}_{t-j}$, we simply store id_{t-j} at index i in B_t. This works as in regular blockchains but with the difference that links can point to blocks further back in the timeline.

Forward links [41], are added retroactively to blocks in the log, as future blocks do not yet exist at the time of block creation. Furthermore, forward links cannot be cryptographic hashes, as this would result in a circular dependency between the forward link of the current and the backward link of the next block. For these reasons, forward links are created as digital (multi-)signatures. For a forward link from $\mathcal{B}_t$ to $\mathcal{B}_{t+j}$, we store the cryptographic signature $\langle \mathsf{id}_{t+j} \rangle_{E_t}$ at index i in F_t where E_t denotes the entity (possibly a decentralized collective such as a BFT-CoSi cothority [41, 42, 69]) that represents the head of trust of the system during time step t. To create the required signatures for the forward links until all slots in F_t are full, in particular, E_t must "stay alive" and watch the head of the skipchain. Once this is achieved, the job of E_t is done and it ceases to exist.

4.2 Useful Properties and Applications

Skipchains provide a framework for timeline tracking, which can be useful in other domains such as cryptocurrencies [42, 43, 56], key-management [41, 51], certificate tracking [1,45] or, in general, for membership evolution in decentralized systems [68,69]. Beyond the standard properties of blockchains, skipchains offer the following two useful features.

First, skipchains enable clients to securely and efficiently traverse arbitrarily long timelines, both forward and backward from any reference point. If the client has the correct hash of an existing block and wants to obtain a future or past block in the timeline from an untrusted source (such as a software-update server or a nearby peer), to cryptographically validate the target block (and all links leading to it), the client needs to download only a logarithmic number of additional, intermediate blocks.

Secondly, suppose two resource-constrained clients have two reference points on a skipchain, but have no access to a database containing the full skipchain, *e.g.*, clients exchanging peer-to-peer software updates while disconnected from any central update server. Provided these clients have cached a logarithmic number of additional blocks with their respective reference points – specifically the reference points' next and prior blocks at each level – then the two clients have all the information they need to cryptographically validate each others' reference points. For software updates, forward validation is important when an out-of-date client obtains a newer update from a peer. Reverse validation (via hashes) is useful for secure version rollback, or in other applications, such as efficiently verifying a historical payment on a skipchain for a cryptocurrency.

5 Design of CHAINIAC

In this section, we present CHAINIAC, a framework enhancing security and transparency of software updates. For clarity of exposition, we describe CHAINIAC step-by-step starting from a strawman update-system that uses one key to sign release binaries, as introduced in Section 3. We begin by introducing a decentralized validation of both source code and corresponding binaries, while alleviating the developer and client overhead. We then improve

transparency and address the evolution of update configurations by using skipchains. Finally, we reduce traversal overheads with multi-level skipchains and demonstrate how to adapt CHAINIAC to multi-package projects.

5.1 Decentralized Release-Approval

The first step towards CHAINIAC involves enlarging the trust base that approves software releases. Instead of using a single (shared) key to sign updates, each software developer signs using their individual keys. At the beginning of a project, the developers collect all their public keys in a *policy* file, together with a threshold value that specifies the minimal number of valid developer signatures required to make a release valid. Complying with our threat model, we assume that this policy file, as a trust anchor, is obtained securely by users at the initial acquisition of the software, *e.g.*, it can reside on a project's website as often is the case with a single signing key in the current software model.

Upon the announcement of a software release, which can be done by a subset or all developers depending on the project structure, all the developers check the source code and, if they approve, they sign the hash of it with their individual keys, *e.g.*, using PGP [14], and they add the signatures to an append-only list. Signing source code, instead of binaries, ensures that developers can realistically verify (human-readable) code.

The combination of the source code and the signature list is then pushed to the software-update center from where a user can download it. For simplicity, we first assume that the update center is trusted, later relaxing this assumption. When a user receives an update, she verifies that a threshold of the developers' signatures is valid, as specified in the policy file already stored on user's machine. If so, the user builds the binary from the obtained source code and installs it. An attacker trying to forge a valid software-release needs to control the threshold of the developers' keys, which is presumably harder than gaining control over any single signing key.

5.2 Build Transparency via Developers

The security benefits of developers signing source-code releases come at the cost of requiring users to build the binaries. This cost is a significant usability disadvantage, as users usually expect to receive fully functional binaries directly from the software center. Therefore in our second step towards CHAINIAC, we transfer the responsibility of building binaries from users to developers.

When a new software release is announced, it includes not only the source code but also a corresponding binary (or a set of binaries for multiple platforms) that users will obtain via an update center. Each developer now first validates the source code, then compiles it using reproducible build techniques [49, 59]. If the result matches the announced binary, he signs the software release. Assuming a threshold of developers is not compromised, this process ensures that the release binary has been checked by a number of independent verifiers. Upon receiving the update, a user verifies that a threshold of signatures is valid; if so, she can directly install the binary without needing to build it herself.

5.3 Release-Validation via Cothority

Although decentralized developer approval and reproducible builds improve software-update security, running reproducible builds for each binary places a high burden on developers (*e.g.*, building the Tor Browser Bundle takes 32 hours on an average modern laptop [60]). The load becomes even worse for developers involved in multiple software projects. Moreover, verifying many developer-signatures in large software projects can be a burden for client devices, especially when upgrading multiple packages. It would naturally be more convenient for an intermediary to take the developers' commitments, run the reproducible builds and produce a result that is easily verifiable by clients. Using a trusted third party is, however, contrary to CHAINIAC's goal of decentralization. Hence to maintain decentralization, we implement the intermediary as a collective authority or *cothority*.

To announce a new software release, the package developers combine the hashes of the associated source-code and binaries in a Merkle tree [52]. Each developer checks the source code and signs the root hash (of this tree), that summarizes all data associated with the release. The developers then send the release data and the list of their individual signatures to the cothority that validates and collectively signs the release. Clients can download and validate the release's source and/or any associated binary by verifying only a single collective signature and Merkle inclusion proofs for the components of interest.

To validate a release, each cothority server checks the developer signatures against the public keys and the threshold defined in the policy file. Remembering the policy for each software project is a challenge for the cothority that is supposed to be stateless. For now, we assume that each cothority member stores a project-to-policy list for all the projects it serves for. We relax this assumption in Section 5.5. The build verifiers then compile the source code and compare the result against the binaries of the release. The latter verification enables the transition from reproducible builds to *verified builds*: a deployment improvement over reproducible builds, which we introduce. The verified builds enable clients to obtain the guarantee of source-to-binary correspondence without

the need to accomplish the resource-consuming building work, due to the broad independent validation.

5.4 Anti-equivocation Measures

Many software projects are maintained by a small group of (often under-funded or volunteer) developers. Hence, it is not unreasonable to assume that a powerful (state-level) attacker could coerce a threshold of group members to create a secret backdoored release used for targeted attacks. In our next step towards CHAINIAC, we tackle the problem of such stealthy developer-equivocation, as well as the threat of an (untrusted) software-update center that accidentally or intentionally forgets parts of the software release history.

We introduce cothority-controlled hash chains that create a public history of the releases for each software project. When a new release is announced, the developers include and sign the summary (Merkle Root) of the software's last version. The cothority then checks the developers' signatures, the collective signature on the parent hash-block, and that there is no fork in the hash-chain (*i.e.*, that the parent hash-block is the last one publicly logged and that there is no other hash-block with the same parent). If everything is valid, it builds the summary for the current release, then runs BFT-CoSi [42] to create a new collective signature. Because the hash chain is cothority controlled, we can distribute the witnessing of its consistency across a larger group: for example, not just across a few servers chosen by the developers of a particular package, but rather across all the servers chosen by numerous developers who contribute to a large software distribution, such as Debian. Even if an attacker controls a threshold of developer keys for a package and creates a seemingly valid release, the only way to convince any client to accept this malicious update is to submit it to the cothority for approval and public logging. As a result, it is not possible for the group to sign the compromised release and keep it “off the public record”.

This approach prevents attackers from secretly creating malicious updates targeted at specific users without being detected. It also prevents software-update centers from "forgetting" old software releases, as everything is stored in a decentralized hash chain. CHAINIAC's transparency provisions not only protect users from compromised developers, but can also protect *developers* from attempts of coercion, as real-world attackers prefer secrecy and would be less likely to attack if they perceive a strong risk of the attack being publicly revealed.

5.5 Evolution of Authoritative Keys

So far, we have assumed that developer and cothority keys are static, hence clients who verify (individual or collective) signatures need not rely on centralized intermediaries such as CAs to retrieve those public keys. This assumption is unrealistic, however, as it makes a compromise of a key only a matter of time. Collective signing exacerbates this problem, because for both maximum independence and administrative manageability, witnesses' keys might need to rotate on different schedules. To lift this assumption without relying on centralized CAs, we construct a decentralized mechanism for a trust delegation that enables the evolution of the keys. As a result, developers and cothorities can change, when necessary, their signing keys and create a moving target for an attacker, and the cothority becomes more robust to churn.

To implement this trust delegation mechanism, we employ skipchains presented in Section 4. For the cothority keys, each cothority configuration becomes a block in a skipchain. When a new cothority configuration needs to be introduced, the current cothority witnesses run BFT on it. If completed successfully, they add the configuration to the skipchain, along with the produced signature as a forward link. For the developer keys, the trust is rooted in the policy file. To enable a rotation of developer keys, a policy file needs to be a part of the Merkle tree of the release, hence examined by the developers. Thus, the consistency of key evolution becomes protected by the hash chain. To update their keys, the developers first specify a new policy file that includes an updated set of keys, then, as usual during a new release, they sign it with a threshold of their current keys, thus delegating trust from the old to the new policy. Once the cothority has appended the new release to the chain, the new keys become active and supersede their older counterparts. Anyone following the chain can be certain that a threshold of the developers has approved the new set of keys. With this approach, developers can rotate their keys regularly and, if needed, securely revoke a sub-threshold number of compromised keys.

5.6 Role Separation and Timeliness

In addition to verifying and authenticating updates, a software-update system must ensure update timeliness, so that a client cannot unknowingly become a victim of freeze or replay attacks (see Section 2.1). To retain decentralization in CHAINIAC, we rely on the update cothority to provide a timestamp service. Using one set of keys for signing new releases and for timestamping introduces tradeoffs between security and usability, as online keys are easier compromisable than offline keys, whereas the latter cannot be used frequently. To address the described challenges, we introduce a multi-layer skipchain-based architecture with different trust roles, each having different responsibilities and rights. We distinguish the four roles ROOT, CONFIG, RELEASE, and TIME. The first three are

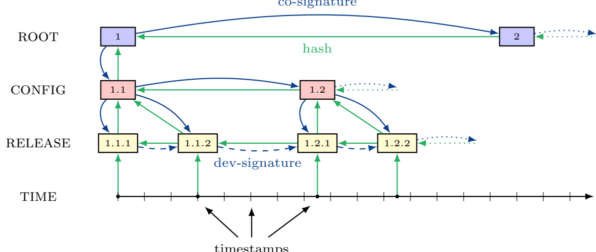

Figure 3: Trust delegation in CHAINIAC

based on skipchains and interconnected with each other through *upward* and *downward* links represented as cryptographic hashes and signatures, respectively. Figure 3 shows an overview of this multi-layer architecture.

The ROOT role represents CHAINIAC's root of trust; its signing keys are the most security-critical. These keys are kept offline, possibly as secrets shared among a set of developer-administrators. They are used to delegate trust to the update cothority and revoke it in case of misbehavior. The ROOT skipchain changes slowly (*e.g.*, once per year), and old keys are deleted immediately. As a result, the ROOT skipchain has a height of one, with only single-step forward and backward links.

The CONFIG role represents the online keys of the update cothority and models CHAINIAC's control plane. These keys are kept online for access to them quicker than to the ROOT keys. Their purpose is to attest to the validity of new release-blocks. The CONFIG skipchain can have higher-level skips, as it can be updated more frequently. If a threshold of CONFIG keys is compromised, the ROOT role signs a new set of CONFIG keys, enabling secure recovery. This is equivalent to a downward link from the ROOT skipchain to the CONFIG skipchain.

The RELEASE role wraps the functionality of the release log, as specified previously, and adds upward links to ROOT and CONFIG skipchains, enabling clients to efficiently look up the latest trusted ROOT and CONFIG configurations required for verifying software releases.

Finally, the TIME role provides a timestamp service that informs clients of the latest version of a package, within a coarse-grained time interval. Every TIME block contains a wall-clock timestamp and a hash of the latest release. The CONFIG leader creates this block when a new RELEASE skipblock is co-signed, or every hour if nothing happens. Before signing it off, the rest of the independent servers check that the hash inside the timestamp is correct and that the time indicated is sufficiently close to their clocks (*e.g.*, within five minutes). From an absence of fresh TIME updates and provided that clients has an approximately accurate notion of the current time[2], the clients can then detect freeze attacks.

5.7 Multiple-Package Projects

To keep track of software packages, users often rely on large software projects, such as Debian or Ubuntu, and their community repositories. Each of these packages can be maintained by a separate group of developers, hence can deploy its own release log. To stay updated with new releases of installed packages, a user would have to frequently contact all the respective release logs and follow their configuration skipchains. This is not only bandwidth- and time-consuming for the user but also requires the maintainers of each package to run a freshness service. To alleviate this burden, we further enhance CHAINIAC to support multi-package projects.

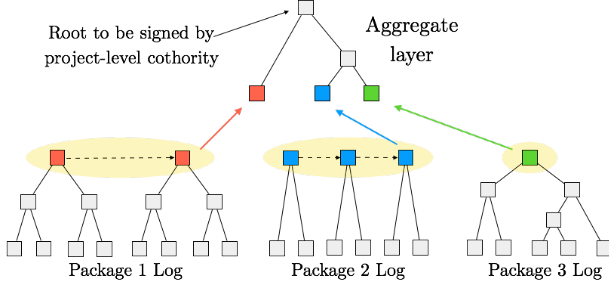

Figure 4: Constructing an aggregate layer in CHAINIAC

We introduce an *aggregate* layer into CHAINIAC: this layer is responsible for collecting, validating and providing to clients information about all the packages included in the project. A project-level update cothority implements a project log where each entry is a *snapshot* of a project state (Figure 4). To publish a new snapshot, the cothority retrieves the latest data from the individual package skipchains, including freshness proofs and signatures on the heads. The witnesses then verify the correctness and freshness of all packages in this snapshot against the corresponding per-package logs. Finally, the cothority forms a Merkle tree that summarizes all package versions in the snapshot, then collectively signs it.

This architecture facilitates the gradual upgrade of large open-source projects, as packages that do not yet have their own skipchains can still be included in the aggregate layer as hash values of the latest release files. The project-level cothority runs an aggregate timestamp service, ensuring that clients are provided with the latest status of all individual packages and a consistent repository state. A

[2] Protecting the client's notion of time is an important but orthogonal problem [50], solvable using a timestamping service with collectively-signed proofs-of-freshness, as in CoSi [69, Section V.A.].

client can request the latest signed project-snapshot from the update cothority and check outdated packages on her system using Merkle proofs. If there are such packages, the client accesses their individual release logs, knowing the hash values of the latest blocks.

A multi-package project can potentially have several aggregate layers, each representing a certain distribution , *e.g.*, based on the development phase of packages, as *stable*, *testing*, and *unstable* in Debian. Individual packages would still maintain a single-view linear skipchain-log but the project developers would additionally tag each release with its distribution affiliation. For example, the stable distribution would then notify clients only when correspondingly tagged releases appear, and would point to the precise block in the package skipchain by providing its hash value, whereas the developers might move ahead and publish experimental versions of the package to its release log. The timeliness is then ensured by maintaining a separate timestamp service for each distribution.

6 Security Analysis

In this section, we informally analyze the security of CHAINIAC against the threat model defined in Section 3.2. We thereby assume that an adversary is computationally bound and unable to compromise the employed cryptosystems (*e.g.*, create hash collisions or forge signatures), except with negligible probability.

Developers. The first point of attack in CHAINIAC is the software-release proposal created by developers. An attacker might try to sneak a vulnerability into the source code, compromise the developers' signing keys, or intercept a release proposal that the developers send to the update cothority, and replace it with a backdoored version. If developers carefully review source-code changes and releases, and fewer than the threshold t_d of developers or their keys are compromised, the attacker alone cannot forge a release proposal that the update cothority would accept.[3] As developer-signed release proposals are cryptographically bound to particular sources and binaries, the update cothority will similarly refuse to sign a release proposal whose sources differ from the signed versions, or whose binaries differ from those reproduced by the build verifiers. If a sub-threshold number of developer keys are compromised without detection, a regular signing key rotation (Section 5.5) can eventually re-establish full security of the developer keys.

Update cothority. The next point an adversary might attack is the update-cothority's witness servers. The witnesses and build verifiers should be chosen carefully by the software project or repository maintainers, should reside in different physical locations, and be controlled by trustworthy, independent parties. For a successful attack, the adversary must compromise at least t_w witnesses to violate the correctness or transparency of the release timeline, and must compromise t_v build verifiers to break the source-to-binary release correspondence. As with developer keys, the regular rotation of cothority keys further impedes a gradual compromise.

If a threshold of online cothority keys are compromised, then, once this compromise is detected, the developers can use the offline ROOT keys to establish a new cothority configuration (see Section 5.6). Non-compromised clients (*e.g.*, those that did not update critical software during the period of compromise) can then "roll forward" securely to the new configuration. An unavoidable limitation of this (or any) recovery mechanism using offline keys, however, is an inability to ensure timeliness of configuration changes. Old clients, whose network connectivity is attacker controlled, could be denied the knowledge of the new configuration, hence remain reliant on the old, compromised cothority configuration. "Fixing" this weakness would require bringing the offline ROOT keys online, defeating their purpose.

Update timeline. An attacker might attempt to tamper with the skipchain-based update timeline containing the authoritative signing keys and the software releases, *e.g.*, by attempting to fork either of the logs, to modify entries, or to present different views to users. The skipchain structure relies on the security of the underlying hash and digital signature schemes. Backward links are hashes ensuring the immutability of the past with respect to any valid release. An attacker can propose a release record with incorrect back-links, but cannot produce a valid collective signature on such a record without compromising a threshold of witnesses, as honest witnesses verify the consistency of new records against their view of history before cosigning. An attacker can attempt to create two distinct successors to the same prior release (a fork), but any honest witness will cosign at most one of these branches. If the cothority is configured with a two-thirds supermajority witness-threshold ($t_w \geq 2n_w + 1$), forks are prevented by the BFT-CoSi consensus mechanism.

Forward links are signatures that can be created only once the (future) target blocks have been appended to the skipchain. This requires that witnesses store the sign-

[3] Of course there is no guarantee that even honest, competent developers will detect all bugs, let alone sophisticated backdoors masquerading as bugs. CHAINIAC's transparency provisions ensure that even compromised releases are logged and open to scrutiny, and the freshness mechanisms ensure that a compromised release does not remain usable in rollback or freeze attacks after being fixed and superseded.

ing keys associated with a given block, until all forward links from that block onwards are generated. This longer key-storage, gives the attacker more time to compromise a threshold of keys. To mitigate this threat, we impose an expiration date on signing keys (*e.g.*, one year), after which honest witnesses delete outdated keys unconditionally, thereby imposing an effective distance limit on forward links. Note that the key expiration-time should be sufficiently long so that the direct forward links are always created to ensure secure trust delegation.

In summary, to manipulate the update timeline managed by the update cothority, an attacker needs to compromise at least a threshold of t_w witness servers. Note that one purpose of the update timeline in CHAINIAC is to ensure accountability so that even if the attacker manages to slip a backdoor into a release, the corresponding source code stays irrevocably available, enabling public scrutiny.

Update center. An adversary might also compromise the software-update center to disseminate malicious binaries, to mount freeze attacks that prevent clients from updating, or to replay old packages with known security vulnerabilities and force clients to downgrade.

Clients can detect that they have received a tampered binary by verifying the associated signature using the public key of the update cothority; the key can be retrieved securely through CHAINIAC's update timeline. The clients will also never downgrade, as they only install packages that are cryptographically linked to the currently installed version through the release skipchain. Finally, assuming the clients have a correct internal clock, they can detect freeze and replay attacks by verifying timestamps and package signatures, because an attacker cannot forge collective signatures of the update cothority to create valid-looking TIME blocks (see Section 5.6).

7 Prototype Implementation

We implemented CHAINIAC in Go [31] and made it publicly available[4], along with the instructions on how to reproduce the evaluation experiments. We built on existing open-source code implementing CoSi [69] and BFT-CoSi [42]. The new code implementing the CHAINIAC prototype was about 1.8kLOC, whereas skipchains, network communication, and BFT-CoSi were 1.2k, 1.5k, and 1.8k lines of code (LOC), respectively. Although the implementation is not yet production quality, it is practical and usable for experimental purposes.

We rely on Git for source-code control and use Git-notes [30], tweaked with server hooks to be append-only, for collecting developer approvals in the form of PGP signatures. For the build verifiers, we use Python to extract the information about the building environment of the packages, and Docker [26] to reproduce it.

[4] https://github.com/dedis/paper_chainiac

8 Experimental Evaluation

In this section, we experimentally evaluate our CHAINIAC prototype. The main question we answer is whether CHAINIAC is usable in practice without incurring large overheads. We begin by measuring the cost of reproducible builds using Debian packages as an example, and we continue with the cost of witnesses who maintain an update-timeline skipchain and the overhead of securing multi-package projects.

8.1 Experimental Methodology

In the experiments of Sections 8.2, 8.3 and 8.4, we used 24-core Intel Xeons at 2.5 GHz with 256 GB of RAM and, where applicable, ran up to 128 nodes on one server with the network-delay set between any two nodes to 100ms with the help of Mininet [54]. Because we had not yet implemented a graceful handling of failing docker-builds, we measured building time in a small grid of 4 nodes and extrapolated this time to the bigger grids in Figure 6. In Section 8.5, we simulated four collectively signing servers on a computer with a 3.1 GHz Intel Core i7 processor and 16 GB of RAM and did not include any network-latencies, as we measured only CPU-time and bandwidth.

To evaluate the witness cost of the long-term maintenance of an update timeline, we used data from the Debian reproducible builds project [22] and the Debian snapshot archive [19]. The former provides checksums and dependency information for reproducible packages. Unfortunately, the information was not available for older package versions, therefore we always verified each package against its newest version. We used the latter as an update history to estimate average cost over time for maintaining an individual update timeline and the overhead of running an aggregate multi-package service. In Section 8.4, we used real-life data from the PyPI package repository [17]. The data represented snapshots of the repository of about 58,000 packages. There were 11,000 snapshots over a period of 30 days. Additionally, we had 1.5 million update-requests from 400,000 clients during the same 30-day period. Using this data, we implemented a simulation in Ruby to compare different bandwidth usages.

8.2 Reproducing Debian Packages

To explore the feasibility of build transparency and to estimate the cost of it for witnesses, we ran an experiment on automatic build reproducing. Using Docker containers, we generated a reproducible build environment for

each package, measured the CPU time required to build a binary and verified the obtained hash against a precalculated hash from Debian.

We tested three sets of packages: (1) *required* is the set of Debian required packages [21], 27 packages as of today; (2) *popular* contains the 50 most installed Debian packages [20] that are reproducible and do not appear in *required*; (3) *random* is a set of 50 packages randomly chosen from the full reproducible testing set [22]. Figure 5 demonstrates a CDF of the build time for each set.

10 packages from the random set, 8 from required and 2 from popular produced a hash value different from the corresponding advertised hash. 90% of packages from both the random and required sets were built in less than three minutes, whereas the packages in the required-set have a higher deviation. This is expected as, to ensure Debian's correct functioning, the required packages tend to be more security critical and complex.

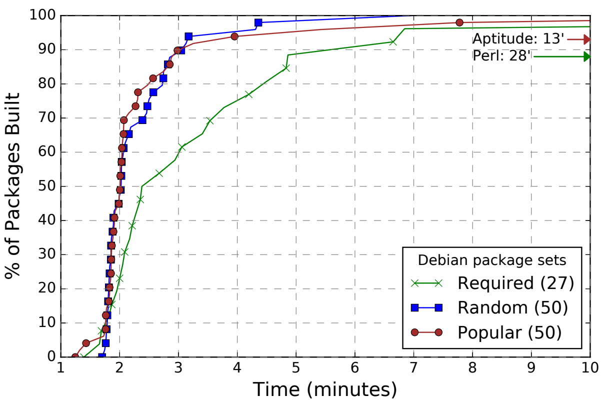

Figure 5: Reproducible build latency for Debian packages

8.3 End-to-End Witness Cost

In this experiment, we measured the cost for a witness of adding a new release to an update timeline. We took a set of six packages, measured the cost for each one individually and then calculated the average values over all the packages. The build time was measured once and copied to the other runs of the experiment, which enabled us to test different configurations quickly and to break out results for each operation. The operations included verifying developers' signatures, reproducible builds, signing off on the new release and generating a timestamp. The witness cost was measured for an update cothorities composed of 7, 31, and 127 nodes.

Figure 6 plots the costs in both CPU time and wall-clock time used. The CPU time is higher than wall-clock time for some metrics, due to the use of a multi-core processor. The verification and build times are constant per node, whereas the time to sign and to generate the timestamp increases with the number of nodes, mostly due to higher communication latency in a larger cothority tree. As expected, the build time dominates the creation of a new skipblock. Every witness spends between 5 and 30 CPU-minutes for each package. Current hosting schemes offer simple servers for 10-US$ per month, enough to run a node doing reproducible builds for the Debian-security repository (about eight packages per day).

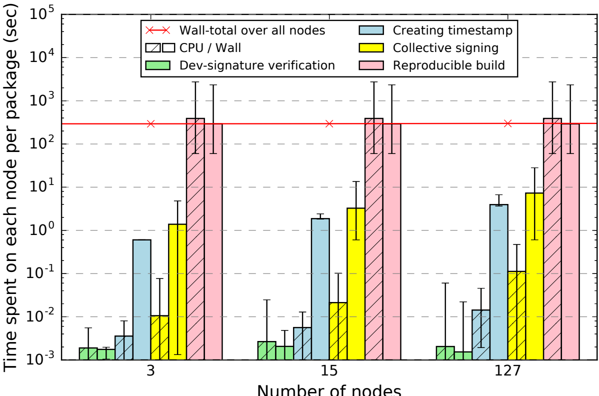

Figure 6: CPU cost of adding a new block to a timeline

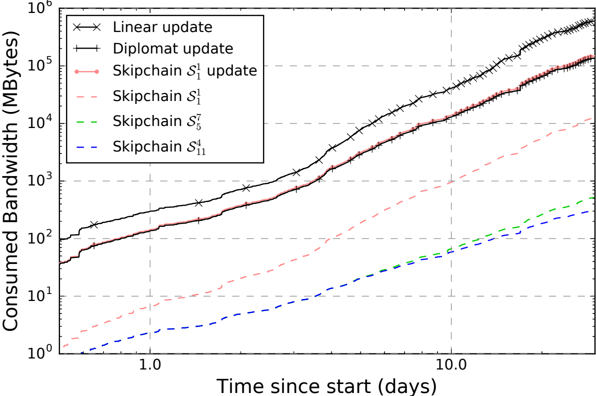

Figure 7: Communication cost for different frameworks

8.4 Skipchain Effect on PyPI Communication Cost

To evaluate the effect on communication cost of using skipchains for update verification, we compare it with two other scenarios using data from the PyPI package repository. The scenarios are as follows:

1. **Linear update:** When a client requests an update, she downloads all the diffs between snapshots, starting

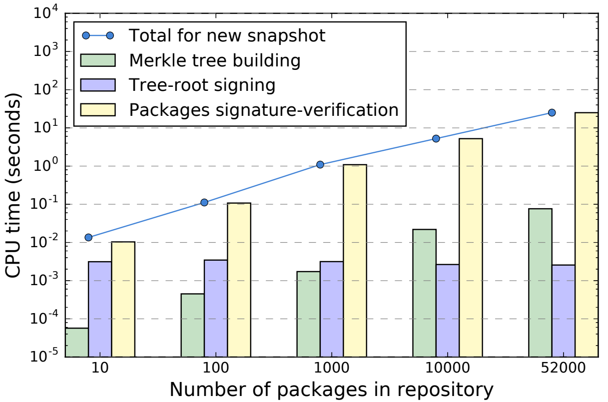

Figure 8: CPU time on server for repository-update

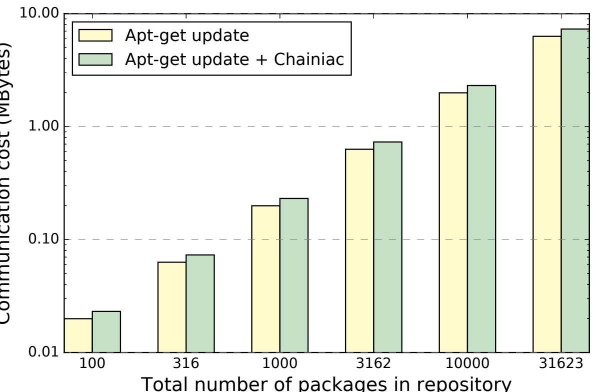

Figure 9: Communication cost to get new repository state

from her last update to the most recent one. This way she validates every step.

2. **Diplomat:** The client only downloads the diff between her last update and the latest update available.
3. **Skipchain S_1^1:** The scenario is as in Diplomat, but every skipblock is also sent to prove the correctness of the current update. The skipchains add security to the snapshots by signing it and by enabling users to efficiently track changes in the signers.

The results over the 30-day data are presented in Figure 7. The straight lines correspond to the aforementioned scenarios. Linear updates increase the communication cost, because the cumulative updates between two snapshots can contain different updates, which are only transferred once, of the same package, as in the case of Diplomat or skipchains. As it can be seen, the communication costs for Diplomat and skipchain are similar, even in the worst case where a skipchain has height-1 only, which corresponds to a simple double-linked list.

To further investigate the best parameters of the skipchain, we plotted only the skipchain overhead using the same data. In Figure 7, the dashed lines show the additional communication cost for different skipchain parameters. We observe that a skipchain with height > 1 can reduce by a factor of 15 the communication cost for proving the validity of a snapshot. Using the base 5 for the skipchain can further reduce the communication cost by another factor of 2.

8.5 Cost of Securing Debian Distribution

In our final experiment, we measured the cost of a witness server that deploys an aggregate-layer skipchain in a multi-package project (Section 5.7) and a client who uses it. . We took the list of all the packages from the snapshot archive of the Debian-testing repository and created one skipchain per package over 1.5-year history, such that each skipblock is one snapshot every five days. We then formed the aggregate Debian-testing skipchain over the same period.

In the first experiment, a witness server receives a new repository-state to validate, verifies the signature for all the packages, builds a Merkle tree from the heads of the individual skipchains and signs its root, thus creating a new aggregate skipblock. Figure 8 depicts the average costs of the operations, over the whole history, against the size of the repository. For a full repository of 52k packages, which corresponds to the actual Debian-testing system, the overall CPU-cost is about 20 seconds per release. This signifies that CHAINIAC generates negligible overhead on the servers that update a skipchain.

The second experiment evaluates the overhead that CHAINIAC introduces to the client-side cost of downloading the latest update of all packages. In order to maintain the security guarantees of CHAINIAC, the client downloads all package hashes and builds a full Merkle tree to verify them, thereby not revealing packages of interest and preserving her privacy. Figure 9 illustrates that CHAINIAC introduces a constant overhead of 16% to the APT manager. This modest overhead suggests CHAINIAC's good scalability and applicability.

9 Related Work

We organize the discussion topically and avoid redundancy with the commentary in Section 2.

Software-update protection. The automatic detection and installation of software updates is a common operation in computer and mobile systems, and there are many tools for this task, such as package- and library-managers [18, 23, 33, 76], and various app stores. There are several security studies [10, 15, 57] that reveal weak-

nesses in the design of software-update systems, and different solutions are proposed to address these weaknesses. Solutions that reduce the trust that end users must have in developers by involving independent intermediaries in testing are shown [3, 4] to be beneficial in open-source projects and content repositories. Several systems, such as Meteor [7], DroidRanger [77] and ThinAV [37], focus on protecting the infrastructure for mobile applications and on detecting malware in mobile markets. Other systems [38, 47, 58] use overlay and peer-to-peer networks for efficient dissemination of security patches, whereas Updaticator [5] enables efficient update distribution over untrusted cache-enabled networks.

Certificate, key, and software transparency. Bringing transparency to different security-critical domains has been actively studied. Solutions for public-key validation infrastructure are proposed in AKI [40], ARPKI [9] and Certificate Transparency (CT) [45] in which all issued public-key certificates are publicly logged and validated by auditors. Public logs are also used in Keybase [39], which enables users to manage their online accounts and provides checking of name-to-key bindings by verifying ownership of third-party accounts. This is achieved via creating a public log of identity information that third-parties can audit. EthIKS [12] provides stronger auditability to CONIKS [51], an end-user key verification service based on a verifiable transparency log, by creating a Smart Ethereum Contract [75] that guarantees that a hash chain is not forked, as long as the ethereum system is stable and correct. Application Transparency (AT) [27] employs the idea of submitting information about mobile applications to a verifiable public log. Thus, users can verify that a provided app is publicly available to everyone or that a given version existed in the market, but was removed. However, AT can protect only against targeted attacks but leaves attacks against all the users outside of its scope. Finally, Baton [8] tries to address the problem of renewing signing keys in Android by chaining them but this solution does not help in the case of stolen signing keys.

Blockchains. The creation of Bitcoin [56] was first perceived as an evolution in the domain of financial technology. Recently, however, there has been an increasing interest in the data structure that enables the properties of bitcoin, namely, the blockchain. There is active work with blockchain in cryptocurrencies [13, 65], DNS alternatives [74] and even general-purpose decentralized computing [75]. All of these systems secure clients in a distributed manner and with a timeline that can be tracked by the clients. However, these systems force the clients to track the full timeline, even if the clients are interested in a very small subset of it, or to forfeit the security of decentralization by trusting a full node.

10 Conclusion

In this work, we have presented CHAINIAC, a novel software-update framework that decentralizes each step of the software-update process to increase trustworthiness and to eliminate single points of failure. The key novel components of CHAINIAC's design are multi-level skipchains and verified builds. The distinct layers of skipchains provide, while introducing minimal overhead for the client, multiple functionalities such as (1) tamper-evident and equivocation-resistant logging of the new updates and (2) the secure evolution of signing keys for both developers and the set of online witnesses. Verified builds further unburden clients by delegating the actual reproducible building process to a decentralized set of build verifiers. The evaluation of our prototype has demonstrated that the overhead of using CHAINIAC is acceptable, both for the clients and for the decentralized group of witnesses, by running experiments on real-world data from Debian. Furthermore, we have replayed 30 days of actual client requests to the PyPI repository and shown that the use of skipchains limits the verification overhead.

Abstract

Security architectures such as Intel SGX need protection against rollback attacks, where the adversary violates the integrity of a protected application state by replaying old persistently stored data or by starting multiple application instances. Successful rollback attacks have serious consequences on applications such as financial services. In this paper, we propose a new approach for rollback protection on SGX. The intuition behind our approach is simple. A single platform cannot efficiently prevent rollback, but in many practical scenarios, multiple processors can be enrolled to assist each other. We design and implement a rollback protection system called ROTE that realizes integrity protection as a distributed system. We construct a model that captures adversarial ability to schedule enclave execution and show that our solution achieves a strong security property: the only way to violate integrity is to reset all participating platforms to their initial state. We implement ROTE and demonstrate that distributed rollback protection can provide significantly better performance than previously known solutions based on local non-volatile memory.

1 Introduction

Intel Software Guard Extensions (SGX) enables execution of security-critical application code, called *enclaves*, in isolation from the untrusted system software [1]. Protections in the processor ensure that a malicious OS cannot read or modify enclave memory at runtime. To protect enclave data across executions, SGX provides a security mechanism called *sealing* that allows each enclave to encrypt and authenticate data for persistent storage. SGX-enabled processors are equipped with certified cryptographic keys that can issue remotely verifiable *attestation* statements on the software configuration of enclaves. Through these security mechanisms (isolation, sealing, attestation) SGX enables development of various applications and online services with hardened security.

The architecture has also its limitations. While sealing prevents a malicious OS from reading or arbitrarily modifying persistently stored enclave data, *rollback attacks* [2, 3, 4, 1] remain a threat. In a rollback attack a malicious OS replaces the latest sealed data with an older encrypted and authenticated version. Enclaves cannot easily detect this replay, because the processor is unable to maintain persistent state across enclave executions that may include platform reboots. Another way to violate state integrity is to create two instances of the same enclave and route update requests to one instance and read requests to the other. To remote clients that perform attestation, the instances are indistinguishable.

Data integrity violation through rollback attacks can have severe implications. Consider, for example, a financial application implemented as an enclave. The enclave repeatedly processes incoming transactions at high speed and maintains an account balance for each user or a history of all transactions in the system. If the adversary manages to revert the enclave to its previous state, the maintained account balance or the queried transaction history does not match the executed transactions.

To address rollback attacks, two basic approaches are known. The first is to store the persistent state of enclaves in a non-volatile memory element on the same platform. The SGX architecture was recently updated to support monotonic counters that leverage non-volatile memory [5]. However, the security guarantees and the performance limits of this mechanism are not precisely documented. Our experiments show that writes of counter values to this memory are slow (80-250 ms), which limits its use in high-throughput applications. More importantly, this memory allows only a limited number of write operations. We show that this limit is reached within just few days of continuous system use after which the memory becomes unusable. Similar limitations also apply to rollback protection techniques that leverage Trusted Platform Modules (TPMs) [2, 4, 3].

The second common approach is to maintain integrity information for protected applications in a sep-

arate trusted server [6, 7, 8]. The drawback of such solutions is that the server becomes an obvious target for attacks. Server replication using standard Byzantine consensus protocols [9] avoids a single point of failure, but requires high communication overhead and multiple replicas for each faulty node.

In this paper we propose a new approach to protect SGX enclaves from rollback attacks. The intuition behind our solution is simple. A single SGX platform cannot prevent rollback attacks efficiently, but in many practical scenarios the owner or the owners of processors can assign multiple processors to assist each other. Our approach realizes rollback protection as a distributed system. When an enclave updates its state, it stores a counter to a set of enclaves running on assisting processors. Later, when the enclave needs to recover its state, it obtains counter values from assisting enclaves to verify that the recovered state data is of the latest version.

We consider a powerful adversary that controls the OS on the target platform and on *any* of the assisting platforms. Additionally, we even assume that the adversary can break SGX protections on some of the assisting processors and control all network communication between the platforms. Our adversary model combines commonly considered network control based on the standard Dolev-Yao model [10] and Byzantine faults [11, 12], but additionally captures the the ability of the adversary to restart trusted processes from a previously saved state and to run multiple instances of the same trusted process. Such adversarial capabilities are crucial for the security analysis of our system, and we believe that the model is of general interest. In fact, using our model we found potential vulnerabilities in recent SGX systems [3, 13, 14].

Secure and practical realization of distributed rollback protection under such a strong adversarial model involves several challenges. One of the main challenges is that when an assisting enclave receives a counter, its own state changes, which implies a set of new state updates that would in turn propagate. To prevent endless update propagation, the counter value must be stored in the volatile runtime memory of enclaves. However, the assisting enclaves may be restarted at any time. Moreover, the adversary can also create multiple instances of the same enclave on all assisting platforms and route counter writes and reads to separate instances.

We design and implement a rollback protection system called ROTE (Rollback Protection for Trusted Execution). The main components of our solution are a state update mechanism that is an optimized version of consistent broadcast protocols [15, 16], and a recovery mechanism that obtains lost counters from the rest of the protection group upon enclave restart. We also design a session key update mechanism to address attacks based on multiple enclave instances.

Our solution achieves a strong security property that we call *all-or-nothing rollback*. Although the attacker can restart enclaves freely, and thus implement subtle attacks where enclave state updates and recovery are interleaved, the adversary cannot roll back any single enclave to its previous state. The only way to violate data integrity is to reset the entire group to its initial state. If desired, similar to [4, 2], our approach can also provide crash resilience, assuming deterministic enclaves and a slightly weaker notion of rollback prevention (the latest input can be executed twice).

We implemented ROTE on SGX and evaluated its performance on four SGX machines. We tested larger groups of up to 20 platforms using a simulated implementation over a local network and geographically distributed enclaves. Our evaluation shows that state updates in ROTE can be very fast (1-2 ms). The number of counter increments is unlimited. This is in contrast to solutions based on SGX counters and TPMs, where state updates are approximately 100 times slower and limited. Compared to Byzantine consensus protocols, our approach requires significantly fewer replicas ($f+1$ instead of the standard $3f+1$). Enclave developers can use our system through a simple API. The ROTE TCB increment is moderate (1100 LoC).

Contributions. We make the following contributions.

- *New security model.* We introduce a new security model for reasoning about the integrity and freshness of SGX applications. Using the model we identified potential security weaknesses in existing SGX systems.
- *SGX counter experiments.* We show that SGX counters have severe performance limitations.
- *Novel approach.* We propose a novel way to protect SGX enclaves. Our main idea is to realize rollback protection by storing enclave-specific counters in a distributed system of collaborative enclaves on distinct nodes.
- ROTE. We propose and implement a system called ROTE that effectively protects against rollback attacks. ROTE ensures integrity and freshness of application data in a powerful adversarial model.
- *Experimental evaluation.* We demonstrate that distributed rollback protection incurs only a small performance overhead. When deployed over a low-latency network, the state update overhead is only 1-2 ms.

The rest of this paper is organized as follows. Section 2 explains models and rollbacks attacks. Section 3 describes our approach. Section 4 describes the ROTE system and Section 5 provides security analysis. Section 6 provides performance evaluation and Section 7 further discussion. We review related work in Section 8. Section 9 concludes the paper.

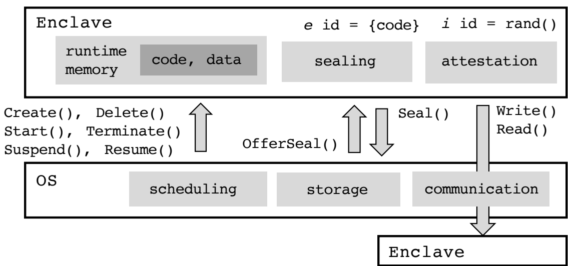

Figure 1: Modeled SGX operations.

2 Problem Statement

In this section we define models for the SGX architecture and the adversary. After that, we explain rollback attacks, limitations of known solutions, and our requirements. Appendix A provides a summary of the SGX architecture for readers that are not familiar with it.

2.1 SGX Model

Figure 1 illustrates our SGX model. We model enclaves and the operating system, their main functionality, and the operations through which they interact. Our model captures the main SGX functionalities that are available on all SGX platforms.

Scheduling operations. Enclave execution is scheduled by the OS.

- $e \leftarrow$ `Create`$(code)$. The system software running on the OS can create an enclave by providing its code. The SGX architecture creates a unique enclave identifier e that is defined by the code measurement.
- $i \leftarrow$ `Start`(e). The system software can start a created enclave using its enclave identifier e. The enclave generates a random and unique instance identifier i for the enclave instance that executes the code that was assigned to it during creation. While an enclave instance is running, the OS and other enclaves are isolated from its runtime memory. Each enclave instance has its own program counter and runtime memory.
- `Suspend`(i) and `Resume`(i). The OS can suspend the execution of an enclave. When an enclave is suspended, its program counter and runtime memory retain their values. The OS can resume suspended enclave execution.
- `Terminate`(i). The OS can terminate the enclave execution. At termination, the enclave runtime memory is erased by the SGX architecture and the enclave instance i is rendered unusable.

Storage operations. The second set of operations is related to sealing data for local persistent storage.

- $s \leftarrow$ `Seal`$(data)$. An enclave can save data for local persistent storage. This operation creates an encrypted, authenticated data structure s that is passed to the OS.
- `OfferSeal`(i, s). The OS can offer sealed data s. The enclave can verify that it previously created the seal, but the enclave cannot distinguish which seal is the latest. Every enclave instance i can unseal data previously sealed by an instance of the same enclave identity e.

Communication operations. Due to attestation, a client can write data such that only a particular enclave can read it. The client can read data from an enclave and verify which enclave wrote it. We model these primitives as single operations that can be called from the same or remote platform, although attestation is an interactive protocol between the enclave and client.

- `Write`(m_e, i). The OS can write message m_e to an enclave instance i. Only an enclave with enclave identity e can read the written message m_e.
- $m_e \leftarrow$ `Read`(i). The OS can read message m_e from an enclave instance i. The read message m_e identifies the enclave identity e that wrote the data.

Note that remote attestation identifies the enclave identity, but not the platform identity, because the attestation protocol is either anonymous or returns client-specific pseudonyms (see Appendix A for details). In local attestation the platform is implicitly known.

We do not model platform reboots, as those have the same effect as enclave restarts. Our model assumes that the runtime memory of each enclave instance is perfectly isolated from the untrusted OS and other enclaves. We consider information leakage from side-channel attacks a realistic threat [17, 18, 19], but an orthogonal problem to rollback attacks, and thus outside of our model.

2.2 Local Adversary Model

We consider a powerful adversary who, after an initial trusted setup phase, controls all system software on the target platform, including the OS. Based on the SGX model, the adversary can schedule enclaves and start multiple instances of the same enclave, offer the latest and previous versions of sealed data, and block, delay, read and modify all messages sent by the enclaves.

The adversary cannot read or modify the enclave runtime memory or learn any information about the secrets held in enclave data. The adversary has no access to processor-specific keys, such as the sealing key or the attestation key, and the adversary cannot break cryptographic primitives provided by the SGX architecture. The enclaves may also implement additional cryptographic operations that the adversary cannot break.

The adversarial capabilities that we identified as part of the model can be critical for many SGX systems. The ability to schedule, restart and create multiple enclave instances, enables subtle attacks that we address in this paper. We analyzed SGX systems using this model and found vulnerabilities that can be addressed through the techniques developed in this paper. These findings are reported in an extended version of this paper [20].

2.3 Rollback Attacks

The goal of the adversary is to violate the integrity of the enclave's state. This is possible with a simple rollback attack. After an enclave has sealed at least two data elements $s_1 \leftarrow \texttt{Seal}(d_1)$ and $s_2 \leftarrow \texttt{Seal}(d_2)$, the adversary performs `Terminate()` and `Start()` to erase the runtime memory of the enclave. When the enclave requests for the latest sealed data d_2, the adversary performs $\texttt{OfferSeal}(i, s_1)$ and the enclave accepts d_1 as d_2. When the sealed data captures the state of the enclave at the time of sealing, we say that the rollback attack reverts the enclave back to its previous state.

Another approach is a *forking attack*, where the adversary leverages two concurrently running enclave instances. The adversary starts two instances $i_1 \leftarrow \texttt{Start}(e)$ and $i_2 \leftarrow \texttt{Start}(e)$ of the same enclave e. The OS receives a request from a remote client to write data m_e to enclave e. The OS writes the data to the first enclave instance $\texttt{Write}(m_e, i_1)$ which causes a state change. Another remote client sends a request to read data from the enclave e. The OS reads data from the second instance $m_e \leftarrow \texttt{Read}(i_2)$ which has an outdated state and returns m_e to the client. The SGX architecture does not enable one enclave instance to check if another instance of the same enclave code is already running [21].

Such attacks can have severe implications, especially for applications that maintain financial data, such as account balances or transaction histories.

2.4 Limitations of Known Solutions

SGX counters. Intel has recently added support for monotonic counters [5] as an optional SGX feature that an enclave developer may use for rollback attack protection, when available. However, the security and performance properties of this mechanism are not precisely documented. We performed a detailed analysis of SGX counters and report our findings in Appendix B.

To summarize, we found out that counter updates take 80-250 ms and reads 60-140 ms. The non-volatile memory used to implement the counter wears out after approximately one million writes, making the counter functionality unusable after a couple of days of continuous use. Thus, SGX counters are unsuitable for systems where state updates are frequent and continuous. Additionally, since the non-volatile memory used to store the counters resides outside the processor package, the mechanism is likely vulnerable to bus tapping and flash mirroring attacks [22] (see Appendix B for details).

TPM solutions. TPMs provide monotonic counters and NVRAM that can be used to prevent rollback attacks [4, 3, 2]. The TPM counter interface is rate-limited (typically one increment every 5 seconds) to prevent memory wear out.[1] Writing to NVRAM takes approximately 100 ms and the memory becomes unusable after 300K to 1.4M writes (few days of continuous use) [2]. Thus, also TPM based solutions are unsuitable for applications that require fast and continuous updates.

Integrity servers. Another approach is to leverage a trusted server to maintain state for protected applications [6, 7, 8]. The drawback of this approach is that the centralized integrity server becomes an obvious target for attacks. To eliminate a single point of failure, the integrity server could be replicated using a Byzantine consensus mechanism. However, standard consensus protocols, such as PBFT [9], require several rounds of communication, have high message complexity, and require at least three replicas for each faulty node.

Architecture modifications. Finally, the SGX architecture could be modified such that the untrusted OS cannot erase the enclave runtime memory. However, this approach would prevent the OS from performing resource management and would not scale to many enclaves. Additionally, rollback attacks through forced reboots and multiple enclave instances would remain possible. Another approach would be to enhance the processor with a non-volatile memory element. Such changes are costly and current NVRAM technologies have the performance limitations we discussed above.

2.5 Rollback Protection Requirements

The goal of our work is to design a rollback protection mechanism that overcomes the performance and security limitations of SGX counters and other known solutions. In particular, our solution should support unlimited and fast state updates, considering a strong adversary model without a single point of failure. When there is a tradeoff between security and robustness, we favor security.

3 Our Approach

The intuition behind our approach is that a single SGX platform cannot efficiently prevent rollback attacks, but the owner or the owners of SGX platforms can enroll multiple processors to assist each other. Thus, our goal is to design rollback protection for SGX as a distributed system between multiple enclaves running on separate processors. Our distributed system is customized for the task of rollback protection to reduce the number of required replicas and communication.

To realize rollback protection, the distributed system should provide, for each participating platform, an ab-

[1] The TPM 2.0 specifications introduce *high-endurance non-volatile memory* that enables rapidly incremented counters [23]. The counter value is maintained in RAM and the value is flushed to non-volatile memory periodically (e.g., mod 100) and at controlled system shutdown. However, if the system is rebooted without calling TPM Shutdown, the counter value is lost and at start-up the TPM assumes the next periodic value. Therefore, such counters do not prevent attacks where the adversary reboots the system.

straction of a *secure counter storage* that consists of two operations:

• `WriteCounter`(*value*). An enclave can use this operation to write a counter value to the secure storage.[2]

• *value*/*empty* ← `ReadCounter()`. An enclave can use this operation to read a counter value from the secure storage. The operation returns the last written value or an empty value if no counter was previously written.

When an enclave performs a security-critical state update operation (e.g., modifies an account balance or extends a transaction history), it distributes a monotonically increasing counter value over the network to a set of enclaves running on assisting processors (`WriteCounter`), stores the counter value to its runtime memory and seals its state together with the counter value for local persistent storage. When the enclave is restarted, it can recover its latest state by unsealing the saved data, obtaining the counter values from enclaves on the assisting processors (`ReadCounter`) and verifying that the sealed state is of the latest version. The same technique allows potentially concurrently running instances of the same enclave identity to determine that they have the latest state. When an enclave needs to verify its state freshness (e.g., upon receiving a request to return the current account balance or transaction history to a remote client), it obtains the counter value from the network (`ReadCounter`) and compares it to the one in its runtime memory. By using enclaves on the assisting platforms, we reduce the required trust assumptions on the assisting platforms.

3.1 Distributed Model

We use the term *target platform* to refer to the node which performs state updates that require rollback protection. We assume n SGX platforms that assist the target platform in rollback protection The platforms can belong to a single administrative domain or they could be owned by private individuals who all benefit from collaborative rollback protection. We model each platform using the SGX model described in Section 2.1. The distributed system can be seen as a composition of $n+1$ SGX instances (target platform included) that are connected over a network. We make no assumptions about the reliability of the communication network, messages may be delayed or lost completely. We assume that while participating in collaborative rollback protection, some platforms may be temporarily down or unreachable.

Distributed adversary model. On each platform, the adversary has the capabilities listed in Section 2.2. Additionally, we assume that the adversary can compromise the SGX protections on $f < n$ participating nodes, excluding the target platform. Such compromise is possible, e.g., through physical attacks. On the compromised SGX nodes the adversary can freely modify the runtime memory (code and data) of any enclave, and read all enclave secrets and the SGX processor keys.

This adversarial model combines a standard Dolev-Yao network adversary [10] with adversarial behaviour (Byzantine faults) on a subset of participating platforms [11, 12]. In addition, the adversary can schedule the execution of trusted processes, replay old versions of persistently stored data, and start multiple instances of the same trusted process on the same platform. In Section 5 we explain subtle attacks enabled by such additional adversarial capabilities.

3.2 Challenges

Secure and practical realization of our approach under a strong adversarial model involves challenges.

Network partitioning. A simple solution would be to store a counter with all the assisting enclaves, and at the time of unsealing require that the counter value is obtained from all assisting enclaves. However, if one of the platforms is unreachable at the time of unsealing (e.g., due to network error, maintenance or reboot), the operation would fail. Our goal is to design a system that can proceed even if some of the participating enclaves are unreachable. In such a system, some of the assisting enclaves may have outdated counter values, and the system must ensure that only the latest counter value is ever recovered, assuming an adversary that can block messages, and partition the network by choosing which nodes are reachable at any given time.

Coordinated enclave restarts. When an enclave seals data, it sends a counter value to a set of enclaves running on assisting platforms and each enclave must store the received counter. However, sealing the received counter for persistent storage would cause a new state update that would propagate endlessly. Therefore, the enclaves must maintain the received counters in their runtime memory. The participating enclaves may be restarted at any time, which causes them to lose their runtime memory. Thus, the rollback protection system must provide a recovery mechanism that allows the assisting enclaves to restore the lost counters from the other assisting enclaves. Such a recovery mechanism opens up a new attack vector. The adversary can launch coordinated attacks where he restarts assisting enclaves to trigger recovery while the target platform is distributing its current counter value.

Multiple enclave instances. Simple approaches that store a counter to a number of assisting enclaves and later read the counter from sufficiently many of the same enclaves are vulnerable to attacks where the adversary creates multiple instances of the same enclave. Assume that

[2] We use counter *write* abstraction instead of counter *increment*, because our distributed secure storage implementation allows writing of any counter value to the storage. However, the ROTE system only performs monotonic counter increments using this functionality.

a counter is saved to the runtime memory of all assisting enclaves. The adversary that controls the OS on all assisting platforms starts second instances of the same enclave on all platforms. The target enclave updates its state and sends an incremented counter to the second instances. Later, the target enclave obtains an old counter value from the first instances and recovers a previous state from the persistent storage.

4 ROTE System

In this section we describe ROTE (Rollback Protection for Trusted Execution), a distributed system for state integrity and rollback protection on SGX. We explain the counter increment technique, our system architecture, group assignment and system initialization. After that, we describe the rollback protection protocols.

4.1 Counter Increment Technique

Two common techniques for counter-based rollback protection exist. The first technique is *inc-then-store*, where the enclave first increments the trusted counter and after that updates its internal state and stores the sealed state together with the counter value on disk. This approach provides a strong security property (no rollback to any previous state), but if the enclave crashes between the increment and store operations, the system cannot recover from the crash.

The second technique is *store-then-inc*, where the enclave first saves its state on the disk together with the latest input value, after that increments the trusted counter, and finally performs the state update [4, 2]. If the system crashes, it can recover from the previous state using the saved input. This technique requires a deterministic enclave and provides a slightly weaker security property: arbitrary rollback is not possible, but the last input may be executed twice on the same enclave state [2].

The stronger security guarantee is needed, for example, in enclaves that generate random numbers, communicate with external parties or create timestamps. Consider a financial enclave that receives a request message from an external party and for each request it should create only one signed response that is randomized or includes a timestamp (`sgx_get_trusted_time` [24]). If store-then-inc is used, the adversary can create multiple different signed responses for the same request.[3]

The weaker security guarantee is sufficient in applications where the execution of the same input on the same state provides no advantage for the adversary.

[3]While some enclaves that require random numbers can be made deterministic by using a stateful PRNG and including its state to the saved enclave state, this may be difficult for enclaves that reuse code from existing libraries not designed for this. Similarly, some replay issues can be addressed on the protocol level, but enclave developers do not always have the freedom to change (standardized) protocols.

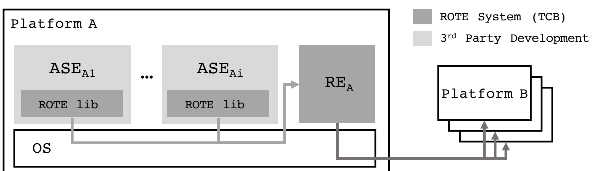

Figure 2: The ROTE system architecture.

In this paper we instantiate ROTE using inc-then-store, because of its strong security guarantee for any enclave. Our goal is to build a generic platform service that can protect various applications. We emphasize that if crash tolerance is required, then store-then-inc should be used. A rollback protection system could even support both counter increment techniques and allow developers to choose the protection style based on their application.

4.2 System Architecture

Figure 2 shows our system architecture. Each platform may run multiple user applications that have a matching Application-Specific Enclave (ASE). The ROTE system consists of a system service that we call the Rollback Enclave (RE) and a ROTE library that ASEs can use for rollback protection.

When an ASE needs to update its state, it calls a counter increment function from the ROTE library. Once the RE returns a counter value, the ASE can safely update its state, save the counter value to its memory and seal any data together with the counter value. When an ASE needs to verify the freshness of its state, it can again call a function from the ROTE library to obtain the latest counter value to verify the freshness of unsealed seal data (or state in its runtime memory).

The RE maintains a Monotonic Counter (MC), increases it for every ASE update, distributes it to REs running on assisting platforms, and includes the counter value to its own sealed data. When the RE needs to verify the freshness of its own state, it obtains the latest counter value from the assisting nodes. The RE realizes the secure counter storage functionality (`WriteCounter` and `ReadCounter`) described in Section 3.

The design choice of introducing a dedicated system service (RE) hides the distributed counter maintenance from the applications. Having a separate RE increases the TCB of our system slightly, but we consider easier application development more important.

The ROTE system has three configurable parameters:

- n is the number of assisting platforms,
- f is the number of compromised processors, and
- u is the maximum number of assisting platforms that can be unreachable or non-responsive at time of state update or read for the system to proceed. Platform restarts are typically less frequent events and during them we require all the assisting platforms to be responsive.

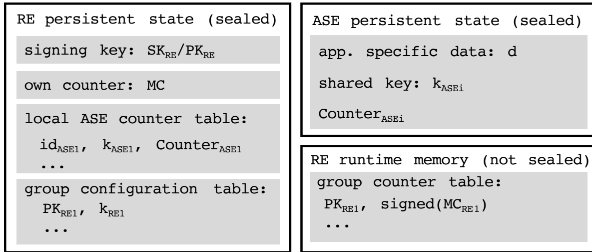

Figure 3: The ROTE system state structures.

These parameters have a dependency $n = f + 2u + 1$ (see Section 5). As an example, a system administrator can select the desired level of security f and robustness u which together determine the required number of assisting platforms n. Alternatively, given n assisting platforms, the administrator can pick f and u. Recall that standard Byzantine consensus protocols require always at least $3f + 1$ replicas.

To avoid *shared-fate* scenarios due to power outages or communication blockades, the participating platforms would ideally have independent or redundant power supply, battery backup, networking and OS maintenance.

4.3 System Initialization

Our system is agnostic to the way the n assisting SGX platforms are chosen. Here we explain an example approach based on a trusted offline authority. Such group assignment is practical when all assisting platforms belong to a single administrative domain (e.g., multiple servers in the same data center). We call the trusted authority that selects the assisting nodes the *group owner*. The group owner can be a fully offline entity to reduce its attack surface. To establish a *protection group*, the group owner selects n platforms.

In this section, we assume that the operating systems on these platforms are trusted at the time of system initialization (e.g., freshly installed OS). Note that although SGX supports remote attestation, this assumption is required, if the group needs to be established among *predefined* platforms. The SGX attestation is anonymous (or pseudonymous) and therefore it does not identify the attested platform. If the application scenario allows that the protection group can be established among *any* SGX platforms, then system initialization is possible without initially trusted operating systems using remote attestation. We discuss such group setup alternatives in Section 4.7.

During its first execution, the RE on each platform generates an asymmetric key pair SK_{RE}/PK_{RE}, and exports the public key. The public keys are delivered to the group owner securely, and the owner issues a certificate by signing all group member keys. The group certificate can be verified by the RE on each selected platform by hard-coding the public key of the group owner to the RE implementation.

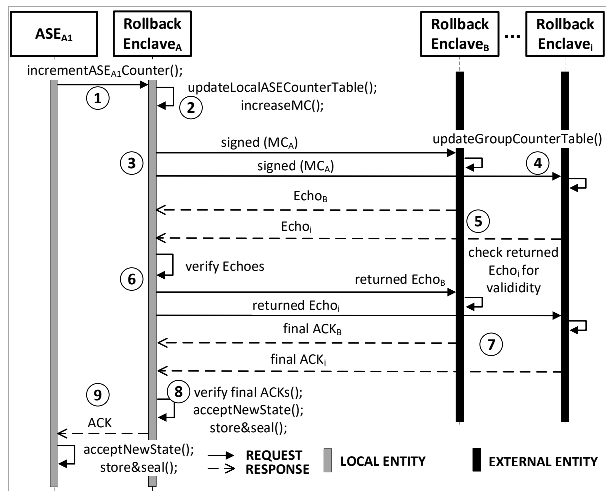

Figure 4: The ASE state update protocol.

The RE is started a second time with the certified list of public keys and a secret *initialization key* as input parameters. The purpose of this secret key for initialization is to indicate a legitimate group establishment operation and to prevent a later, parallel group creation by compromised operating systems on the same certified platforms (see Section 5). The initialization key is hard coded to the RE implementation in hashed format and the RE verifies the correctness of the provided key by hashing it. Without the correct key, the RE aborts initialization. The RE saves the list of certified public keys PK_{REi} to a *group configuration table* and runs an authenticated key agreement protocol to establish pair-wise session keys k_{REi} with all REs, and adds them to the group configuration table. Finally, the RE creates a monotonic counter (MC), sets it to zero, and seals its state.

When an ASE wants to use the ROTE system for the first time, it performs *local* attestation on the RE. The code measurement of the RE can be hard-coded to the ASE implementation or provisioned by the ASE developer. The ASE runs an authenticated key establishment protocol with the RE. The RE adds the established shared key k_{ASEi} to a *local ASE counter table* together with a locally unique enclave identifier id_{ASEi} and adds the same key to its own state. The used state structures are shown in Figure 3.

4.4 ASE State Update Protocol

When an ASE is ready to update its state (e.g., a financial application has received a new transaction and is ready to process it and update the maintained account balances), it starts the state update protocol shown in Figure 4. This protocol can be seen as a customized version of the Echo broadcast [15], as discussed in Section 8. The communication between the enclaves is encrypted and authenticated using the shared session keys in all of our protocols. We add nonces and end point identifiers

to each message to prevent message replay. The protocol proceeds as follows:

(**1**) The ASE triggers a counter increment using the RE.

(**2**) The RE increments a counter for the ASE, increases its own MC, and signs the MC using SK_{RE}. The counter is signed to preserve its integrity in the case of compromised assisting REs.

(**3**) The RE sends the signed counter to all REs in the protection group.

(**4**) Upon receiving the signed MC, each RE updates its group counter table. The table is kept in the runtime memory, and not sealed after every update, to avoid endless propagation.

(**5**) The REs that received the counter send an *echo* message that contains the received signed MC. The REs also save the *echo* in runtime memory for later comparison.

(**6**) After receiving a quorum $q = u + f + 1 = \frac{n+f+1}{2}$ *echos*, the RE returns the *echos* to their senders.[4] The second round of communication is needed to prevent attacks based on RE restarts during the update protocol.

(**7**) Upon receiving back the *echo*, each RE finds the self-sent *echo* in its memory and checks if the MC value from it matches the one in the group counter table and the one received from the target RE. If this is the case, the RE replies with a final ACK message.

(**8**) After receiving q final ACKs, the RE seals its own state together with the MC value to the disk.

(**9**) The RE returns the incremented ASE counter value. The ASE can now safely perform the state update (e.g., update account balance), save the counter value to its runtime memory for later comparison, and seal its state with the counter.

4.5 RE Restart Protocol

Figure 5 shows the protocol that the RE runs after a restart. The goal of the protocol is to allow the RE to join the existing protection group, retrieve its counter value and the MC values of the other nodes.

At restart the RE loses all previously established session keys and has to establish new session keys. In order to preserve our security guarantees, the target RE waits until it establishes new session keys with all other REs residing in the protection group. All assisting REs update their group configuration tables accordingly. The session key refresh mechanism prevents nodes from communicating with multiple RE instances on one platform (see Section 5). Another condition for successfully joining

[4]It might seem that waiting for more than q responses, and therefore allowing more than q nodes to complete the protocol, would increase system robustness. However, the quorum is designed such that writing the latest counter to more than q nodes does not help the system to proceed in case of node unavailability or restarts (see Section 5).

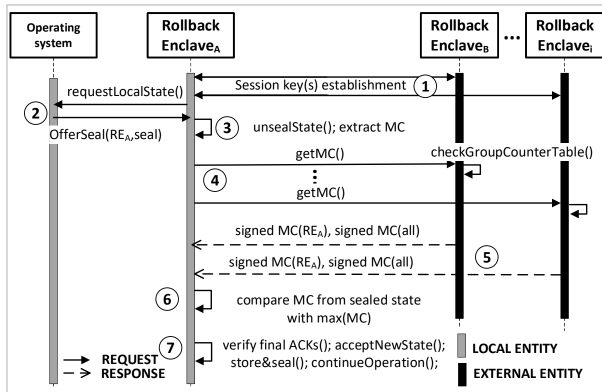

Figure 5: The RE restart protocol.

the protection group is that sufficiently many nodes return non-zero counter values (step 6 below). This check prevents simultaneously restarted REs from establishing a second, parallel protection group. This guarantee can be maintained when at most u nodes restart simultaneously. The protocol proceeds as follows:

(**1**) Session key establishment with other nodes and update of the group configuration table.

(**2**) The RE queries the OS for the sealed state.

(**3**) The RE unseals the state (if received) and extracts the MC.

(**4**) The RE sends a request to all other REs in the protection group to retrieve its MC.

(**5**) The assisting REs check their group counter table. If the MC is found, the enclaves reply with the signed MC. Additionally, the complete table of other signed MCs that the responding node has in its memory is sent to the target RE.

(**6**) When the RE receives q responses from the group (recall that $q = u + f + 1$ and $q \geq n/2$), it selects the maximum value and verifies the signature. We select the maximum value because some REs might have an old counter value or they may have purposefully sent one. The target RE verifies signatures and compares all the group counter table entries with received values for other nodes. For each assisting RE, the target RE picks the highest MC and updates its own group counter table with the value. The RE also verifies that at least $f + 1$ of the received counter values are not zero to prevent creation of the parallel network. If the obtained counter value matches the one in the unsealed data, the unsealed state can be accepted.

(**7**) The RE stores and seals the updated state. The RE will also save the counter value to its runtime memory.

The RE now has an updated group counter table that reflects the latest counters for each node in the group.

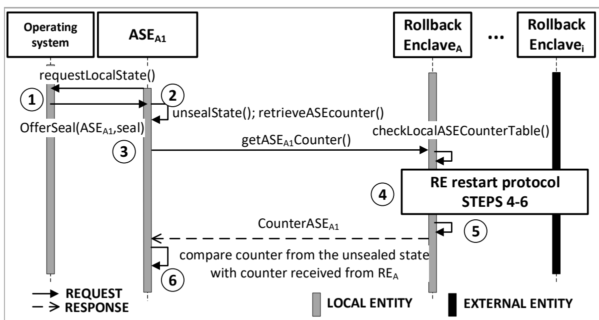

Figure 6: The ASE start/read protocol.

4.6 ASE Start/Read Protocol

When an ASE needs to verify the freshness of its state, it performs the protocol shown in Figure 6. This is needed to verify the freshness of unsealed state after an ASE restart or when an ASE replies to a client request asking its current state (e.g., account balance). The ASE must verify that another ASE instance does not have a newer state. The protocol proceeds as follows:

(**1**) The ASE queries the OS for the sealed data.

(**2**) The ASE unseals the state (if received) and obtains a counter value from it.

(**3**) The ASE issues a request to the local RE to retrieve its latest ASE counter value.

(**4**) To verify the freshness of its runtime state, the RE performs the steps 4-6 from the RE Restart protocol, to obtain the latest MC from the network. This is needed to prevent forking attacks with multiple RE instances. If the obtained MC does not match the MC residing in the memory, the state of the RE is not the latest, so, the RE must abort and be restarted. This is an indication that another instance of the same RE was running and updated the state in the meantime. If the values match, the current data is fresh and the RE can continue normal operation.

(**5**) If all verification checks are successful, the RE returns a value from the local ASE counter table.

(**6**) The ASE compares the received counter value to the one obtained from the sealed data.

If the counters match, ASE loads the previously sealed state or completes a security-critical client request.

4.7 Group Management

Group updates. The group owner issues a signed list of public parts of the public-private key pairs generated by each Rollback Enclave that define the protection group. Assume that later one or more processors in the group are found compromised or need replacement. The group owner should be able to update the previously established group (i.e., exclude or add new nodes) without interrupting the system operation.

During system initialization, the RE verifies the signed list of group member keys and seals the group configuration. When a group update is needed, the group owner issues an updated list that will be processed and sealed by the RE. This approach does not require the entry of the secret initialization key such as in first group establishment. However, the adversary should not be able to revert the group to its previous configuration (e.g., one including compromised nodes) by re-playing the previous group configuration. Since group updates are typically infrequent, they can be protected using SGX or TPM counters.

At system initialization, the RE creates a monotonic counter using SGX counter service or on a local TPM. If this is done using TPM, establishing a shared secret with the TPM (see session authorization in [23]) is necessary. The group owner includes a version number to every issued group configuration. When the RE processes the signed list, it increments the SGX or TPM counter to match the group version, and includes the version number in the sealed data. For every group update, the RE increments either of these counters. When the RE is restarted, it verifies that the version number in the unsealed group configuration matches the counter. The NVRAM memory in TPMs is expected to support approximately 100K write cycles, while with SGX counters support approximately 1M cycles, sufficient for most group management needs. For example, if group updates are issued once a week, the NVRAM would last 2000 years using TPMs and 20000 year using SGX counters.

Group setup with attestation. In Section 4.3 we described group setup for pre-defined platforms. The drawback of this approach is that it requires trusted operating systems at initialization. If the application scenario allows group establishment among *any* SGX platforms, similar trust assumption is not needed. The group owner can attest $n+1$ group members using the attestation mode that returns a pseudonym for each attested platform, establish secure channels to all group members, and distribute keys that group members use to authenticate each other. Because each platform reports a different pseudonym, this process guarantees that the protection group consists of $n+1$ separate platforms in contrast to multiple instances on one compromised CPU.

5 Security Analysis

Our system is designed to provide the following security property: an ASE cannot be rolled back to a previous state. In Section 5.1 we first show that given a secure storage functionality, as defined in Section 3, an RE can verify that its state is the latest. After that, in Section 5.2, we show that the participating REs realize the secure counter storage as a distributed system. Finally, by putting these two together, we show that ASEs cannot be rolled back if the RE cannot be rolled back.

Our system achieves a security guarantee that we call

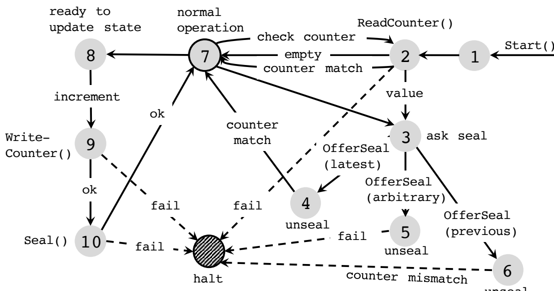

Figure 7: Transition diagram showing enclave *execution states* using an ideal secure counter storage functionality.

all-or-nothing rollback. The only way to violate enclave data integrity is to reset all nodes which brings the entire group to its initial state. In many application scenarios such integrity violation is easy to detect, and we do not consider it an attack on ROTE.

In the event of crashes, restarts or node unavailability, the system may fail to proceed temporarily or permanently. We distinguish three such cases: *Halt-1* where the system may be able to proceed automatically by simply trying again later (e.g., temporary network issue); *Halt-2* where manual intervention from the system administrator is needed (e.g., faulty node that needs to be fixed); and *Halt-X* where the complete system has to be re-initialized and the latest state of enclaves will be lost (e.g., simultaneous crash of all nodes). Recall that as the adversary controls the OS on all nodes, denial of service is always possible.

5.1 Protection with Secure Storage

Given the secure counter storage functionality (see Section 3) rollback can be prevented using the inc-then-store technique. In Figure 7 we illustrate a state transition diagram that represents RE states during sealing, unsealing and memory reading using the secure storage functionality. The notion of state in this section is an *execution state*, in contrast to enclave *data states* created and stored using sealing. We show that any combination of adversary operations, in any of the enclave execution states, cannot force the RE to accept a previous version of sealed data. We also show that in spite of multiple local RE instances, the read enclave state is always the latest. Note that this state transition diagram does not capture system initialization.

First start. After creating and starting the enclave using $e \leftarrow$ `Create(code)` and $i \leftarrow$ `Start(e)`, the RE execution begins from State 1. The MC is set to zero in the runtime memory and RE proceeds to State 2. The RE reads the counter value from the secure storage using `ReadCounter()`. If the `ReadCounter()` operation fails, the RE halts (Halt-1). On the first execution the operation returns *empty* and the RE continues to State 7 to continue normal operation. From State 7 the execution moves to State 2 for verifying freshness if a `Read()` request is received, while the `Write()` request moves execution to State 8.

Sealing. When the RE needs to seal data for local persistent storage, it proceeds to State 8. The RE increments the MC, and performs the `WriteCounter()` operation to the secure storage in State 9. The RE continues to State 10 if the operation succeeds, otherwise it halts (Halt-1). In State 10, the RE seals data ($s \leftarrow$ `Seal(data)`) of its current state along with the counter value. OS confirmation moves the enclave to normal operation in State 7. If sealing fails, the node can try again (Halt-1). If that does not help, the node loses its latest state and becomes unavailable, and a group update is needed (Halt-2).

Unsealing. When the RE needs to unseal data (recover its state), the RE proceeds from State 7 to State 3. The adversary can offer the correct sealed data (`OfferSeal(`$latest \equiv s$`)`) which moves the execution to State 4. Unsealing is successful and the counter value in the seal matches the MC value in the runtime memory, bringing the RE back to State 7. The adversary can offer a previously sealed state (`OfferSeal(`*previous*`)`) which moves the execution to State 6. Unsealing is successful, but counter values do not match and the RE halts (Halt-1 or Halt-2).[5] Finally, the adversary can offer any other data (`OfferSeal(`*arbitrary*`)`) which moves the RE to State 5 where unsealing fails and RE halts (Halt-1 or Halt-2).

Forking. If a new instance of the RE is started, the execution for it moves to State 1 following *First start*. Other instances remain in their original states. If for every `Write()` and `Read()` operation a counter is incremented or respectively retrieved from the secure counter storage to verify freshness, no rollback is possible. When the RE needs to read its runtime state (e.g., to complete a client request), the RE proceeds from State 7 to State 2. The RE reads the MC from the secure counter storage (if this fails, Halt-1) and compares the value to the one residing in its memory. This check is needed to guarantee that another instance of the same enclave does not have a newer state. If comparison succeeds, RE has the latest internal memory state and proceeds back to State 7. If the comparison fails (retrieved MC is higher), the RE moves to State 3 to obtain the latest seal (see above).

Restart. After an RE restart, the execution proceeds to State 2. If the `ReadCounter()` operation returns a non-empty value, the RE proceeds to State 3, otherwise to State 7, from where we follow the same steps as above. If the counter read operation fails, RE enters Halt-1.

If in any of these states the RE is terminated or restarted, its execution continues from State 1. Deleting

[5] If the OS provides an incorrect sealed data, most likely it is faulty an needs to be fixed. From some OS errors it may be possible to recover by simply trying again.

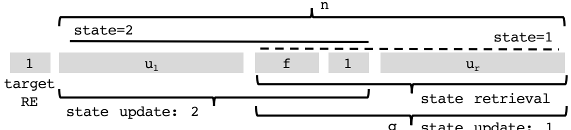

Figure 8: Network partitioning example where the adversary intentionally blocks a part of the nodes.

and creating the same enclave again has the same effect. `Suspend()` and `Resume()` have no effect, i.e., the enclave remains in the same execution state. We conclude that, assuming the secure storage functionality, the adversary cannot rollback the state of the RE.

5.2 Distributed Secure Storage Realization

Next, we show how ROTE realizes the secure counter storage functionality as a distributed system. When obtaining a counter from the distributed protection group (`ReadCounter`), RE receives the latest value that was sent to the protection group (`WriteCounter`). We divide the analysis into four parts: quorum size, platform resets, two-phase counter writing, and forking attacks.

Quorum size. The ROTE system has three parameters: the number of assisting nodes n, compromised nodes f, and unresponsive nodes u. The required quorum for responses at the time of counter writing and reading is $q = f + u + 1 = \frac{n+f+1}{2}$. Figure 8 illustrates that this is an optimal quorum size. We consider an example where the adversary performs network partitioning by blocking messages during writing and reading.

On the first write, the attacker allows the counter value 1 to reach the right side of the group by blocking the messages sent to the left side. On the second write, the adversary allows the counter value 2 to reach the left side of the group by blocking the right side. Finally, on counter read, the adversary blocks the left side again. If the counter is successfully written to $q = f + u + 1$ nodes, there always exists at least $u + 1$ honest platforms in the group that have the latest counter value in the memory. Because counter reading requires the same number of responses, at least one correct counter value is obtained upon reading. The maximum number of tolerated compromised platforms is $f = n - 1$, if $u = 0$ and $q = n$. If the quorum cannot be satisfied in either the state update protocol or any counter retrieval, the system enters Halt-1 and can try to perform the same operation again.

Platform restarts. If an assisting RE is restarted, it needs to first establish session keys and then recover the lost MC values from the protection group. Session key establishment procedure is explained below under *Forking attacks*; the main take-away is that up to u nodes may restart simultaneously and after the nodes are online again the RE needs to establish session keys with *every* node in the group before proceeding with MC recovery.[6] Once the keys are established, some assisting nodes can be inactive or restarted. Three distinct cases are possible. First, the number of inactive/restarted REs is at most u. Since the number of running nodes is $u + f + 1 = q$ there are sufficient available platforms with the correct MC for the counter retrieval. Second, more than u platforms, but not the entire protection group, are restarted. The number of remaining platforms is insufficient for RE recovery and the distributed system no longer provides successful MC access, but no rollback is possible (Halt-X, since there is no guarantee that the non-restarted nodes have the latest counter, thereby risking a rollback. However, before re-initializing the system, the latest states from the non-restarted nodes can be manually saved.) Third, all $n + 1$ nodes are restarted at the same time, in which case a new system configuration has to be deployed again by the group owner to re-initialize the system (Halt-X).

Two-round counter writing. Additionally, it remains to be shown how our update protocol successfully writes the counter to q nodes, despite possible RE restarts *during* the protocol. We illustrate the challenges of counter writing through an example attack on a single-round variant of the update protocol that completes after the RE has received q echoes. During state update the adversary blocks all communication and performs sequential message passing. First, the attacker allows message delivery to only one node that saves the counter and returns an echo. After that, the attacker restarts the RE on that node, which initiates the recovery procedure from the rest of the protection group. The adversary blocks the communication to the target platform, and the restarted RE recovers the previous counter value, because other reachable REs have not yet received the new value. The adversary repeats the same process for all platforms. As a result, the target node has received q echos and accepts the state update, but all the assisting nodes have the previous counter value. Rollback is possible.

The second communication round in our protocol prevents such attacks. No combination of RE restarts during the state update protocol allows the target RE to complete it, unless the counter was written to q nodes. There are four distinct cases to consider. Below, we assume that the adversary restarts at most u platforms simultaneously. If more are restarted, recovery is not possible (Halt-X).

- *Case 1: Echo blocking.* If the attacker blocks communication or restarts assisting REs so that q nodes cannot send the echo, the protocol does not complete (Halt-1).

[6] Consider an example, where two nodes are restarted at the same time. The first node wakes up and attempts to establish new session keys with all assisting nodes. This node has to wait, until the second restarted node wakes up and can communicate. After this point, both of the restarted nodes can establish session keys (with all nodes) and proceed with the RE Restart protocol.

• *Case 2: No echo blocking.* If the attacker allows at least q echoes to pass, RE starts returning them and we have two cases to observe:

• *Case 2a: No restarts during first round.* If none of the assisting REs were restarted during the first protocol round, then at least $u+1$ nodes have the updated MC. If the adversary restarts assisting REs before they sent the final ACK and after they received the self-sent *echo* back from the target RE, the protocol will not complete (Halt-1), because fewer than q final ACKs will be received. The protocol run may be repeated again. The adversary can also restart assisting REs after they have sent the final ACK which will result in successful state update, and successful state recovery of the restarted REs since a sufficient number of the assisting nodes already have the updated counter value.

• *Case 2b: Restarts during first round.* If the adversary restarts assisting REs during the first round, the update protocol will either successfully complete (q final ACKs received) or halt execution (Halt-1) depending on the number of simultaneously restarted nodes. Sequential node restarts, as discussed in the example attack above, are detected. Upon receiving q echoes, the RE sends each of the received echoes to the original sender. Because of sequential RE restarts, all assisting nodes have the previous MC value in their runtime memory, and thus the protocol will fail upon comparison of the echoes and the MC values. None of the assisting REs will deliver the final ACK, and the protocol will not complete (Halt-1).

We conclude that the successful completion of the two-phase state update protocol guarantees that at least q nodes received and at least $u+1$ honest nodes have (i.e., correctly stored) the correct MC.

Forking attacks. Our system prevents attacks based on multiple enclave instances by requiring that the ASE start/read and RE restart protocols contact the assisting nodes and verify the latest counter from the protection group. If the latest counter is correct, RE can be certain that it made the last update. If the session's keys are outdated, communication with other nodes is disabled and RE knows another instance has run in parallel.

The session key refresh mechanism allows us to uniquely identify the latest running instance and prevents parallel communication with two instances running on one platform. After every RE start, keys have to be established *with all nodes* from the protection group to prevent the attacker from instantiating new REs on different platforms in a one-by-one manner while keeping some of the nodes disconnected. Other nodes delete the old session key that they shared with the previous instance residing on the same platform, rendering its communication unusable. The protection group only allows keys for one running instance on each platform. Also, by forcing state retrieval and freshness verification after each instantiation and for all ASE requests, the running instance on each platform will always have the latest state and highest MC, thus preventing rollback.

Our system also ensures that the adversary cannot establish a parallel protection group on the same platforms and re-direct ASEs to the rogue system causing a rollback. If no initialization key is provided and the RE receives all zero MC values from others in the group during setup, it will abort execution. A new network may only be created under the supervision of the group owner with the correct initialization key.

Summary. If the target RE has the latest MC that it sent, it is able to distinguish its latest sealed state, and if the latest sealed state is loaded, all the ASEs state counters kept within are fresh. Upon retrieval, the ASE always receives the latest counter, and thus each ASEs can verify that it has the latest state data. If the target RE is not able to recover the latest MC, the system end ups in either Halt-1, Halt-2 or Halt-X.

6 Performance Evaluation

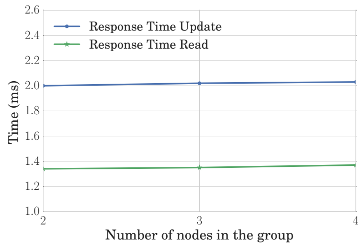
In this section we describe our performance evaluation. First, we describe our implementation that consists of the following components. We implemented the RE (950 LoC), an accompanying *rollback relay* application (1600 LoC), ROTE library (150 LoC), a simple test ASE (100 LoC), and a matching *test relay* application (100 LoC). The purpose of the relays is to mediate enclave-to-enclave communication. We implemented all components in C++, the relays were implemented for the Windows platform. The local communication between the relay applications was implemented using Windows named pipes. The total TCB accounts for 1100 LoC.

The enclaves use asymmetric cryptography for signing (ECDSA) and encryption (256-bit ECC). Our implementation establishes shared keys using authenticated Diffie-Hellman key exchange. For symmetric message encryption and authentication we use 128-bit AES-GCM in encrypt-then-MAC mode. All used cryptographic primitives are provided by the standard Intel SGX libraries.

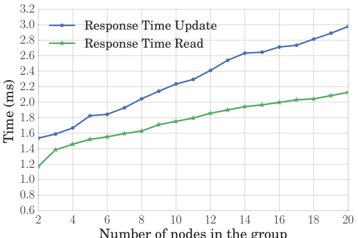
6.1 State Update and Read Delay

The main performance metrics that we measure are the ASE state update and state read delays that include the counter writing to and reading from the protection group. The delays depends on the network characteristics and the size of the protection group ($n+1$). The RE restart operation is typically performed once per platform boot, and thus the operation is not similarly time-critical so we do not measure it. In all test cases we set $u = f = 0$, as their values do not affect state update and read delays.[7]

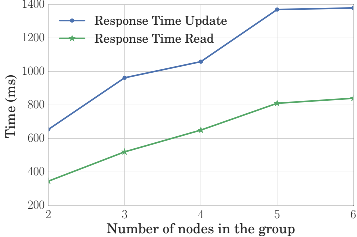
[7]The state update protocol proceeds immediately after receiving q responses, and therefore node unavailability does not affect update de-



(a) 1st exp. setup (ROTE implementation)



(b) 2nd exp. setup (local group, simulated)



(c) 3rd exp. setup (global group, simulated)

Figure 9: Experimental results, state update/read delay. The first figure shows ROTE performance for protection groups that are connected over a local network, the second figure shows the simulated performance for a larger group also over a local network, while the third figure is for geographically distributed protection groups.

Experimental setup. Our first experimental setup consisted of four SGX laptops and our second experimental setup consisted of 20 identical desktop computers, both connected via local network (1Gbps, ping $\leq 1ms$). Our third experimental setup was a geographically distributed (in order, US (West), Europe, Asia, S. America, Australia, US (East)) protection group of sizes from two to six nodes that we tested on Amazon AWS EC2. For the first setup we used the real ROTE implementation while the latter two we used a simulated implementation (the same protocol, but no enclaves).

Results. The state update delay consists of two components: networking and processing overhead. Context switching to enclave execution is fast (few microseconds). Symmetric encryption used in the protocol is also fast (less than a microsecond). The only computationally expensive operation that we use is asymmetric signatures (0.46 ms per signing operation). We provide more performance benchmarks in [20].

The ASE state update protocol has one signature creation which is verified later in the RE and ASE start/read protocols. The required processing time of the state update protocol is less than 0.6 ms, where the creation of the first protocol message takes 0.51 ms (signing). The state read protocol requires one round trip, while the state update protocol needs two. All messages passed between the nodes are 224 bytes (200 payload + 24 header).

Figure 9 shows the results from our three experimental setups. Figure 9a shows that the state update delay was approximately 2 ms, while the state read delay was approximately 1.3 ms for group sizes from two to four nodes using the ROTE implementation. Figure 9b illustrates an increase in the delay as the group size grows. This is as expected, since the target platform needs to communicate with more platforms. For group size of 20 nodes, the delay is 2.98 ms and 2.13 ms, respectively. Lastly, Figure 9c illustrates a less systematic increase in delay, due to the dependency on network connections between various geographic locations in the protection group. The update time between two locations takes 654 ms while between five the update time is 1.37 seconds. The read delay is respectively 342 ms and 810 ms.

We draw two conclusions from these experiments. First, the performance overhead imposed by ROTE is defined largely by the network connections between the nodes. Second, if the nodes are connected over a low-delay network, ROTE supports applications requiring very fast state updates (1-2 ms). For applications tolerating larger delays (e.g., more than 600 ms per state update), ROTE can be run on geographically distant groups.

lay. Similarly, up to f compromised nodes can discard counter values or return fake values, but that does not affect the protocol delay.

Request type	State size (KB)	no rollback protection (ms)	ROTE system (ms)	SGX counter protection (ms)
Write state	1	3.85 (± 0.06)	5.17 (± 0.03)	160.7 (± 0.7)
	10	4.65 (± 0.05)	6.03 (± 0.03)	162.7 (± 1.6)
	100	6.49 (± 0.04)	7.83 (± 0.05)	169.1 (± 2.1)
Read state	1	0.06 (± 0.00)	1.41 (± 0.02)	61.04 (± 3.1)
	10	0.19 (± 0.00)	1.53 (± 0.01)	61.17 (± 3.1)
	100	1.76 (± 0.05)	3.1 (± 0.02)	62.74 (± 3.2)

Table 1: Example application throughput without rollback protection, using ROTE and using SGX counters.

6.2 Example Application Throughput

Additionally, we measured the throughput of an example financial enclave that processes incoming transactions repeatedly (the transaction buffer is never empty). We tested the enclave using (a) no rollback protection, (b) the ROTE implementation, and (c) SGX counter based rollback protection. The experimental setup was a protection group of four nodes. For every update transaction, the enclave updates its state, creates a new seal, and writes it to the disk, while the read transaction includes reading from the disk, unsealing and retrieving the counter for comparison. In case of ROTE and SGX counter variants, the enclave also performs a counter increment. We tested three different enclave state sizes (1 KB, 10 KB, 100 KB) since the state size for transactions can differ based on the exact use case.

Results. Table 1 shows our results. In all three cases the ROTE system provides significantly better state update performance than using SGX counters (e.g., 190 over 6 tx/s for 1KB) while suffering a 20-25% performance drop in comparison to systems which have no rollback protection (e.g., 260 over 190 tx/s for 1KB). We conclude that our system provides significantly faster rollback protection than methods based on local non-volatile memory. Compared to systems with no rollback protection, our solution imposes a moderate overhead.

7 Discussion

Data migration. Although sealing binds encrypted enclave data to a specific processor, our solution enables data migration within the protection group. Migration is especially useful before planned hardware replacements and group updates (e.g., node removal). In a migration operation, an ASE first unseals its persistent data and passes it to the RE. The RE sends the enclave data to another Rollback Enclave within the same protection group together with the measurement of the ASE. The communication channel between the REs is encrypted and authenticated. On the receiving processor, the RE passes the enclave data to an instance of the same ASE (based on attestation using the received measurement) which can seal it. Note that the RE is agnostic to the internal state of ASEs and just re-encrypts data it receives from an ASE without the need to understand its semantics. Combined with group updates (Section 4.7), such enclave data migration enables flexible management of available computing resources. Similar data migration is discussed in [25].

Information leakage. Our model excludes execution side-channels. Here we briefly discuss additional information leakage that our solution may add. Each enclave state update and read causes network communication. An adversary that can observe the network, but does not have access to the local persistent storage, can use the information leakage to determine the timing of sealing and unsealing events. Also the reboot of the target platform causes an observable network pattern. We consider such information leakage a practical concern but developing countermeasures is outside the scope of this paper.

Performance. The main performance characteristic of our solution, the state update delay, is dominated by the networking and the asymmetric signature operation required for the first message of the state update protocol. In case of a local, 1Gpbs, network and an average laptop, the networking takes approximately 1 ms and the signature operation 0.5 ms. A possible optimization is to pre-compute the asymmetric signatures. Since the signed data is predictable MC values, we can pre-compute and store them. This pre-computation may be done at times when the expected load is low or at system initialization depending on the specific scenario.

For communication between the enclaves we use symmetric keys derived from the key agreement protocol for performance reasons, since it is computationally much less expensive. However, depending on the application scenario we could use asymmetric keys which would enable, for example, post-incident forensics. This design choice is dependent on the use case and performance requirements. ROTE can accommodate both approaches.

Consensus applications. In the specific case where all participating enclaves implement a distributed application with the purpose to maintain a consensus (e.g., permissioned blockchain), our rollback protection can be optimized further. In such an application, all participating enclaves have a shared, global state and the state update protocol can be replaced with a suitable Byzantine agreement protocol. When an enclave is restarted (or determines its latest state), it queries its latest state from the participating enclaves similar to our RE restart protocol. We leave a detailed design as future work.

Forking prevention. The current SGX architecture does not provide the ability for one enclave instance to check if another instance of the same enclave is already running. The implementation of this feature would simplify rollback protection significantly.

Forking prevention could be implemented using a TPM. After system boot, the RE instance could extend a PCR that has a known value at boot. If a second RE instance is started, it can check if the PCR value differs from its known initial value [2]. The drawback of this approach is the increase of the system security perimeter outside of the processor.

Periodic check-pointing. For increased robustness, our rollback protection can be complemented with periodic check-pointing. An example approach would be to increment a counter on local NVRAM on selected updates (e.g., mod 100). If all nodes crash at the same time, the administrator has an option to recover from the latest saved checkpoint with the risk of possible rollback.

8 Related work

SGX-counter and TPM solutions. Ariadne [2] uses TPM NVRAM or SGX counters for enclave rollback protection. The counter is incremented using store-then-inc that provides crash resilience, but allows two executions of the latest input. Ariadne minimizes the TPM NVRAM wear using counter increments that flip only a single bit. Compared to our solution, SGX counters are an optional feature, increments are slow and make the non-volatile memory unusable after few days of continuous use. Similar performance limitations apply to TPM NVRAM. SGX counters are also likely vulnerable to bus tapping and flash mirroring attacks [22], while in our solution the trust perimeter is the processor package.

Memoir [4] also leverages TPM NVRAM for rollback protection, and therefore has similar performance limitations. An optimized variant of Memoir assumes the availability of an Uninterrupted Power Supply (UPS). This variant stores the state updates to volatile Platform Configuration Registers (PCRs) and at system shutdown writes the recorded update history to the NVRAM. ICE [3] enhances the CPU with protected volatile memory, a power supply and a capacitor that at system shutdown the flushes the latest state to non-volatile memory. Both the optimized Memoir and ICE require hardware changes. Additionally, reliably flushing data upon a crash or power outage can be challenging in practice.

Client-side detection. Brandenburger [26] proposes client-side rollback detection for SGX in the context of cloud computing. The main difference to our work is that this approach does not prevent a rollback directly on the server. Instead, it allows mutually trusting clients to remain synchronized, and given that certain connectivity requirements are met, detect consistency and integrity violations (including rollback) after the incident.

Integrity servers. Verena [6] maintains authenticated data structures for web applications and stores integrity information on a separate, trusted server. Another use case is to prevent the usage of disabled credentials on mobile devices by storing counters on an integrity-protected server [8]. In such solutions the integrity server becomes a single point of failure.

Byzantine broadcast and agreement. Our state update protocol follows the approach of Echo broadcast [15] with an additional confirmation message in the end. Like other byzantine broadcast primitives, our state update protocol requires $O(n)$ messages. Byzantine agreement typically require $O(n^2)$ messages. Byzantine broadcast and agreement protocol operate on arbitrary values and assume a potentially malicious sender. Thus, such protocols require $3f+1$ replicas. In our system the target enclave is trusted and the distributed data is a signed counter value. Thus, $f+1$ replicas are sufficient.

Secure audit logs. Secure audit log systems [27, 28, 29, 30] provide accountability and in particular prevent manipulation of previous log entries *after* the target platform becomes compromised. Most such audit log systems assume a trusted but infrequently accessible storage. Our goal is to design a system that has no single point of failure, and therefore in ROTE the trusted storage is realized as a distributed system amongst a set of assisting nodes (some of which can be compromised).

Accountability for distributed systems. PeerReview [31] provides accountability for distributed systems and in particular detect nodes that violate from expected behaviour. Instead of fault detection, our goal is to realize distributed secure storage, customized for rollback protection, in the presence of faulty nodes.

Adversary models. Agreement has been considered under models where the faulty nodes have some trusted functionality (e.g., an unmodifiable hardware primitive). Such approaches reduce the number of required replicas to $2f+1$ [32, 33, 34, 35] or $f+1$ [36]. We have no trust assumptions on the compromised nodes. Byzantine agreement has also been considered with dual failure models [37, 38, 39] where the adversary can fully control the faulty processes and can read the secrets of other processes. In our case, the adversary cannot read secrets from trusted enclaves, but it can extract keys from f compromised nodes, and additionally schedule enclaves' execution on all nodes.

Several recently proposed SGX systems [40, 41, 42, 13, 43, 44, 45, 46] consider an adversary model with an untrusted OS. To the best of our knowledge, our work is the first to define a model with explicit adversarial capabilities that cover enclave restarts and multiple instances. These capabilities are critical for the security of our system and also other SGX systems (see the extended version of this paper for details [20]).

9 Conclusion

In this paper we have proposed a new approach for rollback protection on Intel SGX. Our main idea is to implement integrity protection as a distributed system across collaborative enclaves running on separate processors. We consider a powerful adversary that controls the OS on all participating platforms and has even compromised a subset of the assisting processors. We show that our system provides a strong security guarantee that we call *all-or-nothing rollback*. Our experiments demonstrate that distributed rollback protection provides significantly better performance compared to solutions based on local non-volatile memory.

A SGX Background

Here we briefly describe the main protection mechanisms of SGX. For a more elaborate explanation of the architecture, we refer interested readers to [1].

Enclave creation. An enclave is created by the system software. During enclave creation, the system software specifies the enclave code. Security mechanisms in the processors create a data structure called SGX Enclave Control Structure (SECS) that is stored in a protected memory area (see below). Because enclaves are created by the system software running on the OS, their code cannot contain sensitive data. The start of the enclave is recorded by the processor, reflecting the content

of the enclave code as well as the loading procedure (sequence of instructions). The recording of an enclave start is called *measurement* and it can be used for later attestation. Once an enclave is no longer needed, the OS can terminate it and thus erase its memory structure from the protected memory.

Runtime isolation. The SGX security architecture guarantees that enclaves are *isolated* from all software running outside of the enclave, including the OS, other enclaves, and peripherals. By isolation we mean that the control-flow integrity of the enclave is preserved and other software cannot observe its state. The isolation is achieved via protection mechanisms that are enforced by the processor. The code and data of an enclave are stored in a protected memory area called Enclave Page Cache (EPC) that resides in Processor Reserved Memory (PRM) [47]. PRM is a subset of DRAM that cannot be accessed by the OS, applications or direct memory accesses. The PRM protection is based on a series of memory access checks in the processor. Non-enclave software is only allowed to access memory regions outside the PRM range, while enclave code can access both non-PRM memory and the EPC pages owned by the enclave [1].

The untrusted OS can evict EPC pages into the untrusted DRAM and load these back at a later stage. While the evicted EPC pages are stored in the untrusted memory, SGX assures their confidentiality, integrity and freshness via cryptographic protections. The architecture includes the Memory Encryption Engine (MEE) which is a part of the processor uncore (microprocessor function close to but not integrated into the core [1]). The MEE encrypts and authenticates the enclave data that is evicted to the non-protected memory, and ensures enclave data freshness at runtime using counters and a Merkle-tree structure. The root of the tree structure is stored on the processor die. Additionally, the MEE is used to protect SGX's Enclave Page Cache against physical attacks and is connected to the Memory Controller [48, 1].

Attestation. Attestation is the process of verifying that certain enclave code has been properly initialized. In *local attestation* a prover enclave can request a statement that contains measurements of its initialization sequence, enclave code and the issuer key. Another enclave on the same platform can verify this statement using a shared key created by the processor. In *remote attestation* the verifier may reside on another platform. A system service called Quoting Enclave signs the local attestation statement for remote verification. The verifier checks the attestation signature with the help of an online attestation service that is run by Intel. Each verifier must obtain a key from Intel to authenticate to the attestation service. The signing key used by the Quoting Enclave is based on a group signature scheme called EPID (Enhanced Privacy ID) which supports two modes of attestation: fully anonymous and linkable attestation using pseudonyms [49, 1]. The pseudonyms remain invariant across reboot cycles (for the same verifier). Once an enclave has been attested, the verifier can establish a secure channel to it using an authenticated key exchange mechanism.

Sealing. Enclaves can save confidential data across executions. Sealing is the process to encrypt and authenticate enclave data for persistent storage [50]. All local persistent storage (e.g. disk) is controlled by the untrusted OS. For each enclave, the SGX architecture provides a sealing key that is private to the executing platform and the enclave. The sealing key is derived from a Fuse Key (unique to the platform, not known to Intel) and an Identity Key that can be either the Enclave Identity or Signing Identity. The Enclave Identity is a cryptographic hash of the enclave measurement and uniquely identifies the enclave. If data is sealed with Enclave Identity, it is only available to this particular enclave version. The Signing Identity is provided by an authority that signs the enclave prior to its distribution. Data sealed with Signing Identity can be shared among all enclave versions that have been signed with the same Signing Identity.

B SGX Counter Analysis

Intel has recently added support for monotonic counters [5] as an optional SGX feature that an enclave developer may use for rollback attack protection. However, the security and performance properties of this mechanism are not well documented. Furthermore, they are not available on all platforms. In this Appendix we outline all executed experiments and evaluate the SGX counter and trusted time service.

SGX counter service. An enclave can query availability of counters from the Platform Service Enclave (PSE). If supported, the enclave can create up to 256 counters. The default owner policy encompasses that only enclaves with the same signing key may access the counter. Counter creation operation returns an identifier that is a combination of the Counter ID and a nonce to distinguish counters created by different entities. The enclave must store the counter identifier to access it later, as there is no API call to list existing counters. After a successful counter creation, an enclave can increment, read, and delete the counter.

According to the SGX API documentation [5], counter operations involve writing to a non-volatile memory. Repeated write operations can cause the memory to wear out, and thus the counter increment operations may be rate limited. Based on Intel developer forums [51], the counter service is provided by the Management Engine on the Platform Control Hub (PCH).

Experiments. We tested SGX counters on five different platforms: Dell Inspiron 13-7359, Dell Latitude

E5470, Lenovo P50, Intel NUC and Dell Optiplex 7040. The counter service was not available on Intel NUC. On Dell laptops a counter increment operation took approximately 250 ms, while on the Lenovo laptop and Dell Optiplex increment operations took approximately 140 ms and 80 ms, respectively. Strackx et al. [2] report 100 ms for counter updates. Counter read operations took 60-140 ms, depending on the platform. As expected, the counter values remained unchanged across enclave restarts and platform reboots. We tested the wear-out characteristics of the counters and found out that on both Dell laptops, after approximately 1.05 million writes, the tested counter became unusable and other counters on the same platform could not be created, incremented or read (all SGX counter operations return `SGX ERROR BUSY`).

Additionally, we observed that reinstalling the SGX Platform Software (PSW) or removing the BIOS battery deletes all counters. Finally, to our surprise, we noticed that after reinstalling the PSW, first usage of counter service triggered the platform software to connect to a server whose domain is registered to Intel. If Internet connection is not available, the counters are unavailable.

Performance limitations. An enclave developer could attempt to use SGX counters as a rollback protection mechanism. When an enclave needs to persistently store an updated state, it can increment a counter, include the counter value and identifier to the sealed data, and verify integrity of the stored data based on counter value at the time of unsealing. However, such approach may wear out the used non-volatile memory. Assuming a system that updates one of the enclaves on the same platform once every 250 ms, counters would become unusable in few days. Even with a modest update rate of one increment per minute, the counters are exhausted in two years. Services that need to process tens or hundreds of transactions per second are not possible.

Weaker security model. According to Intel developer forums [51], counter service is provided by the Management Engine on the PCH (known as "south bridge" in older architectures). However, to the best of our knowledge, actual location of the non-volatile memory used to store the counters is not publicly stated. Based on Intel specifications [52, 53], the PCH typically does not host non-volatile memory, but it is connected over an SPI bus to a flash memory that is also used by the BIOS. Since Management Engine is an active component, communication between the processor and the Management Engine can be replay protected. However, the SPI flash is a passive component, and therefore any counter stored there is likely to be vulnerable to bus tapping and flash mirroring attacks, as recently demonstrated in the case of mobile devices (inspired by FBI iPhone unlocking debate) [22]. Although the precise storage location of SGX counters remains unknown at the time of writing, it is clear that if the integrity of enclave data relies on the SGX counter feature, then additional hardware components besides the processor must be considered trusted. This is a significant shift from the enclave execution protection model, where the security perimeter is the processor package [48, p. 30].

Other concerns. The current design of SGX counter APIs makes safe programming difficult. To demonstrate this we outline a subtle rollback attack. Assume an enclave that at the beginning of its execution checks for the existence of sealed state, and if one is not provided by the OS, it creates a new state and counter, and stores the state sealed together with the counter value and identifier. The enclave increments the counter after every state update. Later, the OS no longer provides a sealed state to the restarted enclave. The enclave assumes that this is its first execution and creates a new (second) counter and new state. Recall that the SGX APIs do not allow checking existence of previous counter. The enclave updates its state again. Finally, the OS replays a previous sealed state associated with the first counter. A careful developer can detect such attacks by creating and deleting 256 counters (an operation that takes two minutes) to check if a previous counter, and thus sealed state, exists. A crash before counter deletion would render that particular enclave permanently unusable.

We have no good explanation why a connection to an Intel server is needed after the PSW reinstall. Similarly, we do not know why the SGX counters become unavailable after BIOS battery removal or PSW reinstall.

The above attack and availability issues probably could be fixed with better design of SGX APIs and system services, but the performance limitations and the weaker security model are hard to avoid in future versions of the SGX architecture.

SGX trusted time. Another recently introduced and optional SGX feature is the trusted time service [24]. As in the case of SGX counters, also the time service is provided by the Management Engine. The trusted time service allows an enclave developer to query a time stamp that is relative to a reference point. The function returns a nonce in addition to the timestamp, and according to the Intel documentation, the timestamp can be trusted as long as the nonce does not change [24].

We tested the time service and noticed that the provided nonce remained same across platform reboots. Reinstalling PSW resulted in a different nonce, but the provided time was still correct. The reference point is the standard Unix time. As a rollback protection mechanism the trusted time service is of limited use. Including a timestamp to each sealed data version allows an enclave to distinguish which out of two seals is more recent. However, the enclave cannot know if the sealed data provided by the OS is fresh and latest.

A Longitudinal, End-to-End View of the DNSSEC Ecosystem

Abstract

The Domain Name System's Security Extensions (DNSSEC) allow clients and resolvers to verify that DNS responses have not been forged or modified in-flight. DNSSEC uses a public key infrastructure (PKI) to achieve this integrity, without which users can be subject to a wide range of attacks. However, DNSSEC can operate only if each of the principals in its PKI properly performs its management tasks: authoritative name servers must generate and publish their keys and signatures correctly, child zones that support DNSSEC must be correctly signed with their parent's keys, and resolvers must actually validate the chain of signatures.

This paper performs the first large-scale, longitudinal measurement study into how well DNSSEC's PKI is managed. We use data from *all* DNSSEC-enabled subdomains under the `.com`, `.org`, and `.net` TLDs over a period of 21 months to analyze DNSSEC deployment and management by domains; we supplement this with active measurements of more than 59K DNS resolvers worldwide to evaluate resolver-side validation.

Our investigation reveals pervasive mismanagement of the DNSSEC infrastructure. For example, we found that 31% of domains that support DNSSEC fail to publish all relevant records required for validation; 39% of the domains use insufficiently strong key-signing keys; and although 82% of resolvers in our study request DNSSEC records, only 12% of them actually attempt to validate them. These results highlight systemic problems, which motivate improved automation and auditing of DNSSEC management.

1 Introduction

The Domain Name System (DNS) [36] provides a scalable, flexible name resolution service. Unfortunately, DNS has long been fraught with security issues such as DNS spoofing and cache poisoning [3, 28, 46] To address these problems, DNS Security Extensions (DNSSEC) [20] were introduced nearly two decades ago. At its core, DNSSEC is a hierarchical public key infrastructure (PKI) that largely mirrors the DNS hierarchy and is rooted at the root DNS zone. To enable DNSSEC, the owner of a domain signs its DNS records and publishes the signatures along with its public key; this public key is then signed by its parent domain, and so on up to the root DNS zone. A resolver validates a signed DNS record by recursively checking the associated signatures until it reaches the well-known root zone trusted key.

Largely in response to powerful attacks such as the Kaminsky Attack [28], DNSSEC adoption has increased recently. As of early 2017, more than 90% of top-level domains (TLDs) and 47% of country-code TLDs (ccTLDs) are DNSSEC-enabled [26, 47]. Widely-used DNS resolvers now attempt DNSSEC validation by default, e.g., as of January 2012 Comcast (one of the largest ISPs in the US) requests and validates DNSSEC records for all queries [32], and Google (which operates the largest public DNS resolver) did the same in March 2013 [22].[1]

But like any PKI, DNSSEC can only function correctly when all principals—every signatory from root to leaf, and the resolver validating the signatures—fulfill their respective responsibilities. Unfortunately, DNSSEC is complex, creating many opportunities for mismanagement. *On the server side*, a single error such as a weak key, an expired signature, or a broken signature chain can weaken or totally compromise the integrity of a large number of domains. *On the client side*, mismanaged or buggy DNS resolvers can obviate all server-side efforts by simply failing to catch invalid or missing signatures.

Surprisingly little is known about how well the DNSSEC PKI ecosystem is managed. While there have

[1] It is important to note that these resolvers still accept responses without DNSSEC records, as the vast majority of domain administrators have yet to deploy DNSSEC.

been many studies of DNSSEC, we find that no prior efforts had the data to allow them to study the DNSSEC PKI *at scale*—across many domains and resolvers—and *longitudinally*—by monitoring their behavior over time. For example, server-side studies have shown instances of mismanagement, but only for samples of domain names [12–14]. Likewise, prior studies of DNS resolvers have used ad campaigns, which do not permit repeated, controlled measurements of resolvers over time [7, 33, 47]. What has made large-scale, longitudinal studies of DNSSEC so challenging is a dearth of DNSSEC record datasets and a lack of vantage points from which to repeatedly measure resolver behavior.

In this paper, we present a comprehensive study of the entire DNSSEC ecosystem—encompassing signers, authoritative name servers, and validating DNS resolvers—to understand how DNSSEC is (mis)managed today. To study server-side behavior, our work relies on 21 months of daily snapshots, and three months of hourly snapshots, of DNSSEC records for *all* signed `.com`, `.net`, and `.org` second-level domains. To study client-side behavior, we leverage the Luminati HTTP/S proxy service [35], which allows us to perform repeated, controlled tests from 403,355 end hosts—thereby studying 59,513 distinct DNS resolvers—around the world.

Our analysis reveals troubling, persistent mismanagement in the DNSSEC PKI:

- *First*, we find that nearly *one-third* of DNSSEC-enabled domains produce records that *cannot be validated* due to missing or incorrect records. 1.7% of signed domains fail to provide `RRSIG`s for `SOA` records, while 30% of signed domains do not have `DS` records. The vast majority of these missing records are due to large hosting providers that fail to publish the correct records for domains they manage. Additionally, we find that 0.6% of signed domains provide incorrect `RRSIG`s for both `SOA` and `DNSKEY` records.
- *Second*, we identify four large providers that use the same keys to sign all of their managed domains. This unnecessary key reuse makes all of the domains vulnerable to the compromise of a single shared key. For example, we find that a single key is shared by over 132K domains.
- *Third*, we observe widespread use of 1024-bit RSA keys, which are now considered "weak" (smaller than the NIST-recommended minimum size of 2048 bits [1]). 39% of domains use weak Key Signing Keys (KSKs), and over 90% of domains use weak Zone Signing Keys (ZSKs). DNSSEC is designed to be resilient against weak and stolen keys via frequent key rotation, but we find that 70% of domains never rotated their KSK during our 21-month study.
- *Fourth*, we find that although 83% of observed resolvers request DNSSEC records during their queries, only 12% of them actually validate the records (defeating the purpose of DNSSEC). This finding motivates the need to reexamine approaches using query logs from authoritative name servers as a lens to measure DNSSEC adoption by resolvers [21, 23].

In summary, our results paint a distressing picture of widespread mismanagement of keys and DNSSEC records that violate best practices in some cases, and completely defeat the security guarantees of DNSSEC in others. On a more positive note, our findings demonstrate several areas of improvement where management of the DNSSEC PKI can be automated and audited. To this end, we publicly release all of our analysis code and data (where possible[2]) to the research community at

`https://securepki.org`

thereby allowing other researchers and administrators to reproduce and extend our work.

2 Background

We begin by presenting an overview of both DNS and DNSSEC.

DNS and DNSSEC DNS uses *records* to map *domain names* to *values* (e.g., an `A` record maps a domain name to an IPv4 address; an `NS` record maps a domain name to the authoritative name server for a domain). DNS is designed to encourage caching, and every DNS record contains a time-to-live (TTL), specifying how long the records can be cached for. The original DNS protocol did not include security, allowing an adversary to forge DNS responses to carry out attacks. DNS Security Extensions (commonly referred to as DNSSEC) are designed to address this vulnerability [4–6, 19]. DNSSEC provides integrity for DNS records using three primary record types[3]:

`DNSKEY` records, which are public keys used in DNSSEC. Typically, each zone uses two `DNSKEY` records to sign DNS records, as discussed below.

`RRSIG` (Resource Record Signature) records, which are cryptographic signatures of other records. Each `RRSIG` is a signature over all records of a given type for a certain name; this set is called an RRSet.

[2] Our `.com`, `.org`, and `.net` zone files are collected under agreement with the zone operators; while we are not permitted to release this data, we provide links where other researchers can obtain access themselves.

[3] There are other record types for expressing the non-existence of records (`NSEC` and `NSEC3` records) and for a child zone to request an update to their `DS` record (`CDNSKEY` and `CDS` records). As these are not integral to our study, we do not discuss them in detail.

For example, all A records for example.org will be authenticated by a single RRSIG (i.e., the example.org A RRSIG). Each RRSIG is created using the private key that matches a public key in DNSKEY records.

DS (Delegation Signer) records, which are essentially hashes of DNSKEYs. These records are uploaded to the parent zone, which establishes the chain of trust reaching up to the root zone. The DS records in the parent zone are authenticated using RRSIGs, just like any other record type.

Most Internet hosts do not do iterative DNS lookups themselves, but instead are configured to use a local DNS *resolver*. When a host wishes to look up a domain name, it sends a query to its resolver; the resolver then iteratively determines the authoritative name server for that domain and obtains the record. If the resolver supports DNSSEC, it will also fetch all DNSSEC records (DNSKEYs and RRSIGs) necessary to validate the record. Finally, the resolver returns the (validated) record back to the requesting host. It is important to note that resolvers make heavy use of caching, and will typically avoid re-requesting any unexpired records that have already been obtained.

DNSSEC is designed to be backwards-compatible, while enabling resolvers who support DNSSEC to specifically request DNSSEC records. A resolver indicates that it would like DNSSEC records by setting the DO ("DNSSEC OK") bit in its DNS request. If the responding authoritative name server has RRSIGs corresponding to the record type of the request, it is obligated to include them. Should the resolver also need DNSKEYs to validate the record, it may need to request them separately.

DNSSEC keys Unlike other common PKIs (e.g., the SSL/TLS PKI [34]), each zone in DNSSEC typically has *two* public/private key pairs: one called a Key Signing Key (KSK) and another called a Zone Signing Key (ZSK). Typically, the KSK is used only to produce RRSIGs for DNSKEY records (hence the name). In contrast, the ZSK is used to produce the RRSIGs for all other record types.

There is no key revocation (apart from root authorities) in the DNSSEC PKI[4]; rather, to mitigate potential effects of key compromise, ZSKs are intended to be *rolled over* (i.e., replaced) daily or weekly, and the KSKs monthly or yearly (the intention is that the KSK can be stored separately from, and in a safer location than, the ZSK). In fact, RFC 6781, which is the best current practice document for DNSSEC management, recommends rolling

[4]If the current DNSKEYs are suspected of being compromised, a zone administrator can replace existing DNSKEYs by following an emergency key rollover process [30].

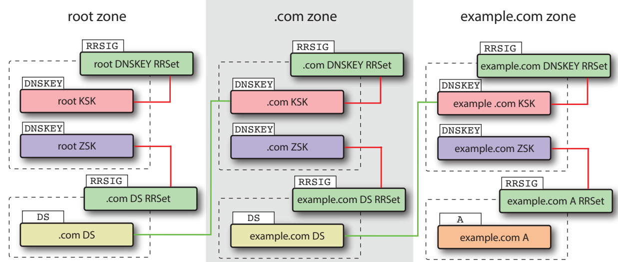

Figure 1: Overview of DNSSEC records necessary to validate example.com's A record. Each RRSIG is the signature of a record set (dashed lines) verified with a DNSKEY (red lines). Each DS record is the hash of a child zone's KSK (green lines).

over KSKs every 12 months and ZSKs even more frequently [30].

Validating a DNSSEC record The DNSSEC PKI is rooted at the KSK of the DNS root zone. This KSK is well-known by DNSSEC-aware resolvers. Validating a DNS response starts at the root and continues down the DNS hierarchy: A resolver begins by using the KSK to validate the root DNSKEY RRSIG, which validates the root zone's ZSK. The resolver can then validate the child zone's DS record (and thereby the child zone's KSK) using the RRSIG for the DS records in the root zone, as this is signed with the root zone's ZSK. This process continues until the record in question is authenticated. Figure 1 shows example records and how they are related.

3 Related Work

In this section, we discuss related studies of the DNSSEC ecosystem, covering both server- (DNSSEC domain) and client-side (DNS resolver) studies.

DNSSEC domain deployment As the DNSSEC deployment has grown, researchers and industrial practitioners have examined the DNSSEC ecosystem. The Internet Society publishes periodic DNSSEC deployment reports [47], the most recent of which found that 89% of generic TLDs (gTLDs) and 47% of country-code TLDs (ccTLDs) are signed. They also report that the major authoritative DNS server software and libraries support DNSSEC. Web-based debugging tools such as the DNSSEC Debugger [15] and DNSViz [18] can help administrators verify correct DNSSEC deployment.

Several studies examined the early deployment of DNSSEC by monitoring the availability, verifiability, and validity of domains [40,41,54]. For example, Deccio et al. [12, 13] studied the misconfiguration of DNSSEC domains by surveying approximately 2,000 domains for five months, finding that 20% of zones where RRSIGs had expired at least once would experience another expi-

ration three or more times. Adrichem et al. [49] analyzed a sample of second-level domains on one day and found that 4% exhibited misconfigurations. Similarly, Dai et al. [14] found that 19.46% of second-level domains from the Alexa Top-1M had an invalid chain of trust from the root.

Our study extends these prior works in three ways. *First*, we examine **all** DNSSEC-enabled domains in three of the largest TLDs, rather than a sample. *Second*, we examine 21 months of DNSSEC behavior, allowing us to investigate temporal trends. *Third*, we examine more types of misconfigurations, including those that require longitudinal data to study (e.g., key rotation behavior).

DNS resolvers Researchers have also studied whether resolvers request and validate DNSSEC records. In general, this is challenging because most resolvers do not allow arbitrary clients to initiate queries. Prior work typically uses one the following techniques to address this limitation:

Passive techniques A number of studies rely on logs from authoritative DNS servers. Guðmundsson et al. [23] measured the deployment of DNSSEC-enabled resolvers using traces of DNS queries made to the `.org` servers. Similarly, Fukuda et al. [21] used snapshots of the `.jp` ccTLD authoritative name server to measure the portion of resolvers requesting `DS` and `DNSKEY` records; they found that 50% of the resolvers requested such records. These studies provide a glimpse into resolvers' DNSSEC queries, but not what they do with the responses. As we show later in this paper, many resolvers do not bother to validate responses.

Active techniques Other approaches issue DNS queries from clients deployed in large numbers of networks, e.g., using dedicated hardware (e.g., RIPE Atlas devices [45]) or software running on web clients (e.g., Java applets [27]). Alternatively, Yi et al. [55] deployed a middlebox that intentionally removed `RRSIGs` from DNS responses to investigate resolver behavior. Unfortunately, these approaches are limited by the coverage of a given deployment platform and user adoption model.

Recent work shows that advertisements embedded in webpages [7, 33, 47] can enable DNS resolver measurements at scale. This approach places ads that cause clients to make HTTP requests to a domain used for testing purposes. Using this methodology, Lian et al. [33] showed that 1% of clients could not resolve DNSSEC-enabled domains at all, while only 3% of clients successfully detected DNSSEC-signed domains with broken signatures. Similarly, APNIC Labs recently reported that the DNSSEC validation rate is increasing, particularly in Africa (16.58%) and Asia (10.17%), due to users' reliance on Google's public DNS service [7].

While the ad-based approach can quickly cover large numbers of resolvers, it gives researchers relatively little control over client selection. This makes it difficult to run multiple experiments using the same client (and their associated resolver) and to understand DNSSEC behavior of resolvers in depth, and makes it difficult to disambiguate lookup failures due to other factors (e.g., loss of connectivity). In Section 5, we address this limitation by using a large-scale platform that enables repeatable measurements of DNSSEC resolvers worldwide.

4 DNSSEC Deployment and Management

We begin our analysis of the DNSSEC PKI by focusing on the deployment and management of DNSSEC records by domains, and how this has changed over time. We perform a longitudinal analysis of nearly 150M domains to answer questions that include: 1) how widely is DNSSEC deployed; 2) when deployed, how often are DNSSEC records correctly published and managed; and 3) how are DNSSEC cryptographic keys managed and maintained, and what is their impact on security? We begin by describing the datasets we use to answer these questions before proceeding with our analysis.

4.1 Datasets

Our goal in this section is to conduct a large-scale, longitudinal, and detailed study of DNSSEC adoption and deployment at authoritative DNS servers. To cover a large number of registered domains, we investigate those listed in zone files for the `.com`, `.net`, and `.org` TLDs. While this does not cover all domains, the approximately 150M domains that we study cover 64% of the Alexa Top-1M and 75% of the Alexa Top-1K websites. To understand how DNSSEC adoption and management changes over time, we use snapshots of DNSSEC records covering nearly two years. Finally, we conduct hourly snapshots of a subset of domains to provide a detailed view of management over shorter timescales.

Taken together, our dataset represents the largest and most comprehensive known set of DNSSEC observations of authoritative DNS servers.

Daily scans Our dataset includes measurements from OpenINTEL [43,52], a project that conducts daily crawls of DNS records for a large number of domains listed in TLD zone files. OpenINTEL first obtains daily snapshots of the `.com`, `.net`, and `.org` TLD zone files, which contain the Name Server (`NS`) and Delegation Signer (`DS`) records for an average of over 147M second-level domains. For each of these, OpenINTEL also collects responses from the authoritative name server for `SOA`, `DNSKEY` records, and the corresponding `RRSIG` records.[5]

[5]This dataset contains only records for domains whose authorita-

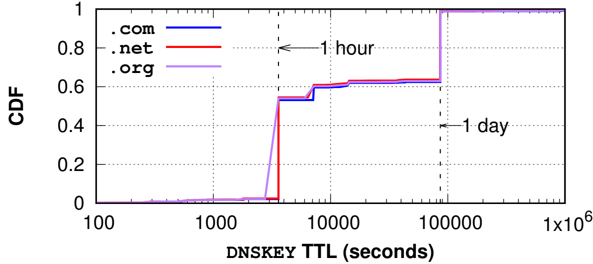

Figure 2: CDF of the TTL of DNSKEY records for .com, .org, and .net second-level domains. Note that 97.9% of TTL values are greater than or equal to one hour and 36.4% of TTL values are greater than or equal to one day (86,400 seconds).

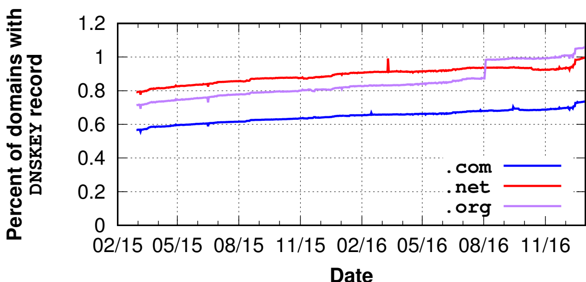

Figure 3: The percentage of all .com, .org, and .net second-level domains that have a DNSKEY record, from the Daily dataset. Between 0.75% and 1.0% of all domains publish a DNSKEY record at the time of writing.

The daily snapshots span 21 months (between March 1st, 2015 and December 31st, 2016); we refer to this as the Daily dataset.

Hourly scans The Daily dataset is sufficient for studying DNSSEC behavior at coarse granularity, but cannot capture dynamics at timescales shorter than one day. For example, consider the case of replacing DNSKEY records. Figure 2 depicts the cumulative distribution of TTL values for DNSKEY records across the entire Daily dataset. The figure shows that more than 63% of records have a TTL of less than one day, meaning the daily scans can potentially miss a large fraction of key replacement operations.

To address this limitation, we collect a second dataset using *hourly* queries, based on the observation that 97% of observed domains have a TTL of one hour or more. For efficiency, we focus only on domains that have a DS record in the TLD zone (i.e., domains that *may* have correctly deployed DNSSEC, as a DS record is a necessary but not sufficient condition for validity). Specifically, once per hour we collected the DNSKEY and corresponding RRSIG records for all second-level domains (an average of 708K domains) in the .com and .org TLDs, between September 29th and December 31st, 2016.[6] We refer to this dataset as the Hourly dataset.

4.2 DNSSEC Prevalence

We begin by examining how support for DNSSEC has evolved over time. Specifically, we focus on the number of second-level domains that publish at least one DNSKEY record according to the Daily dataset. Note that having a DNSKEY record published does not by itself imply that the domain has correctly deployed DNSSEC; there could be other missing records or invalid signatures. We examine the prevalence of *correct* DNSSEC deployment later in the paper.

Figure 3 plots the fraction of .com, .net, and .org second-level domains that publish at least one DNSKEY record. One key observation is that DNSSEC deployment is rare: between 0.6% (.com) and 1.0% (.org) of domains have DNSKEY records published in our latest snapshot. The fraction of domains that have DNSKEYs is, however, steadily growing. For example, for .org, the fraction rose from 0.75% in March 2015 to over 1.0% in December 2016, even though the number of second-level domains in these TLDs is growing as well (e.g., the .com TLD grew from 116M domains to 125M domains during the same time period).

We observe that large portions of the growth in DNSSEC deployment are due to a small number of steep increases in domains with DNSKEY records. Investigating this trend further, we found that these "spikes" were due to actions by a few authoritative name servers. For example, the authoritative server hyp.net enabled DNSSEC for 11,026 domains in the .org TLD between July 21st and August 5th, 2016, which explains the "spike" in the .org line in Figure 3. In addition, starting on December 16th, 2016, a significant number of new domains enabled DNSSEC, all of which used domainnameshop.com as their authoritative name server.

This observation suggests that a small number of authoritative name servers are responsible for most of the growth in DNSSEC deployment. Thus, incentivizing authoritative name server operators to deploy DNSSEC may end up having a large impact on future growth. For example, the .nl and .se ccTLDs incentivize second-level domains to deploy DNSSEC by offering lower registration costs; these second-level domains are tested every day by the registry to ensure they have correct DNSKEYs, RRSIGs, and DS records [37]. Both TLDs show significantly higher levels of DNSSEC deployment than the TLDs we study (47% [39] and 14% [2], respectively).

tive name server responded to a query; on average, the name servers for 9% of domains failed to respond to any queries.

[6]We did not collect hourly scans of .net domains as we did not have access to the hourly snapshots of the .net zone file.

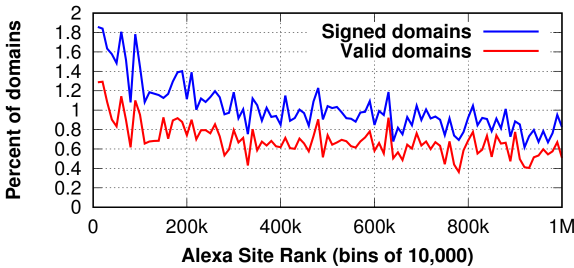

Figure 4: Percentage of domains publishing DNSKEYs as a function of website popularity. Even among the most popular domains, deployment is no more that 1.85% of domains.

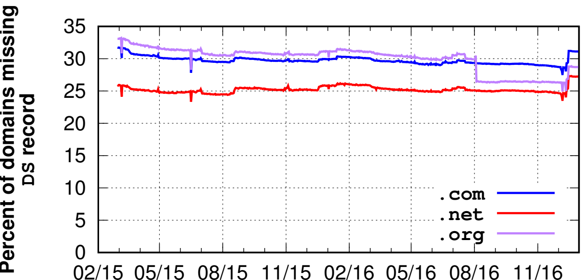

Figure 5: The percentage of signed domains that fail to publish a DS record in the parent zone. Approximately 30% of signed domains fail to do so, meaning they cannot be validated.

Next, we explore whether popular domains are more likely to have deployed DNSSEC. Figure 4 shows the percentage of the Alexa Top-1M domains in .com, .org, and .net that publish DNSKEYs, as of December 31st, 2016. We observe that popular websites are more likely to sign their domains, but the overall deployment remains low even among the most popular domains (e.g., the Top-10K sites have a DNSSEC deployment of only 1.85%).

Figure 4 also shows that not all of these domains have correctly deployed DNSSEC; surprisingly, almost 33% of domains that publish DNSKEYs cannot be validated. Next, we explore why so many domains fail to properly deploy DNSSEC. We focus only on the domains that *attempt* to deploy DNSSEC by publishing a DNSKEY record; consistent with prior work [33, 49], we refer to these domains as *signed domains*.

4.3 Missing Records

We now examine whether domains are publishing all necessary DNSSEC records. For this section, we use the Daily dataset, as the Hourly dataset does not cover domains missing DS records. Recall that properly deploying DNSSEC for a domain means that it must have a DS record in the parent zone, DNSKEY records, and RRSIG records for every published record type. We ask what fraction of signed domains properly publish all such records.

DS records Recall from Section 2 that the Delegation Signer (DS) record, which contains a hash of the domain's KSK, is essential to establish a chain of trust from a parent to a child zone. Unlike other DNSSEC record types, DS records are published in the *parent* zone (e.g., .com), along with the domain's NS records. Thus, correctly installing a DS record is often a manual process, where the administrator contacts its registrar and requests that the registrar add a DS record.[7] Domains that fail to upload a correct DS record are not signed by the parent and therefore cannot be validated, even if they provide correct RRSIGs for all of their records.

We begin by examining the percentage of signed domains that fail to upload a DS record using the Daily dataset (Figure 5). We observe that 28%–32% of signed domains do not have a DS record, meaning they cannot be validated. This observation is in line with previous studies [49, 51]; however, prior work has not explored *why* such a large fraction of domains are missing DS records.

To shed light on why, we focus on domains' authoritative name servers. Specifically, we identify the name servers that are authoritative for the largest number of signed domains from our latest snapshot (December 31st, 2016), and calculate the fraction of their domains that are missing a DS record (a name server can be authoritative for multiple domains if they are managed by the same organization). Table 1 shows the results for the top 15 authoritative name servers, which cover 83% of the

[7] CDNSKEY and CDS can partially reduce the burden of doing manual secure delegation [31] by allowing a domain owner to directly provide the DS record to the registry; unfortunately, we know of no TLDs that currently support CDS or CDNSKEY.

Table 1: Table showing the most popular 15 authoritative name servers, the number of domains with a DS record, and the total number of signed domains for our latest snapshot (December 31st, 2016). The shaded rows represent registrars that fail to publish DS records for nearly all of their domains.

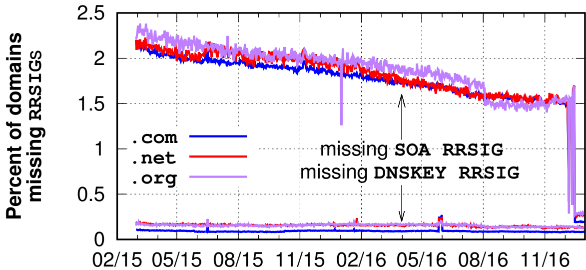

Figure 6: The percentage of signed domains that do not have RRSIGs for SOA and DNSKEY.

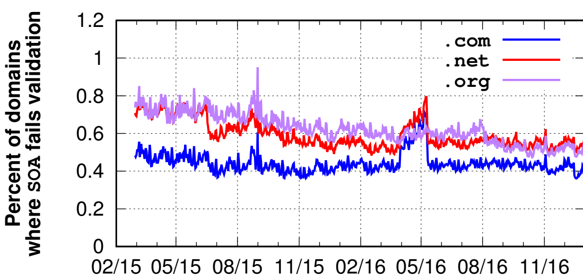

Figure 7: The percent of signed domains for which the RRSIG signatures for the SOA records could not be validated.

signed domains we study. We find a highly skewed distribution, with most of the name servers publishing DS records for almost all signed domains, but with four failing to upload a DS record for nearly all of their domains.[8] For example, Loopia (a Swedish hosting provider) is authoritative for more than 131,000 domains that publish DNSKEYs, but only *one* of these domains actually uploads a DS record, which is invalid.[9] Yet again, large hosting providers and outsourced name servers play a significant role in (im)properly maintaining chains of trust.

Returning to Figure 5, we also observe a few dips and spikes in the fraction of domains missing DS records. For example, the drop in the percentage of .org domains with missing DS records in August 2016 was due to a single registrar (hyp.net) publishing 11,026 new signed domains, all with proper DS records (the same set that was observed in Section 4.2). However, the spike in all three TLDs in December 2016 was caused by one hosting provider, Domain Monster, bulk-signing over 37,000 new domains *without* placing the proper DS records.

RRSIG records We next examine the percentage of signed domains that fail to provide RRSIGs for SOA and DNSKEYs using the Daily dataset. Figure 6 presents these results. We find a surprisingly high fraction of missing SOA RRSIGs (1.7%, on average), and a lower fraction of missing DNSKEY RRSIGs (0.2%, on average). We also observe a decreasing trend of missing SOA RRSIGs, and find sudden drops occur in all three TLDs in December 2016. These were caused by the same hosting provider, Domain Monster, which not only provided DNSKEYs for over 37,000 domains *without* corresponding DS records, *but also did not sign the SOA*, indicating thorough mismanagement. Domain Monster finally started publishing SOA RRSIGs in December 2016.

4.4 Incorrect Records

Despite substantial mismanagement, a large fraction of domains publish all the DNSSEC records required for validation. However, this alone is not sufficient to properly deploy DNSSEC; the signatures (and timestamps) in those records must be correct (and not expired).

RRSIG signatures We begin by examining the correctness and freshness of RRSIGs records for SOA and DNSKEY records, using only domains in the Daily dataset that provide RRSIG records. As all RRSets except DNSKEY records are signed by the same ZSK, we verify SOA records with ZSKs, and DNSKEY records with KSKs. Figure 7 plots the fraction of domains where RRSIG validation for SOA records fails. We find that nearly 99.5% of them are valid. Similarly, we observe that most DNSKEYs are also valid (omitted from the figure for clarity), indicating a common, correct process for generating the records.

Interestingly, the fraction of domains with valid records in Figure 7 fluctuates substantially over the course of days or weeks. To investigate the root causes, we determine the reason for validation failure using a customized dnspython library, and assign them to one

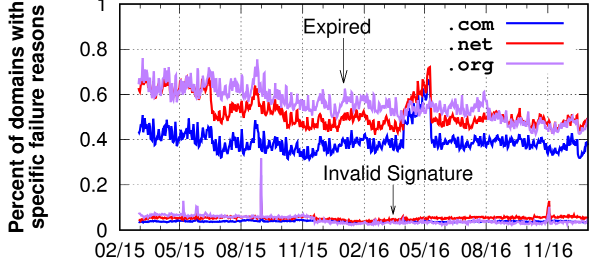

Figure 8: The percent of signed domains with each validation failure type for SOA records.

[8]Interestingly, three of these hosting providers (loopia.se, citynetwork.se, and domainmonster.com) do not even upload a DS record for their *own* (signed) domains.

[9]We contacted all four of these operators to ask the reason behind this behavior. One administrator said "*Most people do not understand DNS, so imagine the white faces when I mention DNSSEC ... I don't think DNSSEC has a high priority anymore currently in our organization or our customer base.*" *[48]*

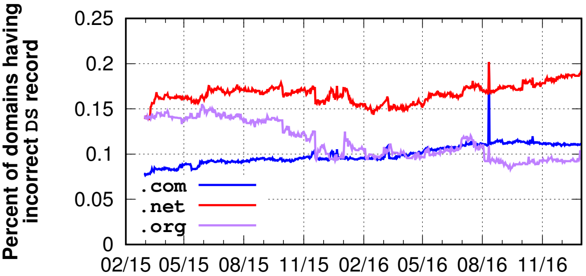

Figure 9: The percent of signed domains having DS records that do not match their KSKs.

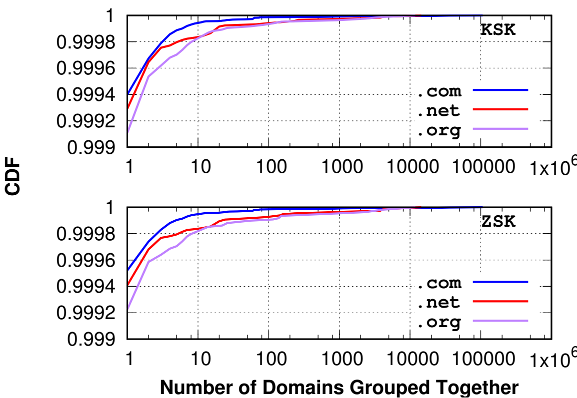

Figure 10: Cumulative distribution of the number of domains grouped by DNSKEYs. The y axis starts at 0.999 and both long tails extend to 106,640 domains (.com).

of three categories: *Expired* RRSIGs (i.e., signatures beyond their expiration date), records with *Signature Invalid* RRSIGs (i.e., signatures that do not match the corresponding DNSKEY), and *Other* reasons (e.g., malformed RRSIGs). We show the fraction of signed domains with the first two failure types for SOA RRSIGs in Figure 8.[10] We find that expired RRSIG records are the primary reason for validation failure. This indicates the need for better automation and auditing of processes for refreshing RRSIG records in DNSSEC.

As one example of this problem, consider the rise in expired signatures in May 2016 for .com and .net. This rise is due to a single registrar: 1,938 .com domains and 254 .net domains, all served by registrar-servers.com, became invalid over this period. This registrar fixed the issue on May 10th, 2016.

Finally, we observe a few intermittent spikes indicated short-lived correlated failures. For example, in September 2015 a total of 1,493 domains with the authoritative name server transip.net published incorrect RRSIGs, a problem that was corrected the following day.

DS records We now examine the correctness of DS records using the Daily dataset. Recall that DS records are basically hashes of KSKs, signed by the parent zone.

Figure 9 shows the results of this analysis. For domains with a DS record, 99.9% of those records are valid (i.e., match the KSK). The spike that occurred in .com and .net in August 2016 was caused by one name server, transip.net, that published incorrect record RRSIGs in September 2016. This name server suddenly changed ZSKs and KSKs for their 381 .com domains and 25 .net domains without switching the DS record, and the problem was corrected the following day.

[10]The results for DNSKEY RRSIGs are similar, and omitted for brevity. Furthermore, less than 0.0006% of domains fail to validate for *Other* reasons, and are similarly omitted.

4.5 Key Management

The previous sections focused on the necessary records for providing valid responses to DNSSEC queries; however, even the best record management practices can result in an insecure system if the cryptographic keys that they rely on are mismanaged. In the next two sections we focus on how administrators manage these keys. In particular, we investigate how often keys are shared across domains (thus increasing the attack surface), how often private keys are weak (e.g., using short keys that can potentially be brute-forced), and whether administrators take the correct steps when rolling over to new keys.

Shared keys In principle, each domain's KSK and ZSK should be unique, as the DS record binds an identity (e.g., a domain) to a KSK, and the ZSK produces RRSIGs for integrity. Otherwise, if the same private key is used for multiple domains, an attacker who steals this key can forge valid DNSSEC records for any of those domains. However, recent work demonstrates that key sharing is common for operational reasons in the SSL/TLS PKI [9]. We thus conducted a study to determine if similar practices occur with DNSSEC keys.

To do so, we extract each domain's DNSKEY record from our latest snapshot (December 31, 2016), and group domains by their KSKs and ZSKs respectively. Figure 10 shows the cumulative distribution of the number of the domains using each ZSK and KSK. We find that 99.95% of keys are used by only one domain. However, this common behavior masks a long tail for key sharing: 384 KSKs (0.04%) and 587 ZSKs (0.05%) are shared by more than one domain, and one KSK and ZSK is shared by over 132,000 domains! Further, we find that ZSK and KSK sharing rates are similar, suggesting that domains sharing ZSKs are highly likely to share KSKs as well.

To understand the key sharing phenomena in more de-

tail, we investigate whether key sharing is mostly explained by a policy from a small set of hosting providers for the affected domains. We first group domains by their authoritative name server, and then group them again by the DNSKEYs in our latest snapshot.

Table 2 shows the most popular 15 authoritative name servers, their total number of domains, and their total number of DNSKEYs. Similar to the previous section, we find highly bimodal behavior, with most name servers having a low prevalence of shared DNSKEYs, but with a few popular name servers using shared DNSKEYs for nearly all of the domains for which they are authoritative. Of course, key sharing may make sense from an operational perspective (easier management) and from a domain ownership perspective (multiple domains owned by the same company). However, key sharing across domains belonging to different companies for efficiency can substantially increase security risks, e.g., when a single shared key is compromised or cracked this affects all domains that share that key.

Weak keys Next, we examine how often weak keys are used in DNSSEC. The National Institute of Standards and Technology (NIST) recommended against the use of 1024-bit keys after December 31, 2013, as rapid advances in computational power and cloud computing make it easier to break 1024-bit keys [1]. Correspondingly, the Certificate Authority/Browser Forum [11] announced that 1024-bit RSA keys should no longer be supported for SSL certificates or code signing [38]. Further, a recent study showed that 66% of DNSKEYs obtained from the Alexa Top-1M domains can be factored due to their short length [56].

While there is no standard minimum key length for DNSSEC, we adopt the NIST recommendations, and thus define *weak* keys as ones meeting any of the following conditions: (1) RSA keys with a length less than or equal to 1024 bits, (2) DSA keys with a length less than or equal to 2048 bits, or (3) elliptic curve keys with a length less than or equal to 160 bits [1].

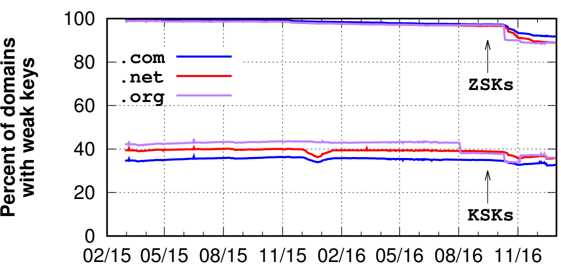

Figure 11: The percentage of domains with weak ZSKs and KSKs. Most keys are weak by NIST standards, even today.

Figure 11 shows the percentage of weak ZSKs and KSKs each day, using the Daily dataset. First, we observe that *the vast majority (91.7%) of ZSKs are weak*, with most being 1024-bit RSA keys. Interestingly, the same trend holds true, but to a lesser extent, for KSKs: over one-third of KSKs are weak keys. Second, there is a small trend towards using stronger keys over time; for example, the fraction of weak ZSK keys began to decline in October 2016. Regardless, the large fraction of weak keys—coupled with the key sharing that we observed in the previous section—further underscores mismanagement of private key material, which can severely weaken security in the DNSSEC PKI.

4.6 Key Rollover

As with any PKI, DNSSEC provides a way for entities to change their public/private key pairs. This process, called key *rollover*, is a recommended best practice in the DNSSEC RFCs [29, 30], and the use of two-key pairs (KSKs and ZSKs) is designed to facilitate frequent rollover.

KSK rollover Rolling over a KSK involves publishing a new DNSKEY and updating the DS in the parent zone.

Unlike many other PKIs, DNSSEC must address issues raised by DNS record caching when considering key rollovers. Recall that all DNS responses contain a TTL field indicating how long a given record can be cached; for efficiency, these TTL values are often on the order of hours to days (see Figure 2). Thus, a domain must carefully manage records during key rollover: if a domain conducts an *Abrupt* rollover (simply publishing a new KSK and DS record), old cached RRSIGs and DS records can cause record validation to fail for clients.

The DNSSEC RFC specifies two schemes by which a domain can roll over their KSK to mitigate this prob-

Scheme	.com	.net	.org
No KSK rollovers	621,213	93,558	65,704
Abrupt	17,724	3,183	1,710
Double Signature	219,547	46,092	32,206

Table 3: Distribution of KSK rollover schemes for all domains for each TLD. We do not observe any KSK rollovers for roughly 70% of domains; for the 320,462 domains where we do see a rollover, we observe that 7.0% conduct rollovers that may cause their domains to fail validation for some clients.

lem: *Double Signature* and *Double DS*. As we do not observe *any* domains using *Double DS*, we focus only on the *Double Signature* scheme. To roll over a KSK using the *Double Signature* scheme, a domain first publishes a new KSK alongside the old KSK, and uses the new KSK to sign additional DNSKEY RRSIGs. At this point, there are *two* KSKs and DNSKEY RRSIGs published. The domain then uploads the new DS record to the parent zone. The domain removes the old DNSKEY and DNSKEY RRSIGs only after the DNSKEY record TTL has expired. By doing so, the domain ensures that all clients will be able to validate the domain, regardless of whether they have cached records.

Table 3 shows the inferred KSK rollover schemes for all domains we measured. We observe that over 70% of domains do *zero* KSK rollovers during our 21 month study period.[11] For those that perform a rollover their KSK, we observe that over 7% of the domains do *Abrupt* rollovers (i.e., simply switching out their keys and DS records without regard for caching effects). These domains may become unavailable during rollover due to failed validation. We also find that between 46% and 50% of the domains that did not rollover their keys have weak keys, underscoring the urgent need for them to quickly perform a rollover their keys to stronger versions.

ZSK rollover We now turn to examine rollovers of ZSKs. Unlike KSK rollovers, a domain need not involve its registrar; the ZSK rollover can be done unilaterally by the domain itself. However, conducting an *Abrupt* rollover can still lead to validation failures, so the DNSSEC RFC defines two schemes for domains to safely roll over their ZSK:

Pre-Publish Under the *Pre-Publish* scheme, a domain publishes a new ZSK DNSKEY, but still uses the old key to sign the RRSIGs (e.g., for A records). After waiting until the TTL of the old DNSKEY expires, the domain then uses the new ZSK to sign the RRSIGs, but continues to publish the old DNSKEY. In this way, cached RRSIGs created with the old key can still be verified. After the maximum TTL of any record in the zone elapses, the old key is no longer published.

[11]These results align with a recent report [53] that showed 55% *of TLDs* had not rolled over their KSKs for 22 months.

Scheme	.com	.org
No ZSK rollovers	279,935	27,166
Abrupt	5,527	66
Double Signature	58,807	9,615
Pre-Publish	259,327	33,518

Table 4: Distribution of ZSK rollover schemes for all domains for each TLD. We do not observe any ZSK rollovers for roughly 45% of domains; for the 366,718 domains where we do see roll over, we observe that 1.5% conduct rollovers that may cause their domains to fail validation for some clients.

Double Signature The *Double Signature* scheme works similarly to the KSK scheme: a new ZSK DNSKEY is introduced, and is used to sign additional RRSIGs immediately. As a result, there are two RRSIGs for each record type: one is signed by the old key, and the other is signed by the new key. After the maximum TTL of any record in the zone, the old key and its RRSIGs are removed.

When detecting the different ZSK rollover schemes, we face a significant challenge: the Daily scans have a resolution of only 24 hours. Thus, we may not observe the rollover behavior of domains that use TTL values of less than 24 hours.[12] Instead, we use the Hourly dataset, which covers nearly all domains (only 2.1% of domains were observed using TTL values smaller than 1 hour).

Table 4 presents the results of our analysis for each TLD. We first observe that both the *Double Signature* and *Pre-Publish* schemes are used, but that the *Pre-Publish* scheme is more popular by a significant margin. However, as with the KSK rollovers, we observe a non-trivial fraction (1.5%) of domains abruptly changing their keys, even though this may lead to validation failures for clients. The lower frequency of *Abrupt* ZSK rollovers may be due to the fact that ZSK rollovers are done entirely by the domain itself, whereas KSK rollovers require coordination with the parent zone.

4.7 Superfluous Signatures

Each DNSKEY RRSIG must be verified by the domain's KSK; but, we find that a large fraction of domains (676,104, or 61% of domains in the December 31, 2016 snapshot) sign their DNSKEY record *twice*: once with the KSK (as expected), and once with the ZSK (which is not used in validation). When focusing only on domains having a corresponding DS record, we find that 644,797 domains (83.6%) exhibit this behavior. While this does not inhibit validation (assuming a valid KSK signature), it does increase the size of DNSKEY packets significantly. When using strong keys (e.g., 2048-bit RSA), this behavior can lead to avoidable DNSKEY packet fragmentation, which not only makes domain resolution inefficient [50],

[12]This was not a problem for detecting KSK rollover schemes, as all TLDs we study use TTL values of at least one day.

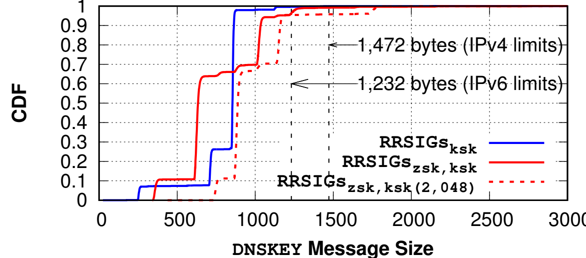

Figure 12: DNSKEY message size for all domains with a DS record. Packets are fragmented when the message size exceeds 1,472 and 1,232 bytes for IPv4 and IPv6, respectively (assuming an MTU of 1,500 bytes).

but also makes DNSSEC vulnerable to poisoning attacks when resolvers do not validate responses [24]. As we show in the next section, the vast majority of the resolvers we studied request DNSSEC records but do not validate such responses.

Fragmentation does not impact a majority of domains today as the main reason is that relatively short (1024-bit RSA) keys are used. Ironically, if operators were to improve the security by using longer keys, substantial numbers of domains may become vulnerable to poisoning. Figure 12 shows the cumulative distribution of estimated DNSKEY packet size per domain when using 1024-bit and 2048-bit keys, and when using only KSK signatures or using both KSK and the unnecessary ZSK signatures in the DNSKEY record.

The figure shows that records today rarely incur IPv4 fragmentation; only 403 (0.01%) of the domains that sign their DNSKEY with just the KSK, and 5,568 (0.8%) of the domains that use both the KSK and ZSK cause fragmentation. Of these latter domains, 3,380 (60.7%) could have avoided fragmentation by using only a KSK signature in the DNSKEY record. Increasing the key size to 2048 bits does not substantially increase fragmentation for those that use only KSK signatures (only 10 additional domains are affected); however, for those that use superfluous signatures, 30,914 (4.6%) of their responses will be fragmented—more than five times as many cases as today.

This behavior is likely due to misconfigured DNS software. For example BIND [17] and Windows Server 2012 [16] both generate DNSKEY RRSIGs using both the KSK and ZSK by default. PowerDNS [44], and OpenDNSSEC [42] correctly generate DNSKEY RRSIGs only with the KSK.

4.8 Summary

We found that DNSSEC deployment is rare but increasing, and nearly a third of DNSSEC-enabled domains are misconfigured in ways that defeat security by providing records that cannot be validated. The latter is primarily caused by a small number of popular hosting providers and registrars that fail to provide DS records, use expired RRSIGs, etc. We also found that almost all ZSKs and one-third of KSKs are weak by NIST standards, that a few hosting providers use the same DNSKEYs for almost all of the domains for which they are authoritative, and many domains exhibit poor rollover hygiene. These issues undermine the security of DNSSEC regardless of resolver behavior, and highlight the need for improved auditing and automation in DNSSEC management.

5 DNS Resolver Support

Even if domains properly manage their DNSSEC records, a client is not protected unless its resolver requests and validates them properly. We now examine the DNSSEC behavior of resolvers.

5.1 Data Collection Methodology

A challenge when studying the behavior of resolvers is that most will respond only to local clients (i.e., they are not open resolvers). To address this limitation, we use the Luminati proxy network [10] to issue DNS requests.

Hola Unblocker [25] is a system that allows users to route traffic via a large number of proxies, often to evade geofencing of content. The Hola software is available on multiple platforms (e.g., as a stand-alone application on Windows, as cross-platform web browser extensions, and on Android) and has been installed more than 91 million times. *Luminati* [35] is a paid HTTP/S proxy service that enables clients to route traffic via Hola users' machines.

To route HTTP/S traffic via Luminati, a client first connects to a Luminati server (called the *super proxy*). The super proxy then checks that the destination domain is valid (via Google's DNS service), and then forwards the request to a Hola client (called the *exit node*). The exit node then makes a DNS request for the destination domain, makes the HTTP/S request, and returns the response back via the super proxy. The super proxy annotates the response with a unique identifier for the exit node that made the request, called the *zID*. An overview is shown in Figure 13; more details about using Luminati for network measurement experiments are provided by Chung et al. [10].

Luminati allows clients to choose the exit node that will forward traffic via two mechanisms. *First*, the client is allowed to select the country where the exit node is located. *Second*, the client can repeatedly send requests via the same exit node by specifying a *session number*; Luminati will continue to use the same exit node as long

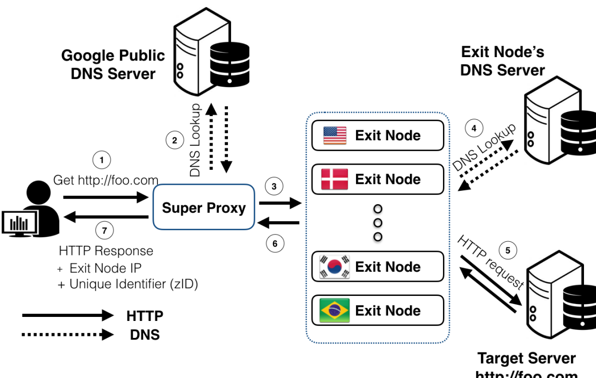

Figure 13: Timeline of a request in Luminati: the client connects to the super proxy and makes a request ①; the super proxy makes a DNS request ② and forwards the request to the exit node ③; the exit node makes a DNS request ④, then requests the HTTP content ⑤. The response is then returned to the super proxy ⑥, then to the client ⑦.

as the node remains alive and no errors are encountered. This functionality allows us to conduct multiple experiments using the same exit node.

Ethics To conduct these experiments, we paid the operators of Luminati for access, and we abided by their terms of service. The owners of exit nodes agreed to route Luminati traffic through their hosts in exchange for free service.[13] Users can opt out by subscribing to Hola (for a fee) or uninstalling the software. We took great care to make sure that our experiments would not harm users, by sending only a small amount of traffic and by not visiting any potentially sensitive domains. For the latter, we mitigated any potential harm to operators of exit nodes by generating traffic only toward domains that we own, which are hosted in our university testbed and serve empty web pages.

5.2 Experimental Setup

Our broad goal in this section is to understand the DNSSEC behavior of resolvers. For these experiments, we built an authoritative DNS server and web server for a testbed domain under our control. Our testbed domain (a second-level domain) fully supports DNSSEC functionality with a chain of trust by uploading its `DS` record to the `.com` zone.

Domain configuration One of our goals is to examine whether DNSSEC resolvers properly validate DNSSEC records. To do so, we configured our DNS server with 10 different subdomains, each of which simulates a different kind of DNSSEC misconfiguration, along with a single *valid* zone. These misconfigurations include missing, incorrect, and expired `RRSIG`s, missing `DNSKEY`s, incorrect `DS` records, *etc*.

For each exit node we test, we generate a unique identifier for that node's DNS requests (e.g., `http://`id_1`.invalid-rr-sig.example.com`). This approach allows us to easily map incoming DNS and HTTP requests to specific exit nodes, and to avoid any potential caching issues at intermediate resolvers. To implement this, we created a custom DNS server that generated `DNSKEY`s, `DS` records, and `RRSIG`s on-the-fly.

Experimental configuration At first glance, measuring whether a resolver supports DNSSEC seems trivial. We configure our server to respond to queries with misconfigured DNSSEC `RRSIG`s, which should be dropped by validating resolvers. If the exit node successfully retrieves the web page, then we know that the exit node's resolver did not provide DNSSEC security.

In practice, implementing this experiment correctly is not so simple. First, Luminati's super proxy checks that the requested domain name is valid using a Google resolver (which does DNSSEC validation) *before* forwarding the request to the exit node. Thus, a simple request for a misconfigured record would be rejected by the super proxy and not forwarded to an exit node. Second, if an exit node's resolver correctly rejects a misconfigured DNSSEC response, it will respond to the exit node with a `SERVFAIL` message. In this case, the super proxy will return an error message to our measurement client and invalidate our session identifier (i.e., we can no longer send requests via that exit node using the identifier). Third, a request may fail for reasons other than DNSSEC validation (e.g., due to network failure at the exit node), so we must develop techniques to disambiguate such cases.

We address these issues as follows:

1. We configure our DNS server to always return a valid response if the request comes from Google's DNS service, to ensure that the super proxy forwards the request to the exit node.[14]
2. Each exit node first fetches a *valid* record for a name with a unique identifier. We record the identifier, the *zID* in the super proxy's response, the IP address of the exit node's resolver (from the incoming DNS request), and the IP address of the exit node (from the incoming web request).
3. If the incoming DNS request from the exit node's resolver does not set the `DO` bit, the resolver does not support DNSSEC and we continue to test a different exit node.
4. Otherwise, we iteratively request each of our 9 misconfigured records from the same exit node. If we

[13] `https://hola.org/legal/sla`

[14] Note that we test Google's DNS resolver, as well as other open resolvers, outside of Luminati.

Country	Hosting ISP	DNS Resolvers	Exit Nodes

Table 5: The top 15 ISPs in terms of the number of DNS resolvers that do not validate our DNSSEC response. Level 3 (shaded) has 522 resolvers that do not validate the DNSSEC response, while six do (not shown).

receive a response from the super proxy with the same *zID*, the exit node's resolver did not validate the DNSSEC record.

5. If the measurement client receives an error (or a response from the super proxy with a different *zID*), it means that the exit node's resolver *may* successfully validate DNSSEC responses (but the error could have been for other reasons). To rule out transient failures unrelated to DNSSEC validation, we repeatedly test each resolver (by finding more exit nodes that use it), and only consider those we test at least 10 times.

During our experiments, we sometimes observed multiple DNS requests (and even multiple HTTP requests) arriving at our servers for the same unique identifier, sometimes hours after we had concluded our experiment. This behavior is likely due to malware, spyware, or intrusion detection systems [10]. To prevent these from biasing our results, we only consider the DNS request that comes before the first HTTP request that arrives at our web servers.

5.3 Results

We use this methodology to measure a total of 403,355 exit nodes—from 177 countries and 8,842 ASes—over a period of 13 days in early 2017. These exit nodes use a total of 59,513 unique resolvers. We observe that 49,424 of the resolvers (83.0% of resolvers, covering 65.9% of the exit nodes) send requests with the `DO` bit set, suggesting that a majority of resolvers support DNSSEC.

Next, we study whether these resolvers actually *validate* the DNSSEC responses they receive. To do so, we need to filter the data to (a) focus only on exit nodes that are configured with a single resolver (exit nodes that use multiple resolvers make it difficult to identify how the different resolvers behave) and (b) only consider resolvers that we were able to measure 10 times or more.

After filtering, we arrive at 4,427 resolvers whose DNSSEC validation policies we can test. We refer to this set of resolvers that request DNSSEC records as *DNSSEC-aware resolvers*. We classify these resolvers into ones that incorrectly validate DNSSEC records (i.e., more than 90% of the exit nodes received a response when the resolver is given an incorrect `RRSIG`), ones that correctly validate DNSSEC records (i.e., more than 90% of the exit nodes received an error), and ones whose policies are ambiguous (all other cases).

Incorrectly validating resolvers We found that 3,635 resolvers (82.1% of the DNSSEC-aware resolvers) from 146 ASes fail to validate the DNSSEC responses, even though they issue the DNS requests with the `DO` bit set;[15] these resolvers cover 149,373 (78.0%) of the exit nodes covered by DNSSEC-aware resolvers. These resolvers all pay the overhead for DNSSEC responses, but do not bother to validate the results they receive.

Table 5 shows the top 15 ASes whose resolvers do not validate DNSSEC responses. Interestingly, we found that even though six resolvers from Level 3 *do* validate DNSSEC responses, another 522 *do not*, indicating that DNSSEC validation can be different between resolvers in the same AS. Most likely, this variance is due to third-party DNS resolvers that are hosted in the Level 3's network, as we are only classifying resolvers by the AS they lie in.[16]

Correctly validating resolvers Only 543 resolvers (12.2% of the DNSSEC-aware resolvers) from 196 ASes correctly validate DNSSEC responses; these resolvers cover 31,811 (16.6%) of the exit nodes covered by DNSSEC-aware resolvers. We found surprisingly few large ASes that validate DNSSEC responses; the largest ones include Comcast (US), Orange (Poland), Bahnhof Internet AB (Sweden), Free SAS (France), and Earthlink (Iraq). Interestingly, we found that all validating resolvers successfully validate all scenarios; we did not find any resolvers that failed some of our misconfiguration tests but passed others. This is in contrast to client behavior for other PKIs, such as the web [34], where browsers pass different subsets of validation tests.

Validation efficiency A concern for DNSSEC is the overhead it places on resolvers, both to fetch DNSSEC

[15] We further verified this behavior by looking for requests for `DNSKEY` and `DS` records that are necessary for validation; in all cases, we did not observe any lookups for these records.

[16] For example, we found similar cases of inconsistent validation in ARNES (Slovenia), Rostelecom (Russia), KDDI (Japan), Stofa (Denmark), Sprint (U.S.), and `hd.net.nz` (New Zealand) as well. Personal communication with the ARNES operators indicated that resolvers with different behavior are managed by different entities (ARNES and Univ. of Ljubljana) [8].

Table 6: Public DNS services that we tested for DNSSEC validation. Five services (shaded) do not validate DNSSEC responses even though they request the DNSSEC records.

records and to validate signatures. For instance, if an RRSIG is invalid due to expiration then a resolver can save time and traffic by withholding requests for the corresponding DNSKEY or DS record. By investigating DNSKEY and DS requests arriving at our DNS server, we found that all but four ISPs (Comcast, Orange Polska, O2 Czech Republic, and The Communication Authority of Thailand) make these unnecessary requests when the RRSIG for A is missing.

5.4 Open Resolvers

We investigate the DNSSEC validation behavior for public DNS resolvers using clients outside of Luminati. Table 6 shows 15 public resolvers and their DNSSEC policies. We found five do not request DNSSEC records at all (DO bit not set), and that half of the resolvers that do request DNSSEC records fail to validate the responses. Strangely, when we send a DNS request to *GreenTeamDNS*, our DNS server observes two queries from different resolver IPs: one from GreenTeamDNS without the DO bit, and the other Google with the DO bit (suggesting that they outsource lookups to Google). However, even though Google is known to return a SERVFAIL for the domains with invalid DNSSEC records, the request ultimately succeeds and we (incorrectly) receive a response.

6 Conclusion

This paper presents a longitudinal, end-to-end study of DNSSEC ecosystem—encompassing more than 147M second-level domains and 59K DNS resolvers—to understand the security implications of how DNSSEC is managed. We found that DNSSEC deployment by domain owners is rare but growing, and that nearly one third of all DNSSEC-supporting domains publish records in ways that prevent validation and thus provides no practical security. Further, we found widespread use of weak, shared keys combined with poor rollover hygiene (mostly due to a small number of hosting providers), undermining the protection DNSSEC provides against stolen or factored keys. We used Luminati to measure resolver behavior in 8.8K ASes in 177 countries, and found that while DNSSEC-aware resolvers are common (83%), only 12% of them actually validate responses to provide any practical security benefits. In summary, our study paints a bleak picture of the security provided by the DNSSEC ecosystem, one that has not improved substantially over time. Our findings highlight the need for continuous auditing of DNSSEC deployments and automated processes for correctly and securely managing DNSSEC material.

Abstract

HTTPS ensures that the Web has a base level of privacy and integrity. Security engineers, researchers, and browser vendors have long worked to spread HTTPS to as much of the Web as possible via outreach efforts, developer tools, and browser changes. How much progress have we made toward this goal of widespread HTTPS adoption? We gather metrics to benchmark the status and progress of HTTPS adoption on the Web in 2017. To evaluate HTTPS adoption from a user perspective, we collect large-scale, aggregate user metrics from two major browsers (Google Chrome and Mozilla Firefox). To measure HTTPS adoption from a Web developer perspective, we survey server support for HTTPS among top and long-tail websites. We draw on these metrics to gain insight into the current state of the HTTPS ecosystem.

1 Introduction

For most of the Internet's history, HTTP Web traffic traveled unencrypted between clients and servers. After widespread tampering and surveillance in transit came to public attention (e.g., [20, 26, 28]), cross-industry efforts arose to promote the use of HTTP over TLS (HTTPS). In response, many large websites transitioned to serve HTTPS by default (e.g., [25, 33, 34]).

How much of the web is currently HTTPS, and are adoption rates trending positively? We want to understand the growth of HTTPS for two reasons:

- Security engineers and researchers have put significant effort into projects like Let's Encrypt,[1] The HTTPS-Only Standard,[2] and search ranking changes [7] to promote HTTPS. HTTPS adoption metrics allow us to see whether these combined efforts have succeeded at shifting the Web at large. Is there more work to do (and if so, where)?

- To protect users, browsers now require HTTPS for certain Web features and UI treatments (e.g., [1, 24, 32, 3]). They plan to make further changes as HTTPS becomes the default standard [30, 3]. How close is the Web to considering HTTPS a default?

In this paper, we measure HTTPS adoption rates from the perspectives of both clients and servers. A key challenge is that there are many ways to measure client usage and server support of HTTPS, each yielding different findings on the prevalence of HTTPS. For example, HTTPS is a much higher fraction of browser page loads if the metrics count certain types of in-page navigations. We address this challenge by examining HTTPS adoption from several angles, surveying a broad set of HTTPS adoption metrics and discussing the considerations of each. This yields a holistic picture of HTTPS adoption.

To understand the user experience of HTTPS, we measured the browsing habits of Chrome and Firefox clients at scale using several browser telemetry metrics. However, browser statistics are weighted towards the larger websites that make up a greater proportion of traffic, and a healthy Web ecosystem also encourages the participation of small- and medium-sized Web developers. We therefore also scanned large sets of servers to see whether they support HTTPS by default, not by default, or not at all. We use publicly available Web scanners and their data sets alongside our own tools and data. Finally, we examined publicly-available data on network traffic volumes at one Internet backbone provider to get a sense of how much web traffic is HTTPS in aggregate.

We find that HTTPS adoption grew substantially over the last few years. A majority of browsing is now done over HTTPS on desktop, having increased by more than ten points in 2016 alone. The number of top websites serving HTTPS by default doubled between early 2016 and early 2017. However, significant work still remains as of February 2017. Half of top websites are still HTTP by default, and most servers in the long tail don't support HTTPS at all. Mobile Web browsing lags behind desktop, and East Asian countries have substantially lower HTTPS usage rates than the rest of the world.

Contributions. We contribute the following:

- We present a holistic view of HTTPS adoption by examining data from many vantage points. We collected large-scale client data from two major browsers, curated and scanned lists of websites, and surveyed other publicly available data sets.
- We evaluate how HTTPS adoption has grown over time, from both client and server perspectives.
- We investigate factors that influence HTTPS adoption rates, including website popularity (top websites vs the long tail), the client's country, and the client's operating system.
- We identify areas where outreach and investigation could have high impact on the HTTPS ecosystem.
- We show that a single metric does not capture HTTPS adoption, discuss why, and provide guidance on when to use different metrics.

2 Background

2.1 What is HTTPS?

> *"...the Web's trustworthiness has become critical to its success. If a person cannot trust that they are communicating with the party they intend, they can't use the Web to shop safely; if they cannot be assured that Web-delivered news isn't modified in transit, they won't trust it as much." [30]*

HTTPS [31] is the secure variant of the HTTP protocol [18] on which the Web is based. HTTPS provides cryptographic security protections by carrying HTTP messages over the Transport Layer Security protocol instead of directly over TCP [9]. Websites are authenticated using digital certificates [8]. In the Web context, browsers also enforce additional policies for HTTPS pages, for example ensuring that HTTPS pages cannot load scripts from non-secure sources [37].

Together, these mechanisms protect Web traffic from network attackers in a few ways:

- **Confidentiality:** Communications between the browser and the web server are not accessible in plaintext to intermediate entities.
- **Integrity:** Intermediate entities cannot make modifications to content sent between the browser and the web server.
- **Server authentication:** The client is assured that the other end of the channel is the one that it intends to communicate with.

Data that are not protected by TLS are also not protected by HTTPS. For example, a network attacker may observe the lengths of TLS records (from which certain features can be inferred [36][22]), or the server name sent in the TLS Server Name Indication extension [13].

HTTPS is focused on protection against network attackers, and does not provide protections against other classes of attacker. For example, it is still possible for a web-level attacker to launch Cross Site Scripting (XSS) attacks against HTTPS websites; to protect against these attacks, a website would need to deploy mechanisms such as Content Security Policy [35]. These mechanisms, however, are dependent on HTTPS to be robust against attacks at the network layer.

Web servers can support HTTPS, HTTP (without TLS), or both. Typically, clients reach web servers over HTTPS by using URLs beginning with the `https:` scheme. We say that a site supports HTTPS "by default" when requests to URLs with the non-secure `http:` scheme are redirected to `https:` URLs. This can be done, for example, with the HTTP 301 status code or HTTP Strict Transport Security [19].

2.2 HTTPS promotion efforts

The security community has invested significant effort into evangelizing, supporting, and requiring HTTPS adoption. A few examples of related projects are:

- Let's Encrypt, "a free, automated, and open Certificate Authority," aims to make certificate provisioning easier for Web developers.[1] As of January 2017, Let's Encrypt supported more than 20,000,000 active certificates [4].
- Google search ranking uses HTTPS support as "a very lightweight signal" [7]. In theory, this encourages ranking-conscious websites to adopt HTTPS.
- In early 2017, Mozilla Firefox and Google Chrome began warning users against entering passwords and credit cards on HTTP websites [3, 32].
- Qualys SSL Labs built an online testing tool that "performs a deep analysis of the configuration of any SSL web server on the public Internet."[3] It is widely used to test TLS configurations.
- Google Chrome added a new Security Panel to help developers debug issues with HTTPS [2].
- Technologists within the United States federal government are moving government websites to HTTPS en masse. The White House Office of Management and Budget issued a memorandum requiring HTTPS for federal websites.[2]

- Google's Transparency Report tracks HTTPS adoption across Google products and popular non-Google websites. Their goal "is to hold ourselves accountable and encourage others to encrypt" [17].

2.3 Related work

Network-based measurements. Several studies have addressed the usage and quality of TLS and HTTPS from the perspective of the network, both by way of scans of the IPv4 address space [12, 27] or by analyzing traffic captured from network links [21, 29]. These projects measure HTTPS adoption at a very broad scale. (For example, they don't distinguish between top-level page loads and subresource requests.) This paper combines browser telemetry, scans, and network-based measurements to form a more holistic view of HTTPS usage.

Alexa Million scans. Durumeric et al. [11] scanned the Alexa Top Million repeatedly from 2012 to 2013, observing a 23% increase in the number of Alexa Top Million websites serving certificates during this time period. We continue this line of work (now updated for 2017) and complement it with additional metrics.

HTTPS errors. Webmasters often misconfigure HTTPS on their websites, either intentionally or accidentally. Several large-scale measurement studies have examined this issue. Akhawe et al. measured the frequency of HTTPS errors from a network perspective, finding that 1.54% of 3.9 billion TLS connections resulted in errors [5]. Follow-up measurement studies looked at the causes of the errors [14] and users' reactions to them [6, 15]. Our work focuses on the broader question of how often HTTPS is used at all.

Blog posts. We previously shared some of our metrics in public blog posts[4] and the Google Transparency Report. This paper gathers the metrics into a single place and adjusts them to be as comparable as possible. This paper also provides an in-depth discussion of our methods and implications of the metrics, which were lacking from the high-level blog posts.

3 Client usage of HTTPS

We aim to measure how much Web browsing happens over HTTPS on end-user devices. To this end, we use browser telemetry in Mozilla Firefox and Google Chrome to measure client usage of HTTPS at scale.

3.1 Browser telemetry background

Google Chrome and Mozilla Firefox have similar user metrics programs, referred to as *telemetry*. We use telemetry to study HTTPS usage statistics over a significant portion of the overall browser user base.

Types of data. Browser telemetry collects metrics in the form of enums, times, and booleans. The metrics are tagged by the client's operating system, client's country, and an opaque identifier for the client. One intentional limitation is that they do **not** include user characteristics like age, gender, or occupation to protect user privacy.

Computation. All of our HTTP(S) telemetry metrics are computed wholly on the client side. When pages are opened or closed, we record the HTTP(S)-related event by incrementing the appropriate histogram or time variable. Thus, we only transmit histograms and floating-point numbers to the server.

Optional participation. Telemetry is optional, with controls available in browser settings. The release version of Firefox is opt-in, with 0.7% of release users opted in. Chrome telemetry is opt-out (it was opt-in prior to Chrome 54). A much larger fraction of users participate in Chrome's telemetry program, amounting to billions of page load events in our Chrome data set. Pre-release versions of both browsers are opt-out.

Non-identifiable. Telemetry metrics are meant to be consumed at scale. Our metrics do **not** include any personally identifiable fields or browsing history.

Browser channel. Most people run the release (i.e., "stable") channel version of their browser. A small number of people use pre-release versions in order to see new browser features early and/or provide feedback to browser vendors. We report telemetry data only from the browsers' release channels because it has more external validity thanks to its "typical" users.

3.2 Metric definitions

We examine four metrics: two page load metrics, one time-based metric, and one transaction-based metric. When designing the metrics, we faced the challenge of flattening a qualitative user experience (browsing) into a quantitative metric (percentage of an event).

3.2.1 Page load metrics

Browser vendors often measure feature usage by page load – "what percentage of page loads use feature X?" – to estimate how often users encounter a feature. We

accordingly measured HTTPS usage by page load, using two page load-based metrics.

Our primary metric is the **strict page load metric**. Every time a top-level page finishes loading, we record the protocol in a histogram.[5] We restrict the metric to page navigations to successful website page loads by excluding non-HTTP(S) protocols like `chrome://`, browser error pages, the New Tab Page, History API navigations, and fragment navigations.

The metric is implemented similarly in Chrome and Firefox, with two differences. First, Chrome and Firefox treat navigations to cached pages differently. The Firefox version of the metric ignores cached pages except in case of cache revalidation. Second, Chrome excludes non-HTML resources (like PDFs) but Firefox includes them. These are implementation artifacts due to the different navigation metric hooks available in each browser.

Our secondary page load metric is the **extended page load metric**, which we record in Chrome.[6] It is identical to the strict page load metric except it also counts in-page navigations. An *in-page navigation* is when a website uses the History API or URL fragments to navigate; this changes the visible URL but does not actually load a new page. Several of the Internet's most popular websites make heavy use of in-page navigations. E.g., Facebook dynamically swaps out page content when someone clicks on a friend's name in the News Feed, using the History API to make it look like the URL changed. Browsing Facebook for an hour generates a large number of extended page loads but only one strict page load. This technique is not commonly used in the long tail of the Internet because it is significantly more technically complex than typical link-based site navigation.

Both page load metrics are sensitive to whether and how people make use of tabs. Consider Alice and Bob both searching for "cats" on Google:

1. *Tabbed window navigation.* Alice opens the first search result in a new tab. When she's done, she goes back to the Google tab and opens the next search result in a new tab. She repeats this for the first nine search results. Consequently, 10% of her page loads were over HTTPS: one Google tab over HTTPS and nine HTTP search result tabs.

2. *Single window navigation.* Bob opens the first search result in his main browser window. When he's done, he hits the "Back" button to return to Google. He repeats this for the first nine search results. Consequently, 50% of his page loads were over HTTPS: Google over HTTPS, HTTP search result, Google, search result, Google, search result...

Alice and Bob saw the same exact websites in the same exact order, but they generated very different page load metrics (10% vs 50%).

3.2.2 Time in foreground

In Chrome, the **time in foreground metric** measures how much wall clock time people spend looking at websites, and whether those websites are HTTP or HTTPS. We added this metric after we grew concerned about the effect of tabbed browsing on page load metrics.

Every time a top-level page is closed, we record the protocol and the amount of time that the page spent in the foreground. Like the page load metrics, we exclude non-HTML resources, non-HTTP(S) protocols, incomplete navigations, and the New Tab Page. It *does* include time spent on cached websites. In-page navigations are irrelevant to this metric because all time spent on a given protocol is summed together.

3.2.3 Transactions

In Firefox, we record the percentage of HTTP transactions that occur over HTTP or HTTPS. The **transaction metric** is implemented similarly to the strict page load metric, but it counts HTTP transactions instead.[7]

The transaction metric is the least likely to reflect the user experience of web browsing. The transaction-based metric is sensitive to hidden implementation details of websites because it includes both top-level page loads and subresource requests. A single page load might issue anywhere from zero to hundreds of resource requests. For example, the Washington Post homepage issues 262 requests to 41 origins. Consider someone who opens two websites — one HTTP and one HTTPS — and spends equal amounts of time on them. Intuitively, this scenario ought to yield a 50% HTTPS usage rate. However, if the HTTP page generated one request and the HTTPS page generated nine requests, the transaction metric would record a 90% HTTPS usage rate.

Despite this metric's limitations, we nonetheless feel this is a useful metric to record and share for reference. The transaction metric is the most similar to network-based HTTPS metrics, which cannot distinguish between top-level page loads and subresources.

3.3 Results

As of February 2017, HTTPS comprises a majority of browsing in Mozilla Firefox and Google Chrome (on desktop). HTTPS usage lags behind on Android in Chrome by the extended page load and time-in-foreground metrics. We also find that HTTPS usage differs globally, with East Asian countries exhibiting markedly lower HTTPS usage rates. Overall, HTTPS usage rates continue to rise over time.

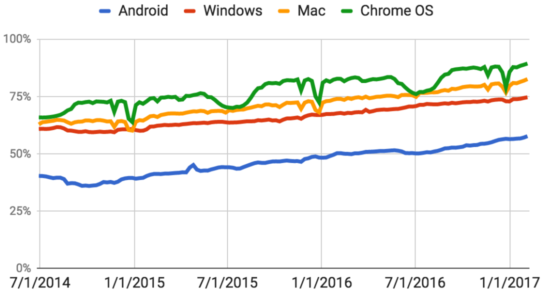

Figure 1: The percentage of extended page loads over HTTPS from July 2014 to February 2017, in Chrome.

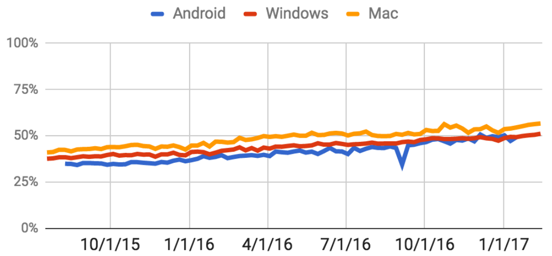

Figure 2: The percentage of strict page loads over HTTPS from July 2015 to February 2017, in Firefox.

3.3.1 Usage over time

Is HTTPS usage still growing? (Yes.)

Given the security community's investments into HTTPS adoption, we hope to see sustained growth in HTTPS usage. At present, HTTPS usage is still growing. Figure 1 shows extended page load metrics in Chrome from July 2014 to February 2017, and Figure 2 shows strict page load metrics in Firefox from July 2015 to February 2017. Both demonstrate consistent (albeit non-monotonic) growth. As of Febrary 2017, HTTPS usage continues to increase overall for clients of both browsers despite short-term fluctuations.

We observe that HTTPS usage has weekly and seasonal variations. As shown in Figure 4, there is more HTTPS usage Monday through Friday than on Saturday and Sunday. (Recall that HTTPS usage is a *percentage* — this does not necessarily indicate a decrease in overall browsing over the weekends.) A chi-squared test on the cross-tabulation of HTTP/HTTPS vs. weekday/weekend shows this difference to be significant with very high confidence ($p < 10^{-15}$). We hypothesize that work- and school-oriented websites are more likely to be accessed over HTTPS than leisure websites, and users' browsing habits shift between these depending on the day of the week. The timelines also show that holidays correlate with temporary HTTPS usage drops for some classes of users. For example, HTTPS usage on Mac and Chrome OS drops during Christmas and New Years. In addition to the winter holidays, HTTPS usage on Chrome OS also dips during the northern hemisphere's summer. We hypothesize that this is also due to differences between work and leisure browsing, and it is especially pronounced in Chrome OS due to Chrome OS's popularity in North American schools.

3.3.2 Client operating system

Does HTTPS usage differ by operating system? (Yes.)

Figure 3 shows our browser HTTPS metrics, split by client operating system. HTTPS comprises a majority of browsing on all three desktop operating systems and Firefox for Android by all available metrics, as of February 6, 2017. However, Chrome for Android users spend more time on HTTP than on HTTPS.

Due to the differences between client operating systems, a single summary statistic across all types of clients would be misleading. Such a statistic would overstate HTTPS usage on Android and understate HTTPS usage on desktop. Further, it would be sensitive to shifts in computing trends; for example, a decrease in Android phone usage would make the overall HTTPS usage rate appear to increase. We therefore split our statistics by operating system, focusing on Windows and Android as the largest populations.

Android. HTTPS usage is lower on Android than other operating systems. The difference is largest in Chrome, where less than half of strict page loads and time in foreground are spent on HTTPS websites. The gap between Android and desktop is smaller among Firefox users, but Android still has the lowest HTTPS usage rates among Firefox platforms.

We hypothesize that lower HTTPS usage rates on Android are due primarily to the popularity of native Android apps like Facebook, Twitter, and Google Search, in place of the equivalent web apps. Browser metrics can't capture search, e-mail, or social media when they are not in the browser. App usage is "invisible" from the browser's perspective, and app usage is concentrated in a small number of popular apps.[8] This leaves Android web browsing more tail-heavy than other operating systems.

The difference between mobile and desktop browsers might also be related to the types of sites users are visiting. If the hypothesis that work-related sites have more HTTPS than leisure sites is valid, then the difference between mobile and desktop might be a result of users tending to visit more leisure sites than work sites on their mobile devices, and vice versa on their desktop computers.

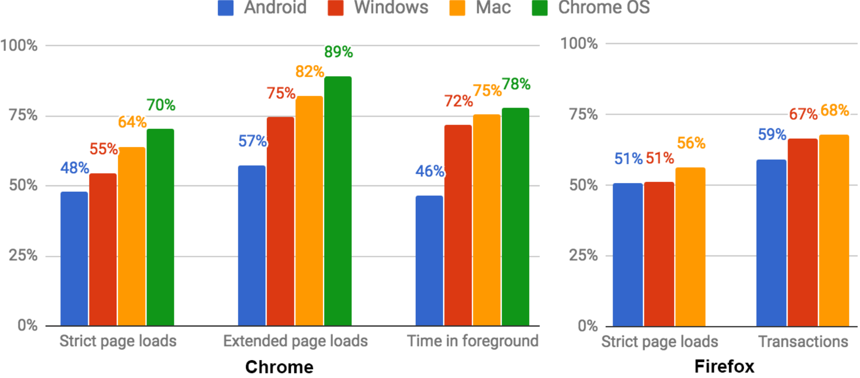

Figure 3: Browser HTTPS usage metrics for the week ending February 6, 2017. (Firefox for Android metrics are for the week ending January 23, 2017 due to a data processing issue.)

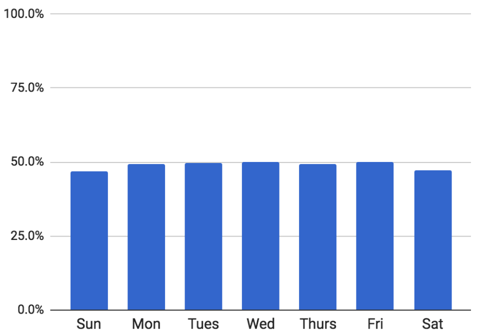

Figure 4: The percentage of strict page loads over HTTPS in December 2016, in Firefox, by day of week.

Desktop operating systems. Windows, Mac, and Chrome OS clients display similar HTTPS usage patterns, with Windows having the lowest HTTPS usage rates and Chrome OS having the highest. The success of HTTPS on Chrome OS might be influenced by demographics: Chrome OS users might be more likely to use other Google products, which are HTTPS by default.

3.3.3 Regional disparities

Is HTTPS usage equal across the world? (No.)

Web browsers serve global audiences, whose cultures and browsing habits differ. This could yield different HTTPS usage rates. Figure 5 shows a global view of HTTPS usage among Firefox users. Table 1 shows metrics for a subset of countries in Chrome, selected for cultural diversity and large Internet-using populations.

Emerging markets. We initially expected that emerging markets would have lower HTTPS usage rates, but we do not see evidence of that in our metrics. For example, India's rates are slightly higher than Germany's by all measures, and Brazil's are slightly higher than France's by several metrics.

Figure 5: A map showing median rate of HTTPS usage among Firefox users by country from February 5–8, 2017, excluding countries with small user populations.

High HTTPS usage. Small countries have the highest HTTPS usage rates. In Chrome, 90% of strict page loads in Tuvalu, Svalbard and Jan Mayem, and Benin are HTTPS. In Firefox, the 75th percentile HTTPS usage rate is above 90% in Mayotte, Libya, Syria, Venezuela, Ecuador, and Iraq, i.e., 25% of users in these countries use HTTPS on more than 90% of page loads. We hypothesize that browser users in small countries spend more time on large, centralized websites like Google and Facebook (which support HTTPS by default) due to the lack of localized long-tail Web content. It is also possible that, due to the small sample sizes, certain groups of "unusual" users skew the statistics in these countries.

Most large countries have similar HTTPS usage rates, within a 10-point range. However, within this range, the United States is a consistently high consumer of HTTPS across all metrics. India and Mexico are close behind.

Low HTTPS usage. East Asian countries are notable outliers. South Korea, Japan, and China have very low HTTPS usage rates, lagging far behind other countries. The only other country outside of East Asia with similarly low HTTPS usage is Iran, which is second only to

		Chrome Android			Chrome Windows			Firefox

Table 1: Strict page load (SPL), extended page load (EPL), and time-in-foreground metrics for thirteen countries with large Internet-using populations. Chrome metrics are for the week ending on February 6, 2017. For Firefox, the median SPL rate among users in each country over the period February 5–8, 2017.

China in terms of median HTTPS usage among Firefox users. The disparity between these countries and the rest of the world highlights the challenge of creating global browser policies when people in some countries have very different browsing experiences.

Efforts to increase HTTPS usage in East Asia would have both local and global benefits. Not only would it increase Internet privacy in those countries, but it would also allow browser vendors to move more aggressively on HTTPS-preferential policies. To start, we recommend investigating *why* Japanese and South Korean browser users are less likely to use HTTPS. Although low HTTPS usage rates in China might be due to the Great Firewall, the same cannot be said for Japan and South Korea. Is it cultural (e.g., less concern about privacy), technical (e.g., legacy infrastructure in popular East Asian websites), or legal (e.g., different laws regarding cryptography)? Once the stumbling blocks are understood, outreach efforts to popular websites in East Asia could target those hurdles.

4 Server support for HTTPS

We cannot look at HTTPS adoption from only the browser perspective. Browser statistics are weighted towards the larger websites that make up a greater proportion of traffic, and we also wish to understand HTTPS adoption among small- and medium-sized websites in the "long tail" of the Web.

To this end, we scan lists of websites to measure HTTPS support across the web. We want to know how many websites (a) support HTTPS at all or (b) offer HTTPS by default. From a methodological standpoint, scanning websites for HTTPS support has two components: the testing technique (how did we determine HTTPS support?), and the list of websites (how do we define "the web"?). We use our own testing tools and lists alongside public tools and lists.

4.1 Testing tools

We want to measure whether a server supports HTTPS. In recent years, several competing tools (including two of our own) have arisen to perform this task using slightly different sets of criteria. We survey these tools and attempt to use them in a comparable fashion.

4.1.1 Mozilla Observatory

Mozilla created the Mozilla Observatory[9] as a tool to test servers' HTTPS configurations, along with a few other security properties. The Mozilla Observatory performs a handful of simple tests to determine whether and how a website is accessible over HTTPS. The results of the scans are publicly available via an API.

HTTPS available. The most basic test is to connect to the domain on port 443 and make a HTTPS request for the root document. If the website returns a valid certificate and the request succeeds – regardless of redirections or status codes – we consider it available over HTTPS.

Default HTTPS. This test assesses whether a website forcibly redirects HTTP traffic to an HTTPS endpoint.

HSTS. When a website sets a HTTP Strict Transport Security (HSTS) header, browsers that support the header will always use HTTPS to connect to that website. We test whether a website provides the HSTS header with a

minimum max-age of six months (the minimum required for preloading at the time the tool was built).

HSTS preloading. A man-in-the-middle attacker can prevent a client from receiving a website's HSTS header. To stop this attack, several browsers use a preloaded list of websites that serve HSTS headers. We check whether each website appears on the preloaded list.

HPKP. If a man-in-the-middle attacker were to collude with a rogue CA, the attacker could present a forged certificate that *appears* legitimate. HTTP Public-Key-Pinning (HPKP) ensures that the browser will only accept specific certificates intended by the website. The Observatory tests whether the HPKP header is implemented for a given website, with any max-age.

4.1.2 Google Transparency Report

The Google Transparency Report[10] scans a set of 100 non-Google websites.[11] The results are updated weekly. We maintain the Transparency Report's pre-existing testing infrastructure to track two criteria over time.

HTTPS available. A website is considered to work on HTTPS "if the Googlebot successfully reaches https://domain and isn't redirected through an HTTP location". The server must provide a valid HTTPS certificate chain for the website. This is more stringent than the "HTTPS available" category as defined by the other tools (Mozilla Observatory, HTTPSWatch, and Censys), which all permit redirects through HTTP.

Default HTTPS. A website is considered HTTPS by default if "the site redirects HTTP requests to a HTTPS URL" in response to a connection attempt from the Googlebot. The server must provide a valid certificate chain for the website. Per their rating system, a website does not need to use HSTS to achieve this designation.

Counter-intuitively, a website can be HTTPS by default without making HTTPS available. This situation occurs most notably with subdomains. For example, "http://domain redirects to https://subdomain.domain, but https://domain refuses the connection".

4.1.3 HTTPSWatch

HTTPSWatch tests prominent websites for HTTPS support.[12] We place websites into two categories based on HTTPSWatch's three-tier rating system. (The authors of this paper are not involved in the HTTPSWatch project; we use it as a public repository of HTTPS data.)

HTTPS available. We assign a website to this category if HTTPSWatch's client server can establish a verified TLS connection to the website. Our label corresponds to either the "Mediocre" or "Good" ratings in HTTPSWatch's published rating system.

Default HTTPS. A website is considered to support HTTPS by default if a verified TLS connection can be established, the HTTP version of the website redirects to HTTPS, and the HSTS header is set. Our label corresponds to the "Good" rating in HTTPSWatch's rating system. This is comparable to the Mozilla Observatory's "HSTS" category and is more strict than the Google Transparency Report's "default HTTPS" category.

4.1.4 Censys

Censys "is a public search engine that enables researchers to quickly ask questions about the hosts and networks that compose the Internet"[13]. It maintains a large database of server configurations, including information about TLS support [10]. We query Censys to test whether servers support HTTPS. (The authors of this paper are not involved in the Censys project; we use it as a public repository of HTTPS data.)

HTTPS available. A server is considered to support HTTPS if it responds on port 443 and provides a valid certificate chain [10]. In Censys syntax, this corresponds to `443.https.tls.validation.browser_trusted: true and protocols: "443/https" and 443.https.tls.validation.matches_domain: true"` for websites. Censys cannot enforce the last restriction for an IPv4 host, so an IPv4 host is considered to support HTTPS even if the certificate might fail to validate in a browser due to a name mismatch error.

4.2 Lists of websites

Different lists of websites are useful for different research questions. Do we care about HTTPS adoption for the whole Internet, popular websites, or websites popular in India? We use several publicly available lists of websites, each of which has its own characteristics. See Appendix A for copies of the lists.

HTTPSWatch Global. The HTTPSWatch project provides a list of 40 "prominent websites" in five areas: search, social media, commerce, cloud storage, and publishing platforms. The list was curated by the project to represent well-known, influential websites in each area. They describe their selection criteria as, "HTTPSWatch's goal is to list several representative sites for each category. Usually these are the most popular sites, so HTTPS

List	List size	Tool	HTTPS available	Default HTTPS
HTTPSWatch Global	40	HTTPSWatch	80%	35%
Google Top 100	100	Googlebot	54%	44%
Alexa Top 100 Global	100	Mozilla Observatory	87%	23%
Alexa Million	969,278	Mozilla Observatory	40%	10%
Alexa Million	856,312	Censys	38%	N/A
IPv4 hosts	101,052,620	Censys	10%	N/A

Table 2: HTTPS support among each set of websites, February 2017.

support on them affects the most users."[12] We recorded the state of HTTPSWatch on February 13, 2017.

The project also maintains country-specific lists, but we do not report them here. Although their country-specific lists have value, they are unsuitable for comparing HTTPS adoption rates across countries because each country's list has different categories and criteria.

Alexa Top 100. The Alexa Top 100 ranking represents the Web's most popular websites, per Alexa traffic estimates. We requested the global Top 100 list as well as country-specific Top 100 lists. The country lists are based on the countries that the websites are popular in, not based on where the servers are physically located.

Alexa aggregates browsing history from millions of Alexa toolbar users,[14] which it complements with a website-embedded analytics script.[15] They compute a ranking based on the resulting corrected traffic estimates, which combines counts of unique visitors and page loads from the two data sources. Their traffic ranking combines all subdomains into a single entry for the website "unless [they] are able to automatically identify them as personal home pages or blogs."[14]

We requested these lists on February 13, 2017. Based on how Alexa computes traffic estimates, this reflects popularity over a three-month period prior to that day.[14] Several of the websites were unreachable on the day of testing, so we omitted them from our results.

Google Top 100. The Google Transparency Report provides HTTPS statuses for a list of 100 top websites. It is intended to represent highly popular, *non-Google* websites. The list was created using a mix of public data (including the Alexa ranking) and Google proprietary data, based on browsing habits in early 2016.[11] The lack of Google websites on the list is notable because the Alexa 100 lists include many Google websites.

Alexa Million. The Alexa Top Million represents a broad snapshot of the active Internet. Although the list's official name alludes to popularity, everything after the first 100,000 is considered part of the long tail of the Internet.[14] The list sees substantial churn, and websites are sometimes unreachable after only a few days. Statistics based on the Alexa Top Million should therefore be viewed as reflecting a broad developer experience, rather than reflecting truly "top" sites. We refer to the list as the "Alexa Million" throughout this paper to avoid the impression that all of the websites on the list are popular. We requested the Alexa Million on April 11, 2016, October 21, 2016, and February 3, 2017.

IPv4 hosts. Censys exposes an Internet-wide view of servers. They "use ZMap to perform single-packet host discovery scans against the IPv4 address space" [10]. Once a host is found, they perform a TLS handshake and record the result. Some — perhaps many — of the full set of responding servers are hobbyist machines, defunct websites, home devices, app backends, etc. We queried Censys on February 13, 2017.

4.3 Results

HTTPS support increased from 2016 to 2017. However, each list that we examined yielded a different HTTPS adoption rate (Table 2). Popular websites are more likely to support HTTPS, and support also varies by region.

4.4 Adoption over time

Is HTTPS support increasing? (Yes.)

Top websites. HTTPS support increased dramatically among the Google Top 100 from February 2016 to February 2017 (Figure 6). Over the course of a year, the number of Google Top 100 websites with basic HTTPS support rose from 39% to 54% (15 points). The number of websites with default HTTPS nearly doubled, increasing from 24% to 44% (20 points).

Long tail. We also observed a big increase in HTTPS support among the Alexa Million from April 2016 to February 2017 (Table 3). In less than a full year, the number of Alexa Million websites with basic HTTPS support rose from 30% to 40%. This continues the growth previously observed by Durumeric et al. in 2012-2013 [11]. On the other hand, the number of websites with default HTTPS remained low, increasing from 5% to only 10%.

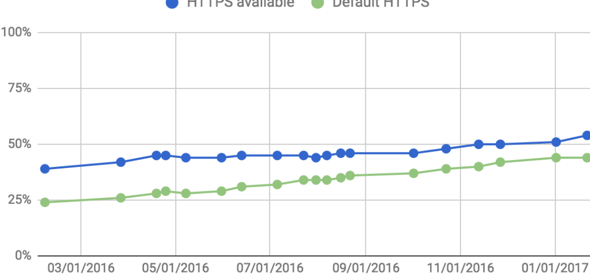

Figure 6: HTTPS support among the Google Transparency Report Top 100, recorded over a year.

	4/2016	10/2016	2/2017
HTTPS available	30%	34%	40%
Default HTTPS	5%	8%	10%
HSTS	1%	3%	3%
HSTS preloading	0.2%	0.2%	0.3%
HPKP	0.4%	0.5%	0.5%

Table 3: Results of testing the Alexa Million with the Mozilla Observatory on three dates.

4.5 Website popularity

Are popular websites more likely to be HTTPS? (Yes.)

As Table 2 shows, the percentage of websites that support HTTPS depends on the list. Websites on the "top" lists are more likely to support HTTPS than others.

Top websites. A majority of all three top website lists (HTTPSWatch Global, Google Top 100, and Alexa Top 100 Global) support HTTPS. Of those three, the Alexa Top 100 Global has the highest rate of HTTPS availability. However, the Alexa Top 100 is not a very diverse list: twenty of the websites are owned by Google, six are owned by Microsoft, and three are owned by Amazon. The Google websites all support HTTPS but not by default (due to an initial HTTP redirection from `google.com` to `www.google.com`). The Google Top 100 avoids this skew by removing Google's own websites; it accordingly yields a lower HTTPS availability rate but a higher default HTTPS rate.

Long tail. We see a steady decrease in HTTPS support as websites get less popular. Of the Alexa Top 100, 87% support HTTPS; of the top 1000, 70% support HTTPS; of the top 10,000, 60% support HTTPS; of the top 100,000, 51% support HTTPS. The full Alexa Million represents the long-but-active tail of the Web, and only 40% support HTTPS (10% by default). IPv4 hosts — representing the long tail and flotsam of the Internet — are even less likely to support HTTPS (10%).

	HTTPS available	Default HTTPS
Brazil	65%	15%
Canada	77%	21%
France	67%	16%
Germany	86%	27%
India	68%	16%
Indonesia	71%	13%
Japan	57%	19%
Mexico	80%	19%
Russia	80%	24%
South Korea	75%	14%
Spain	75%	21%
Turkey	73%	17%
United States	81%	18%
Global	*87%*	*23%*

Table 4: HTTPS support rates among the Alexa Top 100 for each country in February 2017, as tested with the Mozilla Observatory on February 13, 2017.

4.6 Regional disparities

Is HTTPS support equal worldwide? (No.)

We observe different rates of HTTPS support among the Alexa Top 100 lists for fourteen countries (Table 4).

High HTTPS support. Websites that are popular in Germany, the United States, Mexico, and Russia are the most likely to support HTTPS (80% or greater).

Low HTTPS support. Websites that are popular in Japan are the least likely to support HTTPS (57%). To our surprise, Brazil, France, and India are not far behind (65%, 67%, and 68%).

Comparison to browser metrics. We expected to see a clear relationship between regional HTTPS usage and server support. For example, we expected that Japan and South Korea would have very low HTTPS support rates. However, that is not the case: Japanese HTTPS support rates are only slightly lower than others, and South Korea falls in the middle. On the other hand, Indian people have high HTTPS usage rates despite the Indian Top 100 having a relatively low HTTPS support rate.

This discrepancy can be explained by considering that website popularity is not distributed evenly even within the Top 100. People might spend much more time on the first three websites (or first five, or first fifteen...), placing more weight on the HTTPS status of those websites.

Global vs regional. The Alexa Top 100 Global list reports a higher HTTPS support rate (87%) than any individual country list. How can this be? A key insight is

that the global list includes a mix of (a) websites that are popular across many countries, and (b) the most popular websites from the largest countries. The websites on the Top 100 list are more popular overall than the websites on the country-specific lists — and the websites at the very top tend to support HTTPS.

One intriguing artifact of the popularity distribution is that the global list has twenty Google websites. This occurs because nineteen large countries each have a popular regional Google variant (e.g., `google.de` and `google.es`), and `google.com` is popular across many countries. As a result, the global list doesn't represent any single person's normal browsing — no one visits all of the different Google variants! In contrast, someone would likely be familiar with most of the websites on their country's Top 100 list.

5 Network measurements

In addition to client and server measurements, we can also observe HTTPS adoption from the network. HTTP and HTTPS operate on different TCP ports (80 vs. 443), so it is easy to identify HTTP and HTTPS traffic in a given packet flow. We can use network measurements to assess how much of the web is being carried over HTTPS across *all* clients and servers being used over a given network. This includes non-browser clients (which are missing from browser telemetry) and less popular sites (which might not be covered by scans).

5.1 MAWI sample point F

We derive our network observations from the public domain MAWI data set published by the WIDE project,[16] specifically from their sample point F [23]. This data set includes one 15-minute snapshot of Internet traffic per day, taken at a connection point between the WIDE backbone network and a transit provider. Between 160GB and 590GB of HTTP and HTTPS traffic passes this observation point during each collection window.

We report the network data in terms of bytes and packets. Top-level page loads, subresources, and non-Web traffic are all grouped together in this data set.

5.2 Results

Figure 7 shows the fraction of bytes and packets that were sent over HTTPS, from 2014 to 2017.

Traffic over time. By both the byte and packet metrics, HTTPS experienced significant growth from January 2014 to January 2017. The percentage of network traffic using HTTPS grew from around 20% of web traffic to around 40%. In addition, the byte and packet ratios

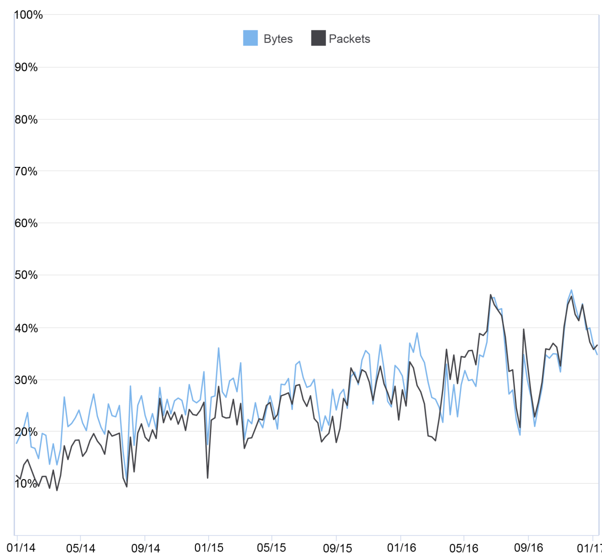

Figure 7: HTTPS as a percentage of all network traffic (HTTP+HTTPS) at the MAWI sample point F, weekly from January 2014 to January 2017.

converged, which suggests that HTTPS is increasingly being used for the same types of activities as HTTP.

Comparison to browser metrics. The HTTPS rate as seen by this link is lower than the HTTPS usage rates observed by browser telemetry. We hypothesize that this might be due to one (or more) of three factors:

- These observations are from a network in Japan, where browser telemetry shows low HTTPS usage.
- Non-browser HTTP clients might have a lower rate of HTTPS usage. They are covered by this measurement and not browser telemetry.
- Content served over HTTP could be different than content served over HTTPS in a way that skews measurements by byte or packet (e.g., streaming video might be more common over HTTP).

The disparity between volume-oriented and connection- or pageload-oriented metrics is similar to an earlier observations made in a residential ISP in 2014 [29]. That study observed the prevalence of HTTPS in terms of both traffic volumes (in bytes) and connections, the latter being similar to the Firefox transaction metric. (Technically a lower bound, since multiple transactions can be carried on a single connection.) As of 2014, they observed that HTTPS was 13.8% of download traffic by volume, but 44.3% of connections, both trending upward over time.

6 Implications

We discuss the implications of our findings for HTTPS outreach, discussion, and policies.

6.1 HTTPS adoption growth

We have seen tremendous growth in HTTPS adoption, from four perspectives:

- **Top websites.** Default HTTPS support among the Google Top 100 nearly doubled in 2016, rising from a quarter to nearly half (Figure 6). We attribute this to growing public demand for HTTPS and a desire among top websites to use new HTTPS-only features like Service Workers.

- **Long tail websites.** Among the Alexa Million, basic HTTPS availability grew from 30% to 40% over 2016, and support for HTTPS by default doubled to 17% (Table 3). We attribute the growth in the long tail to Let's Encrypt and publishing platforms that now support HTTPS (such as Squarespace).

- **End user perspective.** A majority of desktop browsing now occurs over HTTPS. HTTP is still dominant on Android by some measures, but HTTPS usage on Android is growing and poised to soon become the majority by all measures. Figure 1 shows the substantial growth in HTTPS usage (per extended page loads) from July 2014 to February 2017 in Chrome. The growth in HTTPS usage is a direct consequence of the growth in server support.

- **Network traffic.** HTTPS traffic doubled as a percentage of all web traffic, by byte and by packet, from 2014 to 2017 (Figure 7).

We view the steady growth as a sign that HTTPS promotion efforts are succeeding.

6.2 Choice of metric

We would have liked to find a single metric that captures HTTPS adoption. Such a metric would be useful for making HTTPS-related decisions and tracking the impact of adoption efforts. Unfortunately, this unified metric is elusive. The browser metrics that we investigated each have their own nuances (Section 3.2), each yielding different HTTPS usage rates (Figure 3, Table 1). Similarly, server support rates depend on the set of websites and level of HTTPS support desired (Table 2). Network-based metrics have broader scope but less detail than browser metrics (Section 5).

We recommend choosing between metrics based on the following guidelines:

- Use the Alexa Million to measure developer impact.

- Use page load metrics to measure the user impact of browser or ecosystem changes that affect page loads. The strict page load metric is preferable because it is more conservative.

- Use a time-based metric to measure the user impact of changes to long-lasting browser UI changes.

- Consider different demographics. Split user metrics by OS and country, and split Alexa sites by country.

In this section, we give examples of applying those recommendations to scenarios that we have encountered.

6.2.1 Requiring HTTPS for APIs

Mozilla Firefox and Google Chrome have begun requiring HTTPS for some developer APIs like Service Workers [1] and the geolocation API [24]. Their goal is to prevent powerful browser APIs from being abused by network attackers. Browser vendors and standards bodies may wish to know what the compatibility cost is when discussing whether to require HTTPS for a new API.

Developer frustration and low feature adoption rates are the two main concerns in this scenario. How many websites will be able to use the feature if its usage is restricted to HTTPS pages? We recommend measuring how many of the Alexa Million support HTTPS by default, since that list represents a wide set of actively visited websites. The number is currently low, which suggests that many developers will need to do additional work to use HTTPS-only features. This should not necessarily deter browser vendors from setting those restrictions, but understanding the ecosystem status can help set expectations for the reaction to a HTTPS restriction.

6.2.2 Changing security indicators

Browser security indicators have slowly changed over time. Each iteration is accompanied by concerns about how the change affects people's perceptions of security states (e.g., [16]). For example, people might become desensitized to a negative or frightening security indicator for HTTP if they see it all the time.

If the proposed UI treatment is displayed once at page load, we recommend using a page load-based metric to evaluate how often it will be shown. If the proposed UI treatment would be permanently associated with the loaded page, then we instead recommend using a time-based metric. A time-based metric is appropriate because it measures how long people actually see the new browsing treatment. We do not think it is necessary to consult server support rates when measuring the impact of UI changes, since UI is between the browser and end user.

When evaluating UI changes, we recommend splitting the relevant HTTPS metrics by operating system and country to see whether any user populations will be disproportionately impacted. In particular, it would be worth understanding how the change will impact East Asian countries due to their lower HTTPS usage.

6.2.3 Handling unknown protocols

If someone types a new website `www.example.com` into a URL bar, should the browser load the website over HTTP or HTTPS? All major browsers currently default to HTTP in this situation, unless a preloaded HSTS header instructs otherwise. At some point, browsers should change their behavior to default to HTTPS instead. This change cannot be made lightly because it carries risk for websites that are still unavailable or appear broken (e.g., due to mixed content) over HTTPS.

When considering such a change, one might be concerned about end user pain (seeing broken pages). We recommend measuring the impact of a proposal in terms of strict page loads. The strict page load metric is a suitable measure of user pain in this situation because the disappointing event might occur at page load, and it is more conservative than the extended page load metric.

If the proposal results in slowing, breaking, or blocking some websites, one might also be concerned about developer frustration. We therefore also recommend measuring the impact of a proposal on developers in terms of the Alexa Million, to gain insight into the long-yet-still-active tail of the Web.

6.3 Impact of top websites

Our data suggests that top websites drive client HTTPS usage on desktop, but Android is more sensitive to server support among the long tail. We observe:

- Server support for HTTPS is more common for top websites than for the long tail (the Alexa Million or IPv4 hosts). The difference is especially pronounced when considering how many support HTTPS by default (Table 2).

- Websites that use the History API and fragment navigation comprise a large amount of HTTPS web browsing. We see this in Figure 3 by comparing the extended page load metric (which includes those types of navigations) to the strict page load metric (which doesn't). The extended page load metric is 20 points higher than the strict page load metric on desktop Chrome, and 9 points higher on Android Chrome. These navigations are associated with highly engineered, dynamic websites.

- Compared to desktop clients, Android clients load fewer HTTPS pages and spend less time on HTTPS pages in Chrome (Figure 3). We attribute this primarily to the popularity of apps on Android, notably including the Google Search and Facebook apps. Long tail traffic remains in the browser.

- Not only do people spend more time on HTTPS websites overall on desktop Chrome, but the websites that people spend a very long time looking at are more likely to be HTTPS. The distributions for HTTP pages and HTTPS pages are similar log-normal distributions, differing only in the very long tail: 1% of HTTP page loads are kept open for more than an hour, whereas 2% of HTTPS page loads are kept open for more than an hour. An example of this might be keeping GMail or Facebook open all day, frequently returning to the tab.

We conclude that a small number of dynamic websites account for a disproportionate percentage of desktop web browsing. As these websites move to HTTPS by default, HTTPS usage on desktop grows. The effect is smaller on Android than desktop, where people spend more time browsing HTTP websites in the long tail.

6.4 Benchmarking HTTPS adoption

Presenters or journalists may want to provide a summary statistic when discussing the current state of HTTPS. In such a situation, we recommend using the following:

- To give an overview of the end user experience, use Chrome's time-in-foreground metric (split by OS). The time-based metric is intuitive and not sensitive to tabbed browsing habits.

- To illustrate trends among influential websites, scan the Google Top 100. The Google Top 100 list has less repetition than the Alexa Top 100, but it's still grounded in user data (unlike HTTPSWatch).

- To track progress among the long tail, scan the Alexa Million. It has a diverse mix of websites, 90% of which are considered part of the long tail but all of which have been visited by real people over the last three months.

6.5 HTTPS by default

Significant work remains to continue shifting the ecosystem. The long tail (Alexa Million) and very long tail (IPv4) still have little HTTPS support, and support among top websites has only recently come close to 50%.

At current rates, we predict:

- Top websites will be almost entirely HTTPS within a year and a half. Half have moved, more are preparing to move, and the reminder will feel pressured to meet the changing industry standard.
- Widespread HTTPS adoption among the long tail will take five more years unless a tool, hosting service, or outreach effort yields a breakthrough.
- HTTPS usage on desktop will be largely HTTPS within two years, due to an emphasis on top websites. On Android, it will depend on trends in the app vs web ecosystem.

6.6 Future outreach

We identified several areas where additional HTTPS outreach could yield benefits:

- East Asia lags behind the rest of the world in HTTPS adoption. Understanding Japanese and South Korean developers' and users' concerns (or lack of interest) could help address this.
- Moving the long tail to HTTPS should help increase HTTPS usage on Android, which currently lags behind desktop. This is more challenging than doing outreach to top websites because the outreach will need to have massive scale. Moving this long tail will require the change at points of centralization that can upgrade many sites at once, e.g., hosting providers or server software vendors.
- We should encourage new top websites to enable HTTPS. Much of the progress in 2016 came from top websites with *some* HTTPS support transitioning to HTTPS by default (Figure 6); as a result, most of the top websites now have either default HTTPS or no HTTPS at all.

7 Repeatability

Our metrics can be tracked or repeated by others. Google releases summary statistics from Chrome HTTPS telemetry weekly as part of the Google Transparency Report[17]. Mozilla publishes aggregate Firefox telemetry on their telemetry website. [18]

Our server scans can be repeated by others using the information in Section 4. Mozilla provides access to the Mozilla Observatory through a public API.[9] One exception is our scan of the Google Top 100, which used the proprietary Googlebot. However, we provide the results of those scans weekly as part of the Google Transparency Report.[19] Alternately, scans of the Google Top 100 can be run by anyone using the Mozilla Observatory.

8 Acknowledgments

We thank Emily Schechter, Tim Willis, Rutledge Chin Feman, and Hubert Chao for their work on the Google Transparency Report; Bryan McQuade and Vern Paxson for their insightful discussion; and David Adrian and Zakir Durumeric for answering questions about Censys.

A Archived list contents

Where possible, we provide copies of the lists that we scanned in Section 4.2. Please be aware that the lists contain websites with adult material.

“I Have No Idea What I’m Doing” – On the Usability of Deploying HTTPS

Katharina Krombholz
SBA Research

Wilfried Mayer
SBA Research

Martin Schmiedecker
SBA Research

Edgar Weippl
SBA Research

Abstract

Protecting communication content at scale is a difficult task, and TLS is the protocol most commonly used to do so. However, it has been shown that deploying it in a truly secure fashion is challenging for a large fraction of online service operators. While *Let’s Encrypt* was specifically built and launched to promote the adoption of HTTPS, this paper aims to understand the reasons for why it has been so hard to deploy TLS correctly and studies the usability of the deployment process for HTTPS. We performed a series of experiments with 28 knowledgable participants and revealed significant usability challenges that result in weak TLS configurations. Additionally, we conducted expert interviews with 7 experienced security auditors. Our results suggest that the deployment process is far too complex even for people with proficient knowledge in the field, and that server configurations should have stronger security by default. While the results from our expert interviews confirm the ecological validity of the lab study results, they additionally highlight that even educated users prefer solutions that are easy to use. An improved and less vulnerable workflow would be very beneficial to finding stronger configurations in the wild.

1 Introduction

Transport Layer Security (TLS) and its predecessor Secure Sockets Layer (SSL) are fundamental cryptographic protocols to secure information in transit across computer networks and are employed to ensure privacy and data integrity between two communicating parties. They are used hundreds of million of times every day worldwide in applications such as web browsers, smartphone apps or in email communication. Recent studies on TLS usage in the Internet ecosystem for both HTTPS [16, 25] and email [24, 31], however, revealed that a large fraction of communication endpoints are poorly secured and suspectible to a broad array of possible attacks (e.g., Heartbleed [3] and DROWN [11]). Additionally, human-centric studies [20] have shown that warnings are still clicked through and that users have little to no understanding regarding the implications of visiting a website without a valid certificate. Even worse, a large number of services and websites still refrains from using TLS by default for all communication channels despite all efforts in propagating the use of encryption. While the initiative *Let’s Encrypt* was specifically launched to offer free certificates that are trusted by all browsers, it is not yet ubiquitiously used for various reasons, e.g., the lack of Extended Validation (EV) Ceritificates. Besides that, *Let’s Encrypt* still requires to be configured at least once.

To date, most studies on human-centric concerns focused on non-expert end users and, to the best of our knowledge, no user study has yet been conducted to examine the usability of the TLS deployment process directly. Our contribution aims to fill this gap by presenting the first user study with expert users to identify key usability issues in the deployment process of TLS that lead to insecure configurations. We conducted lab sessions that lasted 2 hours each with 28 university students from 14 to 18 December 2015. Data was collected via a think-aloud protocol as well as an entry and exit questionnaire. In addition we collected the bash and browser histories and the resulting server configuration files. We focused on Apache, as this is the most common web server to date [7] (A query at *censys.io* resulted in 20,890,000 websites using Apache). We found that configuring TLS on Apache is perceived as a challenging task even by experienced users. Our results suggest that administrators struggle with important security decisions (e.g., choosing the right cipher suites) which are mainly driven by concerns about compatibility. Furthermore, our participants had a hard time finding reliable sources on the Internet to

support their decision making process. The configuration options in Apache are perceived as difficult to understand and therefore an additional source of error. Through our expert interviews, we collected evidence that insufficiently secure configurations – like those from the majority of participants from our lab study – are frequently encountered during security audits. Our results shed light on major challenges from an expert user's perspective. We are confident that our results are a good baseline for the development of improved tools and policies that are better tied to the expert users' needs.

The contributions of this paper thus are:

- a **lab study with 28 participants** to explore usability challenges in the TLS configuration process
- **expert interviews with 7 security auditors** to provide a baseline for ecological validity and to further explore potential usability improvements and recommendations for the deployment process.

2 Background & Related Work

Transport Layer Security is the foundation of today's web security. Several application layer protocols use TLS to secure their online communication. The most widely used protocol is HTTPS, i.e., TLS provides confidentiality, authenticity and integrity for HTTP. Currently, TLS 1.2 [14] is the most recent version of the SSL/TLS protocol family, with TLS 1.3 on the horizon.[1] Besides securing the majority of today's web traffic, researchers have found several challenges regarding TLS, which are vigorously discussed in the literature [13,37]. Guidelines and best practices for a proper TLS deployment have also been published [12, 38]. The goals of TLS include extensibility and interoperability. This includes the ability to change the quality of the used certificate, settings of used cryptographic primitives (cipher suites), enabling of TLS extensions, use of different TLS versions and the use of additional security features like HTTP Strict Transport Security (HSTS) [23] and HTTP Public Key Pinning (HPKP) [18]. In the last years, many studies focused on empirically testing the quality of TLS configurations by using Internet-wide scanning techniques and showed that the TLS landscape is diverse and full of misconfigurations. Lee et al. [29] analyzed the supported SSL/TLS versions, the EFF started to analyze used certificates [17] with the most comprehensive study by Durumeric et al. [16] and VanderSloot et al. [42]. With a newly introduced search engine it is also possible to monitor the ecosystem more easily [15]. Ristic [36] analyzed different parameters and evaluated the quality by a defined metric [2]. Huang et al. [26] surveyed the use of cipher suites and Kranch and Bonneau [28] scanned domains for HSTS and public key pinning.

[1] https://tools.ietf.org/html/draft-ietf-tls-tls13

Most user studies regarding TLS and human-computer interaction focus on non-expert end users that receive certificate warnings from their browsers. Akhawe et al. [9] performed a large-scale study on the effectiveness of SSL browser warnings and found that that these warnings have high click-through rates, i.e., 70.2% of Google Chrome's SSL warnings did not prevent users from visiting the initially requested insecure site. Harbach et al. [22] presented an empirical analysis of the influence of linguistic properties on the perceived difficulty of descriptive text in warning messages and found that the several steps can help to improve text understandability.

Several studies have been conducted to improve SSL warnings [20, 21, 41, 43]: E.g., Sunshine et al. [41] conducted a survey to examine Internet users' reactions to and understanding of current SSL warnings. Based on their findings, they designed new warnings and showed that they performed significantly better. Weber et al. [43] used a participatory design approach to improve SSL warnings. Felt et al. [21] explored reasons for higher click-through rates for SSL warnings in Google Chrome compared to Mozilla Firefox. They also showed that the design of warnings can lead users towards safer decisions.

Oltrogge et al. [33] conducted an extensive study on the applicability of pinning for non-browser software as in Android apps. They found that only a quarter of their participants understood the concept of pinning. Based on their findings, they presented a web application to support developers in making the right decisions and guiding them through the correct deployment.

Fahl et al. [19] presented the first study with system administrators and found that many of their participants wished for more simplicity, e.g., simpler interfaces and automatic certificate renewal. Their results furthermore highlight the need for a better technical education of responsible personnel. In comparison to our lab experiments, the results from Fahl et al. [19] are based on self-reported data gathered via an online questionnaire and therefore provide a baseline for our study.

3 Lab Experiments

In the following, we describe the methodology used to collect and analyze the data from the lab study.

3.1 Study Design and Procedure

In order to elicit a picture of usability challenges of TLS deployment from an administrator's point of

view, we conducted a series of lab experiments with 28 participants. As described in Section 3.2, we recruited students with expert knowledge in the field of security and privacy-enhancing protocols at our university who fulfilled the criteria to potentially work as an administrator or were actually working as administrators.

Our experiments proceeded as follows: After the recruitment phase, the participants were invited to the lab where they were shortly briefed about the purpose of our study. After signing a consent form, they received the study assignment as presented in Appendix A. In the given scenario, they assumed the role of an administrator of an SME who is in charge of securing the communication to an Apache web server with HTTPS in order to pass a security audit. The server system to secure was based on Raspian, a Debian-based Linux distribution. The Apache version in use was 2.4.11. We prepared and implemented a fictive Certificate Authority (CA) in order to facilitate the process of getting a valid certificate and to remove any bias introduced by the procedures from a certain CA. The fictive CA was available through a simple web interface and required the submission of a valid CSR (certificate signing request) for issuing a valid certificate. The user interface was very simplistic and the browser on the local machine already trusted our CA. Figure 2 in Appendix A shows a screenshot of the user interface. We opted for this study setting as we solely wanted to focus on the actual deployment process instead of the interaction with a CA. There was no existing TLS configuration on the system, hence the participants had to start a new configuration from scratch. We chose Apache for our experimental setup as to date, Apache maintains a clear lead regarding in usage share statistics, followed by Microsoft and nginx, e.g., [1].

We instructed the participants to make the configuration as secure as possible, whereas the assignment did not contain any specific security requirements, such as which cipher suites to use or whether to deploy HSTS or not. In order to collect data, we used a think-aloud protocol. While the participants were working on the task, they articulated their thoughts while an experimenter seated next to them observed their work and took notes. We refrained from video recording due to the results from our pre-test during which we filmed the sessions and noticed a severe impact on the participants' behavior. The participants from the pre-study also explicitly reported that they perceived the cameras as disruptive and distracting, even though they were placed in a discreet way.

In addition to the notes from the observation, we captured the bash and browser history and the final configuration files. After completing the task, the participants were asked to fill out a short questionnaire with closed- and open-ended questions which covered basic demographics, previous security experience in industry and reflections on the experiment. The complete assignment and questionnaire can be found in the Appendix of this paper.
As a result, we had a collection of both qualitative and quantitative data that was further used for analysis as described in Section 3.3.

3.2 Recruitment and Participants

In contrast to most previous studies in the area of TLS usability, we focused on users that have proficient knowledge in the field of security and privacy-enhancing technologies. As it was very difficult to recruit participants from companies, irrespective of a financial incentive, we decided to recruit participants at the university and targeted students that had previously completed a set of security courses similar to recent studies with expert users, e.g., [8, 35, 44].

To ensure that our sample reflected job requirements of real world system administrators we reviewed open job advertisements for system administrators to determine requirements for participation in our study. We then invited a selected set of students that completed several security-related courses to take an online quiz to additionally assess their knowledge irrespective of their previously issued grades. The full set of questions from the quiz can be found in Appendix A. The quiz as well as the required previously completed university courses were selected based on a review of 15 open job advertisements for system administrators in our region. The top 30 students with the best scores were then invited to participate in the lab study, and 28 of them did. The participants' completed the quiz with scores ranging from 8.21 and 10 (out of 10). The average score was 9.15 (median = 9.37). The average time to complete the quiz was 6.1 minutes.

Table 1 summarizes key characteristics of the participants: 2 participants were female, 26 were male; the age range was 21 to 32 with a median of 23. Their experience working in industry ranged from 2 to 120 months with a median of 25 months. 17 of our 28 participants were already experienced system administrators and reported to have deployed TLS before.

We are confident that our participants are suitable to explore usability challenges in TLS deployment that real-world system administrators face. To furthermore strengthen ecological validity of our results we conducted a set of interviews with security auditors (Section 5).

3.3 Data Analysis

For a qualitative analysis of the observation protocols we performed a series of iterative coding which is often used in usable security research to develop models and theories from qualitative data [27, 34, 39]. Our approach involved several steps in the analysis process and was implemented as follows: At first, two researchers traversed all data segments independently point-by-point and assigned descriptive codes. This process is referred to as *open coding*. The two researchers performed the initial coding independently from each other to minimize the susceptibility of biased interpretation. We evaluated the quality of our initial codes and agreed on a final set of codes which was then used to code the protocols. Our analysis showed a good inter-rater agreement between the two coders (Cohen's κ=0.78). On the resulting initial set of coded data we performed *axial coding* to look for explanations and relationships among the codes and topics to uncover structures in the data. Then we performed *selective coding* to put the results together and derive a theory from the data.
In order to structure the data from the open-ended questions collected through the questionnaire we used an *iterative coding* process. Hence we went through the collected data and produced an initial set of codes. Then we revised the retrieved codes and discussed recurring themes, patterns and interconnections. After agreeing on a final set of codes, we coded the entire data. As a result of our analysis, we obtained a picture of usability challenges in the deployment process which is presented in Section 4, grouped by themes.
To evaluate the (mostly) quantitative data acquired via the bash/browser history and Apache log files, we applied metrics and measures to evaluate the quality of the resulting configuration.

4 Results

In this section we present the results from our lab study which are based on the data from the think-aloud protocol, the collected log files and the self-reported data from the exit-questionnaire.

4.1 Security Evaluation

We based our evaluation criteria on Qualy's SSL Test.[2] We consider this rating scheme a useful benchmark to assess the quality of a TLS configuration based on the state of the art recommendations from various RFCs [37, 38] and with respect to the most recently discovered vulnerabilities and attacks in the protocol. Since web services have different requirements, e.g., backward compatibility for outdated browsers, there is no universally applicable recommendation to get the highest grade. Still, the rating is widely accepted and applicable to generic web services like in our study. It must be mentioned that this benchmark reflects the best-case scenario at the time of writing, but could be different in the future if new vulnerabilities are discovered.
The rating of the evaluation criteria is expressed with a grade from A to F and composed out of three independent values: (1) protocol support (30%), (2) key exchange (30%) and (3) cipher strength (40%). Some properties, e.g., support for the RC4 cipher cap the overall grade as shown in Table 3. Table 2 summarizes the results of a security evaluation based on the final configuration per participant with additional information in Table 3. The full set of evaluation criteria based on the metrics used in Qualy's SSL Test is listed in Appendix A.

Only four participants managed to deploy an A grade TLS configuration, P24 received the best overall score. B was the most commonly awarded grade (15 out of 28). Four participants did not manage to deploy a valid TLS configuration in the given time (P7, P18, P23, P26). Two

[2] `https://www.ssllabs.com`

participants (P10 and P19) encrypted their private keys, the passphrases were “abc123” and “pass”. One of these two did not share the passphrase with us, however it was easy to brute-force.
Fortunately, none of our participants chose a key size smaller than 2048 for their RSA key. 15 participants chose 2k- and eight chose 4k-sized keys. Five out of the 28 participants deployed the certificate chain correctly, which is necessary to receive a grade better than B according to our rating scheme.
Two participants did not make use of the study CA and used self-signed certificates. Only one participant enabled a TLS version lower than TLS 1.0 (P8), another participant had all versions but TLS 1.2 disabled (P14). Only two participants configured RC4 support and only one configuration (P8) was vulnerable to the POODLE attack as SSL 3 was still supported. 14 participants fully configured forward secrecy, the remaining participants with valid configurations managed to at least partially support it. Eleven participants included HSTS headers to improve the security of their configuration and only two participants deployed HPKP.

To determine whether the distribution of SSL Test grades from our lab study reflects those from configurations found in the wild, we consider the estimation from *SSL Pulse* [6] who regularly publishes data sets of grade distribution measures based on the Alexa Top 1 Million. This data set as of the time our study was conducted contains 141.890 surveyed sites of which 34.1% were graded with A, 20.2% with B, 27.1% with C and 18.5% failed. Based on the 24 valid configurations from our study, 25% of the study configurations were graded with A, 67% with B and 8% with C. Given that the data set from SSL Pulse [6] contains websites with potentially higher security requirements or sites were administrators were presumably given more time to obtain a secure configuration. In particular the possibly very complex structures of real-world websites, as well as the inclusion of third-party content, make our study non-representative.

4.2 TLS Deployment Model

Our qualitative analysis of the think-aloud protocols from our lab study yielded a process model for a successful TLS configuration. All participants who managed a valid configuration in the given time can be mapped to the stages presented in this model. The four participants who did not manage to deploy TLS in the given time significantly deviate from this model. We divide the steps from our model into two phases, a *setup phase* and a *hardening phase*. We refer to the *setup phase* as to a set of tasks to get a basic TLS configuration, i.e., the service is reachable via https if requested. The *hardening phase* comprises all necessary tasks to get a con-

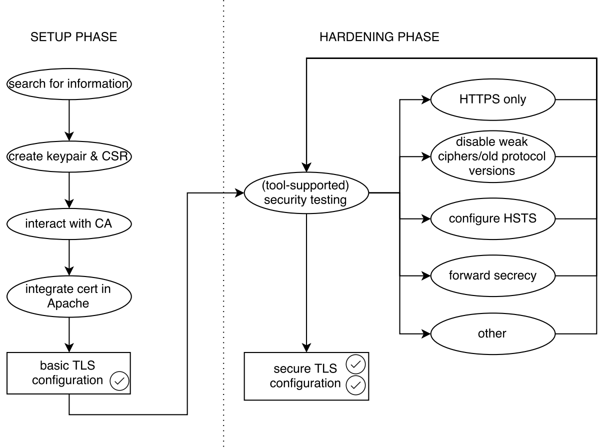

Figure 1: Schematic representation of a successful workflow.

figuration which is widely considered *secure* with respect to the metrics defined in A. Figure 1 shows our deployment model. Participants who achieved at least a basic configuration successfully completed all steps of the setup phase, while better-graded configurations completed some steps from the hardening phase as well. We identified iterative (tool-supported) security testing as a key element for a successful hardening phase, since the participants relied on external sources to evaluate the quality of their configuration.

4.3 Usability Challenges in TLS Deployment

In the following, we present the usability challenges identified through our analysis of qualitative data from the think-aloud protocols and the quantitative data from the collected log files.

Searching for information and finding the right workflow. Except for 3 experienced participants, who explicitly searched for tutorials they were aware of (e.g., `bettercrypto.org`), the study participants visited a high number of websites and used multiple sources of information. The information sources were diverse regarding their suggested deployment approaches and information quality respectively. We frequently observed that a participant started to follow an approach from one tutorial and soon had to switch to another as the presented approach was not feasible for our deployment scenario and the given server configuration.

The lowest number of visited websites during the lab study was 20 (P21). In contrary, participant P4 visited 147 websites during the given time. The average

ID	Grade	Errors / Warnings / Highlights	Cipher Strength Score	Key Exchange Score	Protocol Support Score	Common Name	Key Size	Certificate Chain Length	Used Provided CA to Sign	Encrypted Private Key	SSL 2	SSL 3	TLS 1.0	TLS 1.1	TLS 1.2	RC4 Support	Vulnerable to POODLE (SSL 3)	Forward Secrecy	HSTS	HPKP

Table 2: Security evaluation of the final TLS configuration per participant.

1	Highlight	HTTP Public Key Pinning (HPKP) deployed on this server. Yay!
2	Highlight	HTTP Strict Transport Security (HSTS) with long duration deployed on this server.
3	Warning	This server's certificate chain is incomplete. Grade capped to B.
4	Warning	The server does not support Forward Secrecy with the reference browsers.
5	Warning	This server accepts RC4 cipher, but only with older protocol versions. Grade capped to B.
6	Warning	The server supports only older protocols, but not the current best TLS 1.2. Grade capped to C.
7	Warning	This server uses RC4 with modern protocols. Grade capped to C.
8	Error	This server is vulnerable to the POODLE attack. If possible, disable SSL 3 to mitigate. Grade capped to C.

Table 3: Errors / Highlights / Warnings as referred to in Table 2.

number of visited websites over all participants was 60 (median=49.5, sd=27). We consider this a relatively high number given the low amount of time. Table 5 lists the most visited websites. The top-most visited site points to a German Ubuntu and Linux wiki that is frequently updated. The documentation for SSL on Apache (second-most visited site) contains detailed information on certificate creation and retrieval but only basic information on hardening. In contrast, `sslabs.com` and `bettercrypto.org` contain comprehensive tutorials on hardening but require a detailed understanding of the underlying fundamentals. The tutorial from `raymii.org` provides step by step instructions but is not regularly updated. Most participants expressed annoyance and vexation about the incompatibility of the different information sources. We also found that the number of visited websites (high, medium, low) does not impact the quality of the resulting configuration, but this result is not significant in our sample with $\chi^2(0.23327892, 6) > 0.05$.

Participant ID	Visited websites	Grade
Most visited sites		
P4	147	A
P19	116	B
P8	111	C
P2	109	B
P7	116	-
Least visited sites		
P21	20	B
P12	36	B
P5	49	B
P10	49	B
P18	50	-

Table 4: Participants and their cumulative number of visited sites and overall rating.

"I have absolutely no idea what I'm doing. Neither am I aware of whether my online source is trustworthy. (P23)"

Creating a Certificate Signing Request (CSR). A CSR is a block of PEM-encoded text which is sent to a CA to request a TLS certificate. It therefore contains information that will be included in the certificate such as organization name and common name (FQDN) and enables users to send their public key along with some information that identifies the domain name in a standardized way. When creating a CSR, the user is asked to fill out the respective information. In order to create a CSR, the user has to create a key pair. Our results suggest that many users do not understand the purpose and concept of a CSR, i.e., who it is authenticating towards whom. 19 out of 30 participants from the lab study had to create two or more requests due to errors in the CSR creation. The most common error was that they did not fill out the requested common name field correctly (14 participants) and thus did not receive a valid certificate for their domain. In the end, 20 participants created a CSR with the correct common name as shown in Table 2. As this is a common error in practice, some CAs even highlight that the common name(s) can be altered later on. This is especially useful when adding TLS support for subdomains. Second, two participants (P14 and P15) did not fully understand the difference between a CSR and a (self-signed) certificate. Six participants initially created a self-signed certificate instead of a CSR and tried to upload it to the CA. According to the self-reported work experience, this happened to participants regardless of their experience. E.g., P15 reported to have recently deployed TLS on Apache and still tried to upload a self-signed certificate to the CA. Four participants recognized the error after receiving an error message from the CA and then created a correct CSR including a correct common name.

Choosing the appropriate cipher suites. In TLS, cipher suites are used to determine how secure communication takes place. Cipher suites are composed from building blocks in order to achieve security through diversity. A person in charge of configuring TLS has to select cipher suites that provide authentication and en-

Table 5: Top most visited websites.

cryption that is considered strong. However, this is a task that requires a deep and up-to-date understanding on the underlying algorithms in order to make informed decisions about which cipher suites to support. In the course of our lab experiments, all participants who came to this point during the configuration assignment were aware of the fact that they had to manually select cipher suites to secure the communication. The decision making process was exclusively based on search results and suggestions from online resources without questioning. Some participants also referred to recently published blog posts where they read about the disadvantages of a certain algorithm. This implies that the quality of the used information source is crucial for the overall security of the configuration as our participants lacked profound knowledge and thus had to trust their source of information. Table 2 shows how the selected cipher suites impact the quality of the configuration.

Strict HTTPS. After finishing an initial valid configuration, most participants enforced strict HTTPS as a first step of the hardening phase. Some were annoyed by the fact that HTTPS does not immediately replace HTTP as soon as it is available. Most participants were initially confused when they tested their configuration via the browser and were redirected via http when they entered the URL without the http(s):// prefix. They then spent a significant amount of time to configure the virtual host and the respective ports correctly, mostly also due to misleading or incomplete information from online sources.

Multiple configuration files. All but six participants said that they found the configuration file structure confusing, regardless of their prior experience with Apache. P14 found it particularly challenging to find the right configuration files. According to the think-aloud protocol, this was the main challenge that in the end resulted in an invalid configuration. Several participants copied and pasted entries between different configuration files or had double entries, e.g., for *SSLEngineOn*. Nine participants also struggled with loading the modules, e.g., P18 did not understand where to load the modules in the configuration. Many participants were also not aware of where and how to create a new virtual host which listens on 443. P23, for example, did not understand the differences between the http.conf and apache.conf which distracted him/her from the TLS-specific tasks and security-critical decisions.

Finding the right balance between security and compatibility. We observed that the majority of our participants struggled with the definition of a *secure* configuration. In our assignment we just stated that the configuration should be *as secure as possible to withstand an audit*, without specifying any key properties. Hence, the participants themselves had to make the decisions. About 15 participants expressed concerns regarding compatibility when configuring SSL/TLS versions and cipher suites. A majority of them, however, decided in favor of a securer option, e.g., disabling all TLS versions $<$ TLS v1.1 and thus refraining from supporting older versions of IE.

4.4 Impact of Prior Experience with TLS

As shown in Table 1 a significant proportion of the participant pool has already administered or is currently administering a server and 17 participants have configured TLS before. Regardless of our relatively small sample which is due to the qualitative nature of our study, we provide statistical significance of the interplay between prior experience and the resulting security grade from our study. Table 6 shows the cumulative amount of participants that achieved a certain security grade during the study with respect to their prior experience. None of the participants who did not manage to provide a valid configuration in the given time had prior experience with server administration in a corporate environment. However, Table 6 shows that the majority of experienced users was not able to provide an A grade configuration. A significance test with $\chi^2(7.9982, 3) = 0.046$ provides evidence to suggest that there is an association between prior experience with configuring TLS and the

grade of a participant's TLS configuration from the lab study. We could not identify dependence between prior employment as system administrator and the SSL Test grade based on the configuration from the lab study with $\chi^2(6.7667,3) = 0.07$.

4.5 Perceptions of Usability

After the lab experiments, the study participants filled out a short online questionnaire and reported reflections on the assignment. 18 participants reported that they thought they finished the assignment completely, while nine thought that there were still some configuration steps missing. One participant was not sure about whether or not he/she finished the task. While ten participants perceived the assigned task as difficult and three as very difficult, only four participants thought that it was easy and one that it was very easy. Twelve participants rated the difficulty as neutral.

We also asked our participants what they think are the most severe usability pitfalls in the deployment process. In the following, we provide a respective list. Most frequently mentioned were lack of best practice tutorials (19), followed by misleading terminology (15) and weak default configurations (12).

Lack of best practice tutorials. According to our participants, it was difficult to determine a best practice on how to deploy TLS. Our participants reported that they came across outdated or simply wrong information in online tutorials. 13 participants also mentioned that most tutorials were not generic, but still not specific enough to apply them to the system given in the assignment.

Misleading terminology and error messages. Especially with respect to interactions with the CA, participants expressed confusion about the terminology. Some accidentally uploaded a self-signed certificate instead of a CSR and found the file endings difficult to handle and to distinguish, e.g., *.key*, *.pem*, *.crt*.

Weak default configuration. Eight participants explicitly criticized the high effort necessary to harden the configuration, as too many cipher suites are enabled by default. Also, they criticized that the selection of cipher suites is a time-consuming task that requires profound background knowledge in order to make an informed decision and that bad decisions yield major security vulnerabilities. One participant also suggested a simplified configuration option including a two- or three-way variable to disable certain cipher suites (e.g., tinfoil hat vs. maximum compatibility). Four participants also stated that they would prefer if web servers had TLS configured by default.

"It seems that there is already a certificate called snakeoil, why can't I use this one?" (P7)

Confusing config file structure. During the configuration process, many participants perceived the Apache config file structure as confusing and experienced it as a severe source for errors. We also observed that some participants had simple copy/paste errors in their config files which highly distracted them from the actual main task.

"There are multiple config files in /etc/apache2, how and where do I have to load modules?" (P18)

"Why is there a snakeoil certificate in the config file?" (P22)

Complex workflow. Six participants explicitly stated that the workflow itself is too complex due to the different approaches and branches that can be taken during the configuration process as well as the dependencies of the subtasks. Three participants stated these factors hindered them in finding the source of an error afterwards.

"The configuration process is fiddly and one has to google tons of pages to get it right. Even then one cannot be sure to have a good configuration because SSL vulnerabilities are discovered almost on a regular basis." (P9)

Too much background knowledge required. Many participants expressed their concern about the high amount of background knowledge required to successfully configure TLS in a secure way. Also, the fact that a TLS configuration must be well maintained and frequently updated requires the person in charge to be informed about the latest TLS attacks and other vulnerabilities which our participants considered infeasible in practice.

Confusing permissions. Five participants also stated that they found it hard to choose the correct location and permissions for the certificate and private key.

5 Expert Interviews

In order to address ecological validity, we conducted additional expert interviews with security consultants and auditors about their experiences with insecure TLS configurations. In this section, we describe the interview

Experience	A	B	C	not valid
Configured TLS before?	5	11	1	0
Worked as admin in the past	4	4	0	0
Administering company server	1	3	1	0
Private server	4	9	0	2

Table 6: Prior experience with TLS deployment and server administration.

methodology and results of these expert interviews that were conducted in April 2016. The interview guideline can be found in Appendix A.

5.1 Recruitment and Interview Procedure

The participants were recruited at a security conference in Germany with participants from both academia and industry and via emails to regional security consulting companies. The requirements for participation currently work as a security consultant or auditor and to have at least 2 years of prior experience in auditing web services. The expert interviews were conducted as semi-structured interviews with 7 security experts from well-respected security consulting firms in the German-speaking region. The experts were familiar with TLS misconfigurations and frequently encountered misconceptions on how to combat the trade-off between compatibility and security. The interview segments were coded using iterative coding.

5.2 Results

Our results show that auditors commonly agree that poor usability and too complex workflows and server configurations result in weak TLS configurations. They also mentioned that the deployment process must be simplified and especially the default configuration should favor security. In the following, we discuss their responses in detail. Six interview participants were male, one was female. The average number of months spent as a penetration tester or auditor was 53.2. Two participants work in small companies with less than 10 employees, the remaining participants were employed in companies with more than 10 but less than 100 employees.

Auditing TLS configurations. All expert interview participants reported to focus on the following configuration characteristics during audits: activated TLS/SSL version, activated cipher suites, if the certificate is recognized by commonly used web browsers, whether HSTS is configured and whether public key pinning is activated. E3 and E7 also highlighted that they particularly pay attention if recently discovered attacks are mitigated. E6 and E7 also said that in addition to automated tools, they prefer to evaluate the server configuration directly, if it is accessible.
All seven interview participants use Qualy's SSL Test as the de-facto standard to evaluate public domains. They also use selected Nessus modules[3] and OpenVAS[4] for internal sites. E2, E4 and E6 also reported to use NMap [30].

Configuration mistakes in the wild. According to the interview participants, the main concern when deploying TLS is compatibility. Our interviewees, however, also mentioned that in most cases the compatibility challenge is just a mock argument which is often used as an excuse and not fully elaborated by the responsible employees. Compatibility is a challenge for publicly available sites where almost any client may want to access. However, it is a rather easy-to-solve problem for services that are only accessed internally, hence the set of potentially accessing clients is well known. Also, backward compatibility with older client versions (i.e., <IE7) may not be desired for a variety of reasons beyond TLS and will only affect a minority of clients. However, E1 and E3 also reported that finding the best fit between security and compatibility is hard even for security experts and often arguable. Five of the interviewed auditors also reported that they often find self-signed certificates which do not fulfil the intended purpose. E1, E2, E3 and E7 mentioned that they often encounter weak default TLS configurations with poor ciphers and no additional security measures (e.g., HSTS).

Two auditors mentioned that in the course of looking at TLS configurations for many years, they have never encountered HTTP public key pinning during an audit. Also, one interview participant reported that TLS deployment is not sufficiently streamlined in companies. According to them, most companies have multiple servers with varying configurations and each one is maintained and updated separately.

E2 also highlights that the ideal TLS configuration has changed frequently in the last two years or algo-

[3] https://www.tenable.com/products/nessus-vulnerability-scanner

[4] http://www.openvas.org/

rithms have been deprecated which implies a significant overhead for administrators to keep their configurations up to date. E2, E4 and E7 also reported that companies do not fully make use of the online sources available, such as using Qualy's SSL test for public domains.

"In most cases backward compatibility is the show-stopper regarding proper TLS configurations." (E3)

Concerns in the wild. We also asked our interviewees about the concerns that admins, CSOs and other persons in charge have regarding TLS. Our experts agreed that especially administrators are aware that configuring TLS is a sensitive task during which several things can go wrong. However, lack of time seems to be a major issue and administrators often do not have the resources to get a deep understanding on the fundamentals. To our surprise, E4 and E7 reported that they frequently encounter responsible persons that have little or no experience with security protocols such as TLS. All interview participants reported that in the course of security audits, they also frequently find weak default configurations along with little awareness regarding the weakness of such configurations and how they could easily be hardened. E7 highlighted that responsible persons even report that they are "afraid of using crypto". As an example (described in 5.2), E1 explicitly mentioned HSTS which is easy to deploy and has no impact on compatibility, but is rarely used in practice.

Also, compatibility still remains a key concern as lack of compatibility often leads to overloaded help lines, as reported by E1, E6 and E7. Also, the risk of MITM attacks is often underestimated and companies do not perceive themselves as targets of such attacks. E7 cited an administrator from an SME saying: "Our configuration supports basic encryption, so this should be more than enough... and clearly is better than no encryption." As E2 reports, companies are often concerned about introducing encryption due to the additional performance overhead which is in their opinion not worth the effort.

Suggested usability improvements. A common opinion of all interviewees was that the default server configurations must be improved by simplifications and default security options. They said that server configurations should be secure by default, i.e., that TLS should be enabled by default and hence must be explicitly disabled if necessary. E1 highlighted that Apache has a weak default configuration for compatibility reasons and mentioned the Caddy web server[5] as a good and usable example. Caddy comes with a TLS configuration by default and uses *Let's Encrypt* to get certificates. Also, according to E1 the by default activated cipher suites are a good compromise, and even OCSP stapling and HSTS are deployed by default. Also, the Caddy web server automatically renews certificates. E1 highlights that configuration directives must be simplified to yield strong configurations and that Caddy web server is a good example for this paradigm. E1 also suggests that compatibility flags which administrators can use to configure cipher suites would be much more helpful than letting them deal with cipher suites directly.

Regarding the deployment process in larger enterprises that maintain multiple servers, E1 proposes to create a strong sample configuration on a test server and to then deploy them on all servers. This potentially helps to avoid outdated configurations, as the updating process is simplified and the person in charge is aware of the TLS configuration on all devices by knowing the essentials of the sample configuration.

E1 also suggests to deploy everything that does not result in lower compatibility, i.e., OCSP stapling which is commonly ignored by clients who do not understand the according header. While public key pinning is rather difficult to fully deploy, it can easily be used in report-only mode and thus enables to detect MITM attacks. E1 highlights that these additional functionalities are beneficial for security but rarely encountered in the wild.

E3 also suggests that HTTPS should fully replace HTTP to solve security problems. E3 also thinks that HTTP has no fundamental benefit over HTTPS with TLS. E3 shifts the responsibility from servers to clients and stated that clients should be frequently updated to support the respective ciphers. Furthermore, E3 argues that the concept behind CAs also has its flaws, i.e., lack of certificate transparency, certificate revocation and lawful interception on the CA's side without the end user's consent. She/he also claims that browsers generally trust a high number of CAs with varying trustworthiness.

E7 highlighted the need for professional education and that "doing it right" requires experienced professionals that keep track of the ongoing changes. E7 also suggested that there is a high demand for better configuration guides and easier-to-use default configurations to compensate the lack of know-how of the persons in charge as well as to make it easier for everyone to configure TLS in a secure yet compatible way. Also, this interview participant said that companies should have policies regarding encryption and compatibility to make it easier for administrators to choose the right configuration.

6 Discussion

While related work already showed that TLS configurations in the wild are often weak and thus do not suf-

[5] `https://caddyserver.com/`

ficiently protect Internet users from MITM attacks, our work explores the reasons for this. In comparison to most related user studies, we focus on the expert user role instead of the non-expert end user who is mostly unaware of potential risks and clicks through warnings which are often hard to understand and do not sufficiently communicate security risks.

We were surprised by the helplessness that we encountered during the lab study. The security auditors who participated in our expert interviews draw a similar picture of the administrators' reaction when confronted with the results of an audit which strengthens the ecological validity of our results.

For our sample, we selected top students that successfully completed security courses and proved their technical knowledge in an initial knowledge survey. 17 out of 28 participants were already experienced with managing servers in a corporate environment. We also compare the technical knowledge of our participants with those from Fahl et al. [19] who surveyed 755 webmasters. Their results suggest that webmasters often lack of a detailed understanding of the SSL security features and that they are not sufficiently educated. Fahl et al. [19] also found that real world webmasters heavily rely on online sources to compensate for their lack of knowledge.

Based on this comparison and the results from our expert interviews we are confident that our sample is suited to explore usability challenges and reflects the diverse knowledge of administrators in the wild.

Our results suggest that poor usability is a key issue and by far the main reason for weak configurations. Through both our lab study and the expert interviews we found that even professionals lack the knowledge regarding the underlying cryptographic fundamentals such as cipher suites and even basic concepts like the role of certificates. This result shows that there is a high demand for better default configurations and/or tool support to prevent administrators from dealing with mechanisms they cannot fully understand.

As stated in Section 4.1, we based our evaluation criteria on Qualy's SSL Test to evaluate the configurations from our lab study. Although these metrics are considered a good benchmark to assess TLS configuration, not all of them are feasible for every real-world scenario. For example, HPKP in theory is a mechanism to mitigate MITM attacks with fraudulent certificates but poses additional risks and challenges in practice as key management for HPKP is hard to manage for long tail websites. Possible solutions are to pin the CA certificate and to use a backup key or to use CAA (Certification Authority Authorization) DNS records to allow domain owners to specify which CAs are allowed to issue certificates for the respective domain. During our lab experiments, two participants started deploying HPKP. However, from the data we collected during the experiments, it is unlcear to what extent the participants who wanted to deploy HPKP were aware of the implied key management challenges.

In December 2015, the initiative *Let's Encrypt* released its non-profit CA that provides free domain-validated X.509 certificates and software to enable installation and maintenance of these certificates was launched to make it easier for administrators to deploy TLS. Since then, *Let's Encrypt* changed the TLS market signifcantly. It issued over 27 million active certificates for over 12 million registered domains (Feb. 2017). It is often called the largest CA, but is still not clear how much this influenced the TLS ecosystem, since many certificates are used for less popular web sites [4, 5]. However, *Let's Encrypt* is not directly improving TLS configurations. It seems that the prime goal, the process of certificate issuance was improved, but the full TLS configuration is still a manual process. Some plugins (e.g., for Apache integration) automatically set some TLS configuration parameters (e.g., protocol version, cipher suites) to a balanced configuration in terms of security and backward compatibility. However, it does not include other parameters like HSTS or the DH prime configuration. Therefore, configurations with certificates issued by Let's Encrypt are not generically comparable with other configurations, but it is clearly an opportunity to also improve and automate the configuration process in the future. Hence, *Let's Encrypt* does not entirely automate the workflow as presented in Figure 1. In fact it aimes to ease the creation of a CSR and the interaction with the CA. Regardless of these substantial improvements, *Let's Encrypt* needs to be configured at least once. While there are dedicated tools available (e.g. ACME) it remains to show to what extent the initial effort in configuring an Apache web server actually decreases.

As mentioned by our security experts, there are already servers with a focus on better security: they let their users make configurations less secure if desired instead of providing no security by default and thus forcing users to deploy security themselves. Also, they highlight the demand for easier user interfaces for configuration purposes which corresponds to the findings of Fahl et al. [19]. Our results also suggest that expert users are often unable to decide on the appropriate level of security, which highlights the need for cross-organizational guidelines and policies.

As creating a basic TLS configuration also involves complex decisions (such as choosing the appropriate key length) it is difficult for administrators to maintain or correct errors and wrong decisions.

Both the results from the lab study and the expert interviews highlight that the complex deployment process should be simplified, and that the difference between a basic correct configuration and a secure one should not

be too broad. Hence we suggest that newly designed servers and/or supportive tools should merge the setup and the hardening phase resulting in a best-case working configuration if all steps are completed – which can then be downgraded if necessary.

6.1 Limitations

A severe limitation of our lab study is that we only looked at the initial deployment process and excluded long-term maintenance effects, such as certificate renewal and the administrators' reactions to newly discovered vulnerabilities. The main reason is that it is difficult to reliably study long-term effects in the lab. In the future, we plan to conduct an additional case study in a corporate environment to observe long-term effects over a number of years. Also, as our study was performed in the lab, the participants did not have a deep background of the notional company they were administrating for the study. Our primary goal was to recruit participants who were fully employed as system administrators, but unfortunately did not manage to get enough responses respectively commitments for participation. Therefore, we chose to recruit participants among our computer science students. To overcome this bias, we selected top students that successfully completed security courses with good grades and completed an initial assessment test. As our results suggest, many of them were already experienced with managing servers and some had even worked as system administrators in companies and other organizations. We therefore believe that our data is suited to explore usability challenges. Our expert interviews with security auditors underline the ecological validity of the results from our lab study and suggest that configurations found in the wild are even less secure than those generated by our participants during the lab study. Another limitation of our study is that we instructed the participants to deploy the securest possible configuration. This goal could be unrealistic in a corporate environment where compatibility is a major concern. Therefore our results represent an upper bound for security.

7 Ethical Considerations

Our university located in central Europe unfortunately does not have an ethics board but has a set of guidelines that we followed in our research. Also, we aligned the methodology for our user study in related studies with similar ethical challenges [35, 40, 44].

A fundamental requirement of our university's ethics guidelines is to preserve the participants' privacy and to limit the collection of person-related data as far as possible. Therefore, every study participant was assigned an ID which was used throughout the experiment and for the online questionnaire. All participants signed consent forms prior to participating in our study. The consent form explained the goal of our research, what we expected from them and how the collected data was used. The signed consent forms were stored separately and did not contain the subsequently assigned IDs to make them unlinkable to their real names.

We refrained from video-recording the participants during the study as the participants from our pre-study reported that the awareness of being filmed made them feel uncomfortable and had a negative impact on their performance even if the camera was positioned in a non-obtrusive way.

8 Conclusion

We conducted a lab study with 28 participants to explore usability challenges in the TLS deployment process that lead to insecure configurations. In comparison to related work, we contributed a study that focuses on expert users, i.e., administrators who are in charge of securing servers. Additionally, we conducted seven expert interviews with penetration testers and security auditors who frequently encounter poorly secured servers during security audits.

We found that the TLS deployment process consists of multiple critical steps which, if not done correctly, lead to insecure communications and put Internet users at risk for MITM attacks. Furthermore, our results suggest that even computer scientists who are educated in terms of privacy-enhancing protocols and information security need additional support to make informed security decisions and lack an in-depth understanding of the underlying cryptographic fundamentals. Expert users also struggle with the configuration file structure of Apache web servers and have to put a lot of additional effort into securing default configurations. Our expert interviews underline the ecological validity of the results from our lab study and shed light on the weaknesses of TLS configurations found in the wild. According to our security auditors, the main concern regarding TLS is interoperability. They also highlighted that server infrastructures are often configured with poor defaults and badly maintained and are therefore not up-to-date.

Acknowledgements

We would like to thank the reviewers for their constructive feedback. We would also like to thank our shepherd Serge Egelman for his suggestions that were very helpful in improving our paper. This research was partially funded by COMET K1 and by grant 846028 (TLSiP) from the Austrian Research Promotion Agency (FFG).

A Appendix

Recruitment Questionnaire

- Which of the following directives is used to host two different websites (www.website1.com and www.website2.com) within the same Apache webserver?
  - NamedHost
  - WebRoot
  - VirtualHost
  - ServerRoot
- Certificate files are usualy located at?
  - /root/ssl/certs
  - /etc/ssl/certs
  - /tmp/certs
  - /var/www/static/certs
- CSR means ...
  - common-name signing request
  - comodo signing request
  - certificate signing request
  - cross-site request
- Which is the best file permission for your private keys on a Linux system?
  - 0777
  - 0300
  - 0664
  - 0600
- Which command is used to find out the currently used IPs?
  - ifconfig
  - netstat
  - ipconfig
  - iptables
- Which files can the user www-data read?
  - -rw——- root root filname
  - -rw——- www www-data filename
  - -rwxrwxrwx root root filename
  - -rw-rw—- root www-data filename
- Which command is used to switch the user in Linux?
  - sudo
  - su
  - root
  - switchuser
- A symlink is created with which command?
  - ls -s TARGET LINK_NAME
  - symlink TARGET LINK_NAME
  - ln -s TARGET LINK_NAME
  - ln TARGET LINK_NAME
- TLS uses ...
  - symmetric cryptography
  - asymmetric cryptography
  - pem/der certificates
  - X.509
- TLS is ...
  - computationally very expensive
  - complex to configure correctly
  - originally invented by Facebook
  - easy to buy using cloud services
- Which of the following commands is used to save a file in vim (Vi Improved)?
  - Strg + S
  - Strg + X
  - Esc; :s
  - Esc; :w
- Which commands restarts the webserver?
  - sudo service apache2 restart
  - sudo /etc/init.d/apache2 restart
  - sudo service webserver restart
  - sudo service IIS restart
- The webserver has to have access to?
  - The private key used for TLS
  - The certificate used for TLS
  - The certificate authority private key for TLS
  - The certificate signing request used for TLS
- Where are HTML files served by the Apache Webserver located after default installation?
  - /usr/share/nginx/www
  - /etc/www
  - /var/www
  - /home/www

Lab Study Assignment

You are the system administrator at a SME (small and medium-sized enterprise). Your company runs a web portal and your boss instructed you to secure the communication by using TLS. Unfortunately you only have a very limited amount of time because your company will also soon be under security audit. This is why you should start right away deploying TLS. Make your configuration as secure as possible.

PETS Certificate Authority

Please upload your Certificate Signing Request (CSR) in PEM format

Choose CSR to sign:

Choose File No file chosen

Submit and Sign CSR

Additional:

CA Root Certificate (PEM) (Text)

CA Intermediate Certificate (PEM) (Text)

CA Root+Intermediate Certificate Chain (PEM) (Text)

Figure 2: Screenshot of the CA we implemented for the lab experiments.

System Configuration

- The company's web server (Apache2) is currently found at *http://web.local* on Port 80. There is only HTTP activated. No TLS configuration is made so far.
- You can connect to the web server with the command *ssh web* The username is *pi*, the password is *raspberry*. There is no root password, so you can just use *sudo* to execute commans as root user.
- You will have to use a Certificate Authority. You find a CA at *https://ca.local* Your client's Firefox trusts this CA called *TLS Userstudy Root CA*. You can test the certificate validation with this browser. The DNS names of both servers are locally configured at your client.

Post Lab Study Questionnaire

Demgraphics

- Participant ID (assigned prior to the lab experiments)
- Age
- Gender
- Months of industry experience

Experience with TLS

- Are you currently in charge of a web server? (Yes, I'm currently administrating a company web server./ Yes, I'm currently administrating a private web server./ Yes, I'm currently administrating at a profit/non-profit association. /No.)
- Have you ever installed and configured SSL/TLS before? (yes/no)
- Have you ever worked as a system administrator before? (yes/no)

Reflections on the Study Task

- Did you finish the TLS installation in the given time? (yes, no, I'm not sure)
- If you didn't finish the TLS installation in the given time, which steps are still missing to secure the communication? (open text)
- How difficult did you find TLS deployment? (Likert scale: very easy to very difficult)
- What did you find particularly difficult? (open text)
- What do you think are the key usability pitfalls of TLS deployment? (open text)
- What would you recommend a system administrator who has to deploy TLS? (open text)
- Is there anything else you would like to let us know? (open text)

Interview Questions - Expert Interviews

- As an auditor, how do you usually proceed to evaluate the security of a TLS configuration?
- What are the main vulnerabilities/configuration mistakes that you encounter as an auditor?
- What botheres admins/CSOs the most regarding TLS?
- What are the most critical steps in TLS deployment?
- How should the deployment process be improved?
- What piece of advice would you generally give to anyone in charge of securing communication over HTTPS?

Detailed Evaluation Criteria

Grade The overall grade for the configuration with a valid certificate. The grade is calculated based on the grading scheme from [2]. The score is based on individual ratings for protocol support (30%), key exchange (30%) and cipher strength (40%). The grade is issued based on the following cumulative scores:

- A: score $>=$ 80
- B: score $>=$ 65
- C: score $>=$ 50
- D: score $>=$ 35
- E: score $>=$ 20
- F: score $<$ 20

Errors/warnings/highlights. This refers to remarks that impacted the overall grading. The detailed description of these justifications is shown in Table 3.

Cipher strength score. This is represented by a number between 0 and 100, with 100 being the best possible. The cipher strength score contributes 40% to the overall grade. As weak symmetric ciphers can be easily broken by attackers, it is essential to the overall configuration that strong ciphers are used. SSL Labs evaluate ciphers based on an average cipher between the strongest and weakest. The scores are rated as follows:
0 bits (no encryption): 0
$<$ 128 bits (e.g., 40, 56): 20
$<$ 256 bits (e.g., 128, 168): 80
$>=$ 256: 100

Key exchange score. As described in [2], the key exchange phase serves two functions: (1) authentication to verify the identity of the other party and (2) safe generation and exchange of secret keys to be used for the remaining session. Also, exportable key exchanges where only a part of the key is exchanged can make the session keys easier to compromise. Key exchange without authentication is vulnerable to MITM attacks and allows an attacker to gain access to the communication channel. Furthermore, the strength of the server's private key is crucial. The stronger it is, the more difficult it is to break the key exchange phase. Some servers use the private key just for authentication and not for the key exchange mechanism. Popular algorithms are the Diffie-Hellman key exchange (DHE) and its elliptic curve version (ECDHE). As in [2], the rating is calculated as follows:
Weak key or anonymous key exchange (e.g., Anonymous Diffie-Hellman): 0
Key or DH parameter strength $<$ 512 bits: 20
Exportable key exchange limited to 512 bits: 40
Key or DH parameter strength $<$ 1024 bits: 40
Key or DH parameter strength $<$ 2048 bits: 80
Key or DH parameter strength $<$ 4096 bits: 90
Key or DH parameter strength $>=$ 4096 bits: 100

Protocol support score [2]. Several (older) versions of TLS have known weaknesses or are vulnerable to well-known attacks. The configuration is graded as follows with respect to the activated TLS versions. Again, if multiple versions are supported, the average between the best and worst protocol score is considered.
SSL 2.0: 0
SSL 3.0: 80
TLS 1.0: 90
TLS 1.1: 95
TLS 1.2: 100

Common name. This refers to the common name field specified in the CSR which specifies a FQDN (and respective subdomains if applicable) the certificate is issued for.

Key size. This refers to the size of the server's key pair.

Certificate chain length. This refers to the length of the certificate chain, including the server's certificate and certificates of intermediate CAs, and the certificate of a root CA trusted by all parties in the chain. Every intermediate CA in the chain holds a certificate issued by the CA one level above it in the trust hierarchy. In our example, the ideal length is 3.

Used provided CA to sign. In order to remove the bias from different CAs with varying usability, we implemented our own CA and provided the link to this CA in the assignment. Two participants did not use this CA and generated self-signed certificates instead.

Encrypted private key indicates whether the server's private key was encrypted by the study participant.

SSL 2 – TLS 1.2 indicates which protocol versions are supported.

RC4 support. To date, RC4 is considered weak and should therefore not be supported, unless required for compatibility reasons as found in [10].

Vulnerable to POODLE indicates whether the configuration is vulnerable to POODLE [32].

Forward secrecy indicates whether the configuration supports ciphers with forward secrecy (e.g., ECDHE).

HSTS indicates whether *HTTP Strict Transport Security* is configured. The security benefit of HSTS is that it forces secure communication with websites that use it by automatically converting all plain text and disabling click-through certificate warnings. If a client does not support HSTS, it simply ignores the header. Hence, activating HSTS enhances security with minimal effort without impact on compatibility.

HPKP indicates whether *Public Key Pinning* is used, which is a useful feature to prevent attacks and making the public aware of them.

Abstract

The MPEG-DASH streaming video standard contains an information leak: even if the stream is encrypted, the segmentation prescribed by the standard causes content-dependent packet bursts. We show that many video streams are uniquely characterized by their burst patterns, and classifiers based on convolutional neural networks can accurately identify these patterns given very coarse network measurements. We demonstrate that this attack can be performed even by a Web attacker who does not directly observe the stream, e.g., a JavaScript ad confined in a Web browser on a nearby machine.

1 Introduction

Everything has a fingerprint, and so do encrypted video streams. Transport-layer encryption hides the content but not the network characteristics such as the number of bits transmitted per second. Video streams are known to be bursty [2, 32, 42]. If their traffic patterns are correlated with content, an adversary who can measure them may be able to identify the video being streamed.

There have been several attempts to use traffic analysis to identify encrypted streamed content [1, 11, 43, 44, 46]. Existing techniques, however, generate many false positives, make "closed-world" assumptions (i.e., the adversary must know in advance that the streamed video belongs to a small known set), or are not robust to noise in the network or the adversary's measurements.

Further, prior work assumes that the adversary can directly observe the encrypted video stream either at the network layer (e.g., a malicious Wi-Fi access point) [11] or physical layer (e.g., a Wi-Fi sniffer) [43, 46], or else that the adversary's virtual machine is co-located with the user's virtual machine [1]. These threat models do not include Web and mobile attackers who can remotely execute some confined code on the user's machine (e.g., a malicious JavaScript ad within the browser) but cannot directly observe the encrypted stream.

Our contributions. First, we analyze the root cause of the bursty, on-off patterns exhibited by encrypted video streams. The MPEG-DASH streaming standard (1) creates video segments whose size varies due to variable-rate encoding, and (2) prescribes that clients request content at segment granularity. We demonstrate that packet bursts in encrypted streams correspond to segment requests from the client and that burst sizes are highly correlated with the sizes of the underlying segments.

Second, we demonstrate that this leak is a *fingerprint* for about 20% of YouTube videos because their burst patterns are highly distinct. The adversary can measure video fingerprints on his own network and then use them to recognize videos streamed on the target network. We also argue that if the streamed video does not belong to the set known to the adversary, it will not be mistaken for one of the known videos. This ensures a high Bayesian detection rate: if the adversary identifies a streamed video, then this is likely not a false positive.

Third, we develop a new video identification methodology based on convolutional neural networks and evaluate it on video titles streamed by YouTube, Netflix, Amazon, and Vimeo. Our YouTube detector has 0 false positives with 0.988 recall, while the Netflix detector has a false positive rate of 0.0005 with 0.93 recall. In concurrent independent work, Reed and Kranch achieved comparable results for identifying streamed Netflix videos using direct network observations [44] (see Section 11).

Fourth, we demonstrate that video identification based on burst patterns does not require direct access to the stream. Our attack can be performed by a remote attacker who serves JavaScript code (e.g., a malicious Web ad) running under the confinement of the browser's same origin policy, possibly on a different device. For example, if the user is watching Netflix on his TV using a Roku streaming device, his content may be identified by the JavaScript executing on a PC on the same local network. The attack code saturates a shared network link carrying the targeted video stream and uses the result-

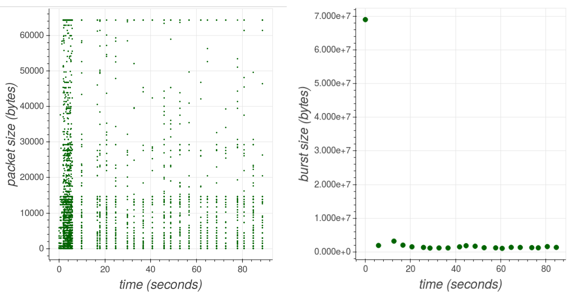

Figure 2.1: Features of a Wireshark capture of Episode 3 of *Mad Men*. The left-hand figure shows packet sizes along the time axis (packet sizes may be larger than Ethernet MTU because of TCP offloading [53])—observe the pattern of buffering followed by the on/off steady state. The right-hand figure shows the size of bursts; the first, largest burst is the size of the buffer.

ing contention to obtain coarse estimates of the stream's traffic rates and identify the video. This attacker is much weaker than malicious ISPs and Wi-Fi access points typically considered in the traffic analysis literature.

In summary, we (1) explain the root causes of burst patterns in encrypted video streams, (2) show how to exploit these patterns for video identification in an "open-world" setting, (3) develop and evaluate a noise-tolerant identification methodology based on deep learning, and (4) demonstrate how a remote attacker without direct observations of the network can identify streamed videos.

2 Information Leak in Video Streams

Video streams are bursty. Video streaming traffic is characterized by an initial short period of buffering, followed by the steady state of alternating "On" (short bursts of packets) and "Off" periods—see Figure 2.1. This pattern has been observed for a wide variety of services, devices, clients, and locations [2, 32, 42].

To avoid creating unnecessary traffic, streaming clients typically throttle their content downloads: after the initial buffering, they download at between 1X and 2X the content presentation speed. Clients maintain a target buffer size proportional to presentation time and request downloads when the buffer is below this target.

Streamed video content is typically segmented at the application layer. Even if packets are encrypted at the transport layer (e.g., using TLS), their sizes and times of arrival—and, consequently, the sizes of packet bursts and inter-burst intervals—are visible to anyone watching the network. This is a repeated theme in the traffic-analysis literature [8, 12, 46]. If the observable traffic features are correlated with application-layer segmentation, they can leak information about the content of the stream.

MPEG-DASH standard. Modern video streaming services have broadly adopted [34, 59] the MPEG-DASH standard [49, 52] for Dynamic Adaptive Streaming over HTTP (DASH, in short). DASH aims to maximize several measures of quality of experience (QoE) while supporting interoperability with popular streaming technologies. DASH specifies a client-server interface for stream fetching that is independent of the content's bitrate and quality. It does not prescribe any particular fetching discipline, encoding of content, or its presentation. DASH uses TLS for content confidentiality. Content may be additionally encrypted for DRM purposes, but this does not change its network characteristics.

Bursty, on/off behavior of video streams predates DASH, but DASH has effectively standardized it. DASH divides video content into segments based on presentation time. The content is stored in segment-files on the server. Each file contains a particular encoding of one segment. When a streaming session is initiated, the server sends to the client a manifest referencing the time segments and the available encodings. To obtain the content, the client submits requests for individual segments. The client may request segment-files of any available encoding depending on the presentation considerations and dynamic evaluation of network conditions.

DASH standardizes a leak. Video compression and encoding algorithms exploit the fact that different video scenes contain different amounts of perceptually meaningful information. All popular streaming services use variable-bitrate (VBR) encoding, where the bitrate of an encoded video varies with its content. Therefore, DASH segments of roughly the same duration (in video-presentation seconds) have very different sizes (in bytes).

DASH video is always streamed in segment-sized chunks. Furthermore, a client requests a new segment when its buffer is just below the target value, and the entire segment finishes downloading long before the client requests another one. Therefore, in a steady-state, on/off stream, burst sizes are correlated with the on-disk segment sizes. The latter sizes, in turn, leak information about the encoded content due to variable-rate encoding. We conjecture that a suffix of the vector of segment sizes, arranged in the order they are fetched from the server (which corresponds to the order of presentation), can be estimated from the observable characteristics of encrypted streaming traffic, up to a small error induced by the varying overheads of lower network layers.

Example. Action scenes, where a lot happens on the screen, are typically encoded with a higher bitrate than slower scenes. Figure 2.2 shows how the bitrate of an excerpt from the "Iguana vs. Snakes" video [40] in the "Planet Earth" series changes over time (based on an MP4 file downloaded from YouTube). The video starts with an intense chase scene as the iguana is escaping from snakes. In the last 15 seconds, the iguana reaches

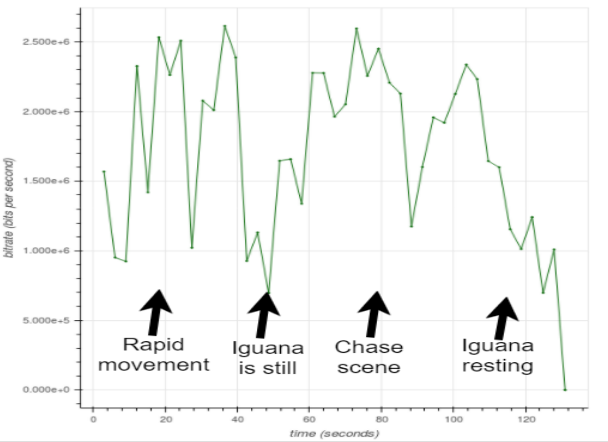

Figure 2.2: Bitrate of the “Iguana vs. Snakes” video.

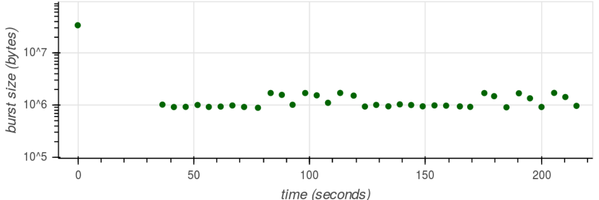

Figure 2.3: Burst sizes when streaming a video with alternating high- and low-bitrate periods. The first, largest burst is the size of the client’s buffer.

higher ground and rests next to another friendly iguana.

To demonstrate this effect more systematically, we created a 45-second “low action” scene by concatenating three copies of the 15-second footage of the resting iguana, and a 45-second “high action” scene by concatenating 15-second footage from the height of the chase. We then repeatedly alternated these scenes to craft an artificial 30-minute video, which we uploaded to YouTube (as a private video). We played this video in a Chrome browser configured with an HTTPS proxy. One of the first HTTPS responses from the YouTube server is an XML Media Presentation Description (MPD), which describes MPEG-DASH segmentation into 5-second segments. The MPD specifies the audio encoding (135 Kilobits per second) and five video encoding options corresponding to different resolutions: 144, 240, 360, 480, and 720. Subsequent HTTPS responses contain audio and 720p video for the requested segments. Audio and video segment-files corresponding to a given time segment are fetched at roughly the same time, on two respective HTTPS request-response pairs.

As this video is being streamed, we observe the initial buffering period of about 50 seconds, during which segment-files are fetched at a rate higher than their presentation rate. Then the client reaches a steady state and is fetching segment-files exactly every 5 seconds.

We used Wireshark to capture the same traffic encrypted under TLS. Figure 2.3 shows the buffer and burst sizes of the “on” periods in the steady state. During this steady state, when segments are fetched every 5 seconds, burst sizes correspond to the sizes of segment-files. When the segments with an escaping iguana are being fetched, burst size increases. When the segments with a resting iguana are being fetched, it decreases. Because of the way this video was crafted, “low” and “high” action—and the correspondingly high and low burst sizes—alternate every 45 seconds (9 time segments). In a video stream with different content, the pattern would have been different.

3 Attack Scenarios

3.1 Evaluated attack scenarios

On-path network attacker. If the attacker has passive on-path access to the victim’s network traffic at the network (IP) or transport (TCP/UDP) layers, he can directly perform measurements needed for the attack. This includes malicious Wi-Fi access points, proxies, routers, enterprise networks, ISPs, tapped network cables, etc.

Cross-site and cross-device attacker. Coarse measurements of the victim’s stream can also be performed without direct access. The attacker (1) saturates a network link between the victim and the server, and (2) estimates the fluctuations in the amount of congestion, which indirectly reveal the victim’s traffic patterns. This is a special case of timing side channels in schedulers [16, 25] that can be exploited in a variety of attack scenarios.

We focus on remote attackers who can execute JavaScript in the victim’s Web browser: rogue websites, advertisers, analytics services, content distribution networks, etc. Their JavaScript is confined by the same origin policy [51], but it does not prevent the code from using the above timing side channel to measure bursts in a concurrent video stream as long as the stream and the attacker’s own traffic share a network link. The client receiving the stream may be running in a different tab or browser instance on the same machine (a *cross-site* attack) or on a different machine on the same local network (a *cross-device* attack). For example, a smart TV may be streaming a movie while the attacker’s JavaScript is running in a browser on a laptop on the same home network.

3.2 Other attack scenarios

There are several other scenarios where the attacker can indirectly estimate the bitrate and other coarse features of the victim’s video stream.

Wi-Fi sniffer. An attacker who is physically close to the victim’s Wi-Fi network but not connected to it can set the NIC of his PC or (rooted) smartphone to the promiscu-

ous mode and estimate traffic rates by sniffing physical-layer WLAN packets [3, 66]. If the connection is protected by 802.11, the attacker obtains frames in which all data on top of the media access control (MAC) layer (the lower sublayer of the link layer) is encrypted. This attacker learns the direction of the frames (upstream or downstream) and their sizes. He can also discard MAC-layer management frames as identified by their headers.

Unlike an on-path attacker, a Wi-Fi sniffer cannot distinguish (1) session-layer packet retransmissions and the original transmissions, nor (2) multiple TCP/IP flows on the same link. Both factors introduce some noise into the attacker's observations. Under reasonable network conditions, however, there will be few link-layer retransmissions. We show that our JavaScript attack works even with a noisy, flow-insensitive estimate of the burst size (total number of bytes on the wire)—see Section 9.1. The Wi-Fi sniffing attack should perform at least as well.

Fully remote attacker. A remote attacker who has no foothold in the victim's network can use the same network congestion side channel as our JavaScript attack for coarse-grained traffic measurement [15, 17, 23].

Shared-machine attacker. Our off-path attack is *active*: it requires saturating the victim's link in order to estimate his traffic. If the attacker can execute code on the same machine where the victim is streaming video (e.g., run an app on the same smartphone or execute JavaScript in a browser on the same PC), he may be able to estimate traffic via other side channels, such as shared cache or Linux virtual filesystems (sysfs and procfs) [41, 67].

4 Overview of the Attack

Create detectors. For every video file that the attacker wants to identify, he constructs a *detector* algorithm that determines, given measurements of a stream, whether the stream is carrying this video file or not.

In this paper, we use machine-learning models as detectors. To generate labeled training data, the attacker streams the video of interest to his own computer and captures the resulting traffic; he also streams other videos as negative examples. This is repeated multiple times (we used up to 100 samples of each video in our experiments). The required capture length depends on the attacker's vantage point: we used 60 seconds per sample for the Netflix on-path attacker, 5-6 minutes per sample for the JavaScript attacker. In our experiments, we targeted the first minutes of the stream, but this approach works for any sufficiently long section of the video.

Critically, our detectors are **network-agnostic**, because the same segment-files streamed over different networks exhibit the same burst patterns. Therefore, the attacker can train detectors using the data collected on his own network, then use them to identify video streams on another, target network (see Section 7.4).

Since our detectors identify a particular segmented file and not the underlying content, the attacker needs a separate detector for each segmented video he wants to identify. The same content served by different streaming services or different CDN nodes of the same service could have different encodings and segment-files. Moreover, to maximize QoE under varying network conditions, the same content usually has several encodings on the same server (e.g., at different resolutions). YouTube and Netflix support a few dozen encodings [35, 65] but typically no more than 10 per title and device type. The segment-files streamed to the attacker when he is collecting training data must be identical to those streamed to the victim. In practice, we found that Netflix videos streamed on Wi-Fi networks from different ISPs in the same city have identical segmentation (see Section 7.4).

If the attacker's client and network support the highest-quality encoding, he can also get the service to stream lower-quality encodings by downgrading through the interface of the streaming application, or by imposing traffic-shaping and policy limitations on his network.

Apply detectors. In the online phase of the attack, the attacker measures the victim's network traffic using one of the methods from Section 3. Because video traffic is very distinct and can be accurately recognized from coarse-grained features [66], we assume that the attacker can tell approximately when video playback begins.

He then applies his detectors to the collected measurements to identify the streamed video or determine that it is not one of the videos for which he has detectors.

5 Experimental Setup

5.1 Targets and attackers

As the streaming client, we used a Chrome browser running in an Ubuntu 14.04 VM on a Windows host with an Intel i7-3720QM CPU. We also experimented with a Roku Premiere streaming device (see Section 9.3).

The clients were connected to a university campus network with over 105 Mbps upload and download bandwidth (measured using [54]). We refer to it as the "training network." For the cross-network experiments in Section 7.4, we also used a campus Wi-Fi network (10 Mbps) and a home Wi-Fi network from a cable ISP (82 Mbps). We refer to them as "test networks."

To evaluate on-path attacks, we assume that the attacker directly observes the target stream as described in Section 5.2. To evaluate off-path attacks, we assume that the attacker executes his JavaScript client code either in the same browser that is receiving the target stream (the *cross-site* attack), or on a machine on the same local network as the device that is receiving the target stream (the *cross-device* attack). In both cases, the attacker's client

is communicating with a colluding *attack server*.

In both the cross-site and cross-device scenarios, (1) the attacker's client and the recipient of the target stream are behind a congested home router, while (2) the attack server and the streaming server are outside this router, in different Internet locations. Consequently, the target stream and the attacker's client-server communications share a congested network link. In Section 9, we described our setup for these experiments in more detail.

5.2 Data collection

We focused on four popular streaming services: Netflix, YouTube, Amazon, and Vimeo. For our proof-of-concept experiments, we manually chose a few titles from each service: 11 popular TV series, with up to 10 episodes per series, for a total of 100 titles from Netflix; 20 titles from YouTube; and 10 titles each from Amazon and Vimeo. See Appendix C for the list of titles.

Additionally, we crawled YouTube starting from the main page and the front pages of topical channels (e.g., sports and movies) and recursively following recommendation links. The links on the channel front pages are very popular, with over 100k views each. Our crawler thus emulates user behavior: it starts with popular videos and follows YouTube's recommendations. This crawl yielded links to 3,558 videos, to be used in Section 6.

Automated capture. For each title, we spawned a Chrome browser instance and used a service-specific "rewind" procedure so that playback commenced at the beginning of the content. For videos with an initial title sequence, this (non-unique) sequence is downloaded as part of the initial buffering; the bursts in the on-off phase correspond to the segments of unique content.

We captured the network traffic of each streaming session for a certain duration (see below) using Wireshark's `tshark` [60]. For Amazon, Netflix, and Vimeo, the application-layer protocol is TLS; for YouTube, it is either QUIC, or TLS. We will refer to the collected data as *captures* or *captured sessions*.

Occasionally, playback failed because of a Chrome failure or network glitch. The resulting captures contained very few bytes and we discarded them.

Feature extraction. From each capture, we kept only the TCP flow with the greatest amount of bits and extracted the time series of the following *flow attributes*: down/up/all bytes per second (BPS), down/up/all packet per second (PPS), and down/up/all average packet length (PLEN). To create uniformly sized vectors, we aggregated the series into 0.25-second chunks by averaging over 0.25-second intervals.

A *burst* is a sequence of points in a time series (t_i, y_i) such that $t_i - t_{i-1} < I$ for some I (we used $I = 0.5$). When the points correspond to arrival times and packet sizes, bursts are presumably associated with the transmission of higher-level elements such as HTTP responses (see Section 2). A **burst series** is a series where every point corresponds to a burst. The time of the burst is the midpoint between the beginning and the end of the point sequence that forms the burst. The value of the burst is the sum of the values of points in the sequence. We aggregate bursts series by summing into 0.25-second chunks.

Netflix. We streamed each of the 100 titles one by one and captured the first minute of network traffic for each stream. This was repeated 100 times.

For the cross-network experiments, we chose a subset consisting of 5 episodes of "Mad Men" and 5 other titles. For each title in this subset, we captured 20 90-second streaming sessions on the training network and 20 sessions on the test networks.

YouTube. We streamed and captured each of the 20 selected titles 100 times, and each of the 3,558 titles from the automated crawl once. Encoding for YouTube videos varies and bitrate can be less variable than for Netflix; also, the content is sometimes preceded by an ad. Therefore, we took 4.5-minute Wireshark captures and cropped the captured streaming flows to 3 minutes. For 2 of the 20 titles, the ad was so long that the capture of the actual content was shorter than 3 minutes. We discarded these and only used the remaining 18 titles, with 3-minute content captures for each.

We also downloaded actual 720p MP4 file video files (as opposed to their network streams) for the 3,558 titles from the crawl, using the SAVEFROM.NET Web tool. These files were used for measuring the uniqueness of burst patterns, not for identification experiments.

Amazon and Vimeo. We streamed every title 100 times. For Amazon, we captured 90 seconds of each stream. For Vimeo, we noticed that burst patterns are very consistent and strongly identifying, so we only needed to capture 60 seconds per stream.

Storage. After feature extraction, the data saved for our attack experiments totals 1.2GB for Netflix, 2.3GB for YouTube, and about 0.5GB each for Vimeo and Amazon.

6 From Leaks to Fingerprints

In Section 2, we explained how DASH leaks information about the segment sizes of video files. We now show that for 19% of YouTube files, this leak is actually a *fingerprint*: the sequence of segment sizes identifies the video with virtually no false positives.

Modeling the server. We used the Bento4 MPEG-DASH toolset [4] to process our 3,558 YouTube videos (see Section 5.2) for standardized streaming, i.e., divide them into time segments and create the manifests. We opted for 5-second segments, which matches our observations of both Netflix and YouTube and is close to a

recent recommendation [10]. We believe that the encoding parameters of these videos are representative of other YouTube videos. The MPEG-DASH client-server interaction induced by our simulated server is close to what we empirically observed on YouTube (see Section 2).

Modeling the attacker. Let m be a video. When m is streamed, let its trace $t \in \mathbb{R}^k$ be the sizes (in bytes) of the first k bursts and let T^m denote the probability distribution of these traces. We assume that T^m is the same whether the video is streamed to the attacker's client (during training) or to the victim's client (during identification). This is empirically justified in Section 7.4.

For the theoretical analysis in this section, we use a very simple fingerprinting algorithm. For any $v = (v_1, \dots v_k) \in \mathbb{R}^k$, define $\alpha(v) \equiv (v_1, \dots v_k, v_2 - v_1, \dots v_k - v_{k-1})$. Intuitively, $\alpha(v)$ accounts for both the absolute magnitudes of segment sizes and their variability pattern.

During training, the attacker acquires n training traces $TS = \{t_1, \dots t_n\}$ drawn from T^m. Let $s^m = \text{mean}(TS)$, the element-wise average over TS. Training produces $\alpha(s^m)$, which is the attacker's *fingerprint* of m.

During the attack, the attacker is given the victim's trace $t \in \mathbb{R}^k$ and computes its *traceprint*, $\alpha(t)$. The attacker concludes that the victim is watching m if and only if $\|\alpha(t) - \alpha(s^m)\|_1 \leq B$, where $B = 3,500,000$ bytes.

Attacker's recall. To compute the recall, or true positive rate, of this attack, we first estimate the error $\alpha(t) - \alpha(s^m)$ by lower-bounding the probability that this error is small: $\Pr_{t \leftarrow T^m}[\|\alpha(t) - \alpha(s^m)\|_1 < B]$.

We expect that the bigger the burst size, the bigger the potential error. For example, the average size of bursts in the "Iguana vs. Snakes" video is particularly high, over 1MB, vs. the average of 693K across the videos in our set. We streamed this video 100 times, aggregated the traces, and computed the 10-burst fingerprint. We then computed the error for each trace (i.e., the discrepancy between the attacker-measured traceprint and the fingerprint of the underlying video) and fitted a Gaussian distribution using SciPy's Maximum Likelihood Estimator. The expected value of the error is 41,643 bytes, standard deviation is 24,970 bytes. Observe that $B/7$ is over 10 standard deviations away from the expectation of the error. Thus, $\Pr_{t \leftarrow T^m}[\|\alpha(t) - \alpha(s^m)\|_1 \leq B/7] \geq 1 - 10^{-12}$, for the aforementioned $k = 10$.

To estimate the error for $k = 40$ (as will be needed later), we partition[1] $t \in \mathbb{R}^{40}$ into 4 contiguous blocks of length 10 and apply the union bound on the probabilities of error in each block and the difference elements in α, i.e., $\left|(t_i - t_j) - (s^m_i - s^m_j)\right|$ for $(i, j) \in (11, 10), (21, 20), (31, 30)$. For each of the 7 elements of α, the error is bounded by $B/7$ with probability $\geq 1 - 10^{-12}$. Total error is thus bounded by B with very high probability, $\Pr_{t \leftarrow T^m}[\|\alpha(t) - \alpha(s^m)\|_1 \leq B] \geq 1 - 7 \cdot (10^{-12}) \geq 1 - 10^{-11}$, implying very high recall.

[1] With longer captures, we could have estimated this error directly.

Attacker's precision. Even if the distance between the attacker-measured "traceprint" and the video's fingerprint is small, the attacker may still misclassify the video if its fingerprint is close to another one. We show that for almost 20% of the videos in our YouTube dataset, such mistake is unlikely (and indeed never occurs in practice).

Let D be the 3,558 videos in our YouTube dataset. For $m \in D$, let $z^m \in \mathbb{R}^k$ denote the series of sizes (in bytes) of the first k segments of m, as produced by the server's segmentation of the corresponding MP4 files. We say that a video has *variable segment size* if (1) the overall bitrate is over 100 kBps, and (2) in z^m, more than half of the adjacent pairs differ by more than 110 kB. Let V be the set of videos with variable segment sizes. We observe that in our dataset, $|V| = 671$ (≈19% of D).

A *collision* is video pair $m \in V, m' \in D \cup V$ such that $m \neq m'$, $\left\|\alpha(z^m) - \alpha(z^{m'})\right\|_1 \leq 2B$. Then our attacker could mistake m for m' even if m's traceprint is B-close to the fingerprint (as must be the case with high probability). There are no such collisions in our dataset.

To estimate the attacker's precision, we need to assume that s^m, the series of average burst sizes used to compute the fingerprint, is similar to the corresponding series of segment sizes z^m in the following sense: if $\left\|\alpha(z^m) - \alpha(z^{m'})\right\|_1 \geq 2B$, then $\left\|\alpha(s^m) - \alpha(s^{m'})\right\|_1 \geq 2B$. This assumption is empirically true. In general, we expect each burst size to be related to the corresponding segment size by an affine function (accounting for the constant and multiplicative overheads of the encoding and headers added by each network layer).

It follows that no two fingerprints $\alpha(s^m), \alpha(s^{m'})$ are $2B$-close in the L_1 norm. Since with probability 10^{-11} a traceprint $\alpha(t)$ (of a video m with variable segment size) is B-close to the correct fingerprint $\alpha(s^m)$ (by the recall bound above), the probability that an attacker mistakes t's video for another one in our dataset is at most 10^{-11}.

Discussion. This theoretical analysis demonstrates that a significant fraction of YouTube videos are unique given a rudimentary fingerprinting algorithm. This algorithm yields a very strong detector for the videos that satisfy the variable segment size criterion, which is 671 videos out of 3,558 in our dataset. The attacker can easily check whether a particular video satisfies this criterion.

While our dataset is small in comparison to the entire YouTube, the extremely low error rate and complete absence of collisions indicate that the attack should generalize. The false positive rate for the the videos satisfying the criterion is very low, which guarantees that the Bayesian detection rate is high even if the base rate is low (see Section 8).

In the following sections, we develop a more sophisticated and accurate classification method based on machine learning, relax the simplifying assumptions made in the theoretical analysis, and empirically evaluate our method against popular streaming services.

7 Video Identification Using Neural Networks

Section 6 explains why DASH-based video streams are fingerprintable, but the theoretical model underestimates the capabilities of realistic attackers who can use traffic features other than burst sizes (e.g., packet timing). Moreover, the simple classifier based on L_1 distance is clearly suboptimal, e.g., it does not account for the asymmetry of the error distribution. Also, the theoretical model assumes that the attacker can reliably detect bursts and is thus not robust to noisy network conditions.

A more sophisticated classifier would process more and lower-level features and construct a more complex model to characterize the network traces of a given video. In this section, we use machine learning to construct such classifiers. One plausible approach is to compute the classifier of a video from its file, but we found it to be relatively ineffective (see Appendix A). Instead, we use multiple streams of the same content to train a classifier.

7.1 Background on CNNs

Deep learning [29] is a branch of machine learning based on multi-layer artificial deep neural networks (DNNs). DNNs have proved very effective for signal recognition tasks such as speech transcription [19], image segmentation [14], image classification [28], and many others.

In a neural network, each layer of neurons does some computation on its input and passes the output to the next layer (or final output)—see Figure 7.1. The first, input layer is a tensor representation of the input, e.g., pixels in the case of image classification. The subsequent (low) levels typically infer representations of the features of the input, and the final (high) layers perform the learning task (e.g., classification) given these features.

DNNs are good at capturing high-level concepts that are easy for humans to agree on but hard to express formally. In our case, we use DNNs to capture traffic-level commonalities of the streaming sessions of a given title, even in the presence of some traffic variations among these sessions. Further, neural networks are flexible and can leverage information from the low-level features, such as packet lengths, as well as sequences of burst sizes (as estimated from encrypted traffic). As input, they can use any time series that characterizes the stream. We exploit this in both on-path and off-path attack scenarios.

Convolutional Neural Networks (CNNs) [9] are deep neural networks whose lower layers apply the same linear transformation on many windows of the input data.

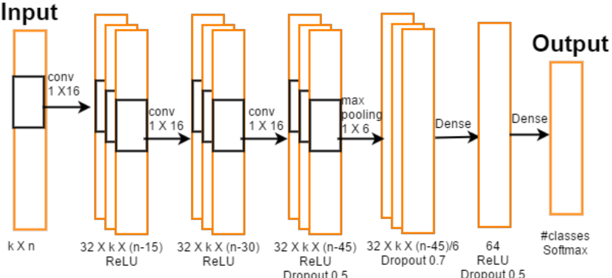

Figure 7.1: Our CNN architecture. k denotes the number of feature types taken. n is the recording time in seconds divided by the time-series sampling rate (0.25).

These layers are typically used to produce representations of local features (e.g., spatially local in an image, or temporally local in a time series). These are suitable for our setting, where the network events corresponding to each DASH burst occur in close temporal proximity.

We use supervised training on a corpus that consists of traffic measurements labeled with their correct class, i.e., the identity of the corresponding video. Training involves multiple *epochs*. During each epoch, an optimization procedure processes a batch of training data and adjusts the parameters in the functions computed by the layers so as to minimize the error between the correct classification and the output of the classifier. Learning is successful only if (1) the classifier reduces the training error, and (2) the reduced error rate generalizes to test samples, i.e., inputs that the classifier was not trained on.

7.2 Our classifier

We use CNNs with three convolution layers, max pooling, and two dense layers (see Figure 7.1). We train them using an Adam [26] optimizer on batches of 64 samples, with categorical cross-entropy as the error function.

The classifier is constructed using TensorFlow with the Keras front end. For each task, we randomly shuffle the samples, apply the 0.7-0.3 train-test split, and train for a specified number of epochs. The dataset was normalized on a per-feature basis: the time-series vector representing a given feature in each sample was divided by the maximum of the aggregated values of this feature.

Table 7.2 shows the training time, on a workstation with Intel i7-5690X CPU and two NVidia Titan X GPUs. For comparison, we also performed training in an Ubuntu virtual machine on a commodity laptop with an i7-6600U CPU (and no GPUs) running Windows 10; in this case training was 35 times slower, but even so, the most time-consuming training (that of the Netflix classifier for 1,400 epochs) took less than 10 hours.

7.3 Classification results

We trained a separate classifier for each dataset and each feature type listed in Section 5.2, as well as for each traffic direction (inbound, outbound, or both). Table 7.2 shows the accuracy of these classifiers as the fraction of correctly classified test samples.

The YouTube classifier is remarkably accurate. Not only it achieves 99% accuracy, but it also distinguishes 20 known classes from a large "other" class (unknown videos) with high probability. Furthermore, it works well with any of the features. For example, it achieves 90% accuracy given just the **times** of packet arrivals at a very coarse granularity of 0.25-second intervals (i.e., the PPS feature). This suggests that YouTube streams are particularly susceptible to adversarial identification.

Netflix 1/100 classifier. To gain some insight into how accurate these classifiers are, consider the Netflix classifier that was trained on the BPS feature for 1,400 epochs, achieving 98% accuracy. Figure 7.3a shows the confusion matrix. The classifier does not consistently mistake any class for another. All mistakes but one happen just once. This indicates that different classes do not collide in the classifier's internal representation.

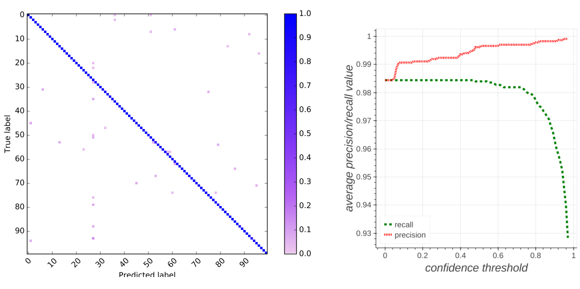
Minimizing false positives. The output of the last, softmax layer of the neural network is traditionally interpreted as a vector of probabilities. The classifier's prediction is the class with the highest probability. We can use this probability as a confidence measure.

Our goal is to ensure that the classifier produces no false positives, at the cost of occasionally failing to detect the match (false negatives). We set a *confidence threshold* and only accept a match if the classifier's confidence is above the threshold. If confidence is below the threshold, we intentionally classify the input as "other" regardless of the class chosen by the classifier.

Figure 7.3b shows the precision and recall of the classifier for various values of the confidence threshold. Precision and recall are calculated by aggregating the false positives and false negatives of all classes except "other". Without any decrease in recall, we can achieve a false positive rate of just 0.005 (precision of 0.995). By accepting a 0.07 false negative rate (0.93 recall), we obtain a false positive rate of less than 0.0005, or precision of 0.9995, with just 1 false positive out of 2224 matches.

YouTube 1/18 classifier. Our YouTube classifier trained for just 150 epochs on BURSTS achieves 0.994 accuracy. Figure 7.4a shows the confusion matrix. Almost all misclassifications are for "other" (i.e., known titles not recognized), thus there are very few false positives.

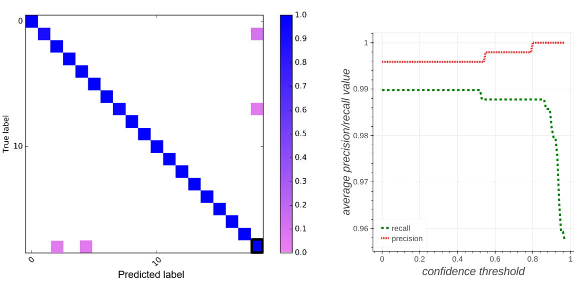
Figure 7.4b shows the precision and recall of the YouTube classifier as a function of the confidence threshold. Even when the threshold is 0 (equivalent to simply taking *argmax* of the classifier's output), the false negative rate is 0.01 (0.99 recall), and precision is better than accuracy (0.995). By accepting a tiny, 0.002 drop in recall, we achieve **zero false positives**.



(a) Confusion matrix. The entries off the diagonal are misclassifications. Color in cell i, j denotes the number of samples of class i classified as j.

(b) Precision vs. recall.

Figure 7.3: Netflix 1/100 classifier.



(a) Confusion matrix. The entries off the diagonal are misclassifications. The bottom row and rightmost column are of the "other" class.

(b) Precision vs. recall.

Figure 7.4: YouTube 1/18 + "other" classifier.

Using multiple feature types. The classifiers discussed above use a single feature type and a one-dimensional input layer ($k = 1$). We also tried more sophisticated classifiers that take in multiple features. In such an architecture, we expect the same one-dimensional layer to pick up localized attributes of different features. We used a greedy search algorithm on the feature set space that begins with an empty set of features and then adds the feature that maximizes test accuracy after training. Training on multiple features was slower and did not produce significantly more accurate classifiers in our experiments. It is possible that a more elaborate neural network architecture with k independent convolutional layers would work better, albeit with slower training.

7.4 Cross-network training

To collect training data, the attacker must stream videos and record traffic. He may be unable to do this on the same local network as the victim, e.g., because that network is secured, or because the attacker wants to identify videos en masse for multiple users on different networks.

Dataset	TIME	EPOCHS	PLEN$_{IN}$	PLEN$_{OUT}$	PLEN	BPS$_{IN}$	BPS$_{OUT}$	BPS	BURSTS	BURSTS$_{IN}$	BURSTS$_{OUT}$	PPS$_{IN}$	PPS$_{OUT}$	PPS
Netflix	497	700	0.318	0.377	0.333	0.983	0.901	0.982	0.926	0.044	0.708	0.917	0.892	0.921
	994	1400	0.301	0.474	0.340	0.983	0.895	**0.985**	0.959	0.949	0.757	0.918	0.881	0.931
YouTube	94	150	0.993	0.993	0.994	**0.995**	0.994	**0.995**	0.984	0.989	0.988	**0.995**	0.993	**0.995**
Amazon	88	700	0.895	**0.925**	0.917	0.899	0.891	0.905	0.790	0.879	0.712	0.792	0.835	0.790

Figure 7.2: Accuracy of our classifiers. TIME is the approximate total training time, in seconds. EPOCHS is the number of epochs. The remaining columns show the test accuracy of the classifier when trained on a given feature. The features are the time series of, respectively, packet length, Bps, bursts series, and packets per second (see Section 5.2), measured in the up, down, and both directions.

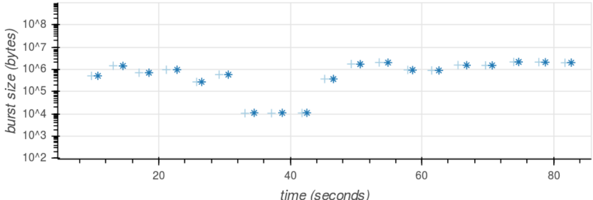

Figure 7.5: Burst sizes of streamed "Reservoir Dogs". The two captures were made on a campus network (+) and a home network ($*$).

The attacker can still collect training data by streaming on his own Internet connection. This connection, however, may have different network characteristics, such as bandwidth, latency, congestions and packet drops, all of which affect the collected traces.

We conjecture that our classifiers learn high-level features of video streams, such as burst patterns, that are robust to reasonable differences in network characteristics and will therefore maintain high accuracy even when trained on a different network (in the absence of pathological conditions such as excessive packet loss or inadequate bandwidth for streaming).

To confirm this, we captured 90-second streaming sessions of 10 Netflix titles on a campus Wi-Fi network and on a home Wi-Fi network from a cable ISP. We trained our classifier on the campus data and measured its accuracy on the home-network data. Our classifier uses only the down BURST series (see Section 5.2). Trained on 50 campus captures per title, it reaches 98% accuracy on the home-network data (20 captures per title). Figure 7.5 shows that the burst patterns on the two networks are highly correlated and aligned in time.

7.5 Possible improvements

Our classifiers attain very high accuracy but can benefit from some potential improvements.

First, our Netflix classifier was trained on just 60-second captures, equivalent to only about 45 seconds of steady-state bursts after the (less discriminative) buffering period. It may be possible to train an even more powerful classifier using 90-second captures.

Second, our relatively simple classifiers are slightly under-fitted. More expressive classifiers (e.g., with more hidden layers) suffer from over-fitting, but it may be solved with more data, e.g., 1000 captures per video.

Finally, the low base rate potentially motivates the use of *detection cascades* [56] consisting of a series of classifiers, each of which is more complex (with a larger input feature space and more hidden layer activations) than the previous one. During training, the $(i+1)^{\text{th}}$ classifier is trained using only the samples accepted (possibly falsely) by the ith classifier. A cascade thus accepts only the inputs that are accepted by all of its classifiers and is efficient to train because most inputs are rejected by the simple lower-level classifiers. Cascades have demonstrated almost human-level accuracy for complex tasks with low base rate such as face detection [64].

8 Bayesian Detection Rate

In Sections 6 and 7, we showed detectors with very low false positive rates. However, the attacker's false detection rate is not the detector's raw false positive rate but the *Bayesian Detection Rate (BDR)*. The BDR of a detector for video m is the probability $\Pr(M|A)$, conditioned on the detector declaring that the victim is streaming m (event A), that the victim is indeed streaming m (event M). This probability is taken over all videos that the victim could be streaming, as well as network conditions and measurement noise.

$\Pr(M|A) = \frac{\Pr(A|M)\Pr(M)}{\Pr(A|M)\Pr(M)+\Pr(A|\neg M)\Pr(\neg M)}$ by Bayes' Law. We can estimate $\Pr(A|M)$ by the detector's recall, and $\Pr(A|\neg M)$ by its false positive rate.

"Open world," when the attacker does not know a priori a relatively small set of possibilities for the video being streamed, is characterized by an extremely low *base rate*, i.e., probability $P(M)$ that the video actually corresponds to any of the attacker's detectors. In this setting, when the attacker's recall is sufficiently high, BDR is dominated by the false positive rate.[2]

[2] For example, suppose the recall is $\Pr(A|M) = 1$, false positive rate is $\Pr(A|\neg M) = \frac{1}{1000}$, and the victim streams 100,000 videos sequentially. If the attacker has a detector for one of them (i.e., the base rate is $\frac{1}{100000}$), he would get roughly 100 false matches before the true match.

We now analyze the detectors from Sections 6 and 7 in the "open-world" setting.

8.1 Distance detector

We first analyze the BDR of the detector from Section 6.

Let $\hat{D}$ be the world of videos, and let $\hat{V} \subseteq \hat{D}$ be the world of videos with variable segment size. $\psi^{\hat{D}}$ is the distribution over $\hat{D}$. Assume that the victim chooses $m' \leftarrow \psi^{\hat{D}}$, and that the videos in our set D were likewise sampled from $\psi^{\hat{D}}$ (i.e., by sampling videos according to their popularity on the service). Let $V \subseteq D$ the the videos in D with variable segment size. Assume the attacker has a detector for some $m \in V$.

Let $t \leftarrow T^{m'}$ be an observed trace. If the detector matches but $m' \neq m$, then either $\left\|\alpha(s^{m'}) - \alpha(t)\right\|_1 \geq B$, or $\left\|\alpha(s^{m}) - \alpha(s^{m'})\right\|_1 \leq 2B$. The probability of the former is low because the recall is very high, $> 1 - 10^{-11}$. Let p_{COL} denote the probability of the latter event, corresponding to a collision between two videos.

If $p_{\mathsf{COL}} \geq \frac{2}{10^6}$, then we are likely to observe a collision in our dataset D. Under the simplifying assumption that collisions in D are independent events,[3] with overwhelming probability $1 - (1 - p_{\mathsf{COL}})^{(|D|-|V|)|V|+|V|^2/2} > 0.986$ there exist $m_V \in V, m_D \in D$ such that $m_V \neq m_D$ and $\|\alpha(s^{m_D}) - \alpha(s^{m_V})\|_1 \leq 2B$. Since we did not observe any such collisions in 2,162,297 pairwise tests over D, it is likely that $p_{\mathsf{COL}} \leq \frac{2}{10^6}$.

In this case, assuming the open-world base rate is $\frac{2}{10^6}$, BDR is very close to 0.5.

8.2 Neural-network detector

YouTube. With our YouTube classifier, when we preferred precision over recall, there were no false positives: we never observed an "other" video that was misclassified as one of the known videos. We view this as an indication that our results generalize.

Netflix. With our Netflix classifier, when we preferred precision over recall, we observed 1 false positive (compared to 2,240 true positives), corresponding to the false positive rate of 0.00045. Our recall is still > 0.93.

At first glance, this result seems harder to generalize. We cannot simply plug $\Pr(A|\neg M)$ and $\Pr(A|M)$ into the BDR formula and expect to get a good estimation, since the distribution that this classifier was trained on—without samples from the catchall "other" class—is fundamentally different from the distribution of videos that might be streamed by the victim.

Similarly to the previous section, there are two causes of false positives: similarities in the videos' burst patterns (which is what the classifier learns), i.e., a *classifier-collision false positive*, and noise in the measurements, i.e., a *network-noise false positive*.

The confusion matrix (Figure 7.3b) shows no pairwise classifier collisions for the 100 titles. The classifier does not consistently confuse any particular title for another (even though many are episodes in the same TV series with presumably similar visual attributes). This indicates that classifier collisions are uncommon.

When collisions do not occur, our classifier, tuned for precision over recall, performs very well and misclassifies only 1 out of 2,224 test samples. No other sample was close enough, in the classifier's eyes, to *any* of the 99 classes. This means that the classifier made one "confident" mistake out of 220,176 possibilities.

9 Off-path Attacks

9.1 Measurement with JavaScript

Consider a remote attacker who has a restricted foothold in the victim's network. For example, he controls an ad embedded in some webpage visited by the victim. An ad may include JavaScript code executing in the victim's browser, but because this code may come from a questionable source with strong commercial interest in users' data (including their viewing habits), it is confined—both by the main browser sandbox, which prevents it from issuing arbitrary requests to the OS, and by the same origin policy [51], which prevents it from accessing the content that belongs to other Web origins. In particular, even if the victim is streaming a video in another tab of the same browser, confined JavaScript code cannot directly access the URL or content displayed in that tab.

The same origin policy does permit the attacker's JavaScript code to communicate with its own origin (e.g., the Web server that served the ad). This communication is carried over the same Internet connection as the video being streamed by the victim. Since Internet links usually have bounded bandwidth, this means that the attacker's JavaScript and the video stream share a limited resource. JavaScript can send and receive arbitrary amounts of data to and from its colluding server to create *artificial congestion* on the shared link.

When the shared link is congested, any attempt to use it can create observable delays in the communication between the attacker's JavaScript code and its own server. The attacker can then estimate how much traffic is flowing over the link by measuring these delays. This leaks information about the content streamed from a different origin by the same browser (a **cross-site attack**, see Fig-

[3] This assumption is an approximation. It could have been strongly violated, e.g., if all collisions are due to a small set Z of videos, each of which collides with many other videos: if we didn't hit any of Z when picking D, we would not observe any collisions. However, due to the geometrical structure of video fingerprints, this seems unlikely. If the fingerprints of videos in Z are close to those of many other videos, then the latter videos also have fingerprints that are geometrically close to each other and are thus likely to collide in D.

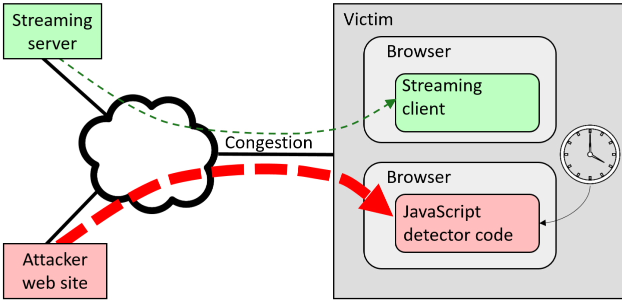

Figure 9.1: Cross-site attack.

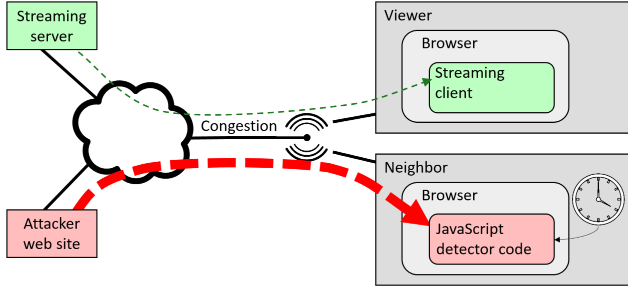

Figure 9.2: Cross-device attack.

ure 9.1), or even by a different device on the same local network (a **cross-device attack**, see Figure 9.2).

9.2 Simulating the attack

We implemented a malicious NODE.JS Web server which, when accessed by the victim's browser, serves *detector code* written in JavaScript. This code, running unprivileged within the browser sandbox, talks back to the server via the SOCKET.IO API. The server sends a stream of messages, causing congestion. The detector code measures the arrival time of these messages, using `window.performance.now()`, to estimate contention from other traffic on the shared link.

Network. To simulate cross-site and cross-device attacks, we run two browser windows concurrently, one streaming the selected video, the other executing a JavaScript attack client. In the cross-site setup, they run on the same virtual machine. In the cross-device setup, they run on different machines. Both machines are on a home network, *victim-LAN*, behind a traffic-throttling router that simulates a bandwidth-limited connection. In the cross-site setup, we simulate *victim-LAN* and the router with VMware Workstation. In the cross-device setup, we use an actual home router. In both cases, the router is connected to the Internet via a university LAN. The attack server is on the same LAN. All traffic between *victim-LAN* (which includes the streaming client and the attack JavaScript client) and the Internet (which includes the streaming server and the attack server) thus flows through a bandwidth-constrained router.

Data. We used 10 Netflix titles: 5 episodes from the first season of "Mad Men" and 5 arbitrary other titles. We streamed each title 100 times and used a JavaScript client to indirectly measure the traffic as described above. We used 5-minute captures in the cross-site experiment and 6-minute captures in the cross-device experiment.

Cross-site attack. The attacked machine was an Ubuntu 14.04 VM, with a simulated 45 Mbps (5.625 MBps) down/upstream bandwidth (capped by VMware Workstation). The attack server's messages contain 6 KB of random data, sent at the rate of 1 per 0.001 seconds and an overall transmission rate of 6 MBps. This is more than enough to saturate the simulated link.[4]

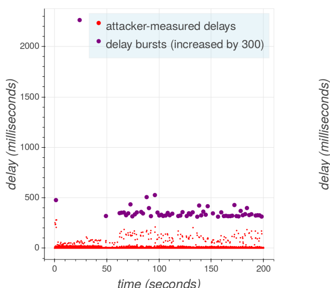
From the $\{X_n\}$ vector of message arrival times measured by the attacker's client, we compute the vector of message delays $Y = (0) \| ((X_2, \dots X_n) - (X_1, \dots X_{n-1}))$ and filter the X, Y time series for delays that exceed 8ms. We then compute the burst series as in Section 5.2 with 0.25-second intervals and filter out the bursts whose sizes are below 80, producing a *delay bursts* time series. To create uniformly sized vectors, we aggregate this series by averaging into 0.25-second chunks.

Cross-device attack. As the viewer device, we used a laptop (Intel i7-5600U CPU) running Ubuntu 16.04. As the neighbor device, we used a laptop (Intel i7-3720QM CPU) running an Ubuntu 14.04 VM guest in a Windows host. Both were connected over Wi-Fi to an Asus RT-AC66U wireless router, connected to a university network. The router was configured to cap its total downlink speed at 45 Mbit, using the "Max Bandwidth Limit" setting of the Tomato Advanced firmware. The attack server was sending an 8KB message every 1.5ms, about 300 KBps short of saturating the network link.

In this experiment, we smoothed the time series of the delay measurements by averaging over 0.1-second intervals, filtered it for delays $y > 2.1$ms, computed the burst series with 0.5-second intervals, and filtered out all bursts whose sizes were below 10. To create uniformly sized vectors, we chunked it into 0.1-second intervals.

Classifier. We used a variant of the classifier from Section 7.2 that we found less prone to overfitting on the noisier, longer samples in this attack. Between the last max-pooling layer and the first fully-connected layer, we added another convolution layer, with kernel size 7, followed by a max pooling layer (both with ReLU activations). We applied 0.7 dropout after every hidden layer. All other convolution-layer dimensions were changed to 1x12 and pooling-layer dimensions to 1x2. We used 16 filters for all hidden layers instead of 32. Finally, we used Adadelta instead of the Adam optimizer.

[4] A portion of messages is queued at the server, taking up to 500MB of memory. In the cross-device attack, we calibrated the transmission rate in a different way, alleviating this.



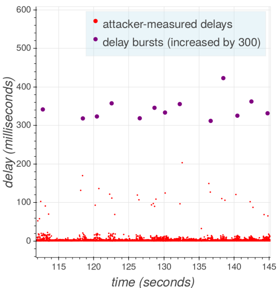


Figure 9.5: Cross-device attack on a Roku streamer. On the left is the global view, including initial buffering. On the right is the local view during steady-state streaming. Bursts cause a visible increase in delays observed on the neighbor machine.

9.3 Results

In all of our experiments, attacks were imperceptible to the user and did not affect the viewing quality.

Cross-site attack. Figure 9.3a shows that bursts in the video stream are very visible in the measurements performed by the JavaScript client. Fig. 9.3b shows that the delay bursts series is strongly correlated with the bursts of the actual stream. Our 1/10 Netflix classifier attains 0.937 accuracy. As in Section 7, we can adjust our confidence threshold to reduce false positives at the cost of reducing recall (see Fig. 9.3c). By accepting 0.793 recall, we obtain precision of 1.

Cross-device attack. The timing of the messages observed by the detector code on the neighbor device exhibits clear patterns corresponding to the stream received by the viewer device. Figure 9.4a shows that bursts in the stream during the steady state cause delays in the messages received by the neighbor. Figure 9.4b shows that delay bursts are correlated with the size of bursts in the stream (which, in turn, reflect segment sizes). Our classifier performs well, with 0.965 accuracy. By accepting 0.933 recall, we obtain precision of 0.997.

Cross-device attack on a Roku streamer. Many users watch streaming video content on a smart TV or a dedicated streaming device connected to a TV. To investigate the feasibility of our attack in this scenario, we used the cross-device attack setup from Section 9.2 except that the viewer was a Roku Premiere streaming device (a very popular brand), connected to the Internet via Wi-Fi.

The bursts corresponding to video segments are clearly observable from a neighbor machine. Figure 9.5 shows the attacker-measured delays while Roku is streaming Episode 1 of "Mad Men." They exhibit the expected pattern of a large burst followed by smaller ones in steady intervals, each lasting a few seconds.

10 Limitations

Our attack relies on two assumptions: (1) the attacker can measure traffic bursts in the victim's video stream, and (2) the pattern of these bursts is similar to what the attacker observed when streaming the same title.

The attack works well using only very coarse traffic features (see Section 7.3) and is therefore robust to minor noise in the stream or in the attacker's measurements. If the noise is so significant as to dramatically change the traffic characteristics of the stream (e.g., if the same network connection is used to watch multiple concurrent videos, upload media files, or for some other bandwidth-intensive activity), the attack may not succeed.

In the off-path attack, the attacker's server sends large amounts of traffic to congest a shared network link and his JavaScript client measures arrival times in the victim's browser. To create congestion, the server needs a high-bandwidth connection to the victim's network. Therefore, success of the off-path attack using a specific server may depend on the victim's location and ISP.

If the client code does not have access to precise time, the roles must be reversed (see Section 12). The ability of malicious JavaScript in the victim's browser to congest the network may be limited by resource-intensive processes executing on the same machine.

As explained in Section 4, different encodings of the same content create different burst patterns. The attack will not succeed if the encoding of the streams used to train the attacker's detector is different from the encoding of the victim's stream. Specifically, in adaptive streaming, encoding quality can be dynamically downgraded or upgraded in response to changing network conditions. In this paper, we did not evaluate a scenario where the victim is experiencing erratic network conditions causing frequent switches between encodings.

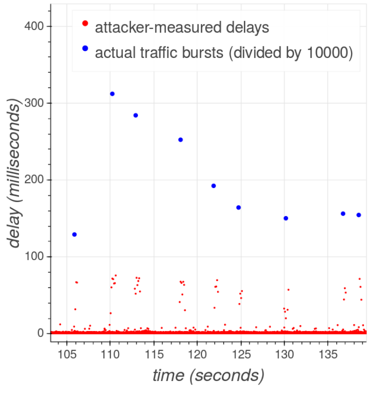
Our techniques aim to identify standard, unmodified streaming video (e.g., Netflix movies). They are not designed to resist evasion. If the user or service re-encodes the video (e.g., at a different resolution), the attacker's previously trained detectors will no longer work.

Our techniques can be automated and deployed on a reasonably large scale to detect hundreds or thousands of titles in an "open-world" setting, without assuming a priori that the video belongs to small known set. Scaling beyond that is likely to be expensive. Data collection is the main bottleneck because training detectors requires the attacker to stream the same title multiple times.

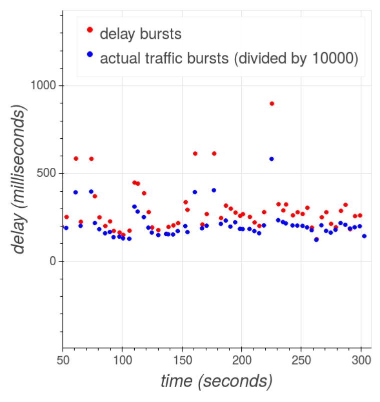
11 Related Work

11.1 Exploiting VBR leaks

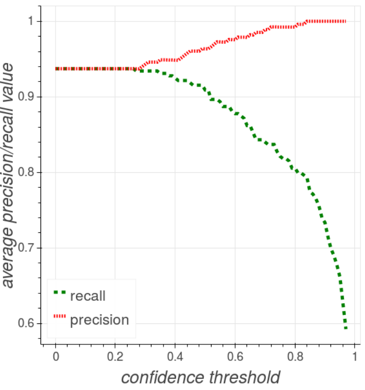
Fine-grained video. Saponas et al. [46] observed that encrypted, VBR-encoded videos leak information about their content. To create a "signature" of a video, they



(a) Actual bursts size vs. measurements from JavaScript in a different origin.

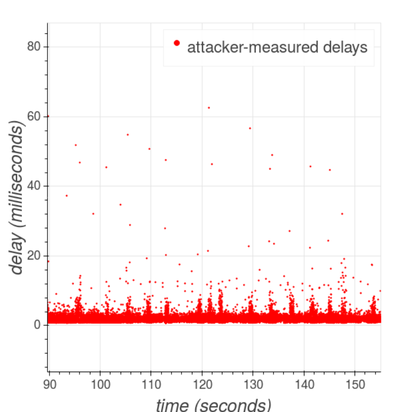


(b) Delay bursts vs. actual traffic bursts (traffic bursts are in units of 10^4 bytes).

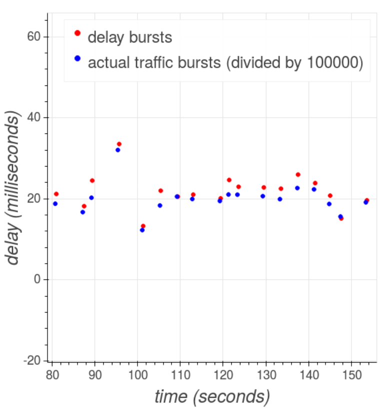


(c) Precision vs. recall of our classifier

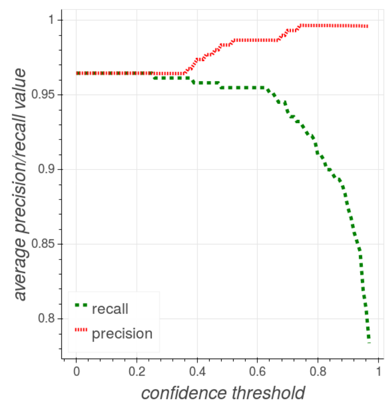
Figure 9.3: Cross-site attack.



(a) Raw attack measurements, showing delays at roughly steady intervals.



(b) Delay bursts vs. actual traffic bursts. Traffic bursts are divided by 100,000 for presentation.



(c) Precision vs. recall of our classifier

Figure 9.4: Cross-device attack.

take its traffic trace as a bits-per-second time series at the granularity of 100 milliseconds, average, and apply a sliding-window DFT. Their detector applies DFT to traffic traces and matches to the closest signature.

Li et al. [30] focus on detecting re-encoded content. They apply a wavelet transform to the time series of frame sizes and cross-correlate the wavelet coefficient series of the observed traffic with those of a reference content file. In [31], Liu et al. use aggregated traffic throughput traces (as opposed to frame-size time series) and report 1% false positive rate and 90% recall rate.

These methods operate on time series resembling, and close to the granularity of, the sizes of individual frames. DFTs and wavelet transforms capture short-term variations due to changes of picture and long-term variations due to changes of scene. In our setting, the observable features are bursts 4–6 seconds (120–180 frames) apart.

Even though these methods rely on fine-grained measurements, their false positive rates are prohibitively high for "open-world" identification (with a low base rate, even 1% false positive rate implies an extremely low Bayesian Detection Rate). None of them would work if the measurements of the attacker (e.g., performed by sandboxed JavaScript) are noisy and coarse-grained.

Dubin et al. [11] suggest using the (unordered) set of segment sizes as a title fingerprint. This detector is far less accurate than our classifiers and vulnerable to noise, and consequently cannot be used by a JavaScript attacker. See Appendix B for the detailed analysis.

Reed and Klimovski [43] implement a Wi-Fi sniffing attack and suggest an approach based on Pearson correlation for identifying Netflix streams. In a preliminary evaluation, they report correctly identifying, given 50 possible titles, 24 out of 25 streaming sessions. Con-

currently and independently from our work, Reed and Kranch [44] scale this approach by fingerprinting the entire Netflix title selection. They assume an on-path attacker who can observe TCP-layer traffic. This approach has not been evaluated in an off-path setting, where the attacker has only noisy side-channel measurements, nor for any streaming services other than Netflix.

Mass fingerprinting in [44] relies on the metadata sent by Netflix to the client at an early stage of the streaming process, namely the .ismv file headers that contain all segment sizes for all possible encodings of the title. They are sent in the clear, while the video content is DRM-encrypted. It is not clear how the approach of [44] would work if these headers were DRM-protected, too.

VoIP. Wright et al. showed that VBR leakage in encrypted VoIP communication can be used to identify the speaker's language [62] and detect phrases [61]. Their detector is a Hidden Markov Model trained to identify a specific phrase. White et al. [58] extended this approach to extract conversation transcripts.

11.2 Congestion and timing attacks

The general approach of creating congestion on a shared resource (network, in our case) and using it to measure a concurrent process's consumption of that resource is used, for example, in shared-cache attacks on cryptographic computations [21, 37, 45].

Our network congestion attack works because traffic-flow scheduling policies for a shared internet link are leaky. Kadloor, Gong, et al. [16, 24, 25] studied the tradeoffs between delays, fairness, and privacy in scheduling policies on shared resources. Kadloor et al. [23] also showed how to exploit the queueing policy in DSL routers: by sending a series of ICMP echo requests (pings) and timing RTTs, they infer the traffic patterns of a remote user. This attack can also help infer the website being visited [15, 17]. This attack is powerful because the attacker only needs to know the user's IP address, but it cannot be deployed if the user is behind a firewall or router that discards unsolicited packets from outside the network (as many modern routers do by default).

Agarwal et al. [1] show how a VM can use link congestion to infer the traffic patterns of a co-located VM.

To the best of our knowledge, the ability of confined JavaScript to perform network measurements at sufficient granularity to identify concurrent video streams has never been empirically demonstrated before. This is a particularly dangerous scenario because untrusted JavaScript code from sources who have commercial interest in users' viewing habits is ubiquitous on the Web.

Timing attacks have a long history in computer security [6, 50]. Felten and Schneider [13] observed that JavaScript can infer information from the timing of cross-origin requests; Bortz and Boneh [5] demonstrated several timing-related Web attacks; Van Goethem et al. [55] proposed timing techniques that tolerate network noise and server-side mitigations. Oren et al. [36] used JavaScript timing mechanisms for a cache attack. Kohlbrenner and Shacham [27] showed that existing browser-based mitigations are insufficient and proposed a new browser-based defense.

11.3 Fingerprinting and traffic analysis

There is a large body of research on identifying websites in encrypted network traffic [7, 8, 15, 18, 20, 39, 48, 57]. Juarez et al. [22] argue that most of these efforts make unrealistic assumptions and fail to cope with the base rate fallacy. Panchenko et al. [38] evaluate a state-of-the-art method for web*site* detection and conclude that web*page* detection is infeasible. Traffic analysis was used to infer application-specific sensitive information, such as health conditions [8, 33], as well as Web sources of video traffic [47]. Prior work also includes mitigations [63] and counter-mitigations [12].

12 Mitigations

Segment size leak. The root cause of information leaks in video streams is that, for any sufficiently long video, the encoding bitrate changes over the presentation time in a unique, identifying way. Segmenting video files and transmitting them in bursts (which is primarily done to maximize quality of experience) reduces the granularity of the leak but does not prevent video fingerprinting.

Decreasing granularity further, to minutes, will not entirely prevent the leak in longer videos, but will degrade QoE and network efficiency. Segmenting VBR video into uniformly sized segments is futile because then their *duration* will differ, thus the timing of client requests will still leak similar information.

Constant-rate encoding with tight rate control and large segments will eliminate the leak, at the cost of a very inefficient encoding. Similarly, padding bursts to the maximum segment size would require transmitting much more traffic than the actual file size.

The VBR pattern is inherently observable in traffic if the duration of the client's buffered video is close to constant (or, in general, an affine function of presentation time). Solving the problem requires a different buffering regime. Client-side-only changes are easier to deploy than changes to segmentation on the server, but devising such a regime is non-trivial even if we allow changes to both client side and server side.

For example, consider a *variable-size buffer* that fetches equally-sized segments every X seconds (where X is fixed). This requires a balance between increasing the fetching rate (lest the buffer runs out in the middle of long high-action scenes) and increasing the initial buffering time (for robustness to network conditions

while also accounting for sudden buffer depletion due to high-bitrate content). Both factors would directly degrade user experience and network efficiency.

Network congestion side channel. The congestion attack requires big, frequent server-to-client messages that may appear anomalous and thus recognizable at the network level. Detection and prevention mechanisms can be placed at the router, network, OS, or browser. A more sophisticated attack implementation may be able to use benign-looking traffic to circumvent such mechanisms. Fuzzy-time sandbox solutions such as [27] would not entirely prevent our attack: the JavaScript client can still send packets to congest the uplink, yet timing measurements can be performed by a colluding server.

13 Conclusions

Leakage of information about video content via network traffic patterns is prevalent in modern streaming protocols and popular services. We implemented and evaluated a novel method based on deep learning that exploits this leak for video identification.

Our method is tuned for high precision and effective in an "open-world" setting. It can be used by on-path adversaries such as ISPs and enterprise networks to spy on their users. Furthermore, it exposes sensitive information of the streaming service itself. For example, ISPs can use it to construct a popularity histogram of Netflix videos (Netflix does not release this information). We also show how an off-path adversary who merely serves a Web page or ad to a user can, via the network congestion side channel, perform the measurements needed for the attack and identify videos being streamed by the user on the same or different device.

A Streams vs. MP4 Files

Since the cause of the leak is the DASH standard, it would be nice to compute detectors directly from video files[5] instead of streaming each video multiple times.

This approach faces several challenges. First, the attacker must infer the exact segmentation parameters, such as segment duration and minimal buffer time, and how they change with respect to file encoding, size, bitrate, view count, etc. Each service has many combinations of these parameters. Furthermore, they change over time but changes may not apply to the already-segmented files. Second, this approach does not work at all if the attacker does not have the file (as in the case of Netflix).

To learn the relationship between MP4 files and streams, we would like to train a classifier that takes in an MP4 file and a traffic capture, and outputs whether the latter is a stream of the former. We used our dataset of 3,558 YouTube videos for which we have both the files and the captures. First, we have to align the stream with the file, i.e., match traffic bursts corresponding to segment-files to the segment-files' presentation time. Then we train a binary classifier on the extracted VBR pattern of an MP4 file and the (aligned) burst series to tell if the former was generated by the latter.

Alignment is a difficult problem because the extracted 720p MP4 files may not be identical to the actual files used by the streaming service (which may not even be in 720p). We heuristically tried several values to align each MP4-capture pair and used neural networks to train a classifier. Our classifier achieved 74% accuracy. This indicates a strong correlation between the files and the streams of the same video, but it is not sufficient for "open-world" identification. Our main approach of using multiple streams of the same video to train the detector achieves much higher accuracy in practice.

B Comparison with Nearest Neighbor

Dubin et al. [11] represent the attacker's measurements of a stream as a set of bursts and use a classifier that maps each such set to the closest training example. If the size of the set intersection is smaller than a threshold for all examples, the stream is classified as "unknown."

[5] There exist tools for downloading MP4 files of content from services such as YouTube and Vimeo.

Dataset	Added noise?	0B	1B	5B	10B	CNN
Netflix	No	0.871	X	X	X	**0.959**
	Yes	0.220	X	X	X	**0.909**
YouTube	No	X	0.962	0.967	0.832	**0.991**
	Yes	X	0.851	0.790	0.379	**0.989**

Table 1: TB (bucketed nearest neighbor classifier with threshold T) vs. CNN (our neural network).

We implemented and tried this approach for the Netflix dataset (which does not contain the "other" class, so we used a threshold of 0, i.e., a match is always accepted) and the YouTube dataset, with thresholds of 1, 5, and 10. The test-train split was 0.9-0.1.

The nearest-neighbor classifier performs very poorly on both datasets. For Netflix, it attained accuracy of 0.393. For YouTube, it attained accuracy of 0.624 with threshold 1, 0.05 with threshold 5, and even less with threshold 10. These results show that exact matches in burst sizes are simply too rare. Even when the nearest neighbor of a capture is actually found in its correct class, there are fewer than 5 matches with it.

To further assess this approach, we "bucketed" all burst sizes by rounding them to a multiple of 10, 100, 1000, and 10000. Rounding to a multiple of 1000 is effective, yielding 0.871 and 0.967 accuracy for the Netflix and YouTube datasets, respectively. We call this classifier the *Bucket* classifier (B).

This classifier is still very sensitive to noise and will perform poorly if the attacker's measurements are noisy or if the streaming service deliberately pads bursts with a few random bytes. We added a random number of bytes between 0 and 2% to each burst size in the dataset and measured the accuracy of the B classifier vs. our CNN-based classifiers, which use the total burst series (see Section 5.2) and are trained for 1,400 and 700 epochs on the Netflix and YouTube data, respectively. We used the 0.7-0.3 train-test split for the CNNs (vs. 0.9-0.1 split for the B classifiers). Table 1 summarizes the results.

The KNN classifier of [11] is designed for direct observations of the streaming traffic. We attempted to apply it to the burst estimates as measured from JavaScript. Because these estimates are sums of values returned by `window.performance.now()`, they are measured in milliseconds and in a floating-point representation that captures time at an even finer granularity. Therefore, to make it easier to recognize a (coarse) fingerprint, we used the same approach as above and divided bursts into coarse-grained buckets. We tried 100-second buckets, 10 seconds, seconds, deciseconds, centiseconds, milliseconds, decimilliseconds, centimilliseconds, and microseconds. The KNN classifier of [11] works best at the granularity of 10 seconds, and even then it only attains 0.22 accuracy. We conclude that the approach proposed in [11] does not work for an off-path attack.

Walkie-Talkie: An Efficient Defense Against Passive Website Fingerprinting Attacks

Abstract

Website fingerprinting (WF) is a traffic analysis attack that allows an eavesdropper to determine the web activity of a client, even if the client is using privacy technologies such as proxies, VPNs, or Tor. Recent work has highlighted the threat of website fingerprinting to privacy-sensitive web users. Many previously designed defenses against website fingerprinting have been broken by newer attacks that use better classifiers. The remaining effective defenses are inefficient: they hamper user experience and burden the server with large overheads.

In this work we propose Walkie-Talkie, an effective and efficient WF defense. Walkie-Talkie modifies the browser to communicate in half-duplex mode rather than the usual full-duplex mode; half-duplex mode produces easily moldable burst sequences to leak less information to the adversary, at little additional overhead. Designed for the open-world scenario, Walkie-Talkie molds burst sequences so that sensitive and non-sensitive pages look the same. Experimentally, we show that Walkie-Talkie can defeat all known WF attacks with a bandwidth overhead of 31% and a time overhead of 34%, which is far more efficient than all effective WF defenses (often exceeding 100% for both types of overhead). In fact, we show that Walkie-Talkie cannot be defeated by any website fingerprinting attack, even hypothetical advanced attacks that use site link information, page visit rates, and intercell timing.

1 Introduction

Website fingerprinting (WF) attacks are classification attacks that allow a local, passively observing eavesdropper[1] to determine which web page a client is visiting by observing the client's sequence of packets. WF attacks succeed against clients using privacy technologies, such as VPNs, IPsec, and Tor, that hide the contents and destinations of packets. The attacker—such as the client's ISP or government—uses various packet sequence features, such as packet counts, packet order, packet directions, and unique packet lengths to classify the web page [5]. WF attacks require only local eavesdropping capabilities, small computational cost, and carry little risk of detection. As web-browsing clients of these privacy technologies do not want to reveal the web pages they are visiting to any eavesdropper, they need to *defend* their privacy against WF in some way.

Website fingerprinting is a well-established threat to privacy in the literature [8, 14, 23], as well as in practice: Tor, a popular anonymity network, has implemented a WF defense [24, 26]. However, Tor's defense does not succeed in lowering the accuracy of WF attacks [6, 31]. Researchers have proposed alternative defenses, but these defenses are either ineffective against newer attacks [31] or carry a very large overhead [4, 8, 20, 31]. We describe previous website fingerprinting work in detail in Section 2.

In this paper, we present **Walkie-Talkie (WT)**, a new WF defense, with the following properties:

1. Effective: Many WF defenses have failed against newer WF attacks. WT succeeds against all known WF attacks, including attacks that leverage timing and packet ordering.

2. Efficient: A high bandwidth overhead burdens the network, while a high time overhead frustrates the user. (We define these terms rigorously in Section 3.2.) WT requires a much smaller overhead than all known effective defenses.

3. Easy to use: WT requires no changes to web servers and therefore does not impact server performance, as it needs to be deployed only on the client and proxies. Our implementation only modifies the application layer. Furthermore, the defense can be de-

[1] Active eavesdroppers are not considered WF attackers in the literature, as later explained in Section 2.

ployed incrementally as it does not depend on other clients using the same defense.

Walkie-Talkie consists of two components: half-duplex communication and burst molding. We describe both components in Section 4. These components transform packet sequences of monitored sensitive pages and benign non-sensitive pages, so that these packet sequences are exactly the same (each packet has the same timing, length, direction and ordering). Since the packet sequences are exactly the same, and WF attacks are based solely on classifying packet sequences, no WF attack can succeed against Walkie-Talkie. To mold sensitive packet sequences into non-sensitive packet sequences, the client would need to have some information about them. We will show that such information can be practically obtained and delivered to the client.

For the purposes of this paper, we base our experiments and implementation on Tor, though Walkie-Talkie works on any other setting where website fingerprinting is a threat (using encryption with proxies to hide from a local attacker). We evaluate Walkie-Talkie on a data set collected over Tor, squaring off our defense against known attacks and other known defenses in Section 5. We show that known website fingerprinting attacks are unable to succeed against packet sequences under Walkie-Talkie, and that our defense has a significantly lower overhead compared to known defenses. We describe ways to defeat a hypothetical attacker using more advanced strategies beyond known website fingerprinting attacks in Section 6. We conclude in Section 7, and we include a link to share our code and data in the Appendix.

2 Related Work

Remote side-channel analysis can be used to attack web clients in a wide range of scenarios, including network timing attacks [3], cache attacks [21], and browser fingerprinting [9]. Some of these involve an active attacker, for example one that may send JavaScript requests when the client visits an attacker-controlled web page. This work focuses on defeating website fingerprinting (WF), where the attacker is passively monitoring web packets. Researchers have identified WF as a potential attack against privacy since 1998 [7]. WF has become especially relevant with the growing popularity and usability of privacy technologies such as Tor and the revelation that state-level adversaries are willing to eavesdrop on Internet users en masse [11]. As a result, Tor currently employs a WF defense [24]. In this section, we discuss known WF attacks and defenses to contextualize our work.

2.1 Attacks

There is a long line of research on WF attacks [6, 12, 13, 15, 16, 22, 23, 30, 31]. In WF, the attacker classifies which web page each testing packet sequence belongs to. To do so, the attacker learns to classify using a set of training packet sequences and a machine learning technique. In the *closed-world scenario*, testing packet sequences come from a (small) list of monitored sensitive web pages the attacker knows, and the attacker must distinguish packet sequences coming from each of those pages. In the more realistic *open-world scenario*, testing packet sequences could also originate from non-sensitive web pages outside of the list and unknown to the attacker. In the open-world scenario, the attacker needs to distinguish between sensitive web pages and be able to identify that a non-sensitive web page is non-sensitive.

Over time, researchers have demonstrated increasingly accurate [22] and noise-tolerant attacks [33] using better classifiers. While older attacks were only able to identify pages in the closed-world scenario, newer attacks are also able to tackle the open-world scenario, thus posing a practical threat to privacy. We refer the reader to previous work [5, 22, 31] for a more detailed discussion of the specific workings of each WF attack and how they have evolved.

2.2 Defenses

Wright et al. (2009) published traffic morphing [34], a defense that randomly pads unique packet lengths so that these packet lengths look as if they came from another distribution of packet lengths corresponding to another web page. They showed that this defense was effective against an earlier attack (2006) by Liberatore and Levine [15], because that attack relies on unique packet lengths and does not consider other features such as packet ordering. Later, Wang et al. (2014) showed that this defense was not effective against their new attack, which uses packet ordering as a feature [31].

Luo et al. (2011) published HTTPOS (HTTP Obfuscation) [17]. They implemented the defense on the client side using features in HTTP: the client sets a `Range` header in order to split traffic into packets of random length and uses HTTP pipelining to change the number of outgoing packets. Luo et al. have shown that this is a successful defense against older attacks [2, 15, 30], but other researchers have also found that it is not a successful defense against several newer attacks [6, 31].

Tor has implemented another WF defense [24] in response to a WF attack by Panchenko et al. [23]. Tor's defense uses HTTP pipelining by randomizing the maximum number of requests in a pipeline, so that the order of requests may change if the number of requests exceeds

the depth of the pipeline. This defense has no bandwidth overhead as pipelining does not introduce extra packets. Tor has updated its defense [26] recently in response to newer attacks, but both versions of Tor's defense have little effect on the accuracy of known attacks [6,31,32].

We are aware of six WF defenses that are still effective: Decoy (Panchenko et al. 2011 [23]), BuFLO (Dyer et al. 2012 [8]), Tamaraw (Cai et al. 2014 [5]), CS-BuFLO (Cai et al. 2014 [4]), Supersequence (Wang et al. 2014 [31]), and Glove (Nithyanand et al. 2014 [20]). We refer to BuFLO, Cs-BuFLO, and Tamaraw as BuFLO defenses, as the latter two are modifications of BuFLO to lower overhead. Supersequence and Glove share the same usability issue as our work: they require the client to have some information about web pages. Whereas the issue is a stumbling block for Supersequence and Glove, our work resolves this issue by using half-duplex communication to minimize the amount of information the client needs to have, which we describe in detail in our evaluation (Section 5). All of these previous effective defenses generally require more than 100% bandwidth and/or time overhead.

3 Preliminaries

3.1 Attack Scenario

We consider a web-browsing client that is connecting to the Internet using one or more proxies over an encrypted connection. A packet received over such a network (e.g., a TLS packet) at some time t and having some length ℓ is denoted as $p = (t, \ell)$. A packet sequence is denoted as $s = \langle p_1, p_2, \ldots \rangle$. We use positive lengths to denote outgoing packets from the client and negative lengths to denote incoming packets.

We assume the attacker is *local* to the client and *passive*, consistent with previous works on website fingerprinting. Possible local attackers may include the client's ISP, wiretappers, packet sniffers, and other eavesdroppers. Since the attacker is local, the attacker knows the client's identity, but does not know which page she is visiting because she is using one or more proxies. As a passive eavesdropper, the attacker never attempts to modify the client's packet sequence. The attacker is therefore very hard to detect.

The attacker seeks to identify static web pages; Walkie-Talkie does not protect dynamic content. It is difficult to defend dynamic content as a whole, as bandwidth and timing requirements vary significantly. For example, it would be overwhelmingly expensive to make an online chatroom confusable with a high-quality video stream. Some types of dynamic content are not susceptible to WF, such as chatting and file downloading. Other works have shown that search queries [18] and videos [27] are susceptible to fingerprinting attacks. As pages are static, they are associated with finite-length packet sequences.

In our scenario, at least one proxy is outside the WF attacker's control. Otherwise, the attacker has already won without the need of website fingerprinting: previous work has shown that an attacker with control over both ends of a multi-proxied connection can compromise the client's privacy completely [19]. The non-compromised proxy (which we simply refer to as the proxy hereafter) is willing to protect the client's privacy by shaping the traffic according to her specification. A proxy who shapes the traffic incorrectly can be easily detected by the client, who sees the whole packet sequence.

As a preliminary, the client and proxy implement a simple defense: all packets they send to each other are of the same length, much like in Tor. They can do so by splitting longer packets and padding shorter ones. Previous work has shown that TCP packet lengths leak too much information to the WF attacker [5]. Indeed, Tor relays use fixed-length *cells* to deliver information; for this reason, previous work has found that Tor is much harder to attack with WF than many other web privacy technologies [13], though Tor is still vulnerable. Borrowing Tor's terminology, we use the term "cells" instead of "packets" to describe the fixed-length data elements, and scale our size units so that a cell has $|\ell| = 1$. Note that although we borrow the fixed-size cell concept from Tor, our defense is nevertheless applicable to other technologies such as VPNs and IPsec.

3.2 Overhead

To show that WT is efficient, we will evaluate its bandwidth overhead and time overhead.

The **bandwidth overhead** of a defense is the number of dummy cells added by the defense, divided by the number of cells in the undefended (original) cell sequence. Dummy cells are necessary to obfuscate the true amount of data on the wire. Bandwidth overhead represents a burden to the proxy and possibly other proxies between the client and the proxy. Note that the web server does not suffer from bandwidth overhead; it will never generate or see dummy cells.

The **time overhead** of a defense is the extra amount of time required to load the cell sequence, divided by the original amount of time required. To keep bandwidth overhead and time overhead separate, we assume that dummy cells do not add to the time overhead by themselves (i.e., the bandwidth is sufficient that extra dummy cells can be sent without delaying real cells). Nevertheless, all known effective WT defenses incur a large time overhead, typically because they artificially delay cells in order to induce desired traffic patterns such as sending

cells at a constant rate. A large time overhead deteriorates the client's experience, as the client needs to wait longer to load web pages, but it does not burden the proxies.

4 Components of Walkie-Talkie

Walkie-Talkie consists of two components: *half-duplex communication* and *burst molding*. To defend a cell sequence from a sensitive web page, half-duplex communication transforms the cell sequence into a burst sequence. which is then molded into a burst sequence from a non-sensitive web page. We describe both components and how they work together in detail in this section.

4.1 Half-Duplex Communication

We modify the client's web browser so that it communicates in half-duplex mode, much like a walkie-talkie. Normally, web browsing is full-duplex: multiple servers are sending web page data to the client while the client simultaneously sends further resource requests, possibly to new servers. The pattern of exactly when the client has received, for example, an `img` tag within an HTML resource, causing it to immediately fetch the corresponding image resource, is a strong feature for the WF attacker. Under our defense, the client only sends requests after the web servers have satisfied all previous requests. As a result, the client and proxy both send data in interleaving bursts of incoming and outgoing cells. Walkie-Talkie does not affect web servers.

The goal of half-duplex communication is to reduce the information available to the WF attacker about the cell sequence s to the form $s = \langle (b_{1+}, b_{1-}), (b_{2+}, b_{2-}), \ldots \rangle$, a *burst sequence*: each b_{i+} is the number of continuous outgoing cells sent in a burst and each b_{i-} is that for the succeeding incoming cells. We can think of half-duplex communication as a way to group same-direction cells together.

The benefit of using burst sequences instead of cell sequences is that they can be *molded* at little overhead, and molding them is computationally cheap. (We describe molding in detail in Section 4.3). Indeed, previous defenses (Supersequence [31], Glove [20]) have attempted to mold cell sequences directly, at a much greater cost in overhead. Another issue with these previous defenses is that they require the client to know the cell sequences of many pages, but cell sequences carry a lot of information and are therefore difficult to deliver and store. Burst sequences are much lighter in information content, and we will show that it is practical to deliver and store hundreds of thousands of burst sequences.

4.1.1 How browsers work

In this section we describe how browsers use persistent connections to load data from a web server. We use the terminology defined in RFC 7230 on "HTTP/1.1 Message Syntax and Routing", especially its discussion on connection management in Section 6 [10]. While our implementation is based on Tor Browser, any browser with persistent connections (i.e., any browser supporting HTTP/1.1) can be modified to support half-duplex communication.

During web browsing, clients make requests to obtain data from the server (or post data to the server). To send requests, the browser creates or re-uses persistent TCP/IP connections (up to a preset maximum number of connections). When requests are complete, the browser may close the attached connections, or keep them alive as open connections in order to send further requests to the same server.

As the total number of simultaneously open connections is (tightly) limited, a browser will often be unable to make further requests until current requests are completed. Until then, the browser stores the request in a pending request queue. When a request completes or when a connection dies, the browser enumerates the pending request queue in an attempt to send requests (sometimes by creating new connections). During the enumeration process, the browser may re-use open connections or close them to make room for new connections to other servers.

4.1.2 Implementation of half-duplex mode

We add two states to the browser to enforce half-duplex communication: *walkie* and *talkie*. Conceptually, the *walkie* state corresponds to an idle browser; the *talkie* state corresponds to a browser that is actively loading a page (which may be any number of resources). We explain each below. Our modification only adds 26 lines of code and removes 12 lines of code from the connection manager in Tor Browser (which is itself a modification of Firefox), and it is available for download with a link in Section 7.

The browser starts in the *walkie* state. When the client starts any request while in the *walkie* state, the browser sends the request immediately, and the browser switches to the *talkie* state. After the page has finished loading, when there are no pending requests left, the browser will return to the *walkie* state.

In the *talkie* state, the browser is currently loading a page. The browser always queues new requests in this state; it never sends requests immediately. Furthermore, the browser does not enumerate the pending request queue whenever any connection dies or become idle. Rather, the browser only enumerates the request

queue and sends out requests when there are *no active connections left* (i.e., all connections have died or become idle). If instead the request queue is empty, the browser returns to the *walkie* state; page loading has stopped.

We justify why the above states implement half-duplex communication by making the following observation: the client never attempts to initiate new HTTP requests when there are any active connections left. This is true in both the *walkie* and the *talkie* state. Since an HTTP server does not actively initiate contact with the client, the lack of active connections means that the server is never sending data when the client initiates new HTTP requests.

However, the above alone is not sufficient to ensure half-duplex communication. This is because making a new HTTP request is not instantaneous. Unless a pre-existing open connection to the server exists, the client must spend an extra round-trip time to open a new connection. The round-trip time creates a time gap that causes the client to talk when the servers are already responding to other HTTP requests. One way to solve this problem is to ensure that the client must establish a connection and send the HTTP request in two bursts rather than one burst. We implement a more efficient solution to this problem, as described below.

4.2 Optimistic data

Normally, when a client wishes to load a resource from a web server, the client makes a TCP connection request, waits for the server's request acknowledged message, and only then will the client send a `GET` request to load the resource. This creates an extra round-trip time that can be removed by having the client send both the TCP connection request[2] and the HTTP `GET` request at the same time. The final hop holds the `GET` request until the TCP connection is established, and then sends out the `GET` request. This is known as *optimistic data* in Tor, and Tor Browser has used optimistic data since 2013 [25]. As optimistic data works on Firefox in general if the client is using a SOCKS proxy, users of other privacy options and anonymity networks can use optimistic data as well.

Optimistic data works at the socket level. Normally, after sending a connection establishment request, the socket waits for an acknowledgement by the server before informing the browser that it is ready to send requests. With optimistic data, the socket does not wait, but rather it immediately pretends to the browser that the server has established the TCP connection, which causes the browser to send the `GET` request immediately. Optimistic data is useful for our defense, as it allows the client to establish a new connection and send the relevant request at the same time. Optimistic data reduces the number of bursts and thus the amount of padding we need to confuse the attacker.

[2]The TCP connection request is here an *application-layer* message instructing the last hop in the anonymity network to make a TCP connection to the desired destination.

4.3 Burst molding

Burst molding draws from the concept of Decoy, the WF defense described by Panchenko et al. [23], which loads two pages in parallel to confuse the adversary, at an approximately 100% bandwidth overhead. The adversary cannot determine which of the two pages is really visited by the client. We can further leverage the open-world scenario to improve the defense mechanism: if the real page is a non-sensitive page, we will choose a sensitive page as the decoy page, and vice versa. If the client's sensitive pages are always loaded with popular non-sensitive pages, the attacker can never determine that she has visited a sensitive page. This is especially effective if the non-sensitive page is sufficiently popular, in which case the attacker suffers from the base rate fallacy. It is plain to see that Decoy is effective no matter what classifier the WF attacker uses. Burst molding is able to achieve the same property.

However, instead of actually loading two pages, burst molding *simulates* loading two pages by loading the *supersequence* of two burst sequences, which allows a much lower overhead than loading two pages. A sequence s' is a supersequence of s if s' contains s; this applies to both cell sequences and burst sequences. The idea of simulating supersequences is inspired by Supersequence [31] and Glove [20]. Allegorically, adding padding cells is like injection molding: burst molding adds cells to the original burst sequence so that it is molded into the supersequence.

Burst molding adds fake cells to burst sequences as follows. If the number of cells in a burst of the real page is $b_i = (b_{i+}, b_{i-})$, and for a burst of the decoy page it is $b'_i = (b'_{i+}, b'_{i-})$, we will send $\hat{b_i} = (\max\{b_{i+}, b'_{i+}\}, \max\{b_{i-}, b'_{i-}\})$ cells. We do so for every burst in each burst sequence. If the number of bursts in the two burst sequences is different, we add fake bursts consisting of entirely fake cells to the shorter sequence. We do so for each burst, resulting in a significantly lower overhead compared to simply loading two pages at once: burst molding uses the *max*, while Decoy would use the *sum* of burst sequences. The attacker knows that any subsequence of the above is possibly the real page—including the real and decoy pages themselves—but cannot tell which is the real page.

Fake cells in a burst add to the bandwidth overhead, but do not add to the time overhead (according to our definition in Section 3.2). Fake bursts consisting of en-

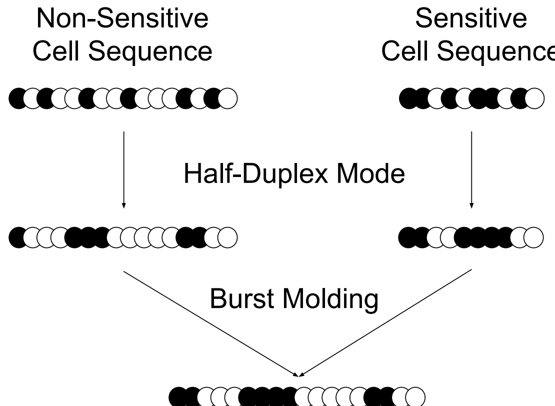

Figure 1: Diagram showing the effect of Walkie-Talkie on cell sequences. Black circles indicate outgoing cells and white circles indicate incoming cells. Walkie-Talkie consists of two steps: half-duplex mode and burst molding. Half-duplex mode groups cells of the same direction together, while burst molding adds fake cells to make sensitive and non-sensitive cell sequences the same.

tirely fake cells add to both the bandwidth and time overhead. We show the effect of half-duplex communication and burst molding in Figure 1 as an illustration.

4.3.1 Advantages

We will show that burst molding is more effective and has lower overhead compared to other defenses in Section 5. Burst molding has several other qualitative advantages, which we describe below:

Cover story.
With burst molding, the client knows and could control what non-sensitive web pages have been used to disguise her page accesses. This gives the client an explicit cover story for her actions. This is not the case in BuFLO [8], Tamaraw [5], and CS-BuFLO [4], where the client cannot know or control which other page her cell sequence appears to come from (rather, the client is only given the assurance that such a page is likely to exist).

Base rate.
Web pages are accessed with vastly different base rates in the real world, but most work in the field (including all defenses) has ignored this fact. Our design specifically takes this into account, as we use more popular (and less sensitive) Alexa's top pages as decoy pages. In the above scenario, an attacker trying to claim the client visited the sensitive page is highly likely to be wrong. We further develop on how varying base rates affect our defense effectiveness in Section 6.2.

Minimizing computation.
Wang et al. pointed out that Supersequence requires the solution of an NP-hard problem [31] to minimize bandwidth overhead for cell sequences. Both Supersequence and Glove use an approximation algorithm to this problem. This approximation algorithm is nevertheless slow, and the client would have trouble computing the supersequence of a large number of cell sequences. For WT, computation of burst supersequences is cheap: we simply take the maximums of several pairs of numbers.

Minimizing client information.
WT, Supersequence, and Glove all require the client to know some decoy pages. The difference is that WT requires burst sequences, whereas the latter two require cell sequences. Burst sequences are much easier to store than cell sequences, because we do not need to store the ordering of cells. On our data, we found that we only need about 20 bytes of information to describe the burst sequence of a web page, whereas cell sequences require 36 kB of information on average; burst sequences are about 1800 times more efficient to store and deliver. For example, the client can know the burst sequences of 100,000 potential decoy web pages by loading and storing 2 MB of data. Currently, a Tor client needs to load about 8 MB of data when starting up Tor for relay discovery, so this amount is feasible on Tor. Tor directory authorities can collaborate with each other to collect cell sequence data, and send the data to clients along with relay data.

4.3.2 Choosing decoy pages

We can optimize the overhead of burst molding by choosing decoy pages cleverly, instead of simply choosing a random burst sequence. For each sensitive page s in our set of known burst sequences, we pre-compute its overhead when sent with each of the set of non-sensitive pages in our set; suppose non-sensitive page s' caused the minimum overhead when sent with s (conceptually, s and s' are similar cell sequences). Then we pair s and s' together, such that when the client needs to visit s, she uses s' as a decoy page; similarly when the client needs to visit s', she uses s as a decoy page. Each decoy page is only paired with one other page. The choice of decoy pages is then symmetric between sensitive and non-sensitive pages, and reveals no information as to which one triggered the cell sequence. This optimization is only possible if the client knows the burst sequence of her real page. In case she does not, she defaults to simply choosing a decoy page randomly. Burst molding is therefore most efficient when the set of decoy pages is large, and we have seen that a large set of decoy pages is practical.

Some clients may not want to use sensitive pages as decoys, as they would rather not attract the attention of eavesdroppers monitoring sensitive page access. It is

however necessary that sensitive pages should be used as decoys; otherwise, whenever the attacker detects that the client is visiting either a sensitive page or a non-sensitive page, the attacker would know that the non-sensitive page is a decoy. Further, we argue that the use of a sensitive decoy page is no more compromising than the use of proxies or encryption: for instance, the presence of ciphertext does not suggest that the plaintext is noteworthy. In particular, the client is never made to visit sensitive pages under WT, which is an advantage over the defense of Panchenko et al. [23] She only adds fake cells in a way that matches the burst sequences of sensitive pages.

We evaluate a fixed set of decoy pages in this work, though it is possible for the client to choose her own decoy pages. For example, a German-speaking client may choose popular German pages to be more convincing.

4.4 Practical implementation

In WT, the client and proxy construct the supersequence together by respectively adding fake cells and bursts to their outgoing packets. The client chooses the decoy page and sends the decoy burst sequence to the proxy before starting a page visit. The proxy counts the number of sent packets in each burst and adds packets if it is lower than the number of required packets in the decoy burst sequence. Therefore, there is almost no computation overhead to the proxy. WT is deployable: any proxy that is willing to carry and encrypt traffic for the client would also be willing to mold it slightly for her privacy.

As a proof of concept, we implemented burst molding by modifying the Tor client. Our implementation adds 143 lines of code to Tor. We added two new cell types, a fake cell and a fake burst end cell. During a real burst, the client sends fake cells before sending real cells. The proxy sees the client's fake cells, drops them, and similarly starts sending fake cells before sending real cells. During a fake burst, the client and the proxy both use fake burst end cells to mark the end of each fake burst.

The chief difficulty in our implementation was that the Tor client had to stop delivering cells in the middle of fake bursts. Otherwise, the fake burst would look different from real bursts. We did so by adding a queue to each Tor circuit, so that each cell that was created in between fake bursts would be queued. At the end of a fake burst (signalled by the fake burst end cell), the client empties the queue and sends the queued Tor cells as the next burst. Our implementation does not rely on any Tor-specific mechanics, and could be applied to other proxy technologies.

Our implementation assumes that that the client can either collect burst sequences or receive them from somewhere else. (Our security analysis assumes that the attacker is allowed to see them.) We describe an alternative construction of Walkie-Talkie for which the client has no information about any real burst sequences in Appendix A.

4.5 Security

We analyze the security of Walkie-Talkie against an attacker who wants to know when a client has visited some sensitive page s. The client really visits s at probability p and chooses s as a decoy page for some other page with probability p'. It is plain to see that the attacker's precision cannot exceed $p/(p+(1-p)p')$, as no attacker can distinguish between real visits and decoy visits.

To achieve the maximum precision, the attacker must be able to correctly determine the two subsequences that make up any given cell sequence of WT. We will see in the evaluation (Section 5.2) that no real attack comes close to doing so. Even a theoretical perfect classifier fails to do so; in Section 5.4.2, we show that there are often hundreds if not thousands of possible realistic subsequences (from a set of 10,000 subsequences) for any given cell sequence of WT.

We extend our analysis to include the scenario that the client may not have chosen s as a decoy page. Consider two types of clients: clients who really visit s at some probability p taken from distribution X, and clients who only use s as a decoy with probability p' taken from some distribution X'. To distinguish between those two types of clients, the attacker must be able to judge if the client's visits of s come from X or X'. It is not practical for the attacker to do so, as the attacker cannot directly measure X, X changes over time in an unpredictable manner, many page visits would include s as a subsequence (even without choosing s as either a real page or a decoy page), and the attacker's estimation of X' is significantly affected by observation error, especially if the set of decoy pages is rotated regularly. Therefore, the attacker cannot determine if any given client has ever really visited s, or merely uses it as a decoy page.

5 Evaluation

Here we evaluate WT on data collected from Tor using the methodology described next in Section 5.1. In Section 5.2 we show that WT is effective against known WF attacks. In Section 5.3 we compare our defense against known defenses to show the significantly lower overhead of WT. WT is in fact effective against all possible WF attacks; we rigorously define this notion and quantify WT's effectiveness against all WF attacks in Section 5.4.

5.1 Setup and Data Collection

We collected our data on Tor Browser 6.0 (based on Firefox 38.7.1) with Tor 0.2.8.1. To collect burst sequences for WT, we modified Tor Browser to enable half-duplex communication, as described in Section 4.1.2.

We collected data from Alexa's top pages [1]; we use long-standing pages to make our results more reproducible and comparable to other papers in the field. We use 100 of the top pages as the non-sensitive set (after removing duplicates due to different localizations or URLs of the same page), and we collected 100 instances of each page in the non-sensitive set. We use the next 10,000 pages in Alexa's top pages as the sensitive set. In the closed-world scenario, we only use the former data set, in which case the 100 top pages are sensitive instead; to avoid confusion, in this case we refer to the top 100 pages as the closed-world set. We dropped any instance with fewer than 50 cells (25 kB) in it, in order to discard pages that failed to load.

We added the capability to generate fake cells on Tor clients and relays, but we will not use the latter to achieve burst molding in this section. Rather, we will simulate burst molding after collecting data using half-duplex mode. This is because we want to present experimental results for a large number of parameter choices for burst molding, and re-collecting data for each set of parameters is infeasible. Our simulated burst molding does not consider network instability events such as packet loss and proxy dropping; these events are rare and unlikely to be caused by and therefore linkable to the server.

5.2 Walkie-Talkie versus Attacks

We implemented nine known WF attacks and tested each of them against WT. Each WF attack we tested was the state of the art at the time of its publication. Since many of the older attacks were not designed for the open-world scenario, we tested all of them in the closed-world scenario for consistent comparison. We use 100 instances of each of the 100 closed-world pages for training and testing with 10-fold cross validation. Since the closed-world scenario is strictly easier to attack than the open-world scenario, our results are a conservative estimate of WT's effectiveness.

We show the results in Table 1 under two columns: the original accuracy on a Tor data set without our defense (Undefended), and the new accuracy on a Tor data set with our defense (Defended).

Jaccard and MNBayes are highly inaccurate even in our Undefended case because they rely on unique packet lengths, but all of our cells have the same length (see Section 3.1). Out of all the attacks, SVM by Panchenko et al. [23] appears to suffer least from WT, performing slightly better than kNN [31]. Indeed, previous authors [5,8] have noted the resilience of this attack against random noise, possibly due to its use of a "kernel trick" transforming distances between cell sequences, allowing greater flexibility in ignoring dummy cells. While our experiments on the closed-world scenario show that WT is successful, WT truly shines in the more realistic open-world scenario, which we investigate next.

Table 1: Closed-world accuracy (TPR) of known attacks against Tor (Undefended), and Tor protected by WT (Defended).

Attack	Undefended	Defended
Jaccard [15]	0.01	0.01
Naive Bayes [15]	0.49	0.16
MNBayes [13]	0.03	0.02
SVM [23]	0.81	0.44
DLevenshtein [6]	0.94	0.19
OSAD [32]	0.97	0.25
FLevenshtein [32]	0.79	0.24
kNN [31]	0.95	0.28
CUMUL [22]	0.64	0.20
kFP [12]	0.86	0.41

Table 2: Open-world accuracy (TPR and FPR) of known attacks against Tor (Undefended), and Tor protected by WT (Defended).

	True Positive Rate (TPR)	
Attack	Undefended	Defended
SVM [23]	0.47	0.33
kNN [31]	0.98	0.68
CUMUL [22]	0.78	0.20
	False Positive Rate (FPR)	
Attack	Undefended	Defended
SVM [23]	0.05	0.20
kNN [31]	0.09	0.62
CUMUL [22]	0.04	0.35

We designed WT for the open world, as it attempts to confuse sensitive and non-sensitive pages. We focus on three WF attacks that have been successful in the open-world scenario: SVM, kNN, and CUMUL, and present their TPR and FPR in Table 2. We see that the FPR for each attack increases significantly with the application of WT. kNN adopts an aggressive strategy, achieving a high TPR but suffering a high FPR, whereas CUMUL and SVM both suffer a low TPR with a low FPR.

The base rate fallacy tells us that since the TPR and FPR are similar for all three attacks, they are highly imprecise if the base rate of sensitive page access is low. This is an important consideration as realistically, clients do not often visit sensitive pages. For example, if the rate

Table 3: Accuracy of each feature category of kNN against Tor (Undefended), and Tor protected by WT (Defended).

Category	Undefended	Defended
Sequence length	0.67	0.14
Location of outgoing cells	0.01	0.01
Ratio of outgoing cells	0.79	0.19
Cell bursts	0.81	0.27
Direction of initial cells	0.04	0.01
Intercell times	0.10	0.04

of sensitive page access is 5%, then kNN would have a precision of only 5.5%; almost all of its sensitive classifications are wrong. Despite having a decent recall rate, kNN would be useless against WT as the attacker cannot act upon its sensitive classifications.

We seek to delve deeper into the success of WT against known WF attacks by examining how WT affects individual features. To do so, we examine the feature categories defined by kNN [31]. We choose kNN because its feature categories are diverse and understandable, and it is one of the better attacks. Returning to the closed-world scenario for this experiment, we measure the effectiveness of each individual category by calculating the classification accuracy if only features from that category were used for kNN classification. We contrast the effectiveness of each category before and after WT is applied on our cell sequences.

We plot the six feature categories and their results in Table 3. Each feature category that was useful for classification in the Undefended case has been covered by WT. Although WT makes no explicit attempt to cover intercell times, the addition of fake cells appears to disrupt intercell times as a feature. Comparing Table 3 and the entry for kNN in Table 1, we see that the accuracy of kNN under WT would be almost unchanged if only the sizes of the cell bursts were used and other feature categories were discarded. This reflects the fact that WT effectively reduces the information available to the attacker to simply the burst sequences.

5.3 Walkie-Talkie versus Defenses

In the other direction, we compare WT with a basket of known website fingerprinting defenses in Table 4, in terms of bandwidth overhead (BWOH), time overhead (TOH), and accuracy of the kNN attack by Wang et al. [31]. We use the kNN attack because it is the current state-of-the-art attack on Tor. We implemented all of these attacks based on their original authors' descriptions. We did not include some older defenses which had no effect on cell sequences, as they only affected packet sizes.

Table 4: Bandwidth overhead (BWOH) and time overhead (TOH) of the best WF defenses, as well as the accuracy of kNN on them in our data set.

Defense	BWOH	TOH	kNN acc.
Adaptive [29]	193%	16%	0.67
Decoy [23]	100%	39%	0.25
BuFLO [8]	145%	180%	0.08
Supersequence [31]	222%	112%	0.05
Tamaraw [5]	103%	140%	0.05
WT (this work)	**31%**	**34%**	**0.28**

We can see from Table 4 that WT has a markedly smaller bandwidth overhead (BWOH) and time overhead (TOH) than many of the previous attacks, and it is still able to defeat kNN. Across our data set, the bandwidth overhead of WT is $31\% \pm 16\%$ and its time overhead is $34\% \pm 5\%$; different cell sequences vary significantly in bandwidth overhead but not time overhead. BuFLO, Supersequence, and Tamaraw are able to further decrease kNN accuracy (0.05 to 0.08) compared to WT (0.28), but this effectiveness comes at a high cost in overhead. kNN's higher accuracy against WT is not practically meaningful: nevertheless, the attacker cannot identify accesses to sensitive pages under WT due to the base rate fallacy. For WT, any cell sequence always looks as if it could have come from at least two different web pages due to burst molding, which means that no WF attack can reach an accuracy above 0.5. We develop this notion further in Section 5.4.

Tamaraw, Supersequence, and WT are all tunable: each defense can decrease its own time overhead by increasing its bandwidth overhead and vice versa. Furthermore, each defense can increase either overhead to increase the effectiveness of the defense against attacks. A proper comparison of these defenses requires further analysis. We focus on Tamaraw as it has a lower overhead than Supersequence.

We investigate the trade-off between time overhead and bandwidth overhead. To do so, we fix the effectiveness of Tamaraw and WT to be the same against attacks in general (see Section 5.4 for details on how we compute this). For Tamaraw, the trade-off is achieved by varying the fixed intercell times. For WT, the trade-off is achieved by changing which cell sequences to choose in burst molding. We can prefer cell sequences that minimize bandwidth overhead at the cost of time overhead and vice versa. We plot the results in Figure 2. We find that the range of possible overheads for WT is quite small compared to Tamaraw. Half-duplex communication induces a 30% time overhead in our experiments, so that is the minimum value for WT. While the overhead of Tamaraw can vary significantly, its range of both bandwidth

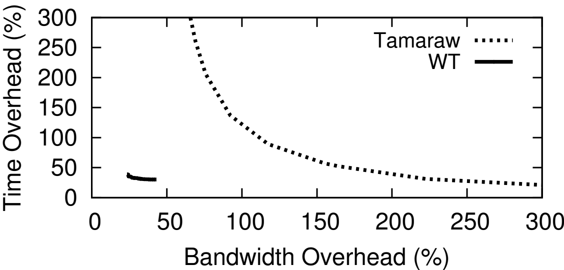

Figure 2: Bandwidth and time overhead for Tamaraw and WT.

and time overhead is in any case much higher than that of WT. To reach a bandwidth overhead less than 100%, for example, a time overhead over 150% is required, which is a large increase in page load time.

To investigate the trade-off between overhead and effectiveness, we need a general notion of effectiveness for all attacks, not just any given attack. We next develop such a notion and show that WT is effective against all WF attacks in general.

5.4 Defending against any classification attack

Observing that many older defenses have not proven effective against newer attacks, authors in the field [4, 31] have suggested that a defense should be designed to be effective against all possible WF attacks. To do so, the output cell sequences of some web pages should be *exactly the same* as some other web pages. To be specific, the cell sequences should be the same length, and the timing, direction, and size of all cells should be the same.[3] If this is achieved, then no attacker can distinguish between those web pages, independent of the classification mechanism they use.

The above is achieved in both Tamaraw and WT. We compare Tamaraw and WT in terms of their effectiveness against all possible WF attacks.

5.4.1 Maximum Attacker Accuracy

Borrowing terminology from the k-anonymity literature, we say that two cell sequences s, s' belong to the same collision set $C(s)$ if they become the same sequence after applying the defense. They may come from different web pages; we denote the page a cell sequence comes from as $Page(s)$. An effective defense's objective is to cause cell sequences to collide. We measure the effectiveness by defining a notion of Maximum Attacker Accuracy (MAA). The MAA of a cell sequence is equal to:

$$MAA(s) = \frac{|\{s' \in C(s)|Page(s') = Page(s)\}|}{|C(s)|}$$

The MAA describes an attacker who, seeing that they cannot distinguish between any of the cell sequences in the collision set, decides to simply randomly guess which page it is. On the other hand, if all cell sequences in the collision set belong to the same page anyway, the attacker's guess will be exactly correct. The attacker maximizes classification accuracy in the sense that they know exactly which page each cell sequence belongs to ($Page(s)$ is known to the attacker for all s). No classifier's accuracy can exceed the MAA; the lower the MAA, the more effective the defense. We thus favor the MAA as an intuitive, attack-agnostic metric for measuring the minimum effectiveness of a defense. Later, in Section 6.2, we expand on the MAA by investigating WT in an open-world scenario with different page visit rates; for now, we evaluate WT on a simpler MAA.

It is easy to see that the MAA of Walkie-Talkie is 0.5. Each cell sequence is in a collision set with exactly one other cell sequence from a different page due to burst molding. Furthermore, since the decoy page selection mechanism is symmetric (Section 4.3.2), the collision set does not reveal which cell sequence is the true cell sequence. However, if we increase the number of colliding cell sequences, the MAA can lower further. We develop this idea next.

5.4.2 Maximum Attacker Accuracy of WT

In the context of WT, the MAA is that of an attacker who knows exactly which two pages can be the decoy page and the real page, but not which is which. In other words, he resorts to guessing one out of two pages. We can decrease his MAA by molding towards the supersequence of several decoy cell sequences, not just one decoy cell sequence.

The greater the number of cell sequences chosen, the greater the overhead. We investigate the MAA of WT and compare it with Tamaraw. We show the results in Figure 3, plotting MAA against bandwidth overhead. WT is generally more efficient even if the user desires a very low MAA. The time overhead of WT goes up to 45% for the values in this graph, while it increases much more quickly for Tamaraw, from 130% to 350%.

WT has another advantage over other WF defenses: any defended cell sequence could have come from many different web pages. This is because any subsequence of a defended cell sequence could have been the original undefended cell sequence. Not all possibilities are equally

[3] We do not need to ensure that the cells were received at the same time including network noise; we only need to ensure that the cells were attempted to be sent at the same time, as any timing difference then would only indicate network noise and reveals no information about the cells themselves.

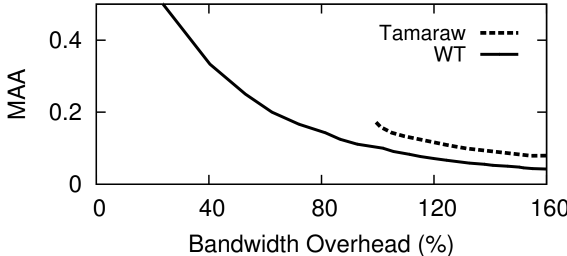

Figure 3: Bandwidth overhead and MAA for Tamaraw and WT across a range of parameters. No WF attack can achieve a classification accuracy above the MAA.

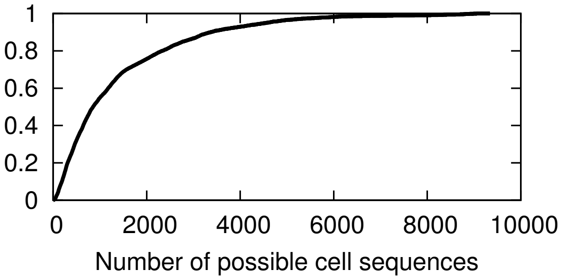

Figure 4: Cumulative distribution frequency graph of WT collision set sizes. A collision set of a defended cell sequence is the set of undefended cell sequences that could have generated it when the defense is applied.

likely: burst molding attempts to minimize overhead, so from the attacker's perspective, the true cell sequence is not likely to be much smaller than the observed cell sequence. Nevertheless, this observation produces a confusing effect on the attacker that has not been accounted for in the MAA; that is, a realistic attacker's accuracy is likely to be lower than the MAA.

We evaluate this effect on our closed-world page set of 100 pages and 100 instances each. For each defended cell sequence, we calculate the number of possible undefended cell sequences from other web pages that could have generated it. We call this the **collision set size**. The maximum collision set size is therefore 9900. We show the cumulative distribution frequency graph in Figure 4. There was only a .1% chance that the collision set size was smaller than 10 (it was always at least 2 because of burst molding), and a 4% chance that it was smaller than 100. The median collision set size was 860. We contrast this with Tamaraw, where on our data set there was a 2% chance that the collision set size was smaller than 10 and a 13% chance it was smaller than 100; the largest collision set size was 795. The attacker's ability to rule out possible web pages given a defended cell sequence is much more limited under WT.

6 Extensions of Walkie-Talkie

In this section, we present several extensions of Walkie-Talkie to defeat three WF attackers that are more advanced than that of previous work. In Section 6.1 we describe multi-page attackers, who understand the relationship between several pages of the same site and can determine when the client is on the same site. In Section 6.2 we describe attackers who know that the client visits pages at different base rates, and can estimate this base rate. In Section 6.3 we investigate attackers that can use timing information to defeat Walkie-Talkie. We show that, with some modifications, WT can effectively defend clients at little extra cost against all of these advanced attackers.

6.1 Defending against multi-page classification

In Section 5, we analyzed Walkie-Talkie against an attacker who classifies pages one at a time, independently of any other page. A realistic attacker could leverage his knowledge of the link structure of web sites to achieve greater accuracy. For example, if the attacker knows a priori that two web page accesses came from the same site, then the attacker can more accurately identify what site that is.

Defending against multi-page classification critically relies on the ability to specify which non-sensitive decoy page to use for each sensitive page. With this feature, we can specify non-sensitive pages from the same site as decoys when the client is visiting sensitive pages from the same site. BuFLO-based defenses are unable to specify decoy pages, while Supersequence and Glove must suffer significant overhead to do so. However, WT is able to choose decoy pages with great efficiency. WT is thus well suited as a defense against multi-page classification. We modify WT so that it chooses decoy pages more cleverly. When the client is visiting sensitive pages from the same site, WT also mimics non-sensitive pages from the same site, each one of which is likely to lead to the next.

With the above modification, WT will succeed in defending clients against multi-page attacks, which no previous WF defense has done. To demonstrate this, we will evaluate its overhead and Maximum Attacker Accuracy against multi-page attackers. We expect the overhead to be higher than before, because the client has less freedom of choice in page selection.

We experiment by configuring our Tor Browser client to randomly follow links on each of Alexa's top 100 sites. Unfortunately, we do not know the true probabilities with which real clients visit links from Alexa's top 100 sites, so we choose the next link uniformly randomly from the set of all links on the page. The client stops after 10 page

loads. Then, we test the bandwidth and time overhead of a client attempting to decoy random sensitive pages with those page loads. We find that, maintaining an MAA of 0.5, the bandwidth overhead necessary to defend against a multi-page attacker increases from 31% to 53%, and the time overhead increases from 34% to 42%. The increase is small, and demonstrates that a client can effectively defend herself against multi-page attacks as well, with no decrease in minimal defense effectiveness.

6.2 Incorporating prior knowledge

For analytical simplicity, our experiments assumed a client that visits all pages with the same likelihood; to our knowledge, all other works in website fingerprinting make this assumption. Realistically, a client would visit pages with different probabilities, and the attacker may have prior knowledge of such a distribution. Here, we remove the previous assumption and adopt a model for estimating page likelihood, assuming that the attacker knows the client's distribution fully. We examine how this affects Walkie-Talkie.

We obtain basic estimated page view data for Alexa's top 10,000 sites from StatShow, and perform least-squared approximation on the logarithm of the number of page views. We attempted to approximate the number of page views with the following function

$$Views = a \cdot e^{bx} \cdot (x+1)^c$$

In the above, a, b, and c are parameters, and x being the index of the page (1 being most popular). We obtain the parameters by performing Levenberg-Marquardt least-squared approximation on the logarithm of the above function, resulting in $a = 36000$, $b = -0.000083$, $c = -1.0$. However, we found that the number of page views dropped precipitously near the end of our data set, rendering parameter estimation inaccurate. We believe this is because our list of top sites was incomplete at the end of the list. Instead of trying to fit all of our data, we fit the top 5,000 sites and then extrapolate. The resultant curve had a mean squared error of 0.0002 on the logarithm of the number of page views.

We simulate clients that visit pages with probability based on this curve, with no limit on the index of the page. Our model suggests that 57% of all page views are in the top 100 sites, and 40% of all page views are in the next 10,000 sites. We use the former set as non-sensitive decoy pages and the latter as monitored sensitive pages. Considering an ambitious, powerful attacker who is always capable of identifying the potential decoy and sensitive page in a WT-protected page access (but not which is which), the attacker can achieve a precision of 41% by simply guessing that all pages are sensitive (with a recall of 100%). In a more realistic scenario when the attacker is interested in much fewer than 10,000 pages, the maximum precision would be proportionally lower.

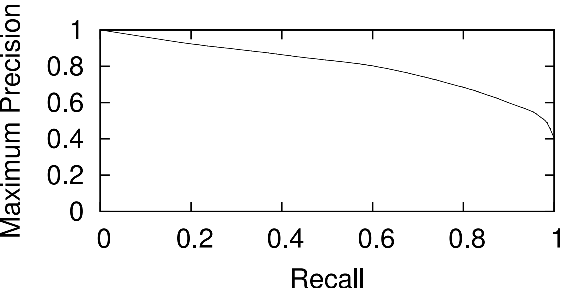

Figure 5: Maximum precision/recall graph for an attacker on Tor defended by WT, after incorporating page likelihood.

We draw the attacker's precision/recall curve by having him cleverly choose to identify sensitive pages in decreasing order of precision, and gradually increasing the set of such pages he was willing to classify. This gives the attacker the maximum precision at each level of recall. We draw the graph in Figure 5. For instance, we find that at 25% recall, the attacker has a maximum precision of 90%. Even with such a low recall, the attacker frequently makes mistakes in identifying sensitive pages. We can contrast this with kNN, which can achieve a precision of 99% with a recall of 80% on a non-defended Tor data set [31]. The attacker's precision does not change even if the attacker had prior information indicating that the client is not visiting certain monitored pages, as long as the visit rate of other pages is unchanged.

We consider a page-view-sensitive variation of WT where we also choose decoy pages based on the popularity of the page, not just the potential overhead. This method would come with a penalty to the overhead. We take the value of maximum precision for at least 25% recall, and we we plot the graph of maximum precision to bandwidth overhead in Figure 6. (Time overhead increased slowly from 34% to 42% within the range of this graph.) The maximum precision starts at 90% and then drops sharply to 64%. (The minimum precision of simply randomly guessing if each page is sensitive is 41%.) However, as we increase the weight for page popularity further, we see that the maximum precision increases counter-productively. This represents the case where the client starts choosing only the first few most popular pages, which limits her set of potential decoys, weakening her defense.

6.3 Intercell timing

WT may have a subtle timing leak: the incoming cell rate may leak information about the destination web page—more precisely, the number of servers that are sending in-

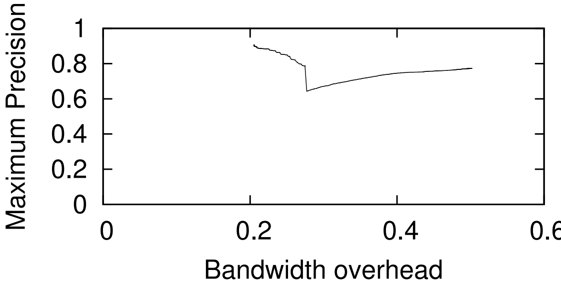

Figure 6: Maximum precision/bandwidth overhead graph for an attacker on Tor defended by a page-view-sensitive variation of WT. The variation decreases precision further for a small increase in bandwidth overhead.

formation simultaneously, and their possible processing times before starting to send the page data. For outgoing cells, timing leaks no information for WT, because there is only one client and half-duplex communication ensures that the client is dumping all the requests she can send as quickly as possible, after which she falls silent. In this section, we first argue with empirical evidence why the incoming intercell timing leak of WT may not be practically usable by any attacker. Nevertheless, we then show how WT can be modified to cover any possible incoming intercell timing leak. Despite the lack of empirical evidence that this timing leakage can be leveraged by any attacker, we provide such a modification to preserve the theoretical guarantees of WT against future WF attacks that may more cleverly use intercell timing.

Is timing useful for classification?

The results of this work have already suggested that intercell timing is not useful: in Section 5.2 and Section 5.3, we allowed WT to leak intercell timing, and WT was nevertheless able to efficiently defeat known attacks. In fact, WF researchers tend to avoid the use of intercell timing in general: out of fourteen known WF attacks we surveyed, we found that only three attacks used intercell timing: the two oldest WF attacks [2, 29] (both are significantly less effective than newer attacks on Tor), and kNN [31]. We specifically saw in Table 3 that intercell timing does not aid classification in kNN either. We ran a further classification test using kNN only on extracted intercell timing values of the top 100 pages, and achieved a 0.5% TPR.

We suggest that this is because intercell timing is highly inconsistent for the same site, but the distribution of timings is similar across different sites. Network conditions fluctuate rapidly as proxies need to be rotated frequently to safeguard anonymity. We constructed kernel density estimators using Scott's rule [28] on intercell timing, and found that the resulting probability density functions overlapped significantly. Experimentally, we

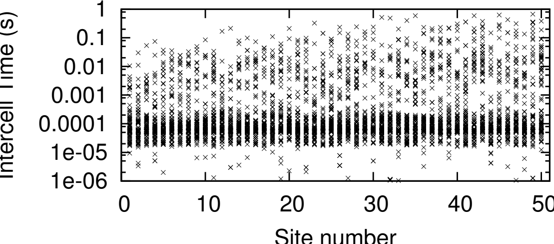

Figure 7: 100 random intercell times from each of 50 top pages. Each cross represents an intercell time. Note that the y-axis is logarithmic.

found that the attacker could only achieve a maximum 2% accuracy on the top 100 pages by choosing the most likely page for each sampled intercell timing value.

To illustrate this point visually, we plotted 100 random intercell times from each of the top 50 pages[4] in Figure 7, in ascending order of mean intercell times. Figure 7 suggests that intercell times vary significantly, but their patterns are not noticeably different across different sites. This shows that individual intercell times are not correlated with the true page of a cell sequence.

Equalizing intercell timing

We have nevertheless designed an extension of WT to hide all timing information, though this comes at the cost of a greater bandwidth and time overhead.

One solution would be to have the proxy behave the same way as the client: it queues all received cells in each burst until the servers have sent all of their data, and sends them all at once back to the client. In this case, timing would contain no information, and this can be implemented with a small time overhead and no bandwidth overhead. However, this implementation may not be practical, because it would require proxies to read client cells to determine when bursts end.

Our timing fix is inspired by a similar mechanism in Tamaraw. We choose a fixed cell rate $r_{control}$ such that whenever it is the proxy's turn to send data, the proxy attempts to deliver $r_{control}$ incoming cells per second. If there is no data to send when a cell is due, the proxy generates a dummy cell, which will be dropped by the client. This covers the incoming intercell timing leak as the intercell time will always be $r_{control}$ for incoming cells. Varying $r_{control}$, we evaluate the added overhead of timing control in Figure 8. For example, we can equalize intercell timing at a cost of 50% bandwidth overhead and 36% time overhead.

We can use the same dummy cells described in Section 4.3 for both burst molding and equalizing intercell timing, without compromising either objective. This

[4]We used 50 pages instead of our full 100 pages so that the graph would be clear.

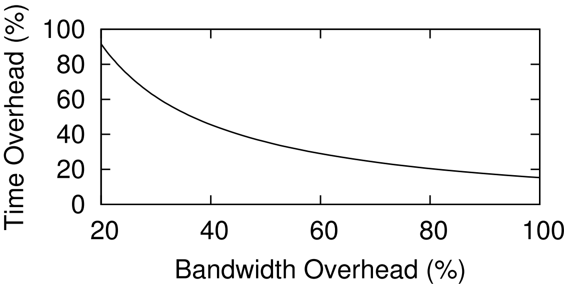

Figure 8: Possible bandwidth and time overhead cost for equalizing intercell timing, obtained by varying $r_{control}$.

means that, effectively, the bandwidth overhead values for timing control and burst molding do not add together in WT; instead, the maximum of the two becomes the bandwidth overhead of WT. The overhead of WT with intercell timing equalized would be 50% bandwidth overhead and 66% time overhead, which is still much lower than known defenses (Table 4).

7 Conclusion

In this paper, we presented Walkie-Talkie: a flexible, easy-to-use defense with low overhead that can defend web clients against all website fingerprinting attacks. Walkie-Talkie consists of two components: half-duplex communication and burst molding. Half-duplex communication produces burst sequences that are concise and easy to manipulate, which allows burst molding to mimic non-sensitive web pages at minimal overhead. Walkie-Talkie is highly effective against all known attacks at overhead costs much lower than all known effective defenses. Furthermore, it is capable of defending against all possible WF attacks, because pairs of sensitive and non-sensitive web pages will be molded to the same cell sequence under WT. We have implemented Walkie-Talkie so that it functions on the Tor client and Tor nodes: in general, it can be implemented on any proxy network (such as VPNs).

We also considered advanced attackers beyond previous work in website fingerprinting, who are able to leverage site link information, page visit rates, and timing information to strengthen their attacks. Walkie-Talkie can defend against all these types of attacks effectively, as it gives the client the freedom to choose which pages to use as decoys. It remains to be seen whether Walkie-Talkie would be useful as well against other advanced attacks, such as active adversaries and dynamic content identification.

A Removing the need for client information

One limitation of burst molding is that the client needs to know the burst sequences of some non-sensitive pages. While it is highly practical to deliver such information to clients on an anonymity network like Tor (see Section 4.3.1), we have also designed a variation of Walkie-Talkie that is useful on networks where there may not be a party that can deliver burst sequence information.

In this variation of Walkie-Talkie, burst molding is *random*: instead of adding cells according to the supersequence of sensitive and non-sensitive pages, we add cells randomly. We refer to this variation of Walkie-Talkie as Random-WT. Random-WT is less efficient, but it can also defend against all possible WF attacks.

A.1 Design of Random-WT

Given a cell sequence $s = (b_1, b_2, b_3, ..., b_{|s|})$ with $b_i = (b_{i+}, b_{i-})$, we apply defense D as follows to produce $D(s)$:

1. Padding real bursts: From two uniform distributions X_{i+} and X_{i-}, we draw x_{i+} and x_{i-} respectively, and add them to b_i, such that $\hat{b_i} = (b_{i+} + x_{i+}, b_{i-} + x_{i-})$.

2. Adding fake bursts: From two uniform distributions X_{id+} and X_{id-}, we draw x_{id+} and x_{id-}, and generate a new fake burst $\hat{b_i} = (x_{id+}, x_{id-})$. In a fake burst, all outgoing and incoming cells are fake cells. We add fake bursts at random with probability p_{fake} before each real burst of cells.

Random-WT is therefore defined by the bounds of the uniform distributions X_{i+}, X_{i-}, X_{id+}, X_{id-}, as well as the probability p_{fake}. We chose uniform distributions after preliminary experiments and analysis indicated that uniform distributions are highly efficient at defending burst sequences. The freedom of choice allows Random-WT to be tunable (i.e., a client may wish to increase collision rate by increasing overhead).

The fact that any burst in an observed cell sequence is equally likely to be fake is a powerful feature of Random-WT. In practice, we found that many cell sequences have multiple bursts with few cells and one or two large bursts with many cells. Random-WT covers the position of large bursts in the cell sequence, so that they cannot be leveraged by the attacker.

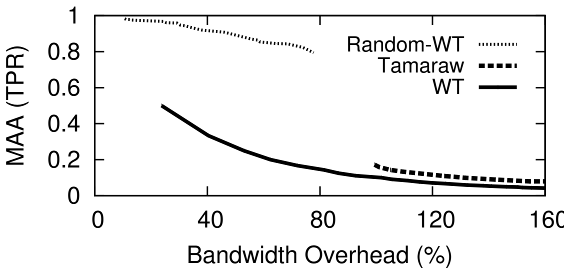

Figure 9: Bandwidth overhead and MAA for Random-WT, WT and Tamaraw across a range of parameters. No WF attack can achieve a classification accuracy above the MAA.

Fake bursts should be similar in length to real bursts so as to maximize collision; we do not want the attacker to be able to distinguish between real bursts and fake bursts with high accuracy. In our experiments, we set the lower bound of the uniform distributions for X_{i+}, X_{i-}, X_{id+}, and X_{id-} to be 0. This minimizes overhead without affecting effectiveness. We set X_{id+} and X_{id-} to fit the observed burst sizes of real cell sequences. Then, we vary the maximum range of X_{i+} and X_{i-}, as well as p_{fake}, to obtain a range of overhead and effectiveness values, which we present below.

A.2 Experimental analysis of Random-WT

We analyze the MAA of Random-WT using the same experimental methodology in Section 5.4. We draw Figure 9 by taking Figure 3 and adding a line for Random-WT to compare with basic WT and Tamaraw. Figure 9 does not plot the time overhead, which is around 30% throughout the graph for both Random-WT and WT, and ranging from 130% to 350% for Tamaraw.

Though Figure 9 shows that the MAA of Random-WT is worse than both WT and Tamaraw, it is still significant enough to confuse an attacker, especially if the attacker needs a low false positive rate (for example, when attempting to identify accesses to rare pages). An advantage of both WT and Random-WT over Tamaraw is that they are not sensitive to network conditions; previous work has shown that Tamaraw performs worse than expected if network conditions are not correctly predicted [4].

B Publication of code and data

To ensure that our results can be reproduced, we publish the following:

- Our implementation of Walkie-Talkie: the Firefox code that modifies the browser to enable half-duplex communication, the Tor code that modifies the Tor client to enable molding, and our experiment code for WT.
- Our experimental data sets: the cell sequences we collected over Tor with and without half-duplex communication.
- Our implementations of previous attacks and defenses.

The code and data are available at `https://crysp.uwaterloo.ca/software/webfingerprint/`.

A Privacy Analysis of Cross-device Tracking*

Abstract

Online tracking is evolving from browser- and device-tracking to people-tracking. As users are increasingly accessing the Internet from multiple devices this new paradigm of tracking—in most cases for purposes of advertising—is aimed at crossing the boundary between a user's individual devices and browsers. It establishes a person-centric view of a user across devices and seeks to combine the input from various data sources into an individual and comprehensive user profile. By its very nature such cross-device tracking can principally reveal a complete picture of a person and, thus, become more privacy-invasive than the siloed tracking via HTTP cookies or other traditional and more limited tracking mechanisms. In this study we are exploring cross-device tracking techniques as well as their privacy implications.

Particularly, we demonstrate a method to detect the occurrence of cross-device tracking, and, based on a cross-device tracking dataset that we collected from 126 Internet users, we explore the prevalence of cross-device trackers on mobile and desktop devices. We show that the similarity of IP addresses and Internet history for a user's devices gives rise to a matching rate of F-1 = 0.91 for connecting a mobile to a desktop device in our dataset. This finding is especially noteworthy in light of the increase in learning power that cross-device companies may achieve by leveraging user data from more than one device. Given these privacy implications of cross-device tracking we also examine compliance with applicable self-regulation for 40 cross-device companies and find that some are not transparent about their practices.

1 Introduction

A recent study by Google showed that 98% of surveyed Internet users in the U.S. use multiple devices on a daily basis, and 90% switch devices sequentially to accomplish a task over time [37]. From an ad network's[1] perspective these developments create a challenging environment as they increase the complexity of targeting advertising to specific users. Attributing conversions of ads to actual purchases and frequency capping to avoid showing a user the same ad over and over again becomes more difficult as well. However, there is a solution to these challenges: cross-device tracking. This technique presents a fundamental shift from device tracking to people tracking. As shown in Figure 1, it principally allows ad networks to follow a user on his or her online journey through all devices. However, at the same time, cross-device tracking of users is potentially more privacy-invasive than the tracking of individual devices without connecting them.

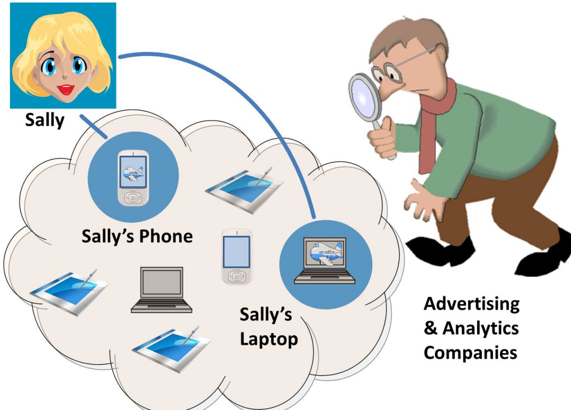

Figure 1: Identifying and correlating Sally's phone and desktop among all devices on the Internet allows cross-device companies to target ads on both of her devices.

In this study we are exploring the emerging cross-device tracking ecosystem from a privacy perspective. Particularly, we are interested in studying the tracking techniques used by cross-device companies,[2] understanding the extent to

*Most of the work on which we are reporting was done when Sebastian Zimmeck and Hyungtae Kim were at Columbia University.

[1] We are using the term ad network broadly encompassing ad exchanges, demand/supply side platforms, and other companies in the online ad space.

[2] The term cross-device company encompasses ad networks, analytics services, and other companies that are using cross-device tracking techniques.

which cross-device tracking occurs on desktop and mobile devices, and evaluating the privacy implications of machine learning applications to cross-device data. We understand cross-device tracking to mean the tracing of an individual's usage of the Internet on multiple devices and combining all resulting information into one comprehensive user profile.

Cross-device tracking exists in a deterministic and probabilistic variant. The former is based on a first-party relationship that often permits user identification with certainty, for example, when a user logs into a social network account from multiple devices. For the majority of our study we focus on probabilistic cross-device tracking, which is used by services that are limited to a third-party relationship with users. To that end, ad networks and analytics services oftentimes cooperate with web and app publishers that have a first-party user relationship and deploy tracking mechanisms on their properties. Applying machine learning they then correlate the various data streams to identify those belonging to the same users. Probabilistic and deterministic cross-device tracking approaches are often combined as companies of different provenance collaborate and exchange data [32]. While we examine cross-device tracking via HTTP cookies, pixel tags, and other traditional mechanisms, such tracking can also occur via ultrasound signals [7,31,59] or other side channels, which we do not examine here.

As some cross-device companies match billions of devices [22] and social networks have cross-device functionality naturally built into their systems lawmakers began to take notice. In particular, the U.S. Federal Trade Commission (FTC) hosted a cross-device workshop [29] facilitating an initial public discussion on the privacy implications of this form of Internet tracking. The regulators discussed with industry representatives, academics, and various other stakeholders privacy risks, consumer transparency, and effective industry self-regulation. They followed up with privacy recommendations for cross-device companies [32]. As evidenced by a recent case on cross-device tracking via ultrasound signals and the withdrawal of the service from the U.S. market, the FTC is determined to enforce the existing laws and regulations [31, 32], however, is hampered by insufficient insight into the used technologies [30].

In this study we are exploring cross-device tracking through the lens of privacy contributing the following:

1. By means of a brief case study we introduce a method for detecting cross-device trackers. We find statistical significance for various ad networks' capabilities of targeting mobile users on their desktop. (§ 3.)
2. We make publicly available a cross-device tracking dataset as well as software that we used for collecting the data.[3] We give a statistical overview of cross-device usage patterns for the users in our dataset. (§ 4.)
3. We design a basic algorithm and evaluate features and parameters for probabilistic cross-device tracking based on relevant patent and other industry documents. Using IP addresses, web domains, and app domains our techniques achieve an F-1 score of 0.91 on the collected data. (§ 5.)
4. Leveraging our dataset we analyze how the availability of both mobile and desktop data may impact the prediction of users' demographics and interests. Specifically, we examine predictions for gender and interest in finance. (§ 6.)
5. Based on our dataset we calculate the penetration of cross-device tracking on the Internet and conclude that some cross-device companies seem to have broad insight into Internet users' cross-device usage. (§ 7.)
6. Finally, we explore the efficacy of the industry's self-regulation and find that some cross-device companies do not transparently disclose their practices. (§ 8.)

2 Related Work

Our study is based on work in online tracking (§ 2.1), human-computer interaction (§ 2.2), and machine learning (§ 2.3).

2.1 Online Tracking

Much research was published on online tracking. Notably, Roesner et al. [72] developed a tracker taxonomy and examined how tracking occurs in the wild. Lerner et al. [56] provided a historical perspective of tracker evolution over time. However, few existing efforts discuss tracking *across* devices. Similar to traditional tracking such cross-device tracking requires the identification of individual users' browser instances. In this regard, Englehardt et al. [27] point out that cookies allow for linking a user's visits to different websites even if his or her device IP address varies. They conducted a large-scale measurement of traditional online tracking using their OpenWPM platform [26]. Cross-device tracking further requires the correlation of users' different devices. As Olejnik et al. [67] remarked, browsing histories could potentially identify the same user across multiple devices.

In the closest work to ours Brookman and his co-authors from the FTC [11] examine the potential for device correlation by surveying the occurrence of cross-device trackers on 100 popular websites. They also evaluate the extent to which cross-device companies notify users of their practices. While this inquiry into privacy transparency is part of our study as well (§ 8), we extend their work. In particular, we provide statistical support for the occurrence of cross-device tracking (§ 3), evaluate cross-device tracking techniques (§ 5), analyze the potential increase in learning power from cross-device data (§ 6), and examine the penetration of cross-device trackers (§ 7); all on real user data (§ 4). Our study is also complementary to the work of

Mavroudis et al. [59] and Arp et al. [7], who present analyses, attacks, and defenses for ultrasound-based cross-device tracking. We are exploring cross-device tracking based on cookies and other traditional tracking mechanisms.

If a browser does not accept cookies, it still can be tracked via device fingerprinting as initially shown by Kohno et al. [51], Eckersley et al. [25], and extensively surveyed by Lerner et al. [56]. Kurtz et al. [52] and Gulyás et al. [39] showed that mobile device fingerprints are often unique, distinguishable, and re-identifiable. Fingerprinting can be based on sensors [19] and, notably for our purposes, can be employed across browsers [15]. With their FPDetective Acar et al. [2] conducted a large-scale study of device fingerprinting. Nikiforakis et al. [66] provided insight into the practices of three popular browser-fingerprinting libraries and introduced PriVaricator [65], which is a defense against browser fingerprinting based on randomization. Three advanced tracking mechanisms—canvas fingerprinting, evercookies, and use of cookie syncing—were investigated by Acar et al. [1]. In our study we are now exploring the extent to which fingerprinting can play a role in cross-device tracking (§§ 5.1, 7.1). Various works on website fingerprinting [12,13,17,41,44,69] inform our study in this regard as well.

As we conduct a first cross-device tracking data flow experiment our work also relates to similar experiments and methodologies in other areas of online tracking. Particularly, our work relates to the study of Meng et al. [60], who showed that there is a correlation between Google ads and users' profiles and evaluated the likelihood of learning users' sensitive information. Focusing on Google as well, Lécuyer et al. [54, 55] were able to show a correlation between users' e-mail content and ads served to them. Further, Book and Wallach [10] collected a set of about 225K ads on 32 simulated devices and analyzed how the ads were targeted by correlating them to targeting profiles. In addition, Zarras et al. [85] performed a large-scale study on the security of ad serving, and Meng et al. [61] presented an ad fraud attack that enables publishers to increase their ad revenue. In our experiment we follow the recommendations given for information flow experiments by Tschantz et al [81].

2.2 Human-Computer Interaction

While there are only few online tracking studies investigating how users are tracked across devices, various efforts on human-computer interaction are informative for our purposes. The goal of these studies is to improve website navigation, browser prediction of user destinations, and search result relevance for search engines [3]. To that end, we leverage the insight of some studies focusing on website revisit patterns and highlighting the identifying potential of such revisits. In this regard, Tauscher and Greenberg [78] found that 58% of a user's visits to websites constitute revisits. People tend to access only a few pages frequently and browse in small clusters of related pages. Adar et al's [3] analysis reveals various patterns of revisits, each with unique behavioral, content, and structural characteristics.

Some studies took a closer look at website revisits across devices. Tossell et al. [79] were able to detect that revisits occurred very infrequently with approximately 25% of URLs revisited by each user. They further found that, compared to desktops, mobile browsers are accessed less frequently, for shorter durations, and to visit fewer pages. Users seem to rely on apps instead. Different from websites, apps have a revisit rate of 97.1% driven by a high number of visits to the five most frequently accessed apps. It appears that mobile web use is more concentrated and narrow than its desktop counterpart. Indeed, Kamvar et al.'s work [46] confirms this conjecture for the use of web search.

In their quest for improving the sharing of bookmarks and other information across devices Kane et al. [47] found that users tend to visit many of the same domains on both their mobile phones and desktops. Specifically, they found that a median of 75.4% of the domains viewed on the phone were also viewed on the desktop, and a median of 13.1% of the domains viewed on the desktop were also viewed on the phone. Despite the differing browsing habits across devices, particularly, the higher number of websites visited on desktops, they conclude that users' web browsing activities are similar across devices. However, users do not use all of their devices in the same way but rather assign them different roles, as Dearman and Pierce [20] found. As we will explore further (§ 6), these different roles could be a reason for why learning about users' interests can be more comprehensive with data from more than one device. While the sharing of devices can also principally impact cross-device companies' ability to track users across those, Matthew et al.'s study [58] found that phones were never shared among multiple individuals for mutual use, and computers were shared moderately.

2.3 Machine Learning

Different from traditional types of online tracking cross-device tracking is often based on machine learning. In 2015, Drawbridge [22], an ad network specialized on cross-device tracking, hosted the ICDM 2015: Drawbridge Cross-Device Connections competition asking competition participants to leverage machine learning techniques to correlate devices to users [23]. The competition participants were given access to an anonymized proprietary dataset with mostly hidden features. The competition generated various short papers [14,48, 50,53,62,71,75,82] that take the perspective of an ad network. They focus on improving machine learning performance for a narrow set of features; essentially, only exploiting similarity of IP addresses. Our evaluation of tracking techniques broadens this research and is centered on privacy implications.

The first place solution of Walthers [82], which reached an F-0.5 score of 0.9, is in some ways representative for the

Figure 2: The mobile browser history (without visits to the Alexa-ranked homepages in the first two months of the experiment). The list shows the domains and the titles of the webpages, if any.

Figure 3: Selected ads served to the desktop browser after visiting the sites in Figure 2 on the mobile browser. We had not seen any of these ads in our desktop browser session two months before.

approaches taken in the competition. Comparable to other participants' solutions [14, 50, 53], it identified IP addresses that devices of the same user were connected to as the most important feature. Intuitively, as conjectured by Cao et al. [14], devices with similar IP footprints are more likely to be used by the same individual. Thus, the simple reliance on IP address history can already lead to an F-0.5 score of 0.86 [14]. However, various studies found that not all IP addresses are equally meaningful, in particular, because the same public or cellular IP address can be assigned to many different users at different times [48, 82].

Participants in the Drawbridge competition [23] did not find online history particularly useful for their task. They reported that correlating online history across devices provided only minimal gain [50, 53]. This seemingly contradictory result to the previously discussed usability studies, which hinted at cross-device website revisit patterns as an important feature, could be due to the fact that the Drawbridge dataset [45] provided only app history for mobile devices. Thus, the absence of mobile web history could be a reason for participants' inability to reach Drawbridge's precision of 0.97 [22]. While the Drawbridge competition was about the correlation of different user devices, it did not address the purpose of the correlation: the prediction of users' demographics and interests, which we will discuss in our study (§ 6).

3 Detecting Cross-device Trackers

In order to evaluate the occurrence of cross-device tracking in the wild we conducted an exploratory case study.

Purpose. It could be argued that our case study is aimed at the obvious: detecting the existence of cross-device tracking. However, we emphasize that it is our intention to show a procedure for identifying *unknown* cross-device companies. The procedure is also intended to be used for determining whether known companies are adhering to the limits that (self-)regulation imposes on them, in particular, as users are given the right to opt out from cross-device tracking [21]. Our case study provides an initial information flow experiment in the cross-device space. However, we caution that we leave a comprehensive analysis, which was done in other areas of online tracking [54, 55], for further research.

Establishing an IP Address Connection. We began our experiment by connecting two devices—a desktop and a mobile device—to the same router and modem. Using a fresh desktop browser without any user data we visited the homepages of five randomly selected news websites from the Alexa rankings [4]—aol.com, latimes.com, nytimes.com, wsj.com, and washingtonpost.com (the test homepages). We refreshed each test homepage ten times, as recommended for these type of information flow experiments [81], and observed the ads that were served. We also set up a desktop device with a fresh browser connected to a different router and modem as control instance. In the following two months we occasionally and randomly visited 100 highly ranked homepages [4] on our fresh mobile browser.

Observing Cross-device Ads. After two months we used the mobile browser to visit the websites shown in Figure 2. We searched Google for various consumer products and clicked on ads served for those on the search results pages. After a few hours we switched to our desktop browser and accessed the test homepages. We refreshed each ten times. Some of the served ads, which we had not seen before, were for products we had searched for on the mobile device. Figure 3 shows the ads and associated information, that is, the

name of the ad (e.g., PetSmart), the domain on which it was served (e.g., nytimes.com), the domain of the ad server (e.g., adsense.com), the ad network serving the ad (e.g., Google AdSense), and the involved cross-device tracking provider (e.g., Google Display Network).[4] Our results suggest that the ad networks serving the ads had learned that the user who did the search on the phone was the same as the user on the desktop.

To assess the similarity of ads we categorized each ad according to Google ad categories [35]. Then, based on an exact one-tailed permutation test, as recommended [81], we compared the ad distribution served on the desktop browser to the ad distribution served on the desktop control browser. We evaluated the null hypothesis that both distributions do not differ from each other at the 0.05 significance level. However, the result of $p = 0.02$ indicates that the null hypothesis should be rejected and that the deviation of both distributions is statistically significant at the 0.05 level. This finding suggests that we successfully identified instances of cross-device tracking. We also found mobile cookie syncing between Rubicon Project and Tapad. However, confirming earlier observations [11], we did not detect any cookie syncing across devices.

Direction of Ad Serving and App-Web Correlation. In addition to cross-device tracking from mobile to desktop we were further interested in the reverse direction. However, searching Google on our desktop for buying products did not seem to lead to ads for these products on our mobile browser. One explanation might be that the ad serving was limited to one direction—from mobile to desktop— as users tend to move from a smaller to a larger screen [33, 37]. Another explanation could be that ad networks attached more weight to the history on the device to which an ad was served and less to other connected devices. Further, we might simply have missed all cross-device campaigns at the time for the products we searched for. Finally, we were not able to notice any correlation in ad serving in either direction when repeating our experiment with mobile apps instead of websites.

4 The Cross-device Tracking Dataset

A major reason for the scarcity of academic research in cross-device tracking is the unavailability of data. Generally, only proprietary industry data exists.[5] Thus, we collected our own cross-device tracking dataset (the CDT dataset). Here we describe how we collected the data and highlight cross-device usage patterns of the users in the dataset.

[4]We assume that the Google Display Network covers sites using AdSense, DoubleClick, Blogger, YouTube, and AdMob. On one side, this is likely an overestimation as not all sites using these trackers are part of the Google Display Network. On the other side, it is an underestimation as there are sites that are part of it, however, not using any of the trackers. In total, the Google Display Network covers over two million sites [34].

[5]The Drawbridge dataset [45] was only accessible to participants of the Drawbridge competition [23] and limited in its use for that purpose.

	Desktop Web	***Mobile Web***	***Mobile Apps***

Table 2: Summary statistics for the CDT dataset per user showing the unique values at the 25th, 50th, 75th percentiles. The data was collected for the same continuous time period for every user. However, not every user made use of his or her devices every day.

Data Collection Procedure. Before we began the data collection we obtained approval from Columbia University's Institutional Review Board (IRB). We built our data collection system such that interested users could sign up on our project website, at which point we also took a device fingerprint for each signed up device. We asked users to supply basic information on their demographics (e.g., age and gender), interests (e.g., finance, games, shopping) [36], and personas (e.g., avid runners, bookworms, pet owners) [84]. In order to capture users' mobile and desktop history we provided them with browser extensions and an Android app that we developed for automatically collecting such information.[6] Details on the types of information that we collected are contained in Appendix A. We do not have any indication that users behaved differently in our study than under real-world conditions.

We only signed up users of Android phones with Android's native browser, Google Chrome, or the Samsung S-Browser. We did not support iOS or other operating systems. Our app requires Android 4.0.3 and runs without root access. Every minute it checks for a new foreground app running on the device as well as new entries in the browsing history database of the phones' browsers. If new apps or URLs are detected, a new history datapoint is transmitted to our server.[7] On the desktop side we provided users of all operating systems with data collection browser extensions for Google Chrome, Mozilla Firefox, and Opera. At the conclusion of the study we rewarded each user with an Amazon gift card for \$15 to \$50 depending on the amount of data we received from them.

Dataset Characteristics. We collected data from 126 users. Tables 1 and 2 show further details. We signed up 125 desktop and 108 mobile users with an intersection of 107

[6]When we refer to desktops, we include laptops but exclude tablets.

[7]For some users with Google Chrome and Android 6.0 or higher we did not receive the full browsing history due to browser restrictions. We asked affected users to send us their history manually.

users from whom we obtained both mobile and desktop data. While our data faithfully represents that not every Internet user has multiple devices, it does not reflect that users in the real world can have more than two devices. However, despite this limitation we believe that our dataset is generally an accurate reflection of real multi-device usage on the Internet because the vast majority of mobile devices is associated with only one desktop browser [71]. Therefore, it seems plausible to adopt this understanding of the problem here as well. Further, only 3/108 (3%) of mobile users and 4/125 (3%) of desktop users in our study reported that they are sharing their devices. As this result seems in line with findings that phones are never shared for mutual use and that computers are only shared for a moderate amount [58], it appears that our data is a realistic representation in this regard.

118 users in our study were affiliates of Columbia University, mostly students. Based on this population we believe that our data is more homogeneous than a data from, say, the general population of New York City. However, we also note that our users are less likely to encounter typical restrictions of device use that many employees face in the workplace, e.g., corporate networks blocking certain websites. For the median user we collected about three weeks of data of which IP addresses and domains are of particular importance for probabilistic cross-device tracking because they can be used to measure the similarity between devices (§ 5.2).

It is noteworthy that the total unique mobile IP count (5,784) is nearly three times the total unique desktop IP count (1,994), which reflects mobile usage on the go. It should be noted, though, that the real unique mobile IP count is likely even higher as our method did not allow us to collect mobile IPs with every datapoint. However, the high number of unique desktop domains (23,517), compared to the homogeneous usage of apps (845), underscores the diversity of desktop browsing. While it is much more diverse in terms of domains (3,876), mobile web usage pales in comparison to app usage. As shown by the 25th, 50th, and 75th percentiles, the median user accessed the mobile web only for 17 days visiting only 31 unique domains.[8] While app usage is more popular with a median of 22 days, the median usage of 30 unique apps is comparable to that of the mobile web. However, the median number of unique mobile IP addresses (63) more than triples desktop IP addresses (17).

Figure 4 shows that many users visit a relatively large number of unique mobile device IP addresses and desktop web domains. However, there does not seem to be a correlation between desktop and mobile devices to the effect that lower usage of one would imply more usage of the other or that both are used to an equal degree.

[8]A day was counted if a user's device had at least one desktop web, mobile web, or app access on a given day. Also, uniqueness of a domain is dependent on its top and second level. Thus, for example, we treat facebook.com and linkedin.com as different domains, however, linkedin.com and blog.linkedin.com as the same domain.

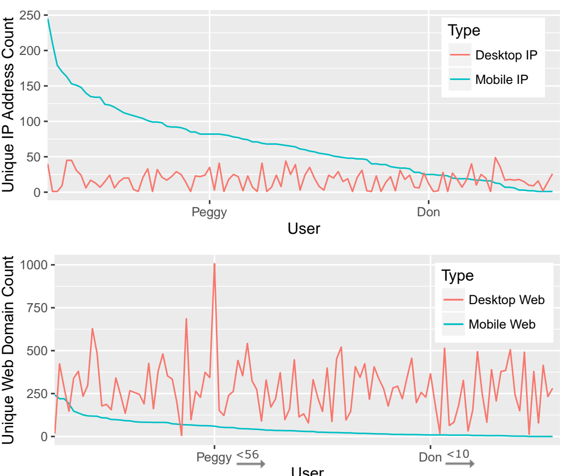

Figure 4: Unique IP address (top) and web domain (bottom) count for each user in our dataset for whom we had both mobile and desktop data. For example, Peggy has 82 unique mobile and 35 unique desktop IP addresses (top). To the right of Peggy about two thirds of users visited fewer than 56 unique mobile domains and to the right of Don about a fourth visited fewer than ten (bottom).

5 Methods for Cross-device Tracking

How cross-device companies operate is not known in detail [49]. In order to get an understanding of their capabilities we designed an algorithm and evaluated features and parameters informed by a review of public materials, particularly, Adelphic's cross-device patent [83] and Tapad's patent application for managing associations between device identifiers [80]. Essentially, cross-device tracking is based on resolving two tasks: first, uniquely identifying users' devices (§ 5.1), and, second, correlating those that belong to the same user (§ 5.2).

5.1 Identifying Devices

Traditionally, HTTP cookies are used to identify desktop devices. Indeed, many cross-device companies are employing cookies for their tracking purposes as well. For mobile devices the use of advertising identifiers, such as Google's Advertising ID (AdID), is common and often combined with cookie tracking. Thus, if users are allowing cookies and do not opt out from being tracked, both their mobile and desktop devices can be easily identified. However, with the surge of tracking- and ad-blocking software, which some consider a mainstream technology on mobile by now [68], unconventional identification technologies, such as device fingerprinting, are becoming more prevalent. While it does not appear that they will generally replace cookies and advertising identifiers any time soon, various cross-device companies—for example, BlueCava [9] and AdTruth [28]—are making use of device fingerprinting.

	Desk Devices $H, H_n, \hat{H}$	***Mob Devices*** $H, H_n, \hat{H}$

Table 3: Entropy (H), normalized entropy (H_n), and estimated entropy ($\hat{H}$) for various browser features in our CDT dataset. The normalized entropy ranges from 0 (all features are the same) to 1 (all features are different). We calculated the estimated entropy according to Chao and Shen [16]. For the totals we considered all listed features. Overall, our dataset contains 3 duplicate mobile fingerprints and 1 duplicate desktop fingerprint.

Cross-device companies that are solely relying on device fingerprinting must be able to identify both desktop and mobile devices using this technique. While it was reported that device fingerprints generally do not work well on mobile devices [25], our results do not support such broad conclusion. Particularly, mobile user agents often contain distinctive features and are far more diverse (6.43 bits) than user agents on desktops (4.46 bits). Also, the entropy in our dataset only represents a lower bound as we imposed substantial limitations for users' participation in our study; most notably, requiring them to have an Android phone with Android 4.0.3 or higher and use the native browser, Chrome, or S-Browser. We also did not consider, for instance, canvas fingerprinting [1], sensor data [19], or the order in which fonts and plugins were detected [25]. However, most mobile devices in our dataset were still identifiable. The detailed findings for the 107 mobile and 126 desktop devices in our CDT dataset are shown in Table 3.[9] Due to the small size of our dataset we caution to interpret our results as indicative for the reliability of mobile device fingerprinting, though.

5.2 Correlating Devices

After uniquely identifying each device cross-device companies must match those that appear similar. Successfully matching devices at scale is the core challenge for cross-device companies. Devices are represented in graphs known as Device Graphs [76], Connected Consumer Graphs [22], or under similar proprietary monikers. From a graph-theoretical perspective a device graph can be built from connected components (each of which represents a user) with a maximum number of vertices (devices) and edges (device connections) [18]. Matching every mobile with exactly one desktop device will result in a bipartite graph. The goal is to achieve a perfect matching of similar devices.

[9]One user did not submit a mobile fingerprint and another user submitted two different desktop fingerprints.

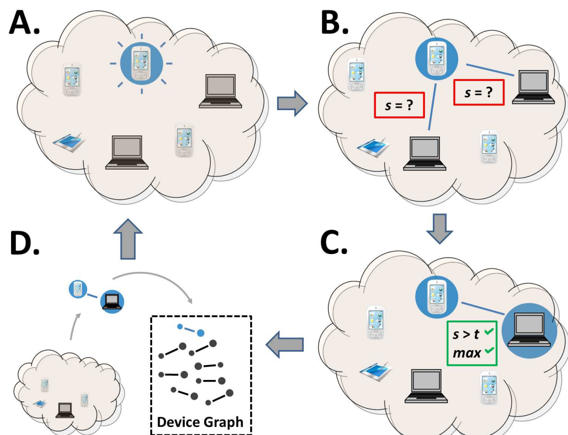

Figure 5: Our cross-device tracking approach. A. First, a mobile device is identified. B. Its similarity to each identified desktop device, s, is calculated. C. The mobile-desktop pair with the maximum similarity, max, that is above a similarity threshold, t, is determined, if any. D. If such pair exists, it is added to the device graph and the next iteration starts with a new mobile device. This routine is repeated in three consecutive stages each evaluating similarities between mobile and desktop IP addresses, mobile and desktop URLs, and mobile apps and desktop URLs, respectively. If a mobile device cannot be matched in one stage due to not overcoming the similarity threshold, a match is attempted in the next.

Algorithm, Features, and Parameters. While deterministic cross-device companies can simply match a user's devices based on his or her login information, which may also extend towards third party properties through single sign-on functionality, achieving a high match rate is more difficult for probabilistic cross-device tracking companies. In the Drawbridge competition [23] many participants applied gradient boosting [48, 50, 53, 62, 71]. However, some participants also combined support vector machines and factorization models into field-aware factorization machines [75] or employed pairwise ranking and ensemble learning techniques [14]. Interestingly, the best performing solution relied on learning-to-rank models instead of using the more conventional binary classification models [82].

In our approach, as outlined in Figure 5, we determine the similarity between devices based on distance metrics, most notably, the Bhattacharyya coefficient, which is defined for the distributions p and q as $Bhatta(p,q) = \sum_{x \in X} \sqrt{p(x)q(x)}$. The use of distance metrics for device correlation was described in Adelphic's cross-device patent [83]. Our cross-device tracking algorithm works in multiple stages. Using a key insight from the patent, for each feature a

	Sim Feature Mapping	*Distance Metric*	*Sim Thresh*	*Mean Sim*	n_q	*Acc*	*Prec*	*Rec*	*F-1*
Stage 1	Mob IPs to Desk IPs	Bhatta	0.07	0.33	44	0.61	1	0.63	0.77
Stage 2	Mob URLs to Desk URLs	Bhatta'	0.13	0.18	44	0.52	0.85	0.59	0.7
Stage 3	Mob Apps to Desk URLs	Bhatta*	0.02	0.11	44	0.16	0.19	0.5	0.27
Stages 1–3	Same as in Individual Stages above			0.33, 0.16, 0.03	44	**0.84**	**0.88**	**0.95**	**0.91**

Table 4: Test set results. The first three rows show the results for running each stage individually. The fourth row shows the results for running the three stages consecutively. We normalized the Bhattacharyya coefficient (Bhatta) to a range between 0 (low similarity) and 1 (high similarity). Bhatta' denotes the exclusion of URLs in the Alexa Top 50 [4] and all columbia.edu URLs. Further, Bhatta* excludes the most used 100 apps according to our training set. We selected the best similarity threshold (Sim Thresh) for each stage according to observations in our training runs. Mean Sim is the mean similarity across all 44 device pairs in the test set, and n_q is the size of the test set.

similarity threshold is set. If a threshold is reached at one stage, a match is declared for the mobile-desktop device pair with the highest similarity score. Otherwise, the algorithm continues to evaluate whether the similarity threshold for a different feature is reached in the next stage. To evaluate the similarity between a mobile and a desktop device it compares mobile to desktop IP addresses, mobile to desktop web URLs, and mobile apps to desktop web URLs.

Test Set Results. To test our approach we randomly separated the set of device pairs in our dataset into a training ($n_t = 63$) and a test set ($n_q = 44$). We used the former to tune our algorithm and features and held out the latter for performance evaluation. As shown in Table 4, running all three stages of the algorithm consecutively on our test set leads to precision, recall, and F-1 scores of 0.88, 0.95, and 0.91, respectively. The F-0.5 score [50], which emphasizes precision over recall, reaches 0.91. In detail, we obtained 37 true positives (TP), 5 false positives (FP), 0 true negatives (TN), and 2 false negatives (FN). These results are based on the usual definitions, i.e., accuracy, $Acc = (TP+TN)/(TP+TN+FP+FN)$, precision, $Prec = TP/(TP+FP)$, recall, $Rec = TP/(TP+FN)$, and F-1 score, $F\text{-}1 = (2 \cdot Prec \cdot Rec)/(Prec+Rec)$.

To make the matching more difficult we included in each run of our algorithm in every stage data from users for which we only had data from one device type: data from one user who only submitted mobile data and from 18 users who only submitted desktop data. Further, our results are based on modeling device correlation as binary classification. Specifically, for each correct match between a user's mobile and desktop device we counted a true positive. For each incorrect match we noted a false positive. If a mobile device would have no corresponding desktop device it would have been counted as a true negative if it remained unmatched. However, as there was only one such instance in our test set and that mobile device was actually matched, we counted it as false positive. A false negative means that an instance should have been matched, however, remained unmatched.

Running the three stages of our algorithm consecutively leads to approximately balanced results for precision (0.88) and recall (0.95), as shown in Table 4. However, when running the stages individually, we obtain relatively higher precision and lower recall in the first two stages and lower

	Bhatta	*Cosine*	*Jaccard*
	F-1, Sim Thresh	*F-1, Sim Thresh*	*F-1, Sim Thresh*
Stage 1	**0.84**, 0.1	0.83, 0.1	0.73, 0
Stage 2	**0.74**, 0.2	0.59, 0.1	0.67, 0
Stage 3	**0.29**, 0.1	0.29, 0.4	0.12, 0

Figure 6: Precision and recall for matching devices based on various distance metrics and thresholds. The table shows the best F-1 scores and their corresponding similarity thresholds. The features are the same as described in the respective stages in Table 4. However, the evaluation is performed here on the full dataset. For higher thresholds recall scores tend to decrease while precision scores tend to increase (except when they exclude too many true positives). Overall, the Bhattacharyya coefficient returns the best results.

precision and higher recall in the third stage. This difference highlights the tradeoff between achieving correct matches (precision) and broad user coverage (recall). While it is challenging to improve one without adversely affecting the other [49, 73], the similarity thresholds provide the controls for adjustment. Figure 6 shows changes in precision and recall for different similarity thresholds and distance metrics.

The high precision scores of Drawbridge (0.97 [22]) and Tapad (0.91 [77]) seem to suggest that the industry favors precision over recall.[10] However, there is also an argument

[10] We interpret Tapad's usage of the term accuracy to mean precision ("[W]henever our Device Graph indicated a relationship between two or more devices, it was accurate 91.2 percent of the time.").

to be made against emphasizing precision: some device mismatches may be irrelevant. Particularly, we believe that mismatches might happen for people living in the same household (in case of mobile IP to desktop IP similarity) or individuals having the same interests (in case of web domain and app to web domain similarity). In these situations a mismatched device might still be a meaningful ad target [24]. The reason is that targeted purchase decisions might be made at the household level or look-alike audiences might be sufficiently valuable for an ad network [80].

Our results show that IP addresses are very meaningful for matching devices, which is in line with Cao et al.'s findings [14]. They reached an average F-0.5 score of 0.86 in the Drawbridge competition [23] using only features from IP address data. However, beyond this finding our results further suggest that visited web domains are a good indicator for device similarity as well. In fact, there might be situations in which they can be more revealing than IP addresses. For example, if users of the same household share an IP address, their devices can not be distinguished based on this feature. Also, while the correlation between apps and desktop domains does not contribute as much as the IP address and domain correlations, it still provides some meaningful signal as the results for the individual run of the third stage in Table 4 demonstrate. Most importantly, however, performance seems to increase if multiple features are applied consecutively. Some users can be better matched based on IP addresses and others on web domains or apps.

We note that we leveraged a manual mapping between apps and desktop domains via company names or other common identifiers thereby transforming a feature with minimal effect in our dataset and the Drawbridge competition [14,48,50,53,62,71,75,82] to a useful feature. Similarly, the domain mapping proved to be useful as well due to users' visits to the same domains across devices. These results highlight that cross-device matching is not completely reliant on IP matching, as suggested by the results in the Drawbridge competition. Our results seem to confirm the conjecture that carefully hand-crafted similarity features are of paramount importance while algorithms play a smaller role for the task of correlating mobile and desktop devices [82].

We experimented with various other features that ultimately did not prove useful. In particular, an algorithm leveraging system language and time zone did not match devices better than random. We also tried excluding sets of frequently used public IP addresses. However, different from excluding domains and apps, which, as described in Table 4, proved to be beneficial, this measure did not lead to better performance. We further tried different matching thresholds and evaluated various distance metrics as shown in Figure 6. In future work it would be interesting to examine the extent to which the time, order, and duration of app and url access play a role for device correlation. E-mail and other message content is an obvious candidate for a useful feature as well.

Applicability to Larger Datasets. With a runtime of $\mathcal{O}(n(n-1)/2)$ our algorithm is suitable for large scale analysis. However, it is obvious that our dataset is many orders smaller than the data that cross-device companies are usually working with. This difference in size begs the question to which extent our findings are applicable to larger datasets. For the similarity of IP addresses this question was already reliably answered. The Drawbridge competition results, for instance, by Landry et al. [53], are based on a set of about 62K mobile devices and confirm the meaningfulness of IP features. For web domain features the situation is different as the Drawbridge data did not contain those for mobile devices. However, we can make an argument that lends some supports for the applicability of our results to larger datasets.

Whether web data can be correlated across devices rests on two premises: first, users visiting an intersecting set of domains on both their mobile and desktop devices and, second, domains being sufficiently distinct to allow identification of users. To examine the first premise we randomly selected 50 U.S. domains out of the top 5K sites that were quantified by Quantcast [70] and found a mean of 17.1% users visiting a website both on a mobile and desktop device (during a 30-day period and at the 95% confidence level with a lower bound of 14.4% and an upper bound of 19.5% using the bootstrap technique). As to the second premise, it was shown for a set of about 368K desktop and mobile Internet users that 97% of them were uniquely identifiable if at least four visited websites were known.[11]

Limitations. It would be an interesting exercise to compare our techniques against those currently in use in industry. However, we are not aware of any publicly available resources allowing us to do so. The same is true for cross-device tracking datasets. To our knowledge, there is no dataset publicly available beyond the CDT dataset that we created. The only other cross-device tracking dataset we know of was made available by Drawbridge to participants of the Drawbridge competition solely for competition purposes [23]. However, even if this dataset would be available, it would only allow an incomplete analysis, particularly, as features were generally anonymized and mobile web history was not included in the dataset. Consequently, at this point it does not seem possible to compare our approach to others or evaluate its performance on a different dataset. However, as we implemented key design elements that we found in available industry materials, we believe that our results provide a first approximation for cross-device tracking approaches applied in practice.

There are various considerations of identifying and correlating devices in practice that we cannot meaningfully test. A first point concerns the time period for which users are being tracked. We believe that the three weeks of data that we have available for most users (Table 2)—the concrete

[11] All users in our dataset who visited at least one mobile and one desktop website had unique web histories as well.

length depending on the number of days on which they used their devices—are realistic. However, we lack the insight for which duration cross-device tracking actually occurs in practice. Also, despite some cross-device companies' broad coverage of websites and apps (§ 7), none of them has access to complete IP, web, and app data of Internet users. However, ultimately this limitation is one of reach and not of performance. By setting similarity thresholds high even companies with limited data can obtain precise results, albeit, at the cost of low recall. Further, our dataset does not contain full IP histories either. In addition, our data is probably more homogenous than real data, and, thus, more difficult to assess. Users in our study were mostly students located in a confined space with many commonly shared web domains and IP addresses.

6 Learning from Cross-device Data

In this section we examine whether cross-device data enables cross-device companies to make more accurate predictions than they could make using data from individual devices alone. We address this question for two inquiries: users' interest in finance—a randomly selected interest category—and gender. Both are relevant ad targeting criteria. For interest in finance we obtained the most accurate predictions by using data from both mobile and desktop devices. Consequently, this is a task in which predictions about a user from cross-device data appear more privacy-invasive than those from single device data sources. However, as we also found a lack of performance increase for predicting a user's gender, it appears that some prediction tasks might not become more accurate with the availability of cross-device data.

Predicting Interest in Finance. As a starting point for our feature creation we used Alexa category rankings [5] and Google Play store categories [38] to identify the top 25 finance domains that have both a website and an app. Then, we used the Weka machine learning toolkit [40] to explore the potential for predicting interest in finance. We experimented with various features and all available standard algorithms. We used a word-to-vector preprocessor and found logistic regression to be the most effective technique. Due to the class imbalance of only 23% users in our dataset expressing an interest in finance we ran logistic regression as a cost-sensitive classifier increasing the cost for a false positive on average 1.5 times over the cost for a false negative. Our results, which are shown in Figure 7 and based on 10-fold cross validation, suggest that predicting an interest in finance for users in our dataset is more accurate if both desktop and mobile data are available.

In particular, predicting from mobile data alone proved to be the weakest option. One reason seems to be that we only had 90 features from the mobile data compared to 106 and 107 for the desktop and combined data, respectively. Using desktop data only we tried to increase the performance to the level of the combined mobile and desktop data, which

	Acc	*95% CI*	*Prec*	*Rec*	*F-1*	*ROC*
A.	0.64	0.55–0.73	0.26	0.22	**0.24**	**0.5**
B.	0.75	0.67–0.83	0.5	0.52	**0.51**	**0.68**
C.	0.79	0.71–0.87	0.57	0.59	**0.58**	**0.75**
D.	0.83	0.76–0.9	0.68	0.63	**0.65**	**0.79**

Figure 7: Logistic regression for predicting interest in finance from mobile web domains and apps (Mob) and desktop web domains (Desk). 95% CI designates the binomial proportion confidence interval for the accuracy at the 95% level assuming a normal distribution. The F-1 score based on features from both types of data (Mob & Desk - 108 Features) is higher than the scores obtained using mobile and desktop data individually (even with more features as in Desk - 2,923 Features). We observed similar results for value shoppers with F-1 scores of 0.17 (Mob - 85 Features), 0.25 (Desk - 99 Features), and 0.41 (Mob & Desk - 104 Features).

reached an F-1 score of 0.65. However, we were only able to obtain an F-1 score of 0.58 by substantially increasing the feature space to 2,923 features, at which point we saw no further improvement. Combining desktop and mobile data and leveraging 107 features outperformed all other approaches. The ROC curves in Figure 7 visualize this finding. The predictions that users have an interest in finance are shown in orange while the negative predictions for not having an interest in finance are displayed in blue. For the latter the F-1 scores are: Mob - 91 Features: 0.77, Desk - 107 Features: 0.83, Desk - 2,923 Features: 0.86, and Mob & Desk - 108 Features: 0.89.

Predicting Gender. While the predictive performance of a user's interest in finance increased with the availability of both desktop and mobile data, it appears that such improvement does not necessarily hold for all classification tasks. Particularly, classifier performance for the prediction of gender from combined desktop and mobile data was not better than the performance using desktop data alone. Applying logistic regression with 10-fold cross validation we obtained identical scores for precision, recall, and F-1 with values of 0.82, 0.81, and 0.82, respectively. It did not make a difference whether mobile data was added to the desktop data or not. This result suggests that for some tasks the availability of cross-device data does not lead to better predictions.

Impact of Device Usage Patterns. What could be the reason for the differing utility of cross-device data in the two prediction tasks? Subject to the results of further experiments

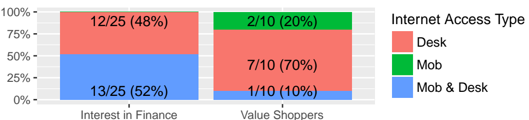

Figure 8: Mobile and desktop device usage patterns. Some users in our dataset access finance and value shopping domains only from their desktop or mobile device (i.e., from a mobile website or app).

it seems that having both mobile and desktop data available can be an advantage for predictions that rely on features exhibited on one device type only. We did not only observe such patterns for users with an interest in finance but also for value shoppers—a randomly selected persona category. For both interest in finance and the value shopper persona we evaluated to which extent users respectively accessed the top 25 finance and value shopping domains on their mobile and desktop devices. Our results, illustrated in Figure 8, support the conclusion that having data available from both mobile and desktop devices increases the chances of capturing (more) salient features for the aforementioned predictions. For example, an ad network without access to desktop data would have difficulty to make correct classifications for users that only access respective domains on their desktop device. We note that the observed patterns are based on a small number of users. Thus, further investigation is warranted.

Absence of Device Usage During our study we realized the possibility of making predictions about users who do not make use of their devices. Predicting a user's Jewish religion serves as an illustrative example.[12] Obviously, religious web domains and apps can be meaningful features for predicting adherence to a particular faith. However, such predictions are also possible based on subtler user behaviors. Most notably, as the data collection of our study covered the last two days of the Jewish Passover holiday we noticed that a few users in our study did not use either of their devices as the Jewish faith prescribes abstinence from using electronics. Among all users in our study the pattern of holiday observation became obvious. This signal was especially clear from the insight into multiple devices. While some users did not use one of their devices, only those observant of Passover did not use both. This example illustrates that device activity as such can be a useful predictor that might be exploitable by cross-device tracking.

7 The Scope of Cross-device Tracking

The scope of cross-device tracking on the Internet is yet to be explored. For example, through their integration into many websites and apps Facebook and Google appear to have vast reach into the various devices of their users as well as the ability to deterministically match those [73]. However, the percentage to which a typical Internet user is tracked across devices by those and other cross-device companies is not known. We examine this question for the users in our dataset based on a procedure for detecting the presence of cross-device trackers in their browsing and app histories (§ 7.1) and analyzing their occurrence accounting for industry collaborations and consolidation (§ 7.2).

[12] As we obtained this result by chance we confirmed that its publication is covered by applicable IRB regulations of Columbia University.

7.1 Detecting Cross-device Trackers

Procedure. We examined the trackers on the websites that the users in our study visited by automating a Firefox browser with Selenium [74]. The browser included Lightbeam [63] and User Agent Switcher [64] browser extensions that allowed us to record the trackers on each domain for both mobile and desktop websites. Third party trackers that we found in a subdomain were added to the domain, however, not vice versa. Thus, for example, the domain linkedin.com contains all trackers that we found on blog.linkedin.com but not the other way around. To identify trackers inside of apps we selected a total of 153 third party software development kits (SDKs) listed on AppBrain [6] encompassing SDKs of ad networks (e.g., Smaato), social networks (e.g., Twitter), and analytics services (e.g., comScore). Leveraging AppBrain's statistics on the inclusion of SDKs in apps we then determined which SDKs are included in the apps of our dataset.

We qualify a company as cross-device company based on our detection of their trackers on both mobile and desktop domains, the former including apps, and their websites' claims that they indeed perform cross-device tracking. We identified cross-device trackers by using Whois domain searches and tracker blocking lists, especially, the list of the Better tracker blocker [42]. For some companies—Google AdSense, Rubicon Project, Skimlinks, Tapad, and Lotame—our information flow experiment (§ 3) provides empirical support for qualifying them as cross-device companies. It would be interesting to extend this or a similar information flow experiment towards other companies.

Lower Bound. Our approach for detecting trackers should be understood as a lower bound for various reasons. First, trackers not identified in Lightbeam will remain undetected. The same is true for SDKs not included in the pre-defined set of 153 SDKs from AppBrain. Further, we only detect app tracking via SDKs and do not account for Android WebViews and app-internal browsers that could contain tracking cookies or other traditional online tracking mechanisms [18]. We believe that these technologies warrant substantial further investigation as we suspect that a large amount of trackers make use of them.

Limitations. It is a limitation of our crawl that some websites in our dataset were not accessible (e.g., sites that required a user login). In some cases our crawl was also redirected or the requested page was not found. However, these limitations only affected few URLs. Also, it should

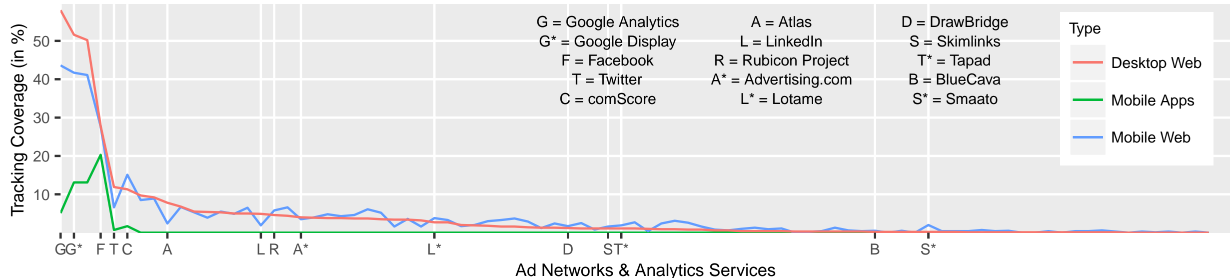

Figure 9: As the ad ecosystem in general, cross-device tracking is characterized by a few large companies with extensive reach and a long tail of smaller companies, some of which are focusing on the mobile space (e.g., Smaato with 2% mobile and 0.2% desktop coverage).

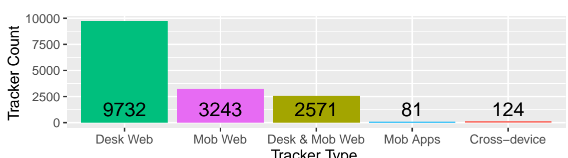

Figure 10: Total unique third party trackers in our dataset. We found 124 cross-device trackers that belong to 87 different companies.

be noted that we crawled the sites about a month after we finished collecting data from the study participants. Thus, in the meantime, some websites might have different trackers than at the time they were actually visited. Ideally, it would have been possible to capture the trackers live from our users' devices during the study. However, such collection is difficult due to the constraints of the Android environment, most notably, the sandboxing of mobile browsers. In addition, our mobile tracker count may be off as we did not use real mobile devices but instead a spoofed desktop browser.

7.2 Cross-Device Tracking Analysis

As shown in Figure 10, websites accessed from desktop and mobile devices contained a respective total of 9,732 and 3,243 unique third party trackers. 2,571 trackers were on both desktop and mobile websites; Brookman et al. [11] found 861 such trackers. Out of the 153 SDKs from AppBrain we found 81 in our dataset.[13] From these sets of third party trackers we identified 124 cross-device trackers; 118 trackers that appeared on both mobile and desktop websites and 6 SDKs that are associated with a desktop tracker as well. We found that the 124 cross-device trackers belong to 87 different companies. It appears that 22 follow a deterministic approach, 39 use probabilistic techniques, and 26 leverage both.

Tracking of the Average User in our Dataset. On average each user is tracked across devices on his or her desktop in 67% of all desktop website visits. We measured a similar average for mobile web visits with 64%. These high percentages illustrate that cross-device tracking is a broadly occurring phenomenon. Table 5 shows the reach of individual companies. Google Analytics, Google Display, and Facebook can capture at least 20% of an average user's online traffic across devices. This percentage is about the same that Roesner et al. [72] provided a few years ago for tracking of individual devices. It is particularly noteworthy that the companies with the broadest reach have a deterministic approach, which means that their cross-device tracking is also very accurate. Figure 9 shows the tracking coverage for the 87 cross-device companies we identified.

	Desk	*Mob*	*Apps*
Google Analytics (D)	58%	43.6%	5.1%
Google Display (D,P)	51.6%	41.7%	13.1%
Facebook (D)	27.8%	27.7%	20.3%
Atlas (Facebook) (D,P)	7.8%	2.4%	N/A*
Facebook & Atlas (D,P)	**27.9%**	**29.1%**	**20.3%**
Twitter (D)	11.9%	6.6%	0.7%
comScore (D,P)	11.3%	15.1%	1.7%
LinkedIn (Microsoft) (D)	4.9%	1.9%	N/A*
Rubicon Project (P)	4.6%	5.8%	N/A*
Tapad (P)	1.1%	1.9%	N/A
Rubicon & Tapad (P)	5.4%	6.7%	N/A*
Advertising.com (AOL) (P)	4%	3.5%	N/A
Lotame (D,P)	2.7%	3.8%	N/A*
Skimlinks (D,P)	1.1%	1.6%	N/A
Lotame & Skimlinks (D,P)	**3.5%**	**5%**	N/A*
Drawbridge (P)	1.2%	1.7%	N/A
BlueCava (P)	0.2%	0.5%	N/A
Smaato (D,P)	**0.2%**	**2%**	**0.1%**

Table 5: Cross-device companies' (D = deterministic and P = probabilistic according to their websites' claims) coverage of websites and apps on average for the users in our dataset ($n = 107$). Some of the companies either do not seem to offer an SDK for app integration (N/A) or we did not analyze it as it was not contained in our initial set of SDKs from AppBrain (N/A*). The full list, including the tracking server domains, is attached in Appendix B.

Partnerships between various cross-device companies extend their reach. For example, Atlas receives user data from Facebook [8] to track users deterministically. However, Atlas

[13] The app tracker count includes affiliated company's SDKs. Thus, for example, the Facebook SDK inside the Instagram app is counted as one tracker.

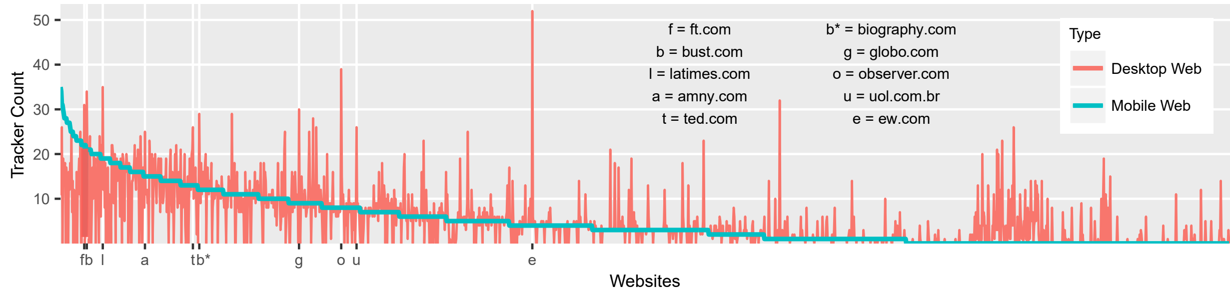

Figure 11: The ten domains with the highest number of cross-device companies on their desktop websites (out of 1,829 total domains). It can be observed that they tend to have higher concentrations of cross-device companies on their mobile sites as well.

Table 6: Domains with the highest cross-device company counts out of 1,829 domains whose URL occurred in both mobile and desktop data in our CDT dataset. With a total of 57 trackers (31 mobile web and 26 desktop web) food.com had the highest count overall.

is intended to serve advertisements outside of Facebook's reach and shares the data it collects with Facebook as well [8]. Particularly, as shown in Table 5, Atlas' cross-device trackers extend Facebook's mobile web reach from 27.7% to 29.1%. As another example, the partnership between Lotame and Skimlinks [57], which we actually observed in our initial experiment (§ 3), also extends their respective reach. In those cases the relationship between companies needs to be accounted for to accurately determine their full coverage.

Domains with Cross-device Company Concentration. It appears that media websites, in particular, websites of newspapers, contain the largest concentration of trackers from cross-device companies. Table 6 shows the top ten domains—separated for desktop and mobile websites—on which we found the highest number of trackers from the 87 identified cross-device companies. Coincidentally, it turns out that the website of the LA Times was a good selection for our case study (§ 3) as it had trackers from 35 cross-device companies on its desktop website.

Beyond the concentration of cross-device companies' trackers in the media category it is also striking that many websites that are hosting those trackers are fairly popular sites. Table 6 shows the Quantcast country rank according to the site's traffic [70]. This placement of cross-device trackers on popular sites exposes them to large audiences. However, as it can be observed in Table 6 as well, the shown domains contain a maximum number of trackers from cross-device companies on either their mobile or desktop sites but not on both. This finding holds in general. While there is a tendency that domains that host many cross-device companies on their desktop site also host many on their mobile site, we could not find any statistically significant correlation in this regard. Figure 11 shows the distribution.

8 Does Self-Regulation Work?

The FTC recommends that cross-device companies should be transparent about their data practices [32]. While there are no specific statutes or regulations for cross-device tracking in the U.S., the field is subject to self-regulation, most notably by the Digital Advertising Alliance (DAA) and the Network Advertising Initiative. The DAA requires its member cross-device companies to disclose "the fact that data collected from a particular browser or device may be used with another computer or device that is linked to the browser or device on which such data was collected." [21] In order to examine the level of compliance with this transparency requirement we randomly selected 40 DAA member ad networks that advertised their cross-device capabilities on their websites and analyzed their privacy policies.

We found that 23 disclosed their cross-device tracking activities while 17 omitted those. After contacting the latter, we received a response from seven. Two pointed us to documents that were linked from the policy that indeed contained

compliant descriptions. A representative from another cross-device company wrote that their cross-device functionality is not yet fully rolled out to clients, and three others announced that they will change their policy (one of those still has to follow through). Another representative simply claimed that the company is "not violating anything." Without contacting us five further cross-device companies simply changed their policies, of which four became compliant. Finally, there was no reaction or policy change from five. As of June 9, 2017 we count a total of eight instances of non-compliance.

Overall, it appears that there is a lack of transparency when it comes to the disclosure of cross-device tracking. At this point, the DAA guidance does not seem to be enforced rigorously. While it may be true that the majority of consumers will not take the time to understand the tracking practices described in privacy policies,[14] we think that it is still a worthwhile endeavor for cross-device companies to properly disclose their practices, particularly, for audit and enforcement purposes as well as for signaling trustworthiness to the marketplace and to build an environment of rules and norms in privacy disclosure.

9 Conclusion

Cross-device tracking is an emerging tracking paradigm that challenges current notions of privacy. This study is intended as a broad overview of selected privacy topics in mainstream cross-device technologies. In a brief case study we have demonstrated how cross-device tracking can be observed with statistical confidence by means of an information flow experiment. Using our own cross-device tracking dataset we designed a cross-device tracking algorithm and evaluated relevant features and parameter settings grounded in a review of publicly available information on the practices of cross-device companies. For some predictive tasks it appears that those companies can learn more about users than from individual device data. As the penetration of cross-device tracking on the Internet already appears relatively high it is even more important that companies active in this field are transparent about their practices.

Going forward we hope that the various privacy implications of cross-device tracking technologies will be studied further. In this regard, proprietary research is substantially ahead of current efforts in academia. While a few major points are known—for example, that IP addresses are a crucial feature for correlating devices—many important details on how cross-device companies operate remain opaque. To shed more light on the subject we publicized our dataset together with the software that we developed for further exploration.

[14] Using tracking protection software and ad blockers is a much more efficient approach from a user perspective. Thus, when evaluating cross-device tracking in terms of a threat model, the most effective defense would be to block tracking. In this regard, the defenses against cross-device tracking are the same as the defenses against the tracking of individual devices.

As cross-device tracking continues to mature and become an integral part of tracking on the Internet we believe that a comprehensive view including legal and business considerations is helpful. Establishing an enforceable self-regulatory framework for companies to be transparent about their practices will help to protect consumer privacy and allow cross-device companies to conduct their businesses responsibly.

Ultimately, cross-device tracking is part of a larger trend: the Internet of Things (IoT). In this regard, we see cross-device tracking as an early harbinger of the increasing inter-connectivity of devices. Increasingly, buildings, cars, appliances, and other things are connected to the Internet and are interacting with other online devices. However, the development and deployment of privacy solutions has to keep pace with the emerging IoT landscape. Ensuring transparency and practicable control mechanisms for information that is traversing device boundaries and permeates between the online and offline worlds is a critical element. Given standardized interfaces [43], perhaps, an intelligent personal privacy assistant that is connected to all services and devices of person could be a solution.

Acknowledgment

We would like to thank the anonymous reviewers as well as our shepherd Alina Oprea for their helpful comments during the paper review phase. We further thank Clément Canonne, Paul Blaer, Daisy Nguyen, and Anupam Das. Tony Jebara is supported in part by DARPA (N66001-15-C-4032) and NSF (III-1526914, IIS-1451500). We also gratefully acknowledge the Comcast Research Grant for our user study. The views and conclusions contained herein are our own.

Abstract

Cryptocurrencies such as Bitcoin and Ethereum are operated by a handful of mining pools. Nearly 95% of Bitcoin's and 80% of Ethereum's mining power resides with less than ten and six mining pools respectively. Although miners benefit from low payout variance in pooled mining, centralized mining pools require members to trust that pool operators will remunerate them fairly. Furthermore, centralized pools pose the risk of transaction censorship from pool operators, and open up possibilities for collusion between pools for perpetrating severe attacks.

In this work, we propose SMARTPOOL, a novel protocol design for a decentralized mining pool. Our protocol shows how one can leverage *smart contracts*, autonomous blockchain programs, to decentralize cryptocurrency mining. SMARTPOOL gives transaction selection control back to miners while yielding low-variance payouts. SMARTPOOL incurs mining fees lower than centralized mining pools and is designed to scale to a large number of miners. We implemented and deployed a robust SMARTPOOL implementation on the Ethereum and Ethereum Classic networks. To date, our deployed pools have handled a peak hashrate of 30 GHs from Ethereum miners, resulting in 105 blocks, costing miners a mere 0.6% of block rewards in transaction fees.

1 Introduction

Cryptocurrencies such as Bitcoin and Ethereum offer the promise of a digital currency that lacks a centralized issuer or a trusted operator. These cryptocurrency networks maintain a distributed ledger of all transactions, agreed upon by a large number of computation nodes (or *miners*). The most widely used protocol for agreement is Nakamoto consensus, which rewards one miner every epoch (lasting, say, 10 minutes as in Bitcoin) who exhibits a solution to a probabilistic computation puzzle called a "proof-of-work" (or PoW) puzzle [1]. The winning miner's solution includes a transaction *block*, which is appended to the distributed ledger that all miners maintain. The reward is substantial (e.g. 12.5 BTC in Bitcoin, or $30,000$ USD at present), incentivizing participation.

Nakamoto-based cryptocurrencies, such as Bitcoin and Ethereum, utilize massive computational resources for their mining. Finding a valid solution to a PoW puzzle is a probabilistic process, which follows a Poisson distribution, with a miner's probability of finding a solution within an epoch determined by the fraction of computation power it possesses in the network. Miners with modest computational power can have extremely high variance. A desktop CPU would mine 1 Bitcoin block in over a thousand years, for instance [2]. To reduce variance, miners join *mining pools* to mine blocks and share rewards together. In a mining pool, a designated pool *operator* is responsible for distributing computation sub-puzzles of lower difficulty than the full PoW block puzzle to its members. Each solution to a sub-puzzle has a probability of yielding a solution to the full PoW block puzzle—so if enough miners solve them, some of these solutions are likely to yield blocks. When a miner's submitted solution yields a valid block, the pool operator submits it to the network and obtains the block reward. The reward is expected to be fairly divided among all pool members proportional to their contributed solutions.

Problem. Centralized pool operators direct the massive computational power of their pools' participants. At the time of this writing, Bitcoin derives at least 95% of its mining power from only 10 mining pools; the Ethereum network similarly has 80% of its mining power emanating from 6 pools. Previous works have raised concerns about consolidation of power on Bitcoin [3,4]. Recent work by Apostolaki *et al.* has demonstrated large-scale network attacks on cryptocurrencies, such as double spending and network partitioning, which exploit centralized mining status quo [5]. By design, if a single pool operator controls more than half of the network's total mining power, then a classical 51% attack threat-

ens the core security of the Nakamoto consensus protocol [1]. Cryptocurrencies have witnessed that a single pool has commandeered more than half of a cryptocurrency's hash rate (*e.g.* `DwarfPool`[1] in Ethereum and `GHash.io`[2] in Bitcoin) on several occasions. In such cases, the pool operator's goodwill has been the only barrier to an attack.

Furthermore, pools currently dictate which transactions get included in the blockchain, thus increasing the threat of transaction censorship significantly [6]. While some Bitcoin pools currently offer limited control to miners of transaction selection via the getblocktemplate protocol [7], this protocol only permits a choice between mining with a transaction set chosen by the pool or mining an empty block. The situation is worse in Ethereum where it is not yet technically possible for miners in centralized pools to reject the transaction set selected by the operator. For example, users recently publicly speculated that a large Ethereum pool favored its own transactions in its blocks to gain an advantage in a public crowdsale [3].

One can combat these security issues by running a pool protocol with a decentralized network of miners in place of a centralized operator. In fact, one such solution for Bitcoin, called P2POOL [8], already exists. However, P2POOL has not attracted significant participation from miners, and consequently its internal operational network remains open to infiltration by attackers. Secondly, technical challenges have hindered widespread adoption. Scalable participation under P2POOL's current design would require the system to check a massive number of sub-puzzles. Furthermore, P2POOL only works for Bitcoin; we are not aware of any decentralized mining approach for Ethereum.

Solution. This work introduces a new and practical solution for decentralized pooled mining called SMARTPOOL. We claim two key contributions. First, we observe that it is possible to run a decentralized pool mining protocol as a *smart contract* on the Ethereum cryptocurrency. Our solution layers its security on the existing mining network of a large and widely deployed cryptocurrency network, thereby mitigating the difficulty of bootstrapping a new mining network from scratch. Secondly, we propose a design that is efficient and scales to a large number of participants. Our design uses a simple yet powerful probabilistic verification technique which guarantees the fairness of the payoff. We also introduce a new data structure, the *augmented Merkle tree*, for secure and efficient verification. Most importantly, SMARTPOOL allows miners to freely select which transaction set they want to include in a block. If widely adopted, SMARTPOOL makes the underlying cryptocurrency network much more censorship-resistant. Finally, SMARTPOOL does not charge any fees [4], unlike centralized pools, and disburses all block rewards to pool participants entirely.

SMARTPOOL can be used to run mining pools for several different cryptocurrencies. In this work, we demonstrate concrete instantiations for Bitcoin and Ethereum. SMARTPOOL can be run natively within the protocol of a cryptocurrency — for instance, it can be implemented in Ethereum itself. We believe SMARTPOOL can support a variety of standard payoff schemes, as in present mining pools. In this work, we demonstrate the standard pay-per-share (or PPS) scheme in our implementation. Supporting other standard schemes like pay-per-last-n-shares (PPLNS) and schemes that disincentivize against block withholding attacks [9–11] is left for future work.

Results. We have implemented SMARTPOOL and a stable SMARTPOOL implementation has been released and deployed on the main network via a crowd-funded community project [12]. As of 18 June 2017, SMARTPOOL-based pools have mined in total 105 blocks on both Ethereum and Ethereum Classic networks and have successfully handled a peak hashrate of 30 GHs from 2 substantial miners. SMARTPOOL costs miners as little as 0.6% for operational transaction fees, which is much less than 3% fees taken in centralized pools like F2Pool [5]. Furthermore, each miner has to send only a few messages per day to SMARTPOOL. Finally, although being decentralized, SMARTPOOL still offers the advantage of low variance payouts like centralized pools.

As a final remark, SMARTPOOL does not make centralized pooled mining in cryptocurrencies impossible, nor does it incentivize against centralized mining or alter the underlying proof-of-work protocol (as done in work by Miller *et al*. [13]). SMARTPOOL simply offers a practical alternative for miners to move away from centralized pools without degrading functionality or rewards.

Contributions. We claim the following contributions:

- We introduce a new and efficient decentralized pooled mining protocol for cryptocurrencies. By leveraging smart contracts in existing cryptocurrencies, a novel data structure, and an efficient verification mechanism, SMARTPOOL provides security and efficiency to miners.

- We implemented SMARTPOOL and deployed real mining pools on Ethereum and Ethereum Classic. The pools have so far mined 105 real blocks and

[4] The caveat here is that cryptocurrency miners will pay Ethereum transaction fees to execute SMARTPOOL distributively.

[5] https://www.f2pool.com/ethereum-blocks

have handled significant hashrates while deferring only 0.6% of block rewards to transaction fee costs.

2 Problem and Challenges

We consider the problem of building a decentralized protocol which allows a large open network to collectively solve a computational PoW puzzle, and distribute the earned reward between the participants proportional to their computational contributions. We expect such a protocol to satisfy the following properties:

- *Decentralization.* There is no centralized operator who operates the protocol and manage other participants. The protocol is collectively run by all participants in the network. There is also no requirement for joining, *i.e.* anyone with sufficient computation power can freely participate in and contribute to solving the PoW puzzle.
- *Efficiency.* The protocol running costs should be low and offer participants comparable reward and low variance guarantees as centralized operations. Furthermore, communication expenses, communication bandwidth, local computation and other costs incurred by participants must be reasonably small.
- *Security.* The protocol protects participants from attackers who might steal rewards or prevent others from joining the protocol.
- *Fairness.* Participants receive rewards in proportion to their share of contributions.

In this paper we focus on this list of properties with respect to mining pools. Cryptocurrencies like Bitcoin and Ethereum reward network participants (or miners) new crypto-coins for solving computationally hard puzzles (or proof-of-work puzzles) [1,14,15]. Typically, Bitcoin miners competitively search for a `nonce` value satisfying

$$\mathsf{H}(\texttt{BlockHeader} \,||\, \texttt{nonce}) \leq D \qquad (1)$$

where H is some preimage-resistant cryptographic hash function (*e.g.* SHA-256), `BlockHeader` includes new set of transactions that the miner wants to append to the ledger and D is a global parameter which determines the puzzle hardness. Ethereum uses a different, ASIC-resistant PoW function [16]. which requires miners to have a (predetermined) big dataset of 1 GB (increasing over time). Thus, in Ethereum, the condition (1) becomes

$$\mathsf{H}(\texttt{BlockHeader} \,||\, \texttt{nonce} \,||\, \texttt{dataset}) \leq D$$

in which the `dataset` includes 64 elements of the 1GB dataset that are randomly sampled with the `nonce` and the `BlockHeader` as the random seed.

Finding a solution for a PoW puzzle in cryptocurrencies requires enormous amount of computation power.

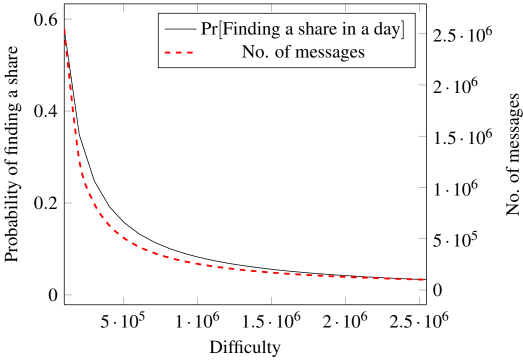

Figure 1: The effect of share's difficulty on i) the probability of a miner with 1 GHs finding a share within a day as per [2]; ii) resource (*i.e.* number of messages) consumed by a miner; in a decentralized mining pool for Bitcoin (*e.g.* P2POOL).

Thus miners often join resources and solve the puzzle together via pooled mining. Currently, most mining pools follow a centralized approach in which an operator manages the pool and distributes work to pool miners. Here we are interested in a decentralized approach that allows miners to collectively run and manage the pool without inherent trust in any centralized operator.

Threat model and security assumptions. Cryptocurrencies like Bitcoin and Ethereum allow users to use pseudonymous identities in the network. Users do not have any inherent identities and there is no PKI in the network. Our solution adheres to this setting.

We consider a threat model where miners are *rational*, which means they can deviate arbitrarily from the honest protocol to gain more reward. An alternative is a *malicious* model where the attacker does anything just to harm other miners. In this work, we are not interested in the malicious model since i) such sustained attacks in cryptocurrencies often require huge capital, and ii) existing centralized pools are not secure in such a model either [9–11]. We also assume that the adversary controls less than 50% of the computation power in the network on which SMARTPOOL runs. This assumption rules out double-spending via 51% attacks [1].

On the other hand, we do not make any assumption on the centralization or trusted setup in our solution apart from what have been made in existing cryptocurrencies [6].

2.1 Existing Solutions

In the widely adopted centralized pooled mining protocol, there is a pool operator who asks pool miners to solve pool sub-puzzles by finding `nonce` so that the hash satisfies some smaller difficulty d ($d \ll D$). A solution

[6]Bitcoin and Ethereum have trusted setups where the first blocks are constructed and provided by Satoshi Nakamoto (for Bitcoin) and Ethereum Foundation (for Ethereum).

for a pool-puzzle is called a *share* and has some probability of being a valid solution for the main PoW puzzle. Once a miner in the pool finds a valid block, the reward, i.e., new crypto-coins, is split among all pool miners in proportion to the number of their valid submitted shares [2].

Despite being widely used in practice, centralized mining pools have several problems including network centralization and transaction censorship as discussed in Section 1. P2POOL for Bitcoin is the first and only deployed solution we are aware of which decentralizes pooled mining for cryptocurrencies [8]. At a high level, P2POOL decides on the contribution of each miner by running an additional Nakamoto Consensus protocol to build a *share-chain* between all miners in the pool. The share-chain includes all shares submitted to the pool, one after another (akin to the normal Bitcoin blockchain, but each block is a share). To guarantee that each share is submitted and credited exactly once, P2POOL leverages coinbase transactions, which are special transactions that pay block reward to miners (see details in Section 3.3).

P2POOL satisfies almost all ideal properties of a decentralized pool (defined in Section 2) except the *efficiency* and *security* properties. Specifically, P2POOL entails a high performance overhead since the number of messages exchanged between miners is a scalar multiple of the number of shares in the pool. When the share difficulty is low, miners have to spend a lot of resources (*e.g.* bandwidth, local computation) to download, and verify each other's shares. Figure 1 demonstrates how adjusting the difficulty of shares affects the variance of miners' reward and the amount of resource (both bandwidth and computation) consumed per miner (with $1GHs$ capacity) in a decentralized pool like P2POOL. As a result, P2POOL requires high share difficulty in order to reduce the number of transmitted messages. Therefore P2POOL miners experience higher reward variance than they would when mining with centralized pools. As discussed in [2], high variance in the reward (*i.e.* the supply of money) decreases miners' utility by making it harder for them to predict their income and verify that their systems are working correctly. Perhaps as a result, P2POOL has to date attracted only a few miners who comprise a negligible fraction of Bitcoin mining power (as of June 23, 2017, the last block mined by P2POOL was 22 days ago [8]).

The security of P2POOL's share-chain depends on the amount of computation power in its pool. As of this writing, P2POOL accounts for less than 0.1% of Bitcoin mining power, thus P2POOL's share chain is vulnerable to 51% attacks from adversaries who control only 0.1% of Bitcoin mining power. Hence P2POOL may not offer better security guarantees than centralized pools.

2.2 Our Solution and Challenges

Our solution for a decentralized pooled mining leverages Ethereum smart contracts which are decentralized autonomous agents running on the blockchain itself [17, 18]. A non-contract account has an address and balance in Ether, the native currency for Ethereum. A smart contract has, in addition, code and private persistent storage (*i.e.* a mapping between variables and values). Smart contract code is akin to a normal program which can manipulates stored variables. To invoke a contract (*i.e.* execute its code) at address *addr*, users send a transaction to *addr* with an appropriate payload, *i.e.* payment for the execution (in Ether) and/or input data for the invocation. The contract code executes correctly on the blockchain as long as a majority of Ethereum miners faithfully follow the Ethereum protocol.

At a high level, SMARTPOOL replaces the mining pool operator with a smart contract. The smart contract acts as a trustless bookkeeper for the pool by storing all shares submitted by miners. When a new share is submitted, the contract verifies the validity of the share, checks that no previous record of the share exists, and then updates the corresponding miner's record. We allow miners to locally generate the block template of the pool (discussed more in Section 3.3). If a miner finds a share which is a valid block, it will broadcast the block to the cryptocurrency network, the reward will be instantly credited to SMARTPOOL. SMARTPOOL then disburses the block reward fairly to all miners in the pool.

Challenges. There are several challenges in building such a smart contract for a mining pool. We illustrate them by considering a straw-man solution (called `StrawmanPool`) in Figure 2 which implements a decentralized pool as a Ethereum smart contract. The solution works by having a smart contract which receives all the shares submitted by miners, verifies each of them and records number of shares one has submitted. The contract has a designated address for receiving block reward. A share is valid if it uses the contract address as the coinbase address (*i.e.*, the address that the block reward is sent to) and satisfies the predefined difficulty (*e.g.* Line 6). On each share submission, the pool verifies the share and updates the contribution statistics of the pool members (Line 13). If a miner finds a valid block, the smart contract distributes the reward to miners in the pool proportional to their contribution by using any of the standard payout schemes [2](Line 16). The solution in Figure 2 has the following shortcomings and challenges.

- *C1.* The number of shares in the pool may be large, thus resulting in an unwieldy number of messages sent to the contract. For example, it may take $1,000,000$ shares on average to get a valid block. A naïve solution might require miners to

```
1 contract StrawmanPool{
2   mapping (uint256 => boolean) mSubmittedShares;
3   mapping (uint256 => int) mContribution;
4   function submitShare(someShare) returns (boolean){
5     // check validity
6     if !isValid(someShare)
7       return false;
8     // check if the share has been submitted
9     if mSubmittedShares[someShare.hash]
10      return false;
11    mSubmittedShares[someShare.hash] = true;
12    // update miner's contribution
13    mContribution[msg.owner] += 1;
14    // distribute reward if is a valid block
15    if isValidBlock(someShare)
16      distributeReward(mContribution);
17    return true;
18  }}
```

Figure 2: Pseudo-code of a straw-man solution which implements a mining pool in a smart contract.

create $1,000,000$ transactions and send all of them to the pool's contract. No existing open network agreement protocol can process that many transactions within the course of a few minutes [19, 20]. On the other hand, reducing the number of shares per block by increasing the share difficulty will increase the variance in reward for miners, thus negating the sole advantage of pooled mining (see [2] for more analysis on the effects of share difficulty).

- *C2.* A valid share earns miners a small amount of reward, but miners may have to pay much more in Ethereum gas fees when submitting their shares to the pool. The gas fee compensates for the storage and computation required to verify shares and update the contract state (see [21, 22]). Thus, `StrawmanPool` may render a negative income for miners when the fee paid to submit a share outweighs the reward earned by the share itself.

- *C3.* In Ethereum, transactions are in plaintext; thus, any network adversary can observe other miners' transactions that include the shares and either steal or resubmit the shares. This challenge does not exist in centralized pools where miners can establish secure and private connections to the pools. In decentralized settings, such secure connections are not immediate since i) there is no centralized operator who can initiate secure connections to miners, and ii) there is no PKI between miners in the pool. Thus, a good design for a mining pool must prevent the adversary from stealing others' shares. Similarly, the pool should prevent miners from over-claiming their contribution by either re-submitting previous shares or submitting invalid shares. Centralized pools can efficiently guarantee this since the pool manager can check every submission from miners.

- *C4.* This challenge is specific to the scenario when one wishes to use SMARTPOOL for a different cryptocurrency (e.g. Bitcoin) than the one on which its contract is deployed (e.g. Ethereum). A smart contract in Ethereum running a Bitcoin mining pool must guarantee correct payments in Bitcoin. This is tricky because Bitcoin miners expect to receive rewards in Bitcoin, but Ethereum contracts can operate only on balances in Ether.

3 Design

SMARTPOOL's design can be used to implement a decentralized mining pool on Ethereum for many existing target cryptocurrencies, but for ease of explanation we fix Ethereum as the target. In Section 5, we discuss how one can use SMARTPOOL-based decentralized mining pools for other cryptocurrencies (e.g. Bitcoin).

3.1 Approach

We briefly describe how we address the challenges from Section 2.2 in SMARTPOOL.

- SMARTPOOL guarantees the *decentralization* property by implementing the pool as a smart contract. Like any smart contract, SMARTPOOL is operated by all miners in the Ethereum network, yet it can secure other cryptocurrency networks including Bitcoin as well as the underlying Ethereum network itself. SMARTPOOL relies on the Ethereum's consensus protocol to agree on the state of the pool. The security of SMARTPOOL depends exclusively on the underlying network (*i.e.* Ethereum) which runs smart contracts, not on how many users adopt the pool.
- SMARTPOOL's *efficiency* comes from allowing miners to claim their shares in batches, *e.g.* one transaction to the SMARTPOOL contract can claim, say, 1 million shares. Furthermore, miners do not have to submit data of all shares but only a few for verification purposes, hence the transaction fee per share is negligible. As a result, the number of transactions required to send to SMARTPOOL is several orders of magnitude less than the number of shares (*i.e.* the number of messages in P2POOL).
- We propose a simple but powerful probabilistic verification of submissions from miners. Our mechanism, aided by a new and efficient Merkle-tree based commitment scheme, guarantees the same average outcome as running a full verification for each submission by enforcing a *penalty* function to disincentivize cheating. Our mechanism detects miners submitting duplicated shares or resubmitting shares in different batched claims. As a result, we guar-

antee *fairness* in that miners receive their expected reward based on their contributions even when other dishonest miners submit invalid shares.

- SMARTPOOL forces the miner to commit the right set of beneficiary addresses in the share before mining, so that it cannot be changed after a solution is found. This commitment prevents share theft, wherein a network participant tries to use someone else's solutions to pay itself.
- For the case of running an external SMARTPOOL-based Bitcoin mining pool on top of Ethereum, SMARTPOOL leverages the Bitcoin `coinbase` transaction to guarantee that miners can mine directly in their target currency (*i.e.* Bitcoin) without trusting a third party to proxy the payment (e.g. between Ethereum and Bitcoin). Nevertheless, miners still need to acquire Ether to pay for the gas when interacting with the SMARTPOOL smart contract. Such costs are less than 1% of miners' reward as we show in our experiments with a deployment in Ethereum testnet. Indeed SMARTPOOL operates at lower cost than today's centralized pools.

3.2 Overview of SMARTPOOL

SMARTPOOL is a smart contract which implements a decentralized mining pool for Ethereum and runs on the Ethereum network. SMARTPOOL maintains two main lists in its contract state — a claim list `claimList` and a verified claim list `verClaimList`. When a miner submits a set of shares as claim for the current Ethereum block, it is added to the `claimList`. This step acts as a cryptographic commitment to the set of shares claimed to be found by the miner. Each claim specifies the number of shares the miner claims to have found, and it has a particular structure that aids verification in a subsequent step. SMARTPOOL then proceeds to verify the validity of the claim, and once verified, it moves it to the `verClaimList`. Claim verification and payments for verified claims happen atomically in a single Ethereum transaction. Each claim allows miners to submit a batch of (say, 1 million) shares. Submitted claims need to include sufficient meta-data for verification purposes. During the first step of mining the shares, if a miner finds a valid block in the target cryptocurrency, it can directly submit the found block to the target cyrptocurrency network with the SMARTPOOL address as the beneficiary. Thus, miners receive payouts for their shares one or more blocks after SMARTPOOL receives reward from the target network; and, the mechanism ensures that the cryptographic commitment strictly preceeds the verification step (the cryptographic reveal phase).

In Section 3.4 we will discuss our verification protocol, a key contribution of this work which enables

Field Size (bytes)	Name	Data type
4	number	uint
32	parent hash	uint
32	TRIEHASH(TX_list)	uint
20	coinbase address	address
32	state root	uint
32	extra_data	char[32]
8	timestamp	uint
8	difficulty	uint
8	nonce	uint

Table 1: Some important fields of a block header in Ethereum. "coinbase address" is the address that receives the block reward, while "extra_data" allows miners to include any data (upto 32 byes) to the block header.

efficiency. The goal of the verification process is to prevent miners from both submitting invalid shares and over-claiming the number of shares they have found. SMARTPOOL pays claimants proportional to the number of shares claimed, if the verification succeeds, and otherwise nothing. The key guarantee here is that of fairness — SMARTPOOL does not advantage miners who cheat by claiming invalid or duplicate shares. The expected payoff from cheating is the same (or worse) as honestly reporting shares.

In order to join the pool, miners only need to prepare a correct block template. SMARTPOOL maintains the `verClaimList` array in the contract which records the contributed shares by different miners to date. To enable efficient verification checks, SMARTPOOL forces miners to search for blocks with a particular structure and dictates a particular template for claim submissions, which we discuss in Section 3.3. Unlike P2POOL, SMARTPOOL miners do not have to run an additional consensus protocol to agree on the list state.

3.3 Claim Submissions

Miners can submit a large batch of shares in a single claim. To permit this, SMARTPOOL defines a `Claim` structure which consists of a few pieces of data. First, the miner cryptographically commits to the set of shares he is claiming. The cryptographic commitment goes via a specific data structure we call an augmented Merkle tree, as discussed in Section 3.5. The Merkle root of this data structure is a single cryptographic hash representing all the shares claimed and is included in the `Claim` as a field called `ShareAugMT`.

After a miner claims several shares in a batch, SMARTPOOL requires the miner to submit proofs to demonstrate that the shares included in the claim are valid. For each claimed share being examined, SMARTPOOL defines a `ShareProof` structure to help validate the share. First, SMARTPOOL requires a Merkle proof, denoted as

AugMkProof, to attest that the share has been committed to ShareAugMT. Furthermore, SMARTPOOL ensures that if a miner finds a share that is a valid Ethereum block, then the corresponding block reward is distributed among the pool members. In an Ethereum block, there is a special field called "coinbase address" which specifies the address that receives the block reward. A share in SMARTPOOL is valid only if the miner uses pool's address as the "coinbase address."

It is straightforward to see how SMARTPOOL's use of cryptographic commitments prevents certain timing vulnerabilities. SMARTPOOL asks the miners to fix their coinbase address before starting to find shares. Once a share is found, it is not possible to change or eliminate the coinbase address. SMARTPOOL also asks miners to put their beneficiary address in the "extra_data" field, so SMARTPOOL can extract the address to credit the share to. Although miners may use different addresses to submit their claims to the contract, SMARTPOOL credits the share to only one account by fetching the beneficial address from the "extra_data" field. This prevents miners from claiming the same share to different Ethereum addresses (or accounts), forcing a one-to-one mapping between shares found and addresses credited for them. If a network attacker steals someone else's share, it cannot pay itself since the coinbase transaction has already committed to a payee.

3.4 Batching & Probabilistic Verification

SMARTPOOL processes share claims efficiently. Miners can claim multiple shares to SMARTPOOL in a single submission. Each Claim includes less than one hundred bytes consisting of a cryptographic commitment for the shares, in a field called ShareAugMT. This cryptographic commitment forces the miner to commit to a set of shares before including them in the claim. Ideally, before accepting any claim of n shares submitted by the miner, we want to verify that

(i) all shares submitted are valid;
(ii) no share is repeated twice in a claim;
(iii) each share appears in at most one claim.

Probabilistic verification. For efficiency, SMARTPOOL uses a simple but powerful observation: if we *probabilistically verify* the claims of a miner, and pay only if no cheating is detected, then expected payoffs of cheating miners are the same or less than those of honest miners. In effect, this observation reduces the effort of verifying millions of shares down to verifying one or two!

We provide a way to sample shares to verify, outline a detailed procedure for checking validity in Section 3.5, and a full proof in Section 4. Here, we explain this observation with an example, since it may appear counter-intuitive at first. Let us consider a case where cheating miner finds 500 valid shares but claims that he has found 1000 valid shares to SMARTPOOL. If SMARTPOOL were able to randomly sample one share from the miner's committed set, and verify its validity, then the odds of having detected the cheating is $500/1000$ (or $1/2$). If the miner is caught cheating, he is paid nothing; if he gets lucky without being detected, he gets rewarded for 1000 shares. Note that the expected payoff for such a miner is still 500, computed as $(0.5 \cdot 1000 + 0.5 \cdot 0) = 500$, which is the same as that of an honest miner that claimed the right amount of valid shares. The argument extends easily to varying amounts of cheating; if the cheater wishes to claim $1,500$ shares, he is detected with with probability $2/3$ and stands to get nothing. The higher his claim away from the true value of found shares, the lower is the chance of a successful payout. By sampling $k \geq 1$ times, SMARTPOOL can reduce the probability of a cheater remaining undetected exponentially small in k, as we show in Section 4.

Searching for shares. To enable probabilistic verification, SMARTPOOL prescribes a procedure for mining shares. Each SMARTPOOL miner is expected to search for shares in a monotonic order, starting from a distinct value that it commits to. Specifically, when a miner claims shares $S = \{s_1, s_2, \ldots, s_n\}$, SMARTPOOL extracts a unique counter from each share, e.g., taking the first k (say 20) bits, and requires that the counters of all $s_i \in S$ to be strictly increasing. Each time a miner finds a valid nonce that yields a valid share, he increases the counter by at least 1 and searches for the next share. When the miner claims for the set S, its submitted elements must be lexicographically ordered by counter values. The miner commits the latest counter in his Claim to this set S, which has at most one share for each counter value. This eliminates any repeats in claimed shares in one claim, and across claims by one miner. In SMARTPOOL implementation as an Ethereum contract, as discussed in Section 3.5, we use the share's timestamp and the used nonce to act as the counter value of a share.

SMARTPOOL guarantees that miners produce distinct shares by providing a unique value in the "extra_data" field in each miner's share template. This ensures that miners search in distinct sub-spaces of the search space.

Checking Validity of Shares. SMARTPOOL checks that miners have followed the prescribed mining procedure by randomly sampling a share from each submitted Claim along with a ShareProof (as described in Section 3.3). SMARTPOOL validates the following:

(i) the hash of the share meets the difficulty criterion;
(ii) the share is constructed correctly, i.e., uses the SMARTPOOL's address as the beneficiary address of the block reward.
(iii) the share correctly satisfies the proof-of-work

(PoW) solution constraints (e.g. the use of predetermined 1GB dataset mandated by the Ethereum PoW scheme)

The checks for (i) and (ii) are straightforward. The check for (iii) is to guarantee that miners actually have and use the data cache when they generate the shares. This 1GB of data cache is introduced in Ethereum to make its PoW ASIC-resistant. Thus, skipping checking (iii) would allow rational miners to easily mine a lot of invalid shares and still get paid from SMARTPOOL. It is not straightforward to efficiently check (iii) inside a smart contract. Indeed a naïve solution would require a massive amount of gas and hence invoke enormous transaction fees. We discuss implementation tricks on how to check (iii) in Section 6.1.1.

It remains to discuss (a) how miners cryptographically commit to a batched set of shares in a claim, (b) how SMARTPOOL verifies that the committed set has monotonically increasing counters, and (c) how shares are sampled. For (a) and (b), one can think of using a standard Merkle tree on all the claimed share set to generate the cryptographic commitment. However, in a standard Merkle tree, verifying the inclusion of a share is efficient, but checking the ordering of the set elements is not efficient. In SMARTPOOL, we devise a new data structure called *augmented Merkle tree* to help us verify inclusion and ordering of shares efficiently.

3.5 Detailed Constructions

In this section, we discuss an efficient verification scheme using probabilistic share sampling and a simple penalty function that penalizes cheaters. The description here takes an Ethereum pool as a target, but the same data structure works for other PoW-based cryptocurrency such as Bitcoin as we discuss in Section 5.

Augmented Merkle tree. Recall that a *Merkle tree* is a binary tree in which each node is the hash of the concatenation of its children nodes. In general, the leaves of a Merkle tree will collectively contain some data of interest, and the root is a single hash value which acts as a certificate commitment for the leaf values in the following sense. If one knows only the root of a Merkle tree and wants to confirm that some data x sits at one of the leaves, then holder of the original data can provide a "Merkle path" from the root to the leaf containing x together with the children of each node traversed in the Merkle tree. Such a path is difficult to fake because one needs to know the children's preimages for each hash in the path, so with high probability the data holder will supply a correct path if and only if x actually sits at one of the leaves.

For the purposes of submitting shares in SMARTPOOL, we not only want to ensure that shares exist in the batch list but also that there are no repeats and ordering of the counters is correct. We therefore introduce an augmented Merkle tree structure which we use to guard against duplicates in the leaves.

Definition 1 (Augmented Merkle tree)**.** Let ctr be a one-to-one function that maps shares to integers. An *augmented Merkle tree* for a set of objects $\mathsf{S} = \{s_1, s_2, \ldots, s_n\}$ is a tree whose nodes x have the form $(\mathsf{min}(x), \mathsf{hash}(x), \mathsf{max}(x))$ where:

(I) $\mathsf{min}(x)$ is the minimum of the children's min (or $ctr(s_i)$, if x is a leaf corresponding to the object s_i),

(II) $\mathsf{hash}(x)$ is the cryptographic hash of the concatenation of the children nodes (or $\mathsf{hash}(s_i)$ if x is a leaf corresponding to the object s_i), and

(III) $\mathsf{max}(x)$ is the maximum of the children's max (or $ctr(s_i)$, if x is a leaf corresponding to the object s_i).

An augmented Merkle tree is called *sorted* if all of its leaves occur in strictly increasing order from left to right with respect to its counter function.

SMARTPOOL expects claims of submitted shares to be monotonically ordered by their counters. Thus, one can think of each share s_i to have a "timestamp" given by its $ctr(x)$, since integer-valued counters can be naturally ordered (ascending or descending). For implementation in Ethereum, we can use the block timestamp and an the nonce to serve as the counter. In Appendix 10.2, we discuss alternative candidates for the ordering function ctr with backward compatibility to serve Bitcoin mining.

Figure 3 gives an example of an augmented Merkle tree based on four submitted shares with timestamps as $1,2,3,4$ respectively. To prove that the share c has been committed, a miner has to submit two nodes d and e to SMARTPOOL. SMARTPOOL can reconstruct other nodes on the path from c to the root (*i.e.* b and a sequentially) and accepts the proof if the computed root is the same as the committed one. The proof for one share, thus, in a Merkle tree of height h will contain h hashes. The algorithm to check the validity of a proof for a valid path in an augmented Merkle is in Algorithm 1.

Batch submission with augmented Merkle trees. After collecting a list of shares, the miner locally constructs an augmented Merkle tree for all the shares in the list. It then submits the data of the root node of the tree along with a number indicating how many shares it finds to SMARTPOOL. For example, the miner in Figure 3 submits the node a as the cryptographic commitment, which has min and max as 1 and 4 respectively. We use this committed data to i) verify that the sampled shares are found before the miner submits the claim; ii) efficiently check whether a share is duplicated in a claim. Verifying i) is straightforward as mentioned before. To verify ii), we observe that any duplicated shares in a claim

Algorithm 1 Algorithm to verify the validity of one path in a augmented Merkle tree

```
1: procedure VALIDATENODEINPATH(x)
2: Check if x is a leaf:
3:     if isALeaf(x) then
4:         if !(x.min == x.max == x.ctr) or !isValidShare(x) then
5:             return false
6:         end if
7:     else
8:         left ← x.leftChild
9:         right ← x.rightChild
10:        if !isHashValid(x,x.hash) then
11:            return false
12:        end if
13:        if (!(x.min < x.max) or !(left.min == x.min)
14:            or !(right.max == x.max)
15:            or !(left.max < right.min)) then
16:            return false
17:        end if
18:    end if
19:
20: Check if x is the root:
21:    if isRoot(x) then
22:        return true
23:    else
24:        return ValidateNodeInPath(x.parent)
25:    end if
26: end procedure
```

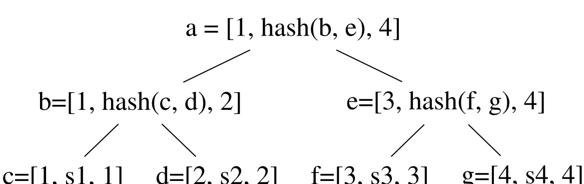

Figure 3: A sorted augmented Merkle tree for a list of shares (s1 to s4) with timestamp values from 1 to 4.

will yield a sorting error in at least one path of the augmented Merkle tree. Thus, by sampling the tree in a constant number of leaves and checking their corresponding paths, with high probability we will detect a sorting error in the augmented Merkle tree if there is one.

Prevent over-claiming shares across claims. Our augmented Merkle tree allows us to detect if miners over claim shares or submit invalid shares in a claim. However, it does not help guarantee that miners do not submit the same shares in two different claims, *i.e.* overclaiming shares across claims. We prevent this problem by tracking counters of the shares in every claim and randomizing the counter start scheme for each claim. For example, we can use the the pair (block-timestamp, nonce) as a counter in an Ethereum block. We observe that, for a single miner, the counters for each claim are distinct because of the nonce. At the same time, timestamps monotonically order shares across claims, since the block timestamp monotonically increases over time.

Thus for any two distinct claims, the maximum share counter among an earlier claim is always smaller than the minimum counter of the shares in a later one. This observation enables a simple duplication check on the shares submitted in two different claims. Specifically, we require miners to submit their claims in chronologically increasing order of timestamp values (which are prefixes in the counter values). We use an additional variable last_max in our smart contract to keep track of the maximum counter (*i.e.* max value of the root node in the augmented Merkle tree) from the last claim. We only accept a new claim if the min value of the root node is greater than last_max, and update last_max properly if the new claim is valid.

Penalty scheme. Miners are rewarded according to the amount of shares that they submitted to the pool. In centralized pools, the pool manager is able to check every share submitted by miners, thus miners cannot cheat. In SMARTPOOL, since we use probabilistic verification, we introduce a *penalty scheme* that penalizes detected cheating, independent of the reward distribution scheme used. The penalty scheme in Definition 2 is simple and suffices to disincentivize cheating, assuming rational miners.

Definition 2 (Penalty Scheme)**.** In SMARTPOOL, the penalty scheme for a claim of n shares is as follow:

$$\begin{cases} \text{Pay all } n \text{ shares if invalid share was not detected;} \\ \text{Pay 0 otherwise.} \end{cases}$$

In Section 4, we prove that our penalty scheme disincentivizes rational miners from submitting wrong or duplicated shares. Our detailed analysis shows that for $k \geq 1$ samples, honesty maximizes payout.

Randomly sampling shares. In order to randomly sample, we need a source of randomness. A practical way to obtain such a random seed to use the hash of a future block. To reduce the amount of bias that any adversary can introduce to the block hash, one can take several samples based on several consecutive block hashes. For example, let us consider a scenario where a miner submits a claim of 1 million shares at block 1, and we wish to sample 2 random shares for our probabilistic verification. The miner is required to submit the data of 2 shares which are corresponding to hashes of blocks 1 and 2 (*e.g.* the hash values modulo 10^6) to SMARTPOOL for verification. If the miner fails to submit any of these determined shares, they will not be able to claim the reward.

Putting everything together, we summarize the entire SMARTPOOL protocol in Figure 4 of the Appendix. Due to the space constraints, we address other technical questions in the full version of the paper [23].

4 Analysis

We analyze the security that SMARTPOOL provides through probabilistic verification and the penalty scheme in Definition 2.

We begin by informally reviewing the properties of our Merkle tree test and then formally establishing its correctness in Corollary 9 below. The intuition is if a claim has n valid shares and m invalid or duplicated ones, by randomly sampling a share from the claim, we can detect invalid shares with probability $m/(n+m)$. Suppose that a claim submitted by the adversary has n valid shares and m invalid or duplicated ones. If our test procedure is correct, the probability that our test on k independently chosen random samples fails to catch the cheating is at most $(1-\frac{m}{n+m})^k$. In this case, the cheating miner gets paid for $n+m$ shares, which is higher than reward for being honest (i.e. n shares). Corollary 9 shows that for all choices of m, for $k \geq 1$, the adversary's advantage (expected payoff) from cheating does not exceed the guaranteed payoff he would obtain from honestly submitting shares. Further, it is easy to see that over all choices of m the attacker's advantage is bounded by a negligible function in k (the number of samples checked).

Note that we establish that the adversary's advantage is minimal using a simple penalty function presented in Definition 2. Our probabilistic verification with penalties provide a basis to determine which shares to pay; however, any rewarding scheme can determine how to pay for the valid shares (e.g. using PPS, PPLNS, and so on).

Finally, we consider other possible attacker manipulations. One further security concern, in particular, merits analysis. The seed for our sampling is based on a block hash chosen by miners. We show that this source of randomness has a (low) bias, assuming that at least 50% of the mining network is honest. However, we establish in Theorem 10 that by sampling $k \geq 2$ times, the expected reward from honest submissions majorizes the expected payoff advantage from biased sampling.

4.1 Analysis of Expected Payoffs

We first analyze the scenario where the adversary cannot drop Ethereum blocks to introduce bias on sampling random seed, so the sample blocks in our probabilistic scheme are randomly selected. Furthermore, we assume that the adversary does not attempt to manipulate the expected format of the submitted data aside from possibly submitting duplicate or invalid shares. We will relax these conditions in Section 4.2.

It suffices for the SMARTPOOL contract to check a single, randomly chosen path through a submitted augmented Merkle tree in order to pay fairly for shares, on average (Corollary 9). If all submitted shares are valid and there are no duplicates, then SMARTPOOL pays for all shares with probability 1 (Theorem 7). The following facts will be useful.

Lemma 3. *For any node x in a augmented Merkle tree,*

(I) $\mathsf{min}(x)$ *is the minimum of all nodes below x, and*

(II) $\mathsf{max}(x)$ *is the maximum of all nodes below x.*

Proof. We will prove (I), and (II) follows by symmetry. Let y be any node below x, and trace a path from x to y in the given augmented Merkle tree. The min of x's immediate children along this path is, by definition of augmented Merkle tree, no greater than $\mathsf{min}(x)$. Similarly for the next children down, and so on, down to y. Therefore $\mathsf{min}(x) \leq y$. □

Proposition 4. *Let A be an augmented Merkle tree. The following are equivalent:*

(I) *A is sorted (see Definition 1).*

(II) *For every node x, the* max *of x's left child is less than the* min *of x's right child.*

Proof. We argue by induction. Assume (I), and further assume than (II) holds restricted to the first n levels above the leaves (the leaves are at the ground, *i.e.* zero level). Consider a node x at depth $n+1$. By the inductive hypothesis, the max of x's left child is less than the min of the next right child down, which is less than the min of the next right child down and so on, all the way down to some leaf y. By a symmetrical argument, the min of x's left child is greater than some leaf z which happens to be to the right of y. Since A is sorted, it follows that $\mathsf{min}(x) < y < z < \mathsf{max}(x)$.

Next assume (II), and let y and z be any two leaves. Let x be the lowest node (farthest from the root) which is an ancestor of both y and z. By Lemma 3, y is less than or equal to the max of x's left child, and z is is greater than or equal to the min of x's right child. Now $y < z$ follows from the assumption, hence A is sorted. □

Definition 5. A node in an augmented Merkle tree which satisfies condition (II) of Proposition 4 is called *valid*. Furthermore, we say that a path from a root to a leaf is *valid* if all its constituent nodes are valid. A path which is not valid is *invalid*.

The adversary can submit any arbitrary tree with the syntactic structure of an augmented Merkle tree, but not satisfying the constraint outlined in Definition 1. Let us call such a tree which syntactically has the structure of a augmented Merkle tree, but not necessarily satisfy the Definition 1 simply as a Merkle tree. A submitted Merkle tree can have any number of invalid or duplicate shares as well as ill-constructed internal nodes. Intuitively, an

Merkle tree with invalid nodes will have *sorting errors*, which are defined below, and include both duplicates as well as decreasing share counters.

Definition 6. An element x in an array is *out of order* if there exists a corresponding witness, namely an element to the left of x which is greater than or equal to x, or an element to the right of x which is less than or equal to x. A leaf in a Merkle tree contains a *sorting error* if its label value is out of order when viewing the leaves' labels as an array.

Now, we will show that any submitted Merkle tree has at least as many invalid paths as the sorting errors it has.

Theorem 7. *Let A be a Merkle tree. If A is sorted, then all paths in A are valid. If A is not sorted, then every leaf containing a sorting error lies on an invalid path.*

Proof. If A is sorted then all its nodes are valid by Proposition 4, hence all paths in A are valid. Now suppose A is not sorted, and consider the highest node x in the tree (farthest from the root) which is is an ancestor of two distinct leaves y and z where y is left of z but $z \leq y$. Now x is not valid, because by Lemma 3 the max of x's left child is at least y and the min of x's right child is no more than z. It follows that neither the path from root to y nor the path from root to z is valid because both pass through x. □

The theorem above shows that miners who submit sorted augmented Merkle trees will receive their proper reward. Algorithm 1 checks the validity of a given path in a tree, and we omit a proof of its correctness here leaving it to inspection. It remains to demonstrate that sampling and checking a single path in the augmented Merkle tree suffices to discourage miners from submitting duplicate shares.

Corollary 8. *Every Merkle tree has at least as many invalid paths as sorting errors among the leaves. In particular, there are at least as many invalid paths as there are duplicate values among the leaves.*

Proof. Theorem 7 gives an injection from sorting errors to invalid paths. Since each duplicate and out of order leaf yields a sorting error, the result follows. □

Finally, we calculate the adversary's expected reward.

Corollary 9. *Under the payment scheme in Definition 2, if* SMARTPOOL *checks one random path in the augmented Merkle tree of a claim, the expected reward when submit invalid or duplicated shares is the same as the expected reward when submit only valid shares.*

Proof. Suppose that in a claim of an adversary, there are k shares which are either invalid or duplicated. Since we randomly pick a path, by Corollary 8, we sample an invalid share with probability k/n and a valid share with probability $(n-k)/n$. Hence the expected profit from the payment scheme in Definition 2 is

$$\left(\frac{k}{n}\right) \cdot 0 + \left(\frac{n-k}{n}\right) \cdot n = n - k.$$

One expects to obtain this same profit by submitting only the $n-k$ valid shares. Thus, on average, it is not profitable to submit invalid shares to SMARTPOOL if we employ the payment scheme in Definition 2 and check one random path from the augmented Merkle tree. □

In summary, SMARTPOOL can efficiently probabilistically check that an augmented Merkle tree is sorted.

4.2 Discussion of Attacker Strategies

In this section, for clarity, we discuss ways in which an adversary might deviate from intended claim submission behavior and argue that these deviations do not obtain him greater rewards.

4.2.1 Rearrangements

The adversary cannot increase his expected profits by permuting the leaves of the Merkle tree. Observe that, given a list of integers L which may include repeats, a non-decreasing arrangement of L's members in the leaves of a Merkle tree minimizes sorting errors. By Theorem 7, every duplicate yields a sorting error regardless of permutation. Furthermore, the number of sorting errors that occur when the leaves are in non-decreasing order is exactly the number of duplicates. Hence a rational miner has no incentive to deviate from this non-decreasing configuration.

4.2.2 Bogus entries in augmented Merkle tree

Falsifying Merkle tree nodes does not decrease the number of invalid paths. Indeed, note that increasing the range for a given node can only increase the number of invalid paths, so we need only consider the case where the cheater makes the range smaller. If the range is made smaller so as to exclude the value of a leaf above that doesn't have a sorting error, then a new invalid path was introduced by cheating. If the range is made smaller so as to exclude a sorting error, then the path leading to that sorting error is still invalid, and therefore injection from Theorem 7 still applies.

4.3 Analysis of Bias In Seed Selection

We next consider the scenario in which the the adversary is able to drop Ethereum blocks to bias the random seed.

Thus, the sample blocks in our probabilistic verification are not randomly selected, *i.e.* the adversary can drop the blocks which sample invalid shares from his claim. We show that, even in the extreme case where the adversary controls up to 50% of Ethereum mining power (*i.e.* can drop 50% of the blocks), it suffices to check only two randomly chosen paths through a submitted augmented Merkle tree in order to discourage the adversary from cheating.

Theorem 10. *If an adversary controls less than* 50% *of Ethereum hash power, then it suffices to sample only two paths of the augmented Merkle tree based on two consecutive blocks to pay miners fairly, on average.*

Proof. We call an Ethereum block a *good* block for the adversary if its hash samples a valid share in the adversary's claim. Suppose that in the adversary's claim, γ fraction of the shares are invalid ($0 \leq \gamma \leq 1$). By Theorem 7, at least γ fraction of the paths in the corresponding augmented Merkle tree are invalid. Hence, on average $1-\gamma$ fraction of the blocks are good blocks, since each block hash is a random number. The probability that the adversary's claim is still valid after two samples is the probability that two consecutive blocks in Ethereum are good blocks. We aim to compute this latter probability.

Let us assume that the choices of the two sample shares are drawn based on the hash of a single block hash, and that attacker controls p fraction of the network's mining power. The attacker's strategy is to successively drop blocks until he finds one that favorably samples his claim submission. We estimate his probability of success. The probability that he succeeds in exactly one round, regardless of who mined the block, is $(1-\gamma)^2$, that is, if the samples drawn are favorable. The chances that the attacker wins in exactly two rounds is the probability that the first block gave unfavorable sampling, but the attacker managed to mine it, and the next sample was favorable. The probability that all three of these independent events occur is $[1-(1-\gamma)^2] \cdot p \cdot (1-\gamma)^2$. In general, the chance that the attacker succeeds in exactly k rounds is

$$f(k) = \left(1-(1-\gamma)^2\right)^{k-1} \cdot p^{k-1} \cdot (1-\gamma)^2.$$

Summing over all possible game lengths k, we find that the chance that the attacker wins is exactly

$$\sum_{k=1}^{\infty} f(k) = (1-\gamma)^2 \cdot \sum_{k=0}^{\infty} \left[\left(1-(1-\gamma)^2\right) \cdot p\right]^k.$$

Since the right-hand side is a geometric series in which the magnitude of the common ratio is less than 1, we obtain

$$\sum_{k=1}^{\infty} f(k) = \frac{1}{1-(1-(1-\gamma)^2) \cdot p} = \frac{1}{1+(\gamma^2-2\gamma)p}.$$

The block withholding strategy is profitable if and only if this probability exceeds the attacker's chances of success without block withholding, namely $1-\gamma$. That is, the value p for which block withholding is advantageous satisfies

$$\frac{1}{1+(\gamma^2-2\gamma)p} > 1-\gamma. \tag{2}$$

We complete the analysis by inspecting the cases where p is greater than or less than the threshold $1/(2\gamma-\gamma^2)$. In the first case it follows that $p \geq 1/2$, since this threshold is always at least $1/2$ when $0 < \gamma \leq 1$, and if $\gamma = 0$ then the attacker has no incentive for dropping blocks. In the second case, the left hand side of (2) is negative, and so the inequality in (2) fails in this case. □

5 Supporting Other Cryptocurrencies

One can use SMARTPOOL's design to build decentralized mining pools for other cryptocurrencies. For clarity of exposition, we fix Bitcoin as the target in this section. The overall protocol is still similar to what have been discussed in previous sections, but here we present the detail changes to make SMARTPOOL work with Bitcoin while the contract is running on the Ethereum blockchain.

Generating a block template. In Ethereum, it is straightforward to to generate a valid block template, i.e., just by using the pool's address in the "coinbase address." It is tricker in Bitcoin since the block header is much simpler, (see Table 3 in Appendix 10.2) and the pool operates in another cryptocurrency (i.e., Ethereum). To generate a share that belongs to the pool, we leverage a special transaction in Bitcoin called a "coinbase transaction" whose outputs consist of a list of Bitcoin addresses paid and along with their payment amounts.

Specifically, in order to generate valid shares, a miner queries the `verClaimList` in the contract which records the contributed shares by different miners to date. The miner then prepares the coinbase transaction such that the first output pays to the miner who mined the block; the latter outputs pay to other miners included in the `verClaimList`. The sum of all outputs in the coinbase transaction equals the block reward. Thus, if a miner finds a fraction f of the shares in SMARTPOOL, he gets paid proportional to f in the reward that SMARTPOOL's miners get every time they mine a valid block.

Verifying a claim. As before, we use the probabilistic approach which samples random shares from a claim. However, in SMARTPOOL, verifying a Bitcoin share is slightly different from verifying an Ethereum share. Typically, a Bitcoin share is valid if the miner can demonstrate that the share has a valid coinbase transaction (labeled as the field `Coinbase`) in their `ShareProof` paid out to the pool members. The miner cannot selectively

choose to omit this transaction; it is required to be the first transaction in the list of transactions (called `TxList`) on which the miner has searched for shares. The claimant must submit a Merkle root as commitment over the set `TxList` he has selected, and a Merkle proof (labeled `CoinProof`) that it contains the coinbase transaction. Second, the `ShareProof` contains an indication of the `verClaimList` based on which the payouts to miners were determined by the claimant. This last field is called a `Snapshot` to allow discretizing payouts over an ever-growing `verClaimList`. This is used to check the correctness of the `coinbase` transaction, i.e. if all the outputs pay to miners correctly. Figure 4 in the Appendix reports on all data fields of our Claim and ShareProof structures.

6 Implementation and Evaluation

We implemented SMARTPOOL and deployed it on Ethereum and Ethereum classic (main) networks. In this section, we describe the implementation (along with a Bitcoin pool implementation) and report actual fees from real mining that was done with SMARTPOOL.

6.1 Implementation

We implement SMARTPOOL protocol (as described in Figure 4) in an Ethereum smart contract and a miner software (client) that interacts with the contract according to our protocol [12]. Our smart contract implementation consists of two main modules, namely, *claim submission, claim verification*.

Claim submission. This module allows miners to submit their shares in batch. A miner submits a batch of shares by calling `submitClaim()` with the parameters: (i) the root of the corresponding augmented Merkle tree for the shares; (ii) number of shares in the tree; (iii) counter interval of the shares. A submission is accepted only if the smallest counter is greater than the current biggest counter.

Claim verification. A miner submits a proof for the validity of his last submitted claim by calling `verifyClaim()` with a branch in the augmented Merkle tree that corresponds to the next block hash. We allow different claims to include different amounts of shares, *i.e.* `NShare` can vary between claims. If the verification fails, then the claim is discarded, and the miner will not be able to submit all the shares (or a subset of them) again (forced by validating the counter in `submitClaim()`). If the verification is successful, then the claim is added to the to the `verClaimList` list.

6.1.1 Verifying Ethereum PoW

The PoW function that Ethereum is using is Ethash [16]. Ethash is not a native opcode nor a pre-compiled contract in the Ethereum virtual machine (EVM). Hence, to verify that a block header satisfies the required difficulty we have to explicitly implement Ethash function. Ethash was designed to be ASIC resistant, which is achieved by forcing miners to extract 64 values from pseudo-random positions of a 1 GB dataset. Thus, to explicitly compute Ethash, one would have to store 1 GB data in a contract, which costs roughly 33,554 Ether (storing 32 bytes of data costs 50,000 gas). Moreover, the Ethereum protocol dictates that the dataset is changed every four days (on average). Hence, one would require a budget of approximately $\$3,000,000$ per day as of June 2017 to maintain the dataset, which is impractical. Alternatively, one could store a smaller subset of the seed elements and calculate the values of the dataset on the fly. Unfortunately, to extract values from the seed one would have to compute several $SHA3_512$ calculations, which is not a native opcode in the EVM, and would require massive gas usage if queried many times.

Fortunately, for our purposes, we do not need to fully compute Ethash. Instead it is enough to just verify the result of an Ethash computation. Thus, we ask the miner to submit along with every block header the 64 dataset values that are used when computing its Ethash and a *witness* for the correctness of the dataset elements. The *witness* shows that the 64 values are from the corresponding positions in the 1 GB dataset. Intuitively, to verify the witness for dataset elements, the contract will keep the Merkle-root of the dataset and a witness for a single element is its Merkle-branch. Formally, the pool contract holds the Merkle-roots of all the 1 GB datasets that are applicable for the next 10 years. We note that the content of the dataset only depends on block number (i.e., the length of the chain). Hence, it is predictable and the values of all future datasets are already known. Storing the Merkle roots of one year dataset requires storing 122 Merkle hashes, and would cost only 0.122 Ether.

We note that technically, our approach does not provide a mathematical guarantee for the correct computation of Ethash. Instead it guarantees the correct computation provided that the public dataset roots stored on the contract were correct. Hence, it is the miner's responsibility (and best interest) to verify the stored values on the contract before joining the pool. As the verification is purely algorithmic, no trust on the intentions of the contract authors is required.

6.1.2 Coinbase Transactions in Bitcoin

Recall that the payment to the Bitcoin miners is done via the coinbase transaction of a block. As per Figure 4,

SMARTPOOL allows miners to fetch the `verClaimList` and build the coinbase transaction locally. This approach, however, has a technical challenge regarding the transaction size when we implement SMARTPOOL in the current Ethereum network. Specifically, a single coinbase transaction may have many outputs to pay to hundreds or thousands of miners. As a result, the size of the coinbase transaction could be in the order of 10KB (e.g., P2POOL's coinbase transactions is of size 10KB [24]). Hence, it is expensive to submit a coinbase transaction of that size to an Ethereum contract. In SMARTPOOL implementation we could not ask miners to construct the coinbase transaction naively and submit as the input for `verifyClaim()` function.

To address the challenge, we modify SMARTPOOL protocol slightly. Instead of asking miners to construct the coinbase transaction naively as in P2POOL, we ask them to work on only a small part of it. Specifically, we observe that we can fix the postfix of the coinbase transaction by using the pay per share scheme. Recall that the block reward consists of the block subsidy (12.5 Bitcoin) and the transaction fees. Thus, in our implementation, we pay the transaction fees to the miner who finds the block. The remaining 12.5 Bitcoin (the block subsidy) is paid to, say, the next 1 million shares in `verClaimList`. This distribution is encoded in all the latter outputs. Thus, we can fix all the outputs but the first one in the coinbase transaction, since the next 1 million shares in `verClaimList` are the same for all miners. This allows us to maintain the postfix of the coinbase transaction in SMARTPOOL and only ask miners to submit the prefix (the first output) when they verify a share. Our approach significantly reduces both the gas fees paid for `verifyClaim()` and also the amount of bandwidth that miners have to send for verification.

Block submission. In SMARTPOOL-based pool for Bitcoin, there exists the block submission module which allows any user to submit a witness for a new valid block in the Bitcoin blockchain so that SMARTPOOL can have the latest state of the blockchain. If the block is mined by miners in SMARTPOOL, SMARTPOOL updates the `verClaimList` to remove the paid shares from the list. This also reduces the amount of persistent storage required in the contract since we do not need to store all verified claims in SMARTPOOL.

There are other technical subtleties in block submission and constructing coinbase transactions. We discuss these in Appendix 10.2.

6.2 Experimental Results

We deployed SMARTPOOL on Ethereum [25] (and Ethereum classic [26]) live networks and mined with them with 30GH/s (4GH/s) hash power for 7 days (1 week). The pool successfully mined over 20 blocks [27] (85 blocks [28]) in corresponding periods. In this section we report the deployment cost of the contract and the fees that our protocol entails.

Function	Gas	Price	% of reward
`submitClaim()`	79,903	0.000319612	0.01%
`verifyClaim()`	2,872,693	0.011490772	0.6%

Table 2: Ethereum fees of contract operations for Ethereum pool. Prices are in Ether. We note that in `verifyClaim()` for the Ethereum pool, 2.1M gas is spent on Ethash verification.

For `verifyClaim()`, we measure the cost to check 1 sample. The cost to check multiple samples can be easily computed from the cost to check 1. The results are presented in Tables 2.

The contract consists of over $1,300$ lines of Solidity code. The deployment of the contract consumed $4,351,573$ gas (6.24 USD). The contract source code is publicly available [29]. To reduce verification costs, we have submitted 1024 Merkle nodes for each 1GB dataset, namely, all the nodes in depth 10 of the Merkle tree. This operation was done is 11 transactions, which consumed in total around $6,000,000$ gas (around 15 USD) [30]. We emphasize that this operation is done only once every $30,000$ Ethereum blocks, or roughly 5 days. We report the evaluation of the claim submission and verification in transactions [31,32]. In our report, a miner with 20 GH/s submits a batch of shares every 3 hours. Every batch is rewarded with around 1.8 Ether (630 USD), and entails total gas fees of 0.011 Ether. Hence, the miner pays 0.6% for the effective pool fees.

7 Related Work

A number of previous works have studied the problem of addressing centralization in cryptocurrencies, and addressing flaws in pool mining protocols. We discuss these here, and further discuss security of smart contract applications of which SMARTPOOL is an instance.

P2POOL. The work which most directly relates to SMARTPOOL is P2POOL [8]. As discussed in Section 2.1, P2POOL consumes much more resources (both computation and network bandwidth), and the variance of reward is much higher than in centralized pools. SMARTPOOL solves these problems in P2POOL by i) relying on the smart contracts which are executed in a decentralized manner; ii) using probabilistic verification and a novel data structure to reduce verification costs significantly; iii) applying simple penalty scheme to discourage cheating miners. As a result, SMARTPOOL is the first decentralized pooled mining protocol which has low costs, guarantees low variance of reward to miners. Further, SMARTPOOL is more secure than P2POOL since

any miner who has more than 50% of the mining power in P2POOL can fork and create a longer share-chain. On the other hand, the adversary has to compromise the Ethereum network to attack SMARTPOOL.

Pooled mining research. Several previous works have analysed the security of pooled mining in Bitcoin [2, 4, 9–11]. In previous works [9–11], researchers study the block withholding attack to mining pools and show that the attack is profitable when conducted properly. In [2] Rosenfeld *et al*. discussed (i) "pool hopping" in which miners hop across different pools to exploit a weakness of an old payoff scheme, and (ii) "lie in wait" attacks that allows miner to strategically calculate the time to submit his blocks. These challenges also apply to SMARTPOOL when SMARTPOOL is used as a decentralized mining pool in existing networks, and have specific payoff schemes to reward miners as solutions. The design of SMARTPOOL is agnostic to the payoff scheme used to reward miners. Furthermore, if SMARTPOOL were to be deployed natively in a cryptocurrency as the only mining pool (see Appendix 10.1), these attacks no longer work.

In [13], Miller *et al*. study different puzzles and protocols which either make pooled mining impossible and/or disincentivize it. Out work is different from [13] in several aspects. First, we aim to provide an efficient and practical decentralized pooled mining protocol so miners have an option to move away from centralized mining pools. Second, SMARTPOOL is compatible with current Bitcoin and Ethereum networks as we do not require any changes in the design of these cryptocurrencies. In [13], the solutions are designed for new and future cryptocurrencies.

In [3, 4], the authors study the decentralization of the Bitcoin network. Previous works have highlighted that Bitcoin is not as decentralized as it was intended initially in terms of services, mining and protocol development [3, 33]. On the other hand, Bonneau *et al*. provided an excellent survey on Bitcoin which also covered the security concerns of pooled mining [4].

Smart contract applications. Previous works proposed several applications which leveraged smart contracts [34–36]. For example, in [35], Juels *et al*. study how smart contracts support criminal activities, *e.g.* money laundering, illicit marketplaces, and ransomware due to the anonymity and the elimination of trust in the platform. Such applications are built separately from the underlying consensus protocol of the network. In this work, we propose a new application of smart contract that enhances the security of the underlying network by supporting decentralized mining pools. Bugs in smart contract implementations are a practical concern; we believe the use of bug-detection tools such as Oyente [17] are useful to SMARTPOOL as well as other.

8 Conclusion

In this paper, we present a new protocol design for an efficient decentralized mining pool in existing cryptocurrencies. Our protocol, namel SMARTPOOL, resolves the centralized mining problem in Bitcoin and Ethereum by enabling a platform where mining is fully decentralized, yet miners still enjoy low variance in reward and better security. Our experiments on Ethereum and Ethereum Classic show that SMARTPOOL is efficient.

9 Acknowledgment

We thank Vitalik Buterin, Andrew Miller, Ratul Saha, Pralhad Deshpande, and anonymous reviewers for useful discussions and feedback on the early version of the paper. We thank 26 pseudonymous donors who donated to support the development of SMARTPOOL. We also thank Victor Tran and Andrew Nguyen for their work on the robust implementation of SMARTPOOL's client.

This work is supported by the Ministry of Education, Singapore under Grant No. R-252-000-560-112 and the European Research Council under the European Union's 7th Framework Programme (FP7/2007-2013, ERC grant no 278410). The deployment of SMARTPOOL on the main Ethereum network is supported by the Ethereum Foundation under a special development grant. All opinions expressed in this work are those of the authors.

10 Appendix

10.1 Applications

We discuss several applications that can be built based on SMARTPOOL. One straightforward application is to build decentralized mining pools for cryptocurrencies as we have established. Apart from requiring low costs, guaranteeing low variance in rewards to miners than the only related solution P2POOL, SMARTPOOL is also more secure. Specifically, one must compromise the entire Ethereum network (*e.g.* having more than 50% of Ethereum network) in order to compromise SMARTPOOL. On the other hand, the adversary only needs to acquire 51% of P2POOL's mining power in order to build the longest share-chain in P2POOL and rule out other miners' contributions.

The second application is a new cryptocurrency based on SMARTPOOL in which mining is fully decentralized. Typically, we enforce the consensus rules such that only blocks generated by SMARTPOOL are accepted valid blocks. One can easily build a SMARTPOOL-based cryptocurrency by using our introduced solution and adding the aforementioned consensus rule which dictates that only SMARTPOOL can produce new valid blocks. Such cryptocurrencies can offer several good properties to the network that existing cryptocurrencies cannot. First, mining is fully decentralized, yet miners still enjoy low variance in reward. This improves the security of the underlying network as a whole significantly. Second, miners are not susceptible to several attacks targeting to pooled mining. For example, in [9–11] the authors demonstrate that if a malicious miner withholds blocks from a victim pool and mines privately in other pool, the miner can earn more profits from the loss of miners in the victim pool. Such block withholding attack does not work in SMARTPOOL-based cryptocurrencies since there is only one pool in the network.

Field Size (bytes)	Name	Data type
4	version	int32_t
32	prevBlock	char[32]
32	TxMerkleRoot	char[32]
4	timestamp	uint32_t
4	bits	uint32_t
4	nonce	uint32_t

Table 3: Header of a Bitcoin block. This is also used as the header for shares in pooled mining.

10.2 Implementation Subtleties for SMARTPOOL-based Bitcoin pool

In this section we address two technical issues that arise from the design of the protocol. The first issue is the format of a witness for a new valid block, and the second issue is how a miner should decide on his coinbase transaction in the next share he mines.

Witness for a new valid block. Intuitively, a witness for a new block is a block header (see Table 3) with sufficient difficulty. However, in Bitcoin network (like in any blockchain based network), some of the mined blocks could be *orphan*, namely, they could be transmitted to the network a short period before or after an *uncle block* (a block that extends the a previous block but does not reach the blockchain) was found. In this case the network will eventually form a consensus over only one of the blocks, and the other block(s) will become orphan (and will not get any block reward from the network). In our protocol we must update the miners `verClaimList` list only according to non-orphan blocks. For this purpose, as a witness we ask for a chain of six blocks. While in theory, even a chain of six blocks could become orphan, in practice this never happens.

Deciding on the coinbase transaction of the next share. In order for a share to be valid it must have a coinbase transaction that corresponds to a `verClaimList` list. However, the `verClaimList` list is updated by the Ethereum contract. Hence, the contract is only aware of the Ethereum timestamp at the time the list is updated. On the other hand, the function `verifyClaim`() is supposed to verify the coinbase transaction according to the Bitcoin timestamp of the share. Hence SMARTPOOL must synchronize Bitcoin and Ethereum time-stamps. The synchronization is done by introducing a new time metric, namely, the number of blocks SMARTPOOL has found. With this new notion of timestamp, we implement the `verClaimList` list in such way that a list of payment claims is maintained for every block number n. The list of n corresponds to the payments that have to be done when SMARTPOOL finds block number n. As new blocks might be reported with some delay, a payment request for a bulk that is verified in time n is added to the payment list of time $n+20$.

Given this implementation, the miner should construct the coinbase transaction in time n in the following way: As long as a new block is not found, the coinbase should correspond to list n. Once a new block is added to Bitcoin's blockchain, the miner should immediately start working on list $n+1$ (which already exists, as it was constructed at time $n-19$), even before the new block is submitted to the contract. If the new block becomes orphan, the miner should switch back to list n. Otherwise, after six blocks he should submit a witness for block n.

We note that in this approach the miner might do some stale unrewarded work in case the new block ends as an orphan block. However, such cases are also not rewarded in standard pools.

Other candidates for counter. Careful readers may realize that the timestamp field has only 4 bytes, thus we will run out of values for the counter after 2^{32} shares. In SMARTPOOL, one can have several ways to implement the share's counter. For example, one can embed the counter inside the coinbase transaction of a share. Specifically, Bitcoin allows users to insert 40 random bytes in a transaction output after the `OP_RETURN` opcode [7]. SMARTPOOL can force miners to store the share's counter in these 40 bytes, which can accommodate much more number of shares (*i.e.* 2^{320}).

[7] https://en.bitcoin.it/wiki/OP_RETURN

Notations

- Let NSize, NSample denote the number of shares included in a claim and the number of random samples SmartPool will verify in each claim respectively.
- Let claimList$[x]$ store all unverified claims submitted by the miner at address x.
- Let verClaimList$[x][y]$ store all verified and unpaid claims submitted by the miner at address x at block y.
- Let maxCounter$[x]$ store the maximum counter of the miner at address x.
- We denote d as the minimum difficulty of a share.

Data structures.

The Claim structure has the following fields.

1. the number NSize of claimed shares;
2. the ShareAugMT commitment of the set of claimed shares.

The ShareProof structure for a share s_i has the following fields.

- the header of the share s_i located at the i-th leaf in the augmented Merkle tree;
- the AugMkProof, attesting that s_i is committed to the ShareAugMT;

For SmartPool-based Bitcoin pool, the following additional data fields are included in the ShareProof

- the Coinbase transaction;
- the CoinProof, attesting that the coinbase transaction is included in the TxList of s_i; and
- the Snapshot of verClaimList that the Coinbase is computed on.

Main executions in SmartPool

- **Accept a claim.** Accept a claim $\mathscr{C}$ which has the Claim structure and includes NSize shares from a miner x. Add $\mathscr{C}$ to claimList$[x]$ and update maxCounter$[x]$.
- **Verify a claim.** Receive a proof p which has ShareProof structure for a share s_i included in a claim $\mathscr{C}$ from miner x. SmartPool verifies the following.
    1. if i is the supposed position that we want to sample based on the intended block hash;
    2. if s_i's hash is included in the claim $\mathscr{C}$ by verifying amkp_{s_i};
    3. if s_i meets the minimum difficulty d;
    4. if s_i's counter is greater than the last maxCounter$[x]$;
    5. if the coinbase address is the pool contract's address for Ethereum; or if Coinbase is included in s_i based on CoinProof and if Coinbase is correctly constructed with respect to Snapshot of verClaimList for Bitcoin.

  We reject the claim $\mathscr{C}$ if any of the above checks fail. If everything is correct and we have verified NSample from $\mathscr{C}$, update verClaimList$[x]$. Otherwise, wait for more proofs from miner x.
- **Get a new valid block** (for Bitcoin's pool only). If a new block is mined by SmartPool, update verClaimList.
- **Request payment** (for Ethereum's pool only). When a miner requests his/ her payment, send the payment in proportional to his/her shares in verClaimList. Update verClaimList when the payment is done.

For miners

- **Construct block template.** For Ethereum, simply use the pool contract's address as the coinbase address. For Bitcoin, fetch verClaimList from SmartPool and build the correct coinbase transaction locally.
- **Find valid shares.** Simply search for valid nonce which yields valid shares.
- **Submit a claim.** If have found enough NSize shares, build an augmented Merkle tree and submit a claim $\mathscr{C}$ to SmartPool to claim these NSize shares.
- **Submit proofs.** Wait until $\mathscr{C}$ is accepted then construct and submit NSample proofs p_i $(i = 1, 2, \ldots, \mathtt{NSample})$, each follows the ShareProof structure, to SmartPool.

Figure 4: Summary of how SmartPool protocol works for both the pool and miners.

Abstract

Blockchains show promise as potential infrastructure for financial transaction systems. The security of blockchains today, however, relies critically on Proof-of-Work (PoW), which forces participants to waste computational resources.

We present REM (Resource-Efficient Mining), a new blockchain mining framework that uses *trusted hardware* (Intel SGX). REM achieves security guarantees similar to PoW, but leverages the partially decentralized trust model inherent in SGX to achieve a fraction of the waste of PoW. Its key idea, *Proof-of-Useful-Work* (*PoUW*), involves miners providing trustworthy reporting on CPU cycles they devote to *inherently useful workloads*. REM flexibly allows any entity to create a useful workload. REM ensures the trustworthiness of these workloads by means of a novel scheme of *hierarchical attestations* that may be of independent interest.

To address the risk of compromised SGX CPUs, we develop a statistics-based formal security framework, also relevant to other trusted-hardware-based approaches such as Intel's Proof of Elapsed Time (PoET). We show through economic analysis that REM achieves less waste than PoET and variant schemes.

We implement REM and, as an example application, swap it into the consensus layer of Bitcoin core. The result is the first full implementation of an SGX-based blockchain. We experiment with four example applications as useful workloads for our implementation of REM, and report a computational overhead of $5-15\%$.

1 Introduction

Despite their imperfections [21, 31, 33, 61, 66], blockchains [34, 60, 62] have attracted the interest of the financial and technology industries [11, 20, 30, 41, 64, 69] as a way to build a transaction systems with distributed trust. One fundamental impediments to the widespread adoption of decentralized or "permissionless" blockchains is that Proofs-of-Work (PoWs) in blockchains are wasteful.

PoWs are nonetheless the most robust solution today to two fundamental problems in decentralized cryptocurrency design: How to select consensus leaders and how to apportion rewards fairly among participants. A participant in a PoW system, known as a *miner*, can only lead consensus rounds in proportion to the amount of computation she invests in the system. This prevents an attacker from gaining majority power by cheaply masquerading as multiple machines. The cost, however, is the above-mentioned waste. PoWs serve no useful purpose beyond consensus and incur huge monetary and environmental costs. Today the Bitcoin network uses more electricity than produced by a nuclear reactor, and is projected to consume as much as Denmark by 2020 [25].

We propose a solution to the problem of such waste in a novel block-mining system called REM. Nodes using REM replace PoW's wasted effort with useful effort of a form that we call *Proof of Useful Work* (PoUW). In a PoUW system, users can utilize their CPUs for any desired workload, and can simultaneously contribute their work towards securing a blockchain.

There have been several attempts to construct cryptocurrencies that recycle PoW by creating a resource useful for an external goal, but they have serious limitations. Existing schemes rely on esoteric resources [49], have low recycling rates [58], or are centralized [36]. Other consensus approaches, e.g., BFT or Proof of Stake, are in principle waste-free, but restrict consensus participation or have notable security limitations.

Intel recently introduced a new approach [41] to eliminating waste in distributed consensus protocols that relies instead on trusted hardware, specifically a new instruction set architecture extension in Intel CPUs called *Software Guard Extensions (SGX)*. SGX permits the execution of trustworthy code in an isolated, tamper-free environment, and can prove remotely that outputs represent the result of such execution. Leveraging this capability, Intel's proposed Proof of Elapsed Time (PoET) is an in-

novative system with an elegant and simple underlying idea. A miner runs a trustworthy piece of code that idles for a randomly determined interval of time. The miner with the first code to awake leads the consensus round and receives a reward. PoET thus promises energy-waste-free decentralized consensus with security predicated on the tamper-proof features of SGX. PoET operates in a *partially-decentralized model*, involving limited involvement of an authority (Intel), as we explain below.

Unfortunately, despite its promise, as we show in this paper, PoET presents two notable technical challenges. First, in the basic version of PoET, an attacker that can corrupt a single SGX-enabled node can win every consensus round and break the system completely. We call this the *broken chip* problem. Second, miners in PoET have a financial incentive to power mining rigs with cheap, outmoded SGX-enabled CPUs used solely for mining. The result is exactly the waste that PoET seeks to avoid. We call this the *stale chip* problem.

REM addresses both the stale and broken chip problems. Like PoET, REM operates in a partially decentralized model: It relies on SGX to prove that miners are generating valid PoUWs. REM, however, avoids PoET's stale chip problem by substituting PoUWs for idle CPU time, disincentivizing the use of outmoded chips for mining. Miners in a PoUW system are thus entities that use or outsource SGX CPUs for computationally intensive workloads, such as scientific experiments, pharmaceutical discovery, etc. All miners can concurrently mine for a blockchain while REM gives them the flexibility to use their CPUs for *any desired workload*.

We present a detailed financial analysis to show that PoUW successfully addresses the stale chip problem. We provide a taxonomy of different schemes, including PoW, PoET, novel PoET variants, and PoUW. We analyze these schemes in a model where agents choose how to invest capital and operational funds in mining and how much of such investment to make. We show that the PoUW in REM not only avoids the stale chip problem, but yields the smallest overall amount of mining waste. Moreover, we describe how small changes to the SGX feature set could enable even more efficient solutions.

Unlike PoET, REM addresses the broken chip problem. Otherwise, compromised SGX-enabled CPUs would allow an attacker to generate PoUWs at will, and both unfairly accrete revenue and disrupt the security of the blockchain [24, 70, 73]. Intel has sought to address the broken chip problem in PoET using a statistical-testing approach, but published details are lacking, as appears to be a rigorous analytic framework. For REM, we set forth a rigorous statistical testing framework for mitigating the damage of broken chips, provide analytic security bounds, and empirically assess its performance given the volatility of mining populations in real-world cryptocurrencies. Our results also apply to PoET.

A further challenge arises in REM due to the feature that miners may choose their own PoUWs workloads. It is necessary to ensure that miner-specified mining applications running in SGX accurately report their computational effort. Unfortunately SGX lacks secure access to performance counters. REM thus includes a *hierarchical attestation* mechanism that uses SGX to attest to compilation of workloads with valid instrumentation. Our techniques, which combine static and dynamic program analysis techniques, are of independent interest.

We have implemented a complete version of REM, encompassing the toolchain that instruments tasks to produce PoUWs, compliance checking code, and a REM blockchain client. As an example use, we swap REM in for the PoW in Bitcoin core. As far as we are aware, ours is the first full implementation of an SGX-backed blockchain. (Intel's Sawtooth Lake, which includes PoET, is implemented only as a simulation.) Our implementation supports trustworthy compilation of any desired workload. As examples, we experiment with four REM workloads, including a commonly-used protein-folding application and a machine learning application. The resulting overhead is about $5-15\%$, confirming the practicality of REM's methodology and implementation.

Paper organization

The paper is organized as follows: Section 2 provides background on proof-of-work and Intel SGX. We then proceed to describe the contributions of this work:

- *PoUW and REM*, a low-waste alternative to PoW that maintains PoW's security properties (§3).
- A *broken-chip countermeasure* consisting of a rigorous statistical testing framework that mitigates the impact of broken chips (§4).
- A *methodology for trustworthy performance instrumentation* of SGX applications using a combination of static and dynamic program analysis and SGX-backed trusted compilation (§5).
- *Design and full implementation of* REM as a resource-efficient PoUW mining system with automatic tools for compiling arbitrary code to a PoUW-compliant module. Ours is the first full implementation of an SGX-backed blockchain protocol (§5).
- A *model of consensus-algorithm resource consumption* that we use to compare the waste associated with various mining schemes. We overview the model and issues with previous schemes (§6) and defer the details to the full version [76].

We discuss related work in §7 and conclude in §8.

2 Background

2.1 Blockchains

Blockchain protocols allow a distributed set of participants, called miners, to reach a form of consensus called Nakamoto consensus. Such consensus yields an ordered list of transactions. Roughly speaking, the process is as follows. Miners collect cryptographically signed transactions from system users. They validate the transactions' signatures and generate blocks that contain these transactions plus a pointer to a parent block. The result is a chain of blocks called (imaginatively) a blockchain.

Each miner, as it generates a block, gets to choose the block's contents, specifically which transactions will be included and in what order. System participants are connected by a peer-to-peer network that propagates transactions and blocks. Occasionally, two or more miners might nearly simultaneously generate blocks that have the same parent, forming two branches in the blockchain and breaking its single-chain structure. Thus a mechanism is used to choose which branch to extend, most simply, the longest chain available [60].[1]

An attacker could naturally seek to generate blocks faster than everyone else, forming the longest chain and unilaterally choosing block contents. To prevent such an attack, a block is regarded as valid only if it contains proof that its creator has performed a certain amount of work, a proof known as a *Proof of Work* (PoW).

A PoW takes the form of a *cryptopuzzle*: In most cryptocurrencies, a miner must change an input (nonce) in the block until a cryptographic hash of the block is smaller than a predetermined threshold. The security properties of hash functions force a miner to test nonces by brute force until a satisfying block is found. Such a block constitutes a solution to the cryptopuzzle and is itself a PoW. Various hash functions are used in practice. Each type puts different load on the processor and memory of a miner's computing device [60, 58, 72].

The process of mining determines an exponentially distributed interval of time between the blocks of an individual miner, and, by extension, between blocks in the blockchain. The expected amount of work to solve a cryptopuzzle, known as its *difficulty*, is set per a deterministic algorithm that seeks to enforce a static expected rate of block production by miners (e.g., 10 minute block intervals in Bitcoin). An individual miner thus generates blocks at a rate that is proportional to its *mining power*, its hashrate as a fraction of that in the entire population of miners. Compensation to miners is granted per block generated, leading to an expected miner revenue that is proportional to the miner's hashrate.

[1] There are alternatives to this protocol [33, 52, 68, 72], however the differences are immaterial to our exploration here.

As the mining power that is invested in a cryptocurrency grows, the cryptocurrency's cryptopuzzle difficulty rises to keep the block generation rate stable. When compensation is sufficiently high, it is worthwhile for a large number of participants to mine, leading to a high difficulty requirement. This, in turn, makes it difficult for an attacker to mine a large enough fraction of blocks to perform a significant attack.

PoW properties. The necessary properties for PoW to support consensus in a blockchain, i.e., resist adversarial control, are as follows. First, a PoW must be tied to a unique block, and be valid only for that block. Otherwise, a miner can generate conflicting blocks, allowing for a variety of attacks. A PoW should be moderately hard [10], and its difficulty should be accurately tunable so that the blockchain protocol can automatically tune the expected block intervals. Validation of PoWs, on the other hand, should be as efficient as possible, given that it is performed by the whole network. (In most cryptocurrencies today, it requires just a single hash.) It should also be possible to perform by any entity with access to the blockchain — If the proofs or data needed for validation are made selectively available by a single entity, for instance, that entity becomes a central point of control and failure.[2]

2.2 SGX

Intel Software Guard Extensions (SGX) [39, 40, 42, 43, 8, 37, 57] is a set of new instructions available on recent-model Intel CPUs that confers hardware protections on user-level code. SGX enables process execution in a Trusted Execution Environment (TEE), and specifically in SGX in a protected address space known as an *enclave*. An enclave protects the confidentiality and the integrity of the process from certain forms of hardware attack and other processes on the same host, including privileged processes like operating systems.

An enclave can read and write memory outside the enclave region as a form of inter-process communication, but no other process can access enclave memory. Thus the isolated execution in SGX may be viewed in terms of an ideal model in which a process is guaranteed to execute correctly and with perfect confidentiality, but relies on a (potentially malicious) operating system for supporting services such as I/O, etc. This model is a simplification: SGX is known to expose some internal enclave state to the OS [73]. Our basic security model assumes

[2] The Bitcoin protocol is expected to soon allow for the so-called segregated witness architecture [17, 55]. Then, transaction signatures (witnesses) are kept in a data structure that is technically separate (segregated) from the blockchain data structure. Despite this separation of data structures, the data in both must be propagated to allow for distributed validation.

ideal isolated execution, but as we detail in Section 4, we have baked a defense against compromised SGX CPUs into REM.

Attestation SGX allows a remote system to verify the software running in an enclave and communicate securely with it. When an enclave is created, the CPU produces a hash of its initial state known as a *measurement*. The software in the enclave may, at a later time, request a report which includes a measurement and supplementary data provided by the process. The report is digitally signed using a hardware-protected key to produce a proof that the measured software is running in an SGX-protected enclave. This proof, known as a *quote*, is part of an *attestation* can be verified by a remote system.

SGX signs quotes in attestations using a group signature scheme called *Enhanced Privacy ID* or *EPID* [67]. This choice of primitive is significant in our design of REM, as Intel made the design choice that attestations can only be verified by accessing Intel's Attestation Service (IAS) [44], a public Web service maintained by Intel whose primary responsibility is to verify attestations upon request.

REM uses attestations as proofs for new blocks, so miners need to access IAS to verify blocks. The current way in which IAS works forces miners to access IAS on every single verification, adding an undesirable round-trip time to and from Intel's server to the block verification time. This overhead, however, is not inherent, and is due only to a particular design choice by Intel. As we suggest in Section 5.4, a simple modification, to the IAS protocol, which Intel is currently testing, can eliminate this overhead entirely.

Randomness As operating systems sit outside of the trusted computing base (TCB) of SGX, OS-served random functions such as `srand` and `rand` are not accessible to enclaves. SGX instead provides a hardware-protected random number generator (RNG) using the `rdrand` instruction. REM relies on the SGX RNG.

3 Overview of PoUW and REM

The basic idea of PoUW, and thus REM, is to replace the wasteful computation of PoW with arbitrary useful computation. A miner proves that a certain amount of useful work has been dedicated to a specific branch of the blockchain. Intuitively, due to the value of the useful work outside of the context of the blockchain supported by REM, the hardware and power are well spent, and there is no waste. A comprehensive analysis of the waste is deferred to the full version [76]. Here we describe the security model of REM and then give an overview of its system mechanics.

3.1 Security Model

A PoW solution embodies a statistical proof of an effort spent by the miner. With PoUW, however, a miner reports its own effort. The rational miner's incentive is to lie, report more work than actually performed, and monopolize the blockchain. In PoUW / REM, use of a TEE — Intel SGX in particular — prevents such attacks and enforces correct reporting of work. The resulting trust model is starkly different from that in traditional PoW.

PoET introduced, and we similarly use in REM, a *partially decentralized* blockchain model. The blockchain is *permissionless*, i.e., any entity can participate as a miner, as in a fully decentralized blockchain such as Bitcoin. It is only partially decentralized, though, in that it relies for security on two key assumptions about the hardware manufacturer's behavior.

First, we must assume that Intel correctly manages identities, specifically that it assigns a signing key (used for attestations) only to a valid CPU. It follows that Intel does not forge attestations and thus mining work. Such forgery, if detected in any context, would undermine the company's reputation and the perceived utility of SGX, costing far more than potential blockchain revenue. Second, we assume that Intel does not blacklist valid nodes in the network, rendering their attestations invalid when the IAS is queried. Such misbehavior would be publicly visible and similarly damaging to Intel if unjustified.

Even assuming trustworthy manufacturer behavior, though, a limited number of individual CPUs might be physically or otherwise compromised by a highly resourced adversary (or adversaries). Our trust model assumes the possibility of such an adversary and makes the strong assumption that she can learn the attestation (EPID signing) key for compromised machines and thus can issue arbitrary attestations for those machines. In particular, as we shall see, she can falsify random number generation and lie about work performed in REM.

Even this strong adversary, though, does have a key limitation: As signing keys are issued by the manufacturer, and given our first assumption above, it is not possible for an adversary to forge identities. We further assume that the signatures are linkable. In SGX, the EPID signature scheme for attestations has a linkable (pseudonymous) mode [44, 8, 67], which permits anyone to determine whether two signatures were generated by the same CPU. As a result, event a compromised node cannot masquerade as multiple nodes.

Outside the REM security model It is important to note that REM is a *consensus framework*, i.e., a means to generate blocks, not a *cryptocurrency*. REM can be integrated into a cryptocurrency, as we show by swapping it into the Bitcoin consensus layer. As REM has roughly

the same exponentially distributed block-production interval, such integration need not change security properties above the consensus layer. For example, fork resolution, transaction validation, block propagation, etc., *remain the same in a REM-backed blockchain as in a PoW-based one*. Thus we do not expand the discussion of the security issues relevant to those elements in the REM security model.

3.2 REM overview

Figure 1 presents an architectural overview of REM.

There are three types of entities in the ecosystem of REM: A *blockchain agent*, one or more *REM miners*, and one or more *useful work clients*.

The useful work clients supply useful workloads to REM miners in the form of *PoUW tasks*, each of which encompass a *PoUW enclave* and some *input*. Any SGX-compliant program can be transformed into a PoUW enclave using the toolchain we developed. Note that a PoUW enclave has to conform to certain security requirements. The most important is that it meters effort correctly, something that can be efficiently verified by a compliance checker and a novel technique we introduce called *hierarchical attestation*. We refer readers to §5.2 and §5.3 for details.

The blockchain agent collects transactions and generates a block template, a block lacking the proof of useful work (PoUW). As detailed later, a REM miner will attach the required PoUW and return it to the agent. The agent then publishes the full block to the P2P network, making it part of the blockchain and receiving the corresponding reward.

A miner takes as input a block template and a PoUW task to produce PoUWs. It launches the PoUW enclave in SGX with the prescribed input and block template. Once the PoUW task halts, its results are returned to the useful work client. The PoUW enclave meters work performed by the miner and declares whether the mining effort is successful and results in a block. Effort is metered on a per-instruction basis. The PoUW enclave randomly determines whether the work results in a block by treating each instruction as a Bernoulli trial. Thus mining times are distributed in much the same manner as in proof-of-work systems. While in, e.g., Bitcoin, effort is measured in terms of executed hashes, in REM, it is the number of executed useful-work instructions. Intuitively, REM may be viewed as *simulating* the distribution of block-mining intervals associated with PoW, but REM does so with PoUW, and thus eliminates wasted CPU effort.

When a PoUW enclave determines that a block has been successfully mined, it produces a PoUW, which consists of two parts: an SGX-generated attestation demonstrating the PoUW enclave's *compliance* with REM and another attestation that a block was successfully mined by the PoUW enclave at a given *difficulty parameter*. The blockchain agent concatenates the PoUW to the block template, forming a full block, and publishes it to the network.

When a blockchain participant verifies a fresh block received on the blockchain network, in addition to verifying higher-layer properties (e.g., in a cryptocurrency such as Bitcoin, that transactions, previous block references, etc., are valid), the participant verifies the attestations in the associated PoUW.

Intel's PoET scheme looks similar to REM in that its enclave randomly determines block intervals and attests to block production. PoET, however, lacks the production of useful work, an essential ingredient, as we explain later in the paper. We now discuss our strategy in REM for handling compromised nodes.

4 Tolerating Compromised SGX Nodes

SGX does not achieve perfect enclave isolation. While no real practical attack is known, researchers have demonstrated potentially dangerous side-channel attacks against applications [73] and even expressed concerns about whether an attestation key might be extracted [24].

Therefore, even if we assume SGX chips are manufactured in a secure fashion, some number of individual instances could be broken by well-resourced adversaries. A single compromised node could be catastrophic to an SGX-based cryptocurrency, allowing an adversary to create blocks at will and perform majority attacks on the blockchain. While she could not spend other people's money, which would require access to their private keys, she could perform denial-of-service attacks, selectively drop transactions, or charge excessive transaction fees.

In principle, a broken attestation key can be revoked through the Intel Attestation Service (IAS), but this can only happen if the break is detected to begin with. Consequently, Intel has explored ways of detecting SGX compromise in PoET [6] by statistically testing for implausibly frequent mining by a given node (using a "z-test"). Details are lacking in published materials, however, and a rigorous analytic framework seems to be needed.

For REM, we explore compromise detection within a rigorous definitional and analytic framework. The centerpiece is what we call a *block-acceptance policy*, a flexibly defined rule that determines whether a proposed block in a blockchain is legitimate. As we show, defining and analyzing policies rigorously is challenging, but we provide strong analytical and empirical evidence that a relatively simple statistical-testing policy (which we denote P_{stat}) can achieve good results. P_{stat} both limits an

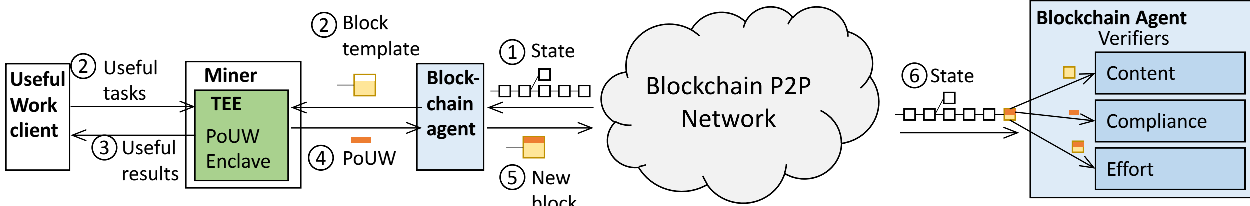

Figure 1: Architecture overview of REM

adversary's ability to harvest blocks unfairly and minimizes erroneous rejection of honestly mined blocks.

4.1 Threat Model and Definitions

4.1.1 Basic notation

To model block-acceptance policies, let $M = \{m_1, \cdots, m_n\}$ be the set of all miners, which we assume to be static. (Miners can join and leave the system; M includes all potential miners.) An adversary $\mathcal{A}$ controls a static subset $M_\mathcal{A} \in M$, where $|M_\mathcal{A}| = k$. $\text{rate}(m_i)$ specifies the *mining rate* of m_i, the number of mining operations per unit time it performs.

We define a candidate *block* to be a tuple $B = (t, m, d)$, where t is a timestamp, $m \in M$ the identity of the CPU that mines the block, and d is the block difficulty. Difficulty d is defined as the win probability per mining operation in the underlying consensus protocol (e.g. a hash in Bitcoin, a unit time of sleep in PoET, an instruction in PoUW). $\mathcal{B}$ denotes the set of possible blocks B.

A *blockchain* is an ordered sequence of blocks. At time τ, blockchain $C(\tau)$ is a sequence of accepted blocks $C(\tau) = \{B_1, B_2, \ldots, B_n\}$ for some n. We drop τ where its clear from context. We let $r(\tau)$ denote the number of rejected blocks of honest miners, i.e., miners in $M - M_\mathcal{A}$, in the history of $C(\tau)$. (Of course, $r(\tau)$ is not and indeed cannot be recorded in a real blockchain system.) Let $\mathcal{C}$ be the space of all possible blockchains C. Let C_m denote blockchain C restricted to blocks mined by miner $m \in M$.

In REM, a blockchain-acceptance policy is used to determine whether a block appears to come from a legitimate miner (CPU that hasn't been compromised).

Definition 1. *(Blockchain-Acceptance Policy) A blockchain-acceptance policy (or simply policy) $P : \mathcal{C} \times \mathcal{B} \rightarrow \{\text{reject}, \text{accept}\}$ is a function that takes as input a blockchain and a proposed block, and outputs whether the proposed block is legitimate.*

4.1.2 Security and efficiency definitions

We model the consensus algorithm for the blockchain, the adversary $\mathcal{A}$, and honest miners respectively as (ideal) programs $\text{prog}_{\text{chain}}$, $\text{prog}_\mathcal{A}$, and prog_m. Together, they define what we call a *security game* $S(P)$ for a particular policy P.

We define security games and their constituent programs formally in Appendix A.2. Where clear from context in what follows, we use the notation S, rather than $S(P)$, i.e., omit P.

A security game S may itself be viewed as a probabilistic algorithm. Thus we may treat the blockchain resulting from execution of S for interval of time τ as a random variable $C_S(\tau)$.

Normalizing the revenue from mining a block to 1, we define the *payoff* for a miner m for a given blockchain C as $\pi_m(C) = |C_m|$.

An adversary $\mathcal{A}$ seeks to maximize payoffs for its miners, as reflected in the following definition:

Definition 2. *(Advantage of $\mathcal{A}$). For a given security game S, the advantage of $\mathcal{A}$ for time τ is:*

$$\text{Adv}^S_\mathcal{A}(\tau) = \frac{\mathbb{E}[\pi_{\hat{m}}(C_S(\tau))]}{\max_{m_j \in M - M_\mathcal{A}} \mathbb{E}[\pi_{m_j}(C_S(\tau))]},$$

for any $\hat{m} \in M_\mathcal{A}$. Note that $\mathbb{E}[\pi_{\hat{m}}(C_S(\tau))]$ is equal for all such $\hat{m}$, as they all use strategy $\Sigma_\mathcal{A}$ and can emit blocks as frequently as desired (ignoring $rate(\hat{m})$).

A policy that keeps $\text{Adv}^S_\mathcal{A}(\tau)$ low is desirable, but there's a trade-off. A policy that rejects too many policies incurs high *waste*, meaning that it rejects many blocks from honest miners. We define waste as follows.

Definition 3. *(Waste of a policy). For a given blockchain $C(\tau) = \{(B_1, B_2, \ldots, B_n)\}$, the waste is defined as*

$$Waste(C(\tau)) = \frac{r(\tau)}{n + r(\tau)}.$$

For security game S, the waste at time τ is defined as

$$Waste^S(\tau) = \mathbb{E}[Waste(C_S(\tau))].$$

Our exploration of policies focuses critically on the trade-offs between low $\text{Adv}^S_\mathcal{A}(\tau)$ and low $\text{Waste}^S(\tau)$. To illustrate the issue, we give a simple example in Appendix A.3 of a policy that allows any CPU to mine only one block over its lifetime. As $\tau \rightarrow \infty$, it achieves the optimal $\text{Adv}^S_\mathcal{A}(\tau) = 1$, but at the cost of $\text{Waste}^S(\tau) = 1$, i.e., 100% waste.

$P_{\text{stat}}^{\alpha,\mathsf{rate}_{\text{best}}}(C,B)$:
  parse $B \rightarrow (\tau, m, d)$
  if $|C_m| > F^{-1}(1-\alpha, d\tau(\mathsf{rate}_{\text{best}}))$:
    output reject
  else
    output accept

Figure 2: P_{stat}^{α}. $F^{-1}(\cdot,\lambda)$ is the quantile function for Poisson distribution with rate λ.

4.2 The REM policy: P_{stat}

REM makes use of a statistical-testing-based policy that we denote by P_{stat}. P_{stat} is compatible not just with PoUW, but also with PoET and potentially other SGX-based mining variants.

There are two parts to P_{stat}. First, P_{stat} estimates the rate of the fastest honest miner(s) (fastest CPU type), denoted by $\mathsf{rate}_{\text{best}} = \max_{m \in M - M_{\mathcal{A}}} rate(m)$. There are various ways to accomplish this; a simple one would be to have an authority (e.g., Intel) publish specs on its fastest CPUs' performance. (In PoET, mining times are uniform, so $\mathsf{rate}_{\text{best}}$ is just a system parameter.) We describe an empirical approach to estimating $\mathsf{rate}_{\text{best}}$ in REM in Appendix A.1.

Given an estimate of $\mathsf{rate}_{\text{best}}$, P_{stat} tests submitted blocks statistically to determine *whether a miner is mining blocks too quickly and may thus be compromised*. The basic principle is simple: On receiving a block B from miner m, P_{stat} tests the null hypothesis

$$H_0 = \{rate(m) \leq \mathsf{rate}_{\text{best}}\}.$$

We use $|C_m(\tau)|$, the number of blocks mined by m at time τ, as the test statistic. Under H_0, $|C_m|$ should obey a Poisson distribution with rate $d\tau(\mathsf{rate}_{\text{best}})$, denoted as $\text{Pois}[d\tau(\mathsf{rate}_{\text{best}})]$. P_{stat} rejects H_0 if $|C_m|$ is greater than the $(1-\alpha)$-quantile of the Poisson distribution. The false rejection rate for a single test is therefore at most α. We specify P_{stat} (for a given $\mathsf{rate}_{\text{best}}$) in Figure 2.

An important property that differentiates P_{stat} from canonical statistical tests is that P_{stat} repeatedly applies a given statistical test to an accumulating history of samples. *The statistical dependency between samples makes the analysis non-trivial, as we shall show.*

4.3 Analysis of P_{stat}

We now analyze the average-case and worst-case waste and adversarial advantage of P_{stat}. We assume for simplicity that $\mathsf{rate}_{\text{best}}$ is accurately estimated. We remove this assumption in the worst-case analysis below. We also assume that the difficulty $d(t)$ is stationary over the period of observation.

Waste Under P_{stat}, a miner generates blocks according to a Poisson process; whether a block is accepted or rejected depends on whether the miner has generated more blocks than a time-dependent threshold. This process is obviously not memoryless and thus not directly representable as a Markov process. We can, however, achieve a close approximation using a discrete-time Markov chain. Indeed, as we show, we can represent waste in P_{stat} using a discrete-time Markov chain that is *periodically identical* to the process it models, meaning that its expected waste is identical at any time $n\tau$, for $n \in \mathbb{Z}^+$ and τ a model parameter specified below. This Markov chain has a stationary distribution that yields an expression upper-bounding waste in P_{stat}. (We believe, and the periodic identical property suggests, that this bound is very tight.)

To construct the Markov Chain, we partition time into intervals of length τ; we regard each such interval as a discrete timestep. Assuming that all honest miners mine at rate $rate$, let $\lambda = d\tau(rate)$. Thus an honest miner generates an expected $\text{Pois}[\lambda]$ blocks in a given timestep i, which we may represent as a random variable Y_i. Without loss of generality, we may set $\tau = 1/(d \times rate)$ and thus $\lambda = 1$ and $E[\text{Pois}[\lambda]] = 1$.

We represent the state of an honest miner at timestep n by a random variable $X_n = \sum_{i=1}^{n}(Y_i - E[Y_i]) = (\sum_{i=1}^{n} Y_i) - n$. Thus $X_n \in \mathbb{Z}$ is simply difference between the miner's actually mined blocks and the expected number.

Our Markov chain consists of a set of states $C = \mathbb{Z}$ representing possible values of X_n (we use the notation C here, as states represent $|C_m|$ for an honest miner m). Figure 3 gives a simple example of such a chain (truncated to only four states).

Our statistical testing regime may be viewed as rejecting blocks when a transition is made to a state whose value is above a certain threshold *thresh*. We denote the set of such states $C_{\text{rej}} = \{j \,|\, j \geq thresh\} \in C$ and depict corresponding nodes visually in our example in Figure 3 as red. P_{stat} sets *thresh* according to the statistical-testing regime we describe above and a desired false-rejection (Type-I) parameter α. Specifically,

$$C_{\text{rej}}[\alpha] = \{j \in \mathbb{Z} \,|\, j \geq F^{-1}(1-\alpha, \tau \times rate)\}. \tag{1}$$

The transition probabilities in our Markov chain are:

$$P[i \rightarrow j \,|\, i \in C \setminus C_{\text{rej}}[\alpha]] = \begin{cases} P(j-i+1) & \text{if } j \geq i-1 \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

$$P[i \rightarrow j \,|\, i \in C_{\text{rej}}[\alpha]] = \begin{cases} P(j+1) & \text{if } j \leq -1 \\ 0 & \text{otherwise.} \end{cases} \tag{3}$$

An example of transitions is given in Figure 3. For instance, from state -1, the next state can be -2 if the

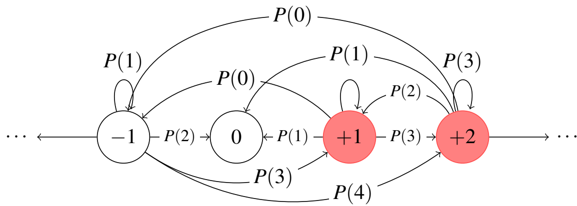

Figure 3: Markov chain with states C representing P_{stat}. Red nodes show the rejection set $C_{\text{rej}} = \mathbb{Z}^+$, i.e., *thresh* $= 1$. Outgoing edges from 0 are omitted for clarity.

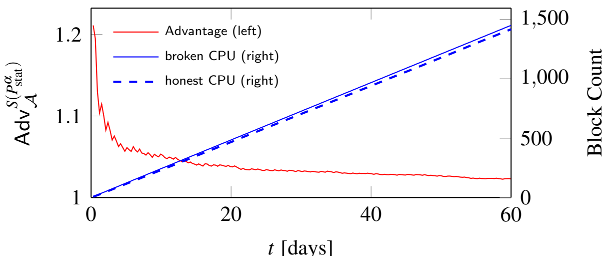
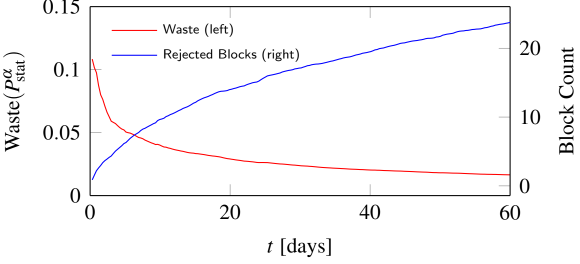


(a) Left y-axis: adversarial advantage of P_{stat}. Right y-axis: the number of blocks mined by a compromised CPU versus an honest CPU.



(b) Left y-axis: the waste of P_{stat}. Right y-axis: the number of rejected blocks.

Figure 4: 60-day simulation of P_{stat}. The fastest honest CPU mines one block per hour. The Markov chain analysis yields a long-term advantage upper bound of 1.006 and waste of 0.006.

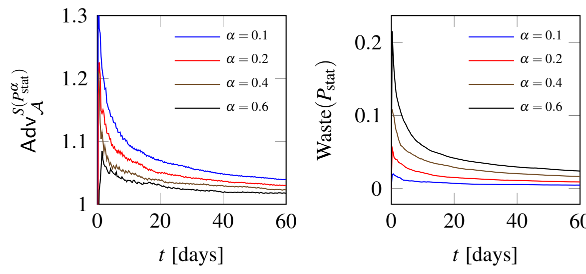
miner doesn't produce any block in this step with probability $P(0)$, or state $-2+i$ if the miner produces $i+1$ blocks in this step, thus with probability $P(i+1)$.

Finally, an upper bound on the false rejection rate can be derived from the stationary probabilities of the Markov chain. Letting $q(s)$ denote the stationary probability of state s,

$$\text{Waste}(P_{\text{stat}}^{\alpha}) = \sum_{s \in C_{\text{rej}}[\alpha]} sq(s). \quad (4)$$

We compare our analytic bounds with simulation results in below.

Adversarial Advantage We denote by Σ_{stat} the strategy of an adversary that publishes blocks as soon as they



(a) The adversarial advantage of P_{stat} under different α

(b) The waste of P_{stat} under different α

Figure 5: 60-day simulation of P_{stat}, under various α. The fastest honest CPU mines an expected one block per hour.

will be accepted by P_{stat}. In Appendix A.4, we show the following:

Theorem 1. *In a (non-degenerate) security game S where $\mathcal{A}$ uses strategy Σ_{stat},*

$$\mathsf{Adv}_{\mathcal{A}}^{S(P_{stat}^{\alpha})} = \frac{1}{1 - Waste(P_{stat}^{\alpha})}.$$

Simulation We simulate P_{stat} to explore its efficacy in both the average case and the worst case. Figure 4 shows the result of 1000 runs of a 60-day mining period simulation under P_{stat}. We set $\alpha = 0.4$. We present statistics with respect to the fastest (honest) CPU in the system, which for simplicity we assume mines one block per hour in expectation and refer to simply as "the honest miner." The adversary uses attack strategy Σ_{stat}.

In Figure 4a, the solid blue line shows the average aggregate number of blocks mined by the adversary, and the dashed one those of the honest miner. The attacker's advantage is, of course, the ratio of the two values. Initially, the adversary achieves a relatively high advantage ($\approx 127\%$), but this drops below 110% within 55 blocks, and continues to drop. Our asymptotic analytic bound on waste (given below) implies an advantage of 100.6%.

Figure 4b shows the average waste of P_{stat} and absolute number of rejected blocks. The waste quickly drops below 10%. As blocks accumulate, the statistical power of P_{stat} grows, and the waste drops further. Analytically, we obtain $\text{Waste}(P_{\text{stat}}^{\alpha}) = 0.006$, or 0.6% from Eqn. 4.

Setting α Setting the parameter α imposes a trade-off on system implementers. As noted, α corresponds to the Type-I error for a single test in P_{stat}. As P_{stat} performs continuous testing, however, a more meaningful security measure is $\text{Waste}(P_{\text{stat}}^{\alpha})$, the rate of falsely rejected blocks. Similarly there is no notion of Type-II error—particularly, as our setting is adversarial. $\mathsf{Adv}_{\mathcal{A}}^{S(P_{\text{stat}}^{\alpha})}$ captures the corresponding notion in REM. As shown in Figure 5, raising α results in a lower $\mathsf{Adv}_{\mathcal{A}}^{S(P_{\text{stat}}^{\alpha})}$, but higher $\text{Waste}(P_{\text{stat}}^{\alpha})$, and vice versa.

Algorithm 1: Miner Loop. The green highlighted line is executed in a TEE (e.g., an SGX enclave).

```
1 while True do
2   template ← read from blockchain agent
3   hash, difficulty ← process(template)
4   task ← get from useful work client
5   outcome, PoUW ← TEE(task, hash, difficulty)
6   send outcome to useful work client
7   if PoUW ≠ ⊥ then
8     block ← formBlock(template, PoUW)
9     send block to blockchain agent
```

5 Implementation Details

We have implemented a full REM prototype using SGX (§5.1), and as an example application swapped REM into the consensus layer of Bitcoin-core [18]. We explain how we implemented secure instruction counting (§5.2), and our hierarchical attestation framework (§5.3) that allows for arbitrary tasks to be used for work. We explain how to reduce the overhead of attestation due to SGX-specific requirements (§5.4). Finally (§5.5) we present two examples of PoUW and evaluate the overhead of REM.

5.1 Architecture

Figure 1 shows the architecture of REM. As discussed in §3.2, the core of REM is a miner program that does useful work and produces PoUWs. Each CPU instruction executed in the PoUW is analogous to one hash function computation in PoW schemes. That is, each instruction has some probability of successfully mining a block, and if the enclave determines this is the case, it produces a proof — the PoUW.

Pseudocode of the miner's iterative algorithm is given in Algorithm 1. In a given iteration, it first takes a block template from the agent and calculates the previous block's hash and difficulty. Then it reads the task to perform as useful work. Note that the enclave code has no network stack, therefore it receives its inputs from the miner untrusted code and returns its outputs to the miner untrusted code. The miner calls the TEE (SGX enclave) with the useful task and parameters for mining, and stores the result of the useful task. It also checks whether the enclave returned a successful PoUW; if so, it combines the agent-furnished template and PoUW into a legal block and sends it to the agent for publication. In REM, the miner untrusted layer is implemented as a Python script using RPC to access the agent.

To securely decide whether an instruction was a "winning" one, the PoUW enclave does the equivalent of generating a random number and checking whether it is smaller than value `target` that represents the desired system-wide block rate, i.e., difficulty. For this purpose, it uses SGX's random number generator (SRNG). However, calling the SRNG and checking for a win after every single instruction would impose prohibitive overhead. Instead, we batch instructions by dividing useful work into subtasks of short duration compared to the inter-block interval (e.g. 10 second tasks for 10 minute average block intervals). We let each such subtask run to completion, and count its instructions. The PoUW enclave then calls the SRNG to determine whether at least one of the instructions has won, i.e., it checks for a result less than `target`, weighted by the total number of executed instructions. If so, the enclave produces an attestation that includes the input block hash and difficulty.

Why Count Instructions While instructions are reasonable estimates of the CPU effort, CPU cycles would have been a more accurate metric. However, although cycles are counted, and the counts can be accessed through the CPU's performance counters, they are vulnerable to manipulation. The operating system may set their values arbitrarily, allowing a rational operator, who controls her own OS, to improve her chances of finding a block by faking a high cycle count. Moreover, counters are incremented even if an enclave is swapped out, allowing an OS scheduler to run multiple SGX instances and having them double-count cycles. Therefore, while instruction counting is not perfect, we find it is the best method for securely evaluating effort with the existing tools available in SGX.

5.2 Secure Instruction Counting

As we want to allow arbitrary useful work programs, it is critical to ensure that instructions are counted correctly even in the presence of malicious useful work programs. To this end, we adopt a hybrid method combining static and dynamic program analysis. We employ a customized toolchain that can instrument any SGX-compliant code with dynamic runtime checks implementing secure instruction counting.

Figure 6 shows the workflow of the PoUW toolchain. First, the useful work code (`usefulwork.cpp`), C / C++ source code, is assembled while reserving a register as the instruction counter. Next, the assembly code is rewritten by the toolchain such that the counter is incremented at the beginning of each basic block (a linear code sequence with no branches) by the number of instructions in that basic block. In particular, we use the `LEA` instruction to perform incrementing for two reasons. First, it completes in a single cycle, and second, it doesn't change flags and therefore does not affect con-

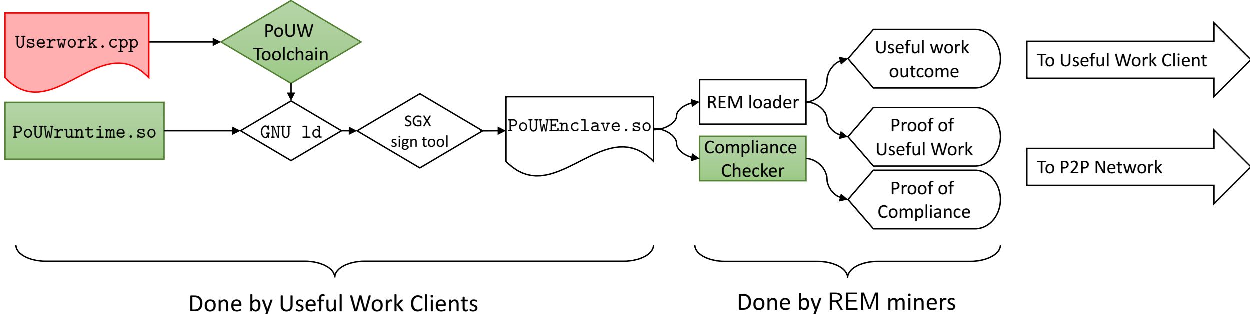


Figure 6: REM toolchain to transfer a useful work to an PoUW-ready program. Everything in the diagram has been implemented besides existing tools such as `ld` and SGX signing tool.

Algorithm 2: PoUW Runtime

ditional jumps. The count is performed at the beginning of a block rather than its end to prevent a cheater from jumping to the middle of a block and gaining an excessive count.

Another challenge is to ensure the result of instruction counting is used properly—we cannot rely on the useful work programs themselves. The solution is to wrap the useful work with a predefined, trusted PoUW runtime, and make sure to the enclave can only be entered through the PoUW runtime. The logic of PoUW runtime is summarized in Algorithm 2, and it is denoted as `PoUWruntime.so` in Figure 6. The PoUW runtime serves as an "in-enclave" loader that launches the useful work program with proper input and collects the result of instruction counting. It takes the block hash and difficulty and starts mining by running the mining program. Once the mining program returns, the PoUW runtime extracts the instruction counter from the reserved register. Then it draws a random value from SRNG and determines whether a new block should be generated, based on the instruction counter and the current difficulty. If a block should be generated, the PoUW runtime produces an attestation recording the template hash that it is called with and the difficulty.

The last step of the toolchain is to compile the resultant assembly and link it (using linker `GNU ld`) with the PoUW runtime (`PoUWruntime.so`), to produce the PoUW enclave. Figure 7 shows a snippet of instrumented assembly code. This PoUW enclave is finally signed by an Intel SGX signing tool, creating an application `PoUWEnclave.so` that is validated for loading into an enclave.

The security of instruction counting relies on the assumption that once instrumented, the code cannot alter its behavior. To realize this assumption in SGX, we need to require two invariants. First, code pages must be non-writable; second, the useful work program must be single threaded.

Enforcing Non-Writable Code Pages Writable code pages allow a program to rewrite itself at runtime. Although necessary in some cases (e.g. JIT), writable code opens up potential security vulnerabilities. In particular, writable code pages are not acceptable in REM because they would allow a malicious useful work program to easily bypass the instrumentation. A general memory protection policy would be to require code pages to have W⊕X permission, namely to be either writable or executable, but not both. However, W⊕X permissions are

```
.section data
ENCLAVE_MTX:
    .long 0

.section text
...
enclave_entry:
    xor %rax, %rax
    xchgl ENCLAVE_MTX(%rip), %rax
    cmp %rax, 0
    jnz enclave_entry
```

Figure 8: Code snippet: a spinlock to allow only the first thread to enter `enclave_entry`

not enforced by the hardware. Intel has in fact acknowledged this issue [5] and recommended that enclave code contain no relocation to enable the W⊕X feature.

REM thus explicitly requires code pages in the enclave code (`usefulwork.so`) to have W⊕X permission. This is straightforward to verify, as with the current implementation of the SGX loader, code page permissions are taken directly from the ELF program headers [4].

Enforcing Single Threading Another limitation of SGX is that the memory layout is largely predefined and known to the untrusted application. For example, the State Save Area (SSA) frames are a portion of stack memory that stores the execution context when handling interrupts in SGX. This also implies that the SSA pages have to be writable. The address of SSA frames for an enclave is determined at the time of initialization, as the Thread Control Structure (TCS) is loaded by the untrusted application through an `EADD` instruction. In other words, the address of SSA is always known to the untrusted application. This could lead to attacks on the instruction counting if a malicious program has multiple threads that interact via manipulation of the execution context in SSA. For example, as we will detail later, REM stores the counter in one of the registers. When one thread is swapped out, the register value stored in an SSA is subject to manipulation by another thread.

While more complicated techniques such as Address Space Layout Randomization (ASLR) for SGX could provide a general answer to this problem, for our purposes it suffices to enforce the condition that an enclave can be launched by at most one thread. As an SGX enclave has only one entry point, we can instrument the code with a spinlock to allow only the first thread to pass, as shown in Figure 8.

Known entry points REM expects the PoUW toolchain and compliance checker to provide and verify a subset of Software Fault Isolation (SFI), specifically indirect control transfers alignment [26, 53, 74, 38]. This ensures that the program can only execute the instruction stream parsed by the compliance checker, and not jump to the middle of an instruction to create its own alternate execution that falsifies the instruction count. Our implementation does not include SFI, as off the shelf solutions such as Google's Native Client could be integrated with the PoUW toolchain and runtime with well quantified overheads [74].

5.3 Hierarchical Attestation

A blockchain participant that verifies a block has to check whether the useful work program that produced the block's PoUW followed the protocol and correctly counted its instructions. SGX attestations require such a verifier to obtain a fingerprint of the attesting enclave. As we allow arbitrary work, a naïve implementation would store all programs on the blockchain. Then a verifier that considers a certain block would read the program from the blockchain, verify it correctly counts instructions, calculate its fingerprint, and check the attestation. Beyond the computational effort, just placing all programs on the blockchain for verification would incur prohibitive overhead and enable DoS attacks via spamming the chain with overly large programs. The alternative of having an entity that verifies program compliance is also unacceptable, as it puts absolute blockchain control in the hands of this entity: it can authorize programs that deterministically win every execution.

To resolve this predicament, we form PoUW attestations with what we call *two-layer hierarchical attestations*. We hard-code only a single program's fingerprint into the blockchain, a static-analysis tool called *compliance checker*. The compliance checker runs in a trusted environment and takes a user-supplied program as input. It validates that it conforms with the requirements defined above. First, it confirms the `text` section is non-writable. Then it validates the work program's compliance by disassembling it and confirming that the dedicated register is reserved for instruction counting and that counts are correct and appear where they should. Next, it verifies that the PoUW runtime is correctly linked and identical to the expected PoUW runtime code. Finally, it verifies the only entry point is the PoUW runtime and that this is protected by a spinlock as shown in Figure 8. Finally, it calculates the program's fingerprint and outputs an attestation including this fingerprint.

Every PoUW then includes two parts: The useful work program attestation on the mining success, and an attestation from the compliance checker of the program's compliance (Figure 9). Note that the compliance attestation and the program's attestation must be signed by the same CPU. Otherwise an attacker that compromises a single CPU could create fake compliance attestations for invalid tasks. Such an attacker could then create blocks at

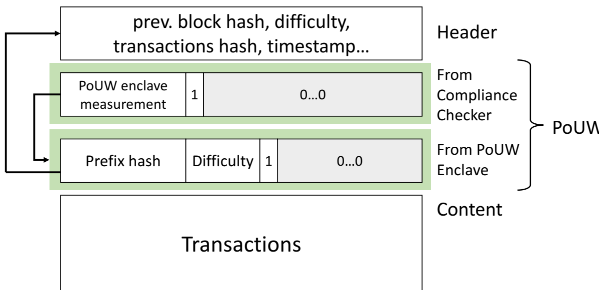

Figure 9: Block structure with a proof comprising the quotes from the compliance enclave and a work enclave.

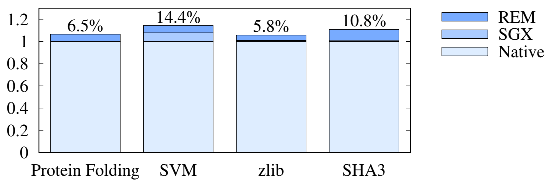

Figure 10: REM Overhead

will from different uncompromised CPUs, circumventing the detection policy of Section 4.

In summary, the compliance enclave is verified through the hard-coded measurement in the blockchain agent. Its output is a measurement that should be identical to the measurement of the PoUW enclave `PoUWEnclave.so`. PoUW Enclave's output should match the block template (namely the hash of the block prefix, up to the proof) and the prescribed difficulty.

Generalized Hierarchical Attestation The hierarchical attestation approach can be useful for other scenarios where participants need to obtain attestations to code they do not know in advance. As a general approach, one hard-codes the fingerprint of a *root compliance checker* that verifies its children's compliance. Each of them, in turn, checks the compliance of its children, and so on, forming a tree. The leaves of the tree are the programs that produce the actual output to be verified. A hierarchical attestation therefore comprises a leaf attestation and a path to the root compliance checker. Each node attests the compliance of its child.

5.4 IAS access overhead

Verifying blocks doesn't require trusted hardware. However, due to a design choice by Intel, miners must contact the IAS to verify attestations. Currently there is no way to verify attestations locally. This requirement, however, does not change the basic security assumptions. Moreover, a simple modification to the IAS protocol, which is being tested by Intel [3], could get rid of the reliance on IAS completely on verifiers' side.

Recall that the IAS is a public web service that receives SGX attestations and responds with verification results. Requests are submitted to the IAS over HTTPS; a response is a signed "report" indicating the validation status of the queried platform [44]. In the current version of IAS, a report is not cryptographically linked with its corresponding request, which makes the report only trustworthy for the client initiating the HTTPS session. Therefore an IAS access is required for every block verification by every blockchain participant.

However, the following modification can eliminate this overhead: simply echoing the request in the body of the report. Since the report is signed by Intel using a published public key [44, 45], only one access to IAS would be needed globally for every new block. Other miners could use the resulting signed report. Such a change is under testing by Intel for future versions of the IAS [3].

5.5 Experiments

We evaluate the overhead of REM with four examples of useful work benchmarks in REM as mining programs: a protein folding algorithm [1], a Support Vector Machine (SVM) classifier [22], the zlib compression algorithm (iterated) [2], and the SHA3-256 hash algorithm (iterated) [7]. We evaluate each benchmark in three modes:

Native We compile with the standard toolchain.

SGX We port to SGX by removing system calls and replacing system libraries with SGX-compliant ones. Then we compile in SGX-prerelease mode and run with the SGX driver v1.7 [43].

REM After porting to SGX, we instrument the code using our REM toolchain. We then proceed as in the SGX mode.

We use the same optimization level (`-O2`) in all modes. The experiments are done on a Dell Precision Workstation with an Intel 6700K CPU and 32GB of memory. For more details on the experiment setup, we refer readers to the full version [76].

We compared the running time in three modes and the results are shown in Figure 10. The running time of the native mode is normalized to one as a baseline. For all four useful workloads, we observe a total overhead of 5.8% $\sim$ 14.4% in REM relative to the native mode. Because the code is instrumented at control flow transfers, workloads with more jumps will incur more counting overhead. For example, SHA3-256 is highly iterative compared with the other workloads, so it incurs the most counting overhead.

We note that overhead for running in SGX is not uniform. For computation-bound workloads such as protein

folding, zlib, and SHA3, SGX introduces little overhead ($< 1\%$) because the cost of switching to SGX and obtaining attestations is amortized by the longer in-enclave execution time of the workload. In the shorter SVM benchmark, the cost of entering SGX is more significant.

In summary, we observe an overhead of roughly $5 - 15\%$ for converting useful-work benchmarks into REM PoUW enclave.

6 Waste Analysis

To compare PoUW against PoET and alternative schemes, we explore a common game-theoretic model (with details deferred to the appendix). We consider a set of operators / agents that can either work locally on their own useful workloads or utilize their resource for mining. Based on the revenue from useful work and mining, and the capital and operational costs, we compute the equilibrium point of the system. We calculate the waste in this context as the ratio of the total resource cost (in U.S. dollars) spent per unit of useful work on a mining node compared with the cost when mining is not possible and all operators do useful work. We plug in concrete numbers for the parameters based on statistics we collected from public data sources.

Initial study of PoET identified a subtle pitfall involving miner's ability to mine simultaneously on multiple blockchains, a problem solved by He et al. [59] in a scheme we call *Lazy-PoET*. Our analysis, however, reveals that even Lazy-PoET suffers from what we call the *stale-chip problem*. Miners are better off maintaining farms of cheap, outdated CPUs just for mining than using new CPUs for otherwise useful goals.

We consider instead an approach in which operators utilize their CPUs while mining, making newer CPUs more attractive due to the added revenue from the useful work done. We call this scheme *Busy PoET*. We find that it improves on Lazy Poet, but remains highly wasteful.

This observation leads to another approach, *Proof of Potential Work* (*PoPW*). PoPW is similar to Busy-PoET, but reduces mining time according to the speed of the CPU (its potential to do work), and thus rewards use of newer CPUs. Although PoPW would greatly reduce waste, SGX does not allow an enclave to securely retrieve its CPU model, making PoPW theoretical only.

We conclude that PoUW incurs the smallest amount of waste among the options under study. For full details on our model, parameter choices, and analyses of the various mining schemes, we refer the reader to the full version [76].

7 Related Work

Cryptocurrencies and Consensus. Modern decentralized cryptocurrencies have stimulated strong interest in Proof-of-Work (PoW) systems [12, 29, 46] as well as techniques to reduce their associated waste.[3]

An approach similar to PoET [41], possibly originating with Dryja [27], is to limit power waste by so-called Proof-of-Idle. Miners buy mining equipment and get paid for proving that their equipment remains idle. Beyond the technical challenges, as in PoET, an operator with a set budget could redirect savings from power to purchase more idle machines, producing capital waste.

Alternative approaches, like PoUW, aim at PoW producing work useful for a secondary goal. Permacoin [58] repurposes mining resources as a distributed storage network, but recycles only a small fraction of mining resources. Primecoin [49] is an active cryptocurrency whose "useful outputs" are Cunningham and Bi-twin chains of prime numbers, which have no known utility. Gridcoin [36, 35], an active cryptocurrency whose miners work for the BOINC [9] grid-computing network, relies on a central entity. FoldingCoin [65] rewards participants for work on a protein folding problem, but as a layer atop, not integrated with, Bitcoin.

Proof-of-Stake [71, 14, 48, 16] is a distinct approach in which miners gain the right to generate blocks by committing cryptocurrency funds. It is used in experimental systems such as Peercoin [50] and Nxt [23]. Unlike PoW, however, in PoS, an attacker that gains majority control of mining resources for a bounded time can control the system forever. PoS protocols also require that funds, used as stake, remain frozen (and unusable) for some time. To remove this assumption, Bentov et al. [15] and Duong et al. [28] propose hybrid PoW / PoS systems. These works, and the line of hybrid blockchain systems starting with Bitcoin-NG [32, 51, 63], can all utilize PoUW as a low-waste alternative to PoW.

Another line of work on PoW for cryptocurrencies aims at PoWs that resist mining on dedicated hardware and prevent concentration of mining power, e.g., via memory-intensive hashing as in Scrypt [54] and Ethereum [19]. Although democratization of mining power is not our focus here, PoUW in fact achieves this goal by restricting mining to general-use CPUs.

SGX. Due to the complexity of the x86-64 architecture, several works [24, 70, 73] have exposed security problems in SGX, such as side-channel attacks [73]. Tramer et al. [70] consider the utility of SGX if its confidentiality guarantees are broken. Similar practical concerns motivate REM's tolerance mechanism of compromised SGX chips.

Ryoan [38] is a framework that allows a server to run code on private client data and return the output to

[3] "Permissioned" systems, as supported in, e.g., Hyperledger [20] and Stellar [56], avoid waste by using traditional consensus protocols at the cost of avoiding decentralization.

the client. The (trusted) Ryoan service instruments the server operator's code to prevent leakage of client data. In contrast, in REM, the useful-workload code is instrumented in an *untrusted* environment, and an attestation of its validity is produced within a trusted environment.

Haven [13] runs non-SGX applications by incorporating a library OS into the enclave. REM, in contrast, takes code amenable to SGX compilation and enforces correct instrumentation. In principle, Haven could allow for non-SGX code to be adapted for PoUW.

Zhang et al. [75] and Juels et al. [47] are the first works we are aware of to pair SGX with cryptocurrencies. Their aim is to augment the functionality of smart contracts, however, and is unrelated to the underlying blockchain layer in which REM operates.

8 Conclusion

We presented REM, which supports permissionless blockchain consensus based on a novel mechanism called Proof of Useful Work (PoUW). PoUW leverages Intel SGX to significantly reduce the waste associated with Proof of Work (PoW), and builds on and remedies shortcomings in Intel's innovative PoET scheme. PoUW and REM are thus a promising basis for partially-decentralized blockchains, reducing waste given certain trust assumptions in a hardware vendor such as Intel.

Using a rigorous analytic framework, we have shown how REM can achieve resilience against compromised nodes with minimal waste (rejected honest blocks). This framework extends to PoET and potentially other SGX-based mining approaches.

Our implementation of REM introduces powerful new techniques for SGX applications, namely instruction-counting instrumentation and hierarchical attestation, of potential interest beyond REM itself. They allow REM to accommodate essentially any desired workloads, permitting flexible adaptation in a variety of settings.

Our framework for economic analysis offers a general means for assessing the true utility of mining schemes, including PoW and partially-decentralized alternatives. Beyond illustrating the benefits of PoUW and REM, it allowed us to expose risks of approaches such as PoET in the use of stale chips, and propose improved variants, including Proof of Potential Work (PoPW). We found that small changes to the TEE framework would be significant for reduced-waste blockcain mining. In particular, allowing for secure instruction (or cycle) counting would reduce PoUW overhead, and a secure chip-model reading instruction would allow for PoPW implementation.

We reported on a complete implementation of REM, swapped in for the consensus layer in Bitcoin core in a prototype system. Our experiments showed minimal performance impact (5-15%) on example benchmarks. In summary, our results show that REM is practically deployable and promising path to fair and environmentally friendly blockchains in partially-decentralized blockchains.

A Tolerating Compromised SGX Nodes: Details

A.1 Mining Rate Estimation

We start by discussing how to statistically infer the power of a CPU from its blocks in the blockchain. Reading the difficulty of each block in the main chain and the rate of blocks from a specific CPU, we can estimate a lower bound of that CPU's power – it follows directly from the rate of its blocks. It is a lower bound since the CPU might not be working continuously, and the estimate's accuracy increases with the number of available blocks.

Recall C_{m_i} is the blocks mined by miner m_i so far. C_{m_i} may contain multiple blocks, perhaps with varying difficulties. Without loss of generality, we write the difficulty as a function of time, $d(t)$. The difficulty is the probability for a single instruction to yield a win. Denote the power of the miner, i.e., its mining rate, by rate_i. Therefore in a given time interval of length T, the number of blocks mined by a specific CPU obeys Poisson distribution (since CPU rates are high and the win probability is small, it's appropriate to approximate a Binomial distribution by a Poisson distribution,) and with rate $\mathsf{rate}_i T d(t)$. Further, under independence assumption, the

mining process of a specific CPU is specified by a Poisson process with rate $\lambda_i(t) = \mathsf{rate}_i d(t)$, the product of the probability and the miner's rate rate_i.

There are many methods to estimate the mean of a Poisson distribution. We refer readers to the full version [76] for more details. Knowing rates for all miners, the rate of the strongest CPU ($\mathsf{rate}_{\text{best}}$) can be estimated. The challenge here is to limit the influence of adversarial nodes. To this end, instead of finding the strongest CPU directly, we approximate $\mathsf{rate}_{\text{best}}$ based on rate_ρ (e.g. $f_{90\%}$), namely the $\rho-$percentile fastest miner.

Bootstrapping. During the launch of a cryptocurrency, it could be challenging to estimate the mining power of the population accurately, potentially leading to poisoning attacks by an adversary. At this early stage, it makes sense to hardwire a system estimate of the maximum mining power of honest miners into the system and set conditions (e.g., a particular mining rate or target date) to estimate $\mathsf{rate}_{\text{best}}$ as we propose above. If the cryptocurrency launches with a large number of miners, an even simpler approach is possible before switching to $\mathsf{rate}_{\text{best}}$ estimation: We can cap the total number of blocks that any one node can mine, a policy we illustrate below. (See P_{simple}.)

A.2 Security game definition

We model REM as an interaction among three entities: a blockchain consensus algorithm, an adversary, and a set of honest miners. Their behavior together defines a *security game*, which we define formally below. We characterize the three entities respectively as (ideal) programs $\mathsf{prog}_{\text{chain}}$, $\mathsf{prog}_{\mathcal{A}}$, and prog_m, which we now define.

Blockchain consensus algorithm ($\mathsf{prog}_{\text{chain}}$). A consensus algorithm determines which valid blocks are added to a blockchain C. We assume that underlying consensus and fork resolution are instantaneous; loosening this assumption does not materially affect our analyses. We also assume that block timestamping is accurate. Timestamps can technically be forged at block generation, but in practice miners reject blocks with large skews [18], limiting the impact of timestamp forgery.

Informally, $\mathsf{prog}_{\text{chain}}$ maintains and broadcasts and authoritative blockchain C. In addition to verifying that block contents are correct, $\mathsf{prog}_{\text{chain}}$ appends to C only blocks that are valid under a policy P. We model the blockchain consensus algorithm as the (ideal) stateful program specified in Figure 11.

Adversary $\mathcal{A}$ ($\mathsf{prog}_{\mathcal{A}}$). In our model, an adversary $\mathcal{A}$ executes a *strategy* $\Sigma_{\mathcal{A}}$ that coordinates the k miners $M_{\mathcal{A}}$ under her control to generate blocks. Specifically:

$\mathsf{prog}_{\text{chain}}[P]$

State:
  C: the chain
On receive "init":
  $C := \varnothing$
  $d := d_0$
  Send (C, P, d) to all miners
On receive "submit" B from m:
  if $P(C, B) = \mathsf{accept}$:
    $C \leftarrow C \cup \{B\}$
    $d \leftarrow \mathsf{adjust}(C, d)$
    Send (C, P, d) to all miners

Figure 11: The program for a blockchain. We omit details here on how difficulty d is set, i.e., how d_0 and adjust are chosen.

$\mathsf{prog}_{\mathcal{A}}[\Sigma_{\mathcal{A}}]$

On receive (C, P, d) from $\mathsf{prog}_{\text{chain}}$
  $\hat{t}, \hat{m} \leftarrow \Sigma_{\mathcal{A}}(M_{\mathcal{A}}, C, P, d)$
  if $\hat{t}$ is not $\perp$:
    wait until $\hat{t}$
    send "submit" $(\hat{t}, \hat{m}, d)$ to $\mathsf{prog}_{\text{chain}}$

Figure 12: The program for an adversary $\mathcal{A}$ that controls k nodes $M_{\mathcal{A}} = \{m_{\mathcal{A}1}, \cdots, m_{\mathcal{A}k}\}$.

Definition 4. *(Adversarial Strategy). An* adversarial strategy *is a probabilistic algorithm $\Sigma_{\mathcal{A}}$ that takes in a set of identities, the current blockchain and the policy, and outputs a time-stamp and identity for block submission. Specifically, $(M_{\mathcal{A}}, C, t, P) \rightarrow (\hat{t}, \hat{m}) \in \mathbb{R}^+ \times M_{\mathcal{A}}$.*

In principle, $\Sigma_{\mathcal{A}}$ can have dependencies among individual node behaviors. In our setting, this would not benefit $\mathcal{A}$, however. As we don't know $M_{\mathcal{A}}$ *a priori*, though, the only policies we consider operate on individual miner block-generation history.

As a wrapper expressing implementation by $\mathcal{A}$ of $\Sigma_{\mathcal{A}}$, we model $\mathcal{A}$ as a program $\mathsf{prog}_{\mathcal{A}}$, specified in Figure 12.

Honest miners (prog_m). Every honest miner $m \in M - M_{\mathcal{A}}$ follows an identical strategy, a probabilistic algorithm denoted Σ_h. In REM, Σ_h may be modeled as a simple algorithm that samples from a probability distribution on block mining times determined by $rate(m)$ (specifically in our setting, an exponential distribution with rate $rate(m)$). We express implementation by honest miner m of Σ_h as a program $\mathsf{prog}_m[\Sigma_h]$ (Figure 13).

To understand the security of REM, we consider a *security game* that defines how an adversary $\mathcal{A}$ interacts with honest miners, a blockchain consensus protocol,

$\mathsf{prog}_m[\Sigma_h]$

On receive (C,P,d) from $\mathsf{prog}_{\mathsf{chain}}$
  $\hat{t} \leftarrow \Sigma_h(C,d)$
  Send "submit" $(\hat{t},m,d)$ to $\mathsf{prog}_{\mathsf{chain}}$

Figure 13: The program for an honest miner. Σ_h is the protocol defined by $\mathsf{prog}_{\mathsf{chain}}$(e.g. PoET or PoUW).

$P_{\text{simple}}(C,B)$:
  parse $B \rightarrow (\tau,m,d)$
  if $|C_m| > 0$:
    output reject
  else
    output accept

Figure 14: A simple policy that allows one block per CPU over its lifetime.

and a policy given the above three ideal programs. Formally:

Definition 5. *(Security Game) For a given triple of ideal programs* $(\mathsf{prog}_{chain}[P],\mathsf{prog}_{\mathcal{A}}[\Sigma_{\mathcal{A}}],\mathsf{prog}_m[\Sigma_h])$*, and policy P, a security game S(P) is a tuple* $S(P) = ((M,M_{\mathcal{A}},rate(\cdot));(\Sigma_{\mathcal{A}},\Sigma_h))$.

We define the *execution* of $S(P)$ as an interactive execution of programs $(\mathsf{prog}_{\mathsf{chain}}[P],\mathsf{prog}_{\mathcal{A}}[\Sigma_{\mathcal{A}}],\mathsf{prog}_m[\Sigma_h])$ using the parameters of $S(P)$. As P, $\Sigma_{\mathcal{A}}$ and Σ_h are randomized algorithms, such execution is itself probabilistic. Thus we may view the blockchain resulting from execution of S for interval of time τ as a random variable $C_S(\tau)$.

A *non-degenerate* security game S is one in which there exists at least one honest miner m with $rate(m) > 0$.

A.3 Warmup policy

As a warmup, we give a simple example of a potential block-acceptance policy. This policy just allows one block throughout the life of a CPU, as shown in Figure 14.

Clearly, an adversary cannot do better than mining one block. Denote this simple strategy Σ_{simple}. For any non-degenerate security game S, therefore, the advantage $\mathsf{Adv}_{\mathcal{A}}^{S(P_{simple})}(\tau) = 1$ as $\tau \rightarrow \infty$. This policy is optimal in that an adversary cannot do better than an honest miner unconditionally. However the asymptotic waste of this policy is 100%.

Another disadvantage of this policy is that it discourages miners from participating. Arguably, a miner would stay if the revenue from mining is high enough to cover the cost of replacing a CPU. But though a CPU is still valuable in other contexts even if it is is blacklisted forever in *this* particular system, repurposing it incurs operational cost. Therefore chances are this policy would cause a loss of mining power, especially when the initial miner population is small, rendering the system more vulnerable to attacks.

A.4 Adversarial advantage

A block-acceptance policy depends only on the number of blocks by the adversary since its first one. Therefore an adversary's best strategy is simply to publish its blocks as soon as they won't be rejected. Denote this strategy as Σ_{stat}.

Clearly, an adversary will submit $F^{-1}(1-\alpha, td\cdot \mathsf{rate}_{\text{best}})$ blocks within $[0,t]$. On the other hand, the strongest honest CPU with rate $\mathsf{rate}_{\text{best}}$ mines $td\cdot\mathsf{rate}_{\text{best}}$ blocks in expectation. Recall that according to our Markov chain analysis, P_{stat} incurs false rejections for honest miners with probability $w_h(\alpha)$, which further reduces the payoff for honest miners. For a (non-degenerate) security game S, in which $\mathcal{A}$ uses strategy Σ_{stat}, the advantage is therefore:

$$\mathsf{Adv}_{\mathcal{A}}^{S(P_{\text{stat}}^{\alpha})} = \lim_{t\to\infty} \frac{F^{-1}(1-\alpha, td\cdot\mathsf{rate}_{\text{best}})}{(1-w_h(\alpha))\; td\cdot\mathsf{rate}_{\text{best}}} \tag{5}$$

Theorem 1. *In a (non-degenerate) security game S where* $\mathcal{A}$ *uses strategy* Σ_{stat}*,*

$$\mathsf{Adv}_{\mathcal{A}}^{S(P_{stat}^{\alpha})} = \frac{1}{1-Waste(P_{stat}^{\alpha})}.$$

Proof. Let $\lambda = td\cdot\mathsf{rate}_{\text{best}}$. It is known that as λ for a Poisson distribution goes to infinity, it converges in the limit to a normal distribution with mean and variance λ. Therefore,

$$\lim_{\lambda\to\infty}\frac{F^{-1}(1-\alpha,\lambda)}{(1-w_h(\alpha))\lambda} = \lim_{\lambda\to\infty}\frac{\lambda+\sqrt{\lambda}z_p}{(1-w_h(\alpha))\;\lambda} = \frac{1}{1-w_h(\alpha)}.$$

□

Early in a blockchain's evolution, the potential advantage of an adversary is relatively high. The confidence interval is wide at this point, allowing the adversary to perform frequent generation without triggering detection. As the adversary publishes more blocks, the confidence interval tightens, forcing the adversary to reduce her mining rate. This is illustrated by our numerical simulation in Section 4.3.

Ensuring Authorized Updates in Multi-user Database-Backed Applications

Kevin Eykholt
University of Michigan Ann Arbor

Atul Prakash
University of Michigan Ann Arbor

Barzan Mozafari
University of Michigan Ann Arbor

Abstract

Database-backed applications rely on access control policies based on views to protect sensitive data from unauthorized parties. Current techniques assume that the application's database tables contain a column that enables mapping a user to rows in the table. This assumption allows database views or similar mechanisms to enforce per-user access controls. However, not all database tables contain sufficient information to map a user to rows in the table, as a result of database normalization, and thus, require the joining of multiple tables. In a survey of 10 popular open-source web applications, on average, 21% of the database tables require a join. This means that current techniques cannot enforce security policies on all update queries for these applications, due to a well-known view update problem.

In this paper, we propose phantom extraction, a technique, which enforces per user access control policies on all database update queries. Phantom extraction does not make the same assumptions as previous work, and, more importantly, does not use database views as a core enforcement mechanism. Therefore, it does not fall victim to the view update problem. We have created SafeD as a practical access control solution, which uses our phantom extraction technique. SafeD uses a declarative language for defining security policies, while retaining the simplicity of database views. We evaluated our system on two popular databases for open source web applications, MySQL and Postgres. On MySQL, which has no built-in access control, we observe a 6% increase in transaction latency. On Postgres, SafeD outperforms the built-in access control by an order of magnitude when security policies involved joins.

1 Introduction

Stateful (server-side) applications often rely on a back-end database to manage their state. When sensitive data is involved, these databases become prime targets for attackers. Web applications, especially, are subject to attacks due the large number of users and easy access through the Internet. To protect the sensitive data these web application store in thee database, proper access control is required. Unfortunately, securing web applications has remained a challenge, mainly for three reasons: (i) the incompatibility of modern web architecture and the security mechanisms of database systems, (ii) limitations of the automated techniques for enforcing a security policy, and (iii) failure to write secure, non-buggy code when implementing access contol logic within the application.

1. Architectural Incompatibility — Some database systems provide vendor-specific syntax for fine-grained access control [13, 16, 18, 23, 24] with support for security policies that involve joins. However, use of a specific database's access control mechanism makes the application DBMS-specific. A larger problem is that existing the web application architecutre is incompatible with the database access control architecture. Most modern web applications use an over-privileged database account with the authority to access and modify any information stored in the database [19, 21]. This setup is popular because it avoids the performance overhead of creating (and tearing down) new database connections on-the-fly for possibly millions of end users. Using an overprivileged account, the web application can simply maintain a pool of active database connections that can execute queries on behalf of any end user.

To use a DBMS' mechnisms, (1) each application user must be assigned a unique database account, and (2) a separate database connection (using the assigned account) must be used for processing each user's requests.[1] Making such changes to web applications would prevent

[1] This is because most databases, for security reasons, disallow [31] or limit [20, 23, 41] a connection's ability to switch its user context once it is created. Databases that allow but limit context switching for existing connections are still vulnerable to (1) application bugs in switching users, and (2) SQL injection whereby malicious users manipulate the functionality to switch to previous user contexts.

them from using a connection pool, and result in performance degradation [33, 48].

2. Limitations of Existing Techniques — The incompatability of DBMS access control with modern web application has resulted in numerous access control solutions, which exist as a security layer between the application and the database. These solutions restrict each application user to a portion of the database [39, 43, 36]. Before issuing a query, the application rewrites the query to use the restricted portion of the datbase based on the authenticated user. Often, *database views* are the central mechnism these systems rely on [39, 43]. Although current techniques can fully restrict database reads [43, 45], they do not support database updates (i.e., `INSERT`, `DELETE`, and `UPDATE` queries) due to the *view update problem* [27]. The view update probem states that write queries cannot execute on a view when there is not a "one-to-one relationship between the rows in the view and those in the underlying table" [22]. Such a problem can occur when a view definition contains a join query.

Consider OsCommerce, an open-source e-commerce web application, which allows customers to leave reviews on products. The metadata for reviews is stored in the *reviews* table. In OsCommerce, customers can only review products they have purchased. The following query represents the allowable set of rows that conform to this access control policy:

```
SELECT R.*
FROM review R,orders_products OP,
   orders O
WHERE   O.customer_id=current_id
   AND
        O.orders_id=OP.orders_ID
           AND
        OP.product_id=R.product_ID
           AND
        R.customer_ID=current_id;
```

The first three conditions in the `WHERE` clause obtain the set of products a customer has ordered, and the last condition ensures that the customer and the current user are the same. Although this view definition correctly captures the intended access control policy, it cannot be enforced with existing query re-writing techniques, as such a view is not updatable. This is because there is no one-to-one mapping between the rows in the view and those in the base tables, e.g., a user can purchase a product multiple times across different orders.

Previous work has largely ignored the view update problem by assuming that any table on which a security policy is defined contains the user id, thus joins are not required to map a user to rows in the table [36, 39, 43]. Unfortunately, as our survey of popular open-source web applications in this paper reveals, on average, 21% (and up to 50%) of the tables do not contain sufficient information to map a user to rows in the table due to a lack of a user id field or similar, thus a join query is required. In other words, existing access control solutions would not be able to fully support database updates for any of these popular applications.

3. Unsecure and Buggy Code — In today's web application architecture, developers cannot rely on databases to enforce access control policies due to the reliance of the applications on a pool of persistent connections. They cannot use existing access control solutions either, due to the lack of support for write queries when tables that do not contain user information. As a result, developers often implement their own access control login within the application and such implementations must be secure [47]. In theory, the application will only issues queries in accordance with the access control rules for the authenticated user.

In practice, however, most implementations have security flaws. According to a five-year study of 396 open-source web applications, over 200 security vulnerabilities were discovered [26]. Likewise, a study of vulnerabilities in open-source Java projects [12] found 8.61 defects for every 100,000 lines of code. Unsecure or buggy code leave web applications vulnerable to numerous access control bypass attacks, such as SQL injection [8, 25, 28, 34, 35, 38, 42] and insecure direct object reference attacks [14, 44]. These issues allow attackers to cause the application to issue unauthorized queries with respect to the current user and leak sensitive data. For example, a vulnerability in Symantec's web-based management console allowed authenticated low-privileged users to execute arbitrary SQL queries on the backend database, and change their account privileges to administrator level [25]. Data leaks have also occurred in mobile apps, such as Uber and SwiftKey, that use a database-backed web service [15, 30].

Such vulernerabilities occur because there is not a declarative way to define an access control policy within the application. Rather, developers have an idea of what the security policy should be and attempt to implement in code whenever database queries are issued. A proper access control solution should exist between the application and the database and allow a devloper to declaratively define an access control policy in a centralized location. Furthermore, the solution should meet the following key criteria:

C1. *Generality*: The access control policy can be enforced for all read (`SELECT`) and write (`UPDATE`, `INSERT`, and `DELETE`) queries on any table (whether it contains the user id as a column or not);

C2. *Correctness*: The application user should only be able to access and modify authorized information as

defined by the developer's policy;

C3. *Database Independence*: The mechanism should not rely on vendor-specific features of the backend database; and

C4. *Connection Sharing*: For compatibility with existing web applications, the solution should allow for reusing a set of persistent and over-privileged database connections to serve requests of multiple end users.

Our Approach — We introduce the **phantom extraction** technique for enforcing access control on write queries, while being robust to policies that involve joins. Before executing a write query, we copy the rows from the target table that the user is authorized to modify into a temporary table. The query is then copied and modified to operate on the temporary table. We refer to modified copy as the query's **phantom**. Once SafeD deems the phantom's modifications on the temporary table to be safe, the changes are copied over to the original table. The view update problem does not apply to phantom extractions because database views are not used in any part of the process. The correctness of phantom extraction is established with a formal notion of *query safety* that guarantees a query is compliant with a given security policy (see Section 5). We present necessary and sufficient conditions to achieve that guarantee.

With phantom extraction, we created SafeD (Safe Driver), a pratical access control solution that supports policy enforcement for both read and write queries. SafeD extends existing database drivers, such as JDBC and ODBC, and transparently enforces an application's access control policy. Policies are defined by a set of declarative statements which use a syntax similar to database views. Since the access control is evaluated at the driver level, SafeD does not require a new database connection to establish a new user context, nor is it tied to a particular database backend. The user context is established when users authenticate themselves to the application, and SafeD enforces the access control policy for all database connections in the application's connection pool.

Contributions —

1. We surveyed 10 popular open-source web applications and show that complex row-level access control policies with joins queries are required for, on average, 21% of the tables to define per-user policies (Section 3).

2. We establish a formal notion of *query safety* and prove the necessary and sufficient conditions for the safety of all database operations, i.e., `SELECT`, `DELETE`, `INSERT`, and `UPDATE` (Section 5).

3. We present a new technique, **phantom extraction**, which ensures the safety of database updates with full generality (Section 6).

4. We present SafeD as a practical solution for enforcing per-user access control policies within the database. On MySQL (which lacks built-in support for row-level access control for read/write queries), a 6% increase in transaction latency is observed (Section 8.1). On Postgres, SafeD provides comparable performance to Postgres' access control for simple policies, but outperforms it by an order of magnitude for row-level access control policies with joins in terms of transaction latency and throughput (Section 8.2).

2 Related Work

The related work on access control can be categorized into application-centered versus database-centered approaches.

2.1 Application Access Control

CLAMP[43] and Nemesis [36] have similarities to SafeD in that each defines a per-user access policy in terms of views on the underlying tables. However, both works assume the underlying tables contain a column, such as a user id, which enables mapping a user to rows in the table. If the underlying table does contain a column, such as a user id [column], a join with one or more additional tables is necessary. For example, in OsCommerce, the security policy for *reviews* requires joining *reviews* with *orders* and *orders_products* to map a user to the set of reviews they can update (see Section 1). A view defined by a join query can result in the *view update problem* [27]. A database view is **updatable** only when there is a one-to-one mapping of rows in the view to rows in the underlying table. Therefore, CLAMP does not support per-user access control for write queries when the database view is not updatable. SafeD does not use database views to define per-user access control policies. Rather, SafeD rewrites queries to conform to the defined access control policy and executes the modified queries on tables in the database, thus avoiding the view update problem entirely.

In addition to assuming a table contain a column that enables mapping a user to rows in the table, Nemesis [36] also assumes that `INSERT` statements do not read existing rows in the database. However, this may not hold in many cases (e.g., consider `INSERT INTO T1 AS SELECT * FROM T2`). This query reads information from table *T2* and copies it into *T1*. In contrast, SafeD makes no such assumption and can handle both blind and nested `INSERT` queries.

Diesel [39] implements module-based access control, whereby an application is broken into a series of code

Solution	Generality	Correctness	Database Independent	Connection Sharing
Diesel [39]	x	x	✓	✓
CLAMP [43]	x	✓	✓	✓
Nemesis [36]	x	✓	✓	✓
Oracle [13]	✓	✓	x	x
Postgres [23]	✓	✓	x	x
SafeD	✓	✓	✓	✓

Table 1: Comparison of SafeD to existing solutions. (See Section 1 for criteria definitions.)

modules, each restricted to only a portion of the database needed to complete its task. While the authors remark that Diesel can be extended to user-based access control (e.g., by duplicating all the modules for each connected user), they also acknowledge that their solution would not scale [39] and suggest using database access control in conjunction. SafeD does not require database access control and is thus compatible with today's web architecture.

Table 1 summarizes SafeD's differences with prior work.

2.2 Database Access Control

Stonebraker and Wong presented the first database access control through query rewriting in INGRES [46], which supported read queries, but not write queries. INGRES' treatment of read access restrictions as predicates has been adopted by modern databases. For instance, Oracle's VPD allows administrators to define a series of functions for each relation based on the mode of access. These functions append a predicate to the query to enforce access rules based on the user context [29]. Defining these functions via procedural code offers flexibility, but is also more error-prone compared to simply writing declarative policy statements as in SafeD.

More recently, Postgres 9.5 has added support for fine-grained access control, whereby administrators define two policy conditions for each table and each role. The first condition is evaluated against `SELECT` and `DELETE` queries, while the second condition is evaluated for `INSERT` queries. (`UPDATE` queries are treated as a `DELETE` followed by an `INSERT`.) Postgres's design assumes that if users can view information, they should also be able to delete it. SafeD does not make this assumption, decoupling a user's read and write permissions.

As mentioned in Section 1, the key advantage of SafeD over access control features of database systems is that the former is compatible with today's web application architecture. Both Oracle and Postgres rely on the database connection to obtain user context. Web applications have avoided this approach due to performance implications of creating new database connections [33]. In contrast, SafeD allows applications to share connections across users. SafeD also provides database-independence, and offers a simple syntax for defining a security policy compared to database solutions. SafeD only requires an understanding of `SELECT` queries. Oracle and Postgres each use a different syntax, and require developers to understand more complicated concepts, such as creating system contexts, system context triggers, and policy functions. (See Table 1.)

3 Survey of Modern Web Applications

Modern web applications currently define and enforces access control policies within the code. MediaWiki, for example, stores user groups and the associated access control rules within a PHP config file [4], and the access control rules are enforced within the PHP functions. As evidenced by numerous attacks on web applications, the current apporach is flawed [8, 25, 28, 34, 35, 38, 42]. Thus, prior work has proposed alternatives that decouple access control logic from the application, but all existing work cannot handle write queries when a declarative policy definition requires a join. These types of policies, which we call **join policies**, occur when a database table does not contain a field corresponding to a user, such as user id, which enables a mapping of rows in the table to a user. To determine the prevalence of join policies in modern web applications, we surveyed 10 open-source Java web applications of varying size and complexity.

Before determining which tables require a join policy, we first must identify the user information table. Typically, the user information table contains a unique user ID that is used in other tables to map a row to a user. Given two tables, A and B, we say that table *A* is the **parent** of table *B* if *B* has a column that refers to the primary key of *A*. Similarly, given two tables, A and B, we say table *A* is the **grandparent** of table *B* if *B* has a column which refers to the primary key of a child of *A*. Often, these relationships are represented as a foreign key reference, but some of the applications we surveyed did not contain any such declarations. The lack of explicit foreign key declarations required us to infer the implied parent and grandparent relationships based on the database schema and structure.

In general, any table that has the user information table as its grandparent requires a join policy to define a per-user access control policy. Additional tables are included in our evaluation if accompanying documentation indicates a relationship between a user and a table despite no parent or grandparent relationship with the user information table. For example, in MediaWiki, pages can be semi-protected so only confirmed and autoconfirmed users[2] can modify them. In MediaWiki 1.10 and later, this information is stored in the *page_restriction* table. In

[2]Users whose account is at least four days old and has at least ten edits to Wikipedia

Table 2: Summary of the number of tables in 9 web applications that require a join query to define a per-user policy declaratively.

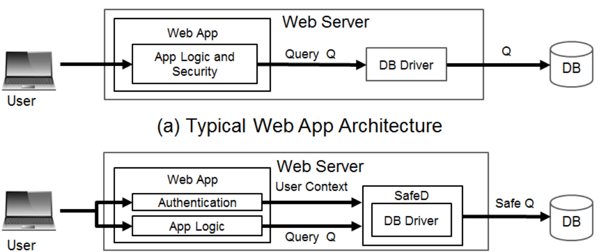

Figure 1: Two web application architectures. A trusted authentication component within the app or on the server provides SafeD with the correct user context.

order to define a policy for the *page* table, a join with *page_restriction* is necessary to determine which pages a user can edit.

For each web application, we recorded the total number of tables in the database and the fraction of those tables that require a join query in a declarative policy definition to enforce a per-user policy.

Our survey results, shown in table 2, indicate that an average of 21% of an application's database tables require a join query to define a per-user policy declaratively. Web applications with a large amount of normalization tend to have a higher number of tables requiring a join query in their policy. LimeSurvey, which has the highest percentage of such tables, contains a user table with only a few children, but the children are heavily normalized resulting in numerous grandchildren. Zen Cart and Cyclos, which contain user tables with only a few children but multiple grandchildren, show similar trends.

4 Overview

Figure 1 shows the deployment architecture of SafeD. SafeD extends an existing database driver (e.g., JDBC or ODBC) to add a security layer that ensures all queries issued by the application are compliant with the defined declarative security policy (see Figure 2).

The application developer (or the system administrator) specifies the desired security policy via a set of declarative rules. These rules define the read and write permissions of each application user in the database (Section 5). At run-time, SafeD automatically transforms each query into a read-safe or write-safe query (i.e., one that is compliant with the read and write policies). SafeD provides Truman model semantics, i.e., the transformed query provides the same results as if the original query executed on a restricted view of the database that is accessible to the user. SafeD supports arbitrary read and write queries. SafeD's query transformation module (Section 6) ensures necessary and sufficient conditions for query safety. A developer can also use SafeD in an experimental debugging mode of operation, in which a query is tested for policy-compliance first. In this mode (a.k.a. non-Truman model [45]), a query is executed only if it is compliant, and is rejected otherwise (see Section 6). We implement our prototype by extending a JDBC driver (Section 7), and evaluate it using the TPC-C benchmark. Our results show that SafeD can protect practical database-backed applications at a negligible cost (Section 8).

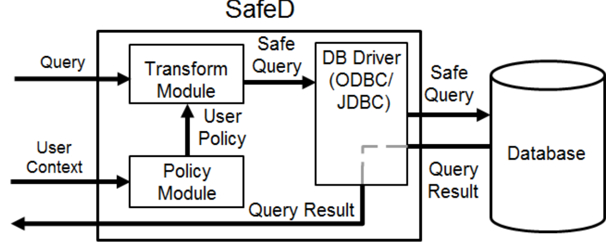

Figure 2: Given a query and a user context, SafeD obtains the user's security policy and creates a safe version of the query, which is executed on the database.

4.1 Threat Model

We assume that a database app (e.g., web app) is benign, but buggy. We assume a remote attacker who attempts to exploit the web app, but cannot authenticate as another user. This is a reasonable assumption since most existing web frameworks, such as Django or Tomcat, have standardized support for authenticating users. In other words, the web application is assumed to reliably verify the end-user's identity and make it available to SafeD along with the issued query, but the query itself can be arbitrarily over-privileged, due to bugs or remote exploits.

Note that there are two causes of data leakage in a web application: incorrect policy definitions and incorrect policy enforcement. SafeD focuses on the latter, ensuring that all queries obey the developer-defined policy. However, if the policy is incorrectly defined, SafeD cannot prevent the undesirable actions of authorized users. One benefit of this decoupling is that developers are

forced to explicitly define their security policies. These explicit definitions are often easier to debug than their implementation code.

5 Formal Results

In this section, we first describe the notion of per-user, row-level security policies. We then formally define the notion of safety for read and write queries. Finally, we derive necessary and sufficient conditions to achieve safety. These conditions are subsequently used to show correctness of our algorithms that render queries safe with respect to a given policy. Appendix B provides several examples of how safety can be enforced based on the results and definitions presented in this section.

5.1 Security Policy Definition

In SafeD, a security policy is composed of two sets of access rules: the *read policy* and the *write policy*. Given a user, the read policy identifies the tuples in the database that the user can read. Likewise, the write policy identifies the tuples in the database that the user can modify, remove, or add. These policies are specified as a *read set* and a *write set* for each table of the database. For each user and each table, a *read (write) set* identifies the set of tuples the user can read from (modify, remove from, or add to) that table. On a given table, the write set of a user must be a subset of his/her read set (i.e., users can read tuples that they can modify).

SafeD assumes that the authentication component of the web application provides the user's identity and, optionally, a 'role' assigned to the user. This role is only relevant to SafeD for selecting a policy and is not related to database roles. The user identity would usually be based on his/her authentication cookie and, possibly, the web request being made. SafeD takes as input a policy file comprised of a set of policy statements defining the read sets and write sets for each user and each role. The following are examples of policy statements for the customer and manager roles [3] :

```
DEFINE WRITESET FOR
    ROLE customer USER $i
     ON TABLE cust_info
          AS SELECT * FROM cust_info
               WHERE cid=$i
```

Listing 1: Customer's write set for the *cust_info* table.

```
DEFINE WRITESET FOR ROLE manager USER $i
     ON TABLE ordertable
          AS SELECT * FROM ordertable
```

Listing 2: Manager's write set for the *ordertable* table.

[3]For simplicity, we define policies at the granularity of entire rows, but SafeD can be extended to finer granularities, e.g., at the attribute level.

Here, \$i is a wildcard that is replaced at runtime with the attribute(s) identifying the current user.[4] Read sets are defined similarly, except that the `READSET` keyword is used instead of `WRITESET`.

The definition of the read and write sets for a table may involve nested queries or joins with other tables. For example, suppose there are two additional tables in the database: *carts* and *cart_info*. The *carts* table maps a customer id to a cart id (cart_id), while the *cart_info* table contains the items in each cart. Since *cart_info* only contains cart_id, a join with *carts* is necessary to retrieve the cid. Listing 3 shows the *cart_info* table's read set for different customers.

```
DEFINE READSET ON ROLE customer USER $i
     ON TABLE cart_info
     AS SELECT * FROM cart_info x,
         carts y
         WHERE x.cart_id = y.cart_id
           AND y.cid=$i;
```

Listing 3: The read set for *cart_info* involving a join.

Next, we define read and write sets formally. In our discussion, an operation can be a `SELECT`, `INSERT`, `DELETE`, or `UPDATE` statement. (We use query and operation interchangeably.) We denote the set S as the **tuple space**, representing the (infinite) universe of all possible tuples. A **relational database** consists of a collection of tables. A **table** T is a finite subset of S. Since each element of a set is unique, we allow for duplicate entries by taking the Cartesian product of S with the natural numbers, $\mathbb{N} \times S$, and use that as our new tuple space. Duplicate entries will have a unique number in S. We also denote the number of tuples in a table T as $|T|$. Furthermore, given any subset $s \subseteq S$, we denote its complement as $s^c = S \setminus s$.

Given a set of **users** U, we define a **security policy** as a pair of two functions (p_r, p_w), where p_r is the **read policy** and p_w is the **write policy**, defined below.

Definition 1 (Read/Write Policy)**.** Given a user u, the read policy $p_r(u)$ is the subset of S that u is allowed to read. Likewise, the write policy $p_w(u)$ is the subset of S that u is allowed to add or modify.

A modification can be addition, removal, or update of a tuple. Based on the definition of a security policy, we now define the **read set** and **write set** for a user u.

Definition 2. (Read/Write Set) Given a user $u \in U$ and a table $T \subseteq S$,

- The read set of T, $V_r(T,u) = T \cap p_r(u)$, represents the set of tuples in T that user u can read.

[4]Currently, we assume the mapping of the current user to their role and identifying attribute is performed by the application.

- The write set of T, $V_w(T,u) = T \cap p_w(u)$, represents the set of tuples in T that user u can modify[5].

Note that the READSET and WRITESET statements introduced earlier correspond to these formal notions of read and write sets, given a table and user information, by simply instantiating the user identifier and applying their SELECT statements to T.

We also define the negated read set of T as $NV_r(T,u) = T \setminus V_r(T,u)$, which is the set of all tuples in T the user cannot read. Similarly, negated write set of T $NV_w(T,u) = T \setminus V_w(T,u)$, which is the set of all tuples in T the user cannot modify. It is trivial to show $NV_r(T,u) = T \setminus p_r(u)$ and $NV_w(T,u) = T \setminus p_w(u)$.

5.2 Safe Reads and Safe Writes

Now that we have formally defined a security policy and the read/write sets, we can formally define safe operations. We first consider read queries, which correspond to SELECT queries in SQL, and then write queries, which correspond to UPDATE, INSERT, and DELETE queries in SQL.

Definition 3 (Read-safety)**.** A query $\mathscr{R}$ by a user u with read policy p_r is **read-safe** if the query would return the same result when executed on the subset of tuples in the accessed tables that are readable to the user, namely $p_r(u)$.

In other words, a read-safe SELECT query should return the same result whether executed on the original tables or on the read sets of those tables. Note that $p_r(u)$ can, in general, be a set of tuples from multiple tables for queries with joins.

Corollary 1. *A query that only accesses tables whose tuples are all in $p_r(u)$ is read-safe.*

The above corollary implies the following: if in a query $\mathscr{R}$, each table T_i of the database accessed in the FROM clause is replaced by a table T_i' where $T_i' = T \cap p_r(u)$, then the resulting query $\mathscr{R}'$ will be read-safe. Such an approach has been proposed by previous systems [43, 46], and is also taken by SafeD. (As we will discuss shortly, enforcing safety for write queries is more challenging.) SafeD automatically transforms any SELECT queries (including those nested within other queries) by appending additional tables and conditions to the operation's FROM and WHERE clauses, respectively, that are implied by the READSET policy rules. We refer to this process as **read policy intersection**. Also, note that checking whether a query is read-safe can be more expensive than transforming it to be safe, since checking may require executing the query twice.

[5] Since an INSERT query adds tuples not in T, the write set is evaluated after the new tuples are added (See Section 5.2)

We next define the notion of read-safety and write-safety for a write query. As in SQL, we assume that a write query can read any set of tables (via nested SELECT statements), but modify only a single table and return, as its result, the modified table. Intuitively, a write query by a user u that updates a table T is **write-safe** if 1) it does not modify anything outside table T's write set, and 2) any nested SELECTs within it are also read-safe (so that it does not leak data via the writes). Formally,

Definition 4. A write query $\mathscr{W}$ by a user u that modifies table T is **read-safe** if all of its nested queries (which must be SELECTs) are read-safe. Furthermore, it is **write-safe** if it does not modify the *set* of tuples that are outside its write set for table T, i.e., $NV_w(T,u) = NV_w(\mathscr{W}(T),u)$, where $\mathscr{W}(T)$ represents the tuples in table T after executing $\mathscr{W}$.

Let $A = \mathscr{W}(T) \setminus T$ represent the new entries added by $\mathscr{W}$ to T, and let $D = T \setminus \mathscr{W}(T)$ represent the entries removed from T. It trivially follows that $\mathscr{W}(T) = (T \cup A) \setminus D$. For INSERT queries, D will be an empty set and for DELETE queries, A will be an empty set. For UPDATE queries, both A and D could be non-empty.

We denote $\langle \mathscr{W}(T) \rangle$ to be the sum of the cardinality of A and the cardinality of D for tuples added or deleted from T as a result of executing $\mathscr{W}$. It can be formally shown that the definition of write-safety does not require comparing $\mathscr{W}(T)$ with T, but only examining cardinality of changes. In particular, the following theorem can be shown to hold:

Theorem 1. *Given a user $u \in U$, a tuple space S, a set of tuples $s \subseteq S$, a table $T \subseteq S$, a write operation $\mathscr{W}$ that is read-safe, the write policy p_w, and the write set $V_w(T,u)$, the following conditions,*

$$(1) \quad V_w(\mathscr{W}(T),u) = \mathscr{W}(V_w(T,u))$$
$$(2) \quad \langle \mathscr{W}(T) \rangle = \langle \mathscr{W}(V_w(T,u)) \rangle$$

are necessary and sufficient to ensure $\mathscr{W}$ is write-safe, i.e.,

$$NV_w(T,u) = NV_w(\mathscr{W}(T),u).$$

Intuitively, condition (1) states that the resulting table from a write-safe write query should be the same whether the write is done on the original table T or on the write set $V_w(T,u)$. Condition (2) states that the total count of tuples added/deleted in T from executing $\mathscr{W}(T)$ should be identical to the count of tuples added/deleted if $\mathscr{W}$ was instead executed on $V_w(T,u)$. This ensures that $\mathscr{W}$ does not cause any tuples to be moved outside its write set as a result of changes. We defer the proof of Theorem 1 to the Appendix.

We now can define the notion of a query being *safe* in terms of read-safety and write-safety for the four types of queries addressed in this paper.

Definition 5 (Safe Query)**.** Given a policy (p_r, p_w), we consider a SELECT query for a user u to be *safe* if it is read-safe. We consider an INSERT, DELETE, or UPDATE query to be *safe* if it is read-safe and write-safe.

Corollary 2 (Safety of INSERT)**. INSERT queries:** *If all created tuples by an INSERT query are within the write set of the user, then the query is write-safe.*

Proof outline: In this case, the same tuple(s) will be added, irrespective of whether they are added to T or $V_w(T,u)$. Thus, conditions (1) and (2) in Theorem 1 hold.

Corollary 3 (Safety of DELETE)**. DELETE queries:** *A DELETE query that only deletes from $V_w(T,u)$ is write-safe.*

Proof outline: The query only deletes tuples in the write set so tuples in $NV_w(T)$ are not changed. Therefore, it trivially satisfies Definition 4. of Theorem 1 and takes advantage of the properties of DELETE.

Corollary 4 (Safety of UPDATE)**. UPDATE queries:** *An UPDATE query $\mathscr{W}$ that only updates tuples in $V_w(T,u)$ is write-safe if $\mathscr{W}(V_w(T,u)) \setminus V_w(T,u)$ is within the user's write set.*

Proof outline: An UPDATE can be thought of as a DELETE of the old tuples followed by an INSERT of the new tuples. From Corollary 3, we know the DELETE operation of the UPDATE is safe. If $\mathscr{W}(V_w(T,u)) \setminus V_w(T,u)$ is in the user's write set, then the INSERT operation of the UPDATE is write-safe due to Corollary 2.

The new value of an updated tuple has to be within the write set. If T is replaced by $V_w(T,u)$ in Theorem 1, it can be shown that the condition in the corollary implies both conditions of the theorem.

6 SafeD Design and Algorithms

SafeD operates as a modified JDBC driver that is transparent to the application. It transforms a submitted query into a safe query and returns the corresponding result. To do that, SafeD applies the Truman model [32] semantics for read queries, in which a query only sees tuples in its read sets. For write queries, SafeD uses a novel technique, called *phantom extraction*, to ensure only the portion of the table within the write set is updated (Section 6.1).

SafeD also provides an experimental (i.e., debugging) mode in which a read/write operation is carried out only if it is safe in the first place (a.k.a. "non-Truman" model [45]). Unfortunately, with the current state of the art, providing such a semantics is expensive. Consider a SELECT query. To know whether the query is safe, one needs to run the query on the original tables as well as their read sets and compare the results. Truman semantics avoid the need to execute the query twice since execution of the query on the original tables is not required. We prototyped this strategy and tested it with the TPC-C benchmark and found it to thrash at low transaction rates. We thus focus on the strategy of transforming queries to make them safe in rest of the paper.

6.1 Phantom Extraction

We say that a write query's **phantom** is a read-safe copy of the query, which only updates rows in the write set. In SafeD, write queries issued by the application are never executed on the database. Instead, each query's phantom is extracted and evaluated for write-safety. Phantom extraction involves 3 steps. First, transform the original query into a read-safe query using read policy intersection (Section 5.2). Then, modify the read-safe query so it only updates rows in the write set. This modified query is the *phantom*. Finally, determine if the phantom is write-safe. If the query's phantom is write-safe, the phantom's changes to the database are made permanent. Otherwise a permission violation error is returned and the changes are rolled back. In 6.2, we present two algorithms for phantom extraction.

6.2 Query Transformation Strategy

The transformation module automatically transforms a query Q into a safe query that is guaranteed to satisfy the two conditions in Theorem 1 for read-safety and write-safety, while providing the illusion that the query operates on the view of tables that are in the user's read set and write set. The algorithm we present can, at times, require issuing multiple queries to the database to check write-safety. Appendix B provides several illustrating examples of query transformation using the algorithms presented in this section.

Algorithm 1 shows the general transformation logic to transform a query Q issued by a user u. The queries currently handled by SafeD include SELECT, INSERT, UPDATE, and DELETE queries, which require row-level access controls. The transformation algorithm is a two-step process. First, SafeD must ensure that the transformed query is read-safe, i.e., $s \subseteq p_r(u)$ is true, where s is the set of tuples read by the query and gives the illusion that the query is running against the read set of accessed tables in the database (lines 2-5). Given a user u and a query Q, SafeD uses read policy intersection (Section 5.2) to create a read-safe query rsQ. Read policy intersection automatically transforms a SELECT query in Q into one that is read-safe by appending additional tables and conditions to each query based on the read policy.

Nested Queries (read-safety) — SELECT queries can be nested within other queries, including write queries. SafeD transforms them recursively to make them read-safe. Starting from the deepest sub-query, SafeD concatenates the associated read view predicates to the

`WHERE` clause of the sub-query.

Write Queries (write-safety) — Given *rsQ*, a read-safe transformation of Q, SafeD next executes the PhantomExtract function that results in a write-safe execution of the query using the phantom extraction technique (line 8). An input to PhantomExtract is the WRITESET definition that applies to this query (which is essentially a `SELECT` statement – see Section 5.1).

Algorithm 1 General Safe Execution Algorithm

```
1: function SAFEEXECUTE(USER u, QUERY Q)
2:     readpolicy ← GetReadPolicy(u)
3:     rsQ ← IntersectReadPolicy(Q, readpolicy)
4:     if (Q is a Select query) then
5:       return Execute(rsQ)
6:     T ← GetWriteTable(rsQ)
7:     writesetdef ← GetWriteSetDef(u, T)
8: return PhantomExtract(rsQ, T, writesetdef)
```

SafeD uses one of two strategies for implementing the PhantomExtract function: V-Copy or No-Copy. Both algorithms will result in only allowing permissible writes on the database. We present V-Copy strategy first.

The V-Copy strategy is shown in Algorithm 2. Instead of modifying T directly, an empty temporary table with the same schema as T is created in the database and the corresponding reference (i.e. the table name), `tempT`, is returned. The algorithm uses Corollary 2 to check the safety of `INSERT` (line 3), which means all inserts are performed on an empty table, $tempT$. For `UPDATE` or `DELETE`, the write set of T is added to $tempT$ during initialization (lines 5-6). After initilizing $tempT$, *rsQ* is modified to execute on it, thus creating $phantom$, the phantom of the original query. After executing $phantom$ on the database (line 8) , either (1) new tuples are inserted into $tempT$; (2) tuples are deleted from $tempT$; or (3) tuples are updated in $tempT$;. The check on Line 10 holds if the query's phantom is write-safe. The remaining lines of Algorithm 2 ensure that inserted or updated tuples have not gone outside the user's write set for table T (if they have, an exception is raised). Finally, T is modified based on the state of $addTup$ and $rmTup$

An alternate strategy, No-Copy (Algorithm 3), can sometimes reduce the amount of work performed by the database and evaluates the conditions of Theorem 1 locally when possible. If the write set does not contain a join, No-Copy parses non-nested queries and determines if the query would result in tuples outside of the write set. This parsing can be always done for blind `INSERT` queries, which contain the new values for a tuple in the `VALUE` clause. Sometimes, the parsing can be done for `UPDATE` queries as well. If the `UPDATE`'s `SET` clause does not assign values based on a computation, i.e., "at-

Algorithm 2 V-Copy PhantomExtract

```
1: function PHANTOMEXTRACT(QUERY rsQ, STRING T, WRITESET writesetdef)
2:     if rsQ is an Insert Query then
3:         tempT ← CreateTemp(T, null)
4:     else
5:         authTup ← GetAuth(T, writesetdef)
6:         tempT ← CreateTemp(T, authTuples)
7:     phantom ← ChangeWriteTable(rsQ, tempT)
8:     Execute(phantom)
9:     curTup ← GetAll(tempT)
10:    authTup ← GetAuth(tempT, writesetdef)
11:    rmTup ← ∅;    addTup ← ∅
12:    if curTup == authTup then
13:        authTup ← GetAuth(T, writesetdef)
14:        addTup ← SetMinus(curTup, authTup)
15:        if rsQ is not an Insert Query then
16:            rmTup ← SetMinus(authTup, curTup)
17:    else   Raise permission exception
18:    Insert(T, addTup)
19:    Delete(T, rmTup)
```

tribute_name = function()", parsing can be performed. No-Copy creates a list of the attributes modified by the query and checks if any of the attribute are part of the write set's definition, i.e., contained in the `WHERE` clause of the write set. If so, then the value assigned to the attribute must satisfy the conditions defined in the write set. If the conditions are not satisfied, then the query will always result in tuples outside of the write set and is therefore not write-safe.

For `DELETE` queries, due to the Corollary 3, No-Copy executes the `DELETE` query on the subset of T that is within its write set, ensuring that only writable tuples are deleted.

Write set intersection is also used to transform *rsQ* into *phantom* if *rsQ* is an `UPDATE`. Since *rsQ* does not add tuples outside of the write set, $phantom$ will not either, which means condition (1) of Theorem 1 is satisfied. Condition (2) requires that the number of modifications made to a table is equal to the number of modifications made in the write set of the table. Since the query's phantom only modifies tuples in the write set by definition, the number of changes made by $phantom$ on T is equal to $\langle \mathscr{W}(V_w(T,u)) \rangle$ where $\mathscr{W}$ is the write operation representing $phantom$.

7 Implementation

We have implemented a prototype of SafeD by extending the JDBC driver. As previously shown in Figure 2, SafeD is comprised of two key modules: a transformation module and a policy one. The transformation module requires 317 lines of code in V-Copy and 452 lines in

Algorithm 3 No-Copy PhantomExtract

```
1: function QUERY rsQ, STRING T, WRITESET writesetdef)
2:     phantom ← NullQuery
3:     if rsQ is not an Insert then
4:         phantom ← IntersectWriteSet(rsQ, writeset)
5:     else
6:         phantom ← rsQ
7:     if phantom is a Delete then
8:       return Execute(phantom)
9:     if (phantom is a nested query) OR
           (writeset contains a join) then
10:        Use Algorithm 2
11:    attList ← GetAttributes(phantom)
12:    if not(CanEvaluateLocal(modifiedList, writeset))
   then
13:        Use Algorithm 2
14:    condList ← GetWhereConditions(writeset)
15:    for all a ∈ modifiedList do
16:        if condList.contains(a.name) then
17:            pass ←IsValidValue(condList, a.value)
18:            if pass == false then
19:                return Execute(NullQuery)
20: return Execute(phantom)
```

No-Copy. The policy module requires 119 lines.

Our policy module stores the read and write policies defined by the developer for each role, as well as a mapping between users and roles. Upon establishing a database connection, this module creates a connection state object that contains the security policy. When a user is identified, the module uses the supplied user context to initialize the read and write sets for the user. Given a SQL query and a user context, SafeD either verifies the compliance of the query before sending it for execution (in debug mode), or transforms it into a compliant query (in run-time mode).

8 Evaluation

Our experiments seek to answer the following questions:

1. What is SafeD's performance overhead for a database without built-in support for access control? (Section 8.1)

2. How does SafeD's performance compare to that of a built-in mechanism in a database that does support row-level access control? (Section 8.2)

3. How does SafeD's performance vary with the ratio of unsafe queries in the workload? (Section 8.3)

When studying SafeD's performance, we compare the V-Copy and No-Copy strategies. We experiment with both MySQL and Postgres. MySQL is perhaps the most popular open source database used by web applications, including several high-volume web sites, such as Facebook and Zappos [6]. However, given MySQL's lack of built-in support for row-level access control, web applications implement their own security policies. Postgres, on the other hand, offers row-level access control and thus provides a comparison point between a database-enforced access control with the costs of SafeD's approach. Postgres is also popular for small to medium-sized web applications [17].

Setup — In all experiments, we used two machines running Ubuntu 12.04 with 32GB of memory, configured as a client and a database server. The server had 8 CPUs (2.40 GHz each), while the client had 12 Xenon CPUs (2.67 GHz each). The client machine was used to send TPC-C queries to the database sever using the OLTP-Bench suite [37]. For TPC-C, we used its standard mixture of transactions (43% payment, 4% order status, 4% delivery, 4% stock-level, and 4% new order) and a scale factor of 20. For our database, we used MySQL 5.7 and Postgres 9.5.

Security Policies — Based on the semantics of the TPC-C benchmark, we used two different security policies. For both policies, there existed an administrator role with full read and write access to every table. In Policy 1, we defined two non-admin roles: a *manager* role and a *customer* role. A manager's user context contains two attributes: the warehouse id (WID) and the district id (DID). A customer's user context contains three attributes: the warehouse id (WID), the district id (DID), and the customer id (CID). Most of the database tables contain attributes that can be mapped directly to values in the user context. In these cases, a user is given read or write access (or both) to tuples where the user context matches the associated attributes in the tuples. When the target tables do not contain the necessary attributes to map the current user to tuples in the table, i.e, the *New_Order* and *Order_Line* tables, a join between the target table(s) and the *OOrder* table is necessary to obtain the set of order ids (O_ID) that the current user can access. The access rules for each role in Policy 1 are summarized in Table 3. We assigned each transaction type in TPC-C to one of the roles. Customers execute the new order, order status, and payment transactions, while managers execute the delivery and stock-level transactions.

Our second policy, Policy 2, tests the sensitivity of the performance results of SafeD and Postgres's row-level access control by adding restrictions to Policy 1. We modified the manager policy for the *OOrder* and *New_Order* tables as follows. First, a manager can read or modify tuples in the *OOrder* table only when the $O_C_ID \geq 0$. Second, a manager can only read and

Table Name	Customer	Manager
Customer(C_ID, C_D_ID, C_W_ID)	=(CID,DID,WID)	Full Access
District(D_ID, D_W_ID)	=(DID,WID)	=(DID,WID)
Warehouse(W_ID)	=(WID)	Full Access
OOrder(O_C_ID, O_D_ID, O_W_ID)	=(CID,DID,WID)	=(DID,WID)
New_Order(NO_O_ID)	Full Access	Full Access
Order_Line(OL_O_ID)	Full Access	Full Access
History(H_C_ID, H_D_ID, H_W_ID)	=(CID,DID,WID)	Full Access
Item	Full Access	Full Access
Stock	No Access	Full Access

Table 3: Policy 1 access rules for users. The user context is compared to the attributes in the table to determine if the user can read/write a tuple. Here, the read and write permissions are identical.

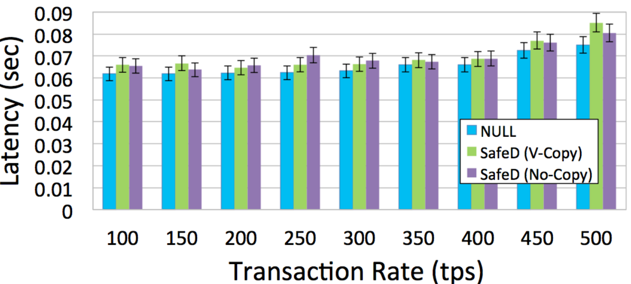

Figure 3: The performance overhead of different access control strategies compared to no access control (NULL) for TPC-C and Policy 1 on MySQL.

modify tuples in the *New_Order* table that correspond to authorized tuples in the *OOrder* table. Note that Policy 2 is still semantically equivalent to Policy 1 for the benchmark application since $O_C_ID \geq 0$ is always true. However, the purpose of these constraints is to introduce artificial join constraints in the manager policy, and thereby assess their impact on SafeD's performance. Table 4 summarizes the change and shows how it alters the database account's privileges.

Table Name	Manager
OOrder(O_C_ID)	$O_C_ID \geq 0$
New_Order(NO_O_ID)	Contain (OID) in OOrder

Table 4: Changes to Policy 1 to get Policy 2 and the new privileges for a database account. The changes result from modifications made to the manager role.

8.1 Performance Overhead of MySQL + SafeD

Since MySQL does not natively support row-based access control, we evaluated the overhead of adding access control to it using SafeD. Figure 3 shows the latency overhead on MySQL when SafeD verifies and enforces Policy 1 for varying transaction rates. The results show that SafeD can enforce a fine-grained security policy at a negligible cost to latency compared to having no protection (6.1% for No-Copy and 5.9% for No-Copy strategy).

8.2 Postgres + SafeD versus Postgres's Built-in Access Control

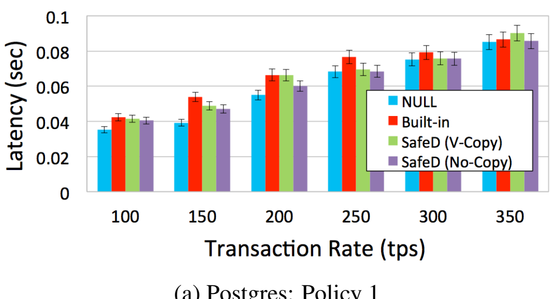
Unlike MySQL, some databases such as Postgres come with their own built-in row-level access control. The main advantage of SafeD over such built-in mechanisms is its compatibility with the common architecture of existing web applications (See Section 1). Nonetheless, we also wanted to compare the performance of the two approaches. We thus compared the costs of enforcing Policies 1 and 2 in Postgres using its internal access control versus using SafeD.

For Policy 1, to allow for reusing the same connections, we created a single role in Postgres for the benchmark application, and granted it the union of the privileges of all users so that the application can execute transactions on behalf of both customers or managers. The results are shown in Figure 4a, where NULL represents the baseline at which no access control was enforced. All three access control strategies (built-in, V-Copy, and No-Copy) had a maximum throughput of 350 to 400 transactions per second. Overall, the average latencies of all three strategies were also comparable (i.e., within 5% of one another). However, note that these results represent best-case scenarios for Postgres's built-in mechanism, since the benchmark application had full access to every table.

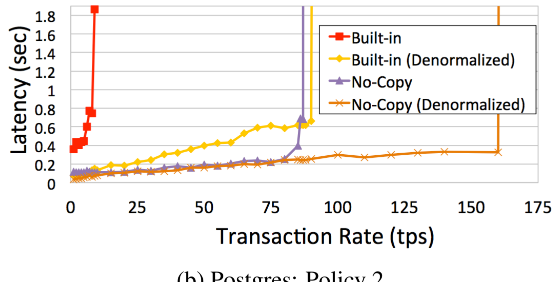
We conducted a second set of experiments using Policy 2 in order to artificially force both strategies (SafeD and built-in) to perform joins during their access control checks.

The results are shown in Figure 4b. In Policy 2, the write set for the *New_Order* table was defined as a join between the *New_Order* and *OOrder* tables. This considerably lowered the performance of V-Copy, due to its creation of temporary tables and copying of the write sets. Since V-Copy resulted in database thrashing and was unable to sustain any transaction rates, it is omitted from Figure 4b. The Postgres's throughput also dropped significantly with its built-in access control, down to only 9 tps (transactions per second). The throughput with No-Copy remained an order of magnitude higher, namely 85 tps. As reported in Table 5, even at 9 tps, Postgres's built-in mechanism is 387 times slower than SafeD when processing delivery transactions. The delivery transaction executes a large number of `SELECT` and `UPDATE` queries on the *New_Order* table. These results indicate that when a user's write set contains joins, SafeD using No-Copy significantly outperforms Postgres's built-in access control.

While SafeD outperforms the built-in access control, the performance of both strategies could be improved. In particular, we identified two sources of overhead when



(a) Postgres: Policy 1



(b) Postgres: Policy 2

Figure 4: The performance overhead of different access control strategies compared to no access control (NULL), using TPC-C on Postgres for Policy 1 (a) and Policy 2 (b). All numbers are average latencies.

Transaction	Null(s)	Built-in(s)	No-Copy(s)	Speedup
Delivery	0.05247	41.03159	0.10597	x387

Table 5: Transaction latency at 9 tps. Speedup is SafeD's performance compared to the built-in access control.

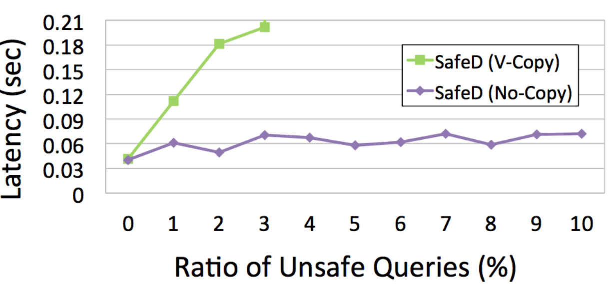


Figure 5: Average latency in SafeD for varying ratio of unsafe queries in the workload, at 100 tps.

enforcing Policy 2: (1) when the write set contains a join, a join query is issued to the database to create a copy of the write set; and (2) when the transformed query introduces a join or a nested sub-query. Thus, to reduce the performance overhead, we repeated the experiment with a denormalized database, i.e, we added a new column, NO_C_ID, to the *New_Order* table. As shown in Figure 4b, while the performance of both strategies improved significantly, SafeD remained the superior strategy.

8.3 Impact of Unsafe Queries on Performance

Unsafe queries are those that attempt to view or modify unauthorized tuples. In previous experiments, we measured SafeD's overhead when all queries in the workload were safe. To measure the impact of having unsafe queries on SafeD's performance, we modified the TPC-C workload by adding additional queries that are unsafe under Policy 1. We varied the ratio of such queries between 1% to 10% of the overall workload. The results for this experiment are shown in Figures 5 and 6.

As the number of unsafe queries increases, V-Copy's latency greatly increases, whereas No-Copy's latency overhead is relatively constant. This is because V-Copy creates temporary tables and executes additional queries to verify write-safety. Consequently, when 3% of the workload is unsafe, V-Copy thrashes. Figure 6 shows a similar trend for throughput. In conclusion, when a large number of unsafe queries are expected, No-Copy is a superior choice in terms of performance.

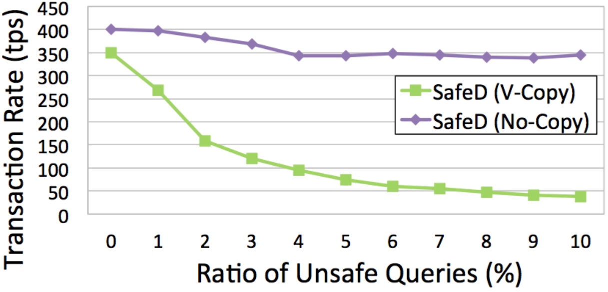

Figure 6: Achievable throughput in SafeD for varying ratio of unsafe queries in the workload.

8.4 Developer Effort

The primary manual effort required by developers when using SafeD is the defining of desired security policies. SafeD's policies are relatively compact. For example, Table 6 reports the number of lines of code needed to define Policy 1 in SafeD, Oracle (which also offers row-level access control), and Postgres. For SafeD, we count each read or write set declaration as one line of code. For Oracle, the count includes all of the procedural code necessary to establish the user context and enforce the read and write policies. For Postgres, we count each policy declaration and each `ALTER TABLE` command as one line. We also count the lines of code required to create an administrator role and a default role with no access.

We observe that Oracle requires the most lines of code, while Postgres and SafeD both require considerably fewer lines. Furthermore, Oracle requires the developer to understand how to define policy functions, policies, and system context triggers. Postgres requires

Access Control Mechanism	LOC
SafeD	36
Postgres's Built-in Access Control	54
Oracle's Built-in Access Control (a.k.a. VPD)	544

Table 6: Lines of code required to define a policy using three different syntaxes.

developers to work with DBAs to define policies and manage end-user roles. SafeD requires an understanding of `SELECT` statements to define policies. Thus, overall, defining security policies in SafeD seems to be relatively straightforward.

SafeD also simplifies developer effort when ensuring the application issues safe queries. To enforce a desired access control policy, developers add multiple security-oriented checks within the code to protect the database. For example, in WordPress 4.6.1, we identified about 515 lines of security-oriented checks in the code base. Each check is required to ensure no sensitive data is leaked, but there may be more checks necessary to fully protect the database [8], especially if the application's code is updated. SafeD reduces the effort required to protect the database because the security policies are declared explicitly within SafeD, thus they exist separately from the application and persist despite changes made to the application's code.

9 Conclusion

Database-backed application developers often implement their access control policies procedurally in code because the access control mechnisms of database systems are not adequate for enforcing access control for multi-user applications. Implementing access control procedurally in applicaton logic is both cumbersome and error-prone. Previous work has examined access control solutions for such situations, often using database views as the main mechanism for enforcing per-user access control. However, due to the view update problem, database views are not updatable when the view definition involves a join query. As our survey of 10 popular open-source web applications showed, on average, 21% of the tables require a join query to define a security policy. Therefore, previous work cannot enforce access control rules on write queries.

We proposed a new technique, phantom extraction that, given a write query, extracts a similar write query (known as the query's phantom), which only modifies permitted tuples in the database. Phantom extraction does not use database views, thus avoiding the view update problem. The correctness of the technique is established by a formal notion of *query safety*. We incorporated this technique into a system, SafeD, and provided a simple syntax for defining per-user (or per-role) access control policies declaratively. We also provide two possible design strategies, V-Copy and No-Copy, for performing query extraction.

A Proof of Theorem 1

To prove Theorem 1, we first prove the following lemmas.

Lemma 1. ***Distributive Laws for Tables and their Read-/Write Sets***

The read and write set, $V \in \{V_r, V_w\}$, are distributive with respect to the basic set operations. That is, for any tables or other subsets $A, B \subseteq \mathscr{S}$,

$$V(A \cup B, u) = V(A, u) \cup V(B, u)$$
$$V(A \cap B, u) = V(A, u) \cap V(B, u)$$
$$V(A \setminus B, u) = V(A, u) \setminus V(B, u)$$

Proof. These follow trivially from laws for set operations since $V(A,u) = A \cap p(u)$, where p is p_r or p_w depending on V being V_r or V_w. We omit the details. For example, $V(A \cup B, u) = A \cup B \cup p(u) = (A \cup p(u)) \cup (B \cup p(u)) = V(A,u) \cup V(B,u)$.

Also, these results apply for $NV \in \{NV_r, NV_w\}$, since $NV(A,u) = A \setminus p_u(u) = A \cup p^c(u)$, where $p^c(u) = S \setminus p(u)$ and S represents the tuple space for the database.

□

Lemma 2. *Given a policy p_w, a user $u \in U$, a write set V_w, a table update operation $\mathscr{W}$, and any table $T \subseteq \mathscr{S}$, the following conditions are equivalent:*

$$
\begin{aligned}
&(1) \quad NV_w(A,u) = NV_w(D,u) = \varnothing, \\
&(2) \quad NV_w(T,u) = NV_w(\mathscr{W}(T),u)
\end{aligned}
$$

where A and D are the set of tuples added and removed from T.

Proof. Suppose that condition (1) holds. Then we find that

$$
\begin{aligned}
NV_w(\mathscr{W}(T),u) &= NV_w((T \cup A) \setminus D, u) && \text{def of } \mathscr{W} \\
&= (NV_w(T,u) \cup NV_w(A,u)) \setminus NV_w(D,u) && \text{Lemma 1} \\
&= NV_w(T,u) && \text{by condition (1)}
\end{aligned}
$$

Conversely, suppose that condition (2) holds. Then

$$
\begin{aligned}
NV_w(A,u) &= NV_w(\mathscr{W}(T) \setminus T, u) && \text{def of } A \\
&= NV_w(\mathscr{W}(T),u) \setminus NV_w(T,u) && \text{Lemma 1} \\
&= NV_w(T,u) \setminus NV_w(T,u) && \text{condition (2)} \\
&= \varnothing
\end{aligned}
$$

The same approach also reveals that $NV_w(D,u) = \varnothing$.

□

Theorem 1. *(Same statement as in Section 5)*

Proof. **Part 1** — First, we show that the two conditions imply

$$NV_w(T,u) = NV_w(\mathscr{W}(T),u)$$

. We can partition the sets A and D into the disjoint portions consisting of those entries accessible to user u, and those that are not, giving

$$\langle \mathscr{W}(T) \rangle = |V_w(A,u) \cup NV_w(A,u)| + |V_w(D,u) \cup NV_w(D,u)|.$$

From their definitions, these are each clearly disjoint so that they may be separated into

$$\langle \mathscr{W}(T) \rangle = |V_w(A,u)| + |NV_w(A,u)| + |V_w(D,u)| + |NV_w(D,u)|.$$

If we define $A_v = \mathscr{W}(V_w(T,u)) \setminus V_w(T,u)$ and $D_v = V_w(T,u) \setminus \mathscr{W}(V_w(T,u))$, then from the definition of $\langle \mathscr{W}(T) \rangle$, we have

$$\langle \mathscr{W}(V_w(T,u)) \rangle = |A_v| + |D_v|$$

However, we also see that from making use of condition (1) we have

$$
\begin{aligned}
V_w(A,u) &= V_w(\mathscr{W}(T) \setminus T, u) && \text{def of } A \\
&= V_w(\mathscr{W}(T)) \setminus V_w(T,u) && \text{Lemma 1} \\
&= \mathscr{W}(V_w(T,u)) \setminus V_w(T,u) && \text{condition (1)} \\
&= A_v && \text{def of } A_v.
\end{aligned}
$$

Likewise, the same procedure reveals that $V_w(D,u) = D_v$.

Applying these two results, along with condition (2), we find that

$$
\begin{aligned}
|A_v| + |D_v| &= \langle \mathscr{W}(V_w(T,u)) \rangle \\
&= \langle \mathscr{W}(T) \rangle \\
&= |V_w(A,u)| + |NV_w(A,u)| + \\
&\quad |V_w(D,u)| + |NV_w(D,u)| \\
&= |A_v| + |NV_w(A,u)| + |D_v| + |NV_w(D,u)|
\end{aligned}
$$

Removing $|A_v|$ and $|D_v|$ from both sides, we are left with

$$|NV_w(A,u)| + |NV_w(D,u)| = 0.$$

But clearly, since both values are non-negative, this means that we must have

$$NV_w(A,u) = NV_w(D,u) = \varnothing$$

Hence by Lemma 2, we also have

$$NV_w(T,u) = NV_w(\mathscr{W}(T),u).$$

We have shown that conditions (1) and (2) imply this condition.

Part 2 — Now we will show that $NV_w(T,u) = NV_w(\mathscr{W}(T),u)$, implies both condition (1) and condition (2). Suppose that for an arbitrary update operation f,

$$NV_w(T,u) = NV_w(\mathscr{W}(T),u)$$

is true. We partition the set A into its disjoint portions consisting of the entries accessible to user u and those that are not, giving

$$
\begin{aligned}
A &= V_w(A,u) \cup NV_w(A,u) \\
&= V_w(A,u) \cup \varnothing && \text{by Lemma 2} \\
&= V_w(A,u)
\end{aligned}
$$

The same procedure shows that $V_w(D,u) = D$. With these results, we find that

$$
\begin{aligned}
V_w(\mathscr{W}(T),u) &= V_w((T \cup A) \setminus D, u) && \text{def of } \mathscr{W}(T) \\
&= (V_w(T,u) \cup V_w(A,u)) \\
&\quad \setminus V_w(D,u) && \text{Lemma 1} \\
&= (V_w(T,u) \cup A) \setminus V_w(D,u) && V_w(A,u) = A \\
&= (V_w(T,u) \cup A) \setminus D && V_w(D,u) = D \\
&= \mathscr{W}(V_w(T,u)) && \text{def of } \mathscr{W}(V_w(T,u))
\end{aligned}
$$

This shows that condition (1) is true. For condition (2), We again partition the sets A and D into the disjoint portions consisting of those entries accessible to user u, and those that are not, giving

$$\langle \mathscr{W}(T) \rangle = |V_w(A,u)| + |NV_w(A,u)| + |V_w(D,u)| + |NV_w(D,u)|.$$

Using Lemma 2, this simplifies to $|V_w(A,u)| + |V_w(D,u)|$. Focusing on $V_w(A,u)$, we find

$$
\begin{aligned}
V_w(A,u) &= V_w(\mathscr{W}(T) \setminus T, u) && \text{def of } A \\
&= V_w(\mathscr{W}(T),u) \setminus V_w(T,u) && \text{Lemma 1} \\
&= \mathscr{W}(V_w(T,u)) \setminus V_w(T,u) && \text{condition (1)}
\end{aligned}
$$

With a similar procedure, we can show that $V_w(D,u) = V_w(T,u) \setminus \mathscr{W}(V_w(T,u))$. If we define $A_v = \mathscr{W}(V_w(T,u)) \setminus V_w(T,u)$ and $D_v = V_w(T,u) \setminus \mathscr{W}(V_w(T,u))$, then from the definition of $\langle \mathscr{W}(T) \rangle$, we have

$$\langle \mathscr{W}(V_w(T,u)) \rangle = |A_v| + |D_v|$$

With this, we find

$$
\begin{aligned}
\langle \mathscr{W}, T \rangle &= |V_w(A,u)| + |V_w(D,u)| \\
&= |\mathscr{W}(V_w(T,u)) \setminus V_w(T,u)| + |V_w(T,u) \setminus \mathscr{W}(V_w(T,u))| \\
&= |A_v| + |D_v| \\
&= \langle \mathscr{W}(V_w(T,u)) \rangle
\end{aligned}
$$

Since conditions (1) and (2) imply $NV_w(T,u) = NV_w(\mathscr{W}(T),u)$ and vice versa, the conditions are necessary and sufficient.

□

B Query Transformation Examples

To better understand the transformation described in Section 6, we describe the steps of the No-Copy Strategy, which is comprised of Algorithms 1 and 3, using three example queries. In these examples, we use the osCommerce database schema and focus on queries that read or modify the *reviews* table. In osCommerce, a customer can read a reviews for any product but can only write reviews for products that the customer has purchased. After writing a review, the customer can also edit it. These policies can be expressed in SafeD as the read and write sets shown in Listings 4 and 5.

```
DEFINE READSET FOR ROLE customer USER $i
     ON TABLE reviews
          AS SELECT * FROM reviews
```

Listing 4: Customer's read set for the *reviews* table.

```
DEFINE WRITESET FOR
    ROLE customer USER $i
     ON TABLE reviews
          AS SELECT R.* FROM reviews
              R,
          orders_products OP,orders O
          WHERE
          O.customers_id=current_id
              AND
          O.orders_id=OP.orders_id
              AND
          OP.products_id=R.
              products_id AND
          R.customers_id=current_id
```

Listing 5: Customer's write set for the *reviews* table.

B.1 Select Query Example

Suppose a customer with current_id=2 manages to (e.g., by exploiting a bug in the application) cause the web application to issue the following query:

```
SELECT * FROM reviews
WHERE products_id IN (
     SELECT products_id
     FROM orders_products OP, orders
         O
     WHERE O.customers_id = 1 AND
     O.orders_id=OP.orders_id)
```

Listing 6: Original SELECT query issued by the application

First, SafeD must obtain the current customer's read policy and intersect it with the customer's query. The only tables appearing in this query are *reviews*, *orders*, and *orders_products*. Hence, SafeD only needs to obtain the read sets of these three tables (Alg. 1 line 2). The read set for *orders*, and *orders_products* are given in Listing 7 and Listing 8. For *orders*, a customer is only permitted to view their own order information. For *orders_products*, a customer is only permitted to view order product information for their own orders.

```
DEFINE READSET FOR ROLE customer USER $i
     ON TABLE orders
          AS SELECT * FROM orders O
               WHERE O.customers_id=
                   current_id
```

Listing 7: Customer's read set for the *orders* table.

```
DEFINE READSET FOR ROLE customer USER $i
     ON TABLE orders_products
          AS SELECT OP.*
          FROM orders_products OP,
          orders O
          WHERE O.customers_id=
              current_id
          AND O.orders_id=OP.
              orders_id
```

Listing 8: Customer's write set for the *orders_products* table.

Since the query in Listing 6 is a nested query, SafeD performs read set intersections recursively, starting with the deepest sub-query (Alg. 1 line 3). As stated in Section 5.2, SafeD appends additional tables and conditions in accordance with the read set definition, thus transforming each SELECT query into a read-safe one. The original query is thus transformed into the following read-safe query and then executed (using Alg. 1 lines 4-5):

```
SELECT * FROM reviews
WHERE products_id IN (
     SELECT products_id
     FROM orders_products OP, orders
         O
     WHERE (O.customers_id = 1 AND
     O.orders_id=OP.orders_id) AND
     O.customers_id = 2 AND
     O.customers_id = 2 AND
     O.orders_id=OP.orders_id);
```

Listing 9: write-safe SELECT query created by SafeD

Note that, in the original query, the customer attempted to see reviews for products purchased by another customer with customers_id=1. Although the customer has full read access to *reviews*, it is a breach of policy for a customer to read another customer's information in the *orders_products* table.

B.2 Delete Query Example

Suppose a customer with current_id=2 causes the application to issue the following query:

```
DELETE FROM reviews
```

Listing 10: Original DELETE query issued by the application

First, SafeD obtains the customer's read policy for tables used in any SELECT's in the query, but there are no SELECT queries. This means, by definition, the current query is write-safe. SafeD then identifies the table modified by the query, *reviews*, and obtains the customer's write set definition for this table (Alg. 1 lines 6-7). SafeD passes the user context, the write-safe DELETE query, and the write set definition to PhantomExtract (Alg. 1 line 8).

Given that the current write-safe query is a DELETE, SafeD performs write set intersection by appending additional conditions to the outer query's WHERE clause (Alg. 3 lines 3-4). This results in the following query:

```
DELETE FROM reviews
WHERE customers_id = 2 AND
products_id IN (
        SELECT products_id
        FROM orders_products OP,
           orders O
        WHERE O.customers_id = 2
           AND
        O.orders_id=OP.orders_id)
```

Listing 11: Transformed write-safe DELETE query created by SafeD 2

Since the write set includes a join (see Listing 5, an additional nested query is added to obtain a list of products purchased by the current customer. This list represents the set of products the customer is allowed to reviews.

Since the transformed query is a DELETE, it is deemed safe and executed by SafeD (Alg. 3 lines 7-8). Note that the original query (Listing 10) attempted to remove all of the reviews in the database, but SafeD transformed it into a safe form, i.e., a query that only deletes the reviews of the customer with current_id=2.

B.3 Insert Query Example

As a last example, suppose a customer with current_id=2 causes the application to issue the following query.

```
INSERT INTO reviews
      (reviews_id, products_id,
       customers_id, customers_name
          ,
       reviews_rating, date_added,
       last_modified, reviews_read)
VALUES(-1, 1, 1, 'John',
          5, 1-1-2016, 1-1-2016, 50)
```

Listing 12: Original INSERT query issued by the application

Similar to the DELETE query example, the original INSERT query is read-safe by definition. SafeD identifies the table modified by the query, *reviews*, obtains the customer's write set definition for that table, and passes the user context, the write-safe INSERT query, and the write set definition to PhantomExtract (Alg. 1 lines 6-8).

Given that the current write-safe query is an INSERT, SafeD does not perform write set intersection (Alg. 3 lines 5-6) . Since the query is not a DELETE and the write set contains a join, Algorithm 2 is invoked (from Alg. 3 lines 9-10). SafeD creates an empty copy of *reviews*, which we will call *temp* (Alg. 2 lines 3-5). Then, it extracts the phantom of the INSERT query, by copying the write-safe query and executing it on temp (Alg 2. lines 8-9). After execution, SafeD determines if the rows added to and removed from *temp* both belong to the write set (Alg. 2 lines 10-12). Based on the query in Listing 12, we see that the original query adds a single row with customers_id=1. Therefore, the phantom adds a single row with customers_id=1 to *temp*, which is not in write set, thus the phantom is not write-safe. No modification is made to the *reviews* table (Alg. 2 line 17) and *temp* is dropped.

Qapla: Policy compliance for database-backed systems

Aastha Mehta[1], Eslam Elnikety[1], Katura Harvey[1,2], Deepak Garg[1], and Peter Druschel[1]

[1]Max Planck Institute for Software Systems (MPI-SWS), Saarland Informatics Campus
[2]University of Maryland, College Park

Abstract

Many database-backed systems store confidential data that is accessed on behalf of users with different privileges. Policies governing access are often fine-grained, being specific to users, time, accessed columns and rows, values in the database (e.g., user roles), and operators used in queries (e.g., aggregators, group by, and join). Today, applications are often relied upon to issue policy compliant queries or filter the results of non-compliant queries, which is vulnerable to application errors. Qapla provides an alternate approach to policy enforcement that neither depends on application correctness, nor on specialized database support. In Qapla, policies are specific to rows and columns and may additionally refer to the querier's identity and time, are specified in SQL, and stored in the database itself. We prototype Qapla in a database adapter, and evaluate it by enforcing applicable policies in the HotCRP conference management system and a system for managing academic job applications.

1 Introduction

Confidential information stored in systems backed by relational databases is often subject to complex access policies. In a personnel management system, for instance, ordinary employees may query their own personal information but not that of others. Members of a workers' council may be able to query the columns containing employee names and ages separately, but not together, to prevent them from linking employees to their ages. Similarly, members of the payroll department may not be able to query the health history of individual employees, but they may be able to query aggregates over the health histories of all employees.

Today, such fine-grained policies are enforced by adding policy compliance checks to application code wherever the database is queried. This approach is cumbersome, error-prone, and inappropriate: Policies are usually derived from the privacy requirements of the broader legal/enterprise context and are code-independent, yet every code path in every application leading to a query must be instrumented by a programmer to perform a check. It is easy to miss such checks. Moreover, when the policy changes, application developers must update these checks everywhere.

Alternatively, policy compliance can rely on fine-grained access-control support in the underlying database management system (DBMS). Unfortunately, the extent of the support and the language used to express the policies varies across DBMSs. For instance, a cell-level policy can be specified in Oracle using its VPD technology [11], whereas the same policy will require a combination of views (for column access control) and row-level policies in PostgreSQL [7].

Furthermore, DBMS support for policies is limited to standard row-, column- and cell-level access control but, in practice, policies are often more complex. For instance, a policy may prohibit the *linking or joining* of two or more columns, while allowing those columns to be read independently. Similarly, a policy may allow certain principals to query for aggregates (sometimes based on user-defined functions), while prohibiting them from reading individual values. To the best of our knowledge, such complex policies can be implemented in existing DBMSs only through extensive use of application-specific views. However, views can neither support link policies nor are they transparent to applications. When using policy-specific views, all queries, even if they are compliant, must be modified whenever policies change.

Goals. Based on these observations, our goal is to provide a policy compliance system for database-backed applications that satisfies the following requirements. (i) It must be able to express a rich class of policies including standard fine-grained row-, column- and cell-level policies and also complex policies that limit data linking or allow aggregation. (ii) The policy specification must be associated with the database schema and independent of applications, and it must be simple and intuitive for pol-

icy administrators to adopt. (iii) The system should not depend on specific support from the DBMS and it should be transparent to applications that issue policy-compliant queries.

We emphasize that our primary goal is to protect the confidentiality of data in the face of *application bugs*. The threat is not from active attacks, although our design defends against some kinds of application compromise.

Our design, Qapla, is a policy-compliance middleware for database-backed systems, which satisfies all the aforementioned goals with moderate overheads on application performance. In Qapla, policies are *specified* in a SQL-like language, as a function of the database schema, and stored in the database (in separate tables). SQL is a natural choice for Qapla's policy language since its syntax is widely understood. Furthermore, the use of SQL syntax leads to a simple enforcement mechanism that we describe below.

For policy *enforcement*, Qapla integrates a reference monitor with a generic database adapter, which intercepts all application queries, looks up applicable policies, and rewrites queries to ensure compliance. The SQL-like syntax of Qapla policies simplifies query rewriting. Moreover, the enforcement is transparent to application queries that are already policy compliant, so the application has to be changed only where its queries are not policy compliant.

Qapla requires no changes to and no specific support from the DBMS (although we describe how database-specific support like materialized views can be used to optimize Qapla's performance). Furthermore, since the Qapla reference monitor is integrated in a generic database adapter and does not depend on DBMS-specific access control support, it is portable across DBMSs. Qapla removes the often large and rapidly evolving applications from the codebase trusted for compliance, simplifies new applications by obviating the need for pervasive filtering code, and avoids compliance bugs due to incorrect or missing application checks.

Qapla's approach of stating policies in a high-level, declarative, and familiar SQL-like language, associated with the database schema and not within the application code provides additional benefits. Declarative, schema-based policies are easier to reason about, analyze, and audit than policies written in application code. Moreover, policy changes can be affected reliably based on the schema, without requiring inspection of queries or modification of compliant queries. The use of SQL-like syntax and the high-level of policy abstraction further aid policy writing, debugging and audit.

We demonstrate Qapla's portability by incorporating it with PHP's and Python's database adapters, and using it to enforce fine-grained policies in two applications: the widely-used HotCRP conference management system [2], and the APPLY system for managing academic job applications, which we use in our organization. HotCRP includes fine-grained policies to maintain confidentiality of paper submissions, provide author and reviewer anonymity, and prevent untimely disclosure of results to authors and PC members. APPLY likewise has policies to control access to application materials, reference letters, and evaluators' notes depending on user roles and to allow users access to aggregated historical information yet prevent them from seeing their own past case materials. The policies cover many important application workflows such as user login, searching for papers, reviews, comments by authors, chair, reviewers, etc., in HotCRP, and applications, letter request, review, and search in APPLY. We identified and implemented a total of 30 policies in HotCRP and 41 policies in APPLY. The policies are concise, specified in one place, and tend to require only local changes or extensions when new features are introduced to applications.

An experimental evaluation shows that Qapla incurs moderate overheads. Interestingly, we also observe that Qapla overheads are generally lower than the overheads of native access control support in a commercial database on policies that can be expressed using the latter.

To summarize, our contributions lie in the architecture, design, policy language and evaluation of Qapla, which enables the specification and enforcement of a rich class of complex and fine-grained policies (including those based on linking and aggregation) in a database-agnostic and application-transparent manner.

Organization. We present Qapla's policy language in Section 2 and its architecture in Section 3. Our application of Qapla to HotCRP and APPLY is described in Section 4, followed by an experimental evaluation in Section 5. We discuss related work in Section 6 and conclude in Section 7.

2 Qapla policy framework

Qapla allows a policy compliance team to associate a set of policies with a database schema. These policies specify data confidentiality requirements that take into account the database schema, contents, the authenticated user, time and operations like joins, aggregations and UDFs. We do not consider data integrity policies although we believe they can be added to our design.

Every Qapla policy applies to a class of queries and specifies how those queries must be restricted to be compliant. These restrictions are specified as SQL WHERE clauses that are added to the query by Qapla before the query is executed, thus filtering out non-compliant records. We formally define when a policy applies to a query and the query rewriting procedure in Section 3. An application can obtain a tuple using a query only if (a) at least one policy applies to that query, and (b) the

query rewritten under the restrictions of the policy produces that tuple. If no policy applies to a query, the query is not executed. This whitelist principle ensures that data is accessed only due to some explicitly written policy and never leaked due to accidental omission of policies.

The remaining section provides an overview of Qapla policies using the running example of the human resource's database of a fictitious company, Acme. The database has three tables `Employees(empID, name, address, age, gender, dept)`, `Payroll(empID, salary)` and `Benefits(empID, health_plan)`. The first table maps employees to their home address, age, gender and department. The second table maps employees to their salary, while the third table specifies which health plan each employee subscribes to.

Single-column policies. The simplest Qapla policy protects a single database column by specifying which rows of the column can be accessed by each user, and when. It has the form: `col` :- W. Here, W is a SQL WHERE clause that specifies which rows from the column `col` can be returned. W may refer to the authenticated user and the wall clock time using the variables \$user and \$time, which are instantiated by the Qapla reference monitor when the clause is added to the query. The policy applies to any query that references only the column `col` (queries that read more than one column are subject to link policies described later).

Example 1 (name, age, health_plan) The names of Acme's employees should be accessible to all other employees. The following policy specifies this.

```
name :- EXISTS(SELECT 1 FROM Employees
        WHERE empID = $user)
```

The SQL fragment EXISTS(...) specifies a condition that holds only if the authenticated user exists in the table `Employees`. An identical policy applies to the columns `age` and `health_plan`. Reading the columns in isolation only allows enumeration of the set of ages or health plans of all employees.

Example 2 (address, salary) The columns `address` and `salary` can be read only by members of the HR (human resources) department. Additionally, an employee may read his or her own address or salary. The following policy enforces this on `address`. A similar policy applies to `salary`.

```
address :- (empID = $user) OR
           EXISTS(SELECT 1 FROM Employees
           WHERE empID = $user AND dept = HR)
```

Compared to the policy of `name`, this policy allows different employees access to different entries in `address`. Note that the WHERE clause is organized as a disjunction of conditions, one for each class of users.

This is an example of a role-based access control (RBAC) policy, where an employee's role is dictated by her affiliation with a particular department. This policy relies on the availability of the mapping from users to their roles in the database itself. In applications where this mapping is outside the database (e.g., on a file system), Qapla's policy language can be easily extended to support predicates that lookup this mapping outside the database. Qapla can interpret these non-database predicates in the policies using native procedures, and apply the remaining SQL policy to the database queries.

Link policies. When a query reads two or more columns, the applicable policy may be more restrictive than the individual policies of all the columns read, because additional information can be exposed by linking the columns to each other, as in the following example.

Example 3 (linking name and age) The policies of the columns `name` and `age` allow any employee to read these columns individually (Example 1). However, not every employee should be able to read the columns `name` and `age` *together* since that reveals every employee's age, which may be private. The right policy is that only members of HR and an employee himself/herself may read the employee's `name` and `age` together. In Qapla, this policy is expressed by mentioning both columns `age` and `name` to the left of :- in the policy.

```
{name,age} :- Employees : ((empID = $user) OR
              EXISTS(SELECT 1 FROM Employees
              WHERE empID = $user AND
                    dept = HR))
```

Such policies, which apply to simultaneous access of two or more columns, are called *link policies*. Their general form is

$$\{\texttt{col}_1,\ldots,\texttt{col}_n\} \text{ :- } \textit{filter conditions}$$

with *filter conditions* of the form $T_1{:}W_1$, ..., $T_m{:}W_m$. Here, $\{\texttt{col}_1,\ldots,\texttt{col}_n\}$ are columns spanning the tables $T_1,\ldots,T_m$ and $W_1,\ldots,W_m$ are separate WHERE clauses for these tables. This policy applies to any query that reads a subset of the columns $\{\texttt{col}_1,\ldots,\texttt{col}_n\}$ (for any purpose including projection, selection, joining, grouping or aggregation). The WHERE clauses of all the tables mentioned in the query are added to the query by Qapla (see Section 3 for details).

Columns in separate tables. When the goal is to restrict the linking of data in two or more *separate* tables, the effect of a link policy can sometimes be simulated by simply restricting access to the individual columns containing the common keys of the two tables. However, when different sets of columns spanning the tables need

different policies, the policies must be specified using the general form of link policies described above.

Transformation policies. Applications often apply functions or transformations to columns to hide sensitive information. A transformed column may have more permissive policies than the column itself. Qapla directly supports such transformations-aware policies.

Example 4 Suppose Acme provides a home-to-office shuttle service to its employees, run by Acme's "logistics" department. The shuttle service has a fixed stop in every neighborhood that houses an employee but it is not door-to-door. In order to provide this service, members of the logistics department must know the neighborhood in which every employee lives, but not their precise home addresses. To enforce this, the privacy compliance team can create a user-defined function (UDF), `neigh`, that maps an address to a neighborhood, and add the following Qapla policy.

$$\{\texttt{name}, \texttt{address}[\texttt{neigh}]\} \text{ :- } (\texttt{empID} = \$\text{user}) \text{ OR } \text{EXISTS}(\text{SELECT } 1 \text{ FROM } \texttt{Employees} \text{ WHERE } \texttt{empID} = \$\text{user AND } (\texttt{dept} = \text{HR OR } \underline{\texttt{dept} = \text{logistics}}))$$

This policy says that an employee's `name` and `neigh(address)` can be linked by the employee, members of HR and members of logistics. The policy is strictly more permissive than the policy on $\{\texttt{name}, \texttt{address}\}$, which allows access only to the respective employee and HR, but not to logistics. The revised policy allows logistics to run the query "SELECT `name`, `neigh(address)` FROM `Employees`", but not "SELECT `name`, `address` FROM `Employees`".

The general form of a Qapla transformation policy is

$$\{\texttt{col}_1[\texttt{t}_1], \ldots, \texttt{col}_n[\texttt{t}_n]\} \text{ :- } \textit{filter conditions}$$

The *filter conditions* are of the same form as in a link policy. The policy applies to any query that accesses a subset of the columns $\texttt{col}_1, \ldots, \texttt{col}_n$ but only after the respective transformations $\texttt{t}_1, \ldots, \texttt{t}_n$ have been applied.

Aggregation policies. Many applications declassify aggregate statistics on otherwise private columns. Accordingly, Qapla provides *aggregation policies*. An aggregation policy specifies two sets of columns: 1) *LS* (link set)—columns which can be projected, used to join or group data (SQL's GROUP BY) or be aggregated in a query, and 2) *JS* (join set)—columns which can be used only to join tables in the query and nothing else. With each column in *LS* an optional transformation or aggregation operation can be specified, which restricts the use of that column to only that transformation or aggregation. The general syntax is

$$\{JS = \{\texttt{jcol}_1, \ldots, \texttt{jcol}_m\}, LS = \{\texttt{col}_1[\texttt{t}_1], \ldots, \texttt{col}_n[\texttt{t}_n]\}\} \text{ :- } \textit{filter conditions}$$

Example 5 Suppose Acme has a workers' council (WoC) that periodically computes salary statistics to ensure fairness in worker compensation. One statistic it computes is the distribution of average salary over age ranges (20-30 years, 30-40 years, etc.). Rather than provide WoC full access to the `Employees` table, the policy compliance team can selectively provide WoC rights to compute only such statistics by writing the following aggregation policy. Here, `age_range` is a function that rounds an individual's age to a 10-year range.

$$\{JS = \{\texttt{Payroll.empID}, \texttt{Employees.empID}\}, LS = \{\texttt{age}[\texttt{age_range}], \texttt{salary}[\texttt{AVG}]\}\} \text{ :- } \text{EXISTS}(\text{SELECT } 1 \text{ FROM } \texttt{Employees} \text{ WHERE } \texttt{empID} = \$\text{user AND } (\texttt{dept} = \text{HR OR } \underline{\texttt{dept} = \text{WoC}}))$$

This policy allows WoC to run any query that joins tables `Payroll` and `Employees`, and then uses only `age_range(age)` and average on `salary` (in any way). For example, it allows the following two queries among many other instances of similar queries:

(i) SELECT `AVG(salary)`, `age_range(age)` FROM `Employees`, `Payroll` GROUP BY `age_range(age)` HAVING `AVG(salary)` > 50000
which lists age groups with average salaries above 50000.

(ii) SELECT `AVG(salary)` FROM `Employees`, `Payroll` WHERE `age_range(age)` = (30, 40)
which lists the average salary of a specific age group.

Correctly, the policy does not allow queries that look at the `age` or `salary` columns directly. For instance, the following query is disallowed by the policy: SELECT `AVG(salary)` WHERE `age` = 75.

Relation between policy classes. Qapla's four policy classes—single-column policies, link policies, transformation policies and aggregation policies—are increasingly more general. Single-column policies are an instance of link policies, where the set of linked columns is a singleton. Link policies are a special case of transformation policies where the transformations are identity functions. A transformation policy S :- *filter conditions* is the same as the aggregation policy $\{JS = \{\}, LS = S\}$:- *filter conditions*.

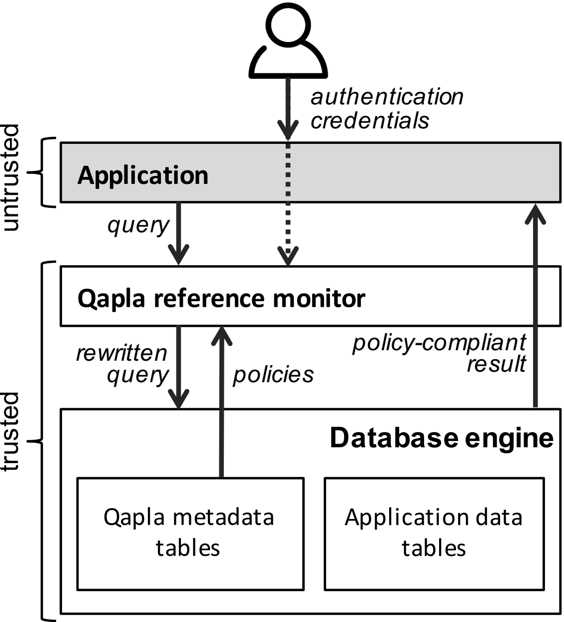

Figure 1: Qapla architecture

Policy inference heuristics. To reduce the burden of specifying policies, Qapla provides safe heuristics.

Heuristic 1: A link policy for a set of columns also automatically applies to any subset of those columns since reading a subset only reveals less information than does reading the whole set. Thus, there is no need to specify a link policy on a subset unless the subset's policy is strictly more permissive than the policy of the whole set, and some application needs the permissiveness.

Heuristic 2: If a query uses column transformations or aggregations but a specific applicable transformation or aggregation policy does not exist, Qapla applies the link policy of the set of columns that occur in the query, if one exists. This is safe because transforming or aggregating a column always reduces the information revealed.

Heuristic 3: In place of writing an explicit link policy on a set of columns, the designer can explicitly instruct Qapla to automatically construct a link policy for a set of columns by combining the policies of the individual columns in the set. This synthesized policy applies the *filter conditions* of the individual columns even when they are read together. This is useful in some cases. For instance, we may want to allow only HR members and an employee simultaneous access to the employee's `name` and `address`. However, this is exactly the policy of the individual column `address` (Example 2), so in this case, the policy designer can ask Qapla to synthesize the link policy for {`name,address`} by combining the individual policies of `name` and `address`.

3 Qapla design

Figure 1 depicts Qapla's architecture. Qapla's metadata and policies are stored in the database separate from the application data. The Qapla reference monitor authenticates with the database with its own unique credentials, and it has the exclusive privilege to access all tables directly. It intercepts the application's database queries, and associates each query with the authenticated end user on whose behalf the query was issued by the application. The query is rewritten to ensure its compliance with policies, and the rewritten query is executed by the database.

3.1 Threat model

Qapla is designed to prevent data leaks due to application *bugs* that result in non-compliant queries to the database. Qapla intercepts all queries to the database in a reference monitor and rewrites the queries to make them policy compliant. In our current design and implementation, the reference monitor runs in the same address space as the application. Consequently, any application-level bugs or vulnerabilities that circumvent this monitor to access the database directly or steal the reference monitor's privileged database credentials are out of scope. Additionally, we rely on the application to correctly tell Qapla which user's behalf it (the application) is acting on. However, it is not difficult to change this design to avoid these limitations (see Section 3.5 for initial ideas).

We also assume that users do not collude offline to combine non-overlapping parts of the database they are individually authorized to read, and that individual users do not link information they have obtained in separate queries.

The Qapla reference monitor, the database adapter it is embedded in, the database system, the operating system, the storage layer, and the communication between the database adapter and the database system are assumed to be correctly configured and trusted. The database curator or compliance team is assumed to have installed correct policies, and any information referenced by policies is assumed to be correctly stored in the database. Under these assumptions, Qapla guarantees that only policy compliant query results are returned to the application.

3.2 Enforcement

Qapla's policy enforcement on a query consists of two steps: 1) Identifying the set of policies that apply to the query, and 2) Rewriting the query to filter out tuples disallowed by all the applicable policies. We describe the two steps in detail.

Applicable policies. Internally, Qapla treats every policy as an aggregation policy of the form $\{JS, LS\}$:- *filter conditions*, where JS and LS are, respectively, the set of columns that may be used to (only) join two or more tables, and the set of columns that may be pro-

Does a policy apply to a query?

```
1 input: Query Q; Policy {JS,LS} :- filter conditions
2 output: true if policy applies to Q, false otherwise

3 {js,ls} = parseQuery(Q)
4 if (js ⊈ JS) return false
5 for each column c in ls:
6     if (c ∉ LS) then return false
7 for each transformed/aggregated column c[t] in ls:
8     if (c[t] ∉ LS and c ∉ LS) then return false
9 return true
```

Figure 2: Algorithm to decide if a policy applies to a query

jected, grouped by and aggregated. As explained in Section 2, this is the most general form of policies; all single-column, link and transformation policies can be expressed in this form. Qapla parses every application query to extract the corresponding sets *js* and *ls* of columns that are used only to join and those that the query actually projects, groups by, or aggregates.

A policy applies to a query if the query's use of the columns *js* and *ls* is allowed by the corresponding sets *JS* and *LS* of the policy. Formally, the policy applies to the query when $js \subseteq JS$ and when every column c and every transformed column c[t] in *ls* is *dominated* by a column or transformed column in *LS*. Domination is defined as follows: Every (transformed) column dominates itself, and a column dominates any transformation of itself. Thus, a policy with $JS = \{$Benefits.empID, Employees.empID$\}$ and $LS = \{$age, health_plan$\}$ applies to a query with $js = \{$Benefits.empID, Employees.empID$\}$ and $ls = \{$age[age_range], health_plan[COUNT]$\}$. Figure 2 summarizes this algorithm.

To efficiently find all policies that apply to a query, Qapla maintains two data structures. The first data structure maps every pair of a column and a transformation (that applies to the column) to a bitvector representing the policies in the system. The *i*th bit is set in the bitvector of the (transformed) column *j* if policy *i*'s *LS* contains a column that dominates *j*. To find all applicable policies whose *LS* matches a given query's *ls*, Qapla simply takes the bit-wise AND of the bitvectors of all (transformed) columns in *ls*. The second data structure is similar but applies to *JS* and allows finding all policies whose *JS* matches a query's *js*.

Query rewriting algorithm. The query rewriting algorithm modifies an application query to make it compliant. In the simple and common case where only one policy applies to the query, the policy rewriting algorithm replaces each reference to a table in the query with a subquery that generates a list of rows compliant with the *filter conditions* of the columns accessed from the table. The subquery is of the form (SELECT ∗ FROM table WHERE *list-of-conditions*), where *list-of-conditions* are the *filter conditions* of the table provided in the policy. The overall effect is that the application query is executed over joins of policy-compliant sub-tables of one or more database tables, where the sub-tables have been created using the *filter conditions* of the applicable policy.

Example 6 In the context of Acme's database, assume that some link policy exists for the column set {name, age, health_plan, Employees.empID, Benefits.empID} and that it specifies the WHERE clauses f_E and f_B for filtering the tables Employees and Benefits, respectively. Consider the following query: SELECT name, age, health_plan FROM Employees JOIN Benefits ON Employees.empID = Benefits.empID. This query will be rewritten to:

```
SELECT name, age, health_plan FROM
  (SELECT * FROM Employees WHERE f_E)
  Employees JOIN
  (SELECT * FROM Benefits WHERE f_B)
  Benefits ON
  (Employees.empID = Benefits.empID)
```

When more than one policy applies to a query and the query does not return an aggregate, Qapla rewrites the query according to each applicable policy and takes a SQL UNION of these. This ensures that a tuple exists in the result only when at least one applicable policy allows it. If the query returns an aggregate value and more than one policy applies, Qapla picks the first applicable policy, but the application may override this to a specific applicable policy at the cost of minor changes to its code. (We have not encountered the need for such changes in our evaluation.)

3.3 Optimizations

We describe three optimizations to reduce the overhead of policy enforcement in Qapla. Our current prototype and evaluation only include the first optimization, but implementing the remaining two optimizations is not difficult.

Query template cache. The Qapla reference monitor implements a query template cache to amortize the overhead of parsing and rewriting queries with the same structure. A query template is a query with all its constant values replaced with placeholder variables. The Qapla template cache maps query templates to their rewritten forms. When a query is received, Qapla converts the query to a template and checks if a query template with the same hash is cached (if the application query is already parametrized, Qapla hashes it directly). For a hit, Qapla retrieves the associated rewritten query template, and binds its variables with the values from the

submitted query. For a miss, Qapla parses and rewrites the query with the applicable policies, and inserts the resulting rewritten query template into the cache.

Partial evaluation. The Qapla reference monitor often generates complex rewritten queries containing several nested sub-queries accessing one or more tables, and having large filter conditions. Executing the query efficiently depends on the ability of the DBMS to generate an efficient execution plan for the rewritten query. To reduce the complexity of the rewritten query, Qapla can pre-evaluate parts of the rewritten query that do not depend on database values (e.g., parts that depend only on the identity of the user on whose behalf the application makes the access) before posting the query to the database. This can significantly simplify the query since any predicates connected by 'AND' to a pre-evaluated predicate that is false can all be replaced by a single false before the query is sent to the database. Similarly, any predicates connected by 'OR' to a pre-evaluated predicate that is true can all be replaced by a single true.

Materialized Views. To offset the cost of policy checks during query evaluation, Qapla can create materialized views, one for each (group of) user(s) with similar permissions, by applying applicable policies to the tables offline. In a group's materialized view, every cell inaccessible to the group is replaced with a special value that is not a legal value for the underlying table. At runtime, every application query is run against the materialized view appropriate for the authenticated user. The query is rewritten by Qapla to disregard any record that contains the special value in a field that is used in the query.[1] Our preliminary evaluation suggests that this optimization can reduce runtime overheads on read-intensive workloads by an order of magnitude. However, proportional to the number of user groups with different policies, maintaining materialized views adds storage cost and runtime overhead to propagate updates to all materialized views.

3.4 Cell-blinding mode

The policy enforcement algorithm described in Section 3.2 drops a row during query execution if any field in the row is inaccessible according to the policy and is used in the query. This *row-suppression mode* of policy enforcement ensures that information about an inaccessible field cannot be inferred even when that information is correlated with other fields in the row. This makes row-suppression a very safe choice for policy enforcement (and, hence, Qapla uses it by default). However, row-suppression is not the only possible way of enforcing Qapla's policies. We briefly describe here a second mode of policy enforcement, the *cell-blinding mode*.

The primary consideration for the cell-blinding mode is compatibility with legacy applications, which may issue broad queries that project more columns than actually necessary, and eventually remove these extra columns internally in their own code. With the row-suppression mode, such broad queries may result in fewer records than expected by the application. Transitioning such applications to make them compatible with row-suppression may require effort and time, as developers may have to rewrite queries to not project unnecessary columns. This transition can be particularly difficult when the set of necessary columns depends on the application state.

The cell-blinding mode changes the semantics of policy enforcement to compromise some security and efficiency in return for accommodating overly broad queries. In this mode, Qapla rewrites the application queries to replace (blind) inaccessible cells with special values that can be returned in results, before executing the original query's logic. (This replacement is identical to the replacement of inaccessible cells in the creation of materialized views from Section 3.3 but, here, the special values must not depend on any secrets since they can be returned directly in query results.)

However, the cell-blinding mode has two drawbacks. First, if some fields of a record are inaccessible according to the policy, the record is still returned (with the inaccessible fields blinded). This leaks some information when the presence of the record in the database is sensitive and when blinded fields are correlated with other non-blinded fields. Second, the cell-blinding mode imposes significant overhead on query execution (up to two orders of magnitude for some queries with MySQL) due to the need to check policies on, and possibly blind, individual cells in every query. We believe that the use of materialized views described in Section 3.3 can reduce this overhead substantially. A full study of this approach remains as future work.

Due to these limitations of the cell-blinding mode, it is preferable to use the row-suppression mode and to modify the application to restrict overly general queries. The rest of the paper uses only the row-suppression mode of policy enforcement.

3.5 Discussion

We discuss some limitations of Qapla's current threat model and some ideas on how to strengthen the design to eliminate these threats. We also discuss how Qapla can be used for logging policy violations.

Isolation of the reference monitor. Currently, we assume that the application, which runs in the same ad-

[1] For confidentiality, it is insufficient to disregard a record only when one of its inaccessible fields is projected. It is also necessary to disregard a record if one of its inaccessible fields will be tested by the query's WHERE clause(s). Doing so prevents implicit information leaks through the WHERE clause(s).

dress space as the reference monitor, cannot circumvent the reference monitor or steal its authentication credentials. However, this is not a fundamental limitation. To provide guarantees against a malicious application, we can also isolate the reference monitor in a separate process [15, 24], or co-locate it with the DB servers. There are also efficient ways of isolating the reference monitor within the application address space, such as using light-weight contexts [30].

User authentication. Qapla's current design requires the application to specify which user's behalf it is acting on. An application may specify the wrong user to Qapla due to a bug, thus breaking Qapla's policy enforcement. This problem can be easily addressed by having the user authenticate to the reference monitor instead of the application. The application can then ask for the authenticated user's identity from the reference monitor.

Protection against offline linking attacks. Qapla does not protect against offline linking attacks that span multiple queries. For two queries whose results can be linked offline (such as in example 3), randomizing the order of query results may mitigate the attack in some cases. However, randomizing the order of query results cannot eliminate linking attacks in all cases. In particular, some linking may be possible due to information contained in the data itself (e.g., names may have high correlation with the nationality of users, or fine-grained aggregate queries may reveal individual records). We expect the policy designer to be aware of potential data leaks of this type, and design the policies such that compliant queries return a minimum threshold number of results (similar to k-anonymity [37]). Tools to check such conditions on policies can be easily designed.

Support for logging. A natural question is whether we can modify Qapla's reference monitor to detect and log non-compliant queries (e.g., for debugging or auditing). While this is not a design goal, Qapla can be used to detect non-compliant queries to a limited extent – by re-running a query twice, with and without policy checks and comparing the results for any differences. Non-compliant queries can then be logged.

3.6 Implementation

The Qapla implementation consists of about 20K lines of C code. It provides the API to create application-specific policies, associates policies with column identifiers, and maintains an in-memory mapping from column identifiers to associated policies. It also provides an API for setting application-specific user authentication parameters in the reference monitor. Qapla uses an existing SQL parser from the MySQL workbench [4] to extract accessed tables and columns. A rewrite module implements the lookup for applicable policies and the query rewriting algorithm. A template cache module maintains a cache of rewritten query templates, and a customizable translation module can translate the SQL dialect of one DBMS to that of another, allowing Qapla uses across DBMSs. In our evaluation, we translate MySQL queries into a commercial DBMS's queries.

Qapla can support existing PHP and Python based applications. For PHP applications, we modified the PHP Data Objects (PDO) [5] module in the PHP interpreter. For Python applications, we rely on the Django framework [1], which provides an object-relational mapping (ORM) API for database interaction. Django provides a database-independent abstraction to the application developer. We modified this abstraction and interface with the Qapla reference monitor using the ctypes library. Both PDO and Django can be used to connect with different databases, such as MySQL, SQLite, MSSQL and Oracle. Modifications to PDO and Django were limited to 135 and 141 lines of code, respectively.

4 Case studies

In this section, we describe our use of Qapla to ensure policy compliance in HotCRP and APPLY.

4.1 HotCRP compliance with Qapla

Policies. We studied HotCRP's schema and wrote policies based on our knowledge of its workflow. In many cases, we reverse-engineered HotCRP's policies by inspecting its code base to confirm and correct our intuition. In total, we specified 30 policies for the 22 tables and 215 columns in the schema of HotCRP version 2.99, which supports a broad range of configurations for a conference. The policies cover a single-track conference with a double-blind submission process, handling of chair conflicts with paper managers, and a review process with no rebuttal. Due to space constraints we cannot show all the policies but Table 1 shows the policies associated with important tables like contacts, papers, reviews, and conflicts. The policies are explained in plain English for clarity and brevity of exposition but are actually written in the language introduced in Section 2. Macros abbreviate common SQL fragments that appear in many policies. Many of the policies are fine-grained access control predicates on user, time, and the content of various database tuples. There are also link and aggregation policies.

Link policy example. An author can independently view the names of all PC members, his own paper submission, and the reviews for his papers after the notification date. However, the author is not allowed to see the join of the three columns, which reveals the reviewers' identities. In the HotCRP schema, these columns reside in three different tables (ContactInfo, Paper, and PaperReview). The PaperReview table can be joined with

id	table	column list	allow the authenticated user U access to row R if ...
C1	ContactInfo	email	(U is a chair) or (R is U's contact information) or (U and R are on the PC)
C2	ContactInfo	password	(R is U's contact information) or (U is chair)
P1	Paper	paperId, title, abstract, timeSubmitted, timeWithdrawn	(U is R's author) or (U is on the PC and either the submission deadline has not passed or R was submitted fully)
P2	PaperStorage	paperStorageId, size, paper, other paper metadata	(U is R's author) or (U is on the PC and R was submitted fully)
P3	Paper	authorInformation, collaborators	(U is R's author) or (the notification deadline has passed, R was accepted and U is on the PC)
P4	Paper	outcome	(the notification deadline has passed and U is R's author or a PC member) or (U is R's paper manager or a non-conflicted PC member)
P5	Paper	shepherdContactId	(the notification deadline has passed and U is R's author) or (U is R's paper manager or a non-conflicted PC member)
P6	Paper	managerContactId	(U is a chair or R's manager or a non-conflicted PC member)
P7	Paper	leadContactId	(U is R's manager) or (U has submitted a review for R) or (U is a non-conflicted PC member and the discussion has started)
R1	PaperReview	reviewId, paperId, <review content>, reviewSubmitted	(P7 conditions) or (the notification deadline has passed and U is R's author or a non-conflicted PC member)
R2	PaperReview	contactId, reviewEditVersion, reviewRound, requestedBy, reviewType, commentToPC, reviewToken, timeRequested	(P7 conditions) or (R is a sub-review and U is the reviewer who asked for it)
C	PaperConflict	all columns	(U is R's author) or (U is a chair) or (U is a PC member and the subject of R)
AL	ActionLog	all columns	U is R's manager or a non-conflicted chair
AO	Outcome statistics	Total number of submissions and accepted papers	the notification deadline has passed
AS	Avg. review scores	Average score across all submitted reviews	U is a PC member
AR	Review statistics	Number of reviews submitted by each PC member	U is a PC member and statistics excludes each row conflicted with U

Table 1: Subset of HotCRP policies

Contact via the contactId key column, and with Paper via the paperId key column. The link policy can be implemented by specifying a restrictive policy for PaperReview.contactId, which does not allow the author to read the column (R2 in Table 1). The policy prevents PC authors from identifying reviewers of their own papers, yet allows them to know and participate in discussions with reviewers of non-conflicted papers.

Aggregation policy example. During the review and discussion process, HotCRP provides aggregate statistics to all reviewers. The statistics include the average review score across all papers as well as the number of reviews submitted by each PC member. To allow this feature to function correctly, we specify two aggregate policies (AS and AR in Table 1), one allowing an AVG computation on the overAllMerit score field and the other allowing a COUNT on the review field grouped by PC member. In the second case, conflicted papers must be excluded.

Implementation effort. We replaced the MySQLi database adapter [6] normally used in HotCRP with our modified Qapla-enabled PDO adapter. We modified HotCRP to forward the user authentication credentials to the Qapla reference monitor. (Apache was configured to fork a separate process for each HotCRP user session, so there is a separate instance of the adapter/reference monitor for each user session.) HotCRP uses broad queries and relies on post-filtering to remove the information the user should not see. We changed approximately 150 LoC in HotCRP's code to make these queries policy compliant so that they can work with Qapla. In most cases, we added a couple of queries to identify the contextual information required to convert the broad queries into more

specific queries. With Qapla in place, we can remove the post-filtering queries, but we ignored them for now. Table 2 summarizes the changes we made in HotCRP.

Type of change	lines of code
Replace MySQLi with PDO adapter	96
Change paper query	110
Change review query	25
Change comment query	17
Authentication with Qapla	5

Table 2: HotCRP changes

4.2 APPLY compliance with Qapla

We briefly describe our use of Qapla to protect the application management system (APPLY) for managing faculty, PhD, post-doc, and internship applications in our organization. APPLY's database is similar to the fictitious Acme database from Section 2 and the confidentiality concerns are also similar. The database contains user accounts for applicants and reviewers, contact and application details of the applicants, references, and internal application review aspects such as comments. Users within the organization are assigned roles based on what application type (intern, PhD, postdoc, faculty) they are allowed to access. APPLY prevents reviewers from accessing applications created before they joined the organization. Additionally, APPLY allows explicit delegation of the right to view (sets of) applications to specific users or roles, and disallows a user from accessing an application in case of a conflict of interest. A single policy condition, listed below, covers a large number of columns across many tables.

User U has access to application A if:
(A is U's own application) or
((U joined before A was submitted) and
(U has no conflict of interest with A) and
((U is faculty) or (U has been delegated access to A)))

There are additional restrictions on many sensitive columns and exceptions for other roles. For example, users cannot see reference letters written for them and an applicant's country of birth and citizenship cannot be seen by reviewers until the application has been accepted (to prevent discrimination). Office staff can access all applicant names, emails, and postal addresses (to correspond with them) and CVs of accepted applicants (to prepare contracts). In total, we wrote 41 policies for APPLY.

Implementation effort. APPLY is implemented using Django and Python and stores its data in a database comprising 36 tables and 202 columns. The modifications necessary for APPLY were quite similar to those required for HotCRP. First, we modified 10 LoC to pass user authentication credentials to the Qapla reference monitor.

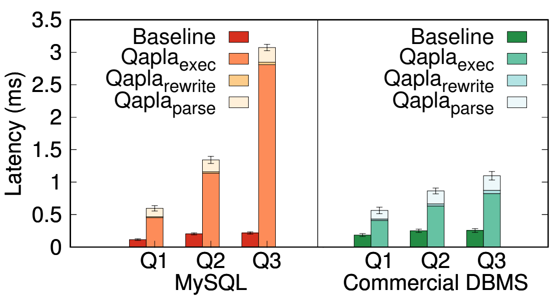

Figure 3: HotCRP query latency on MySQL and a commercial DBMS (baseline is measured without Qapla).

Second, we changed 63 LoC to remove unused columns from queries to make them compatible with our policies.

5 Evaluation

In this section, we present results of an experimental evaluation of Qapla's overhead when used with HotCRP and APPLY. We also perform a brief security evaluation by injecting HotCRP bugs that existed in prior versions.

All experiments were performed on Dell Precision T1600 workstations with an Intel Xeon E3-1225 3.1Ghz quad core CPU, 8GB main memory, and 10Gbit Ethernet links. The client and server machines were running OpenSuse Linux 12.1 (kernel version 3.1.10-1.29, x86-64). The HotCRP server software consisted of Apache HTTP server 2.4.18, PHP 5.6.15, and HotCRP 2.99. The APPLY software included Python 2.7 and Django 1.9.7. By default, the backend database for each application was MySQL Server 5.7.11. In some experiments, we used instead a well-known commercial DBMS, which remains unnamed due to license restrictions on the publication of benchmark results. Both DBMSs were configured with a query cache of 500MB, unless stated differently. Unless stated otherwise, the results correspond to the default setup with MySQL.

For HotCRP, we used an anonymized database snapshot of a major conference hosted on HotCRP in the past. The database included about 150 submissions, over 400 contacts, and over 700 reviews. The papers were reviewed in 3 rounds. For APPLY, we used an anonymized database snapshot of 9396 applications received by our organization for internships, doctoral, postdoc and faculty positions.

5.1 Query latency

The first experiment measures Qapla's latency overhead on individual queries. Qapla introduces overheads associated with query parsing, query rewriting, and executing the rewritten query in the database. Table 3 lists the actual HotCRP queries we used in the experiment. Figure 3 shows the average query latency over 1000 trials, on MySQL and on the commercial DBMS. The Qapla la-

	Baseline query	Policy summary
Q1	select title, abstract from Paper where paperId=X	paper author **or** PC member and the paper is under submission
Q2	select title, overAllMerit from Paper join PaperReview where paperId=X	paper author after notification **or** PC member who is not a conflict and has submitted his/her review and the paper is under submission
Q3	select title, overAllMerit, reviewerName from Paper join PaperReview join ContactInfo where paperId=X	PC member who is not conflicted and has submitted his/her review and the paper is under submission

Table 3: Microbenchmarks queries

tency is broken down into three components: query parsing ($\text{Qapla}_{\text{parse}}$), query rewriting ($\text{Qapla}_{\text{rewrite}}$), and execution of the rewritten query ($\text{Qapla}_{\text{exec}}$). The error bars show the standard deviation. In this experiment, the query caches of the backend DBMSs and Qapla's template cache were disabled.

The contribution of query parsing and rewriting is small, particularly for the more complex queries (on MySQL, 23%, 15%, 8% of the overall query latency for Q1, Q2, and Q3 respectively). The query rewriting overhead is slightly larger with the commercial DBMS, because Qapla has to translate HotCRP queries, which were written for MySQL, to use a SQL syntax appropriate for that DBMS.

In all cases, Qapla's latency overhead is dominated by the execution time of the rewritten queries. A query rewritten with policy conditions may be significantly more complex than the original query as each relation in the query is replaced with a subquery, which may access additional tables that appear in the policy. The efficiency of the rewritten query depends on the database query optimizer being able to generate an efficient query plan. The costs of executing the rewritten queries are lower with the commercial DBMS, whose query optimizer likely is more sophisticated than that of MySQL. Thus, while the commercial DBMS has a slightly higher baseline latency, it is able to execute the rewritten queries relatively faster than MySQL, reducing Qapla's overhead substantially for the more complex queries Q2 and Q3.

Our experiment inflates Qapla's true overheads to some extent, because the rewritten query may require accessing tables that are not mentioned in the original query to ensure compliance. HotCRP accesses these same tables in a separate query to perform the filtering in its own code. To understand this further, we measure the overheads for traces of queries corresponding to user actions in the next experiment.

5.2 Action overhead and latency

A user task in HotCRP and APPLY typically involves multiple actions, such as logging in, clicking on a url to visit a page, and clicking on a button to save a form. For each action, the application in turn issues several SQL queries to get the required data for the response and for policy compliance checks. In this section, we measure the overhead for the sequence of SQL queries involved in several application user tasks. We recorded the SQL queries issued for each of the tasks, and replay the query trace with and without Qapla.

We measured the overhead for executing the query traces and the client-perceived latency overhead under various configurations of the baseline and Qapla. **Base** is the baseline system without Qapla. **Qapla** is Qapla and $\textbf{Qapla}_{\textbf{t-cache}}$ is Qapla with the template cache enabled. In all configurations, the query cache of the backend DBMS was enabled.

5.2.1 HotCRP

In HotCRP, we measured four user tasks: **H1**: As an author, view reviews for a submission (resulting in two actions). **H2**: As a PC member, search for a paper with a keyword, and add a comment (resulting in four actions). **H3**: As PC chair, search for a paper with a keyword, and declare a conflict with a PC member (resulting in five actions). **H4**: As PC chair, invoke the automatic review assignment for all submissions (resulting in three actions).

Task trace execution overhead. First, we measured the average time for executing the traces for tasks H1-H4 on MySQL and the commercial DBMS, respectively, under the three configurations and across 1000 trials (all standard deviations are below 5%).

With MySQL, the relative overheads of $\textbf{Qapla}_{\textbf{t-cache}}$ are 6x, 4.7x, 5.4x, and 7.8x for the tasks, respectively. With the commercial DBMS, the relative overheads of $\textbf{Qapla}_{\textbf{t-cache}}$ are 2.5x, 6.5x, 3.8x, and 2.9x. The results for $\textbf{Qapla}_{\textbf{t-cache}}$ show that Qapla's query template cache is effective in reducing the overhead resulting from Qapla's query parsing and rewriting. The template cache hit rates for each action are 25%, 71%, 82%, and 99%, respectively, yielding a reduction in Qapla's overhead of up to 22%, relative to **Qapla**, for H4 with the commercial DBMS. In the case of H1, we observe a net increase in overhead, because the cost of maintaining the template cache cannot be offset due to the low hit rate.

Client-side latency. To measure the client-perceived latencies from the perspective of a Web client, we executed each task with a client-side driver that issues HTTP requests to HotCRP for each action involved in per-

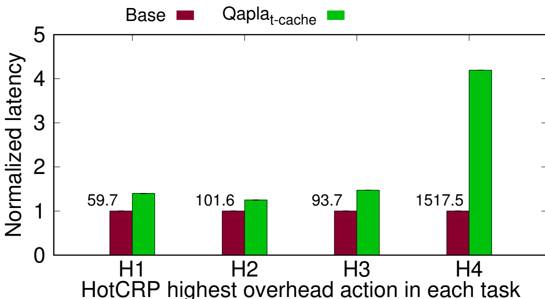

Figure 4: HotCRP client latency of highest overhead action in each task. MySQL, normalized to **Base**. The labels show **Base** absolute latency numbers in milliseconds.

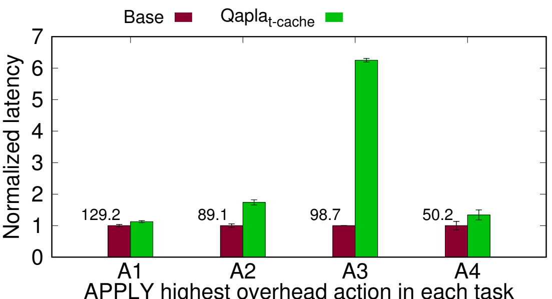

Figure 5: APPLY client latency of highest overhead action, MySQL, normalized to **Base**. The labels show **Base** absolute latency numbers in milliseconds.

forming the task manually. The driver fetches the static HTML pages (but excludes dynamic content such as css, javascripts) from HotCRP and stores them locally. Thus, the experiment includes the overheads of executing PHP code, including database queries, and sending the HTML pages over the network. The template cache as well as the database query cache were flushed after each iteration of a task to fully expose worst-case latency overheads.

Figure 4 shows the average latency, across 1000 trials, of the action with the highest relative overhead in **Qapla$_{t\text{-cache}}$** (all standard deviations are below 0.05%). The latency overheads for the actions are 40%, 25%, 47%, and 320%, respectively. The latency could be reduced further by removing the redundant post-filtering queries in HotCRP.

Most of the latency is due to the PHP execution (including database queries), while the network overhead is minimal (0.2ms on average). All the actions are performed in less than 150ms, except the assignment page generated in H4, which takes 1.5 seconds in **Base** and 6.4 seconds in **Qapla$_{t\text{-cache}}$**. The assignment algorithm invokes about 3780 queries for the given set of papers and reviewers, while the remaining actions invoke less than 200 queries. H4 is a task used by the PC chair(s) only, and normally only a few times per conference, depending on the number of reviewing rounds.

5.2.2 APPLY

In APPLY, we measured the following tasks: **A1**: As an applicant, view the status of a submitted application (resulting in 3 actions). **A2**: As the faculty member in charge of post-doc applications, mark the status of multiple applications to reject, and send rejection emails to the marked applications (resulting in 7 actions). **A3**: As a faculty member, search for an applicant by name, and request recommendation letters from the applicant's recommenders (resulting in 7 actions). **A4**: As a student reviewing doctorate applications, see a list of doctorate applications currently under review, and view the details of a single application (resulting in 4 actions).

Task execution trace overhead. With MySQL, the relative overheads of **Qapla$_{t\text{-cache}}$** are 5.35x, 5.4x, 5.2x, and 4.5x for A1-A4, respectively. With the commercial DBMS, the relative overheads are 4.2x, 3x, 3.3x, and 3.3x, respectively.

Client-side latency. Figure 5 shows the average latency, across 100 trials, of the action with the highest relative overhead in **Qapla$_{t\text{-cache}}$** (all standard deviations are below 12%). The latency overheads are low except for an action in A3: 12.5%, 74%, 6.25x, and 34%, respectively. The high overhead in action A3 is due to a single query with very high runtime, which is the cause of nearly all the overhead. On investigating the query behavior, we found that the performance overhead is due to the MySQL query optimizer's inability to deal with a specific query pattern, possibly because this pattern is unlikely to occur in hand-written queries. When we ran the same query on the commercial DBMS, the overheads came down to approximately 50%.

5.3 HotCRP submission throughput

For most HotCRP actions, latency is the metric of interest, as it affects user-perceived delays. Right before a submission deadline, however, throughput is also a measure of interest, because many authors re-submit a final revision of their submission within the last minutes before a deadline. To examine the performance under such conditions, we measured the number of submissions per second HotCRP can sustain with and without Qapla.

In this experiment, clients concurrently upload submissions of size 356KB, which is close to the average submission size in the past HotCRP conference deployment. We varied the number of concurrent clients from 1 to 64. 32 clients were sufficient to saturate the CPU. Prior to the experiment, we cached the entire conference database (∼880MB) in memory. Figure 6 shows the number of submissions per second our HotCRP installation can sustain for different numbers of concurrently connected clients. The results were averaged across 3

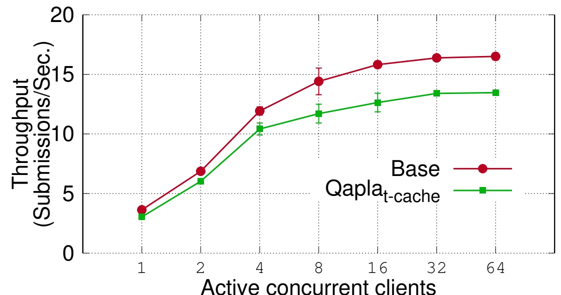

Figure 6: Submission throughput

runs, each of 120 seconds. The error bars show the standard deviation across 3 runs. The overheads are moderate (below 20.2%), and can be compensated by provisioning a somewhat faster server.

5.4 Trace replay

In the next experiment, we check if HotCRP-Qapla can correctly execute all the actions performed in a HotCRP conference deployment across the various review stages, and produce the same output as the unmodified HotCRP. We use a trace derived from the anonymized logfile of the past HotCRP deployment. The logfile contains over 10,000 log entries that correspond to HotCRP database updates. From it, we constructed a trace by inspecting the HotCRP codebase to determine the set of SELECT queries that typically precede a specific update. For example, submitting a review for a submission must have been preceded by viewing the submission page. Since update queries are not subject to policy checks in Qapla, they are not of interest to our experiment and were not included in the trace. Table 4 shows the actions performed for each log entry.

The trace consists of actions corresponding to four phases: submissions, review, discussion, and post notification stage. We replayed the entire trace against the original HotCRP and HotCRP-Qapla and compared the outputs. Because the trace is read-only, we replayed it against the final state of the HotCRP database at the end of the conference review period. As a result, several policies were not exercised the way they would be in a real deployment and, consequently, the outputs of approximately 27% of the actions differed with and without Qapla enforcement (e.g., withdraw link enabled or not, papers may have been withdrawn at a later stage of the conference). Most of these actions were in the first phase. We verified separately that the relevant policies are enforced as expected.

We found that approximately 3% of action outputs differed for other reasons. These reasons are: (i) some non-compliant queries we have not yet modified (e.g., chair unable to make assignments to conflict papers), (ii) policies that are more restrictive than HotCRP assumes (e.g., conflicted PC members unable to download the paper), and (iii) missing policies (e.g., external reviewers not considered).

Log entry	High-level task reads	Count
Create/update account	User logs in, visits her profile	1090
Register, update, submit, or withdraw paper	User logs in, visits the submission page	2082
Added primary/none reviewer	Chair logs in, visits the paper's reviewers assignment/conflicts	1335
Set paper lead-/shepherd	Chair logs in, visits the paper's page	126
Save/submit/delete review/comment	Reviewer logs in, visits the paper's page	3279
Download paper(s)	Reviewer logs in, visits the paper's page, downloads the paper	2582
Send accept/reject notification	Chair logs in, sends decisions to contact authors	2

Table 4: Trace actions for HotCRP

5.5 Native DBMS access control

As discussed in Section 6, some production DBMS systems support fine-grained access control over tables and views to a limited extent. In this section, we compare using Qapla to enforcing policies directly in our commercial DBMS, which unlike MySQL has some support for fine-grained access control. More precisely, this database supports the equivalent of our single-column policies through a special configuration mechanism. We specified many of the HotCRP policies through this mechanism. However, as our work on HotCRP and APPLY demonstrates, applications often require richer policies (such as link and aggregate policies), which cannot be expressed using the DBMS's policy mechanism. To enforce these policies, we had to create additional views on all HotCRP tables, restrict access to those views and update all queries, whether compliant or not, to use views rather than the underlying tables.

We ran the experiments from Section 5.2 to compare the performance of the DBMS access control mechanism with that of Qapla. Figure 7 shows the average latency for HotCRP actions, across 100 trials, normalized to **Base**. The error bars show the standard deviation. Qapla policy enforcement overhead is lower than the overhead of enforcing policies through the DBMS access control for most actions.

The results show that using the native support for fine-grained access control in the commercial DBMS is less efficient than Qapla's policy enforcement. Moreover, to get this level of performance from the commercial DBMS, we had to carefully tune its cache configuration

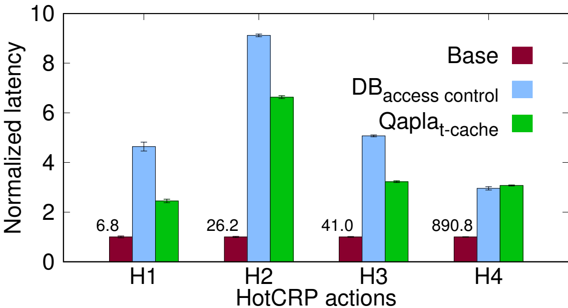

Figure 7: HotCRP action latency with policies enforced using a commercial DBMS's native support for fine-grained access control, normalized to **Base**. Numerical labels indicate absolute **Base** latency in milliseconds.

for this experiment. Qapla, on the other hand, achieves better performance with both MySQL and the commercial DBMS, has a DBMS-independent policy language, and does not require the use of views and the resulting changes to compliant queries.

5.6 Fault injection experiments

To verify that Qapla is effective at preventing accidental data leaks, we manually reviewed HotCRP's change logs for bugs that caused data leaks and other policy violations [2]. We are confident that Qapla can prevent any data leaks that are related to missing or incorrect filtering code in HotCRP, which appear to account for the majority of cases.

As a sanity check, we reproduced two sample bugs HotCRP had in the past. One bug notified authors about changes to PC-only fields during response periods. Another bug allowed PC members to search for papers based on their acceptance status and learn of the acceptance of their papers prematurely. We simulated these bugs by making changes to the policy check functions implemented in HotCRP, or by removing the invocations of these functions at certain places in the application. We executed user actions on the buggy HotCRP application with and without Qapla and manually examined the outputs. We verified that Qapla prevents the data from being revealed to unauthorized parties.

There is one class of data leaks that Qapla cannot prevent by itself, namely when a policy depends on incorrect data recorded in the database. For instance, if HotCRP failed to record the conflicts declared by users correctly in the database, Qapla could not prevent the associated leak. We have not found instances of such bugs in HotCRP's change logs, but it is possible that such bugs might occur.

6 Related work

Database access control. The database community has explored fine-grained access and disclosure control within databases, using SQL conditions [28], queries against restricted authorization views [34], and data-derived security views [13]. A formal framework for the design of database access control is presented by Guarnieri *et al.* [26]. In contrast to these systems, Qapla's goal is to provide a portable policy layer that works with existing DBMSs and applications, without relying on any support for policies within the DBMSs.

DataLawyer [40] is a database middleware system that analyzes and rejects non-compliant queries to a relational DBMS. Policies are stated as SQL queries on the database and a usage log, which contains provenance information. DataLawyer supports rich policies, motivated, for instance, by medical databases. Since policies are associated with the entire database, each query must be checked against all policies, each requiring a separate query. Qapla policies are more restricted (e.g., they cannot refer to provenance), but Qapla is much more efficient because policies are indexed by columns. Also Qapla policies are expressed directly as filter conditions, making them easy to write and understand.

In the context of link policies, DiMon [16], its extension D^2Mon [38] and Biskup's work [14] enforce access policies by relying on an explicit, complete specification of information that a querier can infer from past queries. These systems deny a query when the query would allow the inference of policy-prohibited information. Qapla's approach is complementary and easier to implement and use; we require the specification of only access rules, abstracting away the inferences those accesses would allow. If indeed a complete specification of possible inferences were to exist, it could be used to assist the policy designer understand the consequences of Qapla policies.

Turan *et al.* [39] present an algorithm to partition a database schema such that two pieces of data that should not be linked (according to a policy) lie in separate logical subschemas. This could be a useful optimization in a Qapla deployment. However, it cannot be used for policies where, of three columns, any two may be linked together, but all three may not be linked simultaneously.

IVD [31] is an authorization system deployed in Facebook, which automatically learns write access control rules on their graph database system from production logs, and enforces them at runtime. Qapla's focus, on the other hand, is on read access control and link policies in relational DBMSs.

Access control in production DBMSs. Current production DBMSs support access control at various levels of granularity. However, the extent of support and the language used to express policies varies among DBMSs

and, as far as we know, no DBMS can support all of Qapla's policies without requiring changes to either the schema or queries (including queries that are policy compliant). Qapla enforces fine-grained policies without requiring changes to the schema or policy compliant queries, and requires no support for such policies in the backend DBMS. Moreover, as shown in Section 5.5, Qapla's overhead is lower than a commercial database's native support for fine-grained policies.

Oracle VPD [11] provides extensive support for cell-level access control on tables and views. However, a policy on a table cannot depend on the results of a query on the table itself. Such policies occur in our applications. For instance, the first clause in policy C1 in Table 1 checks that the user is the chair, which is defined using the table that the policy protects. Such policies can be enforced in VPD only by either changing the schema or creating additional views. The use of views, in general, also requires changing queries to use the views instead of the underlying tables. On the other hand, automatic query rewriting as in Qapla is transparent to applications that issue policy compliant queries.

IBM DB2 [9] and SQL Server [10] require a combination of row-level (data-dependent) access control and column masking policies to specify fine-grained policies, which can obscure the policy specification. PostgreSQL [7] has support for row-level policies, but they apply to all columns of a table uniformly. A policy on a subset of columns requires the creation of a view containing only those columns. MySQL and MariaDB do not support data-dependent access control. Fine-grained access control in these DBMSs requires creating a separate view for every group of users with the same privilege, or creating stored procedures and granting privileges to users to execute the procedures [3, 8].

In all production DBMSs we know of, enforcing link policies requires creating a separate view for each policy. Transformation and aggregation policies require separate views or stored procedures. As mentioned above, creating additional views or using stored procedures requires significant changes even to applications that issue only policy-compliant queries.

Database interposition. Interposing on database queries to improve security is a common technique. Perhaps most closely related to our work is CLAMP [33], which has the same goals as Qapla. However, CLAMP's architecture and policy language are different from Qapla's. In CLAMP, when a user initiates a session, the enforcement framework performs user authentication, instantiates a logical view of the database restricted only to data that the user can access (based on applicable policies), and isolates a fresh instance of the application in a virtual machine, restricting it to only communicate with the authenticated user and giving it access to only the logical view of the database via query interposition (as in Qapla). CLAMP's design supports a stronger threat model than Qapla's current prototype—CLAMP isolates user sessions from each other and from the reference monitor, and does not rely on the application to authenticate the user (see Section 3.5)—but the expressiveness of policies, which is really the focal point of our work, is limited in CLAMP. CLAMP only supports per-table policies, which specify the rows that each user has access to. Support for finer policies that differentiate columns of a table from each other or take into account linking, transformation and aggregation is missing in CLAMP. Qapla can be strengthened with CLAMP's isolation and authentication techniques in a straightforward manner.

Diesel [24] is a framework for applying the principle of least privilege on relational databases. Diesel policies specify subsets of a database that each application *module* can access. For example, a policy may specify that a user-facing module can only access the Users table, but not administrative tables, thus limiting damage in the event of a user session compromise. This is very different from Qapla's (and CLAMP's) goal of specifying what data each *user* can access. Nonetheless, Diesel also relies on query interposition (as in Qapla) to enforce its policies.

Passe [15] hardens the web framework Django to isolate application modules from each other. Like Diesel, it uses query interposition to enforce least privilege on data accessible to each module. Unlike Diesel, but like CLAMP and Qapla, Passe's policies are sensitive to the authenticated user. However, Passe's policies are fundamentally different from those of Qapla, CLAMP and Diesel—they enforce data-dependency relations on query parameters. For example, a Passe policy may enforce that the third parameter of the second query made by a specific application module is always a value returned for the first query of the module. Moreover, Passe's policies are not specified by administrators. Instead, they are learnt by automated testing in an offline phase. This learning can have both false positives (it may learn a policy that is too restrictive) and false negatives (it may not learn a required policy). Due to the very different nature of Passe's policies, it is not possible to directly compare their expressiveness to that of Qapla's policies.

Policy languages. EPAL [12] specifies enterprise privacy policies in terms of user categories, data categories, purposes, actions, obligations, and conditions. Qapla relies on authentication-based access control instead of purpose-based access control. Also, Qapla uses SQL syntax to specify policy languages, similar to [19, 28]. SQL is a natural choice to specify policies for database-backed applications, since it enables specifying complex policies on query operators easily, and developers are al-

ready familiar with it.

CMS confidentiality. CoCon is a new conference management system whose confidentiality properties were verified formally in the Isabelle proof assistant [27]. Qapla on the other hand, is a general, language-independent runtime compliance layer for database queries, which we have used to enforce compliance in an existing and widely used conference management system, HotCRP.

Privacy in statistical databases. Differential privacy [23] and privacy-preserving queries [32, 17] are focused on statistical databases, where only statistical information, but no information about individual records, should be revealed. Qapla instead focuses on applications that require access to specific database records, subject to fine-grained policies.

Information Flow Control. UrFlow [19], Hails [25], Jacqueline [41], DBTaint [22], RESIN [42], LabelFlow [18] and Nemesis [21] use language-based techniques to enforce information flow control in web applications written in specific languages. In contrast, Qapla can be ported to any language easily but it enforces access policies, not information flow control. Qapla can be integrated with a language-based technique to control information flow with fine-grained policies.

IFDB [36] enforces authorization policies by modifying the PostgreSQL database engine, as well as the application environments in PHP and Python. For enforcing column policies, IFDB relies on declassifying views. Row policies are specified with secrecy and integrity labels, which are associated with database records. IFDB enforces row policies by tracking the labels through the application process and stored procedures. Qapla specifies all policies using one mechanism. Qapla's enforcement uses query rewriting and is database-agnostic.

Sif [20], SeLINQ [35], and Li *et al.* [29] assign labels or security types to database columns, and use security-typed programming languages to write restricted query interfaces to the database and the application code. However, these systems cannot enforce data-dependent policies. Furthermore, some of these systems [35, 29] rely on programming applications in languages that integrate database query mechanisms. While the current prototype of Qapla focuses on applications using SQL to query databases, it can be easily extended to protect applications using other programming paradigms for database queries. Qapla does not impose any restrictions on the programming language for the applications themselves.

7 Conclusion

We have presented and evaluated Qapla, a system that ensures compliance with confidentiality policies in database-backed systems. Fine-grained access policies are stated in a SQL-like language separate from application code, and may refer to user id, time, tables, columns, rows, as well as query operators like aggregation, group by, and join. Qapla adds a reference monitor to the database adapter, which intercepts and rewrites queries to ensure compliance.

Qapla reliably prevents a large class of data confidentiality breaches due to application bugs. Qapla's declarative specification of applicable policies, separate from application code and associated with the database schema, eases the task of specifying, enforcing and auditing confidentiality policy. The system's policy language and enforcement is independent of the DBMS used as a backend.
