Message from the 26th USENIX Security Symposium Program Co-Chairs

Welcome to the USENIX Security Symposium in Vancouver! The symposium, now in its 26th year, is a premier venue for security and privacy research, and gathers together researchers from both industry and academia to discuss the latest on improving computer security. The program consists of research papers selected during a peer-review process, invited talks, and professional and social events.

This was the biggest year ever for our peer-review submissions process. Like last year, the symposium had two chairs. We were supported by an excellent program committee (PC) consisting of 77 members. Of those, 35 were remote PC members whereas 42 also attended an in-person PC meeting in Boston that lasted a day and a half. The PC members did an incredible amount of work, and we can't thank them enough for their efforts!

The double-blind review process this year worked as follows: We received 572 submissions—the most ever for the symposium—by the submission deadline of February 16, 2017. Of these, 19 were desk-rejected for various violations of the call for papers. Reviewing proceeded in two rounds. In the first round, every paper was assigned to two reviewers, and 199 papers were marked for rejection after the first round (due to unanimously low scores by two confident reviewers). We allowed a special appeals process in case of reviewer error; none of the appealed papers were revived after inspection of the authors' concerns. The remaining papers passed on to a second round, and received one or more additional reviews.

In an online discussion phase, the committee attempted to accept or reject a large number of papers before the in-person meeting. This was to ensure that there was sufficient time at the meeting to discuss the most contentious papers. We pre-accepted 49 papers during online discussions and discussed about 80 papers during the meeting. Each paper was allowed up to eight minutes of discussion, with few exceptions. The vast majority were easily decided upon within that time. Unlike last year, we did not unblind the authors during the PC meeting and believe the benefits (in terms of discouraging negative or positive bias) outweighed the few situations that arose in which the PC members would have benefited from knowing the authorship. The chairs also decided to keep the PC members somewhat in the dark about the number of papers being accepted over the course of the meeting in the hope that discussions could focus on the merit of individual papers rather than on the need to "fill a program."

At the meeting, the committee had an extensive discussion about whether more theory-oriented papers are suitably in-scope for the symposium. Over the last few years, the symposium has seen an increasing number of papers that only very tangentially target computer security problems faced in practice, most notably in the context of papers developing or improving cryptographic protocols not yet addressing specific security applications. After extensive discussion, the committee decided that the broader community would be better served by encouraging such papers to seek other venues. This was not a decision taken lightly, and it resulted in a number of very good papers being rejected for reason of fit.

Ultimately, the committee decided to accept 85 papers, a record number for the symposium. Of these, 38 were conditionally accepted and shepherded to ensure that the camera-ready version of the paper reflected reviewer feedback. In the end, this resulted in a 15% acceptance rate, meaning that the conference continues to be exceptionally competitive. We believe the final set of accepted papers represent excellent work, and the authors should be congratulated for their notable achievement!

The conference would not be possible without the help of a huge number of people. The staff at USENIX ensure that everything runs smoothly behind the scenes, and Casey Henderson and Michele Nelson specifically helped us in innumerable ways. The PC, of course, did a tremendous amount of work, with each member reviewing about 20 papers, for a total of over 1600 reviews and over 2200 comments across the entire process. We also thank the external reviewers who were brought in due to their particular expertise to review a smaller number of papers. We would also like to thank for their hard work: the invited talks committee (Michael Bailey, Casey Henderson, David Molnar, and Franziska Roesner); the Test-of-Time award committee (Matt Blaze, Dan Boneh, Kevin Fu, and David Wagner); the poster-session chair Nick Nikiforakis; and the lightning talks chairs Kevin Butler and Deian Stefan. Finally, we thank all of the authors of the 572 submitted papers for participating in the 26th USENIX Security Symposium.

Engin Kirda, *Northeastern University*
Thomas Ristenpart, *Cornell Tech*
USENIX Security '17 Program Co-Chairs

USENIX Security '17: 26th USENIX Security Symposium

Bug Finding I

How Double-Fetch Situations turn into Double-Fetch Vulnerabilities: A Study of Double Fetches in the Linux Kernel 1
Pengfei Wang, *National University of Defense Technology;* Jens Krinke, *University College London;* Kai Lu and Gen Li, *National University of Defense Technology;* Steve Dodier-Lazaro, *University College London*

Postmortem Program Analysis with Hardware-Enhanced Post-Crash Artifacts 17
Jun Xu, *The Pennsylvania State University;* Dongliang Mu, *Nanjing University;* Xinyu Xing, Peng Liu, and Ping Chen, *The Pennsylvania State University;* Bing Mao, *Nanjing University*

Ninja: Towards Transparent Tracing and Debugging on ARM 33
Zhenyu Ning and Fengwei Zhang, *Wayne State University*

Side-Channel Attacks I

Prime+Abort: A Timer-Free High-Precision L3 Cache Attack using Intel TSX 51
Craig Disselkoen, David Kohlbrenner, Leo Porter, and Dean Tullsen, *University of California, San Diego*

On the effectiveness of mitigations against floating-point timing channels 69
David Kohlbrenner and Hovav Shacham, *UC San Diego*

Constant-Time Callees with Variable-Time Callers 83
Cesar Pereida García and Billy Bob Brumley, *Tampere University of Technology*

Systems Security I

Neural Nets Can Learn Function Type Signatures From Binaries 99
Zheng Leong Chua, Shiqi Shen, Prateek Saxena, and Zhenkai Liang, *National University of Singapore*

CAn't Touch This: Software-only Mitigation against Rowhammer Attacks targeting Kernel Memory 117
Ferdinand Brasser, *Technische Universität Darmstadt;* Lucas Davi, *University of Duisburg-Essen;* David Gens, Christopher Liebchen, and Ahmad-Reza Sadeghi, *Technische Universität Darmstadt*

Efficient Protection of Path-Sensitive Control Security 131
Ren Ding and Chenxiong Qian, *Georgia Tech;* Chengyu Song, *UC Riverside;* Bill Harris, Taesoo Kim, and Wenke Lee, *Georgia Tech*

Bug Finding II

Digtool: A Virtualization-Based Framework for Detecting Kernel Vulnerabilities 149
Jianfeng Pan, Guanglu Yan, and Xiaocao Fan, *IceSword Lab, 360 Internet Security Center*

kAFL: Hardware-Assisted Feedback Fuzzing for OS Kernels 167
Sergej Schumilo, Cornelius Aschermann, and Robert Gawlik, *Ruhr-Universität Bochum;* Sebastian Schinzel, *Münster University of Applied Sciences;* Thorsten Holz, *Ruhr-Universität Bochum*

Venerable Variadic Vulnerabilities Vanquished 183
Priyam Biswas, *Purdue University;* Alessandro Di Federico, *Politecnico di Milano;* Scott A. Carr, *Purdue University;* Prabhu Rajasekaran, Stijn Volckaert, Yeoul Na, and Michael Franz, *University of California, Irvine;* Mathias Payer, *Purdue University*

(continued on next page)

Side-Channel Countermeasures

Towards Practical Tools for Side Channel Aware Software Engineering: 'Grey Box' Modelling for Instruction Leakages 199
David McCann, Elisabeth Oswald, and Carolyn Whitnall, *University of Bristol*

Strong and Efficient Cache Side-Channel Protection using Hardware Transactional Memory 217
Daniel Gruss, *Graz University of Technology, Graz, Austria;* Julian Lettner, *University of California, Irvine, USA;* Felix Schuster, Olya Ohrimenko, Istvan Haller, and Manuel Costa, *Microsoft Research, Cambridge, UK*

CacheD: Identifying Cache-Based Timing Channels in Production Software 235
Shuai Wang, Pei Wang, Xiao Liu, Danfeng Zhang, and Dinghao Wu, *The Pennsylvania State University*

Malware and Binary Analysis

BinSim: Trace-based Semantic Binary Diffing via System Call Sliced Segment Equivalence Checking 253
Jiang Ming, *University of Texas at Arlington;* Dongpeng Xu, Yufei Jiang, and Dinghao Wu, *Pennsylvania State University*

PlatPal: Detecting Malicious Documents with Platform Diversity 271
Meng Xu and Taesoo Kim, *Georgia Institute of Technology*

Malton: Towards On-Device Non-Invasive Mobile Malware Analysis for ART 289
Lei Xue, *The Hong Kong Polytechnic University;* Yajin Zhou, *unaffiliated;* Ting Chen, *University of Electronic Science and Technology of China;* Xiapu Luo, *The Hong Kong Polytechnic University;* Guofei Gu, *Texas A&M University*

Censorship

Global Measurement of DNS Manipulation 307
Paul Pearce, *UC Berkeley;* Ben Jones, *Princeton;* Frank Li, *UC Berkeley;* Roya Ensafi and Nick Feamster, *Princeton;* Nick Weaver, *ICSI;* Vern Paxson, *UC Berkeley*

Characterizing the Nature and Dynamics of Tor Exit Blocking 325
Rachee Singh, *University of Massachusetts – Amherst;* Rishab Nithyanand, *Stony Brook University;* Sadia Afroz, *University of California, Berkeley and International Computer Science Institute;* Paul Pearce, *UC Berkeley;* Michael Carl Tschantz, *International Computer Science Institute;* Phillipa Gill, *University of Massachusetts – Amherst;* Vern Paxson, *University of California, Berkeley and International Computer Science Institute*

DeTor: Provably Avoiding Geographic Regions in Tor 343
Zhihao Li, Stephen Herwig, and Dave Levin, *University of Maryland*

Embedded Systems

SmartAuth: User-Centered Authorization for the Internet of Things 361
Yuan Tian, *Carnegie Mellon University;* Nan Zhang, *Indiana University, Bloomington;* Yueh-Hsun Lin, *Samsung;* Xiaofeng Wang, *Indiana University, Bloomington;* Blase Ur, *University of Chicago;* Xianzheng Guo and Patrick Tague, *Carnegie Mellon University*

AWare: Preventing Abuse of Privacy-Sensitive Sensors via Operation Bindings 379
Giuseppe Petracca, *The Pennsylvania State University, US;* Ahmad-Atamli Reineh, *University of Oxford, UK;* Yuqiong Sun, *The Pennsylvania State University, US;* Jens Grossklags, *Technical University of Munich, DE;* Trent Jaeger, *The Pennsylvania State University, US*

6thSense: A Context-aware Sensor-based Attack Detector for Smart Devices 397
Amit Kumar Sikder, Hidayet Aksu, and A. Selcuk Uluagac, *Florida International University*

Networking Security

Identifier Binding Attacks and Defenses in Software-Defined Networks 415
Samuel Jero, *Purdue University;* William Koch, *Boston University;* Richard Skowyra and Hamed Okhravi, *MIT Lincoln Laboratory;* Cristina Nita-Rotaru, *Northeastern University;* David Bigelow, *MIT Lincoln Laboratory*

HELP: Helper-Enabled In-Band Device Pairing Resistant Against Signal Cancellation 433
Nirnimesh Ghose, Loukas Lazos, and Ming Li, *Electrical and Computer Engineering, University of Arizona, Tucson, AZ*

Attacking the Brain: Races in the SDN Control Plane 451
Lei Xu, Jeff Huang, and Sungmin Hong, *Texas A&M University;* Jialong Zhang, *IBM Research;* Guofei Gu, Texas A&M University

Targeted Attacks

Detecting Credential Spearphishing Attacks in Enterprise Settings 469
Grant Ho, *UC Berkeley;* Aashish Sharma, *The Lawrence Berkeley National Laboratory;* Mobin Javed, *UC Berkeley;* Vern Paxson, *UC Berkeley and ICSI;* David Wagner, *UC Berkeley*

SLEUTH: Real-time Attack Scenario Reconstruction from COTS Audit Data 487
Md Nahid Hossain, *Stony Brook University;* Sadegh M. Milajerdi, *University of Illinois at Chicago;* Junao Wang, *Stony Brook University;* Birhanu Eshete and Rigel Gjomemo, *University of Illinois at Chicago;* R. Sekar and Scott Stoller, *Stony Brook University;* V.N. Venkatakrishnan, *University of Illinois at Chicago*

When the Weakest Link is Strong: Secure Collaboration in the Case of the Panama Papers 505
Susan E. McGregor, *Columbia Journalism School;* Elizabeth Anne Watkins, *Columbia University;* Mahdi Nasrullah Al-Ameen and Kelly Caine, *Clemson University;* Franziska Roesner, *University of Washington*

Trusted Hardware

Hacking in Darkness: Return-oriented Programming against Secure Enclaves 523
Jaehyuk Lee and Jinsoo Jang, *KAIST;* Yeongjin Jang, *Georgia Institute of Technology;* Nohyun Kwak, Yeseul Choi, and Changho Choi, *KAIST;* Taesoo Kim, *Georgia Institute of Technology;* Marcus Peinado, *Microsoft Research;* Brent Byunghoon Kang, *KAIST*

vTZ: Virtualizing ARM TrustZone 541
Zhichao Hua, Jinyu Gu, Yubin Xia, and Haibo Chen, *Institute of Parallel and Distributed Systems, Shanghai Jiao Tong University; Shanghai Key Laboratory of Scalable Computing and Systems, Shanghai Jiao Tong University;* Binyu Zang, *Institute of Parallel and Distributed Systems, Shanghai Jiao Tong University;* Haibing Guan, *Shanghai Key Laboratory of Scalable Computing and Systems, Shanghai Jiao Tong University*

Inferring Fine-grained Control Flow Inside SGX Enclaves with Branch Shadowing 557
Sangho Lee, Ming-Wei Shih, Prasun Gera, Taesoo Kim, and Hyesoon Kim, *Georgia Institute of Technology;* Marcus Peinado, *Microsoft Research*

Authentication

AuthentiCall: Efficient Identity and Content Authentication for Phone Calls 575
Bradley Reaves, *North Carolina State University;* Logan Blue, Hadi Abdullah, Luis Vargas, Patrick Traynor, and Thomas Shrimpton, *University of Florida*

Picking Up My Tab: Understanding and Mitigating Synchronized Token Lifting and Spending in Mobile Payment 593
Xiaolong Bai, *Tsinghua University;* Zhe Zhou, *The Chinese University of Hong Kong;* XiaoFeng Wang, *Indiana University Bloomington;* Zhou Li, *IEEE Member;* Xianghang Mi and Nan Zhang, *Indiana University Bloomington;* Tongxin Li, *Peking University;* Shi-Min Hu, *Tsinghua University;* Kehuan Zhang, *The Chinese University of Hong Kong*

(continued on next page)

TrustBase: An Architecture to Repair and Strengthen Certificate-based Authentication 609
Mark O'Neill, Scott Heidbrink, Scott Ruoti, Jordan Whitehead, Dan Bunker, Luke Dickinson, Travis Hendershot, Joshua Reynolds, Kent Seamons, and Daniel Zappala, *Brigham Young University*

Malware and Obfuscation

Transcend: Detecting Concept Drift in Malware Classification Models 625
Roberto Jordaney, *Royal Holloway, University of London;* Kumar Sharad, *NEC Laboratories Europe;* Santanu K. Dash, *University College London;* Zhi Wang, *Nankai University;* Davide Papini, *Elettronica S.p.A.;* Ilia Nouretdinov and Lorenzo Cavallaro, *Royal Holloway, University of London*

Syntia: Synthesizing the Semantics of Obfuscated Code 643
Tim Blazytko, Moritz Contag, Cornelius Aschermann, and Thorsten Holz, *Ruhr-Universität Bochum*

Predicting the Resilience of Obfuscated Code Against Symbolic Execution Attacks via Machine Learning 661
Sebastian Banescu, *Technische Universität München;* Christian Collberg, *University of Arizona;* Alexander Pretschner, *Technische Universität München*

Web Security I

Extension Breakdown: Security Analysis of Browsers Extension Resources Control Policies 679
Iskander Sanchez-Rola and Igor Santos, *DeustoTech, University of Deusto;* Davide Balzarotti, *Eurecom*

CCSP: Controlled Relaxation of Content Security Policies by Runtime Policy Composition 695
Stefano Calzavara, Alvise Rabitti, and Michele Bugliesi, *Università Ca' Foscari Venezia*

Same-Origin Policy: Evaluation in Modern Browsers 713
Jörg Schwenk, Marcus Niemietz, and Christian Mainka, *Horst Görtz Institute for IT Security, Chair for Network and Data Security, Ruhr-University Bochum*

Privacy

Locally Differentially Private Protocols for Frequency Estimation 729
Tianhao Wang, Jeremiah Blocki, and Ninghui Li, *Purdue University;* Somesh Jha, *University of Wisconsin Madison*

BLENDER: Enabling Local Search with a Hybrid Differential Privacy Model 747
Brendan Avent and Aleksandra Korolova, *University of Southern California;* David Zeber and Torgeir Hovden, *Mozilla;* Benjamin Livshits, *Imperial College London*

Computer Security, Privacy, and DNA Sequencing: Compromising Computers with Synthesized DNA, Privacy Leaks, and More 765
Peter Ney, Karl Koscher, Lee Organick, Luis Ceze, and Tadayoshi Kohno, *University of Washington*

Systems Security II

BootStomp: On the Security of Bootloaders in Mobile Devices 781
Nilo Redini, Aravind Machiry, Dipanjan Das, Yanick Fratantonio, Antonio Bianchi, Eric Gustafson, Yan Shoshitaishvili, Christopher Kruegel, and Giovanni Vigna, *UC Santa Barbara*

Seeing Through The Same Lens: Introspecting Guest Address Space At Native Speed 799
Siqi Zhao and Xuhua Ding, *Singapore Management University;* Wen Xu, *Georgia Institute of Technology;* Dawu Gu, *Shanghai JiaoTong University*

Oscar: A Practical Page-Permissions-Based Scheme for Thwarting Dangling Pointers 815
Thurston H.Y. Dang, *University of California, Berkeley;* Petros Maniatis, *Google Brain;* David Wagner, *University of California, Berkeley*

Web Security II

PDF Mirage: Content Masking Attack Against Information-Based Online Services 833
Ian Markwood, Dakun Shen, Yao Liu, and Zhuo Lu, *University of South Florida*

Loophole: Timing Attacks on Shared Event Loops in Chrome 849
Pepe Vila, *IMDEA Software Institute & Technical University of Madrid (UPM);* Boris Köpf, *IMDEA Software Institute*

Game of Registrars: An Empirical Analysis of Post-Expiration Domain Name Takeovers 865
Tobias Lauinger, *Northeastern University;* Abdelberi Chaabane, *Nokia Bell Labs;* Ahmet Salih Buyukkayhan, *Northeastern University;* Kaan Onarlioglu, *www.onarlioglu.com;* William Robertson, *Northeastern University*

Applied Cryptography

Speeding up detection of SHA-1 collision attacks using unavoidable attack conditions 881
Marc Stevens, *CWI;* Daniel Shumow, *Microsoft Research*

Phoenix: Rebirth of a Cryptographic Password-Hardening Service 899
Russell W. F. Lai, *Friedrich-Alexander-University Erlangen-Nürnberg, Chinese University of Hong Kong;* Christoph Egger and Dominique Schröder, *Friedrich-Alexander-University Erlangen-Nürnberg;* Sherman S. M. Chow, *Chinese University of Hong Kong*

Vale: Verifying High-Performance Cryptographic Assembly Code 917
Barry Bond and Chris Hawblitzel, *Microsoft Research;* Manos Kapritsos, *University of Michigan;* K. Rustan M. Leino and Jacob R. Lorch, *Microsoft Research;* Bryan Parno, *Carnegie Mellon University;* Ashay Rane, *The University of Texas at Austin;* Srinath Setty, *Microsoft Research;* Laure Thompson, *Cornell University*

Web Security III

Exploring User Perceptions of Discrimination in Online Targeted Advertising 935
Angelisa C. Plane, Elissa M. Redmiles, and Michelle L. Mazurek, *University of Maryland;* Michael Carl Tschantz, *International Computer Science Institute*

Measuring the Insecurity of Mobile Deep Links of Android 953
Fang Liu, Chun Wang, Andres Pico, Danfeng Yao, and Gang Wang, *Virginia Tech*

How the Web Tangled Itself: Uncovering the History of Client-Side Web (In)Security 971
Ben Stock, *CISPA, Saarland University;* Martin Johns, *SAP SE;* Marius Steffens and Michael Backes, *CISPA, Saarland University*

Software Security

Towards Efficient Heap Overflow Discovery 989
Xiangkun Jia, *TCA/SKLCS, Institute of Software, Chinese Academy of Sciences;* Chao Zhang, *Institute for Network Science and Cyberspace, Tsinghua University;* Purui Su, Yi Yang, Huafeng Huang, and Dengguo Feng, *TCA/SKLCS, Institute of Software, Chinese Academy of Sciences*

DR. CHECKER: A Soundy Analysis for Linux Kernel Drivers 1007
Aravind Machiry, Chad Spensky, Jake Corina, Nick Stephens, Christopher Kruegel, and Giovanni Vigna, *UC Santa Barbara*

Dead Store Elimination (Still) Considered Harmful 1025
Zhaomo Yang and Brian Johannesmeyer, *University of California, San Diego;* Anders Trier Olesen, *Aalborg University;* Sorin Lerner and Kirill Levchenko, *University of California, San Diego*

Side-Channel Attacks II

Telling Your Secrets Without Page Faults: Stealthy Page Table-Based Attacks on Enclaved Execution ... 1041
Jo Van Bulck, *imec-DistriNet, KU Leuven;* Nico Weichbrodt and Rüdiger Kapitza, *IBR DS, TU Braunschweig;* Frank Piessens and Raoul Strackx, *imec-DistriNet, KU Leuven*

(continued on next page)

CLKSCREW: Exposing the Perils of Security-Oblivious Energy Management 1057
Adrian Tang, Simha Sethumadhavan, and Salvatore Stolfo, *Columbia University*

AutoLock: Why Cache Attacks on ARM Are Harder Than You Think 1075
Marc Green, *Worcester Polytechnic Institute;* Leandro Rodrigues-Lima and Andreas Zankl, *Fraunhofer AISEC;* Gorka Irazoqui, *Worcester Polytechnic Institute;* Johann Heyszl, *Fraunhofer AISEC;* Thomas Eisenbarth, *Worcester Polytechnic Institute*

Understanding Attacks

Understanding the Mirai Botnet 1093
Manos Antonakakis, *Georgia Institute of Technology;* Tim April, *Akamai;* Michael Bailey, *University of Illinois, Urbana-Champaign;* Matt Bernhard, *University of Michigan, Ann Arbor;* Elie Bursztein, *Google;* Jaime Cochran, *Cloudflare;* Zakir Durumeric and J. Alex Halderman, *University of Michigan, Ann Arbor;* Luca Invernizzi, *Google;* Michalis Kallitsis, *Merit Network, Inc.;* Deepak Kumar, *University of Illinois, Urbana-Champaign;* Chaz Lever, *Georgia Institute of Technology;* Zane Ma and Joshua Mason, *University of Illinois, Urbana-Champaign;* Damian Menscher, *Google;* Chad Seaman, *Akamai;* Nick Sullivan, *Cloudflare;* Kurt Thomas, *Google;* Yi Zhou, *University of Illinois, Urbana-Champaign*

MPI: Multiple Perspective Attack Investigation with Semantics Aware Execution Partitioning 1111
Shiqing Ma, *Purdue University;* Juan Zhai, *Nanjing University;* Fei Wang, *Purdue University;* Kyu Hyung Lee, *University of Georgia;* Xiangyu Zhang and Dongyan Xu, *Purdue University*

Detecting Android Root Exploits by Learning from Root Providers 1129
Ioannis Gasparis, Zhiyun Qian, Chengyu Song, and Srikanth V. Krishnamurthy, *University of California, Riverside*

Hardware Security

USB Snooping Made Easy: Crosstalk Leakage Attacks on USB Hubs 1145
Yang Su, *Auto-ID Lab, The School of Computer Science, The University of Adelaide;* Daniel Genkin, *University of Pennsylvania and University of Maryland;* Damith Ranasinghe, *Auto-ID Lab, The School of Computer Science, The University of Adelaide;* Yuval Yarom, *The University of Adelaide and Data61, CSIRO*

Reverse Engineering x86 Processor Microcode 1163
Philipp Koppe, Benjamin Kollenda, Marc Fyrbiak, Christian Kison, Robert Gawlik, Christof Paar, and Thorsten Holz, *Ruhr-University Bochum*

See No Evil, Hear No Evil, Feel No Evil, Print No Evil? Malicious Fill Patterns Detection in Additive Manufacturing 1181
Christian Bayens, *Georgia Institute of Technology;* Tuan Le and Luis Garcia, *Rutgers University;* Raheem Beyah, *Georgia Institute of Technology;* Mehdi Javanmard and Saman Zonouz, *Rutgers University*

Privacy & Anonymity Systems

The Loopix Anonymity System 1199
Ania M. Piotrowska and Jamie Hayes, *University College London;* Tariq Elahi, *KU Leuven;* Sebastian Meiser and George Danezis, *University College London*

MCMix: Anonymous Messaging via Secure Multiparty Computation 1217
Nikolaos Alexopoulos, *TU Darmstadt;* Aggelos Kiayias, *University of Edinburgh;* Riivo Talviste, *Cybernetica AS;* Thomas Zacharias, *University of Edinburgh*

ORide: A Privacy-Preserving yet Accountable Ride-Hailing Service 1235
Anh Pham, Italo Dacosta, Guillaume Endignoux, and Juan Ramon Troncoso Pastoriza, *EPFL;* Kevin Huguenin, *UNIL;* Jean-Pierre Hubaux, *EPFL*

Software Integrity

Adaptive Android Kernel Live Patching 1253
Yue Chen, *Florida State University;* Yulong Zhang, *Baidu X-Lab;* Zhi Wang, *Florida State University;* Liangzhao Xia, Chenfu Bao, and Tao Wei, *Baidu X-Lab*

CHAINIAC: Proactive Software-Update Transparency via Collectively Signed Skipchains and Verified Builds 1271
Kirill Nikitin, Eleftherios Kokoris-Kogias, Philipp Jovanovic, Nicolas Gailly, and Linus Gasser, *École polytechnique fédérale de Lausanne* (*EPFL*)*;* Ismail Khoffi, *University of Bonn;* Justin Cappos, *New York University;* Bryan Ford, *École polytechnique fédérale de Lausanne* (*EPFL*)

ROTE: Rollback Protection for Trusted Execution 1289
Sinisa Matetic, Mansoor Ahmed, Kari Kostiainen, Aritra Dhar, David Sommer, and Arthur Gervais, *ETH Zurich;* Ari Juels, *Cornell Tech;* Srdjan Capkun, *ETH Zurich*

Crypto Deployment

A Longitudinal, End-to-End View of the DNSSEC Ecosystem 1307
Taejoong Chung, *Northeastern University;* Roland van Rijswijk-Deij, *University of Twente and SURFnet bv;* Balakrishnan Chandrasekaran, *TU Berlin;* David Choffnes, *Northeastern University;* Dave Levin, *University of Maryland;* Bruce M. Maggs, *Duke University and Akamai Technologies;* Alan Mislove and Christo Wilson, *Northeastern University*

Measuring HTTPS Adoption on the Web 1323
Adrienne Porter Felt, *Google;* Richard Barnes, *Cisco;* April King, *Mozilla;* Chris Palmer, Chris Bentzel, and Parisa Tabriz, *Google*

"I Have No Idea What I'm Doing" - On the Usability of Deploying HTTPS 1339
Katharina Krombholz, Wilfried Mayer, Martin Schmiedecker, and Edgar Weippl, *SBA Research*

Privacy Attacks & Defense

Abstract

We present the first static approach that systematically detects potential double-fetch vulnerabilities in the Linux kernel. Using a pattern-based analysis, we identified 90 double fetches in the Linux kernel. 57 of these occur in drivers, which previous dynamic approaches were unable to detect without access to the corresponding hardware. We manually investigated the 90 occurrences, and inferred three typical scenarios in which double fetches occur. We discuss each of them in detail. We further developed a static analysis, based on the Coccinelle matching engine, that detects double-fetch situations which can cause kernel vulnerabilities. When applied to the Linux, FreeBSD, and Android kernels, our approach found six previously unknown double-fetch bugs, four of them in drivers, three of which are exploitable double-fetch vulnerabilities. All of the identified bugs and vulnerabilities have been confirmed and patched by maintainers. Our approach has been adopted by the Coccinelle team and is currently being integrated into the Linux kernel patch vetting. Based on our study, we also provide practical solutions for anticipating double-fetch bugs and vulnerabilities. We also provide a solution to automatically patch detected double-fetch bugs.

1 Introduction

The wide use of multi-core hardware is making concurrent programs increasingly pervasive, especially in operating systems, real-time systems and computing intensive systems. However, concurrent programs are also notorious for difficult to detect concurrency bugs. Real-world concurrency bugs can be categorized into three types: atomicity-violation bugs, order-violation bugs, and deadlocks [20].

A data race is another common situation in concurrent programs. It occurs when two threads are accessing one shared memory location, at least one of the two accesses is a write, and the relative ordering of the two accesses is not enforced by any synchronization primitives [30, 15]. Data races usually lead to concurrency bugs because they can cause atomicity-violations [22, 21, 23] or order-violations [33, 40]. In addition to occurring between two threads, data races can also happen across the kernel and user space. Serna [32] was the first to use the term "double fetch" to describe a Windows kernel vulnerability due to a race condition in which the kernel fetches the same user space data twice. A double-fetch bug occurs when the kernel reads and uses the same value that resides in the user space twice (expecting it to be identical both times), while a concurrently running user thread can modify the value in the time window between the two kernel reads. Double-fetch bugs introduce data inconsistencies in the kernel code, leading to exploitable vulnerabilities such as buffer overflows [1, 32, 14, 37].

Jurczyk and Coldwind [14] were the first to study double fetches systematically. Their dynamic approach detected double fetches by tracing memory accesses and they discovered a series of double-fetch vulnerabilities in the Windows kernel. However, their dynamic approach can achieve only limited coverage. In particular, it cannot be applied to code that needs corresponding hardware to be executed, so device drivers cannot be analyzed without access to the device or a simulation of it. Thus, their analysis cannot cover the entirety of the kernel. In fact, their approach has not discovered any double-fetch vulnerability in Linux, FreeBSD or OpenBSD [13]. Besides, Jurczyk and Coldwind have brought attention to not only on how to find but also on *how to exploit* double-fetch vulnerabilities. Instructions on how to exploit double fetches have recently become publicly available [11]. Thus, auditing kernels, in particular drivers, for double-fetch vulnerabilities has become urgent.

Device drivers are critical kernel-level programs that bridge hardware and software by providing interfaces between the operating system and the devices attached to the system. Drivers are a large part of current operat-

ing systems, e.g., 44% of the Linux 4.5 source files belong to drivers. Drivers were found to be particularly bug-prone kernel components. Chou et al. [7] empirically showed that the error-rate in device drivers is about ten times higher than in any other parts of the kernel. Swift et al. [34] also found that 85% of system crashes in Windows XP can be blamed on driver errors. Furthermore, Ryzhyk et al. [29] found that 19% of the bugs in drivers were concurrency bugs, and most of them were data races or deadlocks.

Because drivers are such a critical point of failure in kernels, they must be analyzed for security vulnerabilities even when their corresponding hardware is not available. Indeed, 26% of the Linux kernel source files belong to hardware architectures other than x86 which cannot be analyzed with Jurczyk and Coldwind's x86-based technique. Thus, dynamic analysis is not a viable, affordable approach. Therefore, we developed a static pattern-based approach to identify double fetches in the Linux kernel, including the complete space of drivers. We identified 90 double fetches which we then investigated and categorized into three typical scenarios in which double fetches occur. We found that most double fetches are not double-fetch bugs because although the kernel *fetches* the same data twice, it only *uses* the data from one of the two fetches. We therefore refined the static pattern-based approach to detect actual double-fetch bugs and vulnerabilities, and analyzed Linux, Android and FreeBSD with it.

We found that most of the double fetches in Linux 4.5 occur in drivers (57/90) and so do most of the identified double-fetch bugs (4/5). This means dynamic analysis methods fail to detect a majority of double fetch bugs, unless researchers have access to the complete range of hardware compatible with the kernel they analyze. This is confirmed by a comparison with Bochspwn, a dynamic analysis approach, which was unable to find any double-fetch bug in Linux 3.5.0 [13] where our approach finds three. In summary, we make the following contributions in this paper:

(1) First systematic study of double fetches in the Linux kernel. We present the first (to the best of our knowledge) study of double fetches in the complete Linux kernel, including an analysis of how and why a double fetch occurs. We used pattern matching to automatically identify 90 double-fetch situations in the Linux kernel, and investigated those candidates by manually reviewing the kernel source. We categorize the identified double fetches into three typical scenarios (*type selection*, *size checking*, *shallow copy*) in which double fetches are prone to occur, and illustrate each scenario with a detailed double fetch case analysis. Most (57/90) of the identified double fetches occur in drivers.

(2) A pattern-based double-fetch bug detection approach. We developed a static pattern-based approach to detect double-fetch bugs[1]. The approach has been implemented on the Coccinelle program matching and transformation engine [17] and has been adapted for checking the Linux, FreeBSD, and Android kernels. It is the first approach able to detect double-fetch vulnerabilities in the complete kernel including all drivers and all hardware architectures. Our approach has been adopted by the Coccinelle team and is currently being integrated into the Linux kernel patch vetting through Coccinelle.

(3) Identification of six double-fetch bugs. In total, we found six real double-fetch bugs. Four are in the drivers of Linux 4.5 and three of them are exploitable vulnerabilities. Moreover, all four driver-related double-fetch bugs belong to the same *size checking* scenario. The bugs have been confirmed by the Linux maintainers and have been fixed in new versions as a result of our reports. One double-fetch vulnerability has been found in the Android 6.0.1 kernel, which was already fixed in newer Linux kernels.

(4) Strategies for double-fetch bug prevention. Based on our study, we propose five solutions to anticipate double-fetch bugs and we implemented one of the strategies in a tool that automatically patches double-fetch bugs.

The rest of the paper is organized as follows: Section 2 presents relevant background on memory access in Linux, specifically in Linux drivers, and on how double-fetch bugs occur. Section 3 introduces our approach to double fetch detection, including our analysis process, the categorization of the identified double fetches into three scenarios, and what we learned from the identified double-fetch bugs. Section 4 presents the evaluation of our work, including statistics on the manual analysis and the results of applying our approach to the Linux, FreeBSD, and Android kernels. Section 5 discusses the detected bugs, implications of double-fetch bug prevention, an interpretation of our findings, as well as limitations of our approach. Related work is discussed in Section 6, followed by conclusions.

2 Background

We provide readers with a reminder of how data is exchanged between the Linux kernel and its drivers and the user space, and of how race conditions and double-fetch bugs can occur within this framework.

[1] Our analysis is available at `https://github.com/UCL-CREST/doublefetch`

2.1 Kernel/User Space Protection

In modern computer systems, memory is divided into kernel space and user space. The kernel space is where the kernel code executes and where its internal data is stored, while the user space is where normal user processes run. Each user space process resides in its own address space, and can only address memory within that space. Those virtual address spaces are mapped onto physical memory by the kernel in such a way that isolation between separate spaces is guaranteed. The kernel also has its own independent address space.

Special schemes are provided by the operating system to exchange data between kernel and user space. In Windows, we can use the device input and output control (IOCTL) method, or a shared memory object method to exchange data between kernel and user space[2] which is very similar to shared memory regions. In Linux and FreeBSD, functions are provided to safely transfer data between kernel space and user space which we call *transfer functions*. For instance, Linux has four often used transfer functions, `copy_from_user()`, `copy_to_user()`, `get_user()`, and `put_user()`, that copy single values or an arbitrary amount of data to and from user space in a safe way. Transfer functions not only exchange data between kernel and user space but also provide a protection mechanism against invalid memory access, such as illegal addresses or page faults. Therefore, any double fetch in Linux will involve multiple invocations of transfer functions.

2.2 Memory Access in Drivers

Device drivers are kernel components responsible for enabling the kernel to communicate with and make use of hardware devices connected to the system. Drivers have typical characteristics, such as support for synchronous and asynchronous operations and the ability to be opened multiple times [8]. Drivers are critical to security because faults in them can result in vulnerabilities that grant control of the whole system. Finally, drivers often have to copy messages of variable type or variable length from the user space to the hardware, and, as we will see later, this often leads to double-fetch situations that cause vulnerabilities.

In Linux, all devices have a file representation which can be accessed from user space to interact with the hardware's driver. The kernel creates a file in the `/dev` directory for each driver, with which user space processes can interact using file input/output system calls. The driver provides implementations of all file related operations, including `read()` and `write()` functions. In such functions, the driver needs to fetch the data from the user space (in `write`) or copy data to the user space (in `read`). The driver uses the transfer functions to do so, and again, any double fetch will involve multiple invocations of transfer functions.

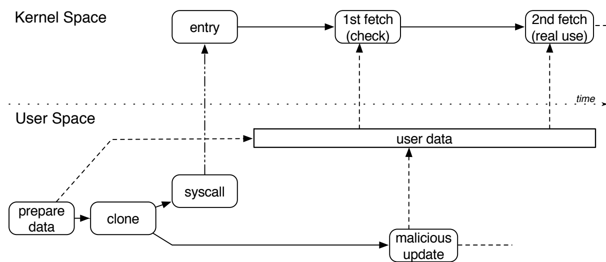

Figure 1: Principal Double Fetch Race Condition

2.3 Double Fetch

A double fetch is a special case of a race condition that occurs in memory access between the kernel and user space. The first vulnerability of this type was presented by Serna [32] in a report on Windows double-fetch vulnerabilities. Technically, a double fetch takes place within a kernel function, such as a syscall, which is invoked by a user application from user mode. As illustrated in Figure 1, the kernel function fetches a value twice from the same memory location in the user space, the first time to check and verify it and the second time to use it (note that the events are on a timeline from left to right, but the user data is the same object all the time). Meanwhile, within the time window between the two kernel fetches, a concurrently running user thread modifies the value. Then, when the kernel function fetches the value a second time to use, it gets a different value, which will not only result in a different computation outcome, but may cause a buffer overflow, a null-pointer crash or even worse consequences.

To avoid confusion, we use the term *double fetch* or *double-fetch situation* in this paper to represent all the situations in which the kernel fetches the same user data more than once, and a so-called double fetch can be further divided into the following cases:

Benign double fetch: A benign double fetch is a case that will not cause harm, owing to additional protection schemes or because the double-fetched value is not used twice (details will be discussed in Section 5.3).

Harmful double fetch: A harmful double fetch or a *double-fetch bug* is a double fetch that could actually cause failures in the kernel in specific situations, e.g., a race condition that could be triggered by a user process.

Double-fetch vulnerability: A double-fetch bug can also turn into a *double-fetch vulnerability* once the consequence caused by the race condition is exploitable, such

```
140 int cmsghdr_from_user_compat_to_kern(struct msghdr *kmsg,
141               unsigned char *stackbuf, int stackbuf_size)
142 {
143   struct compat_cmsghdr __user *ucmsg;
144   struct cmsghdr *kcmsg, *kcmsg_base;
145   compat_size_t ucmlen;
...
149   kcmsg_base = kcmsg = (struct cmsghdr *)stackbuf;
150   ucmsg = CMSG_COMPAT_FIRSTHDR(kmsg);
151   while(ucmsg != NULL) {
152     if(get_user(ucmlen, &ucmsg->cmsg_len))
153       return -EFAULT;
...
156     if(CMSG_COMPAT_ALIGN(ucmlen) <
157        CMSG_COMPAT_ALIGN(sizeof(struct compat_cmsghdr)))
158       return -EINVAL;
159     if((...)(((char __user *)ucmsg - (char __user*)...
160                        + ucmlen) > kmsg->msg_controllen)
161       return -EINVAL;
...
166     ucmsg = cmsg_compat_nxthdr(kmsg, ucmsg, ucmlen);
167   }
168  if(kcmlen == 0)
169    return -EINVAL;
...
183  ucmsg = CMSG_COMPAT_FIRSTHDR(kmsg);
184  while(ucmsg != NULL) {
185    __get_user(ucmlen, &ucmsg->cmsg_len);
186    tmp = ((ucmlen - CMSG_COMPAT_ALIGN(sizeof(*ucmsg))) +
187            CMSG_ALIGN(sizeof(struct cmsghdr)));
188    kcmsg->cmsg_len = tmp;
...
193    if(copy_from_user(CMSG_DATA(kcmsg),
194            CMSG_COMPAT_DATA(ucmsg),
195            (ucmlen - CMSG_COMPAT_ALIGN(sizeof(*ucmsg)))))
...
212 }
```

Figure 2: Double-Fetch Vulnerability in Linux 2.6.9

as through a buffer overflow, causing privilege escalation, information leakage or kernel crash.

In this paper, we investigate both harmful double fetches and benign double fetches. Even though benign double fetches are currently not vulnerable, some of them can turn into harmful ones when the code is changed or updated in the future (when the double-fetched data is reused). Moreover, some benign double fetches them can cause performance degradation when one of the fetches is redundant (discussed in Section 5).

Double-fetch vulnerabilities occur not only in the Windows kernel [14], but also in the Linux kernel. Figure 2 shows a double-fetch bug in Linux 2.6.9, which was reported as CVE-2005-2490. In file `compat.c`, when the user-controlled content is copied to the kernel by `sendmsg()`, the same user data is accessed twice without a sanity check at the second time. This can cause a kernel buffer overflow and therefore could lead to a privilege escalation. The function `cmsghdr_from_user_compat_to_kern()` works in two steps: it first examines the parameters in the first loop (line 151) and copies the data in the second loop (line 184). However, only the first fetch (line 152) of `ucmlen` is checked (lines 156–161) before use, whereas after the second fetch (line 185) there are no checks before use, which may cause an overflow in the copy operation (line 195) that can be exploited to execute arbitrary code by modifying the message.

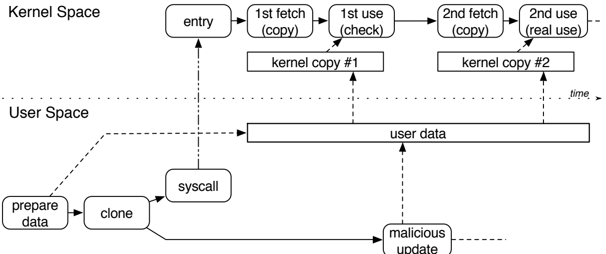

Figure 3: Double Fetch with Transfer Functions

Plenty of approaches have been proposed for data race detection at memory access level. Static approaches analyze the program without running it [35, 28, 12, 6, 10, 19, 38]. However, their major disadvantage is that they generate a large number of false reports due to lack the full execution context of the program. Dynamic approaches execute the program to verify data races [31, 16, 15], checking whether a race could cause a program failure in executions. Dynamic approaches usually control the active thread scheduler to trigger specific interleavings to increase the probability of a bug manifestation [41]. Nevertheless, the runtime overhead is a severe problem and testing of driver code requires the support of specific hardware or a dedicated simulation. Unfortunately, none of the existing data race detection approaches (whether static or dynamic) can be applied to double-fetch bug detection directly, for the following reasons:

(1) A double-fetch bug is caused by a race condition between kernel and user space, which is different from a common data race because the race condition is separated by the kernel and user space. For a data race, the read and write operations exist in the same address space, and most of the previous approaches detect data races by identifying *all* read and write operations accessing the same memory location. However, things are different for a double-fetch bug. The kernel only contains two reads while the write resides in the user thread. Moreover, the double-fetch bug exists if there is a possibility that the kernel fetches and uses the same memory location twice, as a malicious user process can specifically be designed to write between the first and second fetch.

(2) The involvement of the kernel makes a double-fetch bug different from a data race in the way of accessing data. In Linux, fetching data from user space to kernel space relies on the specific parameters passed to transfer functions (e.g., `copy_from_user()` and `get_user()`) rather than dereferencing the user pointer directly, which means the regular data race detection approaches based on pointer dereference are not applicable anymore.

(3) Moreover, a double-fetch bug in Linux is more complicated than a common data race or a double-fetch bug in Windows. As shown in Figure 3, a double-fetch bug in Linux requires a first fetch that copies the data, usually followed by a first check or use of the copied data, then a second fetch that copies the same data again, and a second use of the same data. Although the double fetch can be located by matching the patterns of fetch operations, the use of the fetched data varies a lot. For example, in addition to being used for validation, the first fetched value can be possibly copied to somewhere else for later use, which means the first use (or check) could be temporally absent. Besides, the fetched value can be passed as an argument to other functions for further use. Therefore, in this paper, we define the *use* in a double fetch to be a conditional check (read data for comparison), an assignment to other variables, a function call argument pass, or a computation using the fetched data. We need to take into consideration these double fetch characteristics.

For these reasons, identifying double-fetch bugs requires a dedicated analysis and previous approaches are either not applicable or not effective.

2.4 Coccinelle

Coccinelle [17] is a program matching and transformation engine with a dedicated language SmPL (Semantic Patch Language) for specifying desired matches and transformations in C code. Coccinelle was initially targeted for collateral evolution in Linux drivers, but now is widely used for finding and fixing bugs in systems code.

Coccinelle's strategy for traversing control-flow graphs is based on temporal logic CTL (Computational Tree Logic) [3], and the pattern matching implemented on Coccinelle is path-sensitive, which achieves better code coverage. Coccinelle is highly optimized to improve performance when exhaustively traversing all the execution paths. Besides, Coccinelle is insensitive to newlines, spaces, comments, etc. Moreover, the pattern-based analysis is applied directly to the source code, therefore operations that are defined as macros, such as `get_user()` or `__get_user()`, will not be expanded during the matching, which facilitates the detection of double fetches based on the identification of transfer functions. Therefore, Coccinelle is a suitable tool for us to carry out our study of double fetches based on pattern matching.

3 Double Fetches in the Linux Kernel

In this paper, our study of double fetches in the Linux kernel is divided into two phases. As shown in Figure 4, in the first phase, we analyze the Linux kernel with the Coccinelle engine using a basic double-fetch pattern that identifies when a function has multiple invocations of a transfer function. Then we manually investigate the candidate files found by the pattern matching, to categorize the scenarios in which a double fetch occurs and when a double-fetch bug or vulnerability is prone to happen based on the context information that is relevant to the bug. In the second phase, based on the knowledge gained from the manual analysis, we developed a more precise analysis using the Coccinelle engine to systematically detect double-fetch bugs and vulnerabilities throughout the kernel, which we also used to additionally analyze FreeBSD and Android.

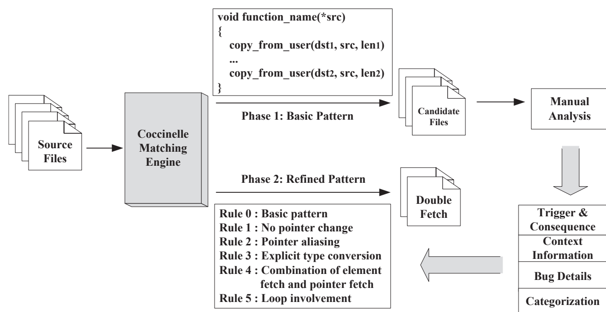

Figure 4: Overview of our Two-Phase Coccinelle-Based Double-Fetch Situation Detection Process

3.1 Basic Pattern Matching Analysis

There are situations in which a double fetch is hard to avoid, and there exist a large number of functions in the Linux kernel that fetch the same data twice. According to the definition, a double fetch can occur in the kernel when the same user data is fetched twice within a short interval. Therefore we can conclude a basic pattern that we will use to match all the potential double-fetch situations. The pattern matches the situation in which a kernel function is using transfer functions to fetch data from same user memory region at least twice. In the case of the Linux kernel, the transfer functions to match are mainly `get_user()` and `copy_from_user()` in all their variants. The pattern allows the target of the copy and the size of the copied data to be different, but the source of copy (the address in user space) must be the same. As shown in Figure 4, we implemented the basic pattern matching in the Coccinelle engine.

Our approach examines all source code files of the Linux kernel and checks whether a kernel function contains two or more invocations of transfer functions that fetch data from the same user pointer. From the 39,906 Linux source files, 17,532 files belong to drivers (44%), and 10,398 files belong to non-x86 hardware architec-

tures (26%) which cannot be analyzed with Jurczyk and Coldwind's x86-based technique. We manually analyzed the matched kernel functions to infer knowledge on the characteristics of double fetches, i.e., how the user data is transferred to and used in the kernel, which helped us to carry out a categorization of double-fetch situations, as we discuss in Section 3.2. The manual analysis also helped us refine our pattern matching approach and more precisely detect actual double-fetch bugs, as explained in Section 3.3.

During the investigation, we noticed that there are plenty of cases where the transfer functions fetch data from different addresses or from the same address but with different offsets. For example, a kernel function may fetch the elements of a specific structure separately instead of copying the whole structure to the kernel. By adding different offsets to the start address of that structure, the kernel fetches different elements of the structure separately, which results in multiple fetches. Another common situation is adding a fixed offset to the source pointer, so as to process a long message separately, or just using self-increment (++) to process a message automatically in a loop. All these cases are false positives caused by the basic pattern matching, and 226 cases of our initial reports were identified as false positives, which have been automatically removed in our refined phase since they are not considered as double-fetch situations and cannot cause a double-fetch bug because every single piece of the message is only fetched once.

The first phase of our study concentrates on the understanding of the contexts in which double fetches are prone to happen, rather than on exhaustively finding potential double-fetch bugs. Even though the analysis and characterization is not fully automated, it only resulted in 90 candidates that needed manual investigation, which took only a few days to analyze them, making the needed manual effort of our approach acceptable.

3.2 Double Fetch Categorization

As we manually inspected the double fetch candidates, we noticed that there are three common scenarios in which double fetches are prone to happen, which we categorized as *type selection*, *size checking* and *shallow copy*. We now discuss these in detail.

Most of the time, copying data from the user space to the kernel space is straightforward via a single invocation of a transfer function. However, things get complicated when the data has a variable type or a variable length, depending on the data itself. Such data usually starts with a *header*, followed by the data's *body*. In the following, we consider such data to be *messages*, as we empirically found that variable data was often used by drivers to pass messages to the hardware from user space.

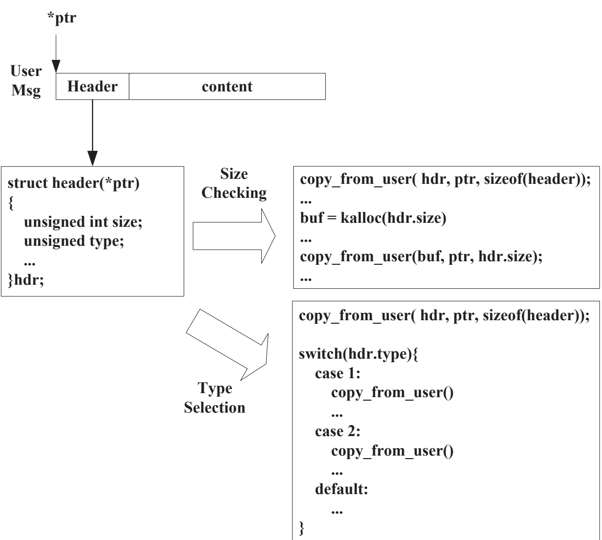

Figure 5: How Message Structure Leads to Double Fetches

Figure 5 illustrates the scenario: A message copied from the user space to the kernel (driver) space usually consists of two parts, the header and the body. The header contains some meta information about the message, such as an indicator of the message *type* or the *size* of the message body. Since messages have different types and the message lengths may also vary, the kernel usually fetches (copies) the header first to decide which buffer type needs to be created or how much space needs to be allocated for the complete message. A second fetch then copies the complete message into the allocated buffer of the specified type or size. The second fetch not only copies the body, but also copies the complete message including the header which has been fetched already. Because the header of the message is fetched (copied) twice, a double-fetch situation arises. The double-fetch situation turns into a double-fetch bug when the size or type information from the **second** fetch is used as the user may have changed the size or type information between the two fetches. If, for example, the size information is used to control buffer access, the double-fetch bug turns into a vulnerability.

The double-fetch situations where a message header is copied twice could easily be avoided by only copying the message body in the second fetch and then joining the header with the body. However, copying the complete message in the second step is more convenient, and therefore such a double-fetch situation occurs very often in the Linux kernel. Moreover, large parts of the Linux kernel are old, i.e., they have been developed before double-fetch bugs were known or understood. Therefore, we will discuss such double-fetch situations in the kernel in

more detail and also highlight three cases we have found during the manual analysis.

3.2.1 Type Selection

A common scenario in which double fetches occur is when the message header is used for type selection. In other words, the header of the message is fetched first to recognize the message type and then the whole message is fetched and processed dependent on the identified type. We have observed that it is very common in the Linux kernel that one single function in a driver is designed to handle multiple types of messages by using a `switch` statement structure, in which each particular message type is fetched and then processed. The result of the first fetch (the message type) is used in the `switch` statement's condition and in every case of the `switch`, the message is then copied by a second fetch to a local buffer of a specific type (and then processed).

Figure 6 shows an example of a double-fetch situation due to type selection in the file `cxgb3_main.c`, part of a network driver. The function `cxgb_extension_ioctl()` first fetches the type of the message (a command for the attached hardware) into `cmd` from the pointer into user space `useraddr` at line 2136. It then decides based on `cmd` which type the message has (e.g., `CHELSIP_SET_QSET_PARAMS`, `CHELSIP_SET_QSET_NUM` or `CHELSIO_SETMTUTAB`) and copies the complete message into the corresponding structure (of type `ch_qset_params`, `ch_reg`, `ch_mtus`, ...). The type of the message will be fetched a second time as part of the whole message (lines 2149, 2292, 2355 respectively). As long as the header part of the message is not used again, the double fetch in this situation does not cause a double-fetch bug. However, if the header part (the type/command) of the second fetch would be used again, problems could occur as a malicious user could have changed the header between the two fetches. In the case of `cxgb_extension_ioctl()`, a manual investigation revealed no use of the type part in the buffers `t`, `edata`, `m`, ... and the double-fetch situation here does not cause a double-fetch vulnerability.

We found 11 occurrences of this double-fetch category, 9 of them in drivers. None of the 11 occurrences used the header part of the second fetch and therefore, they were not causing double-fetch bugs.

3.2.2 Size Checking

Another common scenario occurs when the actual length of the message can vary. In this scenario, the message header is used to identify the size of the complete message. The message header is copied to the kernel first to get the message size (first fetch), check it for validity, and allocate a local buffer of the necessary size, then a second fetch follows to copy the whole message, which also includes the header, into the allocated buffer. As long as only the size of the first fetch is used and not retrieved from the header of the second fetch, the double fetch in this situation does not cause a double-fetch vulnerability or bug. However, if the size is retrieved from the header of the second fetch and used, the kernel becomes vulnerable as a malicious user could have changed the size element of the header.

```
2129 static int cxgb_extension_ioctl(struct net_device *dev,
                                   void __user *useraddr)
2130 {
...
2133   u32 cmd;
...
2136   if (copy_from_user(&cmd, useraddr, sizeof(cmd)))
2137     return -EFAULT;
2138
2139   switch (cmd) {
2140   case CHELSIO_SET_QSET_PARAMS:{
...
2143     struct ch_qset_params t;
...
2149     if (copy_from_user(&t, useraddr, sizeof(t)))
2150       return -EFAULT;
2151     if (t.qset_idx >= SGE_QSETS)
2152       return -EINVAL;

Figure 6: A Double-Fetch Situation Belonging to the Type Selection Category in `cxgb3_main.c`

One such double-fetch bug (CVE-2016-6480) was found in file `commctrl.c` in the Adaptec RAID controller driver of the Linux 4.5. Figure 7 shows the responsible function `ioctl_send_fib()` which fetches data from user space pointed by pointer `arg` via `copy_from_user()` twice in line 81 and line 116. The

```
 60 static int ioctl_send_fib(struct aac_dev* dev,
                             void __user *arg)
 61 {
 62   struct hw_fib * kfib;
...
 81   if (copy_from_user((void *)kfib, arg, sizeof(...))) {
 82     aac_fib_free(fibptr);
 83     return -EFAULT;
 84   }
...
 90   size = le16_to_cpu(kfib->header.Size) + sizeof(...);
 91   if (size < le16_to_cpu(kfib->header.SenderSize))
 92     size = le16_to_cpu(kfib->header.SenderSize);
 93   if (size > dev->max_fib_size) {
...
101     kfib = pci_alloc_consistent(dev->pdev, size, &daddr);
...
114   }
115
116   if (copy_from_user(kfib, arg, size)) {
117     retval = -EFAULT;
118     goto cleanup;
119   }
120
121   if (kfib->header.Command == cpu_to_le16(...)) {
...
128   } else {
129     retval =
        aac_fib_send(le16_to_cpu(kfib->header.Command),...
130               le16_to_cpu(kfib->header.Size) , FsaNormal,
131               1, 1, NULL, NULL);
...
139   }
...
160 }
```

Figure 7: A Double-Fetch Vulnerability in `commctrl.c` (CVE-2016-6480)

first fetched value is used to calculate a buffer size (line 90), to check the validity of the size (line 93), and to allocate a buffer of the calculated size (line 101), while the second copy (line 116) fetches the whole message with the calculated size. Note that the variable `kfib` pointing to the kernel buffer storing the message is reused in line 101. The header of the message is large and various elements of the header are used after the message has been fetched the second time (e.g., `kfib->header.Command` in line 121 and 129). The function also uses the size element of the header a second time in line 130, causing a double-fetch vulnerability as a malicious user could have changed the `Size` field of the header between the two fetches.

We observed 30 occurrences of such size checking double-fetch situations, 22 of which occur in drivers, and four of them (all in drivers) are vulnerable.

3.2.3 Shallow Copy

The last special case of double-fetch scenario we identified is what we call *shallow copy issues*. A shallow copy between user and kernel space happens when a buffer (the first buffer) in the user space is copied to the kernel space, and the buffer contains a pointer to another

```
55 static int sclp_ctl_ioctl_sccb(void __user *user_area)
56 {
57   struct sclp_ctl_sccb ctl_sccb;
58   struct sccb_header *sccb;
59   int rc;
60
61   if (copy_from_user(&ctl_sccb, user_area,
                        sizeof(ctl_sccb)))
62     return -EFAULT;
...
65   sccb = (void *) get_zeroed_page(GFP_KERNEL | GFP_DMA);
66   if (!sccb)
67     return -ENOMEM;
68   if (copy_from_user(sccb, u64_to_uptr(ctl_sccb.sccb),
                       sizeof(*sccb))) {
69     rc = -EFAULT;
70     goto out_free;
71   }
72   if (sccb->length > PAGE_SIZE || sccb->length < 8)
73     return -EINVAL;
74   if (copy_from_user(sccb, u64_to_uptr(ctl_sccb.sccb),
                        sccb->length)) {
75     rc = -EFAULT;
76     goto out_free;
77   }
...
81   if (copy_to_user(u64_to_uptr(ctl_sccb.sccb), sccb,
                   sccb->length))
82     rc = -EFAULT;
...
86 }
```

Figure 8: A Double-Fetch Bug in `sclp_ctl.c` (CVE-2016-6130)

buffer in user space (the second buffer). A transfer function only copies the first buffer (a shallow copy) and the second buffer has to be copied by the second invocation of a transfer function (to perform a deep copy). Sometimes it is necessary to copy data from user space into kernel space, act on the data, and copy the data back into user space. Such data is usually contained in the second buffer in user space and pointed to by a pointer in the first buffer in user space containing additional data. The transfer functions perform shallow copies and therefore data pointed to in the buffer copied by a transfer function must be explicitly copied as well, so as to perform a deep copy. Such deep copies will cause multiple invocations of transfer functions which are not necessarily double fetches as each transfer function is invoked with a different buffer to be copied. We observed 31 of such situations, 19 of them in drivers.

The complexity of performing a deep copy with transfer functions that only do shallow copies can cause programmers to introduce bugs, and we found one such bug in file `sclp_ctl.c` of the IBM S/390 SCLP console driver, where the bug is caused by a shallow copy issue (CVE-2016-6130). The function `sclp_ctl_ioctl_sccb` in Figure 8 performs a shallow copy of a data structure from user space pointed to by `user_area` into `ctl_sccb` (line 61). To do a deep copy, it then has to copy another data structure from user space pointed to by `ctl_sccb.sccb`. However, the size of the

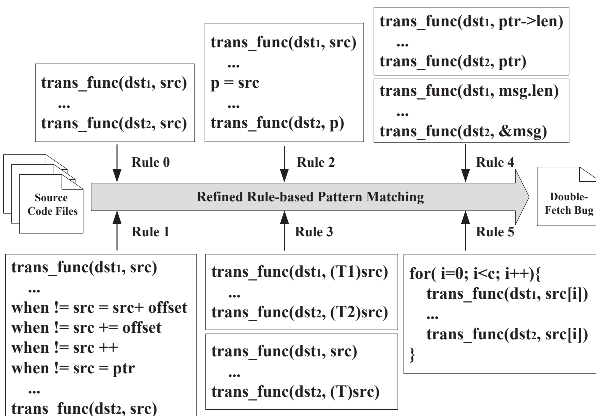

Figure 9: Refined Coccinelle-Based Double-Fetch Bug Detection

data structure is variable, causing a *size checking* scenario. In order to copy the data, it first fetches the header of the data structure into the newly created kernel space pointed to by `sccb` (line 68) to get the data length in `sccb->length` which is checked for validity in line 72. Then, based on `sccb->length`, it copies the whole content with a second fetch in line 74. Finally at line 81, the data is copied back to the user space. While it looks like both invocations of the transfer functions in lines 74 and 81 use the same length `sccb->length`, line 81 actually uses the value as copied in line 74 (the second fetch) while line 74 uses the value from the first fetch.

Again, this is a double-fetch bug as a user may have changed the value between the two fetches in lines 68 and 74. However, this double-fetch bug is not causing a vulnerability because neither can the kernel be crashed by an invalid size given to a transfer function, nor can information leakage occur when the kernel copies back data beyond the size that it received earlier because the copied buffer is located in its own memory page. An attempt to trigger the bug will simply end in termination of the system call with an error code in line 82. The double-fetch bug has been eliminated in Linux 4.6.

3.3 Refined Double-Fetch Bug Detection

In this section, we present the second phase of our study which uses a refined double-fetch bug detection approach that is again based on the Coccinelle matching engine. While the first phase of our study was to identify and categorize scenarios in which double fetches occur, the second phase exploited the gained knowledge from the first phase to design an improved analysis targeted at specifically identifying double-fetch bugs and vulnerabilities.

As shown in Figure 9, in addition to the basic double-fetch pattern matching rule (**Rule 0**), which is triggered when two reads fetch data from the same source location, we added the following five additional rules to improve precision as well as discover corner cases. The Coccinelle engine applies these rules one by one when analyzing the source files. A double-fetch bug could involve different transfer functions, therefore, we have to take the four transfer functions that copy data from user space (`get_user()`, `__get_user()`, `copy_from_user()`, `__copy_from_user()`) into consideration. We use `trans_func()` in Figure 9 to represent any possible transfer functions in the Linux kernel.

Rule 1: No pointer change. The most critical rule in detecting double-fetch bugs is keeping the user pointer unchanged between two fetches. Otherwise, different data is fetched each time instead of the same data being double-fetched, and false positives can be caused. As can be seen from Rule 1 in Figure 9, this change might include cases of self-increment (++), adding an offset, or assignment of another value, and the corresponding subtraction situations.

Rule 2: Pointer aliasing. Pointer aliasing is common in double-fetch situations. In some cases, the user pointer is assigned to another pointer, because the original pointer might be changed (e.g., processing long messages section by section within a loop), while using two pointers is more convenient, one for checking the data, and the other for using the data. As can be seen from Rule 2 in Figure 9, this kind of assignment might appear at the beginning of a function or in the middle between the two fetches. Missing aliasing situation could cause false negatives.

Rule 3: Explicit type conversion. Explicit pointer type conversion is widely used when the kernel is fetching data from user space. For instance, in the size checking scenario, a message pointer would be converted to a header pointer to get the header in the first fetch, then used again as a message pointer in the second fetch. As can be seen from Rule 3 in Figure 9, any of the two source pointers could involve type conversion. Missing type conversion situations could cause false negatives. In addition, explicit pointer type conversions are usually combined with pointer aliasing, causing the same memory region to be manipulated by two types of pointers.

Rue 4: Combination of element fetch and pointer fetch. In some cases, a user pointer is used to both fetch the whole data structure as well as fetching only a part by dereferencing the pointer to an element of the data structure. For instance, in the size checking scenario, a user pointer is first used to fetch the message length by `get_user(len, ptr->len)`, then to copy the whole message in the second fetch by `copy_from_user(msg, ptr, len)`, which means the two fetches are not using exactly the same pointer as the transfer function arguments, but they cover the same

value semantically. As we can see from Rule 4 in Figure 9, this situation may use a user pointer or the address of the data structure as the argument of the transfer functions. This situation usually appears with explicit pointer type conversion, and false negatives could be caused if this situation is missed.

Rule 5: Loop involvement. Since Coccinelle is path-sensitive, when a loop appears in the code, one transfer function call in a loop will be reported as two calls, which could cause false positives. Besides, as can be seen from Rule 5 in Figure 9, when there are two fetches in a loop, the second fetch of the last iteration and the first fetch of the next iteration will be matched as a double fetch. This case should be removed as false positive because the user pointer should have been changed when crossing the iterations and these two fetches are getting different values. Moreover, cases that use an array to copy different values inside a loop also cause false positives.

Table 1: Basic Double Fetch Analysis Results

Category	Occurrences		In Drivers	
Size Checking	30	33%	22	73%
Type Selection	11	12%	9	82%
Shallow Copy	31	34%	19	61%
Other	18	20%	7	39%
Total	90	100%	57	63%
True Bugs	5	6%	4	80%

Table 2: Refined Double-Fetch Bug Detection Results

Kernel	Total Files	Reported Files	True Bugs	Size Check.	Type Sel.
Linux 4.5	39,906	53	5	23	6
Android 6.0.1	35,313	48	3	18	6
FreeBSD	32,830	16	0	8	3

4 Evaluation

In this section, we present the evaluation of our study, which includes two parts: the statistics of the manual analysis, and the results of the refined approach when applied to three open source kernels: Linux, Android, and FreeBSD. We obtained the most up-to-date versions available at the time of the analysis.

4.1 Statistics and Analysis

In Linux 4.5, there are 52,881 files in total and 39,906 of them are source files (with a file extension of .c or .h), which are our analysis targets (other files are ignored). 17,532 source files belong to drivers (44%). After the basic pattern matching of the source files and the manual inspection to remove false positives, we obtained 90 double-fetch candidate files for further inspection. We categorized the candidates into the three double-fetch scenarios *Size Checking*, *Type Selection* and *Shallow Copy*. They are the most common cases on how a double fetch occurs while user space data is copied to the kernel space and how the data is then used in the kernel. We have discussed these scenarios in detail with real double-fetch bug examples in the previous section. As shown in Table 1, of the 90 candidates we found, 30 were related to the size checking scenario, 11 were related to the type selection scenario, and 31 were related to the shallow copy scenario, accounting for 33%, 12%, and 34% respectively. 18 candidates did not fit into one of the three scenarios.

Furthermore, 57 out of the 90 candidates were part of Linux drivers and among them, 22 were size checking related, 9 were type selection related and 19 were shallow copy related.

Most importantly, we found five previously unknown double-fetch bugs which include four size checking scenarios and one shallow copy scenario which also belongs to the size checking scenario. Three of them are exploitable vulnerabilities. The five bugs have been reported and they all have been confirmed by the developers and have meanwhile been fixed. From the statistical result, we can observe the following:

1. 57 out of 90 (63%) of the candidates were driver related and 22 out of 30 (73%) of the size checking cases, 9 out of 11 (82%) of the type selection cases and 19 out of 31 (61%) of the shallow copy cases occur in drivers.

2. 4 out of 5 (80%) of the double-fetch bugs we found inside drivers and belong to the size checking category.

Overall, this leads to the conclusion that most double fetches do not cause double-fetch bugs and that double fetches are more likely to occur in drivers. However, as soon as a double fetch is due to size checking, developers have to be careful: Four out of 22 size checking scenarios in drivers turned out to be double-fetch bugs.

4.2 Analysis of Three Open Source Kernels

Based on the double fetch basic pattern matching and manual analysis, we refined our double fetch pattern and developed a new double-fetch bug detection analysis based on the Coccinelle engine. In order to fully evaluate our approach, we analyzed three popular open source kernels, namely Linux, Android, and FreeBSD. Results are shown in Table 2.

For the Linux kernel, the experiment was conducted on version 4.5, which was the newest version when the experiment was conducted. The analysis took about 10 minutes and reported 53 candidate files. An investigation of the 53 candidates revealed five true double-fetch bugs, which were also found by the previous manual analysis. Among the reported files, 23 were size checking related, and 6 were type selection related.

For Android, even though it uses Linux as its kernel as well, we analyzed version 6.0.1 which is based on Linux 3.18. There are still differences between the Android kernel and original Linux kernel: A kernel for Android is a mainstream Linux kernel, with additional drivers for the specific Android device, and other additional functionality, such as enhanced power management or faster graphics support. Our analysis took about 9 minutes and reported 48 candidate files, including seven files that were not included in the original Linux kernel reports. Among the reported candidates, three were true double-fetch bugs, including two that were shared with the Linux 4.5 report above, and one that was only reported for Android. Among the results, 18 candidates were size checking related, and six candidates were type selection related.

For FreeBSD, we needed to change the transfer functions `copy_from_user()` and `__copy_from_user()` to the corresponding ones in FreeBSD, `copyin()` and `copyin_nofault()`. We obtained the source code from the master branch[3]. This analysis took about 2 minutes and only 16 files were reported, but none of them turned out to be a vulnerable double-fetch bug. Among the reported candidates, eight were size checking related, and three were type selection related. It is interesting to note that 5 out of these 16 files were benign double fetches, which would have been double-fetch bugs but were prevented by additional checking schemes. The developers of FreeBSD seem to be more aware of double-fetch bugs and try to actively prevent them. In comparison, for Linux, only 5 out of the 53 reports were protected by additional checking schemes.

In this experiment, we only counted the size checking and type selection cases because the refined pattern matching approach discards shallow copy cases that are not able to cause a double-fetch bug. Our approach matches the double fetch pattern that fetches data from the same memory region, which ignores the first buffer fetches in the case of a shallow copy and only considers multiple fetches to the same second buffer. Such shallow copy cases usually combine with other scenarios such as size checking and type selection. In Table 2, the size checking cases of the Linux kernel also includes one case that occurred in a shallow copy scenario.

[3]From GitHub as of July 2016 (https://github.com/freebsd/freebsd)

5 Discussion

In this section, we discuss the discovered double-fetch bugs and vulnerabilities in Linux 4.5 and how double-fetch bugs can be prevented in the presence of double-fetch situations. We also interpret our findings and the limitations of our approach.

5.1 Detected Bugs and Vulnerabilities

Based on our approach, we found six double-fetch bugs in total. Five of them are previously unknown bugs that have not been reported before (CVE-2016-5728, -6130, -6136, -6156, -6480), and the sixth one (CVE-2015-1420) is a double-fetch bug present in the newest Android (version 6.0.1) which is based on an older Linux kernel (version 3.18) containing the bug, which has been fixed in the mainline Linux kernel since Linux 4.1. Three of the five new bugs are exploitable double-fetch vulnerabilities (CVE-2016-5728, -6136, -6480). Four of the five are in drivers (CVE-2016-5728, -6130, -6156, -6480). All bugs have been reported to the Linux kernel maintainers who have confirmed them. All of these reported bugs are fixed as of Linux 4.8. We did not find any new double-fetch bugs in FreeBSD. Details on the detected bugs are shown in Table 3.

The presented approach identifies a large number of double-fetch situations for which only a small number are double-fetch bugs (or even vulnerabilities). However, even though the cases we call benign double-fetch situations are not currently faulty, they could easily turn into a double-fetch bug or vulnerability when the code is updated without paying special attention to the double-fetch situation. We observed an occurrence of such a situation when investigating the patch history of the double-fetch bug CVE-2016-5728. A reuse of the second fetched value was introduced when the developer moved functionality from the MIC host driver into the Virtio Over PCIe (VOP) driver, therefore introducing a double-fetch bug. A major part of our future work will be preventing such benign double fetch situations from turning into harmful ones.

We did not find any false negatives while manually checking random samples of Linux kernel source code files.

5.2 Comparison

Only a few systematic studies have been conducted on double fetches. Bochspwn [14, 13] is the only approach similar enough to warrant a comparison with. An analysis of Linux 3.5.0 with Bochspwn did not find any double-fetch bug, while producing up to 200KB of double fetch logs. In the same kernel, our approach identi-

Table 3: Description of Identified Double Fetch Bugs and Vulnerabilities (*)

IDs	File	Description
CVE-2016-5728*	`mic_virtio.c` MIC architecture VOP (Virtual I/O Over PCIe) driver *Linux 4.5*	Race condition in the `vop_ioctl` function allows local users to obtain sensitive information from kernel memory or cause a denial of service (memory corruption and system crash) by changing a certain header, aka a "double fetch" vulnerability. *Belongs to the size checking scenario.*
CVE-2016-6130	`sclp_ctl.c` IBM S/390 SCLP console driver *Linux 4.5*	Race condition in the `sclp_ctl_ioctl_sccb` function allows local users to obtain sensitive information from kernel memory by changing a certain length value, aka a "double fetch" vulnerability. *Belongs to the size checking scenario.*
CVE-2016-6136*	`auditsc.c` Linux auditing subsystem *Linux 4.5*	Race condition in the `audit_log_single_ execve_arg` function allows local users to bypass intended character-set restrictions or disrupt system-call auditing by changing a certain string, aka a "double fetch" vulnerability.
CVE-2016-6156	`cros_ec_dev.c` Chrome OS Embedded Controller driver *Linux 4.5*	Race condition in the `ec_device_ioctl_xcmd` function allows local users to cause a denial of service (out-of-bounds array access) by changing a certain size value, aka a "double fetch" vulnerability. *Belongs to the size checking scenario.*
CVE-2016-6480*	`commctrl.c` Adaptec RAID controller driver *Linux 4.5*	Race condition in the `ioctl_send_fib` function allows local users to cause a denial of service (out-of-bounds access or system crash) by changing a certain size value, aka a "double fetch" vulnerability. *Belongs to the size checking scenario.*
*CVE-2015-1420**	`fhandle.c` File System *Android 6.0.1, (Linux 3.18)*	Race condition in the `handle_to_path` function allows local users to cause a denial of service (out-of-bounds array access) by changing a certain size value, aka a "double fetch" vulnerability. *Belongs to the size checking scenario.*

fied 3 out of the above discussed 6 double-fetch bugs (the other 3 bugs we found are in files that were not present in Linux 3.5.0).

It is likely that Bochspwn could not find these bugs because they were present in drivers. Indeed, dynamic approaches cannot support drivers without corresponding hardware or simulations of hardware. Bochspwn reported an instruction coverage of only 28% for the kernel, while our approach statically analyses the complete source code.

As for efficiency, our approach takes only a few minutes to conduct a path-sensitive exploration of the source code of the whole Linux kernel. In contrast, Bochspwn introduces a severe runtime overhead. For instance, their simulator needs 15 hours to boot the Windows kernel.

While it only took a few days to investigate the 90 double-fetch situations, Jurczyk and Coldwind did not report the time they needed to investigate the 200KB of double fetch logs generated by their simulator.

5.3 Double-Fetch Bug Prevention

Even though we provide an analysis to detect double-fetch bugs, developers must still be aware of how they occur and preemptively prevent double-fetch bugs. Human mistakes are to be expected in driver development when dealing with variable messages leading to new double-fetch situations.

(1) Don't Copy the Header Twice. Double-fetch situations can be completely avoided if the second fetch only copies the message body and not the complete message which copies the header a second time. For example, the double-fetch vulnerability in Android 6.0.1 (Linux 3.18) is resolved in Linux 4.1 by only copying the body in the second fetch.

(2) Use the Same Value. A double-fetch situation turns into a bug when there is a use of the "same" data from both fetch operations because a (malicious) user can change the data between the two fetches. If developers only use the data from one of the fetches, problems are avoided. According to our investigation, most of the double-fetch situations are benign because they only use the first fetched value.

(3) Overwrite Data. There are also situations in which the data has to be fetched and used twice, for example, the complete message is passed to a different function for processing. One way to resolve the situation and eliminate the double-fetch bug is to overwrite the header from the second fetch with the header that has been fetched first. Even if a malicious user changed the header between the two fetches, the change would have no impact. This approach is widely adopted in FreeBSD code, such as in `sys/dev/aac/aac.c` and `sys/dev/aacraid/aacraid.c`.

(4) Compare Data. Another way to resolve a double-fetch bug is to compare the data from the first fetch to the data of the second fetch before using it. If the data is not the same, the operation must be aborted.

(5) Synchronize Fetches. The last way to prevent a double-fetch bug is to use synchronization approaches to guarantee the atomicity of two inseparable operations, such as locks or critical sections. As long as we guarantee that the fetched value cannot be changed between the two fetches, then nothing wrong will come out of fetching multiple times. However, this approach will incur performance penalties for the kernel, as synchronization is introduced on a critical section.

Since the *Compare Data* approach does not need to modify very much of the source code, most of the identified double-fetch bugs we found have been patched in this way by the Linux developers (CVE-2016-5728, -6130, -6156, -6480). If the overlapped data sections from the two fetches are not the same, the kernel will now return an error. One can argue that it would have been better to avoid the double fetch of the headers with any of the other first three recommendations. However, comparing the data has two advantages: it not only allow detecting attacks by malicious users but also protects from situation in which the data is changed without malicious intent (e.g., by some bug in user space code).

We have implemented the *Compare Data* approach in Coccinelle as an automatic patch that injects code to compare the data from the first fetch with the data from the second fetch at places where a double-fetch bug has been found. It is able to automatically patch all size checking double-fetch bugs, which accounts for most of the identified bugs (5/6).

5.4 Interpretation of Results

Double fetches are a fundamental problem for kernel development. Popular operating systems like Windows, Linux, Android, and FreeBSD all had double-fetch bugs and vulnerabilities in the past. Double-fetch issues have a long history, and one bug we identified (CVE-2016-6480) has existed for over ten years.

Double fetches are prevalent and sometimes inevitable in kernels. We categorized three typical double fetch scenarios from the occurrences we detected. 63% of these double fetches occur in drivers, which implies that drivers are the hard-hit area. Four out of the five new bugs belong to size checking scenarios, indicating that variable length message processing needs vetting for double-fetch bugs.

In the Linux kernel, double-fetch bugs are more complex than in Windows because transfer functions separate the fetches from the uses in a double-fetch bug, making it harder to separate benign from vulnerable double fetches. A previous dynamic approach has not found any double-fetch bug in Linux, where our static approach found some, demonstrating the power of a simple static analysis.

Our approach requires manual inspection, however, the manual inspection does not have to be repeated for the full kernel as future analyses can be limited to changed files. Moreover, developing a static analysis that automatically identifies double-fetch bugs with higher accuracy would have cost much more time than developing our current approach, running it on different kernels, and the manual investigating the results together. Also, before our analysis and categorization, it was not known in which situations double-fetch bugs occur in the Linux kernel—knowledge that was needed in order to design a more precise static double-fetch bug analysis. With the refined approach, one would only have had to look at the 53 potential double-fetch bugs, not at all 90 double-fetch situations. Therefore, the manual analysis part of our approach is inevitable but highly beneficial.

As for prevention, all of the four size checking bugs are patched by the *Compare Data* method, indicating the double fetches are not avoided completely as the patched situations still abort the client program by returning an error. Moreover, even benign double-fetch situations are not safe because they can turn into harmful ones easily. One such bug (CVE-2016-5728) was introduced from a benign double-fetch situation by a code update. However, most of these potential cases are not fixed as they are currently not vulnerable.

Even if a double fetch is benign, i.e., is not vulnerable, it can be considered a performance issue since one of the fetches (invocations of the transfer functions) is redundant.

5.5 Limitations

We focused on analyzing situations in which double fetches occur in Linux with a pattern-based analysis of the source code. However, the nature of the analysis prevents the detection of double fetches that occur on a lower level, e.g., in preprocessed or compiled code.

Double-fetch bugs can even occur in macros. In one such case [24], the macro fetches a pointer twice, the first time to test for NULL and the second time to use it. However, due to the potential pointer change between the two fetches, a null-pointer crash may be caused.

A double-fetch bug can also be introduced through compiler optimization. It then occurs in the compiled binary but not in the source code. Wilhelm [37] recently found such a compiler-generated double-fetch bug in the Xen Hypervisor, which is because the pointers to shared memory regions are not labeled as *volatile*, allowing the compiler to turn a single memory access into multiple accesses at the binary level, since it assumes that the memory will not be changed.

6 Related Work

So far, research conducted on double-fetch analysis has exclusively focused on dynamic analysis, whereas we proposed a static analysis approach. In addition to the already discussed work on Bochspwn [14, 13], there are also a few related studies as follows.

Wilhelm [37] used a similar approach to Bochspwn to analyze memory access pattern of para-virtualized devices' backend components. His analysis identified 39 potential double fetch issues and discovered three novel security vulnerabilities in security-critical backend components. One of the discovered vulnerabilities does not exist in the source code but is introduced through compiler optimization (see the discussion in Section 5.5). Moreover, another discovered vulnerability in the source code is usually not exploitable because the compiler optimizes the code in a way that the second fetch is replaced with a reuse of the value of the first fetch.

Double-fetch race conditions are very similar to Time-Of-Check to Time-Of-Use (TOCTOU) race conditions caused by changes occurring between checking a condition and the use of the check's result (by which the condition no longer holds). The data inconsistency in TOCTOU is usually caused by a race condition that results from improper synchronized concurrent accesses to a shared object. There are varieties of shared objects in any computer system, such as files [2], sockets [36] and memory locations [39], therefore, a TOCTOU can exist in different layers throughout the system. TOCTOU race conditions often occur in file systems and numerous approaches [5, 9, 18, 4, 27] have been proposed to solve these problems, but there is still no general, secure way for applications to access file systems in a race-free way.

Watson [36] worked on exploiting wrapper concurrency vulnerabilities that come from system call interposition. He focused on the wrapper vulnerabilities that will lead to security issues such as privilege escalation and audit bypass. By identifying resources relevant to access control, audit, or other security functionality that are accessed concurrently across a trust boundary, he found vulnerabilities from the wrappers and demonstrated the exploit techniques with examples. He also categorized the Time-Of-Audit to Time-Of-Use and Time-Of-Replacement to Time-Of-Use issues in addition to the Time-Of-Check to Time-Of-Use issue. However, he focused on the system call interposition security extensions rather than the kernel as we do. He did not provide details of how he found these vulnerabilities either.

Yang et al. [39] cataloged concurrency attacks in the wild by studying 46 different types of exploits and presented their characteristics. They pointed out that the risk of concurrency attacks was proportional to the duration of the vulnerability window. Moreover, they found that previous TOCTOU detection and prevention techniques are too specific and cannot detect or prevent general concurrency attacks.

Coccinelle [17], the program matching and transformation engine we use in our approach, was initially targeted for collateral evolution in Linux drivers, but now is widely used for finding and fixing bugs in systems code. With Coccinelle, Nicolas et al. [26, 25] performed a study of all the versions of Linux released between 2003 and 2011, ten years after the work of Chou et al. [7], who gave the first thorough study on faults found in Linux. Nicolas et al. pointed out that the kind of faults considered ten years ago were still relevant, and were still present in both new and existing files. They also found that the rate of the considered kinds of faults were falling in the driver directory, which supported Chou et al.

7 Conclusion

This work provides the first (to the best of our knowledge) static analysis of double fetches in the Linux kernel. It is the first approach able to detect double-fetch vulnerabilities in the complete kernel including all drivers and all hardware architectures (which was impossible using dynamic approaches). Based on our pattern-based static analysis, we categorized three typical scenarios in which double fetches are prone to occur. We also provide recommended solutions, specific to typical double-fetch scenarios we found in our study, to prevent double-fetch bugs and vulnerabilities. One solution is used to automatically patch double-fetch bugs, which is able to automatically patch all discovered bugs occurring in the size-checking scenario.

Where a known dynamic analysis of the Linux, FreeBSD, and OpenBSD kernels found no double-fetch bug, our static analysis discovered six real double-fetch bugs, five of which are previously unknown bugs, and three of which are exploitable double-fetch vulnerabilities. All of the reported bugs have been confirmed and

fixed by the maintainers. Our approach has been adopted by the Coccinelle team and is currently being integrated into the Linux kernel patch vetting.

Abstract

While a core dump carries a large amount of information, it barely serves as *informative* debugging aids in locating software faults because it carries information that indicates only a partial chronology of how program reached a crash site. Recently, this situation has been significantly improved. With the emergence of hardware-assisted processor tracing, software developers and security analysts can trace program execution and integrate them into a core dump. In comparison with an ordinary core dump, the new post-crash artifact provides software developers and security analysts with more clues as to a program crash. To use it for failure diagnosis, however, it still requires strenuous manual efforts.

In this work, we propose POMP, an automated tool to facilitate the analysis of post-crash artifacts. More specifically, POMP introduces a new reverse execution mechanism to construct the data flow that a program followed prior to its crash. By using the data flow, POMP then performs backward taint analysis and highlights those program statements that actually contribute to the crash.

To demonstrate its effectiveness in pinpointing program statements truly pertaining to a program crash, we have implemented POMP for Linux system on x86-32 platform, and tested it against various program crashes resulting from 31 distinct real-world security vulnerabilities. We show that, POMP can accurately and efficiently pinpoint program statements that truly pertain to the crashes, making failure diagnosis significantly convenient.

1 Introduction

Despite the best efforts of software developers, software inevitably contains defects. When they are triggered, a program typically crashes or otherwise terminates abnormally. To track down the root cause of a software crash, software developers and security analysts need to identify those program statements pertaining to the crash, analyze these statements and eventually figure out why a bad value (such as an invalid pointer) was passed to the crash site. In general, this procedure can be significantly facilitated (and even automated) if both control and data flows are given. As such, the research on postmortem program analysis primarily focuses on finding out control and data flows of crashing programs. Of all techniques on postmortem program analysis, record-and-replay (*e.g.,* [10, 12, 14]) and core dump analysis (*e.g.,* [16, 26, 36]) are most common.

Record-and-replay is a technique that typically instruments a program so that one can automatically log non-deterministic events (*i. e.,* the input to a program as well as the memory access interleavings of the threads) and later utilize the log to replay the program deterministically. In theory, this technique would significantly benefit root cause diagnosis of crashing programs because developers and security analysts can fully reconstruct the control and data flows prior to a crash. In practice, it however is not widely adopted due to the requirement of program instrumentation and the high overhead it introduces during normal operations.

In comparison with record-and-reply, core dump analysis is a lightweight technique for the diagnosis of program crashes. It does not require program instrumentation, nor rely upon the log of program execution. Rather, it facilitates program failure diagnosis by using more generic information, *i. e.,* the core dump that an operating system automatically captures every time a process has crashed. However, a core dump provides only a snapshot of the failure, from which core dump analysis techniques can infer only partial control and data flows pertaining to program crashes. Presumably as such, they have not been treated as the first choice for software debugging.

Recently, the advance in hardware-assisted processor tracing significantly ameliorates this situation. With the emergence of Intel PT [6] – a brand new hardware feature in Intel CPUs – software developers and security analysts can trace instructions executed and save them in a

circular buffer. At the time of a program crash, an operating system includes the trace into a core dump. Since this post-crash artifact contains both the state of crashing memory and the execution history, software developers not only can inspect the program state at the time of the crash, but also fully reconstruct the control flow that led to the crash, making software debugging more informative and efficient.

While Intel PT augments software developers with the ability of obtaining more informative clues as to a software crash, to use it for the root cause diagnosis of software failures, it is still time consuming and requires a lot of manual efforts. As we will discuss in Section 2, a post-crash artifact[1] typically contains a large amount of instructions. Even though it carries execution history that allows one to fully reconstruct the control flow that a crashing program followed – without an automated tool to eliminate those instructions not pertaining to the failure – software developers and security analysts still need to manually examine each instruction in an artifact and identify those that actually contribute to the crash.

To address this problem, recent research [22] has proposed a technical approach to identify program statements that pertain to a software failure. Technically speaking, it combines static program analysis with a cooperative and adaptive form of dynamic program analysis that uses Intel PT. While shown to be effective in facilitating failure diagnosis, particularly those caused by concurrency bugs, this technique is less likely to be effective in analyzing crashes resulting from memory corruption vulnerabilities (e.g. buffer overflow or use after free). This is due to the fact that a memory corruption vulnerability allows an attacker to manipulate the control (or data) flow, whereas the static program analysis heavily relies upon the assumption that program execution does not violate control nor data flow integrity. Given that the technique proposed in [22] needs to track data flow using hardware watchpoints in a collaborative manner, this technique is also less suitable to the situation where program crashes cannot be easily collected in a crowd-sourcing manner.

In this work, we design and develop POMP, a new automated tool that analyzes a post-crash artifact and pinpoints statements pertaining to the crash. Considering that the control flow of a program might be hijacked and static analysis is unreliable, the design of POMP is exclusively on the basis of the information residing in post-crash artifacts. In particular, POMP introduces a reverse execution mechanism which takes as input a post-crash artifact, analyzes the crashing memory and reversely executes the instructions residing in the artifact. With the support of this reverse execution, POMP reconstructs the data flow that a program followed prior to its crash, and then utilizes backward taint analysis to pinpoint the critical instructions leading up to the crash.

[1] By a post-crash artifact, without further specification, we mean a core dump including both the snapshot of crashing memory and the instructions executed prior to the crash.

The reverse execution proposed in this work is novel. In previous research, the design of reverse execution is under the assumption of the data integrity in crashing memory [16, 37] or heavily relies upon the capability of recording critical objects in memory [7–9, 13]. In this work, considering a software vulnerability might incur memory corruption and object recording imposes overhead on normal operations, we relax this assumption and the ability of data object recording, and introduce a recursive algorithm. To be specific, the algorithm performs the restoration of memory footprints by constructing the data flow prior to the crash. In turn, it also employs recovered memory footprints to improve data flow construction. If needed, the algorithm also verifies memory aliases and ensures data flow construction does not introduce errors or uncertainty. We detail this algorithm in Section 4.

To the best of our knowledge, POMP is the first work that can recover the data flow prior to a program crash. Since POMP relies only upon a post-crash artifact, it is non-intrusive to normal operations and, more importantly, generally applicable to any settings even though crash report collection cannot be performed in a cooperative manner. Last but not least, it should be noted that the impact of this work is not just restricted to analyzing the abnormal program termination caused by memory corruption vulnerabilities. The technique we proposed is generally applicable to program crashes caused by other software bugs, such as dereferencing null pointers. We will demonstrate this capability in Section 6.

In summary, this paper makes the following contributions.

- We designed POMP, a new technique that analyzes post-crash artifacts by reversely executing instructions residing in the artifact.
- We implemented POMP on 32-bit Linux for facilitating software developers (or security analysts) to pinpoint software defects, particularly memory corruption vulnerabilities.
- We demonstrated the effectiveness of POMP in facilitating software debugging by using various post-crash artifacts attributable to 31 distinct real world security vulnerabilities.

The rest of this paper is organized as follows. Section 2 defines the problem scope of our research. Section 3 presents the overview of POMP. Section 4 and 5 describe the design and implementation of POMP in detail. Section 6 demonstrates the utility of POMP. Section 7 summarizes the work most relevant to ours followed by some discussion on POMP in Section 8. Finally, we conclude this work in Section 9.

```
1  void test(void){
2     ...
3  }
4
5  int child(int *a){
6     a[0] = 1; // assigning value to var
7     a[1] = 2; // overflow func
8     return 0;
9  }
10
11 int main(){
12    void (*func)(void);
13    int var;
14    func = &test;
15    child(&var);
16    func(); // crash site
17 }
```

Table 1: A toy example with a stack overflow defect.

2 Problem Scope

In this section, we define the problem scope of our research. We first describe our threat model. Then, we discuss why failure diagnosis can be tedious and tough even though a post-crash artifact carries information that allows software developers to fully reconstruct the control flow that a program followed prior to its crash.

2.1 Threat Model

In this work, we focus on diagnosing the crash of a process. As a result, we exclude the program crashes that do not incur the unexpected termination of a running process (*e.g.,* Java program crashes). Since this work diagnoses a process crash by analyzing a post-crash artifact, we further exclude those process crashes that typically do not produce an artifact. Up to and including Linux 2.2, the default action for CPU time limit exceeded, for example, is to terminate the process without a post-crash artifact [3].

As is mentioned above, a post-crash artifact contains not only the memory snapshot of a crashing program but also the instructions that the program followed prior to its crash[2]. Recall that the goal of this work is to identify those program statements (*i. e.,* instructions) that actually pertain to the crash. Therefore, we assume the instruction trace logged in an artifact is sufficiently long and the root cause of a program failure is always enclosed. In other words, we assume a post-crash artifact carries all the instructions that actually contribute to the crash. We believe this is a realistic assumption because a software defect is typically close to a crash site [19, 27, 39] and an operating system can easily allocate a memory region to store the execution trace from a defect triggered to an actual crash. Since security analysts may not have the access to source code of crashing programs and they can only pinpoint software defects using execution traces left behind crashes, it should be noted that we do not assume the source code of the crashing program is available.

[2] While Intel PT does not log unconditional jumps and linear code, a full execution trace can be easily reconstructed from the execution trace enclosed in a post-crash artifact. By an execution trace in a post-crash artifact, without further specification, we mean a trace including conditional branch, unconditional jump and linear code.

2.2 Challenge

As is mentioned earlier, Intel PT records program execution in a circular buffer. At the time a software defect is triggered and incurs a crash, the circular buffer has generally accumulated a large amount of conditional branches. After the control flow reconstruction from these branches, a full execution trace may carry more than a billion instructions. Even if zooming in the trace from where a fault is triggered to where a crash occurs, a software developer (or security analyst) may confront tens of thousands of instructions. As such, it is tedious and arduous for a software developer to plow through an execution trace to diagnose the root cause of a software failure.

In fact, even though an execution trace is short and concise, it is still challenging for commonly-adopted manual diagnosis strategies (like backward analysis). Here, we detail this challenge using a toy example shown in Table 1. As is shown in the table, the program crashes at `line 16` due to an overflow that occurs at `line 7`. After the crash, an execution trace is left behind in a post-crash artifact shown in Figure 1. In addition to the trace, the artifact captures the state of the crashing memory which is illustrated as the values shown in column T_{20}.

To diagnose the root cause with backward analysis for the program crash shown in Figure 1, a software developer or security analyst typically follows through the execution trace reversely and examines how the bad value in register `eax` was passed to the crash site (*i. e.,* instruction `A20` shown in Figure 1). In this procedure, his effort can be prematurely blocked when his analysis reaches instruction `A19`. In that instruction `mov` overwrote register `eax` and an inverse operation against this instruction lacks information to restore its previous value.

To address this problem, one straightforward solution is to perform forward analysis when backward analysis reaches a non-invertible instruction. Take instruction `A19` for the example. By following a use-define chain, we can construct a data flow. Then, we can easily observe that instruction `A15` specifies the definition of register `eax`, and that definition can reach instruction `A19` without any other intervening definitions. As a result, we can restore the value in register `eax` and thus complete the inverse operation for instruction `A19`.

While the backward and forward analysis provides security analysts with an effective method to construct data

		Time								
		T_{20}	T_{19}	T_{18}	T_{17}	T_{16}	T_{15}	T_{14}	T_{13}	T_{12}
Register	eax	0x0002	0x0002	0x0000	0x0000	0x0000	0x0000	0xff1c	0xff1c	0xff18
	ebp	0xff28	0xff28	0xff28	0xff28	0xff28	0xff08	0xff08	0xff08	0xff08
	esp	0xff14	0xff14	0xff14	0xff10	0xff0c	0xff08	0xff08	0xff08	0xff08
Memory Address	0xff1c	0x0002	0x0002	0x0002	0x0002	0x0002	0x0002	0x0002	test	test
	0xff18	0x0001	0x0001	0x0001	0x0001	0x0001	0x0001	0x0001	0x0001	0x0001
	0xff14	0x0000	0x0000	0x0000	0x0000	0x0000	0x0000	0x0000	0x0000	0x0000
	0xff10	0xff18	0xff18	0xff18	0xff18	0xff18	0xff18	0xff18	0xff18	0xff18
	0xff0c	A18	A18	A18	A18	A18	A18	A18	A18	A18
	0xff08	0xff28	0xff28	0xff28	0xff28	0xff28	0xff28	0xff28	0xff28	0xff28

Figure 1: A post-crash artifact along with the memory footprints recovered by reversely executing the trace enclosed in the artifact. Note that, for simplicity, all the memory addresses and the value in registers are trimmed and represented with two hex digits. Note that `A18` and `test` indicate the addresses at which the instruction and function are stored.

flows, this is not sufficient for completing program failure diagnosis. Again, take for example the execution trace shown in Figure 1. When backward analysis passes through instruction `A15` and reaches instruction `A14`, through forward analysis, a security analyst can quickly discover that the value in register `eax` after the execution of `A14` is dependent upon both instruction `A12` and `A13`. As a result, an instinctive reaction is to retrieve the value stored in the memory region specified by `[ebp+0x8]` shown in instruction `A12`. However, memory indicated by `[ebp+0x8]` and `[eax]` shown in instruction `A14` might be alias of each other. Without an approach to resolve memory alias, one cannot determine if the definition in instruction `A14` interrupts the data flow from instructions `A12` and `A13`. Thus, program failure diagnosis has to discontinue without an outcome.

3 Overview

In this section, we first describe the objective of this research. Then, we discuss our design principle followed by the basic idea on how `POMP` performs postmortem program analysis.

3.1 Objective

The goal of software failure diagnosis is to identify the root cause of a failure from the instructions enclosed in an execution trace. Given a post-crash artifact containing an execution trace carrying a large amount of instructions that a program has executed prior to its crash, however, any instructions in the trace can be potentially attributable to the crash. As we have shown in the section above, it is tedious and tough for software developers (or security analysts) to dig through the trace and pinpoint the root cause of a program crash. Therefore, the objective of this work is to identify only those instructions that truly contribute to the crash. In other words, given a post-crash artifact, our goal is to highlight and present to software developers (or security analysts) the minimum set of instructions that contribute to a program crash. Here, our hypothesis is that the achievement of this goal can significantly reduce the manual efforts of finding out the root cause of a software failure.

3.2 Design Principle

To accomplish the aforementioned objective, we design `POMP` to perform postmortem analysis on binaries – though in principle this can be done on a source code level – in that this design principle can provide software developers and security analysts with the following benefits. Without having `POMP` tie to a set of programs written in a particular programming language, our design principle first allows software developers to employ a single tool to analyze the crashes of programs written in various language (*e.g.,* assembly code, C/C++ or JavaScript). Second, our design choice eliminates the complication introduced by the translation between source code and binaries in that a post-crash artifact carries an execution trace in binaries which can be directly consumed by analysis at the binary level. Third, with the choice of our design, `POMP` can be generally applied to software failure triage or categorization in which a post-crash artifact is

the only resource for analysis and the source code of a crashing program is typically not available [16, 18].

3.3 Technical Approach

As is mentioned earlier in Section 1, it is significantly convenient to identify the instructions pertaining to a program crash if software developers and security analysts can obtain the control and data flows that a program followed prior to its crash.

We rely on Intel PT to trace the control flow of a program and integrate it into the post-crash artifact. PT is a low-overhead hardware feature in recent Intel processors (*e.g.,* Skylake series). It works by capturing information about software execution on each hardware thread [6]. The captured information is orgranized in different types of data packets. Packets about program flow encodes the transfers of control flow (*e.g.,* targets of indirect branches and taken/not-taken indications of conditional direct branches). With the control flow transfers and the program binaries, one is able to fully reconstruct the trace of executed instructions. Details of our configuration and use with PT are presented in Section 5.

Since a post-crash artifact has already carried the control flow that a crashing program followed, the main focus is to reconstruct the data flow from the post-crash artifact that a crashing program left behind.

To reconstruct the data flow pertaining to a program failure, `POMP` introduces a reverse execution mechanism to restore the memory footprints of a crashing program. This is due to the fact that the data flow can be easily derived if machine states prior to a program crash are all available. In the following, we briefly describe how to recover memory footprints and build a data flow through reverse execution, and how to utilize that data flow to refine instructions that truly pertain to a program crash.

Our reverse execution mechanism is an extension of the aforementioned forward-and-backward analysis. Not only does it automate the forward-and-backward analysis, making the inverse operations for instructions effortless, but also automatically verifies memory aliases and ensures an inverse operation does not introduce errors or uncertainty.

With this reverse execution mechanism, `POMP` can easily restore the machine states prior to the execution of each instruction. Here, we illustrate this with the example shown in Figure 1. After reverse execution completes the inverse operation for instruction `A19` through the aforementioned forward and backward analysis, it can easily restore the value in register `eax` and thus the memory footprint prior to the execution of `A19` (see memory footprint at time T_{18}). With this memory footprint, the memory footprint prior to instruction `A18` can be easily recovered because arithmetical instructions do not introduce non-invertible effects upon memory (see the memory footprint at time T_{17}).

Since instruction `A17` can be treated as `mov eip, [esp]` and then `add esp, 0x4`, and instruction `A16` is equivalent to `mov ebp, [esp]` and then `add esp, 0x4`, reverse execution can further restore memory footprints prior to their execution by following the scheme of how it handles `mov` and arithmetical instructions above. In Figure 1, we illustrate the memory footprints prior to the execution of both instructions.

Recall that performing an inverse operation for instruction `A15`, forward and backward analysis cannot determine whether the use of `[ebp+0x8]` specified in instruction `A12` can reach the site prior to the execution of instruction `A15` because `[eax]` in `A14` and `[ebp+0x8]` in `A12` might just be different symbolic names that access data in the same memory location.

To address this issue, one instinctive reaction is to use the value-set analysis algorithm proposed in [11]. However, value-set analysis assumes the execution complies with standard compilation rules. When memory corruption happens and leads to a crash, these rules are typically violated and, therefore, value-set analysis is very likely to be error-prone. In addition, value-set analysis produces less precise information, not suitable for reverse execution to verify memory aliases. In this work, we employ a hypothesis test to verify possible memory aliases. To be specific, our reverse execution creates two hypotheses, one assuming two symbolic names are aliases of each other while the other assuming the opposite. Then, it tests each of these hypotheses by emulating inverse operations for instructions.

Let's continue the example shown in Figure 1. Now, reverse execution can create two hypotheses, one assuming `[eax]` and `[ebp+0x8]` are aliases of each other while the other assuming the opposite. For the first hypothesis, after performing the inverse operation for instruction `A15`, the information carried by the memory footprint at T_{14} would have three constraints, including $eax = ebp + 0x8$, $eax = [ebp + 0x8] + 0x4$ and $[eax] = 0x2$. For the second hypothesis, the constraint set would include $eax \neq ebp + 0x8$, $eax = [ebp + 0x8] + 0x4$ and $[eax] = 0x2$. By looking at the memory footprint at T_{14} and examining these two constraint sets, reverse execution can easily reject the first hypothesis and accept the second because constraint $eax = ebp + 0x8$ for the first hypothesis does not hold. In this way, reverse execution can efficiently and accurately recover the memory footprint at time T_{14}. After the memory footprint recovery at T_{14}, reverse execution can further restore earlier memory footprints using the scheme we discussed above, and Figure 1 illustrates part of these memory footprints.

With memory footprints recovered, software developers and security analysts can easily derive the correspond-

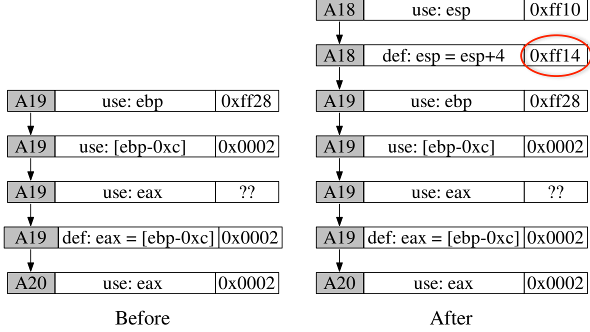

Figure 2: A use-define chain before and after appending new relations derived from instruction `A18`. Each node is partitioned into three cells. From left to right, the cells carry instruction ID, definition (or use) specification and the value of the variable. Note that symbol ?? indicates the value of that variable is unknown.

ing data flow and thus pinpoint instructions that truly contribute to a crash. In our work, `POMP` automates this procedure by using backward taint analysis. To illustrate this, we continue the aforementioned example and take the memory footprints shown in Figure 1. As is described earlier, in this case, the bad value in register `eax` was passed through instruction `A19` which copies the bad value from memory `[ebp-0xC]` to register `eax`. By examining the memory footprints restored, `POMP` can easily find out that the memory indicated by `[ebp-0xC]` shares the same address with that indicated by `[eax]` in instruction `A14`. This implies that the bad value is actually propagated from instruction `A14`. As such, `POMP` highlights instructions `A19` and `A14`, and deems they are truly attributable to the crash. We elaborate on the backward taint analysis in Section 4.

4 Design

Looking closely into the example above, we refine an algorithm to perform reverse execution and memory footprint recovery. In the following, we elaborate on this algorithm followed by the design detail of our backward taint analysis.

4.1 Reverse Execution

Here, we describe the algorithm that `POMP` follows when performing reverse execution. In particular, our algorithm follows two steps – *use-define chain construction* and *memory alias verification*. In the following, we elaborate on them in turn.

4.1.1 Use-Define Chain Construction

In the first step, the algorithm first parses an execution trace reversely. For each instruction in the trace, it extracts uses and definitions of corresponding variables based on the semantics of that instruction and then links them to a use-define chain previously constructed. For example, given an initial use-define chain derived from instructions `A20` and `A19` shown in Figure 1, `POMP` extracts the use and definition from instruction `A18` and links them to the head of the chain (see Figure 2).

As we can observe from the figure, a definition (or use) includes three elements – instruction ID, use (or definition) specification and the value of the variable. In addition, we can observe that a use-define relation includes not only the relations between operands but also those between operands and those base and index registers enclosed (see the use and definition for instruction `A19` shown in Figure 2).

Every time appending a use (or definition), our algorithm examines the reachability for the corresponding variable and attempts to resolve those variables on the chain. More specifically, it checks each use and definition on the chain and determines if the value of the corresponding variable can be resolved. By resolving, we mean the variable satisfies one of the following conditions – ① the definition (or use) of that variable could reach the end of the chain without any other intervening definitions; ② it could reach its consecutive use in which the value of the corresponding variable is available; ③ a corresponding resolved definition at the front can reach the use of that variable; ④ the value of that variable can be directly derived from the semantics of that instruction (*e.g.,* variable `eax` is equal to `0x00` for instruction `mov eax, 0x00`).

To illustrate this, we take the example shown in Figure 2. After our algorithm concatenates definition `def:esp=esp+4` to the chain, where most variables have already been resolved, reachability examination indicates this definition can reach the end of the chain. Thus, the algorithm retrieves the value from the post-crash artifact and assigns it to `esp` (see the value in circle). After this assignment, our algorithm further propagates this updated definition through the chain, and attempts to use the update to resolve variables, the values of which have not yet been assigned. In this case, none of the definitions and uses on the chain can benefit from this propagation. After the completion of this propagation, our algorithm further appends use `use:esp` and repeats this process. Slightly different from the process for definition `def:esp=esp+4`, for this use, variable `esp` is not resolvable through the aforementioned reachability examination. Therefore, our algorithm derives the value of `esp` from the semantics of instruction `A18`

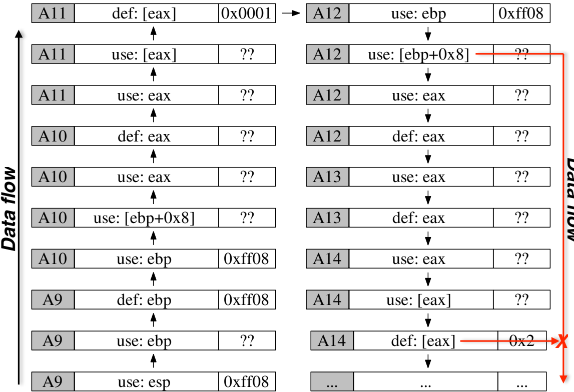

Figure 3: A use-define chain with one intervening tag conservatively placed. The tag blocks the propagation of some data flows. Note that ✗ represents the block of a data flow.

(*i. e.,* `esp=esp-4`).

During use-define chain construction, our algorithm also keeps track of constraints in two ways. In one way, our algorithm extracts constraints by examining instruction semantics. Take for example instruction `A19` and dummy instruction sequence `cmp eax, ebx;` ⇒ `ja target;` ⇒ `inst_at_target`. Our algorithm extracts equality constraint `eax=[ebp-0xc]` and inequality constraint `eax>ebx`, respectively. In another way, our algorithm extracts constraints by examining use-define relations. In particular, ① when the definition of a variable can reach its consecutive use without intervening definitions, our algorithm extracts a constraint indicating the variable in that definition shares the same value with the variable in the use. ② When two consecutive uses of a variable encounters no definition in between, our algorithm extracts a constraint indicating variables in both uses carry the same value. ③ With a variable resolved, our algorithm extracts a constraint indicating that variable equals to the resolved value. The reason behind the maintenance of these constraints is to be able to perform memory alias verification discussed in the following section.

In the process of resolving variables and propagating definitions (or uses), our algorithm typically encounters a situation where an instruction attempts to assign a value to a variable represented by a memory region but the address of that region cannot be resolved by using the information on the chain. For example, instruction `A14` shown in Figure 1 represents a memory write, the address of which is indicated by register `eax`. From the use-define chain pertaining to this example shown in Figure 3, we can easily observe the node with `A13 def:eax` does not carry any value though its impact can be propagated to the node with `A14 def:[eax]` without any other intervening definitions.

As we can observe from the example shown in Figure 3, when this situation appears, a definition like `A14 def:[eax]` may potentially interrupt the reachability of the definitions and uses of other variables represented by memory accesses. For example, given that memory indicated by `[ebp+0x08]` and `[eax]` might be an alias of each other, definition `A14 def:[eax]` may block the reachability of `A12 use:[ebp+0x08]`. As such, in the step of use-define chain construction, our algorithm treats those unknown memory writes as an intervening tag and blocks previous definitions and uses accordingly. This conservative design principle ensures that our algorithm does not introduce errors to memory footprint recovery.

The above forward-and-backward analysis is mainly designed to discover the use-define reltaions. Other techniques, such as static program slicing [34], can also identify use-define relations. However, our analysis is novel. To be specific, our analysis discovers the use-define relations and use them to perform the restoration of memory footprints. In turn, it leverages recovered memory footprints to further find use-define relations. This interleaving approach leads more use-define relations to being identified. Additionally, our analysis conservatively deals with memory aliases and verifies them in an error-free manner. This is different from previous techniques that typically leverage less rigorous methods (*e.g.,* value-set analysis). More details about how we resolve memory alias are presented in the next section.

4.1.2 Memory Alias Verification

While the aforementioned design principle prevents introducing errors to memory footprint recovery, this conservative strategy hinders data flow construction and limits the capability of resolving variables (see the flow block and non-recoverable variables shown in Figure 3). As a result, the second step of our algorithm is to minimize the side effect introduced by the aforementioned strategy.

Since the conservative design above roots in "undecidable" memory alias, the way we tackle the problem is to introduce a hypothesis test mechanism that examines if a pair of symbolic names points to the same memory location. More specifically, given a pair of symbolic names, this mechanism makes two hypotheses, one assuming they are alias of each other and the other assuming the opposite. Based on the hypotheses, our algorithm adjusts the use-define chain as well as constraints accordingly. For example, by assuming `[eax]` is not aliased to `[ebp+0x8]`, our algorithm extracts inequility constraint `eax≠ebp+0x8` and releases the block shown in Figure 3, making `A12 use:[ebp+0x8]` further propagated.

During the propagation, our algorithm walks through

each of the nodes on the chain and examines if the newly propagated data flow results in conflicts. Typically, there are two types of conflicts. The most common is inconsistence data dependency in which constraints mismatch the data propagated from above (*e.g.,* the example discussed in Section 3). In addition to the conflict commonly observed, another type of conflict is invalid data dependency in which a variable carries an invalid value that is supposed to make the crashing program terminate earlier or follow a different execution path. For example, given a use-define chain established under a certain hypothesis, the walk-through discovers that a register carries an invalid address and that invalid value should have the crashing program terminate at a site ahead of its actual crash site.

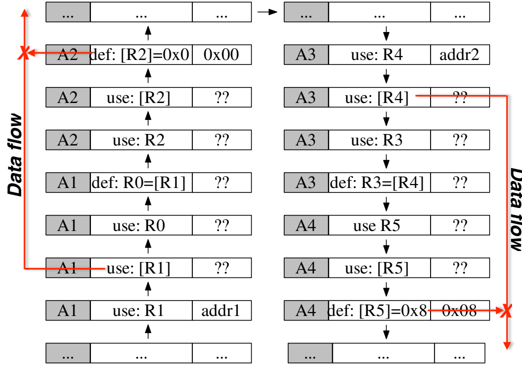
It is indisputable that once a constraint conflict is observed, our algorithm can easily reject the corresponding hypothesis and deem the pair of symbolic names is alias (or non-alias) of each other. However, if none of these hypotheses produce constraint conflicts, this implies that there is a lack of evidence against our hypothesis test. Once this situation appears, our algorithm holds the current hypothesis and performs an additional hypothesis test. The reason is that a new hypothesis test may help remove an additional intervening tag conservatively placed at the first step, and thus provides the holding test with more informative evidence to reject hypotheses accordingly.

To illustrate this, we take a simple example shown in Figure 4. After the completion of the first step, we assume that our algorithm conservatively treats `A2 def:[`R_2`]` and `A4 def:[`R_5`]` as intervening tags which hinder data flow propagation. Following the procedure discussed above, we reversely analyze the trace and make a hypothesis, *i. e.,* `[`R_4`]` and `[`R_5`]` are not alias. With this hypothesis, the data flow between the intervening tags can propagate through, and our algorithm can examine conflicts accordingly. Assume that the newly propagated data flow is insufficient for rejecting our hypothesis. Our algorithm holds the current hypothesis and makes an additional hypothesis, *i. e.,* `[`R_1`]` and `[`R_2`]` are not alias of each other. With this new hypothesis, more data flows pass through and our algorithm obtains more information that potentially helps reject hypotheses. It should be noted that if any of the hypotheses fail to reject, our algorithm preserves the intervening tags conservatively placed at the first step.

It is not difficult to spot that our hypothesis test can be easily extended as a recursive procedure which makes more hypotheses until they can be rejected. However, a recursive hypothesis test introduces computation complexity exponentially. In the worse case, when performing execution reversely, the inverse operation of each instruction may require alias verification and each verification may require further alias examination. When this situa-

```
     ...
A1:  mov R0, [R1]      ; R1 = addr1
A2:  mov [R2], 0x00    ; R2 = ??
     ...
     ...
A3:  mov R3, [R4]      ; R4 =addr2
A4:  mov [R5], 0x08    ; R5 = ??
     ...
```

(a) The execution trace.



(b) The use-define chain.

Figure 4: A dummy use-define chain and execution trace with two pairs of memory aliases. Note that $R_0, R_1, \cdots R_5$ represent registers in which the values of R_2 and R_5 are unknown. Note that ✗ represents the block of a data flow.

tion appears, the algorithm above becomes an impractical solution. As such, this work empirically forces a hypothesis test to follow at most a recurssion depth of two. As we will show in Section 6, this setting allows us to perform reverse execution not only in an efficient but also relatively effective manner.

4.1.3 Discussion

During the execution of a program, it might invoke a system call, which traps execution into kernel space. As we will discuss in Section 6, we do not set Intel PT to trace execution in kernel space. As a result, intuition suggests that the loss of execution tracing may introduce problems to our reverse execution. However, in practice, a majority of system calls do not incur modification to registers and memory in user space. Thus, our reverse execution can simply ignore the inverse operations for those system calls. For system calls that potentially influence the memory footprints of a crashing program, our reverse execution handles them as follows.

In general, a system call can only influence memory footprints if it manipulates register values stored by the crashing program or touches the memory region in user space. As a result, we treat system calls in different manners. For system calls that may influence a register holding a value for a crashing program, our algorithm

simply introduces a definition on the use-define chain. For example, system call `read` overwrites register `eax` to hold its return value, and our algorithm appends definition `def:eax=?` to the use-define chain accordingly. Regarding the system calls that manipulate the memory content in user space (*e.g.,* `write` and `recv`), our algorithm checks the memory regions influenced by that call. To be specific, it attempts to identify the starting address as well as the size of that memory region by using the instructions executed prior to that call. This is due to the fact that the starting address and size are typically indicated by arguments which are handled by those instructions prior to the call. Following this procedure, if our algorithm identifies the size of that memory region, it appends definitions to the chain accordingly. Otherwise, our algorithm treats that system call as an intervening tag which blocks the propagation through that call[3]. The reason behind this is that a non-deterministic memory region can potentially overlap with any memory regions in user space.

4.2 Backward Taint Analysis

Recall that the goal of this work is to pinpoint instructions truly pertaining to a program crash. In Section 3, we briefly introduce how backward taint analysis plays the role in achieving this goal. Here, we describe more details.

To perform backward taint analysis, `POMP` first identifies a sink. In general, a program crash results from two situations – executing an invalid instruction or dereferencing an invalid address. For the first situation, `POMP` deems the program counter (`eip`) as a sink because executing an invalid instruction indicates `eip` carries a bad value. For the second situation, `POMP` treats a general register as a sink because it holds a value which points to an invalid address. Take the example shown in Figure 1. `POMP` treats register `eax` as a sink in that the program crash results from retrieving an invalid instruction from the address held by register `eax`.

With a sink identified, `POMP` taints the sink and performs taint propagation backward. In the procedure of this backward propagation, `POMP` looks up the aforementioned use-define chain and identifies the definition of the taint variable. The criteria of this identification is to ensure the definition could reach the taint variable without any other intervening definitions. Continue the example above. With sink `eax` serving as the initial taint variable, `POMP` selects `A19 def:eax=[ebp-0xc]` on the chain because this definition can reach taint variable `eax` without intervention.

[3]Note that an intervening tag placed by a system call blocks only definitions and uses in which a variable represents a memory access (*e.g.,* `def:[eax]` or `use:[ebp]`).

From the definition identified, `POMP` parses that definition and passes the taint to new variables. Since any variables enclosed in a definition could potentially cause the corruption of the taint variable, the variables which `POMP` selects and passes the taint to include all operands, base and index registers (if available). For example, by parsing definition `A19 def:eax=[ebp-0xc]`, `POMP` identifies variables `ebp` and `[ebp-0xc]`, and passes the taint to both of them. It is not difficult to note that such a taint propagation strategy can guarantee `POMP` does not miss the root cause of a program crash though it over-taints some variables that do not actually contribute to the crash. In Section 6, we evaluate and discuss the effect of the over-tainting.

When passing a taint to a variable indicated by a memory access (*e.g.,* `[`R_0`]`), it should be noted that `POMP` may not be able to identify the address corresponding to the memory (*e.g.,* unknown R_0 for variable `[`R_0`]`). Once this situation appears, therefore, `POMP` halts the taint propagation for that variable because the taint can be potentially propagated to any variables with a definition in the form of `def:[`R_i`]` (where R_i is a register).

Similar to the situation seen in reverse execution, when performing taint propagation backward, `POMP` may encounter a definition on the chain which intervenes the propagation. For example, given a taint variable `[`R_0`]` and a definition `def:[`R_1`]` with R_1 unknown, `POMP` cannot determine whether R_0 and R_1 share the same value and `POMP` should pass the taint to variable `[`R_1`]`. When this situation appears, `POMP` follows the idea of the aforementioned hypothesis test and examines if both variables share the same address. Ideally, we would like to resolve the unknown address through a hypothesis test so that `POMP` can pass that taint accordingly. However, in practice, the hypothesis test may fail to reject. When "fail-to-reject" occurs, therefore, `POMP` over-taints the variable in that intervening definition. Again, this can ensure that `POMP` does not miss the enclosure of root cause.

5 Implementation

We have implemented a prototype of `POMP` for Linux 32-bit system with Linux kernel 4.4 running on an Intel i7-6700HQ quad-core processor (a 6th-generation Skylake processor) with 16 GB RAM. Our prototype consists of two major components – ① a sub-system that implements the aforementioned reverse execution and backward taint analysis and ② a sub-system that traces program execution with Intel PT. In total, our implementation carries about 22,000 lines of `C` code which we will make publicly available at https://github.com/junxzm1990/pomp.git. In the following, we present some important implementation details.

Following the design description above, we implemented 65 distinct instruction handlers to perform reverse execution and backward taint analysis. Along with these handlers, we also built core dump and instruction parsers on the basis of `libelf` [2] and `libdisasm` [1], respectively. Note that for instructions with the same semantics (*e.g.,* je, jne, and jg) we dealt with their inverse operations in one unique handler. To keep track of constraints and perform verification, we reuse the Z3 theorem prover [5, 17].

To allow Intel PT to log execution in a *correct* and *reliable* manner, we implemented the second sub-system as follows. We enabled Intel PT to run in the Table of Physical Addresses (ToPA) mode, which allows us to store PT packets in multiple discontinuous physical memory areas. We added to the ToPA an entry that points to a `16 MB` physical memory buffer. In our implementation, we use this buffer to store packets. To be able to track if the buffer is fully occupied, we clear the `END` bit and set the `INT` bit. With this setup, Intel PT can signal a performance-monitoring interrupt at the moment the buffer is fully occupied. Considering the interrupt may have a skid, resulting in a potential loss in PT packets, we further allocated a `2 MB` physical memory buffer to hold those packets that might be potentially discarded. In the ToPA, we introduced an additional entry to refer this buffer.

At the hardware level, Intel PT lacks the capability of distinguishing threads within each process. As a result, we also intercepted the context switch. With this, our system is able to examine the threads switched in and out, and stores PT packets for threads individually. To be specific, for each thread that software developers and security analysts are interested in, we allocated a `32MB` circular buffer in its user space. Every time a thread is switched out, we migrated PT packets stored in the aforementioned physical memory buffers to the corresponding circular buffer in user space. After migration, we also reset the corresponding registers and make sure the physical memory buffers can be used for holding packets for other threads of interest. Note that our empirical experiment indicates the aforementioned `16 MB` buffer cannot be fully occupied between consecutive context switch, and `POMP` does not have the difficulty in holding all the packets between the switch.

Considering the Intel CPU utilizes Supervisor Mode Access Prevention (SMAP) to restrict the access from kernel to user space, our implementation toggles SMAP between packet migration. In addition, we configured Intel PT to exclude packets irrelevant to control flow switching (*e.g.,* timing information) and paused its tracing when execution traps into kernel space. In this way, `POMP` is able to log an execution trace sufficiently long. Last but not least, we introduced new resource limit `PT_LIMIT` into the Linux kernel. With this, not only can software developers and security analysts select which processes to trace but also configure the size of the circular buffer in a convenient manner.

6 Evaluation

In this section, we demonstrate the utility of `POMP` using the crashes resulting from real-world vulnerabilities. To be more specific, we present the efficiency and effectiveness of `POMP`, and discuss those crashes that `POMP` fails to handle properly.

6.1 Setup

To demonstrate the utility of `POMP`, we selected 28 programs and benchmarked `POMP` with their crashes resulting from 31 real-world PoCs obtained from Offensive Security Exploit Database Archive [4]. Table 2 shows these crashing programs and summarizes the corresponding vulnerabilities. As we can observe, the programs selected cover a wide spectrum ranging from sophisticated software like `BinUtils` with lines of code over `690K` to lightweight software such as `stftp` and `psutils` with lines of code less than `2K`.

Regarding vulnerabilities resulting in the crashes, our test corpus encloses not only memory corruption vulnerabilities (*i. e.,* stack and heap overflow) but also common software defects like null pointer dereference and invalid free. The reason behind this selection is to demonstrate that, beyond memory corruption vulnerabilities, `POMP` can be generally applicable to other kinds of software defects.

Among the 32 PoCs, 11 of them perform code injection (*e.g.,* `nginx-1.4.0`), one does return-to-libc attack (`aireplay-ng-1.2b3`), and another one exploits via return-oriented-programming (`mcrypt-2.5.8`). These exploits crashed the vulnerable program either because they did not consider the dynamics in the execution environments (*e.g.,* ASLR) or they mistakenly polluted critical data (*e.g.,* pointers) before they took over the control flow. The remaining 18 PoCs are created to simply trigger the defects, such as overflowing a stack buffer with a large amount of random characters (*e.g.,* `BinUtils-2.15`) or causing the execution to use a null pointer (*e.g.,* `gdb-7.5.1`). Crashes caused by these PoCs are similar to those occured during random exercises.

6.2 Experimental Design

For each program crash shown in Table 2, we performed manual analysis with the goal of finding out the minimum set of instructions that truly contribute to that program

Table 2: The list of program crashes resulting from various vulnerabilities. `CVE-ID` specifies the ID of the CVEs. `Trace length` indicates the lines of instructions that `POMP` reversely executed. `Size of mem` shows the size of memory used by the crashed program (with code sections excluded). `# of taint` and `Ground truth` describe the lines of instructions automatically pinpointed and manually identified, respectively. `Mem addr unknown` illustrates the amount of memory locations, the addresses of which are unresolvable.

crash. We took our manual analysis as ground truth and compared them with the output of `POMP`. In this way, we validated the effectiveness of `POMP` in facilitating failure diagnosis. More specifically, we compared the instructions identified manually with those pinpointed by `POMP`. The focuses of this comparison include ① examining whether the root cause of that crash is enclosed in the instruction set `POMP` automatically identified, ② investigating whether the output of `POMP` covers the minimum instruction set that we manually tracked down, and ③ exploring if `POMP` could significantly prune the execution trace that software developers (or security analysts) have to manually examine.

In order to evaluate the efficiency of `POMP`, we recorded the time it took when spotting the instructions that truly pertain to each program crash. For each test case, we also logged the instructions that `POMP` reversely executed in that this allows us to study the relation between efficiency and the amount of instructions reversely executed.

Considering pinpointing a root cause does not require reversely executing the entire trace recorded by Intel PT, it is worth of noting that, we selected and utilized only a partial execution trace for evaluation. In this work, our selection strategy follows an iterative procedure in which we first introduced instructions of a crashing function to reverse execution. If this partial trace is insufficient for spotting a root cause, we traced back functions previously invoked and then included instructions function-by-function until that root cause can be covered by `POMP`.

6.3 Experimental Results

We show our experimental results in Table 2. Except for test cases `0verkill` and `aireplay-ng`, we observe, every root cause is included in a set of instructions that `POMP` pinpointed. Through a comparison mentioned above, we also observe each set encloses the corresponding instructions we manually identified (*i. e.,* ground truth). These observations indicate that `POMP` is effective

in locating instructions that truly contribute to program crashes.

In comparison with instructions that POMP needs to reversely execute, we observe, the instructions eventually tainted are significantly less. For example, backward analysis needs to examine 10,905 instructions in order to pinpoint the root cause for crashing program Unalz, whereas POMP highlights only 14 instructions among which half of them truly pertain to the crash. Given that backward taint analysis mimics how a software developer (or security analyst) typically diagnoses the root cause of a program failure, this observation indicates that POMP has a great potential to reduce manual efforts in failure diagnosis.

Except for test case coreutils, an instruction set produced by POMP generally carries a certain amount of instructions that do not actually contribute to crashes. Again, take Unalz for example. POMP over-tainted 7 instructions and included them in the instruction set it identified. In the usage of POMP, while this implies a software developer needs to devote additional energies to those instructions not pertaining to a crash, this does not mean that POMP is less capable of finding out instructions truly pertaining to a crash. In fact, compared with hundreds and even thousands of instructions that one had to manually walk through in failure diagnosis, the additional effort imposed by over-tainting is minimal and negligible.

Recall that in order to capture a root cause, the design of POMP taints all variables that possibly contribute to the propagation of a bad value. As our backward taint analysis increasingly traverses instructions, it is not difficult to imagine that, an increasing number of variables might be tainted which causes instructions corresponding to these variables are treated as those truly pertaining to program crashes. As such, we generally observe more instructions over-tainted for those test cases, where POMP needs to reversely execute more instructions in order to cover the root causes of their failures.

As we discuss in Section 4, ideally, POMP can employ a recursive hypothesis test to perform inverse operations for instructions that carry unknown memory access. Due to the concern of computation complexity, however, we limit the recursion in at most two depths. As such, reverse execution leaves behind a certain amount of unresolvable memory. In Table 2, we illustrate the amount of memory the addresses of which remain unresolvable even after a 2-depth hypothesis test has been performed. Surprisingly, we discover POMP can still effectively spot instructions pertaining to program crashes even though it fails to recover a certain amount of memory. This implies that our design reasonably balances the utility of POMP as well as its computation complexity.

Intuition suggests that the amount of memory unresolvable should correlate with the number of instructions that POMP reversely executes. This is because the effect of an unresolvable memory might be propagated as more instructions are involved in reverse execution. While this is generally true, an observation from test case corehttp indicates a substantially long execution trace does not always necessarily amplify the influence of unknown memory access. With more instructions reversely executed, POMP may obtain more evidence to reject the hypotheses that it fail to determine, making unknown memory access resolvable. With this in mind, we speculate POMP is not only effective in facilitating failure diagnosis perhaps also helpful for executing substantially long traces reversely. As a future work, we will therefore explore this capability in different contexts.

In Table 2, we also illustrate the amount of time that POMP took in the process of reverse execution and backward taint analysis. We can easily observe POMP typically completes its computation in minutes and the time it took is generally proportional to the number of instructions that POMP needs to reversely execute. The reason behind this observation is straightforward. When reverse execution processes more instructions, it typically encounters more memory aliases. In verifying memory aliases, POMP needs to perform hypothesis tests which are slightly computation-intensive and time-consuming.

With regard to test case aireplay-ng in which POMP fails to facilitate failure diagnosis, we look closely to instructions tainted as well as those reversely executed. Prior to the crash of aireplay-ng, we discover the program invoked system call sys_read which writes a data chunk to a certain memory region. Since both the size of the data chunk and the address of the memory are specified in registers, which reverse execution fails to restore, POMP treats sys_read as a "super" intervening tag that blocks the propagation of many definitions, making the output of POMP less informative to failure diagnosis.

Different from aireplay-ng, the failure for 0verkill results from an insufficient PT log. As is specified in Table 2, the vulnerability corresponding to this case is an integer overflow. To trigger this security loophole, the PoC used in our experiment aggressively accumulates an integer variable which makes a PT log full of arithmetic computation instructions but not the instruction corresponding to the root cause. As such, we observe POMP can taint only one instruction pertaining to the crash. We believe this situation can be easily resolved if a software developer (or security analyst) can enlarge the capacity of the PT buffer.

7 Related Work

This research work mainly focuses on locating software vulnerability from its crash dump. Regarding the tech-

niques we employed and the problems we addressed, the lines of works most closely related to our own include reverse execution and postmortem program analysis. In this section, we summarize previous studies and discuss their limitation in turn.

Reverse execution. Reverse execution is a conventional debugging technique that allows developers to restore the execution state of a program to a previous point. Pioneering research [7–9, 13] in this area relies upon restoring a previous program state from a record, and thus their focus is to minimize the amount of records that one has to save and maintain in order to return a program to a previous state in its execution history. For example, the work described in [7–9] is mainly based on regenerating a previous program state. When state regeneration is not possible, however, it recovers a program state by state saving.

In addition to state saving, program instrumentation is broadly used to facilitate the reverse execution of a program. For example, Hou *et al.* designed compiler framework `Backstroke` [21] to instrument C++ program in a way that it can store program states for reverse execution. Similarly, Sauciuc and Necula [30] proposed to use an SMT solver to navigate an execution trace and restore data values. Depending on how the solver performs on constraint sets corresponding to multiple test runs, the technique proposed automatically determines where to instrument the code to save intermediate values and facilitate reverse execution.

Given that state saving requires extra memory space and program instrumentation results in a slower forward execution, recent research proposes to employ a core dump to facilitate reverse execution. In [16] and [37], new reverse execution mechanisms are designed in which the techniques proposed reversely analyzes code and then utilizes the information in a core dump to reconstruct the states of a program prior to its crash. Since the effectiveness of these techniques highly relies upon the integrity of a core dump, and exploiting vulnerabilities like buffer overflow and dangling pointers corrupts memory information, they may fail to perform reverse execution correctly when memory corruption occurs.

Different from the prior research works discussed above, the reverse execution technique introduced in this paper follows a completely different design principle, and thus it provides many advantages. First, it can reinstate a previous program state without restoring that state from a record. Second, it does not require any instrumentation to a program, making it more generally applicable. Third, it is effective in performing execution backward even though the crashing memory snapshot carries corrupted data.

Postmortem program analysis. Over the past decades, there is a rich collection of literature on using program analysis techniques along with crash reports to identify faults in software (*e.g.,* [15, 20, 24, 25, 28, 29, 32, 38]). These existing techniques are designed to identify some specific software defects. In adversarial settings, an attacker exploits a variety of software defects and thus they cannot be used to analyze a program crash caused by a security defect such as buffer overflow or unsafe dangling pointer. For example, Manevich *et al.* [24] proposed to use static backward analysis to reconstruct execution traces from a crash point and thus spot software defects, particularly typestate errors [33]. Similarly, Strom and Yellin [32] defined a partially path-sensitive backward dataflow analysis for checking typestate properties, specifically uninitialized variables. While demonstrated to be effective, these two studies only focus on specific typestate problems.

Liblit *et al.* proposed a backward analysis technique for crash analysis [23]. To be more specific, they introduce an efficient algorithm that takes as input a crash point as well as a static control flow graph, and computes all the possible execution paths that lead to the crash point. In addition, they discussed how to narrow down the set of possible execution paths using a wide variety of post-crash artifacts, such as stack traces. As is mentioned earlier, memory information might be corrupted when attackers exploit a program. The technique described in [23] highly relies upon the integrity of the information resided in memory, and thus fails to analyze program crash resulting from malicious memory corruption. In this work, we do not infer program execution paths through the stack traces recovered from memory potentially corrupted. Rather, our approach identifies the root cause of software failures by reversely executing program and reconstructing memory footprints prior to the crash.

Considering the low cost of capturing core dumps, prior studies also proposed to use core dumps to analyze the root cause of software failures. Of all the works along this line, the most typical ones include `CrashLocator` [35], `!analyze` [18] and `RETracer` [16] which locate software defects by analyzing memory information resided in a core dump. As such, these techniques are not suitable to analyze crashes resulting from malicious memory corruption. Different from these techniques, Kasikci *et al.* introduced `Gist` [22], an automated debugging technique that utilizes off-the-shelf hardware to enhance core dump and then employs a cooperative debugging technique to perform root cause diagnosis. While `Gist` demonstrates its effectiveness on locating bugs from a software crash, it requires the collection of crashes from multiple parties running the same software and suffering the same bugs. This could significantly limit its adoption. In our work, we introduce a different technical approach which can perform analysis at the binary level

without the participation of other parties.

In recent research, Xu *et al.* [36] introduced CREDAL, an automatic tool that employs the source code of a crashing program to enhance core dump analysis and turns a core dump to an informative aid in tracking down memory corruption vulnerabilities. While sharing a common goal as POMP– pinpointing the code statements where a software defect is likely to reside – CREDAL follows a completely different technical approach. More specifically, CREDAL discovers the mismatch in variable values and deems the code fragments corresponding to the mismatch as the possible vulnerabilities that lead to the crash. While it has been shown that CREDAL is able to assist software developers (or security analysts) in tracking down a memory corruption vulnerability, in most cases, it still requires significant manual efforts for locating a memory corruption vulnerability in a crash for the reasons that the mismatch in variable values may be overwritten or the code fragments corresponding to mismatch may not include the root cause of the software crash. In this work, POMP precisely pinpoints the vulnerability by utilizing the memory footprints recovered from reverse execution.

8 Discussion

In this section, we discuss the limitations of our current design, insights we learned and possible future directions.

Multiple threads. POMP focuses only on analyzing the post-crash artifact produced by a crashing thread. Therefore, we assume the root cause of the crash is enclosed within the instructions executed by that thread and other threads do not intervene the execution of that thread prior to its crash. In practice, this assumption however may not hold, and the information held in a post-crash artifact may not be sufficient and even misleading for root cause diagnosis.

While this multi-thread issue indeed limits the capability of a security analyst using POMP to pinpoint the root cause of a program crash, this does not mean the failure of POMP nor significantly downgrades the utility of POMP because of the following. First, a prior study [31] has already indicated that a large fraction of software crashes involves only the crashing thread. Thus, we believe POMP is still beneficial for software failure diagnosis. Second, the failure of POMP roots in incomplete execution tracing. Therefore, we believe, by simply augmenting our process tracing with the capability of recording the timing of execution, POMP can synthesize a *complete* execution trace, making POMP working properly. As part of the future work, we will integrate this extension into the next version of POMP.

Just-in-Time native code. Intel PT records the addresses of branching instructions executed. Using these addresses as index, POMP retrieves instructions from executable and library files. However, a program may utilize Just-in-Time (JIT) compilation in which binary code is generated on the fly. For programs assembled with this JIT functionality (*e.g.,* JavaScript engine), POMP is less likely to be effective, especially when a post-crash artifact fails to capture the JIT native code mapped into memory.

To make POMP handle programs in this type, in the future, we will augment POMP with the capability of tracing and logging native code generated at the run time. For example, we may monitor the executable memory and dump JIT native code accordingly. Note that this extension does not require any re-engineering of reverse execution and backward taint analysis because the limitation to JIT native code also results from incomplete execution tracing (*i. e.,* failing to reconstruct all the instructions executed prior to a program crash).

9 Conclusion

In this paper, we develop POMP on Linux system to analyze post-crash artifacts. We show that POMP can significantly reduce the manual efforts on the diagnosis of program failures, making software debugging more informative and efficient. Since the design of POMP is entirely on the basis of the information resided in a post-crash artifact, the technique proposed can be generally applied to diagnose the crashes of programs written in various programming languages caused by various software defects.

We demonstrated the effectiveness of POMP using the real-world program crashes pertaining to 31 software vulnerabilities. We showed that POMP can reversely reconstruct the memory footprints of a crashing program and accurately identify the program statements (*i. e.,* , instructions) that truly contribute to the crash. Following this finding, we safely conclude POMP can significantly downsize the program statements that a software developer (or security analyst) needs to manually examine.

Ninja: Towards Transparent Tracing and Debugging on ARM

Zhenyu Ning and Fengwei Zhang
Wayne State University
{*zhenyu.ning, fengwei*}*@wayne.edu*

Abstract

Existing malware analysis platforms leave detectable fingerprints like uncommon string properties in QEMU, signatures in Android Java virtual machine, and artifacts in Linux kernel profiles. Since these fingerprints provide the malware a chance to split its behavior depending on whether the analysis system is present or not, existing analysis systems are not sufficient to analyze the sophisticated malware. In this paper, we propose NINJA, a transparent malware analysis framework on ARM platform with low artifacts. NINJA leverages a hardware-assisted isolated execution environment TrustZone to transparently trace and debug a target application with the help of Performance Monitor Unit and Embedded Trace Macrocell. NINJA does not modify system software and is OS-agnostic on ARM platform. We implement a prototype of NINJA (i.e., tracing and debugging subsystems), and the experiment results show that NINJA is efficient and transparent for malware analysis.

1 Introduction

Malware on the mobile platform exhibits an explosive growth in recent years. To solve the threat of the malicious applications, a variety of tools have been proposed for malware detection and analysis [18, 22, 37, 44, 45, 52, 55, 56]. However, sophisticated malware, which is also known as evasive malware, is able to evade the analysis by collecting the artifacts of the execution environment or the analysis tool, and refuses to perform any malicious behavior if an analysis system is detected.

As most of the existing mobile malware analysis systems [18, 45, 52] are based on emulation or virtualization technology, a series of anti-emulation and anti-virtualization techniques [29, 36, 48] have been developed to challenge them. These techniques show that the emulation or virtualization can be easily detected by footprints like string properties, absence of particular hardware components, and performance slowdown. The hardware-assisted virtualization technique [17, 50] can improve the transparency of the virtualization-based systems; however, this approach still leaves artifacts on basic instruction execution semantics that could be easily detected by malware [39].

To address this challenge, researchers study the malware on bare-metal devices via modifying the system software [22, 37, 44, 55] or leveraging OS APIs [15, 56] to monitor the runtime behavior of malware. Although bare-metal based approaches eliminate the detection of the emulator or hypervisor, the artifacts introduced by the analysis tool itself are still detectable by malware. Moreover, privileged malware can even manipulate the analysis tool since they run in the same environment. How to build a transparent mobile malware analysis system is still a challenging problem.

This transparency problem has been well studied in the traditional x86 architecture, and similar milestones have been made from emulation-based analysis systems [2, 40] to hardware-assisted virtualization analysis systems [19, 20, 32], and then to bare-metal analysis systems [30, 31, 41, 54]. However, this problem still challenges the state-of-the-art malware analysis systems.

We consider that an analysis system consists of an *Environment* (e.g., operating system, emulator, hypervisor, or sandbox) and an *Analyzer* (e.g., instruction analyzer, API tracer, or application debugger). The *Environment* provides the *Analyzer* with the access to the states of the target malware, and the *Analyzer* is responsible for the further analysis of the states. Consider an analysis system that leverages the emulator to record the system call sequence and sends the sequence to a remote server for further analysis. In this system, the *Environment* is the emulator, which provides access to the system call sequence, and both the system call recorder and the remote server belong to the *Analyzer*. Evasive malware can detect this analysis system via anti-emulation techniques and evade the analysis.

To build a transparent analysis system, we propose three requirements. Firstly, the *Environment* must be isolated. Otherwise, the *Environment* itself can be manipulated by the malware. Secondly, the *Environment* exists on an off-the-shelf (OTS) bare-metal platform without modifying the software or hardware (e.g., emulation and virtualization are not). Although studying the anti-emulation and anti-virtualization techniques [29, 36, 39, 48] helps us to build a more transparent system by fixing the imperfections of the *Environment*, we consider perfect emulation or virtualization is impractical due to the complexity of the software. Instead, if the *Environment* already exists in the OTS bare-metal platform, malware cannot detect the analysis system by the presence of the *Environment*. Finally, the *Analyzer* should not leave any detectable footprints (e.g., files, memory, registers, or code) to the outside of the *Environment*. An *Analyzer* violating this requirement can be detected.

In light of the three requirements, we present NINJA [1], a transparent malware analysis framework on ARM platform based on hardware features including TrustZone technology, Performance Monitoring Unit (PMU), and Embedded Trace Macrocell (ETM). We implement a prototype of NINJA that embodies a trace subsystem with different tracing granularities and a debug subsystem with a GDB-like debugging protocol on ARM Juno development board. Additionally, hardware-based traps and memory protection are leveraged to keep the use of system registers transparent to the target application. The experimental results show that our framework can transparently monitor and analyze the behavior of the malware samples. Moreover, NINJA introduces reasonable overhead. We evaluate the performance of the trace subsystem with several popular benchmarks, and the result shows that the overheads of the instruction trace and system call trace are less than 1% and the Android API trace introduces 4 to 154 times slowdown.

The main contributions of this work include:

- We present a hardware-assisted analysis framework, named NINJA, on ARM platform with low artifacts. It does not rely on emulation, virtualization, or system software, and is OS-agnostic. NINJA resides in a hardware isolation execution environment, and thus is transparent to the analyzed malware.

- NINJA eliminates its footprints by novel techniques including hardware traps, memory mapping interception, and timer adjusting. The evaluation result demonstrates the effectiveness of the mitigation and NINJA achieves a high level of transparency. Moreover, we evaluate the instruction-skid problem and show that it has little influence on our system.

[1] A NINJA in feudal Japan has invisibility and transparency ability

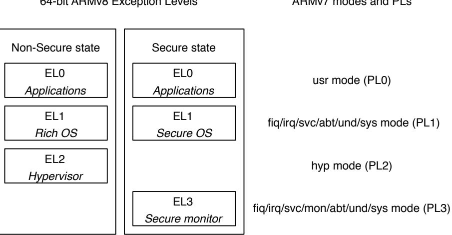

Figure 1: The ARMv8 and ARMv7 Architectures.

- We implement debugging and tracing subsystems with a variety of program analysis functionalities. NINJA is capable of studying kernel- or hypervisor-level malware. The tracing subsystem exhibits a low performance overhead and the instruction and system call tracing is immune to timing attacks.

2 Background

2.1 TrustZone and Trusted Firmware

ARM TrustZone technology [12] introduces a hardware-assisted security concept that divides the execution environment into two isolated domains, i.e., secure domain and non-secure domain. Due to security concerns, the secure domain could access the resources (e.g., memory and registers) of the non-secure domain, but not vice versa. In ARMv8 architecture, the only way to switch from normal domain to secure domain is to trigger a secure exception [8], and the exception return instruction `eret` is used to switch back to the normal domain from the secure domain after the exception is handled.

Figure 1 shows the difference between the ARMv8 and the ARMv7 architectures. In the new architecture, ARM removes the execution modes in ARMv7 and renames the Privilege Level (PL) to Exception Level (EL). The term EL indicates the level where an exception can be handled and all ELs except EL0 can handle exceptions. Any exception occurs in a certain level could only be handled in the same level or a higher level.

The names of the system registers in 64-bit ARMv8 architecture contain a suffix that indicating the lowest EL at which the register can be accessed. For example, the name of the `PMEVCNTR_EL0` register indicates that the lowest EL to access this register is EL0. Similarly, the registers with suffix `EL3` can only be accessed in EL3.

ARM Trusted Firmware [7] (ATF) is an official implementation of secure domain provided by ARM, and it supports an array of hardware platforms and emulators. While entering the secure domain, the ATF saves the context of the normal domain and dispatches the secure exception to the corresponding exception handler. After the handler finishes the handling process, the ATF

restores the context of the normal domain and switches back with `eret` instruction. ATF also provides a trusted boot path by authenticating the firmware image with several approaches like signatures and public keys.

2.2 PMU and ETM

The Performance Monitors Unit (PMU) [8] is a feature widely implemented in both x86 and ARM architectures [42], which leverages a set of performance counter registers to calculate CPU events. Each architecture specifies a list of common events by event numbers, and different CPUs may also maintain additional event numbers. A Performance Monitor Interrupt (PMI) can be triggered while a performance counter register overflows. Note that the PMU is a non-invasive debug feature that does not affect the performance of the CPU.

The Embedded Trace Macrocell (ETM) [11] is another non-invasive debug component in ARM architecture. It traces instructions and data by monitoring instruction and data buses with low performance impact. Actually, ARM expects that ETM has no effect on the functional performance of the processor. The ETM generates an element for executed signpost instructions that could be further used to reconstruct all the executed instructions. The generated elements are encoded into a trace stream and sent to a pre-allocated buffer on the chip.

According to Futuremark [23], 21 of the most popular 50 smartphones and tablets are equipped with ARM Cortex-A5x or Cortex-A7x series processors, in which the PMU and ETM components are included.

3 Related Work

3.1 Transparent Malware Analysis on x86

Ether [20] leverages hardware virtualization to build a malware analysis system and achieves high transparency. Spider [19] is also based on hardware virtualization, and it focuses on both applicability and transparency while using memory page instrument to gain higher efficiency. Since the hardware virtualization has transparency issues, these systems are naturally not transparent. LO-PHI [41] leverages additional hardware sensors to monitor the disk operation and periodically poll memory snapshots, and it achieves a higher transparency at the cost of incomplete view of system states.

MalT [54] increases the transparency by involving System Manage Mode (SMM), a special CPU mode in x86 architecture. It leverages PMU to monitor the program execution and switch into SMM for analysis. Comparing with MalT, NINJA improves in the following aspects: 1) The PMU registers on MalT are accessible by privileged malware, which breaks the transparency by checking the values of these registers. By leveraging TrustZone technology, NINJA configures needed PMU registers as secure ones so that even the privileged malware in the normal domain cannot access them. 2) MalT is built on SMM. However, SMM is not designed for security purpose such as transparent debugging (originally for power management); frequent CPU mode switching introduces a high performance overhead (12 μs is required for a SMM switch [54]). NINJA is based on TrustZone, a dedicated security extension on ARM. The domain switching only needs 0.34 μs (see Appendix B). 3) Besides a debugging system, NINJA develops a transparent tracing system with existing hardware. The instruction and system call tracing introduce negligible overhead, which is immune to timing attacks while MalT suffers from external timing attack.

BareCloud [31] and MalGene [30] focus on detecting evasive malware by executing malware in different environments and comparing their behavior. There are limitations to this approach. Firstly, it fails to transparently fetch the malware runtime behavior (e.g., system calls and modifications to memory/registers) on a bare-metal environment. Secondly, it assumes that the evasive malware shows the malicious behavior in at least one of the analysis platforms. However, sophisticated malware may be able to detect all the analysis platforms and refuse to exhibit any malicious behavior during the analysis. Lastly, after these tools identify the evasive malware from the large-scale malware samples, they still need a transparent malware analysis tool which is able to analyze these evasive samples transparently. NINJA provides a transparent framework to study the evasive malware and plays a complementary role for these systems.

3.2 Dynamic Analysis Tools on ARM

Emulation-based systems. DroidScope [52] rebuilds the semantic information of both the Android OS and the Dalvik virtual machine based on QEMU. CopperDroid [45] is a VMI-based analysis tool that automatically reconstructs the behavior of Android malware including inter-process communication (IPC) and remote procedure call interaction. DroidScibe [18] uses CopperDroid [45] to collect behavior profiles of Android malware, and automatically classifies them into different families. Since the emulator leaves footprints, these systems are natural not transparent.

Hardware virtualization. Xen on ARM [50] migrates the hardware virtualization based hypervisor Xen to ARM architecture and makes the analysis based on hardware virtualization feasible on mobile devices. KVM/ARM [17] uses standard Linux components to improve the performance of the hypervisor. Although the hardware virtualization based solution is considered to

be more transparent than the emulation or traditional virtualization based solution, it still leaves some detectable footprints on CPU semantics while executing specific instructions [39].

Bare-metal systems. TaintDroid [22] is a system-wide information flow tracking tool. It provides variable-level, message-level, method-level, and file-level taint propagation by modifying the original Android framework. TaintART [44] extends the idea of TaintDroid on the most recent Android Java virtual machine Android Runtime (ART). VetDroid [55] reconstructs the malicious behavior of the malware based on permission usage, and it is applicable to taint analysis. DroidTrace [56] uses `ptrace` to monitor the dynamic loading code on both Java and native code level. BareDroid [34] provides a quick restore mechanism that makes the bare-metal analysis of Android applications feasible at scale. Although these tools attempt to analyze the target on real-world devices to improve transparency, the modification to the Android framework leaves some memory footprints or code signatures, and the ptrace-based approaches can be detected by simply check the `/proc/self/status` file. Moreover, these systems are vulnerable to privileged malware.

3.3 TrustZone-related Systems

TZ-RKP [13] runs in the secure domain and protects the rich OS kernel by event-driven monitoring. Sprobes [51] provides an instrumentation mechanism to introspect the rich OS from the secure domain, and guarantees the kernel code integrity. SeCReT [28] is a framework that enables a secure communication channel between the normal domain and the secure domain, and provides a trust execution environment. Brasser *et al*. [14] use TrustZone to analyze and regulate guest devices in a restricted host spaces via remote memory operation to avoid misusage of sensors and peripherals. C-FLAT [1] fights against control-flow hijacking via runtime control-flow verification in TrustZone. TrustShadow [25] shields the execution of an unmodified application from a compromised operating system by building a lightweight runtime system in the ARM TrustZone secure world. The runtime system forwards the requests of system services to the commodity operating systems in the normal world and verifies the returns. Unlike previous systems, NINJA leverage TrustZone to transparently debug and analyze the ARM applications and malware.

4 System Architecture

Figure 2 shows the architecture of NINJA. The NINJA consists of a target executing platform and a remote debugging client. In the target executing platform, Trust-

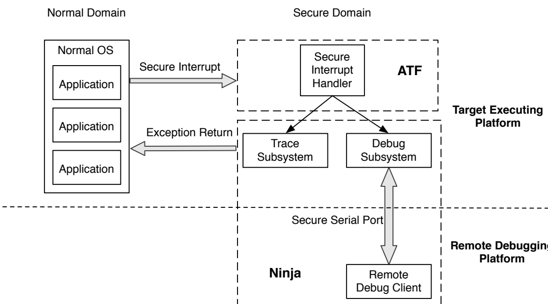

Figure 2: Architecture of NINJA.

Zone provides hardware-based isolation between the normal and secure domains while the rich OS (e.g., Linux or Android) runs in the normal domain and NINJA runs in the secure domain. We setup a customized exception handler in EL3 to handle asynchronous exceptions (i.e., interrupts) of our interest. NINJA contains a Trace Subsystem (TS) and a Debug Subsystem (DS). The TS is designed to transparently trace the execution of a target application, which does not need any human interaction during the tracing. This feature is essential for automatic large-scale analysis. In contrast, the DS relies on human analysts. In the remote debugging platform, the analysts send debug commands via a secure serial port and the DS then response to the commands. During the execution of an application, we use secure interrupts to switch into the secure domain and then resume to the normal domain by executing the exception return instruction `eret`.

4.1 Reliable Domain Switch

Normally, the `smc` instruction is used to trigger a domain switch by signaling a Secure Monitor Call (SMC) exception which is handled in EL3. However, as the execution of the `smc` instruction may be blocked by privileged malware, this software-based switch is not reliable.

Another solution is to trigger a secure interrupt which is considered as an asynchronous exception in EL3. ARM Generic Interrupt Controller (GIC) [5] partitions all interrupts into secure group and non-secure group, and each interrupt is configured to be either secure or non-secure. Moreover, the GIC Security Extensions ensures that the normal domain cannot access the configuration of a secure interrupt. Regarding to NINJA, we configure PMI to be a secure interrupt so that an overflow of the PMU registers leads to a switch to the secure domain. To increase the flexibility, we also use similar technology mentioned in [43] to configure the General Purpose Input/Output (GPIO) buttons as the source of secure Non-Maskable Interrupt (NMI) to trigger the switch. The switch from secure domain to normal domain is achieved by executing the exception return instruction `eret`.

4.2 The Trace Subsystem

The Trace Subsystem (TS) provides the analyst the ability to trace the execution of the target application in different granularities during automatic analysis including instruction tracing, system call tracing, and Android API tracing. We achieve the instruction and system call tracing via hardware component ETM, and the Android API tracing with help of PMU registers.

By default, we use the GPIO button as the trigger of secure NMIs. Once the button is pressed, a secure NMI request is signaled to the GIC, and GIC routes this NMI to EL3. NINJA toggles the enable status of ETM after receiving this interrupt and outputs the tracing result if needed. Additionally, the PMU registers are involved during the Android API trace. Note that the NMI of GPIO buttons can be replaced by any system events that trigger an interrupt (e.g., system calls, network events, clock events, and etc.), and these events can be used to indicate the start or end of the trace in different usage scenarios.

Another advanced feature of ETM is that PMU events can also be configured as an external input source. In light of this, we specify different granularities of the tracing. For example, we trace all the system calls by configure the ETM to use the signal of PMU event `EXC_SVC` as the external input.

4.3 The Debug Subsystem

In contrast to the TS, the Debug Subsystem (DS) is designed for manual analysis. It establishes a secure channel between the target executing platform and the remote debugging platform, and provides a user interface for human analysts to introspect the execution status of the target application.

To interrupt the execution of the target, we configure the PMI to be secure and adjust the value of the PMU counter registers to trigger an overflow at a desired point. NINJA receives the secure interrupt after a PMU counter overflows and pauses the execution of the target. A human analyst then issues debugging commands via the secure serial port and introspects the current status of the target following our GDB-like debugging protocol. To ensure the PMI will be triggered again, the DS sets desirable values to the PMU registers before exiting the secure domain.

Moreover, similar to the TS, we specify the granularity of the debugging by monitoring different PMU events. For example, if we choose the event `INST_RETIRED` which occurs after an instruction is retired, the execution of the target application is paused after each instruction is executed. If the event `EXC_SVC` is chosen, the DS takes control of the system after each system call.

5 Design and Implementation

We implement NINJA on a 64-bit ARMv8 Juno r1 board. There are two ARM Cortex-A57 cores and four ARM Cortex-A53 cores on the board, and all of them include the support for PMU, ETM, and TrustZone. Based on the ATF and Linaro's deliverables on Android 5.1.1 for Juno, we build a customized firmware for the board. Note that NINJA is compatible with commercial mobile devices because it relies on existing deployed hardware features.

5.1 Bridge the Semantic Gap

As with the VMI-based [27] and TEE-based [54] systems, bridging the semantic gap is an essential step for NINJA to conduct the analysis. In particular, we face two layers of semantic gaps in our system.

5.1.1 Gap between Normal and Secure Domains

In the DS, NINJA uses PMI to trigger a trap to EL3. However, the PMU counts the instructions executed in the CPU disregarding to the current running process. That means the instruction which triggers the PMI may belong to another application. Thus, we first need to identify if the current running process is the target. Since NINJA is implemented in the secure domain, it cannot understand the semantic information of the normal domain, and we have to fill the semantic gap to learn the current running process in the OS.

In Linux, each process is represented by an instance of `thread_info` data structure, and the one for the current running process could be obtained by `SP & ~(THREAD_SIZE - 1)` , where `SP` indicates the current stack pointer and `THREAD_SIZE` represents the size of the stack. Next, we can fetch the `task_struct`, which maintains the process information (like pid, name, and memory layout), from the `thread_info`. Then, the target process can be identified by the pid or process name.

5.1.2 Gap in Android Java Virtual Machine

Android maintains a Java virtual machine to interpret Java bytecode, and we need to figure out the current executing Java method and bytecode during the Android API tracing and bytecode stepping. DroidScope [52] fills the semantic gaps in the Dalvik to understand the current status of the VM. However, as a result of Android upgrades, Dalvik is no longer available in recent Android versions, and the approach in DroidScope is not applicable for us.

By manually analyzing the source code of ART, we learn that the bytecode interpreter uses `ExecuteGotoImpl` or `ExecuteSwitchImpl` function to execute the bytecode. The approaches we used to fill the semantic gap in these two functions are similar, and

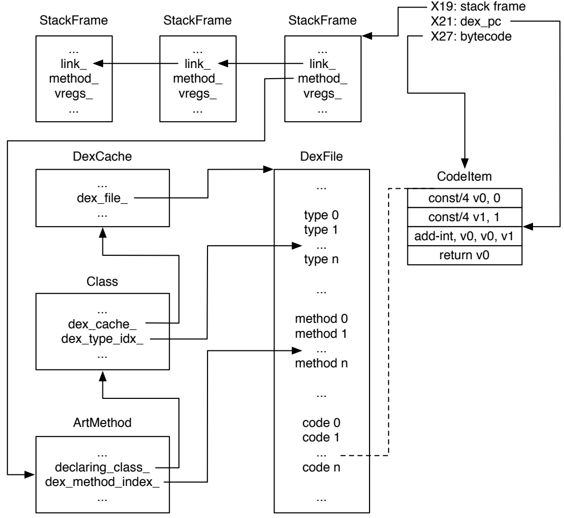

Figure 3: Semantics in the Function `ExecuteGotoImpl`.

we use function `ExecuteGotoImpl` as an example to explain our approach. In Android, the bytecode of a Java method is organized as a 16-bit array, and ART passes the bytecode array to the function `ExecuteGotoImpl` together with the current execution status such as the current thread, caller and callee methods, and the call frame stack that stores the call stack and parameters. Then, the function `ExecuteGotoImpl` interprets the bytecode in the array following the control flows, and a local variable `dex_pc` indicates the index of the current interpreting bytecode in the array. By manual checking the decompiled result of the function, we find that the pointer to the bytecode array is stored in register `X27` while variable `dex_pc` is kept by register `X21`, and the call frame stack is maintained in register `X19`. Figure 3 shows the semantics in the function `ExecuteGotoImpl`. By combining registers `X21` and `X27`, we can locate the current executing bytecode. Moreover, a single frame in the call frame stack is represented by an instance of `StackFrame` with the variable `link_` pointing to the previous frame. The variable `method_` indicates the current executing Java method, which is represented by an instance of `ArtMethod`. Next, we fetch the declaring class of the Java method following the pointer `declaring_class_`. The pointer `dex_cache_` in the declaring class points to an instance of `DexCache` which is used to maintain a cache for the DEX file, and the variable `dex_file_` in the `DexCache` finally points to the instance of `DexFile`, which contains all information of a DEX file. Detail description like the name of the method can be fetched via the index of the method (i.e., `dex_method_index_`) in the method array maintained by the `DexFile`. Note that both `ExecuteGotoImpl` and `ExecuteSwitchImpl` functions have four different template implementations in ART, and our approach is applicable to all of them.

5.2 Secure Interrupts

In GIC, each interrupt is assigned to Group 0 (secure interrupts) or Group 1 (non-secure interrupts) by a group of 32-bit `GICD_IGROUPR` registers. Each bit in each `GICD_IGROUPR` register represents the group information of a single interrupt, and value 0 indicates Group 0 while value 1 means Group 1. For a given interrupt ID `n`, the index of the corresponding `GICD_IGROUPR` register is given by $n / 32$, and the corresponding bit in the register is $n \bmod 32$. Moreover, the GIC maintains a target process list in `GICD_ITARGETSR` registers for each interrupt. By default, the ATF configures the secure interrupts to be handled in Cortex-A57 core 0.

As mentioned in Section 4.1, NINJA uses secure PMI and NMI to trigger a reliable switch. As the secure interrupts are handled in Cortex-A57 core 0, we run the target application on the same core to reduce the overhead of the communication between cores. In Juno board, the interrupt ID for PMI in Cortex-A57 core 0 is 34. Thus, we clear the bit 2 of the register `GICD_IGROUPR1` ($34 \bmod 32 = 2, 34 / 32 = 1$) to mark the interrupt 34 as secure. Similarly, we configure the interrupt 195, which is triggered by pressing a GPIO button, to be secure by clearing the bit 3 of the register `GICD_IGROUPR6`.

5.3 The Trace Subsystem

5.3.1 Instruction Tracing

NINJA uses ETM embedded in the CPU to trace the executed instructions. Figure 4 shows the ETM and related components in Juno board. The funnels shown in the figure are used to filter the output of ETM, and each of them is controlled by a group of CoreSight Trace Funnel (CSTF) registers [9]. The filtered result is then output to Embedded Trace FIFO (ETF) which is controlled by Trace Memory Controller (TMC) registers [10].

In our case, as we only need the trace result from the core 0 in the Cortex-A57 cluster, we set the `EnS0` bit in CSTF Control Register of funnel 0 and funnel 2, and clear other slave bits. To enable the ETF, we set the `TraceCaptEn` bit of the TMC CTL register.

The ETM is controlled by a group of trace registers. As the target application is always executed in non-secure EL0 or non-secure EL1, we make the ETM only trace these states by setting all `EXLEVEL_S` bits and clearing all `EXLEVEL_NS` bits of the `TRCVICTLR` register. Then, NINJA sets the `EN` bit of `TRCPRGCTLR` register to start the instruction trace. In regard to stop the trace, we first clear the `EN` bit of `TRCPRGCTLR` register to disable

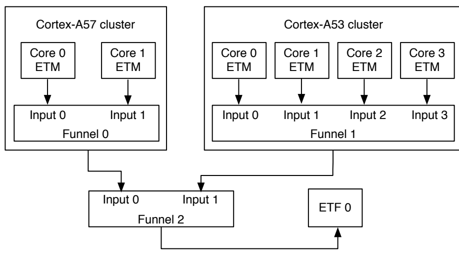

Figure 4: ETM in Juno Board.

ETM and then set the `StopOnFl` bit and the `FlushMan` bits of `FFCR` register in the TMC registers to stop the ETF. To read the trace result, we keep reading from `RRD` register until `0xFFFFFFFF` is fetched. Note that the trace result is an encoded trace stream, and we use an open source analyzer `ptm2human` [26] to convert the stream to a readable format.

5.3.2 System Call Tracing

The system call of Linux in ARM platforms is achieved by supervisor call instruction `svc`, and an immediate value following the `svc` instruction indicates the corresponding system call number. Since the ETM can be configured to trace the PMU event `EXC_SVC`, which occurs right after the execution of a `svc` instruction, we trace the system calls via tracing this event in ETM.

As mentioned in Section 4.2, we can configure the ETM to trace PMU events during the instruction trace. The `TRCEXTINSELR` register is used to trace at most four external input source, and we configure one of them to trace the `EXC_SVC` event. In Cortex-A57, the event number of the `EXC_SVC` event is `0x60`, so we set the `SEL0` bits of the `TRCEXTINSELR` register to be `0x60`. Also, the `SELECT` bits of the second trace resource selection control register `TRCRSCTLR2` (`TRCRSCTLR0` and `TRCRSCTLR1` are reserved) is configured to 0 to select the external input 0 as tracing resource 2. Next, we configure the `EVENT0` bit of `TRCEVENTCTL0R` register to 2 to select the resource 2 as event 0. Finally, the `INSTEN` bit of `TRCEVENTCTL1R` register is set to 0x1 to enable event 0. Note that the `X` bit of PMU register `PMCR_EL0` should also be set to export the events to ETM. After the configuration, the ETM can be used to trace system calls, and the configuration to start and stop the trace is similar to the one in Section 5.3.1.

5.3.3 Android API Tracing

Unlike the instruction trace and system call trace, we cannot use ETM to directly trace the Android APIs as the existence of the semantic gap. As mentioned in Section 5.1.2, each Java method is interpreter by `ExecuteGotoImpl` or `ExecuteSwitchImpl` function, and ART jumps to these functions by a branch instruction `bl`. Since a PMU event `BR_RETIRED` is fired after execution of a branch instruction, we use PMU to trace the `BR_RETIRED` event and reconstruct the semantic information following the approach described in Section 5.1.2 if these functions are invoked.

There exist six PMU counters for each processor on Juno board, and we randomly select the last one to be used for the Android API trace and the DS. Firstly, the `E` bit of `PMCR_EL0` register is set to enable the PMU. Then, both `PMCNTENSET_EL0` and `PMINTENSET_EL1` registers are set to `0x20` to enable the counter 6 and the overflow interrupt of the counter 6. Next, we set `PMEVTYPER5_EL0` register to `0x80000021` to make the counter 6 count the `BR_RETIRED` event in non-secure EL0. Finally, the counter `PMEVCNTR5_EL0` is set to its maximum value `0xFFFFFFFF`. With this configuration, a secure PMI is routed to EL3 after the execution of the next branch instruction. In the interrupt handler, the `ELR_EL3` register, which is identical to the `PC` of the normal domain, is examined to identify whether the execution of normal domain encounters `ExecuteGotoImpl` or `ExecuteSwitchImpl` function. If true, we fill the semantic gap and fetch the information about the current executing Java method. By the declaring class of the method, we differentiate the Android APIs from the developer defined methods. Before returning to the normal domain, we reset the performance counter to its maximum value to make sure the next execution of a branch instruction leads to an overflow.

5.4 The Debug Subsystem

Debugging is another essential approach to learn the behavior of an application. NINJA leverages a secure serial port to connect the board to an external debugging client. There exists two serial port (i.e., `UART0` and `UART1`) in Juno board, and the ATF uses `UART0` as the debugging input/output of both normal domain and secure domain. To build a secure debugging bridge, NINJA uses `UART1` as the debugging channel and marks it as a secure device by configuring NIC-400 [3]. Alternatively, we can use a USB cable for this purpose. In the DS, an analyst pauses the execution of the target application by the secure NMI or predefined breakpoints and send debugging commands to the board via the secure serial port. NINJA processes the commands and outputs the response to the serial port with a user-friendly format. The table in Appendix A shows the supported debugging commands. The information about symbols in both bytecode and machine code are not supported at this moment, and we consider it as our future work.

5.4.1 Single-instruction Stepping

The ARMv8 architecture provides instruction stepping support for the debuggers by the SS bit of MDSCR_EL1 register. Once this bit is set, the CPU generates a software step exception after each instruction is executed, and the highest EL that this exception can be routed is EL2. However, this approach has two fundamental drawbacks: 1) the EL2 is normally prepared for the hardware virtualization systems, which does not satisfy our transparency requirements. 2) The instruction stepping changes the value of PSTATE, which is accessible from EL1. Thus, we cannot use the software step exception for the instruction stepping. Another approach is to modify the target application's code to generate a SMC exception after each instruction. Nonetheless, the modification brings the side effect that the self-checking malware may be aware of it.

The PMU event INST_RETIRED is fired after the execution of each instruction, and we use this event to implement instruction stepping by using similar approach mentioned in Section 5.3.3. With the configuration, NINJA pauses the execution of the target after the execution of each instruction and waits for the debugging commands.

Moreover, NINJA is capable of stepping Java bytecode. Recall that the functions ExecuteGotoImpl and ExecuteSwitchImpl interpret the bytecode in Java methods. In both functions, a branch instruction is used to switch to the interpretation code of each Java bytecode. Thus, we use BR_RETIRED event to trace the branch instructions and firstly ensure the pc of normal domain is inside the two interpreter functions. Next, we fill the semantic gap and monitor the value of dex_pc. As the change of dex_pc value indicates the change of current interpreting bytecode, we pause the system once the dex_pc is changed to achieve Java bytecode stepping.

5.4.2 Breakpoints

In ARMv8 architecture, a breakpoint exception is generated by either a software breakpoint or a hardware breakpoint. The execution of brk instruction is considered as a software breakpoint while the breakpoint control registers DBGBCR_EL1 and breakpoint value registers DBGBVR_EL1 provide support for at most 16 hardware breakpoints. However, similar to the software step exception, the breakpoint exception generated in the normal domain could not be routed to EL3, which breaks the transparency requirement of NINJA. MalT [54] discusses another breakpoint implementation that modifies the target's code to trigger an interrupt. Due to the transparency requirement, we avoid this approach to keep our system transparent against the self-checking malware. Thus, we implement the breakpoint based on the instruction stepping technique discussed above. Once the analyst adds a breakpoint, NINJA stores its address and enable PMU to trace the execution of instructions. If the address of an executing instruction matches the breakpoint, NINJA pauses the execution and waits for debugging commands. Otherwise, we return to the normal domain and do not interrupt the execution of the target.

5.4.3 Memory Read/Write

NINJA supports memory access with both physical and virtual addresses. The TrustZone technology ensures that EL3 code can access the physical memory of the normal domain, so it is straight forward for NINJA to access memory via physical addresses. Regarding to memory accesses via virtual addresses, we have to find the corresponding physical addresses for the virtual addresses in the normal domain. Instead of manually walk through the page tables, a series of Address Translation (AT) instructions help to translate a 64-bit virtual address to a 48-bit physical address[2] considering the translation stages, ELs and memory attributes. As an example, the at s12e0r *addr* instruction performs stage 1 and 2 (if available) translations as defined for EL0 to the 64-bit address *addr*, with permissions as if reading from *addr*. The [47:12] bits of the corresponding physical address are storing in the PA bits of the PAR_EL1 register, and the [11:0] bits of the physical address are identical to the [11:0] bits of the virtual address *addr*. After the translation, NINJA directly manipulates the memory in normal domain according to the debugging commands.

5.5 Interrupt Instruction Skid

In ARMv8 manual, the interrupts are referred as asynchronous exceptions. Once an interrupt source is triggered, the CPU continues executing the instructions instead of waiting for the interrupt. Figure 5 shows the interrupt process in Juno board. Assume that an interrupt source is triggered before the MOV instruction is executed. The processor then sends the interrupt request to the GIC and continues executing the MOV instruction. The GIC processes the requested interrupt according to the configuration, and signals the interrupt back to the processor. Note that it takes GIC some time to finish the process, so some instructions following the MOV instruction have been executed when the interrupt arrives the processor. As shown in Figure 5, the current executing instruction is the ADD instruction instead of the MOV instruction when the interrupt arrives, and the instruction shadow region between the MOV and ADD instructions is considered as interrupt instruction skid.

[2]The ARMv8 architecture does not support more bits in the physical address at this moment

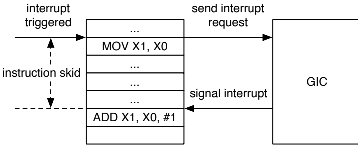

Figure 5: Interrupt Instruction Skid.

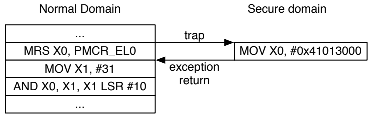

Figure 6: Protect the `PMCR_EL0` Register via Traps.

The skid problem is a well-known problem [42, 49] and affects NINJA since the current executing instruction is not the one that triggers the PMI when the PMI arrives the processor. Thus, the DS may not exactly step the execution of the processor. Although the skid problem cannot be completely eliminated, the side-effect of the skid does not affect our system significantly, and we provide a detailed analysis and evaluation in Section 7.5.

6 Transparency

As NINJA is not based on the emulator or other sandboxes, the anti-analysis techniques mentioned in [29, 36, 48] cannot detect the existence of NINJA. Moreover, other anti-debugging techniques like anti-ptrace [53] do not work for NINJA since our analysis does not use ptrace. Nonetheless, NINJA leaves artifacts such as changes of the registers and the slow down of the system, which may be detected by the target application. Next, we discuss the mitigation of these artifacts.

6.1 Footprints Elimination

Since NINJA works in the secure domain, the hardware prevents the target application from detecting the code or memory usage of NINJA. Moreover, as the ATF restores all the general purpose registers while entering the secure domain and resumes them back while returning to the normal domain, NINJA does not affect the registers used by the target application as well. However, as we use ETM and PMU to achieve the debugging and tracing functions, the modification to the PMU registers and the ETM registers leaves a detectable footprint. In ARMv8, the PMU and ETM registers are accessible via both system-instruction and memory-mapped interfaces.

6.1.1 System-Instruction Interface

The system-instruction interface makes the system registers readable via `MRS` instruction and writable via `MSR` instruction. In NINJA, we ensure that the access to the target system registers via these instructions to be trapped to EL3. The `TPM` bit of the `MDCR_EL3` register and the `TTA` bit of the `CPTR_EL3` register help to trap the access to PMU and ETM registers to EL3, respectively; then we achieve the transparency by providing artificial values to the normal domain. Figure 6 is an example of manipulating the reading to the `PMCR_EL0` register and returning the default value of the register. Before the `MRS` instruction is executed, a trap is triggered to switch to the secure domain. NINJA then analyzes the instruction that triggers the trap and learns that the return value of `PMCR_EL0` is stored to the general-purpose register `X0`. Thus, we put the default value 0x41013000 to the general-purpose register `X0` and resume to the normal domain. Note that the `PC` register of the normal domain should also be modified to skip the `MRS` instruction. We protect both the registers that we modified (e.g., `PMCR_EL0`, `PMCNTENSET_EL0`) and the registers modified by the hardware as a result of our usage (e.g., `PMINTENCLR_EL1`, `PMOVSCLR_EL0`).

6.1.2 Memory Mapped Interface

Each of the PMU or ETM related components occupies a distinct physical memory region, and the registers of the component can be accessed via offsets in the region. Since these memory regions do not locate in the DRAM (i.e., main memory), the TrustZone Address Space Controller (TZASC) [12], which partitions the DRAM into secure regions and non-secure regions, cannot protect them directly. Note that this hardware memory region is not initialized by the system firmware by default and the system software such as applications and OSes cannot access it because the memory region is not mapped into the virtual memory. However, advanced malware might remap this physical memory region via functions like `mmap` and `ioremap`. Thus, to further defend against these attacks, we intercept the suspicious calls to these functions and redirect the call to return an artificial memory region.

The memory size for both the PMU and ETM memory regions is 64k, and we reserve a 128k memory region on the DRAM to be the artificial PMU and ETM memory. The ATF for Juno board uses the DRAM region 0x880000000 to 0x9ffffffff as the memory of the rich OS and the region 0xa00000000 to 0x1000000000 of the DRAM is not actually initialized. Thus, we randomly choose the memory region 0xa00040000 to 0xa00060000 to be the region for artificial memory mapped registers. While the system is booting, we firstly duplicate the values in the PMU and ETM memory regions into the artificial regions. As the function calls are achieved by `bl` instruction, we intercept the call to the interested functions by using PMU to trigger a PMI on

the execution of branch instructions and compare the pc of the normal domain with the address of these functions. Next, we manipulate the call to these functions by modification to the parameters. Take ioremap function as an example. The first parameter of the function, which is stored in the register X0, indicates the target physical address, and we modify the value stored at the register to the corresponding address in the artificial memory region. With this approach, the application never reads the real value of PMU and ETM registers, and cannot be aware of NINJA.

6.2 Defending Against Timing Attacks

The target application may use the SoC or external timers to detect the time elapsed in the secure domain since the DS affects the performance of the processor and communicates with a human analyst. Note that the TS using ETM does not affect the performance of the processor and thus is immune to the timing attack.

The ARMv8 architecture defines two types of timer components, i.e., the memory-mapped timers and the generic timer registers [8]. Other than these timers, the Juno board is equipped with an additional Real Time Clock (RTC) component PL031 [6] and two dual-timer modules SP804 [4] to measure the time. For each one of these components, we manipulate its value to make the time elapsed of NINJA invisible.

Each of the memory-mapped timer components is mapped to a pre-defined memory region, and all these memory regions are writable in EL3. Thus, we record the value of the timer or counter while entering NINJA and restore it before existing NINJA. The RTC and dual-timer modules are also mapped to a writable memory region, so we use a similar method to handle them.

The generic timer registers consist of a series of timer and counter registers, and all of these registers are writable in EL3 except the physical counter register CNTPCT_EL0 and the virtual counter register CNTVCT_EL0. For the writable registers, we use the same approach as handling memory-mapped timers to manipulate them. Although CNTPCT_EL0 is not directly writable, the ARM architecture requires a memory-mapped counter component to control the generation of the counter value [8]. In the Juno board, the generic counter is mapped to a controlling memory frame 0x2a430000-0x2a43ffff, and writing to the memory address 0x2a430008 updates the value of CNTPCT_EL0. The CNTVCT_EL0 register always holds a value equal to the value of the physical counter register minus the value of the virtual offset register CNTVOFF_EL2. Thus, the update to the CNTPCT_EL0 register also updates the CNTVCT_EL0 register.

Note that the above mechanism only considers the time consumption of NINJA, and does not take the time consumption of the ATF into account. Thus, to make it more precise, we measure the average time consumption of the ATF during the secure exception handling (see Appendix B) and minus it while restoring the timer values. Besides the timers, the malware may also leverage the PMU to count the CPU cycles. Thus, NINJA checks the enabled PMU counters and restores their values in a similar way to the writable timers.

The external timing attack cannot be defended by modifying the local timer since external timers are involved. As the instruction tracing in NINJA is immune to the timing attack, we can use the TS to trace the execution of the target with DS enabled and disabled. By comparing the trace result using the approaches described in BareCloud [31] and MalGene [30], we may identify the suspicious instructions that launch the attack and defend against the attack by manipulating the control flow in EL3 to bypass these instructions. However, the effectiveness of this approach needs to be further studied. Currently, defending against the external timing attack is an open research problem [20, 54].

7 Evaluation

To evaluate NINJA, we fist compare it with existing analysis and debugging tools on ARM. NINJA neither involves any virtual machine or emulator nor uses the detectable Linux tools like ptrace or strace. Moreover, to further improve the transparency, we do not modify Android system software or the Linux kernel. The detailed comparison is listed in Table 1. Since NINJA only relies on the ATF, the table shows that the Trusted Computing Base (TCB) of NINJA is much smaller than existing systems.

7.1 Output of Tracing Subsystem

To learn the details of the tracing output, we write a simple Android application that uses Java Native Interface to read the /proc/self/status file line by line (which can be further used to identify whether ptrace is enabled) and outputs the content to the console. We use instruction trace of the TS to trace the execution of the application, and also measure the time usage. The status file contains 38 lines in total, and it takes about 0.22 *ms* to finish executing. After the execution, the ETF contains 9.92 *KB* encoded trace data, and the datarate is approximately 44.03 MB/s. Next, we use ptm2human [26] to decode the data, and the decoded trace data contains 1341 signpost instructions (80 in our custom native library and the others in libc.so). By manually introspect the signpost instructions in our custom native library, we can rebuild the whole execution control flow. To reduce the

Table 1: Comparing with Other Tools. The source lines of code (SLOC) of the TCB is calculated by `sloccount` [47] based on Android 5.1.1 and Linux kernel 3.18.20.

storage usage of the ETM, we can use real-time continuous export via either a dedicated trace port capable of sustaining the bandwidth of the trace or an existing interface on the SoC (e.g., a USB or other high-speed port) [11].

7.2 Tracing and Debugging Samples

We pickup two samples `ActivityLifecycle1` and `PrivateDataLeak3` from DroidBench [21] project and use NINJA to analyze them. We choose these two specific samples since they exhibit representative malicious behavior like leaking sensitive information via local file, text message, and network connection.

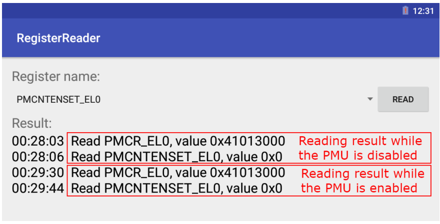
Analyzing *ActivityLifecycle1*. To get an overview of the sample, we first enable the Android API tracing feature to inspect the APIs that read sensitive information (source) and APIs that leak information (sink), and find a suspicious API call sequence. In the sequence, the method `TelephonyManager.getDeviceId` and method `HttpURLConnection.connect` are invoked in turn, which indicates a potential flow that sends IMEI to a remote server. As we know the network packets are sent via the system call `sys_sendto`, we attempt to intercept the system call and analyze the parameters of the system call. In Android, the system calls are invoked by corresponding functions in `libc.so`, and we get the address of the function for the system call `sys_sendto` by disassembling `libc.so`. Thus, we use NINJA to set a breakpoint at the address, and the second parameter of the system call, which is stored in register `X1`, shows that the sample sends a 181 bytes buffer to a remote server. Then, we output the memory content of the buffer and find that it is a `HTTP GET` request to host `www.google.de` with path `/search?q=353626078711780`. Note that the digits in the path is exactly the IMEI of the device.

Analyzing *PrivateDataLeak3*. Similar to the previous analysis, the Android API tracing helps us to find a suspicious API call sequence consisting of the methods `TelephonyManager.getDeviceId`, `Context.openFileOutput`, and `SmsManager.sendTextMessage`. As the Android uses the system calls `sys_openat` to open a file and `sys_write` to write a file, we set breakpoints at the address of these calls. Note that the second parameter of `sys_openat` represents the full path of the target file and the second parameter of `sys_write` points to a buffer writing to a file. Thus, after the breakpoints are hit, we see that sample writing IMEI 353626078711780 to the file `/data/data/de.ecspride/files/out.txt`. The API `SmsManager.sendTextMessage` uses `binder` to achieve IPC with the lower-layer `SmsService` in Android system, and the semantics of the IPC is described in CopperDroid [45]. By intercepting the system call `sys_ioctl` and following the semantics, we finally find the target of the text message "+49" and the content of the message 353626078711780.

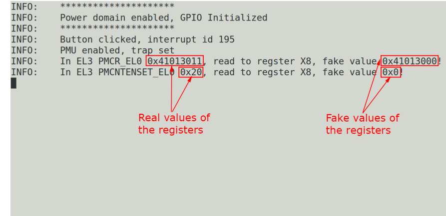
7.3 Transparency Experiments

7.3.1 Accessing System Instruction Interface

To evaluate the protection mechanism of the system instruction interface, we write an Android application that reads the `PMCR_EL0` and `PMCNTENSET_EL0` registers via `MRS` instruction. The values of these two registers represent whether a performance counter is enabled. We first use the application to read the registers with NINJA disabled, and the result is shown in the upper rectangle of Figure 7a. The last bit of the `PMCR_EL0` register and the value of the `PMCNTENSET_EL0` register are 0, which means that all the performance counters are disabled. Then we press a GPIO button to enable the Android API tracing feature of NINJA and read the registers again. From the console output shown in Figure 7b, we see that the access to the registers is successfully trapped into EL3. And the output shows that the real values of the `PMCR_EL0` and `PMCNTENSET_EL0` registers are 0x41013011 and 0x20, respectively, which indicates that the counter `PMEVCNTR5_EL0` is enabled. However, the lower rectangle in Figure 7a shows that the value of the registers fetched by the application keep unchanged.



(a) Reading PMU Register in an Application.



(b) EL3 Output in the Secure Console.

Figure 7: Accessing System Instruction Interface.

This experiment shows that NINJA effectively eliminates the footprint on the system instruction interface.

7.3.2 Accessing Memory Mapped Interface

In this section, we take `ioremap` function as an example to evaluate whether the interception to the memory-mapping functions works. As the `ioremap` function can be called only in the kernel space, we write a kernel module that remaps the memory region of the ETM by the `ioremap` function, and print the content of the first 32 bytes in the region. Similar to the approach discussed above, we first load the kernel module with NINJA disabled, and the output is shown in the upper rectangle in Figure 8a. Note that the 5th to the 8th bytes are mapped as the `TRCPRGCTLR` register and the `EN` bit, which indicates the status of the ETM, is the last bit of the register. In the upper rectangle, the `EN` bit 0 shows that the ETM is disabled. Next, we enable the instruction tracing feature of NINJA and reload the kernel module. The lower rectangle in Figure 8a shows that the content of the memory fetched by the module remains the same. However, in the Figure 8b, the output from EL3 shows that the memory of the ETM has changed. This experiment shows that we successfully hide the ETM status change to the normal domain, and NINJA remains transparent.

7.3.3 Adjusting the Timers

To evaluate whether our mechanism that modifies the local timers works, we write a simple application that launches a dummy loop for 1 billion times, and calculate the execution time of the loop by the return values of the API call `System.currentTimeMillis()`. In the first experiment, we record the execution time with NINJA disabled, and the average time for 30 runs is 53.16s with a standard deviation 2.97s. In the second experiment, we enable the debugging mode of NINJA and pause the execution during the loop by pressing the GPIO button. To simulate the manual analysis, we send a command `rr` to output all the general purpose registers and then read them for 60s. Finally, a command `c` is sent to resume

Table 2: The TS Performance Evaluation Calculating 1 Million Digits of π.

	Mean	STD	# Slowdown
Base: Tracing disabled	2.133 s	0.69 ms	
Instruction tracing	2.135 s	2.79 ms	∼ 1x
System call tracing	2.134 s	5.13 ms	∼ 1x
Android API tracing	149.372 s	1287.88 ms	∼70x

the execution of the target. We repeat the second experiment with the timer adjusting feature of NINJA enabled and disabled for 30 times each, and record the execution time of the loop. The result shows that the average execution time with timer adjusting feature disabled is 116.33s with a standard deviation 2.24s, and that with timer adjusting feature enabled is 54.33s with a standard deviation 3.77s. As the latter result exhibits similar execution time with the original system, the malware cannot use the local timer to detect the presence of the debugging system.

7.4 Performance Evaluation

In this section, we evaluate the performance overhead of the trace subsystem due to its automation characteristic. Performance overhead of the debugging subsystem is not noticed by an analyst in front of the command console, and the debugging system is designed with human interaction.

To learn the performance overhead on the Linux binaries, we build an executable that using an open source π calculation algorithm provided by the GNU Multiple Precision Arithmetic Library [46] to calculate 1 million digits of the π for 30 times with the tracing functions disabled and enabled, and the time consumption is shown in Table 2. Since we leverage ETM to achieve the instruction tracing and system call tracing, the experiment result shows that the ETM-based solution has negligible overhead — less than 0.1%. In the Android API tracing, the overhead is about 70x. This overhead is mainly due to the frequent domain switch during the execution and bridging the semantic gap. To reduce the overhead, we

can combine ETM instruction trace with data trace, and leverage the trace result to rebuild the semantic information and API usage offline.

To measure the performance overhead on the Android applications, we use CF-Bench [16] downloaded from Google Play Store. The CF-Bench focuses on measuring both the Java performance and native performance in Android system, and we use it to evaluate the overhead for 30 times. The result in Table 3 shows that the overheads of instruction tracing and system call tracing are sufficiently small to ignore. The Android API tracing brings 4x slowdown on the native score and 154x slowdown on the Java score, and the overall slowdown is 8x. Note that we make these benchmarks to be executed only on Cortex-A57 core 0 by setting their CPU affinity mask to 0x1 since NINJA only stays in that core.

7.5 Skid Evaluation

In this subsection, we evaluate the influence of the skid problem to NINJA. Since the instruction tracing, system call tracing, and memory read/write do not involve PMI, these functionalities are not affected by the skid problem. In ART, each bytecode is interpreted as an array of machine code. Our bytecode stepping mechanism recognizes the corresponding bytecode once it is executing any machine code in the array, i.e., the skid problem affects the bytecode stepping if and only if the instruction shadow covers all the machine code for a bytecode. We evaluate the listed 218 bytecode opcode [24] on the Android official website, and it shows that the shadow region cannot cover the machine code for any of them. Thus, the bytecode stepping does not suffer from the skid problem. For a similar reason, the skid problem has no influence on the Android API tracing.

However, the native code stepping and the breakpoint

Table 4: Instructions in the Skid Shadow with Representative PMU Events.

Event Number	Event Description	# of Instructions	
		Mean	STD
0x81-0x8F	Exception related events that firing after taking exceptions	0	0
0x11	CPU cycle event that firing after each CPU cycle	2.73	2.30
0x08	Instruction retired event that firing after executing each instruction	6.03	4.99

are still affected, and both of them use instruction retired event to overflow the counter. Since the skid problem is due to the delay between the interrupt request and the interrupt arrival, we first use PMU counter to measure this delay by CPU cycles. Similar with the instruction stepping, we make the PMU counter to count `CPU_CYCLES` event and initialize the value of the counter to its maximum value. Then, the counter value after switching into EL3 is the time delay of the skid in CPU cycles. The results of 30 experiments show that the delay is about 106.3 CPU cycles with a standard deviation 2.26. As the frequency of our CPU is 1.15GHz, the delay is about 0.09μs. We also evaluate the number of instructions in the skid shadow with some representative PMU events. For each event, we trigger the PMI for 30 times and calculate the mean and standard deviation of the number of instructions in the shadow. Table 4 shows the result with different PMU events. Unlike the work described in [42], the exception related events exhibits no instruction shadow in our platform, and we consider it is caused by different ARM architectures. It is worth noting that the number of instructions in the skid shadow of the CPU cycle event is less than the instruction retired event. However, using the CPU cycle event may lead to multiple PMIs for a single instruction since the

execution of a single instruction may need multiple CPU cycles, which introduces more performance overhead but with more fine-grained instruction-stepping. In practice, it is a trade off between the performance overhead and the debugging accuracy, and we can use either one based on the requirement.

8 Discussion

NINJA leverages existing deployed hardware and is compatible with commercial mobile devices. However, the secure domain on the commercial mobile devices is managed by the Original Equipment Manufacturer (OEM). Thus, it requires cooperation from the OEMs to implement NINJA on a commercial mobile device.

The approach we used to fill the semantic gaps relies on the understanding of the kernel data structures and memory maps, and thus is vulnerable to the privileged malware. Patagonix [33] leverages a database of whitelisted applications binary pages to learn the semantic information in the memory pages of the target application. However, this approach is limited by the knowledge of the analyzer. Currently, how to transparently bridge the semantic gap without any assumption to the system is still an open research problem [27].

The protection mechanism mentioned in Section 6.1 helps to improve transparency when the attackers try to use PMU or ETM registers, and using shadow registers [35] can further protect the critical system registers. However, if an advanced attacker intentionally uses PMU or ETM to trace CPU events or instructions and checks whether the trace result matches the expected one, the mechanism of returning artificial or shadow register values may not provide accurate result and thus affects NINJA's transparency. To address this problem, we need to fully virtualize the PMU and ETM, and this is left as our future work.

Though NINJA protects the system-instruction interface access to the registers, the mechanism we used to protect the memory mapped interface access maybe vulnerable to advanced attacks such as directly manipulating the memory-mapping, disabling MMU to gain physical memory access, and using DMA to access memory. Note that these attacks might be difficult to implement in practice (e.g., disabling MMU might crash the system). To fully protect the memory-mapped region of ETM and PMU registers, we would argue that hardware support from TrustZone is needed. Since the TZASC only protects the DRAM, we may need additional hardware features to extend the idea of TZASC to the whole physical memory region.

Although the instruction skid of the PMI cannot be completely eliminated, we can also enable ETM between two PMIs to learn the instructions in the skid. Moreover, since the instruction skid is caused by the delay of the PMI, similar hardware component like Local Advanced Programmable Interrupt Controller [54] on x86 which handles interrupt locally may help to mitigate the problem by reducing the response time.

9 Conclusions

In this paper, we present NINJA, a transparent malware analysis framework on ARM platform. It embodies a series of analysis functionalities like tracing and debugging via hardware-assisted isolation execution environment TrustZone and hardware features PMU and ETM. Since NINJA does not involve emulator or framework modification, it is more transparent than existing analysis tools on ARM. To minimize the artifacts introduced by NINJA, we adopt register protection mechanism to protect all involving registers based on hardware traps and runtime function interception. Moreover, as the TrustZone and the hardware components are widely equipped by OTS mobile devices, NINJA can be easily transplanted to existing mobile platforms. Our experiment results show that performance overheads of the instruction tracing and system call tracing are less than 1% while the Android API tracing introduces 4 to 154 times slowdown.

A Debugging Commands

Command	Description
rr	Output the value of all general purpose registers `X0` to `X30`, the stack pointer, and the program counter.
rw `n v`	Write 64-bit value `v` to the register named `n` and output the name the register and its new value.
mr `a s`	Output the content of the memory starting from 64-bit virtual address `a` with size `s`. If the virtual address does not exist, output `Incorrect address`.
mw `a v`	Write 8-bit value `v` to the 64-bit virtual address `a` and output the address and the 8-bit value stored in the address. If the virtual address does not exist, output `Incorrect address`.
ba `a`	Add a breakpoint at the 64-bit virtual address `a` and output the address. If the virtual address does not exist, output `Incorrect address`.
bd `a`	Delete the breakpoint at the 64-bit virtual address `a` and output the address. If the virtual address or breakpoint does not exist, output `Incorrect address`.
bc	Clear all the breakpoints and output `succeed`.
n	Step to the next instruction and output the instruction.
nb	Step to the next Java bytecode and output the bytecode.
nm	Step to the next Java method and output the call stack.
c	Continue the execution after a breakpoint and output `continued`.

B Domain Switching Time

We use the PMU counter to count the `CPU_CYCLES` event and calculate the elapsed time by the delta of the value and the frequency of the CPU. First we read the PMU counter twice continuously and calculate the elapsed cycles, and the difference in CPU cycles indicate the time elapsed between the two continuous PMU read instructions. Then we insert an `SMC` instruction between the two read instructions to trigger a domain switching with NINJA disabled, and the difference of the CPU cycles represents the round trip time of the domain switching in ATF. At last, we measure the CPU cycles with NINJA enabled, and this time consumption includes the time consumption of both ATF and our customized exception handler. To avoid the bias introduced by the CPU frequency scaling, we set the minimum scaling frequency equal to the maximum one to ensure that the CPU is always running in the same frequency. The results of 30 experiments are shown in the following table.

ATF Enabled	NINJA Enabled	Mean	STD	95% CI
		0.007 μs	0.000 μs	[0.007 μs, 0.007 μs]
✓		0.202 μs	0.013 μs	[0.197 μs, 0.207 μs]
✓	✓	0.342 μs	0.021 μs	[0.349 μs, 0.334 μs]

PRIME+ABORT: A Timer-Free High-Precision L3 Cache Attack using Intel TSX

Abstract

Last-Level Cache (LLC) attacks typically exploit timing side channels in hardware, and thus rely heavily on timers for their operation. Many proposed defenses against such side-channel attacks capitalize on this reliance. This paper presents PRIME+ABORT, a new cache attack which bypasses these defenses by not depending on timers for its function. Instead of a timing side channel, PRIME+ABORT leverages the Intel TSX hardware widely available in both server- and consumer-grade processors. This work shows that PRIME+ABORT is not only invulnerable to important classes of defenses, it also outperforms state-of-the-art LLC PRIME+PROBE attacks in both accuracy and efficiency, having a maximum detection speed (in events per second) 3× higher than LLC PRIME+PROBE on Intel's Skylake architecture while producing fewer false positives.

1 Introduction

State-of-the-art cache attacks [35, 7, 11, 21, 25, 29, 33, 34, 43] leverage differences in memory access times between levels of the cache and memory hierarchy to gain insight into the activities of a victim process. These attacks require the attacker to frequently perform a series of timed memory operations (or cache management operations [7]) to learn if a victim process has accessed a critical address (e.g., a statement in an encryption library).

These attacks are highly dependent on precise and accurate timing, and defenses can exploit this dependence. In fact, a variety of defenses have been proposed which undermine these timing-based attacks by restricting access to highly precise timers [15, 27, 31, 39].

In this work, we introduce an alternate mechanism for performing cache attacks, which does not leverage timing differences (timing side channels) or require timed operations of any type. Instead, it exploits Intel's implementation of Hardware Transactional Memory, which is called TSX [19]. We demonstrate a novel cache attack based on this mechanism, which we will call PRIME+ABORT.

The intent of Transactional Memory (and TSX) is to both provide a simplified interface for synchronization and to enable optimistic concurrency: processes abort only when a conflict exists, rather than when a potential conflict may occur, as with traditional locks [14, 12]. Transactional memory operations require transactional data to be buffered, in this case in the cache which has limited space. Thus, the outcome of a transaction depends on the state of the cache, potentially revealing information to the thread that initiates the transaction. By exploiting TSX, an attacker can monitor the cache behavior of another process and receive an abort (call-back) if the victim process accesses a critical address. This work demonstrates how TSX can be used to trivially detect writes to a shared block in memory; to detect reads and writes by a process co-scheduled on the same core; and, most critically, to detect reads and writes by a process executing anywhere on the same processor. This latter attack works across cores, does not assume that the victim uses or even knows about TSX, and does not require any form of shared memory.

The advantages of this mechanism over conventional cache attacks are twofold. The first is that PRIME+ABORT does not leverage any kind of timer; as mentioned, several major classes of countermeasures against cache attacks revolve around either restricting access or adding noise to timers. PRIME+ABORT effectively bypasses these countermeasures.

The second advantage is in the efficiency of the attack. The TSX hardware allows for a victim's action to directly trigger the attacking process to take action. This means the TSX attack can bypass the detection phase required in conventional attacks. Direct coupling from event to handler allows PRIME+ABORT to provide over 3× the throughput of comparable state-of-the-art attacks.

The rest of this work is organized as follows. Sec-

tion 2 presents background and related work; Section 3 introduces our novel attack, PRIME+ABORT; Section 4 describes experimental results, making comparisons with existing methods; in Section 5, we discuss potential countermeasures to our attack; Section 7 concludes.

2 Background and Related Work

2.1 Cache attacks

Cache attacks [35, 7, 11, 21, 25, 29, 33, 34, 43] are a well-known class of side-channel attacks which seek to gain information about which memory locations are accessed by some victim program, and at what times. In an excellent survey, Ge et al. [4] group such attacks into three broad categories: PRIME+PROBE, FLUSH+RELOAD, and EVICT+TIME. Since EVICT+TIME is only capable of monitoring memory accesses at the program granularity (whether a given memory location was accessed during execution or not), in this paper we focus on PRIME+PROBE and FLUSH+RELOAD, which are much higher resolution and have received more attention in the literature. Cache attacks have been shown to be effective for successfully recovering AES [25], ElGamal [29], and RSA [43] keys, performing keylogging [8], and spying on messages encrypted with TLS [23].

Figure 1 outlines all of the attacks which we will consider. At a high level, each attack consists of a pre-attack portion, in which important architecture- or runtime-specific information is gathered; and then an active portion which uses that information to monitor memory accesses of a victim process. The active portion of existing state-of-the-art attacks itself consists of three phases: an "initialization" phase, a "waiting" phase, and a "measurement" phase. The initialization phase prepares the cache in some way; the waiting phase gives the victim process an opportunity to access the target address; and then the measurement phase performs a timed operation to determine whether the cache state has changed in a way that implies an access to the target address has taken place.

Specifics of the initialization and measurement phases vary by cache attack (discussed below). Some cache attack implementations make a tradeoff in the length of the waiting phase between accuracy and resolution—shorter waiting phases give more precise information about the timing of victim memory accesses, but may increase the relative overhead of the initialization and measurement phases, which may make it more likely that a victim access could be "missed" by occurring outside of one of the measured intervals. In our testing, not all cache attack implementations and targets exhibited obvious experimental tradeoffs for the waiting phase duration. Nonetheless, fundamentally, all of these existing attacks can only gain temporal information at the waiting-interval granularity.

2.1.1 PRIME+PROBE

PRIME+PROBE [35, 21, 25, 34, 29] is the oldest and largest family of cache attacks, and also the most general. PRIME+PROBE does not rely on shared memory, unlike most other cache attacks (including FLUSH+RELOAD and its variants, described below). The original form of PRIME+PROBE [35, 34] targets the L1 cache, but recent work [21, 25, 29] extends it to target the L3 cache in Intel processors, enabling PRIME+PROBE to work across cores and without relying on hyperthreading (Simultaneous Multithreading [38]). Like all L3 cache attacks, L3 PRIME+PROBE can detect accesses to either instructions or data; in addition, L3 PRIME+PROBE trivially works across VMs.

PRIME+PROBE targets a single cache set, detecting accesses by any other program (or the operating system) to any address in that cache set. In its active portion's initialization phase (called "prime"), the attacker accesses enough cache lines from the cache set so as to completely fill the cache set with its own data. Later, in the measurement phase (called "probe"), the attacker reloads the same data it accessed previously, this time carefully observing how much time this operation took. If the victim did not access data in the targeted cache set, this operation will proceed quickly, finding its data in the cache. However, if the victim accessed data in the targeted cache set, the access will evict a portion of the attacker's primed data, causing the reload to be slower due to additional cache misses. Thus, a slow measurement phase implies the victim accessed data in the targeted cache set during the waiting phase. Note that this "probe" phase can also serve as the "prime" phase for the next repetition, if the monitoring is to continue.

Two different kinds of initial one-time setup are required for the pre-attack portion of this attack. The first is to establish a timing threshold above which the measurement phase is considered "slow" (i.e. likely suffering from extra cache misses). The second is to determine a set of addresses, called an "eviction set", which all map to the same (targeted) cache set (and which reside in distinct cache lines). Finding an eviction set is much easier for an attack targeting the L1 cache than for an attack targeting the L3 cache, due to the interaction between cache addressing and the virtual memory system, and also due to the "slicing" in Intel L3 caches (discussed further in Sections 2.2.1 and 2.2.2).

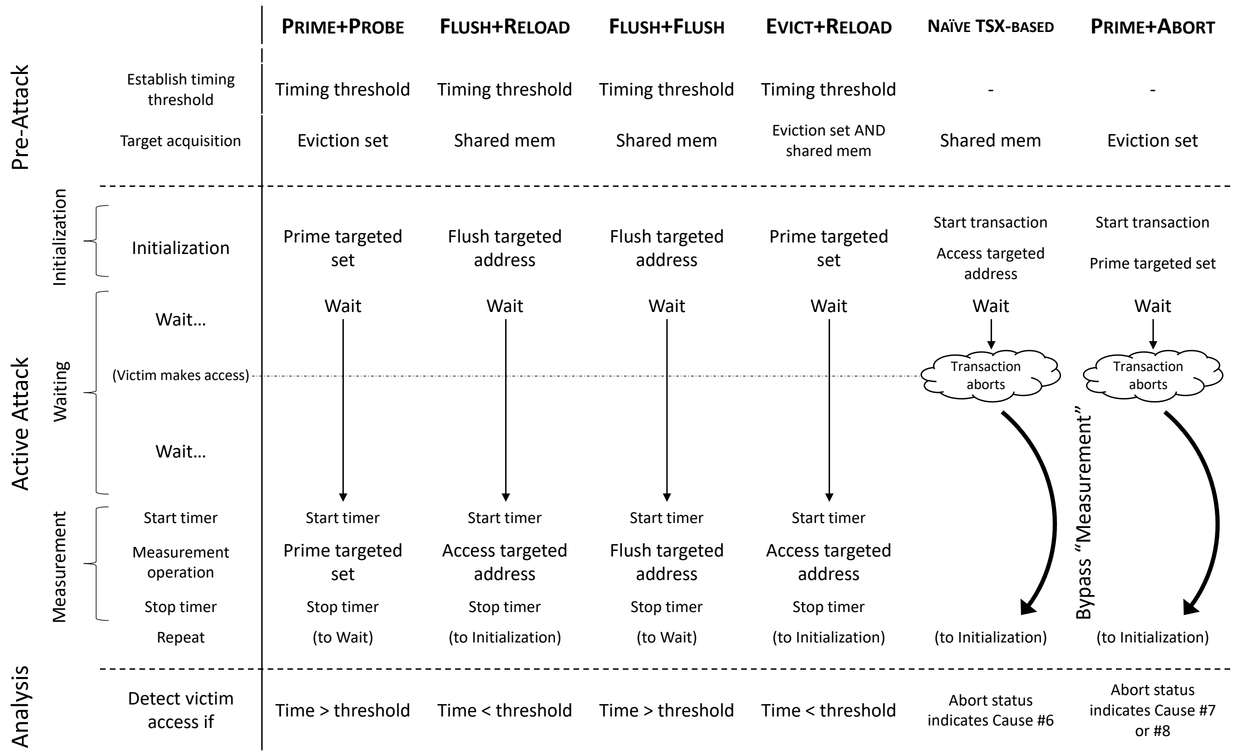

Figure 1: Comparison of the operation of various cache attacks, including our novel attacks.

2.1.2 FLUSH+RELOAD

The other major class of cache attacks is FLUSH+RELOAD [7, 11, 43]. FLUSH+RELOAD targets a specific address, detecting an access by any other program (or the operating system) to that exact address (or another address in the same cache line). This makes FLUSH+RELOAD a much more precise attack than PRIME+PROBE, which targets an entire cache set and is thus more prone to noise and false positives. FLUSH+RELOAD also naturally works across cores because of shared, inclusive, L3 caches (as explained in Section 2.2.1). Again, like all L3 cache attacks, FLUSH+RELOAD can detect accesses to either instructions or data. Additionally, FLUSH+RELOAD can work across VMs via the page deduplication exploit [43].

The pre-attack of FLUSH+RELOAD, like that of PRIME+PROBE, involves determining a timing threshold, but is limited to a single line instead of an entire "prime" phase. However, FLUSH+RELOAD does not require determining an eviction set. Instead, it requires the attacker to identify an exact target address; namely, an address in the attacker's virtual address space which maps to the physical address the attacker wants to monitor. Yarom and Falkner [43] present two ways to do this, both of which necessarily involve shared memory; one exploits shared libraries, and the other exploits page deduplication, which is how FLUSH+RELOAD can work across VMs. Nonetheless, this step's reliance on shared memory is a critical weakness in FLUSH+RELOAD, limiting it to only be able to monitor targets in shared memory.

In FLUSH+RELOAD's initialization phase, the attacker "flushes" the target address out of the cache using Intel's `CLFLUSH` instruction. Later, in the measurement phase, the attacker "reloads" the target address (by accessing it), carefully observing the time for the access. If the access was "fast", the attacker may conclude that another program accessed the address, causing it to be reloaded into the cache.

An improved variant of FLUSH+RELOAD, FLUSH+FLUSH [7], exploits timing variation in the `CLFLUSH` instruction itself; this enables the attack to combine its measurement and initialization phases, much like PRIME+PROBE. A different variant, EVICT+RELOAD [8], performs the initialization phase by evicting the cacheline with PRIME+PROBE's "prime" phase, allowing the attack to work without the `CLFLUSH` instruction at all—e.g., when the instruction has been disabled, as in Google Chrome's NaCl [6].

2.1.3 Timer-Free Cache Attacks

All of the attacks so far discussed—PRIME+PROBE, FLUSH+RELOAD, and variants—are still fundamentally timing attacks, exploiting timing differences as their underlying attack vector. One recent work which, like this work, proposes a cache attack without reference to timers is that of Guanciale et al. [10]. Instead of timing side channels, Guanciale et al. rely on the undocumented hardware behavior resulting from disobeying ISA programming guidelines, specifically with regards to virtual address aliasing and self-modifying code. However, they demonstrate their attacks only on the ARM architecture, and they themselves suggest that recent Intel x86-64 processors contain mechanisms that would render their attacks ineffective. In contrast, our attack exploits weaknesses specifically in recent Intel x86-64 processors, so in that respect our attack can be seen as complementary to Guanciale et al.'s work. We believe that our work, in addition to utilizing a novel attack vector (Intel's hardware transactional memory support), is the first timer-free cache attack to be demonstrated on commodity Intel processors.

2.2 Relevant Microarchitecture

2.2.1 Caches

[Basic Background] Caches in modern processors store data that is frequently or recently used, in order to reduce access time for that data on subsequent references. Data is stored in units of "cache lines" (a fixed architecture-dependent number of bytes). Caches are often organized hierarchically, with a small but fast "L1" cache, a medium-sized "L2" cache, and a large but comparatively slower "L3" cache. At each level of the hierarchy, there may either be a dedicated cache for each processor core, or a single cache shared by all processor cores.

Commonly, caches are "set-associative" which allows any given cacheline to reside in only one of N locations in the cache, where N is the "associativity" of the cache. This group of N locations is called a "cache set". Each cacheline is assigned to a unique cache set by means of its "set index", typically a subset of its address bits. Once a set is full (the common case) any access to a cacheline with the given set index (but not currently in the cache) will cause one of the existing N cachelines with the same set index to be removed, or "evicted", from the cache.

[Intel Cache Organization] Recent Intel processors contain per-core L1 instruction and data caches, per-core unified L2 caches, and a large L3 cache which is shared across cores. In this paper we focus on the Skylake architecture which was introduced in late 2015; important Skylake cache parameters are provided in Table 1.

Table 1: Relevant cache parameters in the Intel Skylake architecture.

	L1-Data	L1-Inst	L2	L3
Size	32 KB	32 KB	256 KB	2-8 MB[1]
Assoc	8-way	8-way	4-way	16-way
Sharing	Per-core	Per-core	Per-core	Shared
Line size	64 B	64 B	64 B	64 B

[1] depending on model. This range covers all Skylake processors (server, desktop, mobile, embedded) currently available as of January 2017 [20].

[Inclusive Caches] Critical to all cross-core cache attacks, the L3 cache is inclusive, meaning that everything in all the per-core caches must also be held in the L3. This has two important consequences which are key to enabling both L3-targeting PRIME+PROBE and FLUSH+RELOAD to work across cores. First, any data accessed by any core must be brought into not only the core's private L1 cache, but also the L3. If an attacker has "primed" a cache set in the L3, this access to a different address by another core necessarily evicts one of the attacker's cachelines, allowing PRIME+PROBE to detect the access. Second, any cacheline evicted from the L3 (e.g., in a "flush" step) must also be invalidated from all cores' private L1 and L2 caches. Any subsequent access to the cacheline by any core must fetch the data from main memory and bring it to the L3, causing FLUSH+RELOAD's subsequent "reload" phase to register a cache hit.

[Set Index Bits] The total number of cache sets in each cache can be calculated as (total number of cache lines) / (associativity), where the total number of cache lines is (cache size) / (line size). Thus, the Skylake L1 caches have 64 sets each, the L2 caches have 1024 sets each, and the shared L3 has from 2K to 8K sets, depending on the processor model.

In a typical cache, the lowest bits of the address (called the "line offset") determine the position within the cache line; the next-lowest bits of the address (called the "set index") determine in which cache set the line belongs, and the remaining higher bits make up the "tag". In our setting, the line offset is always 6 bits, while the set index will vary from 6 bits (L1) to 13 bits (L3) depending on the number of cache sets in the cache.

[Cache Slices and Selection Hash Functions] However, in recent Intel architectures (including Skylake), the situation is more complicated than this for the L3. Specifically, the L3 cache is split into several "slices" which can be accessed concurrently; the slices are connected on a ring bus such that each slice has a different latency depending on the core. In order to balance the load on these slices, Intel uses a proprietary and undocumented hash function, which operates on a physical address (ex-

cept the line offset) to select which slice the address 'belongs' to. The output of this hash effectively serves as the top N bits of the set index, where 2^N is the number of slices in the system. Therefore, in the case of an 8 MB L3 cache with 8 slices, the set index consists of 10 bits from the physical address and 3 bits calculated using the hash function. For more details, see [25], [32], [44], [16], or [22].

This hash function has been reverse-engineered for many different processors in Intel's Sandy Bridge [25, 32, 44], Ivy Bridge [16, 22, 32], and Haswell [22, 32] architectures, but to our knowledge has not been reverse-engineered for Skylake yet. Not knowing the precise hash function adds additional difficulty to determining eviction sets for PRIME+PROBE—that is, finding sets of addresses which all map to the same L3 cache set. However, our attack (following the approach of Liu et al. [29]) does not require knowledge of the specific hash function, making it more general and more broadly applicable.

2.2.2 Virtual Memory

In a modern virtual memory system, each process has a set of *virtual addresses* which are mapped by the operating system and hardware to *physical addresses* at the granularity of pages [2]. The lowest bits of an address (referred to as the page offset) remain constant during address translation. Pages are typically 4 KB in size, but recently larger pages, for instance of size 2 MB, have become widely available for use at the option of the program [25, 29]. Crucially, an attacker may choose to use large pages regardless of whether the victim does or not [29].

Skylake caches are physically-indexed, meaning that the physical address of a cache line (and not its virtual address) determines the cache set which the line is mapped into. Like the slicing of the L3 cache, physical indexing adds additional difficulty to the problem of determining eviction sets for PRIME+PROBE, as it is not immediately clear which virtual addresses may have the same set index bits in their corresponding physical addresses. Pages make this problem more manageable, as the bottom 12 bits (for standard 4 KB pages) of the address remain constant during translation. For the L1 caches, these 12 bits contain the entire set index (6 bits of line offset + 6 bits of set index), so it is easy to choose addresses with the same set index. This makes the problem of determining eviction sets trivial for L1 attacks. However, L3 attacks must deal with both physical indexing and cache slicing when determining eviction sets. Using large pages helps, as the 21-bit large-page offset completely includes the set index bits (meaning they remain constant during translation), leaving only the problem of the hash function. However, the hash function is not only an unknown function itself, but it also incorporates bits from the entire physical address, including bits that are still translated even when using large pages.

Table 2: Availability of Intel TSX in recent Intel CPUs, based on data drawn from Intel ARK [20] in January 2017. Since Broadwell, all server CPUs and a majority of i7/i5 CPUs support TSX.

Series (Release[1])	Server[2]	i7/i5	i3/m/etc[3]
Kaby Lake (Jan 2017)	3/3 (100%)	23/32 (72%)	12/24 (50%)
Skylake (Aug 2015)	23/23 (100%)	27/42 (64%)	4/34 (12%)
Broadwell (Sep 2014)	77/77 (100%)	11/22 (50%)	2/18 (11%)
Haswell (Jun 2013)	37/85 (44%)	2/87 (2%)	0/82 (0%)

[3] (i3/m/Pentium/Celeron)

2.3 Transactional Memory and TSX

Transactional Memory (TM) has received significant attention from the computer architecture and systems community over the past two decades [14, 13, 37, 45]. First proposed by Herlihy and Moss in 1993 as a hardware alternative to locks [14], TM is noteworthy for its simplification of synchronization primitives and for its ability to provide optimistic concurrency.

Unlike traditional locks which require threads to wait if a conflict is possible, TM allows multiple threads to proceed in parallel and only abort in the event of a conflict [36]. To detect a conflict, TM tracks each thread's read and write sets and signals an abort when a conflict is found. This tracking can be performed either by special hardware [14, 13, 45] or software [37].

Intel's TSX instruction set extension for x86 [12, 19] provides an implementation of hardware TM and is widely available in recent Intel CPUs (see Table 2).

TSX allows any program to identify an arbitrary section of its code as a 'transaction' using explicit `XBEGIN` and `XEND` instructions. Any transaction is guaranteed to either: (1) **complete**, in which case all memory changes which happened during the transaction are made visible *atomically* to other processes and cores, or (2) **abort**, in which case all memory changes which happened during the transaction, as well as all other changes (e.g. to registers), are discarded. In the event of an abort, control is transferred to a fallback routine specified by the user, and a status code provides the fallback routine with some information about the cause of the abort.

From a security perspective, the intended uses of hardware transactional memory (easier synchronization

Table 3: Causes of transactional aborts in Intel TSX

1. Executing certain instructions, such as CPUID or the explicit XABORT instruction
2. Executing system calls
3. OS interrupts[1]
4. Nesting transactions too deeply
5. Access violations and page faults
6. Read-Write or Write-Write memory conflicts with other threads or processes (including other cores) at the cacheline granularity—whether those other processes are using TSX or not
7. A cacheline which has been written during the transaction (i.e., a cacheline in the transaction's "write set") is evicted from the L1 cache
8. A cacheline which has been read during the transaction (i.e., a cacheline in the transaction's "read set") is evicted from the L3 cache

[1] This means that any transaction may abort, despite the absence of memory conflicts, through no fault of the programmer. The periodic nature of certain interrupts also sets an effective maximum time limit on any transaction, which has been measured at about 4 ms [41].

or optimistic concurrency) are unimportant, so we will merely note that we can place arbitrary code inside both the transaction and the fallback routine, and whenever the transaction aborts, our fallback routine will immediately be given a callback with a status code. There are many reasons a TSX transaction may abort; important causes are listed in Table 3. Most of these are drawn from the Intel Software Developer's Manual [19], but the specifics of Causes #7 and #8—in particular the asymmetric behavior of TSX with respect to read sets and write sets—were suggested by Dice et al. [3]. Our experimental results corroborate their suggestions about these undocumented implementation details.

While a transaction is in process, an arbitrary amount of data must be buffered (hidden from the memory system) or tracked until the transaction completes or aborts. In TSX, this is done in the caches—transactionally written lines are buffered in the L1 data cache, and transactionally read lines marked in the L1–L3 caches. This has the important ramification that the cache size and associativity impose a limit on how much data can be buffered or tracked. In particular, if cache lines being buffered or tracked by TSX must be evicted from the cache, this necessarily causes a transactional abort. In this way, details about cache activity may be exposed through the use of transactions.

TSX has been addressed only rarely in a security context; to the best of our knowledge, there are only two works on the application of TSX to security to date [9, 24]. Guan et al. use TSX as part of a defense against memory disclosure attacks [9]. In their system, operations involving the plaintext of sensitive data necessarily occur inside TSX transactions. This structurally ensures that this plaintext will never be accessed by other processes or written back to main memory (in either case, a transactional abort will roll back the architectural state and invalidate the plaintext data).

Jang et al. exploit a timing side channel in TSX itself in order to break kernel address space layout randomization (KASLR) [24]. Specifically, they focus on Abort Cause #5, access violations and page faults. They note that such events inside a transaction trigger an abort but not their normal respective handlers; this means the operating system or kernel are *not* notified, so the attack is free to trigger as many access violations and page faults as it wants without raising suspicions. They then exploit this property and the aforementioned timing side channel to determine which kernel pages are mapped and unmapped (and also which are executable).

Neither of these works enable new attacks on memory accesses, nor do they eliminate the need for timers in attacks.

3 Potential TSX-based Attacks

We present three potential attacks, all of which share their main goal with cache attacks—to monitor which cachelines are accessed by other processes and when. The three attacks we will present leverage Abort Causes #6, 7, and 8 respectively. Figure 1 outlines all three of the attacks we will present, as the PRIME+ABORT entry in the figure applies to both PRIME+ABORT–L1 and PRIME+ABORT–L3.

All of the TSX-based attacks which we will propose have the same critical structural benefit in common. This benefit, illustrated in Figure 1, is that these attacks have no need for a "measurement" phase. Rather than having to conduct some (timed) operation to determine whether the cache state has been modified by the victim, they simply receive a hardware callback through TSX immediately when a victim access takes place. In addition to the reduced overhead this represents for the attack procedure, this also means the attacker can be actively waiting almost indefinitely until the moment a victim access occurs—the attacker does not need to break the attack into predefined intervals. This results in a higher resolution attack, because instead of only coarse-grained knowledge of when a victim access occurred (i.e. which predefined interval), the attacker gains precise estimates of the relative timing of victim accesses.

All of our proposed TSX-based attacks also share a structural weakness when compared to PRIME+PROBE and FLUSH+RELOAD. Namely, they are unable to monitor multiple targets (cache sets in the case of PRIME+PROBE, addresses in the case of FLUSH+RELOAD) simultaneously while retaining the ability to distinguish accesses to one target from accesses to another. PRIME+PROBE and FLUSH+RELOAD

are able to do this at the cost of increased overhead; effectively, a process can monitor multiple targets concurrently by performing multiple initialization stages, having a common waiting stage, and then performing multiple measurement stages, with each measurement stage revealing the activity for the corresponding target. In contrast, although our TSX-based attacks could monitor multiple targets at once, they would be unable to distinguish events for one target from events for another without additional outside information. Some applications of PRIME+PROBE and FLUSH+RELOAD rely on this ability (e.g. [33]), and adapting them to rely on PRIME+ABORT instead would not be trivial. However, others, including the attack presented in Section 4.4, can be straightforwardly adapted to utilize PRIME+ABORT as a drop-in replacement for PRIME+PROBE or FLUSH+RELOAD.

We begin by discussing the simplest, but also least generalizable, of our TSX-based attacks, ultimately building to our proposed primary attack, PRIME+ABORT–L3.

3.1 Naïve TSX-based Attack

Abort Cause #6 enables a potentially powerful, but limited attack.

From Cause #6, we can get a transaction abort (which for our purposes is an immediate, fast hardware callback) whenever there is a read-write or write-write conflict between our transaction and another process. This leads to a natural and simple attack implementation, where we simply open a transaction, access our target address, and wait for an abort (with the proper abort status code); on abort, we know the address was accessed by another process.

The style of this attack is reminiscent of FLUSH+RELOAD [43] in several ways. It targets a single, precise cacheline, rather than an entire cache set as in PRIME+PROBE and its variants. It does not require a (comparatively slow) "prime eviction set" step, providing fast and low-overhead monitoring of the target cacheline. Also like FLUSH+RELOAD, it requires the attacker to acquire a specific address to target, for instance exploiting shared libraries or page deduplication.

Like the other attacks using TSX, it benefits in performance by not needing the "measurement" phase to detect a victim access. In addition to the performance benefit, this attack would also be harder to detect and defend against. It would execute without any kind of timer, mitigating several important classes of defenses (see Section 5). It would also be resistant to most types of cache-based defenses; in fact, this attack has so little to do with the cache at all that it could hardly be called a cache attack, except that it happens to expose the same information as standard cache attacks such as FLUSH+RELOAD or PRIME+PROBE do.

However, in addition to only being able to monitor target addresses in shared memory (the key weakness shared by all variants of FLUSH+RELOAD), this attack has another critical shortcoming. Namely, it can only detect read-write or write-write conflicts, not read-read conflicts. This means that one or the other of the processes—either the attacker or the victim—must be issuing a write command in order for the access to be detected, i.e. cause a transactional abort. Therefore, the address being monitored must not be in read-only memory. Combining this with the earlier restriction, we find that this attack, although powerful, can only monitor addresses in writable shared memory. We find this dependence to render it impractical for most real applications, and for the rest of the paper we focus on the other two attacks we will present.

3.2 PRIME+ABORT–L1

The second attack we will present, called PRIME+ABORT–L1, is based on Abort Cause #7. Abort Cause #7 provides us with a way to monitor evictions from the L1 cache in a way that is precise and presents us with, effectively, an immediate hardware callback in the form of a transactional abort. This allows us to build an attack in the PRIME+PROBE family, as the key component of PRIME+PROBE involves detecting cacheline evictions. This attack, like all attacks in the PRIME+PROBE family, does not depend in any way on shared memory; but unlike other attacks, it will also not depend on timers.

Like other PRIME+PROBE variants, our attack requires a one-time setup phase where we determine an eviction set for the cache set we wish to target; but like early PRIME+PROBE attacks [35, 34], we find this task trivial because the entire L1 cache index lies within the page offset (as explained earlier). Unlike other PRIME+PROBE variants, for PRIME+ABORT this is the sole component of the setup phase; we do not need to find a timing threshold, as we do not rely on timing.

The main part of PRIME+ABORT–L1 involves the same "prime" phase as a typical PRIME+PROBE attack, except that it opens a TSX transaction first. Once the "prime" phase is completed, the attack simply waits for an abort (with the proper abort status code). Upon receiving an abort, the attacker can conclude that some other program has accessed an address in the target cache set. This is similar to the information gleaned by ordinary PRIME+PROBE.

The reason this works is that, since we will hold an entire cache set in the write set of our transaction, any ac-

cess to a different cache line in that set by another process will necessarily evict one of our cachelines and cause our transaction to abort due to Cause #7. This gives us an immediate hardware callback, obviating the need for any "measurement" step as in traditional cache attacks. This is why we call our method PRIME+ABORT—the abort replaces the "probe" step of traditional PRIME+PROBE.

3.3 PRIME+ABORT–L3

PRIME+ABORT–L1 is fast and powerful, but because it targets the (core-private) L1 cache, it can only spy on threads which share its core; and since it must execute simultaneously with its victim, this means it and its victim must be in separate hyperthreads on the same core. In this section we present PRIME+ABORT–L3, an attack which overcomes these restrictions by targeting the L3 cache. The development of PRIME+ABORT–L3 from PRIME+ABORT–L1 mirrors the development of L3-targeting PRIME+PROBE [29, 21, 25] from L1-targeting PRIME+PROBE [35, 34], except that we use TSX. PRIME+ABORT–L3 retains all of the TSX-provided advantages of PRIME+ABORT–L1, while also (like L3 PRIME+PROBE) working across cores, easily detecting accesses to either instructions or data, and even working across virtual machines.

PRIME+ABORT–L3 uses Abort Cause #8 to monitor evictions from the L3 cache. The only meaningful change this entails to the active portion of the attack is performing reads rather than writes during the "prime" phase, in order to hold the primed cachelines in the read set of the transaction rather than the write set. For the pre-attack portion, PRIME+ABORT–L3, like other L3 PRIME+PROBE attacks, requires a much more sophisticated setup phase in which it determines eviction sets for the L3 cache. This is described in detail in the next section.

3.4 Finding eviction sets

The goal of the pre-attack phase for PRIME+ABORT is to determine an eviction set for a specified target address. For PRIME+ABORT–L1, this is straightforward, as described in Section 2.2.2. However, for PRIME+ABORT–L3, we must deal with both physical indexing and cache slicing in order to find L3 eviction sets. Like [29] and [21], we use large (2 MB) pages in this process as a convenience. With large pages, it becomes trivial to choose virtual addresses that have the same physical set index (i.e. agree in bits 6 to N, for some processor-dependent N, perhaps 15), again as explained in Section 2.2.2. We will refer to addresses which agree in physical set index (and in line offset, i.e. bits 0 to 5) as *set-aligned* addresses.

Algorithm 1: Dynamically generating a prototype eviction set for each cache slice, as implemented in [42]

```
Input: a set of potentially conflicting cachelines lines, all
       set-aligned
Output: a set of prototype eviction sets, one eviction set for each
        cache slice; that is, a "prototype group"
group ← {};
workingSet ← {};
while lines is not empty do
    repeat forever :
        line ← random member of lines;
        remove line from lines;
        if workingSet evicts line then // Algorithm 2 or 3
            c ← line;
            break;
        end
        add line to workingSet;
    end
    foreach member in workingSet do
        remove member from workingSet;
        if workingSet evicts c then    // Algorithm 2 or 3
            add member back to lines;
        else
            add member back to workingSet;
        end
    end
    foreach line in lines do
        if workingSet evicts line then // Algorithm 2 or 3
            remove line from lines;
        end
    end
    add workingSet to group;
    workingSet ← {};
end
return group;
```

We generate eviction sets dynamically using the algorithm from Mastik [42] (inspired by that in [29]), which is shown as Algorithm 1. However, for the subroutine where Mastik uses timing methods to evaluate potential eviction sets (Algorithm 2), we use TSX methods instead (Algorithm 3).

Algorithm 3, a subroutine of Algorithm 1, demonstrates how Intel TSX is used to determine whether a candidate eviction set can be expected to consistently evict a given target cacheline. If "priming" the eviction set (accessing all its lines) inside a transaction followed by accessing the target cacheline consistently results in an immediate abort, we can conclude that a transaction cannot hold both the eviction set and the target cacheline in its read set at once, which means that together they contain at least ($associativity + 1$, or 17 in our case) lines which map to the same cache slice and cache set.

Conceptually, the algorithm for dynamically generating an eviction set for any given address has two phases: first, creating a "prototype group", and second, specializing it to form an eviction set for the desired target ad-

Algorithm 2: PRIME+PROBE (timing-based) method for determining whether an eviction set evicts a given cacheline, as implemented in [42]

```
Input: a candidate eviction set es and a cacheline line
Output: true if es can be expected to consistently evict line
times ← {};
repeat 16 times :
    access line;
    repeat 20 times :
        foreach member in es do
            access member;
        end
    end
    timed access to line;
    times ← times + {elapsed time};
end
if median of times > predetermined threshold then return true;
else return false;
```

Algorithm 3: PRIME+ABORT (TSX-based) method for determining whether an eviction set evicts a given cacheline

```
Input: a candidate eviction set es and a cacheline line
Output: true if es can be expected to consistently evict line
aborts ← 0;
commits ← 0;
while aborts < 16 and commits < 16 do
    begin transaction;
    foreach member in es do
        access member;
    end
    access line;
    end transaction;
    if transaction committed then increment commits;
    else if transaction aborted with appropriate status code then
      increment aborts;
end
if aborts >= 16 then return true;
else return false;
```

dress. The algorithms shown (Algorithms 1, 2, and 3) together constitute the first phase of this larger algorithm. In this first phase, we use only set-aligned addresses, noting that all such addresses, after being mapped to an L3 cache slice, necessarily map to the same cache set inside that slice. This phase creates one eviction set for each cache slice, targeting the cache set inside that slice with the given set index. We call these "prototype" eviction sets, and we call the resulting group of one "prototype" eviction set per cache slice a "prototype group".

Once we have a prototype group generated by Algorithm 1, we can obtain an eviction set for any cache set in any cache slice by simply adjusting the set index of each address in one of the prototype eviction sets. Not knowing the specific cache-slice-selection hash function, it will be necessary to iterate over all prototype eviction sets (one per slice) in order to find the one which collides with the target on the same cache slice. If we do not know the (physical) set index of our target, we can also iterate through all possible set indices (with each prototype eviction set) to find the appropriate eviction set, again following the procedure from Liu et al. [29].

4 Results

4.1 Characteristics of the Intel Skylake Architecture

Our test machine has an Intel Skylake i7-6600U processor, which has two physical cores and four virtual cores. It is widely reported (e.g., in all of [16, 22, 25, 29, 32, 44]) that Intel processors have one cache slice per physical core, based on experiments conducted on Sandy Bridge, Ivy Bridge, and Haswell processors. However, our testing on the Skylake dual-core i7-6600U leads us to believe that it has four cache slices, contrary to previous trends which would predict it has only two. We validate this claim by using Algorithm 1 to produce four distinct eviction sets for large-page-aligned addresses. Then we test our four distinct eviction sets on many additional large-page-aligned addresses not used in Algorithm 1. We find that each large-page-aligned address conflicts with exactly one of the four eviction sets (by Algorithm 3), and further, that the conflicts are spread relatively evenly over the four sets. This convinces us that each of our four eviction sets represents set index 0 on a different cache slice, and thus that there are indeed four cache slices in the i7-6600U.

Having determined the number of cache slices, we can now calculate the number of low-order bits in an address that must be fixed to create groups of set-aligned addresses. For our i7-6600U, this is 16. Henceforth we can use set-aligned addresses instead of large-page-aligned addresses, which is an efficiency gain.

4.2 Dynamically Generating Eviction Sets

In the remainder of the Results section we compare PRIME+ABORT–L3 to L3 PRIME+PROBE as implemented in [42]. We begin by comparing the PRIME+ABORT and PRIME+PROBE versions of Algorithm 1 for dynamically generating prototype eviction sets.

Table 4 compares the runtimes of the PRIME+ABORT and PRIME+PROBE versions of Algorithm 1. The PRIME+ABORT-based method is over 5× faster than the PRIME+PROBE-based method in the median case, over 15× faster in the best case, and over 40% faster in the worst case.

Next, we compare the "coverage" of prototype groups (sets of four prototype eviction sets) derived and tested

Table 4: Runtimes of Prime+Abort- and Prime+Probe-based versions of Algorithm 1 to generate a "prototype group" of eviction sets (data based on 1000 runs of each version of Algorithm 1)

	Prime+Abort	Prime+Probe
Min	4.5 ms	68.3 ms
1Q	10.1 ms	76.6 ms
Median	15.0 ms	79.3 ms
3Q	21.3 ms	82.0 ms
Max	64.7 ms	91.0 ms

with the two methods. We derive 10 prototype groups with each version of Algorithm 1; then, for each prototype group, we use either timing-based or TSX-based methods to test 1000 additional set-aligned addresses not used for Algorithm 1 (a total of 10,000 additional set-aligned addresses for Prime+Abort and 10,000 for Prime+Probe). The testing procedure is akin to a single iteration of the outer loop in Algorithm 2 or 3 respectively. Using this procedure, each of the 10,000 set-aligned addresses is tested 10,000 times against each of the four prototype eviction sets in the prototype group. This produces four "detection rates" for each set-aligned address (one per prototype eviction set). We assume that the highest of these four detection rates corresponds to the prototype eviction set from the same cache slice as the tested address, and we call this detection rate the "max detection rate" for the set-aligned address. Both Prime+Abort and Prime+Probe methods result in "max detection rates" which are consistently indistinguishable from 100%. However, we note that out of the 100 million trials in total, 13 times we observed the Prime+Probe-based method fail to detect the access (resulting in a "max detection rate" of 99.99% in 13 cases), whereas with the Prime+Abort-based method, all 100 million trials were detected, for perfect max detection rates of 100.0%. This result is due to the structural nature of transactional conflicts—it is impossible for a transaction with a read set of size $(1 + associativity)$ to ever successfully commit; it must always abort.

Since each address maps to exactly one cache slice, and ideally each eviction set contains lines from only one cache slice, we expect that any given set-aligned address conflicts with only one out of the four prototype eviction sets in a prototype group. That is, we expect that out of the four detection rates computed for each line (one per prototype eviction set), one will be very high (the "max detection rate"), and the other three will be very low. Figure 2 shows the "second-highest detection rate" for each line—that is, the maximum of the remaining three detection rates for that line, which is a measure of false positives. For any given detection rate on the x-axis, the figure shows what percentage of the 10,000 set-aligned addresses had a false-positive detection rate at or above that level. Whenever the "second-highest detection rate" is greater than zero, it indicates that the line appeared to be detected by a prototype eviction set meant for an entirely different cache slice (i.e. a false positive detection). In Figure 2, we see that with the Prime+Probe-based method, around 22% of lines have "second-highest detection rates" over 5%, around 18% of lines have "second-highest detec-

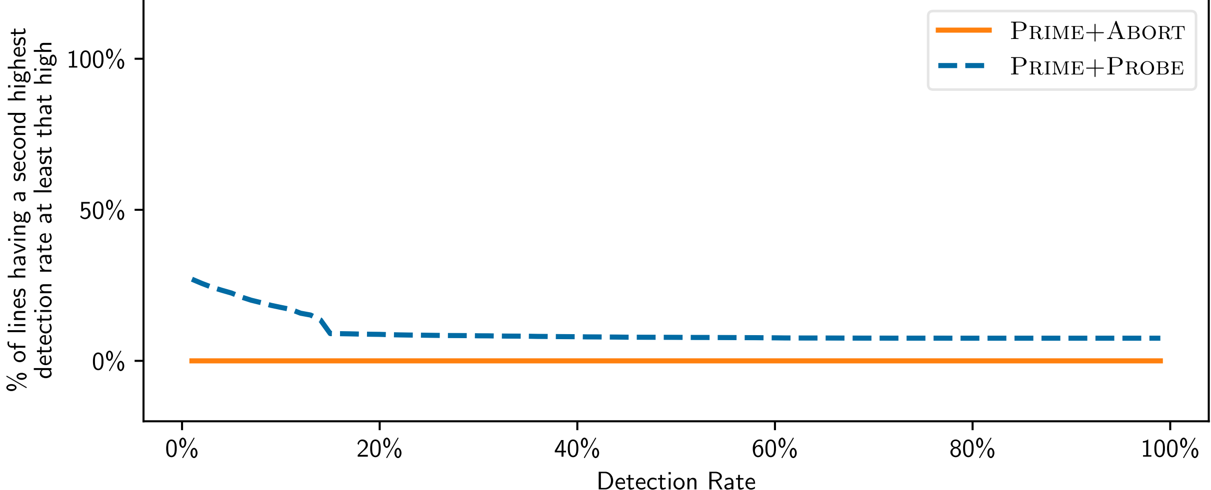

Figure 2: "Double coverage" of prototype groups generated by Prime+Abort- and Prime+Probe-based versions of Algorithm 1. With Prime+Probe, some tested cachelines are reliably detected by more than one prototype eviction set. In contrast, with Prime+Abort each tested cacheline is reliably detected by only one prototype eviction set.

tion rates" over 10%, and around 7.5% of lines even have "second-highest detection rates" of 100%, meaning that more than one of the "prototype eviction sets" each detected that line in 100% of the 10,000 trials. In contrast, with the PRIME+ABORT-based method, none of the 10,000 lines tested had "second-highest detection rates" over 1%. PRIME+ABORT produces very few false positives and cleanly monitors exactly one cache set in exactly one cache slice.

4.3 Detecting Memory Accesses

Figures 3, 4, and 5 show the success of PRIME+ABORT and two variants of PRIME+PROBE in detecting the memory accesses of an artificial victim thread running on a different physical core from the attacker. The victim thread repeatedly accesses a single memory location for the duration of the experiment—in the "treatment" condition, it accesses the target (monitored) location, whereas in the "control" condition, it accesses an unrelated location. We introduce delays (via busy-wait) of varying lengths into the victim's code in order to vary the frequency at which it accesses the target location (or unrelated location for control). Figures 3, 4, and 5 plot the number of events observed by the respective attackers, vs. the actual number of accesses by the victim, in "control" and "treatment" scenarios. Data were collected from 100 trials per attacker, each entailing separate runs of Algorithm 1 and new targets. The $y = x$ line is shown for reference in all figures; it indicates perfect performance for the "treatment" condition, with all events detected but no false positives. Perfect performance in the "control" condition, naturally, is values as low as possible in all cases.

We see in Figure 3 that PRIME+ABORT detects a large fraction of the victim's accesses at frequencies up to several hundred thousand accesses per second, scaling up smoothly and topping out at a maximum detection speed (on our test machine) of around one million events per second. PRIME+ABORT exhibits this performance while also displaying relatively low false positive rates of around 200 events per second, or one false positive every 5000 µs. The close correlation between number of detected events and number of victim accesses indicates PRIME+ABORT's low overheads—in fact, we measured its transactional abort handler as executing in 20-40 ns—which allow it to be essentially "always listening" for victim accesses. Also, it demonstrates PRIME+ABORT's ability to accurately count the number of victim accesses, despite only producing a binary output (access or no access) in each transaction. Its high speed and low overheads allow it to catch each victim access in a separate transaction.

Figure 4 shows the performance of unmodified PRIME+PROBE as implemented in Mastik [42][1]. We see false positive rates which are significantly higher than those observed for PRIME+ABORT—over 2000 events per second, or one every 500 µs. Like PRIME+ABORT, this implementation of PRIME+PROBE appears to have a top speed around one million accesses detected per second under our test conditions. But most interestingly, we observe significant "oversampling" at low frequencies—PRIME+PROBE reports many more events than actually occurred. For instance, when the victim thread performs 2600 accesses per second, we expect to observe 2600 events per second, plus around 2000 false positives per second as before. However, we actually observe over 18,000 events per second in the median case. Likewise, when the victim thread provides 26,000 accesses per second, we observe over 200,000 events per second in the median case. Analysis shows that for this implementation of PRIME+PROBE on our hardware, single accesses can cause long streaks of consecutive observed events, sometimes as long as hundreds of observed events. We believe this to be due to the interaction between this PRIME+PROBE implementation and our hardware's L3 cache replacement policy. One plausible explanation for why PRIME+ABORT is not similarly afflicted, is that the replacement policy may prioritize keeping lines that are part of active transactions, evicting everything else first. This would be a sensible policy for Intel to implement, as it would minimize the number of unwanted/unnecessary aborts. In our setting, it benefits PRIME+ABORT by ensuring that a "prime" step inside a transaction cleanly evicts all other lines.

To combat the oversampling behavior observed in PRIME+PROBE, we investigate a modified implementation of PRIME+PROBE which "collapses" streaks of observed events, meaning that a streak of any length is simply counted as a single observed event. Results with this modified implementation are shown in Figure 5. We see that this strategy is effective in combating oversampling, and also reduces the number of false positives to around 250 per second or one every 4000 µs. However, this implementation of PRIME+PROBE performs more poorly at high frequencies, having a top speed around 300,000 events per second compared to the one million per second of the other two attacks. This effect can be explained by the fact that as the victim access frequency increases, streaks of observed events become more and more likely to "hide" real events (multiple real events occur in the same streak)—in the limit, we expect to observe an event

[1] We make one slight modification suggested by the maintainer of Mastik: every probe step, we actually perform multiple probes, "counting" only the first one. In our case we perform five probes at a time, still alternating between forwards and backwards probes. All of the results which we present for the "unmodified" implementation include this slight modification.

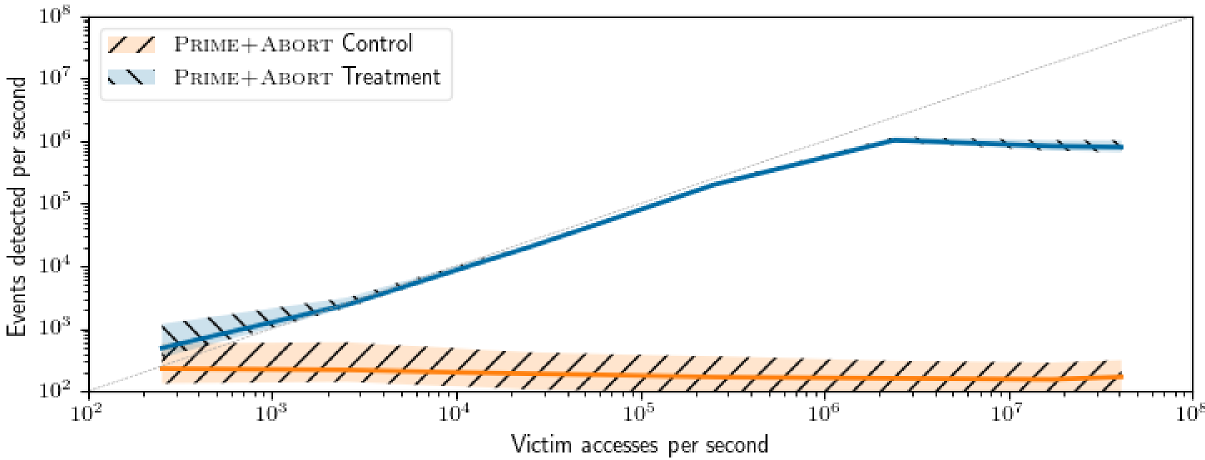

Figure 3: Access detection rates for PRIME+ABORT in the “control” and “treatment” conditions. Data were collected over 100 trials, each involving several different victim access speeds. Shaded regions indicate the range of the middle 75% of the data; lines indicate the medians. The $y = x$ line is added for reference and indicates perfect performance for the “treatment” condition (all events detected but no false positives or oversampling).

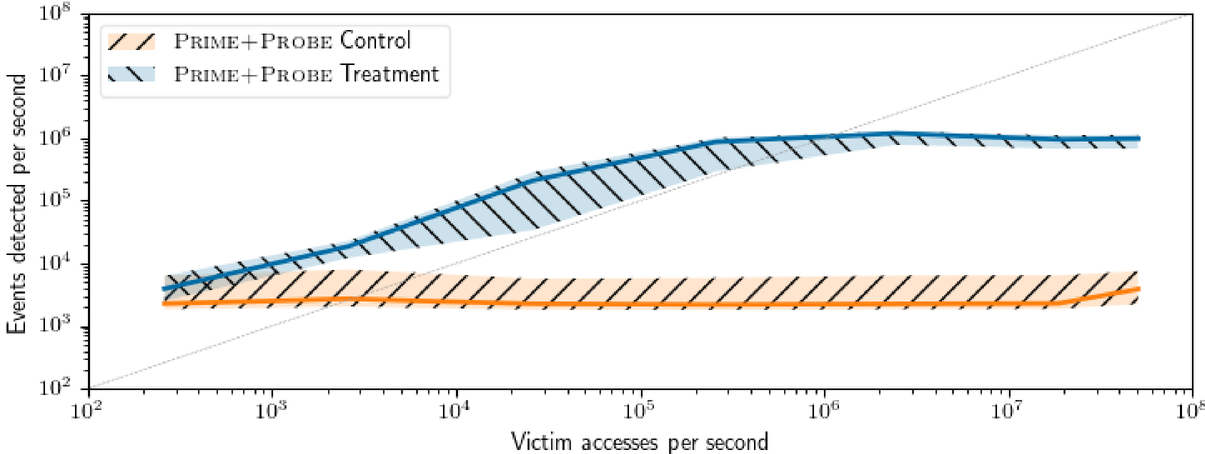

Figure 4: Access detection rates for unmodified PRIME+PROBE in the “control” and “treatment” conditions. Data were collected over 100 trials, each involving several different victim access speeds. Shaded regions indicate the range of the middle 75% of the data; lines indicate the medians. The $y = x$ line is added for reference and indicates perfect performance for the “treatment” condition (all events detected but no false positives or oversampling).

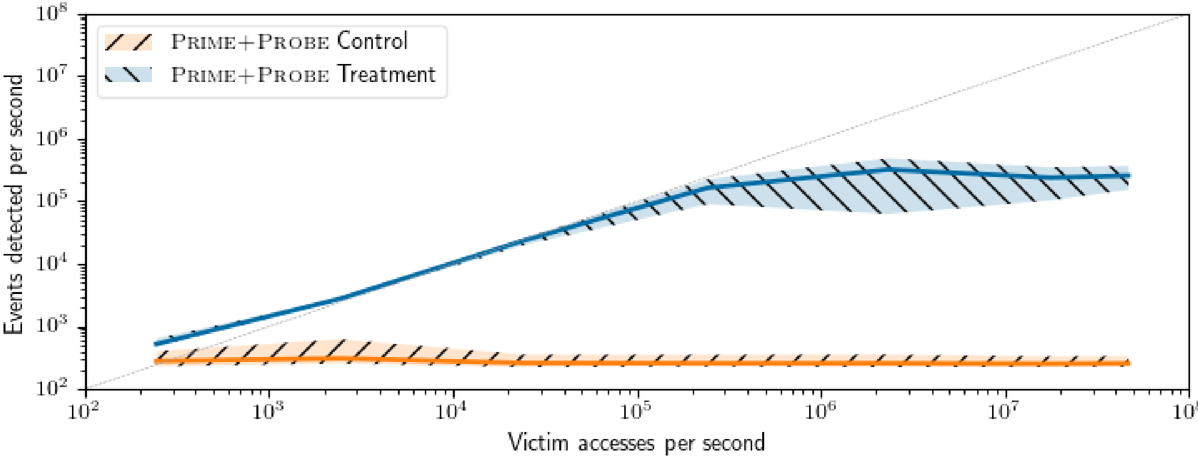

Figure 5: Access detection rates for our modified implementation of PRIME+PROBE which "collapses" streaks. Data were collected over 100 trials, each involving several different victim access speeds. Shaded regions indicate the range of the middle 75% of the data; lines indicate the medians. The $y = x$ line is added for reference and indicates perfect performance for the "treatment" condition (all events detected but no false positives or oversampling).

during every probe, but this approach will observe only a single streak and indicate a single event occurred.

Observing the two competing implementations of PRIME+PROBE on our hardware reveals an interesting tradeoff. The original implementation has good high frequency performance, but suffers from both oversampling and a high number of false positives. In contrast, the modified implementation has poor high frequency performance, but does not suffer from oversampling and exhibits fewer false positives. For the remainder of this paper we consider the modified implementation of PRIME+PROBE only, as we expect that its improved accuracy and fewer false positives will make it more desirable for most applications. Finally, we note that PRIME+ABORT combines the desirable characteristics of both PRIME+PROBE implementations, as it exhibits the fewest false positives, does not suffer from oversampling, and has good high frequency performance, with a top speed around one million events per second.

4.4 Attacks on AES

In this section we evaluate the performance of PRIME+ABORT in an actual attack by replicating the attack on OpenSSL's T-table implementation of AES, as conducted by Gruss et al. [7]. As those authors acknowledge, this implementation is no longer enabled by default due to its susceptibility to these kinds of attacks. However, as with their work, we use it for the purpose of comparing the speed and accuracy of competing attacks. Gruss et al. compared PRIME+PROBE, FLUSH+RELOAD, and FLUSH+FLUSH [7]; we have chosen to compare PRIME+PROBE and PRIME+ABORT, as these attacks do not rely on shared memory. Following their methods, rather than using previously published results directly, we rerun previous attacks alongside ours to ensure fairness, including the same hardware setup.

Figures 6 and 7 provide the results of this experiment. In this chosen-plaintext attack, we listen for accesses to the first cacheline of the first T-Table (`Te0`) while running encryptions. We expect that when the first four bits of our plaintext match the first four bits of the key, the algorithm will access this cacheline one extra time over the course of each encryption compared to when the bits do not match. This will manifest as causing more events to be detected by PRIME+ABORT or PRIME+PROBE respectively, allowing the attacker to predict the four key bits. The attack can then be continued for each byte of plaintext (monitoring a different cacheline of `Te0` in each case) to reveal the top four bits of each key byte.

In our experiments, we used a key whose first four bits were arbitrarily chosen to be `1110`, and for each method we performed one million encryptions with each possible 4-bit plaintext prefix (a total of sixteen million encryptions for PRIME+ABORT and sixteen million for PRIME+PROBE). As shown in Figures 6 and 7, both methods correctly predict the first four key bits to be `1110`, although the signal is arguably cleaner and stronger when using PRIME+ABORT.

5 Potential Countermeasures

Many countermeasures against side-channel attacks have already been proposed; Ge et al. [4] again provide an

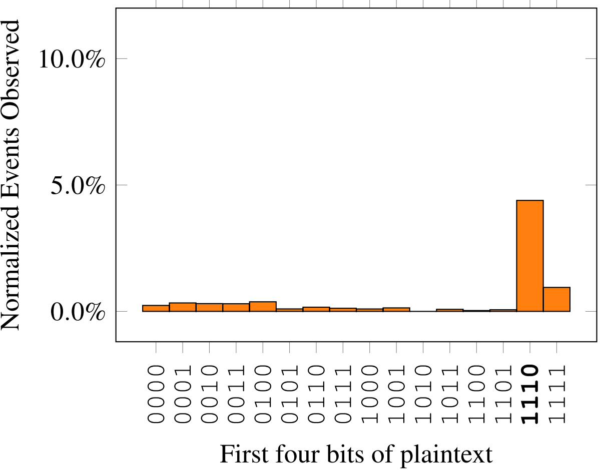

Figure 6: PRIME+ABORT attack against AES. Shown is, for each condition, the percentage of additional events that were observed compared to the condition yielding the fewest events.

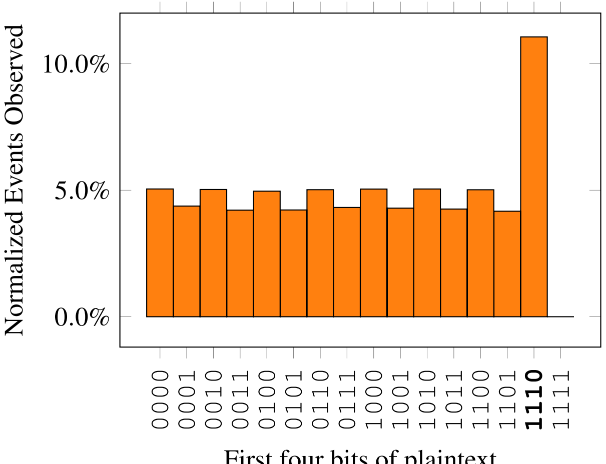

Figure 7: PRIME+PROBE attack against AES. Shown is, for each condition, the percentage of additional events that were observed compared to the condition yielding the fewest events.

excellent survey. Examining various proposed defenses in the context of PRIME+ABORT reveals that some are effective against a wide variety of attacks including PRIME+ABORT, whereas others are impractical or ineffective against PRIME+ABORT. This leads us to advocate for the prioritization and further development of certain approaches over others.

We first examine classes of side-channel countermeasures that are impractical or ineffective against PRIME+ABORT and then move toward countermeasures which are more effective and practical.

Timer-Based Countermeasures: A broad class of countermeasures ineffective against PRIME+ABORT are approaches that seek to limit the availability of precise timers, either by injecting noise into timers to make them less precise, or by restricting access to timers in general. There are a wide variety of proposals in this vein, including [15], [27], [31], [39], and various approaches which Ge et al. classify as "Virtual Time" or "Black-Box Mitigation". PRIME+ABORT should be completely immune to all timing-related countermeasures.

Partitioning Time: Another class of countermeasures that seems impractical against PRIME+ABORT is the class Ge et al. refer to as Partitioning Time. These countermeasures propose some form of "time-sliced exclusive access" to shared hardware resources. This would technically be effective against PRIME+ABORT, because the attack is entirely dependent on running simultaneously with its victim process; any context switch causes a transactional abort, so the PRIME+ABORT process must be active in order to glean any information. However, since PRIME+ABORT targets the LLC and can monitor across cores, implementing this countermeasure against PRIME+ABORT would require providing each user process time-sliced exclusive access to the LLC. This would mean that processes from different users could never run simultaneously, even on different cores, which seems impractical.

Disabling TSX: A countermeasure which would ostensibly target PRIME+ABORT's workings in particular would be to disable TSX entirely, similarly to how hyperthreading has been disabled entirely in cloud environments such as Microsoft Azure [30]. While this is technically feasible—in fact, due to a hardware bug, Intel already disabled TSX in many Haswell CPUs through a microcode update [17]—TSX's growing prevalence (Table 2), as well as its adoption by applications such as `glibc` (pthreads) and the JVM [24], indicates its importance and usefulness to the community. System administrators are probably unlikely to take such a drastic step.

Auditing: More practical but still not ideal is the class of countermeasures Ge et al. refer to as Auditing, which is based on behavioral analysis of running processes. Hardware performance counters in the target systems can be used to monitor LLC cache misses or miss rates, and thus detect when a PRIME+PROBE- or FLUSH+RELOAD-style attack is being conducted [1, 7, 46] (as any attack from those families will introduce a large number of cache misses—at least in the victim process). As a PRIME+PROBE-style attack, PRIME+ABORT would be just as vulnerable to these countermeasures as other cache attacks are. However, any behavioral auditing scheme is necessarily imperfect and subject to misclas-

sification errors in both directions. Furthermore, any auditing proposal targeting PRIME+ABORT which specifically monitors TSX-related events, such as transactions opened or transactions aborted, seems less likely to be effective, as many benign programs which utilize TSX generate a large number of both transactions and aborts, just as PRIME+ABORT does. This makes it difficult to distinguish PRIME+ABORT from benign TSX programs based on these statistics.

Constant-Time Techniques: The class of countermeasures referred to as "Constant-Time Techniques" includes a variety of approaches, some of which are likely to be effective against PRIME+ABORT. These countermeasures are generally software techniques to ensure important invariants are preserved in program execution regardless of (secret) input data, with the aim of mitigating side channels of various types. Some "Constant-Time Techniques" merely ensure that critical functions in a program always execute in constant time regardless of secret data. This is insufficient to defend against PRIME+ABORT, as PRIME+ABORT can track cache accesses without relying on any kind of timing side-channel. However, other so-called "Constant-Time Techniques" are actually more powerful than their name suggests, and ensure that no data access or control-flow decision made by the program ever depends on any secret data. This approach is effective against PRIME+ABORT, as monitoring cache accesses (either for instructions or data) would not reveal anything about the secret data being processed by the program.

Randomizing Hardware Operations: Another interesting class of defenses proposes to insert noise into hardware operations so that side-channel measurements are more difficult. Although PRIME+ABORT is immune to such efforts related to timers, other proposals aim to inject noise into other side-channel vectors, such as cache accesses. For instance, RPcache [40] proposes to randomize the mapping between memory address and cache set, which would render PRIME+ABORT and other cache attacks much more difficult. Other proposals aim to, for instance, randomize the cache replacement policy. Important limitations of this kind of noise injection (noted by Ge et al.) include that it generally can only make side-channel attacks more difficult or less efficient (not completely impossible), and that higher levels of mitigation generally come with higher performance costs. However, these kinds of schemes seem to be promising, providing relatively lightweight countermeasures against a quite general class of side-channel attacks.

Cache Set Partitioning: Finally, a very promising class of countermeasures proposes to partition cache sets between processes, or disallow a single process to use all of the ways in any given LLC cache set. This would be a powerful defense against PRIME+ABORT or any other PRIME+PROBE variant. Some progress has been made towards implementing these defenses, such as CATalyst [28], which utilizes Intel's "Cache Allocation Technology" [18]; or "cache coloring" schemes such as STEALTHMEM [26] or that proposed by [5]. One undesirable side effect of this approach is that it would reduce the maximum size of TSX transactions, hindering legitimate users of the hardware transactional memory functionality. However, the technique is still promising as an effective defense against a wide variety of cache attacks. For more examples and details of this and other classes of side-channel countermeasures, we again refer the reader to Ge et al. [4].

Our work with PRIME+ABORT leads us to recommend the further pursuit of those classes of countermeasures which are effective against all kinds of cache attacks including PRIME+ABORT, specifically so-called "Constant-Time Techniques" (in their strict form), randomizing cache operations, or providing mechanisms for partitioning cache sets between processes.

6 Disclosure

We disclosed this vulnerability to Intel on January 30, 2017, explaining the basic substance of the vulnerability and offering more details. We also indicated our intent to submit our research on the vulnerability to USENIX Security 2017 in order to ensure Intel was alerted before it became public. We did not receive a response.

7 Conclusion

PRIME+ABORT leverages Intel TSX primitives to yield a high-precision, cross-core cache attack which does not rely on timers, negating several important classes of defenses. We have shown that leveraging TSX improves the efficiency of algorithms for dynamically generating eviction sets; that PRIME+ABORT has higher accuracy and speed on Intel's Skylake architecture than previous L3 PRIME+PROBE attacks while producing fewer false positives; and that PRIME+ABORT can be successfully employed to recover secret keys from a T-table implementation of AES. Additionally, we presented new evidence useful for all cache attacks regarding Intel's Skylake architecture: that it may differ from previous architectures in number of cache slices, and that it may use different cache replacement policies for lines involved in TSX transactions.

On the effectiveness of mitigations against floating-point timing channels

David Kohlbrenner*
UC San Diego

Hovav Shacham†
UC San Diego

Abstract

The duration of floating-point instructions is a known timing side channel that has been used to break Same-Origin Policy (SOP) privacy on Mozilla Firefox and the Fuzz differentially private database. Several defenses have been proposed to mitigate these attacks.

We present detailed benchmarking of floating point performance for various operations based on operand values. We identify families of values that induce slow and fast paths beyond the classes (normal, subnormal, etc.) considered in previous work, and note that different processors exhibit different timing behavior.

We evaluate the efficacy of the defenses deployed (or not) in Web browsers to floating point side channel attacks on SVG filters. We find that Google Chrome, Mozilla Firefox, and Apple's Safari have insufficiently addressed the floating-point side channel, and we present attacks for each that extract pixel data cross-origin on most platforms.

We evaluate the vector-operation based defensive mechanism proposed at USENIX Security 2016 by Rane, Lin and Tiwari and find that it only reduces, not eliminates, the floating-point side channel signal.

Together, these measurements and attacks cause us to conclude that floating point is simply too variable to use in a timing security sensitive context.

1 Introduction

The time a modern processor takes to execute a floating-point instruction can vary with the instruction's operands. For example, subnormal floating-point values consumed or produced by an instruction can induce an order-of-magnitude execution slowdown. In 2015, Andrysco et al. [2] exploited the slowdown in subnormal processing to break the privacy guarantees of a differentially private database system and to mount pixel-stealing attacks against Firefox releases 23–27. In a pixel-stealing attack, a malicious web page learns the contents of a web page presented to a user's browser by a different site, in violation of the browser's origin-isolation guarantees.

Andrysco et al. proposed mitigations against floating-point timing attacks:

- Replace floating-point computations with fixed-point computations relying on the processor's integer ALU.
- Use processor flags to cause subnormal values to be treated as zero, avoiding slowdowns associated with subnormal values.
- Shift sensitive floating-point computations to the GPU or other hardware not known to be vulnerable.

At USENIX Security 2016, Rane, Lin, and Tiwari [15] proposed additional mitigations:

- Use program analysis to identify floating-point operations whose inputs cannot be subnormal; these operations will not experience subnormal slowdowns.
- Run floating-point operations whose inputs might be subnormal on the the processor's SIMD unit, loading the a SIMD lane with a dummy operation chosen to induce consistent worst-case execution time.

Rane, Lin, and Tiwari implemented their proposed mitigations in a research prototype Firefox browser. Variants of the Andrysco et al. mitigations have been adopted in the latest versions of Firefox, Safari, and Chrome.

We evaluate how effective the proposed mitigations are at preventing pixel stealing. We find that, other than avoiding the floating point unit altogether, the proposed mitigations are *not effective* at preventing pixel stealing — at best, they reduce the rate at which pixels can be read. Our attacks make use of details of floating point performance beyond the subnormal slowdowns observed by Andrysco et al.

Our contributions are as follows:

1. We give a more refined account of how floating-point instruction timing varies with operand values than did Andrysco et al. In particular, we show that operands with a zero exponent or significand induce small but exploitable speedups in many operations.
2. We evaluate the SIMD defense proposed by Rane, Lin, and Tiwari, giving strong evidence that processors execute the two operations sequentially, not in parallel.

†hovav@cs.ucsd.edu

Format Name	Size Bits	Subnormal Min	Normal Min	Normal Max
Half	16	$6.0e{-}8$	$6.10e{-}5$	$6.55e4$
Single	32	$1.4e{-}45$	$1.18e{-}38$	$3.40e38$
Double	64	$4.9e{-}324$	$2.23e{-}308$	$1.79e308$

Figure 1: IEEE-754 Format type ranges (Reproduced with permission from [2])

3. We revisit browser implementations of SVG filters two years after the Andrysco et al. attacks. Despite attempts at remediation, we find that the latest versions of Chrome, Firefox, and Safari are all vulnerable to pixel-stealing attacks.

4. We show that subnormal values induce slowdowns in CUDA calculations on modern Nvidia GPUs.

Taken together, our findings demonstrate that the floating point units of modern processors are more complex than previously realized, and that defenses that seek to take advantage of that unit without creating timing side channels require careful evaluation.

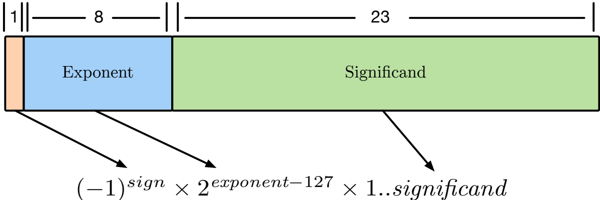

Figure 2: IEEE-754 single precision float

Ethics and disclosure. We have disclosed the pixel-stealing attacks we found to Apple, Google, and Mozilla. Mozilla has already committed to deploying a patch. We will give Apple and Google adequate time to patch before publishing our findings.

2 Background

Many floating point instructions are known to exhibit performance differences based on the operands. Andrysco et al. [2] leveraged these timing differences to defeat the claimed privacy guarantees of two systems: Mozilla Firefox (versions 23–27) and the Fuzz differentially private database. Andrysco et al.'s attack on Firefox, and the attacks on browsers we present, use SVG filter timing to break the Same-Origin Policy, an idea introduced by Stone [16] and Kotcher et al. [13].

2.1 IEEE-754 floating point

For the purposes of this paper we will refer to floating point, floats, and doubles to mean the IEEE-754 floating point standard (see Figure 1) unless otherwise specified. The floating point unit (FPU) accessed via Intel's single scalar Streaming SIMD (Single Instruction, Multiple Data) Extensions (SSE) instructions adheres to this standard on all processors we discuss. We omit discussion of the x87 legacy FPU that is still accessible on a modern x86_64 processor.

The IEEE-754 floating point standard is the most common floating point implementation available on commodity CPUs. Figure 2 shows the layout of the IEEE-754 single precision float and the value calculation. Note that the actual exponent used in the 2^{exp} portion is $exponent - bias$ where the bias is half the unsigned maximum value of the exponent's range. This format allows for the full range of positive and negative exponent values to be represented easily. If the exponent has any non 0 bits the value is *normal*, and the significand has an implicit leading 1 bit. If the exponent is all 0 bits (i.e., $exponent - bias = -bias$) then the value is *subnormal*, and there is no implicit leading 1 bit. As shown in figure 1 this means that subnormal values are fantastically small. Subnormal values are valuable because they enable gradual underflow for floating point computations. Gradual underflow guarantees that given any two floats, $a \neq b$, there exists a floating point value $c \neq 0$ that is the difference $a - b = c$. The use of this property is demonstrated by the simple pseudocode "if $a \neq b$ then $x \big/ (a-b)$," which does not expect to generate an infinity by dividing by zero. Without subnormals the IEEE-754 standard could not guarantee gradual underflow for normals and a number of adverse scenarios such as the one above can occur. As Andrysco et al. [2] observe, subnormal values do not frequently arise, and special hardware or microcode is used to handle them on most CPUs.

Andrysco et al.'s attacks made use of the substantial timing differences between operations on subnormal (or denormal) floating point values and on normal floating point values. See Figure 8 for a list of non-normal IEEE-754 value types. In this paper we present additional benchmarks that demonstrate that (smaller) timing differences arise from more than just subnormal operands. Section 3 describes our benchmarking results.

2.2 SVG floating point timing attacks

Andrysco et al. [2] presented an attack on Firefox SVG filters that is very similar to the attacks detailed later in this paper. Thus, we provide an overview of how that attack works for reference.

Figure 3 shows the workflow of the SVG timing attack.

1. The attacking page creates a large `<iframe>` of the victim page inside of a container `<div>`

2. The container `<div>` is sized to 1x1 pixel and can be scrolled to the current target pixel

Figure 4: Multiplication timing for single precision floats on Intel i5-4460

on the `<iframe>` using the `scrollTop` and `scrollLeft` properties.

3. The target pixel is duplicated into a larger container `<div>` using the `-moz-element` CSS property. This creates a `<div>` that is arbitrarily sized and consists only of copies of the target pixel.

4. The SVG filter that runs in variable time (`feConvolveMatrix`) is applied to the the pixel duplication `<div>`

5. The rendering time of the filter is measured using `requestAnimationFrame` to get a callback when the next frame is completed and `performance.now` for high resolution timing.

6. The rendering time is compared to the threshold determined during the learning phase and categorized as white or black.

Since the targeted `<iframe>` and the attacker page are on different origins, the attacking page should not be able to learn any information about the `<iframe>`'s content. However, since the rendering time of the SVG filter is visible to the attacker page, and the rendering time is dependent on the `<iframe>` content, the attacking page is able to violate this policy and learn pixel information.

3 New floating point timing observations

Andryso et al. [2] presented a number of timing variations in floating point computation based on subnormal and special value arguments. We expand this category to note that *any* value with a zero significand or exponent exhibits different timing behavior on most Intel CPUs.

Figure 9 shows a summary of our findings for our primary test platform running an Intel i5-4460 CPU. Unsurprisingly, double precision floating point numbers show more types of, and larger amounts of, variation than single precision floats.

Figures 4, 5, 6, and 7 are crosstables showing average cycle counts for division and multiplication on double and single precision floats on the Intel i5-4460. We refer to the type of operation (add, subtract, divide, etc) as the operation, and the specific combination of operands

and operation as the computation. Cells highlighted in blue indicate computations that averaged 1 cycle higher than the mode across all computations for that operation. Cells in orange indicate the same for 1 cycle less than the mode. Bold face indicates a computation that had a standard deviation of >1 cycle (none of the tests on the Intel i5-4460 had standard deviations above 1 cycle). All other crosstables in this paper follow this format unless otherwise noted.

We run each computation (operation and argument pair) in a tight loop for 40,000,000 iterations, take the total number of CPU cycles during the execution, remove loop overheads, and find the average cycles per computation. This process is repeated for each operation and argument pair and stored. Finally, we run the entire testing apparatus 10 times and store all the results. Thus, we execute each computation 400,000,000 times split into 10 distinct samples. This apparatus measures the steady-state execution time of each computation.

The entirety of our data across multiple generations of Intel and AMD CPUs, as well as tools and instructions for generating this data, are available at `https://cseweb.ucsd.edu/~dkohlbre/floats`.

It is important to note that the Andrysco et al. [2] focused on the performance difference between subnormal and normal operands, while we observe that there are additional classes of values worth examining. The specific differences on powers-of-two are more difficult to detect with a naive analysis as they cause a slight speedup when compared to the massive slowdown of subnormals.

4 Fixed point defenses in Firefox

In version 28 Firefox switched to a new set of SVG filter implementations that caused the attack presented by Andrysco et al. [2] to stop functioning. Many of these implementations no longer used floating point math, instead using their own fixed point arithmetic.

As the `feConvolveMatrix` implementation now consists entirely of integer operations, we cannot use floating point timing side channels to exploit it. We instead examined a number of the other SVG filter implementations and found that several had not yet been ported to the new fixed point implementation, such as the lighting filters.

4.1 Fixed point implementation

The fixed point implementation used in Firefox SVG filters is a simple 32-bit format with no Not-a-Number, Infinity, or other special case handling. Since they make use of the standard add/subtract/multiply operations for 32-bit integers, we know of no timing side channels based on operands for this implementation. Integer division is known to be timing variable based on the upper 32-bits of 64-bit operands, but none of the filters can generate intermediate values requiring the upper 32-bits. Thus, none of the filters we examined using fixed point had any instruction data timing based side channels. Handling the full range of floating point functionality in a fixed point and constant time way is expensive and complex, as seen in [2].

A side effect of a simple implementation is that it cannot handle more complex operations that could induce NaNs or infinities and must process them.

4.2 Lighting filter attack

Our Firefox SVG timing attack makes use of the `feSpecularLighting` lighting model with an `fePointLight`. This particular filter in this configuration is not ported to fixed point, and performs a scaling operation over the input alpha channel. The `surfaceScale` property in `feSpecularLighting` controls this scaling operation and can be set to an arbitrary floating point value when creating the filter. With this tool, we perform the following attack similar to the one in section 2.2. We need only to modify step 4 as seen below to enable the use of the new lighting filter attack.

1. Steps 1-3 are the same as section 2.2.

   4.1. Apply an `feColorMatrix` to the pixel multiplier `<div>` that sets the alpha channel based entirely on the input color values. This sets the alpha channel to 1 for a black pixel input, and 0 for a white pixel input.

   4.2. Apply the timing variable `feSpecularLighting` filter with a subnormal `surfaceScale` and an attached `fePointLight` as the timing vulnerable filter.

5. Steps 5 and 6 are the same as section 2.2.

In this case, we differentiate between n^2 multiplications of *subnormal* $\times$ 0 (black) vs *subnormal* $\times$ 1 (white) where n is the width/height of the copied pixel <div>. Since our measurements show a difference of 7 cycles vs 130 cycles for each multiplication (see Figure 4), we can easily detect this difference once we scale n enough that the faster white pixel case takes longer than 16ms (circa $n = 200$) in our tests. We need to cross this 16ms threshold as frames take a minimum of 16ms to render (60fps) on our test systems.

In our tests on an Intel i5-4460 with Firefox 49+ we were able to consistently obtain $> 99\%$ accuracy (on black and white images) at an average of 17ms per pixel. This is approximately as fast as an attack using this method can operate, since Firefox animates at a capped 60fps on all our test systems.

We notified Mozilla of this attack and they are working on a comprehensive solution. Firefox has patched the `surfaceScale` based attack on the `feSpecularLighting` filter in Firefox 52 and assigned the attack CVE-2017-5407.

5 Safari

At the time of writing this paper, Safari has not implemented any defensive mechanisms that hamper the SVG timing attack presented in [2]. Thus, with a rework of the attack framework, we are able to modify the attack presented in Andrysco et al against the `feConvolveMatrix` filter for Firefox 25 to work against current Safari.

Webkit (Safari) uses its own SVG filter implementations not used in other browsers. None of the SVG filters had GPU support at the time of this paper, but some CSS transforms could be GPU accelerated.

The Webkit `feConvolveMatrix` filter is implemented in the obvious way; multiply each kernel sized pixel region against the kernel element-by-element, sum, and divide the result by the divisor. We can therefore cause operations with 0×subnormal or normal×subnormal depending on the target pixel. Since as we have seen these can a 0×subnormal can be 21× faster than a subnormal times a normal, we can easily detect the difference between executing over a black pixel or a white pixel.

We have disclosed the attack to Apple, and discussed options for entirely disabling cross-origin SVG filtering. Apple is working to address the issue.

We have removed details on the needed technical modifications to the attack for Safari as a patch is not yet available for all users. A full description of the modifications required for the Safari variant will be released upon a patch being available.

6 DAZ/FTZ FPU flag defenses in Chrome

Google Chrome implements CSS and SVG filter support through the Skia [1] graphics library. As of July of 2016, when executing Skia filters on the CPU, Chrome enables an FPU control flag based countermeasure to timing attacks. Specifically, Chrome enables the Flush-to-Zero (FTZ) and Denormals-are-Zero (DAZ) flags.

These flags are two of the many FPU control flags that can be set. Flags determine options such as when to set a floating point exception, what rounding options to use, and how to handle subnormals. The FTZ flag indicates to the FPU that whenever it would produce a subnormal as the result of a calculation, it instead produces a zero. The DAZ flag indicates to the FPU that any subnormal operand should be treated as if it were zero in the computation. Generally these flags are enabled together as a performance optimization to avoid any use or generation of subnormal values. However, these flags break strict IEEE-754 compatibility and so some compilers do not enable them without specific optimization flags. In the case of Chrome, FTZ and DAZ are enabled and disabled manually in the Skia rendering path.

6.1 Attacking Chrome

We present a cross-origin pixel stealing attack for Google Chrome using the `feConvolveMatrix` filter. As in our previous attacks, we observe the timing differences between white and black pixels rendered with a specific convolution matrix. This attack works without any changes on all major platforms for Chrome that support GPU acceleration. We have tested it on Windows 10 (Intel i7-6700k), Ubuntu Linux 16.10 (Intel i5-4460), OSX 10.11.6 (Intel i7-3667U Macbook Air), and a Chromebook Pixel LS ChromeOS 55.0.2883.105 (i7-5500U) on versions of Chrome from 54-56. The attack is very similar to the one detailed in section 2.2 and figure 3.

Unlike Firefox, we cannot trivially supply subnormal value like “1e-41”, as the Skia SVG float parsing code treats them as 0s. The float parsing in Skia attempts to avoid introducing subnormal values by disallowing exponents ≤ -37. Thus we use the value $0.0000001e-35$ or simply the fully written out form, which is correctly parsed into a subnormal value. Since the FTZ and DAZ flags are set only on entering the Skia rendering code, the parsing is not subject to these flags and we can always successfully generate subnormals at parse time.

The largest obstacle we bypass is the use of the FTZ and DAZ control flags. These flags reduce the precision and representable space of floats, but prevent any performance impact caused by subnormals for these filters in our experiments. As shown in section 3 even with these flags enabled the `div` and `sqrt` operations still have timing variation. Unfortunately none of the current SVG filter implementations we examined have tight division

Figure 11: Division timing for double precision floats on Intel i5-4460+FTZ/DAZ

loops over doubles, or tight square root operations over floats. Thus, our attack must circumvent the use of the FTZ and DAZ flags altogether.

Chrome enables the FTZ and DAZ control flags whenever a filter is set to run on the CPU, which disallows our Firefox or Safari attacks from applying directly to Chrome. However, we found that the FTZ and DAZ flags are not set when a filter is going to execute on the GPU. This would normally only be useful for a GPU-based attack but we can force the `feConvolveMatrix` filter to abort from GPU acceleration at the last possible moment and fall back to the CPU implementation by having a kernel matrix over the maximum supported GPU size of 36 elements. Chrome does not enable the FTZ and DAZ flags when it executes this fallback, allowing our timing attack to use subnormal values.

We force the target `<div>` to start on the GPU rendering path by applying a CSS `transform:rotateY()` to it. This is a well known trick for causing future animations and filters to be performed on the GPU, and it works consistently. Without this, the `feConvolveMatrix` GPU implementation would never fire, as it will not choose the GPU over the CPU on its own. It is only because of our ability to force CPU fallback with the FTZ and DAZ flags disabled that allows our CPU Chrome attack to function.

Note that even if FTZ/DAZ are enabled in all cases there are still scenerios that show timing variation as seen in figures 11 and 9. Chrome's Skia configuration currently uses single precision floats, and thus only need avoid sqrt operations as far as we know. However, any use of double precision floats will additionally require avoidance of division. We did not observe any currently vulnerable uses of single precision sqrt, or of double precision floating point operations in the Skia codebase.

We notified Google of this attack and a fix is in progress.

6.2 Frame timing on Chrome

An additional obstacle to our Chrome attack was obtaining accurate frame render times. Unlike on Firefox or Safari, adding a filter to a `<div>`'s style and then calling `getAnimationFrame` is insufficient to be sure that the time until the callback occurs will accurately represent the rendering time of the filter. In fact, the frame that the filter is actually rendered on differs by platform and is not consistent on Linux. We instead run algorithm 1 to get the approximate rendering time of a given frame. Since we only care about the relative rendering time between white and black pixels, the possibly extra time included doesn't matter as long as it is moderately consistent. This technique allowed our attack to operate on all tested platforms without modification.

7 Revisiting the effectiveness of Escort

Escort [15] proposes defenses against multiple types of timing side channels, notably a defense using SIMD vec-

Result: Duration of SVG filter rendering

```
total_duration = 0ms;
long_frame_seen = False;
while true do
    /* Wait for next frame                */
    requestAnimationFrame;
    if duration > 40ms then
        /* Long frame probably
           containing the SVG
           rendering occurred             */
        long_frame_seen = True;
        total_duration += duration;
    else
        if long_frame_seen then
            /* A short frame after a
               long frame                 */
            return total_duration;
        end
    end
    total_duration += duration;
end
```

Algorithm 1: How to measure SVG filter rendering times in Chrome

tor operations to protect against the floating point attack presented by Andrysco et al in [2].

Single Instruction, Multiple Data (SIMD) instructions are an extension to the x86_64 ISA designed to improve the performance of vector operations. These instructions allow 1-4 independent computations of the same operation (divide, add, subtract, etc) to be performed at once using large registers. By placing the first set of operands in the top half of the register, and the second set of operands in the bottom half, multiple computations can be easily performed with a single opcode. Intel does not provide significant detail about the execution of these instructions and does not provide guarantees about their performance behavior.

7.1 Escort overview

Escort performs several transforms during compilation designed to remove timing side channels. First, they modify 'elementary operations' (floating point math operations for the purpose of this paper). Second, they perform a number of basic block linearizations, array access changes, and branch removals to transform the control flow of the program to constant time and minimize side effects.

We do not evaluate the efficacy of the higher level control flow transforms and instead evaluate only the elementary operations.

Escort's tool is to construct a set of dummy operands (the *escort*) that are computed at the same time as the

secret operands to obscure the running time of the secret operands. Escort places the dummy arguments in one lane of the SIMD instruction, and the sensitive arguments in another lane. Since the instruction only retires when the full set of computations are complete, the running time of the entire operation is hypothesized to be dependent only on the slowest operation. This is true if and only if the different lanes are computed in parallel. To obscure the running time of the sensitive operands, Escort places two subnormal arguments in the dummy lane of all modified operations under the assumption that this will exercise the slowest path through the hardware.

Escort will replace most floating point operations it encounters. However, if it can prove (using the Z3 SMT solver [4]) that the operation will never have subnormal values as operands it declines to replace the operation. This means that if a function filters out subnormals be-

Figure 15: Division timing for double precision floats on Intel i5-4460 macro-test

fore performing computation, the computation will be done with standard scalar floating point operations and not vector operations. This results in significant performance gains when applicable, as the scalar operations can be two orders of magnitude faster than the subnormal vector operations. The replacement operations consist of hand-coded assembly contained in a library; `libdrag`.

However, operations that do not receive subnormals can still exhibit timing differences. As seen in figure 7 and summarized in figure 9 timing differences arise on value types that can commonly occur (0, powers of 2, etc). While significantly less obvious than the impact of subnormals, these still constitute a potential timing side channel. `libdrag` can easily fix this, at serious performance cost, by enabling the floating point replacements for all floating point operations with no exceptions.

To determine if Escort closes floating point timing side channel when enabled, we measured the timing behavior of Escort's `libdrag` floating point operations, as well as the end-to-end runtime of toy programs compiled under Escort.

7.2 `libdrag` micro-benchmarks

For the micro-benchmarking of the `libdrag` functions we use a simple tool we developed for running timing tests of library functions based on Intel's recommendations for instruction timing. This is the same tool we used to produce measurements for section 3.

We benchmarked each of `libdrag`'s functions against a range of valid numbers on several different CPUs. We do not present results for Not-a-Number (NaN) or infinities.

7.2.1 Results on Intel i5-4460

Our results for the Intel i5-4460 CPU roughly correspond to the variations presented in [15] (which tested on an Intel i7-2600) for `libdrag`. We do not observe any measurable timing variation in any add, multiply, or subtract operations for single or double precision floating point. We do observe notable timing differences based on argument values for single and double precision division and square-root operations. The cross table results for double precision division are shown in figure 14. Figure 12 summarizes the timing variations we observed.

For division, it appears that the numerator has no im-

pact on the running time of the computation. The denominator shows variation based on if the significand or exponent is all zero bits. When either portion is zero in the denominator computations run consistently faster in both single and double precision floating point. Differences observed range from 2% to 5% in contrast to the 2500% differences observed in section 3.

Square root shows a similar behavior, where if either the significand or exponent is all 0 bits the computation runs consistently faster. This matches the behavior seen for many operations in scalar computations. (See figure 9)

An interesting outcome of this behavior is that subnormal values cause a *speedup* under `libdrag` rather than the slowdown observed under scalar operations.

We speculate that this is the result of fast paths in the microcode handling for vector operations. Using performance counters we determined that all vector operations containing a subnormal value execute microcode rather than hardwired logic on the FPU hardware. As all values with a zero significand or exponent experienced a speedup, we believe that the division and square root microcode handles these portions separately with a shortcut in the case of zero. Intel did not release any details on the cause of these timing effects when asked.

7.2.2 AMD Phenom II X2 550

Figure 13 summarizes our results on the AMD Phenom II X2 550. As with the Intel i5-4460 we observe timing variation in the AMD Phenom II X2 550. However, the variation is now confined to addition and subtraction with subnormal values. By examining the cycle times for each operation in the default and `libdrag` case we found that the total cycle time for an escorted add or subtract is approximately equal to the sum of the cycle counts for a subnormal,subnormal operation and the test case. Thus, we believe that the AMD Phenom II X2 550 is performing each operation sequentially and with the same hardware or microcode as scalar operations for addition and subtraction.

7.3 Escort compiled toy programs

For end-to-end tests we wrote toy programs that perform a specified floating point operation an arbitrary number of times, and compiled them under Escort and `gcc`. We then use the Linux `time` utility to measure runtimes of the entire program. We designed the test setup such that each run of the test program performed the same value parsing and setup steps regardless of the test values, with only the values entering the computation differing between runs. We ran the target computation 160,000,000 times per execution, and ran each test 10 times. We see the same effects as in our microbenchmarks. Figure 15 shows the crosstable for these results. Note that cells are colorized if they differ by 2% rather than 1 cycle.

7.4 `libdrag` modified Firefox

We modified a build of Firefox 25 in consultation with Rane et al [15] to match the version they tested. Since multiply no longer shows any timing variation in `libdrag` we are restricted to observing a potential $\leq$ 2% difference in only the divide, which occurs once per pixel regardless of the kernel. Additionally, since the denominator is the portion controlled by the attacker and the secret value is the numerator, we are not able to update the pixel stealing attack for the modified Firefox 25.

The modifications to Firefox 25 were confined to hand made changes to the `feConvolveMatrix` implementation targeted in [2]. We did not test other SVG filters for vulnerability under the Escort/`libdrag` modifications.

Given the observed timing variations in the AMD Phenom II X2 550 in section 7.2.2 we believe that multiple SVG filters would be timing side channel vulnerable under Escort on that CPU.

7.5 Escort summary

Unfortunately our benchmarks consistently demonstrated a small but detectable timing difference for `libdrag`'s vector operations based on operand values. For our test Intel CPUs it appears that `div` and `mul` exhibit timing differences under Escort. For our AMD CPUs we observed variation only for `add`/`sub`. Additionally, these differences are no more than 5% as compared to the 500% or more differences observed in scalar operations. We have made Rane, Lin and Tiwari aware of these findings.

The 'escort' mechanism can only serve as an effective defense if vector operations are computed in parallel. In all CPUs we tested the most likely explanation for the observed timing difference is that vector operations are executed serially when in microcode. As mentioned in section 7.2.1 we know that any vector operation including a subnormal argument is executed in microcode, and all evidence supports the microcode executing vector operations serially. Thus, absent substantial architectural changes, we do not believe that the 'escort' vector mechanism can close all floating point data timing channels.

8 GPU floating point performanace

In this section we discuss the results of GPU floating point benchmarks, and the use of GPU acceleration in SVG filters for Google Chrome.

8.1 Browser GPU support

All major browsers make use of GPU hardware acceleration to improve performance for various applications. However, only two currently make use of GPUs for SVG

Dividend	Divisor 0.0	1.0	1e10	1e+30	1e-30	1e-41	1e-42	256	257

Figure 16: Division timing for single precision floats on Nvidia GeForce GT 430

and CSS transforms; Safari and Chrome. Currently, Safari only supports a subset of CSS transformations on the GPU, and none of the SVG transforms. Chrome supports a subset of the CSS and SVG filters on the GPU. Firefox intends to port filters to the GPU, but there is currently no support.

8.2 Performance

We performed a series of CUDA benchmarks on an Nvidia GeForce GT 430 to determine the impact of subnormal values on computation time. The results for division are shown in figure 16. All other results (add, sub, mul) were constant time regardless of the inputs..

As figure 16 shows, subnormals induce significant slowdowns on divsion operations for single precision floats. Unfortunately, no SVG filters implemented in Chrome on the GPU perform tight division loops. Thus, extracting timing differences from the occational division they do perform is extremely difficult.

If a filter were found to perform tight division loops, or a GPU that has timing variation on non-division operations were found, the same attacks as in previous sections could be ported to the GPU accelerated filters.

We believe that even without a specific attack, the demonstration of timing variation based on operand values in GPUs should invalidate "move to the GPU" as a defensive strategy.

9 Related work

Felten and Schneider were the first to mount timing side-channel attacks against browsers. They observed that resources already present in the browser's cache are loaded faster than ones that must be requested from a server, and that this can be used by malicious JavaScript to learn what pages a user has visited [6]. Felten and Schneider's history sniffing attack was later refined by Zalewski [18]. Because many sites load resources specific to a user's approximate geographic location, cache timing can reveal the user's location, as shown by Jia et al. [10].

JavaScript can also ask the browser to make a cross-origin request and then learn (via callback) how long the response took to arrive and be processed. Timing channels can be introduced by the code that runs on the server to generate the response; by the time it takes the response to be transmitted over the network, which will depend on how many bytes it contains; or by the browser code that attempts to parse the response. These cross-site timing attacks were introduced by Bortz, Boneh, and Nandy [3], who showed they could be used to learn the number of items in a user's shopping cart. Evans [5] and, later, Gelernter and Herzberg [7], showed they could be used to confirm the presence of a specific string in a user's search history or webmail mailbox. Van Goethem, Joosen, and Nikiforakis [17] observed that callbacks introduced to support HTML5 features allow attackers to time individual stages in the browser's response-processing pipeline, thereby learning response size more reliably than with previous approaches.

The interaction of new browser features — TypedArrays, which translate JavaScript variable references to memory accesses more predictably, and nanosecond-resolution clocks — allow attackers to learn whether specific lines have been evicted from the processor's last-level cache. Yossi Oren first showed that such microarchitectural timing channels can be mounted from JavaScript [14], and used them to learn gross system activity. Recently, Gras et al. [8] extended Oren's techniques to learn where pages are mapped in the browser's virtual memory, defeating address-space layout randomization. In response, browsers rounded down the clocks provided to JavaScript to 5 μs granularity. Kohlbrenner and Shacham [12] proposed a browser architecture that degrades the clocks available to JavaScript in a more principled way, drawing on ideas from the "fuzzy time" mitigation [9] in the VAX VMM Security Kernel [11].

Browsers allow Web pages to apply SVG filters to elements including cross-origin iframes. If filter processing time varies with the underlying pixel values, those pixel values will leak. Paul Stone [16] and, independently, Kotcher et al. [13], showed that such pixel-stealing attacks are feasible; the filters they exploited had pixel-dependent branches. Andrysco et al. [2] showed that pixel-stealing was feasible even when the filter executed the same instruction trace regardless of pixel values, provided those instructions exhibit data-dependent timing behavior, as floating-point instructions do. Rane, Lin, and Tiwari [15] proposed program transformation that allow the processor floating-point unit to be used while eliminating data-dependent instruction timing, in the hope of defeating Andrysco et al.'s attacks.

10 Conclusions and future work

We have extensively benchmarked floating point performance on a range of CPUs under scalar operations, FTZ/-DAZ FPU flags, `-ffast-math` compiler options, and Rane, Lin, and Tiwari's Escort. We identified operand-dependent timing differences on all tested platforms and in all configurations; many of the timing differences we identified were overlooked in previous work.

In the case of Escort, our data strongly suggests that processors execute SIMD operations on subnormal values sequentially, not in parallel. If this is true, a redesign of the vector processing unit would be required to make Escort effective at closing all floating-point timing channels.

We have revisited browser implementations of SVG filters, and found (and responsibly disclosed) exploitable timing variations in the latest versions of Chrome, Firefox, and Safari.

Finally, we have shown that modern GPUs exhibit slowdowns in processing subnormal values, meaning that the problem extends beyond x86 processors. We are currently evaluating whether these slowdowns allow pixel stealing using SVG filters implemented on the GPU.

We have uncovered enough variation in timing across Intel and AMD microarchitectural revisions that we believe that comprehensive measurement on many different processor families — in particular, ARM — will be valuable. For the specific processors we studied, we believe we are in a position to identify specific flags, specific operations, and specific operand sizes that run in constant time. Perhaps the best one can hope for is an architecture-aware library that could ensure no timing variable floating point operations occur while preserving as much of the IEEE-754 standard as possible.

Tools, proof-of-concept attacks, and additional benchmark data are available at `https://cseweb.ucsd.edu/~dkohlbre/floats`.

We close with broader lessons from our work.

For software developers: We believe that floating point operations as implemented by CPUs today are simply too unpredictable to be used in a timing-security sensitive context. Only defensive measures that completely remove either SSE floating point operations (fixed-point implementations) or remove the sensitive nature of the computation are completely effective. Software that operates on sensitive, non-integer values should use fixed-point math, for example by including Andrysco et al.'s `libfixedtimefixedpoint`, which Almeida et al. recently proved runs in constant time [1].

For browser vendors: Some browser vendors have expended substantial effort in redesigning their SVG filter code in the wake of the Andrysco et al. attacks. Even so, we were able to find (different) exploitable floating-point timing differences in Chrome, Firefox, and Safari. We believe that the attack surface is simply too large; as new filters and features are added additional timing channels will inevitably open. We recommend that browser vendors disallow cross-origin SVG filters and other computation over cross-origin pixel data in the absence of Cross-Origin Resource Sharing (CORS) authorization.

It is important that browser vendors also consider patching individual timing side channels in SVG filters as they are found. Even with a origin policy that blocks the cross-origin pixel stealing, any timing side channel allows an attacking page to run a history sniffing attack. Thus, a comprehensive approach to SVG filters as a threat to user privacy combines disallowing cross-origin SVG filters and removes timing channels with constant time coding techniques.

For processor vendors: Processor vendors have resisted calls to document which of their instructions run in constant time regardless of operands, even for operations as basic as integer multiplication. It is possible that floating point instructions are unusual not because they exhibit timing variation but because their operands have meaningful algebraic structure, allowing intelligent exploration of the search space for timing variations; even so, we identified timing variations that Andrysco et al. overlooked. How much code that is conjectured to be constant-time is in fact unsafe? Processor vendors should document possible timing variations in at least those instructions commonly used in crypto software.

Constant-Time Callees with Variable-Time Callers

Cesar Pereida García　　Billy Bob Brumley
Tampere University of Technology
{*cesar.pereidagarcia,billy.brumley*}@*tut.fi*

Abstract

Side-channel attacks are a serious threat to security-critical software. To mitigate remote timing and cache-timing attacks, many ubiquitous cryptography software libraries feature constant-time implementations of cryptographic primitives. In this work, we disclose a vulnerability in OpenSSL 1.0.1u that recovers ECDSA private keys for the standardized elliptic curve P-256 despite the library featuring both constant-time curve operations and modular inversion with microarchitecture attack mitigations. Exploiting this defect, we target the errant modular inversion code path with a cache-timing and improved performance degradation attack, recovering the inversion state sequence. We propose a new approach of extracting a variable number of nonce bits from these sequences, and improve upon the best theoretical result to recover private keys in a lattice attack with as few as 50 signatures and corresponding traces. As far as we are aware, this is the first timing attack against OpenSSL ECDSA that does not target scalar multiplication, the first side-channel attack on cryptosystems leveraging P-256 constant-time scalar multiplication and furthermore, we extend our attack to TLS and SSH protocols, both linked to OpenSSL for P-256 ECDSA signing.

Keywords: applied cryptography; elliptic curve cryptography; digital signatures; side-channel analysis; timing attacks; cache-timing attacks; performance degradation; ECDSA; modular inversion; binary extended Euclidean algorithm; lattice attacks; constant-time software; OpenSSL; NIST P-256; CVE-2016-7056

1 Introduction

Being a widely-deployed open-source cryptographic library, OpenSSL is a popular target for different cryptanalytic attacks, including side-channel attacks that target cryptosystem implementation weaknesses that can leak critical algorithm state. As a software library, OpenSSL provides not only TLS functionality but also cryptographic functionality for applications such as SSH, IPSec, and VPNs.

Due to its ubiquitous usage, OpenSSL contains arguably one of the most popular software implementations of the Elliptic Curve Digital Signature Algorithm (ECDSA). OpenSSL's scalar multiplication algorithm was shown vulnerable to cache-timing attacks in 2009 [6], and attacks continue on the same code path to this date [2, 4, 10, 27]. Recognizing and responding to the threat cache-timing attacks pose to cryptosystem implementations, OpenSSL mainlined constant-time scalar multiplication for several popular standardized curves already in 2011 [16].

In this work, we disclose a software defect in the OpenSSL (1.0.1 branch) ECDSA implementation that allows us to design and implement a side-channel cache-timing attack to recover private keys. Different from previous work, our attack focuses on the modular inversion operation instead of the typical scalar multiplication, thus allowing us to target the standardized elliptic curve P-256, circumventing its constant-time scalar multiplication implementation. The root cause of the defect is failure to set a flag in ECDSA signing nonces that indicates only constant-time code paths should be followed.

We leverage the state-of-the-art FLUSH+RELOAD [28] technique to perform our cache-timing attack. We adapt the technique to OpenSSL's implementation of ECDSA and the *Binary Extended Euclidean Algorithm* (BEEA). Our spy program probes relevant memory addresses to create a timing signal trace, then the signal is processed and converted into a sequence of right-shift and subtraction (LS) operations corresponding to the BEEA execution state from which we extract bits of information to create a lattice problem. The solution to the lattice problem yields the ECDSA secret key.

We discover that observing as few as 5 operations

from the LS sequence allows us to use every single captured trace for our attack. This significantly reduces both the required amount of signatures and side-channel data compared to previous work [8], and maintains a good signature to lattice dimension ratio.

We build upon the performance degradation technique of Allan et al. [2] to efficiently find the memory addresses with the highest impact to the cache during the degrading attack. This new approach allows us to accurately find the best candidate memory addresses to slow the modular inversion by an average factor of 18, giving a high resolution trace and allowing us to extract the needed bits of information from all of the traces.

Unlike previous works targeting the *w*NAF scalar multiplication code path (for curves such as BitCoin's secp256k1) or performing theoretical side-channel analysis of the BEEA, we are the first to demonstrate a practical cache-timing attack against the BEEA modular inversion, and furthermore OpenSSL's ECDSA signing implementation with constant-time P-256 scalar multiplication.

Our contributions in this work include the following:

- We identify a bug in OpenSSL that allows a cache-timing attack on ECDSA signatures, despite constant-time P-256 scalar multiplication. (Section 3)
- We describe a new quantitative approach that accurately identifies the most accessed victim memory addresses w.r.t. data caching, then we use them for an improved performance degradation attack in combination with the FLUSH+RELOAD technique. (Section 4.3)
- We describe how to combine the FLUSH+RELOAD technique with the improved performance degradation attack to recover side-channel traces and algorithm state from the BEEA execution. (Section 4)
- We present an alternate approach to recovering nonce bits from the LS sequences, focused on minimizing required side-channel information. Using this approach, we recover bits of information from every trace, allowing us to use every signature query to construct and solve a lattice problem, revealing the secret key with as few as 50 signatures and corresponding traces. (Section 4.4)
- We perform a key-recovery cache-timing attack on the TLS and SSH protocols utilizing OpenSSL for ECDSA functionality. (Section 5)

2 Background

2.1 Elliptic Curve Cryptography

ECC. Developed in the mid 1980's, elliptic curves were introduced to cryptography by Miller [20] and Koblitz [17] independently. Elliptic Curve Cryptography (ECC) became popular mainly for two important reasons: no sub-exponential time algorithm to solve the elliptic curve discrete logarithm problem is known for well-chosen parameters and it operates in the group of points on an elliptic curve, compared to the classic multiplicative group of a finite field, thus allowing the use of smaller parameters to achieve the same security levels—consequently smaller keys and signatures.

Although there are more general forms of elliptic curves, for the purposes of this paper we restrict to short Weierstrass curves over prime fields. With prime $p > 3$, all of the $x, y \in GF(p)$ solutions to the equation

$$E : y^2 = x^3 + ax + b$$

along with an identity element form an abelian group. Due to their performance characteristics, the parameters of interest are the NIST standard curves that set $a = -3$ and p a Mersenne-like prime.

ECDSA. Throughout this paper, we use the following notation for the Elliptic Curve Digital Signature Algorithm (ECDSA).

Parameters: A generator $G \in E$ of an elliptic curve group of prime order n and an approved hash function h (e.g. SHA-1, SHA-256, SHA-512).

Private-Public key pairs: The private key α is an integer uniformly chosen from $\{1 \mathinner{..} n-1\}$ and the corresponding public key $D = [\alpha]G$ where $[i]G$ denotes scalar-by-point multiplication using additive group notation. Calculating the private key given the public key requires solving the elliptic curve discrete logarithm problem and for correctly chosen parameters, this is an intractable problem.

Signing: A given party, Alice, wants to send a signed message m to Bob. Using her private-public key pair (α_A, D_A), Alice performs the following steps:

1. Select uniformly at random a secret nonce k such that $0 < k < n$.
2. Compute $r = ([k]G)_x \bmod n$.
3. Compute $s = k^{-1}(h(m) + \alpha_A r) \bmod n$.
4. Alice sends (m, r, s) to Bob.

Verifying: Bob wants to be sure the message he received comes from Alice—a valid ECDSA signature gives strong evidence of authenticity. Bob performs the following steps to verify the signature:

1. Reject the signature if it does not satisfy $0 < r < n$ and $0 < s < n$.
2. Compute $w = s^{-1} \bmod n$ and $h(m)$.
3. Compute $u_1 = h(m)w \bmod n$ and $u_2 = rw \bmod n$.
4. Compute $(x, y) = [u_1]G + [u_2]D_A$.
5. Accept the signature if and only if $x = r \bmod n$ holds.

2.2 Side-Channel Attacks

Thanks to the adoption of ECC and the increasing use of digital signatures, ECDSA has become a popular algorithm choice for digital signatures. ECDSA's popularity makes it a good target for side-channel attacks.

At a high level, an established methodology for ECDSA is to query multiple signatures, then partially recover nonces k_i from the side-channel, leading to a bound on the value $\alpha t_i - u_i$ that is shorter than the interval $\{1..n-1\}$ for some known integers t_i and u_i. This leads to a version of the Hidden Number Problem (HNP) [5]: recover α given many (t_i, u_i) pairs. The HNP instances are then reduced to Closest Vector Problem (CVP) instances, solved with lattice methods.

Over the past decade, several authors have described practical side-channel attacks on ECDSA that exploit partial nonce disclosure by different microprocessor features to recover long-term private keys.

Brumley and Hakala [6] describe the first practical side-channel attack against OpenSSL's ECDSA implementation. They use the EVICT+RELOAD strategy and an L1 data cache-timing attack to recover the LSBs of ECDSA nonces from the library's *w*NAF (a popular low-weight signed-digit representation) scalar multiplication implementation in OpenSSL 0.9.8k. After collecting 2,600 signatures (8K with noise) from the `dgst` command line tool and using the Howgrave-Graham and Smart [15] lattice attack, the authors recover a 160-bit ECDSA private key from standardized curve secp160r1.

Brumley and Tuveri [7] attack ECDSA with binary curves in OpenSSL 0.9.8o. Mounting a remote timing attack, the authors show the library's Montgomery Ladder scalar multiplication implementation leaks timing information on the MSBs of the nonce used and after collecting that information over 8,000 TLS handshakes a 162-bit NIST B-163 private key can be recovered with lattice methods.

Benger et al. [4] target OpenSSL's *w*NAF implementation and 256-bit private keys for the standardized GLV curve [11] secp256k1 used in the BitCoin protocol. Using as few as 200 ECDSA signatures and the FLUSH+RELOAD technique [28], the authors find some LSBs of the nonces and extend the lattice technique of [21, 22] to use a varying amount of leaked bits rather than limiting to a fixed number.

van de Pol et al. [27] attack OpenSSL's 1.0.1e *w*NAF implementation for the curve secp256k1. Leveraging the structure of the modulus n, the authors use more information leaked in consecutive sequences of bits anywhere in the top half of the nonces, allowing them to recover the secret key after observing as few as 25 ECDSA signatures.

Allan et al. [2] improve on previous results by using a performance-degradation attack to amplify the side-channel. This amplification allows them to additionally observe the sign bit of digits in the *w*NAF representation used in OpenSSL 1.0.2a and to recover secp256k1 private keys after observing only 6 signatures.

Fan et al. [10] increase the information extracted from each signature by analyzing the *w*NAF implementation in OpenSSL. Using the curve secp256k1 as a target, they perform a successful attack after observing as few as 4 signatures.

Our work differs from previous ECDSA side-channel attacks in two important ways. (1) We focus on NIST standard curve P-256, featured in ubiquitous security standards such as TLS and SSH. Later in Section 2.5, we explain the reason previous works were unable to target this extremely relevant curve. (2) We do not target the scalar-by-point multiplication operation (i.e. the bottleneck of the signing algorithm), but instead Step 3 of the signing algorithm, the modular inversion operation.

2.3 The FLUSH+RELOAD Attack

The FLUSH+RELOAD technique is a cache-based side-channel attack technique targeting the Last-Level Cache (LLC) and used during our attack. FLUSH+RELOAD is a high resolution, high accuracy and high signal-to-noise ratio technique that positively identifies accesses to specific memory lines. It relies on cache sharing between processes, typically achieved through the use of shared libraries or page de-duplication.

Input: Memory Address *addr*.
Result: True if the victim accessed the address.

```
begin
    flush(addr)
    Wait for the victim.
    time ← current_time()
    tmp ← read(addr)
    readTime ← current_time() - time
    return readTime < threshold
```

Figure 1: FLUSH+RELOAD Attack

A round of attack, depicted in Figure 1, consists of three phases: (1) The attacker evicts the target memory line from the cache. (2) The attacker waits some time so the victim has an opportunity to access the memory line. (3) The attacker measures the time it takes to reload the memory line. The latency measured in the last step tells whether or not the memory line was accessed by the victim during the second step of the attack, i.e. identifies cache-hits and cache-misses.

The FLUSH+RELOAD attack technique tries to achieve the best resolution possible while keeping the

error rate low. Typically, an attacker encounters multiple challenges due to several processor optimizations and different architectures. See [2, 24, 28] for discussions of these challenges.

2.4 Binary Extended Euclidean Algorithm

The modular inversion operation is one of the most basic and essential operations required in public key cryptography. Its correct implementation and constant-time execution has been a recurrent topic of research [1, 3, 8].

A well known algorithm used for modular inversion is the Euclidean Extended Algorithm and in practice is often substituted by a variant called the *Binary Extended Euclidean Algorithm (BEEA)* [18, Chap. 14.4.3]. This variant replaces costly division operations by simple right-shift operations, thus, achieving performance benefits over the regular version of the algorithm. BEEA is particularly efficient for very long integers—e.g. RSA, DSA, and ECDSA operands.

```
Input: Integers k and p such that gcd(k, p) = 1.
Output: k^{-1} mod p.
v ← p, u ← k, X ← 1, Y ← 0
while u ≠ 0 do
    while even(u) do
        u ← u/2                          /* u loop */
        if odd(X) then X ← X + p
        X ← X/2
    while even(v) do
        v ← v/2                          /* v loop */
        if odd(Y) then Y ← Y + p
        Y ← Y/2
    if u ≥ v then
        u ← u − v
        X ← X − Y
    else
        v ← v − u
        Y ← Y − X
return Y mod p
```

Figure 2: Binary Extended Euclidean Algorithm.

Figure 2 shows the BEEA. Note that in each iteration only one u or v while-loop is executed, but not both. Additionally, in the very first iteration only the u while-loop can be executed since v is a copy of p which is a large prime integer n for ECDSA.

In 2007, independent research done by Aciiçmez et al. [1], Aravamuthan and Thumparthy [3] demonstrated side-channel attacks against the BEEA. Aravamuthan and Thumparthy [3] attacked BEEA using Power Analysis attacks, whereas Aciiçmez et al. [1] attacked BEEA through Simple Branch Prediction Analysis (SBPA), demonstrating the fragility of this algorithm against side-channel attacks.

Both previous works reach the conclusion that in order to reveal the value of the nonce k, it is necessary to identify four critical input-dependent branches leaking information, namely:

1. Number of right-shift operations performed on v.
2. Number of right-shift operations performed on u.
3. Number and order of subtractions $u := u - v$.
4. Number and order of subtractions $v := v - u$.

Moreover, both works present a BEEA reconstruction algorithm that allows them to fully recover the nonce k—and therefore the secret signing key—given a perfect side-channel trace that distinguish the four critical branches.

Aravamuthan and Thumparthy [3] argue that a countermeasure to secure BEEA against side-channel attacks is to render u and v subtraction branches indistinguishable, thus the attack is computationally expensive to carry out. As a response, Cabrera Aldaya et al. [8] demonstrated a Simple Power Analysis (SPA) attack against a custom implementation of the BEEA. The authors' main contribution consists of demonstrating it is possible to partially determine the order of subtractions on branches u and v only by knowing the number of right-shift operations performed in every while-loop iteration. Under a perfect SPA trace, the authors use an algebraic algorithm to determine a short execution sequence of u and v subtraction branches.

They manage to recover various bits of information for several ECDSA key sizes. The authors are able to recover information only from some but not all of their SPA traces by using their algorithm and the partial information about right-shift and subtraction operations. Finally, using a lattice attack they recover the secret signing key.

As can be seen from the previous works, depending on the identifiable branches in the trace and quality of the trace it is possible to recover full or partial information about the nonce k. Unfortunately, the information leaked by most of the real world side-channels does not allow us to differentiate between subtraction branches u and v, therefore limiting the leaked information to three input-dependent branches:

1. Number of right-shift operations performed on v.
2. Number of right-shift operations performed on u.
3. Number of subtractions.

2.5 OpenSSL History

OpenSSL has a rich and storied history as a prime security attack target [19], a distinction ascribed to the li-

brary's ubiquitous real world application. One of the main contributions of our work is identifying a new OpenSSL vulnerability described later in Section 3. To understand the nature of this vulnerability and facilitate root cause analysis, in this section we give a brief overview of side-channel defenses in the OpenSSL library, along with some context and insight into what prompted these code changes. Table 1 summarizes the discussion.

0.9.7. Side-channel considerations started to induce code changes in OpenSSL starting with the 0.9.7 branch. The RSA cache-timing attack by Percival [23] recovered secret exponent bits used as lookup table indices in sliding window exponentiation using an EVICT+RELOAD strategy on HyperThreading architectures. His work prompted introduction of the `BN_FLG_CONSTTIME` flag, with the intention of allowing special security treatment of BIGNUMs having said flag set. At the time—and arguably still—the most important use case of the flag is modular exponentiation. Introduced alongside the flag, the `BN_mod_exp_mont_consttime` function is a fixed-window modular exponentiation algorithm featuring data cache-timing countermeasures. Recent research brings the security of this solution into question [29].

0.9.8. The work by Aciiçmez et al. [1] targeting BEEA prompted the introduction of the `BN_mod_inverse_no_branch` function, an implementation with more favorable side-channel properties than that of BEEA. The implementation computes modular inversions in a way that resembles the classical extended Euclidean algorithm, calculating quotients and remainders in each step by calling `BN_div` updated to respect the `BN_FLG_CONSTTIME` flag. Tracking callers to `BN_mod_inverse`, the commit[1] enables the `BN_FLG_CONSTTIME` across several cryptosystems where the modular inversion inputs were deemed security critical, notably the published attack targeting RSA.

1.0.1. Based on the work by Käsper [16], the 1.0.1 branch introduced constant-time scalar multiplication implementations for several popular elliptic curves. This code change was arguably motivated by the data cache-timing attack of Brumley and Hakala [6] against OpenSSL that recovered digits of many ECDSA nonces during scalar multiplication on HyperThreading architectures using the EVICT+RELOAD strategy. This information was then used to construct a lattice problem and calculate ECDSA private keys. The commit[2] included several new `EC_METHOD` implementations, of which arguably `EC_GFp_nistp256_method` has the most real world application to date. This new scalar multiplication implementation uses fixed-window combing combined with secure table lookups via software multiplexing (masking), and is enabled with the `ec_nistp_64_gcc_128` option at build time. For example, Debian 8.0 "Jessie" (current LTS, not EOL) and 7.0 "Wheezy" (previous LTS, not EOL) and Ubuntu 14.04 "Trusty" (previous LTS, not EOL) enable said option when possible for their OpenSSL 1.0.1 package builds. From the side-channel attack perspective, we note that this change is the reason academic research (see Section 2.2) shifted to the secp256k1 curve—NIST P-256 no longer takes the generic *w*NAF scalar multiplication code path like secp256k1.

Table 1: OpenSSL side-channel defenses across versions. Although `BN_mod_exp_mont_consttime` was introduced in the 0.9.7 branch, here we are referring to its use for modular inversion via FLT.

OpenSSL version	0.9.6	0.9.7	0.9.8	1.0.0	1.0.1	1.0.2
`BN_mod_inverse`	✓	✓	✓	✓	✓	✓
`BN_FLG_CONSTTIME`	—	✓	✓	✓	✓	✓
`BN_mod_inverse_no_branch`	—	—	✓	✓	✓	✓
`ec_nistp_64_gcc_128`	—	—	—	—	✓	✓
`BN_mod_exp_mont_consttime`	—	—	—	—	—	✓
`EC_GFp_nistz256_method`	—	—	—	—	—	✓

1.0.2. Motivated by performance and the potential to utilize Intel AVX extensions, a contribution by Gueron and Krasnov [14] included fast and secure curve P-256 operations with their custom `EC_GFp_nistz256_method`. Here we focus on a cherry picked commit[3] that affected the ECDSA sign code path for all elliptic curves. While speed motivated the contribution, Möller observes[4]: "It seems that the `BN_MONT_CTX`-related code (used in `crypto/ecdsa` for constant-time signing) is entirely independent of the remainder of the patch, and should be considered separately." Gueron confirms: "The optimization made for the computation of the modular inverse in the ECDSA sign, is using const-time modexp. Indeed, this is independent of the rest of the patch, and it can be used independently (for other usages of the library). We included this addition in the patch for the particular usage in ECDSA." Hence following this code change, ECDSA signing for all curves now compute modular inversion via `BN_mod_exp_mont_consttime` and Fermat's Little Theorem (FLT).

3 A New Vulnerability

From Table 1, starting with 1.0.1 the reasonable expectation is that cryptosystems utilizing P-256 resist timing attacks, whether they be remote, data cache, instruction

[1] https://github.com/openssl/openssl/commit/bd31fb21454609b125ade1ad569ebcc2a2b9b73c

[2] https://github.com/openssl/openssl/commit/3e00b4c9db42818c621f609e70569c7d9ae85717

[3] https://github.com/openssl/openssl/commit/8aed2a7548362e88e84a7feb795a3a97e8395008

[4] https://rt.openssl.org/Ticket/Display.html?id=3149&user=guest&pass=guest

cache, or branch predictor timings. We focus here on the combination of ECDSA and P-256 within the library. The reason this is a reasonable expectation is that ec_nistp_64_gcc_128 provides constant-time scalar multiplication to protect secret scalar nonces, and BN_mod_inverse_no_branch provides microarchitecture attack defenses when inverting these nonces. For ECDSA, these are the two most critical locations where the secret nonce is an operand—to produce r and s, respectively.

The vulnerability we now disclose stems from the changes introduced in the 0.9.8 branch. The BN_mod_inverse function was modified to first check the BN_FLG_CONSTTIME flag of the BIGNUM operands—if set, the function then early exits to BN_mod_inverse_no_branch to protect the security-sensitive inputs. If the flag is not set, i.e. inputs are not secret, the control flow continues to the stock BEEA implementation.

Paired with this code change, the next task was to identify callers to BN_mod_inverse within the library, and enable the BN_FLG_CONSTTIME flag for BIGNUMs in cryptosystem implementations that are security-sensitive. Our analysis suggests this was done by searching the code base for uses of the BN_FLG_EXP_CONSTTIME flag that was replaced with BN_FLG_CONSTTIME as part of the changeset, given the evolution of constant-time as concept within OpenSSL and no longer limited to modular exponentiation. As a result, the code changes permeated RSA, DSA, and Diffie-Hellman implementations, but not ECC-based cryptosystems such as ECDH and ECDSA.

This leaves a gap for 1.0.1 with respect to ECDSA. While ec_nistp_64_gcc_128 provides constant-time scalar multiplication to compute the r component of P-256 ECDSA signatures, the s component will compute modular inverses of security-critical nonces with the stock BN_mod_inverse function, not taking the BN_mod_inverse_no_branch code path. In the end, the root cause is that the ECDSA signing implementation does not set the BN_FLG_CONSTTIME flag for nonces. Scalar multiplication with ec_nistp_64_gcc_128 is oblivious to this flag and always treats single scalar inputs as security-sensitive, yet BN_mod_inverse requires said flag to take the new secure code path.

Figure 3 illustrates this vulnerability running in OpenSSL 1.0.1u. The caller function ecdsa_sign_setup contains the bulk of the ECDSA signing cryptosystem—generating a nonce, computing the scalar multiple, inverting the nonce, computing r, and so on. When control flow reaches callee BN_mod_inverse, inputs a and n are the nonce and generator order, respectively. Stepping by instruction, it shows that the call to BN_mod_inverse_no_branch never takes place, since the BN_FLG_CONSTTIME flag is not set for either of these operands. Failing this security critical branch, the control flow continues to the stock, classical BEEA implementation.

Figure 3: Modular inversion within OpenSSL 1.0.1u (built with ec_nistp_64_gcc_128 enabled) for P-256 ECDSA signing. Operands a and n are the nonce and generator order, respectively. The early exit to BN_mod_inverse_no_branch never takes place, since the caller ecdsa_sign_setup fails to set the BN_FLG_CONSTTIME flag on the operands. Control flow continues to the stock, classical BEEA implementation.

3.1 Forks

OpenSSL is not the only software library affected by this vulnerability. Following HeartBleed, OpenBSD forked OpenSSL to LibreSSL in July 2014, and Google forked OpenSSL to BoringSSL in June 2014. We now discuss this vulnerability within the context of these two forks.

LibreSSL. An 04 Nov 2016 commit[5] cherry picked the EC_GFp_nistz256_method for LibreSSL. Interestingly, LibreSSL is the library most severely affected by this vulnerability. The reason is they did not cherry pick the BN_mod_exp_mont_consttime ECDSA nonce inversion. That is, as of this writing (fixed during disclosure) the current LibreSSL master branch can feature constant-time P-256 scalar multiplication with either EC_GFp_nistz256_method or EC_GFp_nistp256_method callees depending on compile-time options and minor code changes, but inverts all ECDSA nonces with

[5] https://github.com/libressl-portable/openbsd/commit/85b48e7c232e1dd18292a78a266c95dd317e23d3

the BN_mod_inverse callee that fails the same security critical branch as OpenSSL, due to the caller ecdsa_sign_setup not setting the BN_FLG_CONSTTIME flag for ECDSA signing nonces. We confirmed the vulnerability using a LibreSSL build with debug symbols, checking the inversion code path with a debugger.

BoringSSL. An 03 Nov 2015 commit[6] picked up the EC_GFp_nistz256_method implementation for BoringSSL. That commit also included the BN_mod_exp_mont_consttime ECDSA nonce inversion callee, which OpenSSL cherry picked. The parent tree[7] is slightly older on the same day. Said tree features constant-time P-256 scalar multiplication with callee EC_GFp_nistp256_method, but inverts ECDSA signing nonces with callee BN_mod_inverse that fails the same security critical branch, again due to the BN_FLG_CONSTTIME flag not being set by the caller—i.e. it follows essentially the same code path as OpenSSL. We verified the vulnerability affects said tree using a debugger.

4 Exploiting the Vulnerability

Exploiting the vulnerability and performing our cache-timing attack is a long and complex process, therefore the analysis details are decomposed in several subsections. Section 4.1 discusses the hardware and software setup used during our experimentation phase. Section 4.2 analyzes and describes the sources of leakage in OpenSSL and the exploitation techniques. Section 4.3 and Section 4.4 describe in detail our improvements on the performance degradation technique and key recovery, respectively. Figure 4 gives an overview of the attack scenario followed during our experiments.

4.1 Attack Setup

Our attack setup consists of an Intel Core i5-2400 Sandy Bridge 3.10GHz (32 nm) with 8GB of memory running 64-bit Ubuntu 16.04 LTS “Xenial”. Each CPU core has an 8-way 32KB L1 data cache, an 8-way 32KB L1 instruction cache, an 8-way 256KB L2 unified cache, and all the cores share a 12-way 6MB unified LLC (all with 64B cache lines). It does not feature HyperThreading.

We built OpenSSL 1.0.1u with debugging symbols on the executable. Debugging symbols facilitate mapping source code to memory addresses, serving a double purpose to us: (1) Improving our degrading attack (see Section 4.3); (2) Probing the sequence of operations accurately. Note that debugging symbols are not loaded during run time, thus not affecting victim’s performance. Attackers can map source code to memory addresses by using reverse engineering techniques [9] if debugging symbols are not available. We set enable-ec_nistp_64_gcc_128 and shared as configuration options at build time to ensure faster execution, constant-time scalar multiplication and compile OpenSSL as a shared object.

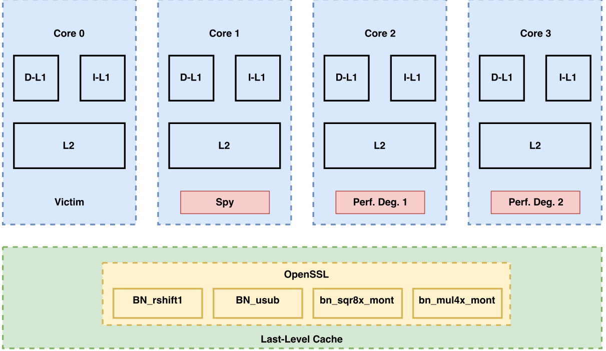

Figure 4: Simplified attack scenario depicting a victim, a spy and two performance degradation processes each running on a different core. OpenSSL is a shared library and all the processes have a shared LLC.

4.2 Source of Leakage

As seen in the Figure 3 backtrace, when performing an ECDSA digital signature, OpenSSL calls ecdsa_sign_setup to prepare the required parameters and compute most of the actual signature. The random nonce k is created and to avoid possible timing attacks [7] an equivalent fixed bit-length nonce is computed. The length of the equivalent nonce $\hat{k}$ is fixed to one bit more than that of the group’s prime order n, thus the equivalent nonce satisfies $\hat{k} = k + \gamma \cdot n$ where $\gamma \in \{1,2\}$.

Additionally, ecdsa_sign_setup computes the signature’s r using a scalar multiplication function pointer wrapper (i.e. for P-256, traversing the constant-time code path instead of generic wNAF) followed by the modular inverse k^{-1}, needed for the s component of the signature. To compute the inversion, it calls BN_mod_inverse, where the BN_FLG_CONSTTIME flag is checked but due to the vulnerability discussed in Section 3 the condition fails, therefore proceeding to compute k^{-1} using the classical BEEA.

Note that before executing the BEEA, the equivalent nonce $\hat{k}$ is unpadded through a modular reduction operation, resulting in the original nonce k and voiding the fixed bit-length countermeasure applied shortly before by ecdsa_sign_setup.

The goal of our attack is to accurately trace and re-

cover side-channel information leaked from the BEEA execution, allowing us to construct the sequence of right-shift and subtraction operations. To that end, we identify the routines used in the `BN_mod_inverse` method leaking side-channel information.

The `BN_mod_inverse` method operates with very large integers, therefore it uses several specific routines to perform basic operations with BIGNUMs. Addition operations call the routine `BN_uadd`, which is a wrapper for `bn_add_words`—assembly code performing the actual addition. Two different routines are called to perform right-shift operations. The `BN_rshift1` routine performs a single right-shift by one bit position, used on X and Y in their respective loops. The `BN_rshift` routine receives the number of bit positions to shift right as an argument, used on u and v at the end of their respective loops. OpenSSL keeps a counter for the shift count, and the loop conditions test u and v bit values at this offset. This is an optimization allowing u and v to be right-shifted all at once in a single call instead of iteratively. Additionally, subtraction is achieved through the use of the `BN_usub` routine, which is a pure C implementation.

Similar in spirit to previous works [4, 24, 27] that instead target other functionality within OpenSSL, we use the FLUSH+RELOAD technique to attack OpenSSL's BEEA implementation. As mentioned before in Section 2.4, unfortunately the side-channel and the algorithm implementation do not allow us to efficiently probe and distinguish the four critical input-dependent branches, therefore we are limited to knowing only the execution of addition, right-shift and subtraction operations.

After identifying the input-dependent branches in OpenSSL's implementation of the BEEA, using the FLUSH+RELOAD technique we place probes in code routines `BN_rshift1` and `BN_usub`. These two routines provide the best resolution and combination of probes, allowing us to identify the critical input-dependent branches.

The modular inversion is an extremely fast operation and only a small fraction of the entire digital signature. It is challenging to get good resolution and enough granularity with the FLUSH+RELOAD technique due to the speed of the technique itself, therefore, we apply a variation of the performance degradation attack to slow down the modular inversion operation by a factor of ~18. (See Section 4.3.)

Maximizing performance degradation by identifying the best candidate memory lines gives us the granularity required for the attack. Combining the FLUSH+RELOAD technique with a performance degradation attack allows us to determine the number of right-shift operations executed between subtraction calls by the BEEA. From the trace, we reconstruct the sequence of right-shift and subtraction operations (*LS sequence*) executed by the BEEA.

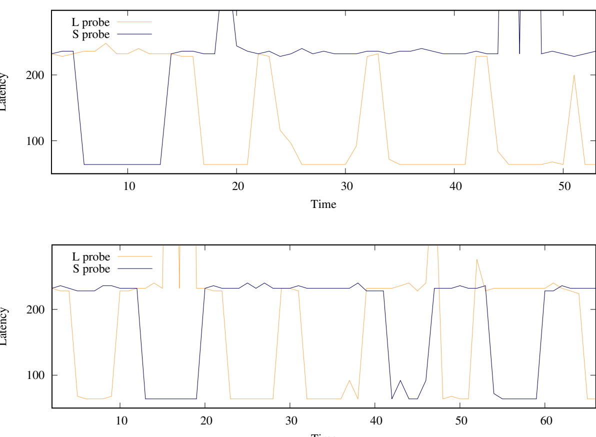

Figure 5: Raw traces for the beginning of two BEEA executions. The L probe tracks right-shift latencies and the S probe tracks subtraction. Latency is in CPU clock cycles. For visualization, focus on the amplitude valleys, i.e. low latency. Top: LS sequence starting SLLLL corresponds to $j = 5$, $\ell_i = 4$, $a_i = 1$. Bottom: LS sequence starting LSLLSLS corresponds to $j = 7$, $\ell_i = 5$, $a_i = 10$. See Section 4.4 for notation.

As Figure 4 illustrates, our attack scenario exploits three CPU cores by running a malicious process in every core and the victim process in the fourth core. The attack consists of a spy process probing the right-shift and subtraction operations running in parallel with the victim application. Additionally, two degrading processes slow down victim's execution, allowing us to capture the LS sequence almost perfectly. Unfortunately there is not always a reliable indicator in the signal for transitions from one right-shift operation to the next, therefore we estimate the number of adjacent right-shift operations by taking into account the latency and the horizontal distance between subtractions. Figure 5 contains sample raw traces captured in our test environment.

Our spy process accurately captures all the subtraction operations but duplicates some right-shift operations, therefore we focus on the first part of the sequence to recover a variable amount of bits of information from every trace. (See Section 4.4.)

4.3 Improving Performance Degradation

Performance degradation attacks amplify side-channel signals, improving the quality and the amount of information leaked. Our performance degradation attack improves upon the work of Allan et al. [2]. In their work, the authors first need to identify "hot" memory addresses, i.e. memory addresses frequently accessed. They suggest two approaches to find suitable memory lines to degrade. The first approach is to read and under-

stand the victim code in order to identify frequently accessed code sections such as tight loops. This approach requires understanding the code, a task that might not always be possible, takes time and it is prone to errors [26], therefore the authors propose another option.

The second and novel approach they propose is to automate code analysis by collecting code coverage information using the gcov tool. The code coverage tool outputs accessed code lines and then using this information it is possible for an attacker to locate the memory lines corresponding to the code lines. Some caveats of this approach are that source lines can be replicated due to compiler optimizations, thus the gcov tool might misreport the number of memory accesses. Moreover, code lines containing function calls can be twice as effective compared to the gcov output. In addition to the caveats mentioned previously, we note that the gcov profiling tool adds instrumentation to the code. The instrumentation skews the performance of the program, therefore this approach is suboptimal since it requires building the target code twice, one with instrumentation to identify code lines and other only with debugging symbols to measure the real performance.

Once the "hot" memory addresses are identified, the next step is to evict them from the cache in a tight loop, thus increasing the execution time of the process accessing those addresses. This technique allows to stealthily degrade a process without alerting the victim, since the increased execution time is not noticeable by a typical user. Performance degradation attacks have been used previously in conjunction with other side-channel attacks (see e.g. [24]).

We note that it can be difficult and time consuming to identify the "hot" memory addresses to degrade that result in the best information leak. To that end, we follow a similar but faster and more quantitative approach, potentially more accurate since it leverages additional metrics. Similar to [2] we test the efficiency of the attack for several candidate memory lines. We compare cache-misses between a regular modular inversion and a degraded modular inversion execution, resulting in a list of the "hottest" memory lines, building the code only once with debugging symbols and using hardware register counters.

The perf command in Linux offers access to performance counters—CPU hardware registers counting hardware events (e.g. CPU cycles, instructions executed, cache-misses and branch mispredictions). We execute calls to OpenSSL's modular inverse operation, counting the number of cache-misses during a regular execution of the operation. Next, we degrade—by flushing in a loop from the cache—one memory line at a time from the caller BN_mod_inverse and callees BN_rshift1, BN_rshift, BN_uadd, bn_add_words, BN_usub.

The perf command output gives us the real count of cache-misses during the regular execution of BN_mod_inverse, then under degradation of each candidate memory line. This effectively identifies the "hottest" addresses during a modular inverse operation with respect to both the cache and the actual malicious processes we will use during the attack.

Table 2 summarizes the results over 1,000 iterations of a regular modular inversion execution versus the degradation of different candidate memory lines identified using our technique. The table shows cache-miss rates ranging from ~35% (BN_rshift and BN_usub) to ~172% (BN_rshift1) for one degrading address. Degrading the overall 6 "hottest" addresses accessed by the BN_mod_inverse function results in an impressive cache-miss rate of ~1,146%.

Interestingly, the last column of Table 2 reveals the real impact of cache-misses in the execution time of the modular inversion operation. Despite the impressive cache-miss rates, the clock cycle slow down is more modest with a maximum slow down of ~18. These results suggest that in order to get a quality trace, the goal is to achieve an increased rate of cache-misses rather than a CPU clock cycle slow down because whereas the cache-misses suggest a CPU clock cycle slow down, it is not the case for the opposite direction.

The effectiveness of the attack varies for each use case and for each routine called. Some of the routines iterate over internal loops several times (e.g. BN_rshift1) whereas in some other routines, iteration over internal loops happens few times (e.g. BN_usub) or none at all. Take for example previous "hot" addresses from Table 2—degrading the most used address from each routine does not necessarily give the best result. Overall "hottest" addresses in Table 2 shows the result of choosing the best strategy for our use case, where the addresses degraded in every routine varies from multiple addresses per routine to no addresses at all.

For our use case, we observe the best results with 6 degrading addresses across two degrading processes executing in different CPU cores. Additional addresses do not provide any additional slow down, instead they impact negatively the FLUSH+RELOAD technique.

4.4 Improving Key Recovery

Arguably the most significant contribution of [8] is they show the LS sequence is sufficient to extract a certain number of LSBs from nonces, even when it is not known whether branch u or v gets taken. They give an algebraic method to recover these LSBs, and utilize these partial nonce bits in a lattice attack, using the formalization in [21, 22]. The disadvantage of that approach is that it fixes the number of known LSBs (denoted ℓ) per equation [8,

Table 2: perf cache-misses and CPU clock cycle statistics over $1,000$ iterations for relevant routines called by the BN_mod_inverse method.

Target	Cache misses (*CM*)	Clock cycles (*CC*)	$\frac{CM}{CM_{BL}}$	$\frac{CC}{CC_{BL}}$
Baseline (*BL*)	13	211,324	1.0	1.0
BN_rshift1	2,396	947,925	172.6	4.4
BN_usub	489	364,399	35.2	1.7
BN_mod_inverse	956	540,357	68.9	2.5
BN_uadd	855	485,088	61.6	2.2
bn_add_words	1,124	558,839	81.0	2.6
BN_rshift	514	367,929	37.0	1.7
Previous "hot"	10,280	2,576,360	740.5	12.1
Overall "hottest"	15,910	3,817,748	1,146.2	18.0

Sec. 5]: "when a set of signatures are collected such that, for each of them, [ℓ] bits of the nonce are known, a set of equations ... can be obtained and the problem of finding the private key can be reduced to an instance of the [HNP]." Fixing ℓ impacts their results in two important ways. First, since their lattice utilizes a fixed ℓ, they focus on the ability to algebraically recover only a fixed number of bits from the LS sequence. From [8, Tbl. 1], our target implementation is similar to their "Standard-M0" target, and they focus on $\ell \in \{8,12,16,20\}$. For example, to extract $\ell = 8$ LSBs they need to query on average 4 signatures, discarding all remaining signatures that do not satisfy $\ell \geq 8$. Second, this directly influences the number of signatures needed in the lattice phase. From [8, Tbl. 2-3], for 256-bit n and $\ell = 8$, they require 168 signatures. This is because they are discarding three out of four signatures on average where $\ell < 8$, then go on to construct a $d+1$-dimension lattice where $d = 168/4 = 42$ from the signatures that meet the $\ell \geq 8$ restriction. The metric of interest from the attacker perspective is the number of required signatures.

In this section, we improve with respect to both points—extracting a varying number of bits from every nonce, subsequently allowing our lattice problem to utilize every signature queried, resulting in a significantly reduced number of required signatures.

Extracting nonce bits. Rather than focusing on the average number of required signatures as a function of a number of target LSBs, our approach is to examine the average number of bits extracted as a function of LS sequence length. We empirically measured this quantity by generating β_i uniformly at random from $\{1\,..\,n-1\}$ for P-256 n, running the BEEA on β_i and n to obtain the ground truth LS sequence, and taking the first j operations from this sequence. We then grouped the β_i by these length-j subsequence values, and finally determined the maximal shared LSBs value of each group. Intuitively, this maps any length-j subsequence to a known LSBs value. For example, a sequence beginning LLS has $j = 3$, $\ell = 3$, $a = 4$ interpreted as a length-3 subsequence that leaks 3 LSBs with a value of 4.

We performed 2^{26} trials (i.e. $1 \leq i \leq 2^{26}$) for each length $1 \leq j \leq 16$ independently and Figure 6 contains the results (see Table 6 in the appendix for the raw data). Naturally as the length of the sequence grows, we are able to extract more bits. But at the same time, in reality for practical side-channels longer sequences are more likely to contain trace errors (i.e. incorrectly inferred LS sequences), ultimately leading to nonsensical lattice problems for key recovery. So we are looking for the right balance between these two factors. Figure 6 allows us to draw several conclusions, including but not limited to: (1) Sequences of length 5 or more allow us to extract a minimum of 3 nonce bits per signature; (2) Similarly length 7 or more for a minimum of 4 nonce bits; (3) The average number of bits extracted grows rapidly at first, then the growth slows as the sequence length increases. This observation pairs nicely with the nature of side-channels: attempting to target longer sequences (risking trace errors) only marginally increases the average number of bits extracted. From the lattice perspective, $\ell \geq 3$ is a practical requirement [21, Sec. 4.2] so in that respect sequences of length 5 is the minimum to guarantee that every signature can be used as an equation for the lattice problem.

To summarize, the data used to produce Figure 6 allows us to essentially build a dictionary that maps LS sequences of a given length to an (ℓ_i, a_i) pair, which we now define and utilize.

Recovering private keys. We follow the formalization of [21, 22] with the use of per-equation ℓ_i due to [4, Sec. 4]. Extracted from our side-channel, we are left with equations $k_i = 2^{\ell_i} b_i + a_i$ where ℓ_i and a_i are known, and since $0 < k_i < n$ it follows that $0 \leq b_i \leq n/2^{\ell_i}$. Denote $\lfloor x \rfloor_n$ modular reduction of x to the interval $\{0\,..\,n-1\}$ and $|x|_n$ to the interval $\{-(n-1)/2\,..\,(n-1)/2\}$. Define the following (attacker-known) values.

$$t_i = \lfloor r_i/(2^{\ell_i} s_i) \rfloor_n$$
$$\hat{u}_i = \lfloor (a_i - h_i/s_i)/2^{\ell_i} \rfloor_n$$

It now follows that $0 \leq \lfloor \alpha t_i - \hat{u}_i \rfloor_n < n/2^{\ell_i}$. Setting

$$u_i = \hat{u}_i + n/2^{\ell_i+1}, \text{ we obtain}$$
$$v_i = |\alpha t_i - u_i|_n \leq n/2^{\ell_i+1},$$

i.e. integers λ_i exist such that $|\alpha t_i - u_i - \lambda_i n| \leq n/2^{\ell_i+1}$ holds. The u_i approximate αt_i since they are closer than a uniformly random value from $\{1\,..\,n-1\}$, leading to an instance of the HNP [5]: recover α given many (t_i, u_i) pairs.

Consider the rational $d+1$-dimension lattice gener-

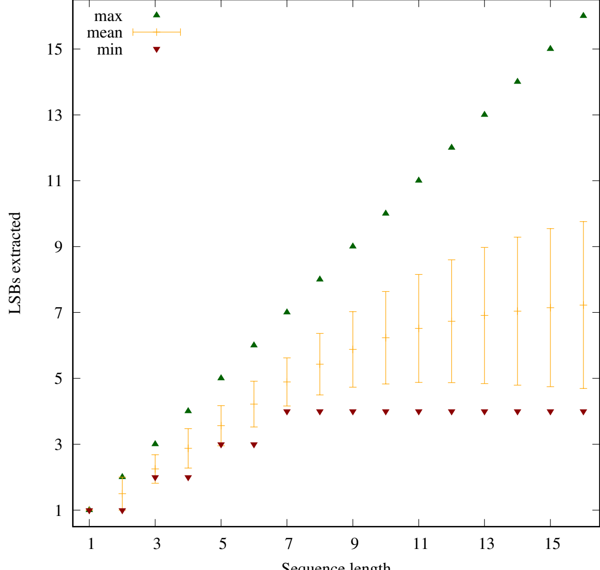

Figure 6: Empirical number of extracted bits for various sequence lengths. Each sequence length consisted of 2^{26} trials, over which we calculated the mean (with deviation), maximum, and minimum number of recovered LSBs. Error bars are one standard deviation on each side. See Table 6 in the appendix for the raw data.

ated by the rows of the following matrix.

$$B = \begin{bmatrix} 2^{\ell_1+1}n & 0 & \dots & \dots & 0 \\ 0 & 2^{\ell_2+1}n & \ddots & \vdots & \vdots \\ \vdots & \ddots & \ddots & 0 & \vdots \\ 0 & \dots & 0 & 2^{\ell_d+1}n & 0 \\ 2^{\ell_1+1}t_1 & \dots & \dots & 2^{\ell_d+1}t_d & 1 \end{bmatrix}$$

Setting

$$\vec{x} = (\lambda_1, \dots, \lambda_d, \alpha)$$
$$\vec{y} = (2^{\ell_1+1}v_1, \dots, 2^{\ell_d+1}v_d, \alpha)$$
$$\vec{u} = (2^{\ell_1+1}u_1, \dots, 2^{\ell_d+1}u_d, 0)$$

establishes the relationship $\vec{x}B - \vec{u} = \vec{y}$. Solving the CVP with inputs B and $\vec{u}$ yields $\vec{x}$ and hence α. We use the embedding strategy [13, Sec. 3.4] to heuristically reduce CVP approximations to Shortest Vector Problem (SVP) approximations. Consider the rational $d+2$-dimension lattice generated by the rows of the following matrix.

$$\hat{B} = \begin{bmatrix} B & 0 \\ \vec{u} & n \end{bmatrix}$$

There is a reasonable chance that lattice-reduced $\hat{B}$ will contain the short lattice basis vector $(\vec{x}, -1)\hat{B} = (\vec{y}, -n)$, revealing α. To extend the search space, we use the randomization technique inspired by Gama et al. [12, Sec. 5], shuffling the order of t_i and u_i and multiplying by a random sparse unimodular matrix between lattice reductions.

Empirical results. Table 3 contains our empirical results for various lattice parameters targeting P-256. As part of our experiments, we were able to successfully reproduce and verify the $\ell \in \{8, 12\}$, $\lg n \approx 256$ lattice results of Cabrera Aldaya et al. [8] in our environment for comparison. While the goal is to minimize the number of required signatures, this should be weighed with observed HNP success probability, affecting search duration. From Figure 6 we focus on LS subsequence lengths $j \in \{5, 7\}$ that yield ℓ_i nonce LSBs from ranges $\{3..5\}$ and $\{4..7\}$, respectively. Again this is in contrast to [8] that fixes ℓ and discards signatures—this is the reason their signature count is much higher than the $d+2$ lattice dimension in their case, but equal in ours.

A relevant metric affecting success probability is the total number of known nonce bits for each HNP instance. Naturally as this sum approaches $\lg n$ one expects correct solutions to start emerging. On the other hand, increasing this sum demands querying more signatures, at the same time increasing d and lattice methods become less precise. For a given HNP instance, denote $l = \sum_{i=1}^{d} \ell_i$, i.e. the total number of known nonce bits over all the equations for the particular HNP instance. Table 3 denotes μ_l the mean value of l over all successful HNP instances—intuitively tracking how many known nonce bits needed in total to reasonably expect success.

We ran 200 independent trials for each set of parameters on a computing cluster with Intel Xeon X5650 nodes. We allowed each trial to execute at most four hours, and we say successful trials are those HNP instances recovering the private key within this allotted time. Our lattice implementation uses Sage software with BKZ [25] reduction, block size 30.

To summarize, utilizing every signature in our HNP instances leads to a significant improvement over previous work with respect to both the number of required signatures and amount of side-channel data required.

5 Attacking Applications

OpenSSL is a shared library and therefore any vulnerability present in it can potentially be exploited from any application linked against it. This is the case for the present work and to demonstrate the feasibility of our attack in a concrete real-life scenario, we focus on two applications implementing two ubiquitous security protocols: TLS within stunnel and SSH within OpenSSH.

OpenSSL provides ECDSA functionality for both applications and therefore we mount our attack against

Table 3: P-256 ECDSA lattice attack improvements for BEEA leakage. Empirical values are over 200 trials (4hr max trial duration). Lattice dimension is $d+2$. The number of leaked LSBs per nonce is ℓ. LS subsequence length is j. The average total number of leaked nonce bits per successful HNP instance is μ_l. CPU time is the median.

Source	Signa-tures	d	ℓ	j	μ_l	Success Rate (%)	CPU Minutes

OpenSSL's ECDSA running within them. More precisely, this section describes the tools and the setup followed to successfully exploit the vulnerability within these applications. In addition, we explain the relevant messages collected for each application, later used for private key recovery together with the trace data and the signatures.

5.1 TLS

Stunnel[8] is a popular portable open source software application that forwards network connections from one port to another and provides a TLS wrapper. Network applications that do not natively support TLS communication benefit from the use of stunnel. More precisely, stunnel can be used to provide a TLS connection between a public port exposing a TLS-enabled network service and a localhost port providing a non-TLS network service. It links against OpenSSL to provide TLS functionality.

For our experiments, we used stunnel 5.39 compiled from stock source and linked against OpenSSL 1.0.1u. We generated a P-256 ECDSA certificate for the stunnel service and chose the `ECDHE-ECDSA-AES128-SHA` TLS 1.2 cipher suite.

In order to collect digital signature and digest tuples, we wrote a custom TLS client that connects to the stunnel service. Our TLS client initiates TLS connections, collects the protocol messages and continues the handshake until it receives the `ServerHelloDone` message, then it drops the connection. The protocol messages contain relevant information for the attack. The `ClientHello` and `ServeHello` messages contain each a 32-byte `random` field, in practice these bytes represent a 4-byte UNIX timestamp concatenated with a 28-byte nonce. The `Certificate` message contains the P-256 ECDSA certificate generated for the stunnel service. The `ServerKeyExchange` message contains ECDH key exchange parameters including the curve type (`named_curve`), the curve name (`secp256r1`) and the `SignatureHashAlgorithm`. Finally, the digital signature itself is sent as part of the `ServerKeyExchange` message. The ECDSA signature is over the concatenated string

```
ClientHello.random + ServerHello.random +
ServerKeyExchange.params
```

and the hash function is SHA-512, proposed by the client in the `ClientHello` message and accepted by the server in the `SignatureHashAlgorithm` field (explicit values `0x06`, `0x03`). Our TLS client saves the hash of the concatenated string and the DER-encoded ECDSA signature sent by the server.

In order to achieve synchronization between the spy and the victim processes, our spy process is launched prior to the TLS handshakes, therefore it collects the trace for each ECDSA signature performed during the handshakes, then it stops when the `ServerHelloDone` message is received. The process is repeated as needed to build up a set of distinct trace, digital signature, and digest tuples. Section 5.3 contains accuracy results for several LS subsequence patterns for an stunnel victim.

5.2 SSH

OpenSSH[9] is a widely used open source software suite to provide secure communication over an insecure channel. OpenSSH is a set of tools implementing the SSH network protocol and it is typically linked against OpenSSL to perform several cryptographic operations, including digital signatures (excluding `ed25519` signatures) and key exchange.

For our experiments, we used OpenSSH 7.4p1 compiled from stock source and linked against OpenSSL 1.0.1u. The ECDSA key pair used by the server and targeted by our attack is the default P-256 key pair generated during installation of OpenSSH.

Following a similar approach to Section 5.1, we wrote a custom SSH client that connects to the OpenSSH server to collect digital signatures and digest tuples. At the same time, our spy process running on the server side collects the timing signals leaked by the server during the handshake.

Relevant to this work, the OpenSSH server was configured with the `ecdsa-sha2-nistp256` host key algorithm and the default P-256 key pair. After the initial `ClientVersion` and `ServerVersion` messages, the protocol defines the Diffie-Hellman key exchange parameters, the signature algorithm and the hash function

Figure 7: ECC SSH handshake flow with corresponding parameters from all the messages to construct the digest. Our spy process collects timing traces in parallel to the server's ECDSA sign operation, said digital signature being included in a SSH_MSG_KEX_ECDH_REPLY field and collected by our client.

identifiers in the SSH_MSG_KEXINIT message. To provide host authentication by the client and the server, a 16-byte random nonce is included in the SSH_MSG_KEXINIT message. The SSH_MSG_KEX_ECDH_REPLY[10] message contains the server's public host key K_S (used to create and verify the signature), server's ECDH ephemeral public key Q_S (used to compute the shared secret K in combination with the client's ECDH ephemeral public key Q_C) and the signature itself. The ECDSA signature is over the hash of the concatenated string

```
ClientVersion + ServerVersion +
Client.SSH_MSG_KEXINIT +
Server.SSH_MSG_KEXINIT +
K_S + Q_C + Q_S + K
```

Our SSH client was configured to use ecdh-sha2-nistp256 and ecdsa-sha2-nistp256 as key exchange and public key algorithms, respectively.

Similar to the previous case, our SSH client saves the hash of the concatenated string and the raw bytes of the ECDSA signature sent by the server. To synchronize the spy and victim processes, our spy process is launched prior to the SSH handshakes and it stops when the SSH_MSG_NEWKEYS message is received, therefore it collects the trace for each ECDSA signature performed during the handshakes. All the protocol messages starting from SSH_MSG_NEWKEYS and any client responses are not required by our attack, therefore the client drops the connection and repeats the process as needed to build up a set of distinct trace, digital signature, and digest tuples. Section 5.3 contains accuracy results for several LS subsequence patterns for an SSH server victim.

5.3 Attack Results

Procurement accuracy. Table 4 and Table 5 show the empirical accuracy results for patterns of length $j = 5$ and $j = 7$, respectively. These patterns represent the beginning of the LS sequence in the context of OpenSSL ECDSA executing in real world applications (TLS via stunnel, SSH via OpenSSH). From our empirical results we note three trends: (1) Similar to previous works [4, 24, 27], the accuracy of the subsequence decreases as ℓ increases due to the deviation in the right-shift operation width. (2) The accuracy also decreases for subsequences containing several contiguous right-shift operations, e.g. first and last rows, due to the variable width of right-shift operations within a single trace. (3) SSH traces are slightly noisier than TLS traces; we speculate this is due to the computation of the ECDH shared secret prior to the ECDSA signature itself. Using our improved degradation technique (Section 4.3) we can recover a with very high probability, despite the speed of the modular inversion operation and the imperfect traces.

Key recovery. We close with a few data points for our end-to-end attack, here focusing on TLS. In this context, end-to-end means all steps from the attacker perspective—i.e. launching the degrade processes,

launching the spy process, and launching our custom TLS client. Finally, repeating these steps to gather multiple trace and signature pairs, then running the lattice attack for key recovery. That is, no steps in the attack chain are abstracted away.

The experiments for Table 3 assume perfect traces. However, as seen in Table 4 and Table 5, while we observe quite high accuracy, in our environment we are unable to realize absolutely perfect traces. Trace errors will occur, and lattice methods have no recourse to compensate for them. We resort to oversampling and randomized brute force search to achieve key recovery in practice.

For the $j = 5$ case, we procured 150 signatures with (potentially imperfect) trace data. Consulting Table 3, we took 400 random subsets of size 80 from this set and ran lattice attack instances on a computing cluster. The first instance to succeed in recovering the private key did so in roughly 8 minutes. Checking the ground truth afterwards, 142 of these original 150 traces were correct, i.e. ~0.18% of all possible subsets are error-free. This successful attack is consistent with the probability $1-(1-0.0018)^{400} \approx 51.4\%$.

Similarly for the $j = 7$ case, we procured 150 signatures with (potentially imperfect) trace data. Consulting Table 3, we took 400 random subsets of size 55 from this set and ran lattice attack instances on a computing cluster. The first instance to succeed in recovering the private key did so in under a minute. Checking the ground truth afterwards, 137 of these original 150 traces were correct, i.e. ~0.19% of all possible subsets are error-free. This successful attack is also consistent with the probability $1-(1-0.0019)^{400} \approx 53.3\%$.

It is worth noting that with this naïve strategy, it is always possible to trade signatures for more offline search effort. Moreover, it is possible to traverse the search space by weighting trace data subsets according to known pattern accuracy, e.g. explore patterns with accuracy $\geq 95\%$ sooner.

6 Conclusion

In this work, we disclose a new vulnerability in widely-deployed software libraries that causes ECDSA nonce inversions to be computed with the BEEA instead of a code path with microarchitecture attack mitigations. We design and demonstrate a practical cache-timing attack against this insecure code path, leveraging our new performance degradation metric. Combined with our improved nonce bits recovery approach and lattice parameterization, this enable us to recover P-256 ECDSA private keys from OpenSSL despite constant-time scalar multiplication. As far as we are aware, this is the first cache-timing attack targeting nonce inversion in OpenSSL, and furthermore the first side-channel attack against cryptosystems leveraging its constant-time P-256 scalar multiplication methods. Our contributions traverse both practice and theory, recovering keys with as few as 50 signatures and corresponding traces.

Stepping back from the concrete side-channel attack we realized here, our improved nonce bit recovery approach coupled with tuned lattice parameters demonstrates that even small leaks of BEEA execution can have disastrous consequences. Observing as few as the first 5 operations in the LS sequence allows every signature to be used as an equation for the lattice problem. Moreover, our work highlights the fact that constant-time considerations are ultimately about the software stack, and not

necessarily a single component in isolation.

The rapid development of cache-timing attacks paired with the need for fast solutions and mitigations led to the inclusion of the `BN_FLG_CONSTTIME` flag in OpenSSL. Over the years, the flag proved to be useful when introducing new constant-time implementations, but unfortunately its usage is now beyond OpenSSL's original design. As new cache-timing attacks emerged, the usage of the flag increased throughout the library. At the same time the programming error probability increased, and many of those errors permeated to forks such as LibreSSL and BoringSSL. The recent exploitation surrounding the flag's usage, this work included, highlights it as a prime example of why failing securely is a fundamental concept in security by design. For example, P-256 takes the constant-time scalar multiplication code path by default, oblivious to the flag, while in stark contrast modular inversion relies critically on this flag being set to follow the code path with microarchitecture attack mitigations.

Following responsible disclosure procedures, we reported the issue to the developers of the affected products after our findings. We lifted the embargo in December 2016. Despite OpenSSL's 1.0.1 branch being a standard package shipped with popular Linux distributions such as Ubuntu (12.04 LTS and 14.04 LTS), Debian (7.0 and 8.0), and SUSE, it reached EOL in January 2017. Backporting security fixes to EOL packages is a necessary and challenging task, and to contribute we provide a patch to mitigate our attack. OpenSSL assigned CVE-2016-7056 based on our work. See the appendix for the patch.

Neural Nets Can Learn Function Type Signatures From Binaries

Abstract

Function type signatures are important for binary analysis, but they are not available in COTS binaries. In this paper, we present a new system called EKLAVYA which trains a recurrent neural network to recover function type signatures from disassembled binary code. EKLAVYA assumes no knowledge of the target instruction set semantics to make such inference. More importantly, EKLAVYA results are "explicable": we find by analyzing its model that it auto-learns relationships between instructions, compiler conventions, stack frame setup instructions, use-before-write patterns, and operations relevant to identifying types directly from binaries. In our evaluation on Linux binaries compiled with `clang` and `gcc`, for two different architectures (x86 and x64), EKLAVYA exhibits accuracy of around 84% and 81% for function argument count and type recovery tasks respectively. EKLAVYA generalizes well across the compilers tested on two different instruction sets with various optimization levels, without any specialized prior knowledge of the instruction set, compiler or optimization level.

1 Introduction

Binary analysis of executable code is a classical problem in computer security. Source code is often unavailable for COTS binaries. As the compiler does not preserve a lot of language-level information, such as types, in the process of compilation, reverse engineering is needed to recover the semantic information about the original source code from binaries. Recovering semantics of machine code is important for applications such as code hardening [54, 34, 53, 26, 52], bug-finding [39, 47, 10], clone detection [18, 38], patching/repair [17, 16, 41] and analysis [12, 22, 21]. Binary analysis tasks can vary from reliable disassembly of instructions to recovery of control-flow, data structures or full functional semantics. The higher the level of semantics desired, the more specialized the analysis, requiring more expert knowledge.

Commercial binary analysis tools widely used in the industry rely on domain-specific knowledge of compiler conventions and specialized analysis techniques for binary analysis. Identifying idioms common in binary code and designing analysis procedures, both principled and heuristic-based, have been an area that is reliant on human expertise, often engaging years of specialized binary analysts. Analysis engines need to be continuously updated as compilers evolve or newer architectures are targeted. In this work, we investigate an alternative line of research, which asks whether we can *train* machines to learn features from binary code directly, without specifying compiler idioms and instruction semantics explicitly. Specifically, we investigate the problem of *recovering function types / signatures* from binary code — a problem with wide applications to control-flow hardening [54, 34, 53] and data-dependency analysis [31, 40] on binaries — using techniques from *deep learning*.

The problem of function type recovery has two subproblems: recovering the *number* of arguments a function takes / produces and their *types*. In this work, we are interested in recovering argument counts and `C`-style primitive data types .[1] Our starting point is a list of functions (bodies), disassembled from machine code, which can be obtained using standard commercial tools or using machine learning techniques [7, 43]. Our goal is to perform type recovery without explicitly encoding any semantics specific to the instruction set being analyzed or the conventions of the compiler used to produce the binary. We restrict our study to Linux x86 and x64 applications in this work, though the techniques presented extend naturally to other OS platforms.

Approach. We use a recurrent neural network (RNN) architecture to learn function types from disassembled

*Lead authors are alphabetically ordered.

[1] `int`, `float`, `char`, `pointers`, `enum`, `union`, `struct`

binary code of functions. The goal is to ascertain if neural networks can effectively learn such types without prior knowledge of the compiler or the instruction set (beyond that implied by disassembly). Admittedly, the process of designing such a system has been experimental or ad-hoc (in our experience), fraught with trial-and-error, requiring sifting through the choice of architectures and their parameters. For instance, we considered designs wherein disassembled code was directly fed as text input, as one-hot encoded inputs, and with various training epoch sizes and network depth. In several cases, the results were unimpressive. In others, while the results were positive, we had little insight into what the model learnt from inputs.

Our guiding principle in selecting a final architecture is its *explicability*: to find evidence whether the learning network could learn something "explainable" or "comparable" to conventions we know which experts and other analysis tools use. To gather evidence on the correctness of a learning network's outputs, we employ techniques to measure its explicability using analogical reasoning, dimensionality reduction (t-SNE visualization plots), and saliency maps. Using these techniques, we select network architectures that exhibit consistent evidence of learning meaningful artifacts. Our resulting system called EKLAVYA automatically learns several patterns arising in binary analysis in general, and function type recovery specifically. At the same time, its constructional design is modular, such that its instruction set specific dependencies are separated from its type recovery tasks. EKLAVYA is the first neural network based systems that targets function signature recovery tasks, and our methodology for explaining its learnt outcomes is more generally useful for debugging and designing such systems for binary analysis tasks.

Results. We have tested EKLAVYA on a testing set consisting of a large number of Linux x86 and x64 binaries, compiled at various optimization levels. EKLAVYA demonstrates several promising results. First, EKLAVYA achieves high accuracy of around 84% for count recovery and has accuracy around 81% for type recovery. Second, EKLAVYA generalizes in a compiler-agnostic manner over code generated from `clang` and `gcc`, and works for the x86 and x64 binaries, with a modest reduction of accuracy with increase in optimization levels. In comparison to previous methods which use knowledge of instruction sets and compiler conventions in their analysis, EKLAVYA has comparable accuracy. Third, EKLAVYA's learnt model is largely "explicable". We show through several analytical techniques which input features the model emphasizes in its decisions. These features match many patterns that are familiar to human analysts and used in existing tools as rules, such as identifying calling conventions, caller- and callee- save registers, stack-based arguments, "use- before-write" instructions, function stack allocation idioms, and many more. All these are derived automatically without any explicit knowledge of the instruction semantics or compiler used.

EKLAVYA's architecture bears resemblance to other neural network architectures that have been successful in natural language processing (NLP) problems such as machine translation, automatic summarization, and sentence-generation. Specifically, we find the use of word-embedding of instructions has been particularly useful in our problem, which is used in NLP problems too. We hypothesize a deeper similarity between (problems arising in) natural language and the language of machine instructions, and consider it worthy of future work.

Contributions. We present EKLAVYA, a novel RNN-based engine that recovers functions types from x86/x64 machine code of a given function. We find in our experimental evaluation that EKLAVYA is *compiler-agnostic* and the same architecture can be used to train for different instruction sets (x86 and x64) without any specification of its semantics. On our x86 and x64 datasets, EKLAVYA exhibits *comparable accuracy* with traditional heuristics-based methods. Finally, we demonstrate that EKLAVYA's learning methods are *explicable*. Our analysis exhibits consistent evidence of identifying instruction patterns that are relevant to the task of analyzing function argument counts and types, lending confidence that it does not overfit to its training datasets or learn unexplained decision criteria. To our knowledge, ours is the first use of techniques such as t-SNE plots, saliency maps, and analogical reasoning to explain neural network models for binary analysis tasks.

2 Problem Overview

Function type recovery involves identifying the number and primitive types of the arguments of a function from its binary code. This is often a sub-step in constructing control-flow graphs and inter-procedural data dependency analysis, which is widely used in binary analysis and hardening tools.

Traditional solutions for function type recovery use such conventions as heuristics for function type recovery, which encode the semantics of all instructions, ABI conventions, compiler idioms, and so on. These are specified apriori in the analysis procedure by human analysts. Consider the example of a function in x64 binary code shown in Figure 1. The example illustrates several conventions that the compiler used to generate the code, such as:

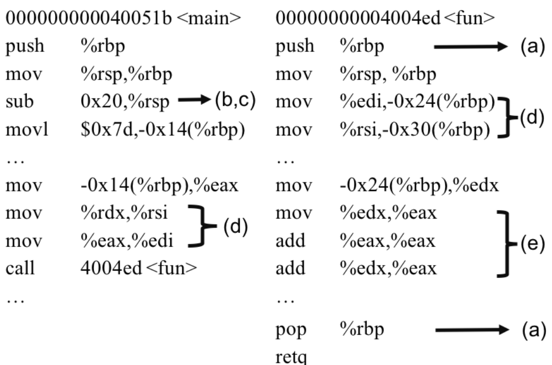

Figure 1: Example assembly code with several idioms and conventions. `(a)` refers to the `push`/`pop` instructions for register save-restore; `(b)` refers to the instruction using `rsp` as a special stack pointer register; `(c)` refers to arithmetic instructions to allocate stack space; `(d)` refers to instructions passing the arguments using specific registers; `(e)` refers to the subsequent use of integer-typed data in arithmetic operations.

(a) the use of `push/pop` instructions for register save-restore;
(b) the knowledge of `rsp` as a special stack pointer register which allocates space for the local frame before accessing arguments;
(c) the use of arithmetic instructions to allocate stack space;
(d) the calling convention (use of specific register, stacks offset for argument passing); and
(e) subsequent use of integer-typed data in arithmetic operations only.

Such conventions or rules are often needed for traditional analysis to be able to locate arguments. Looking one step deeper, the semantics of instructions have to be specified in such analysis explicitly. For instance, recognizing that a particular byte represents a `push` instruction and that it can operate on any register argument. As compilers evolve, or existing analyses are retargeted to binaries from newer instructions sets, analysis tools need to be constantly updated with new rules or target backends. An ideal solution will minimize the use of specialized knowledge or rules in solving the problem. For instance, we desire a mechanism that could be trained to work on any instruction set, and handle a large variety of standard compilers and optimization supported therein.

In this work, we address the problem of function type recovery using a stacked neural network architecture. We aim to develop a system that automatically learns the rules to identify function types directly from binary code, with minimal supervision. Meanwhile, we design techniques to ensure that the learnt model produces explicable results that match our domain knowledge.

Problem Definition. We assume to have the following knowledge of a binary: (a) the boundaries of a function, (b) the boundary of instructions in a function, and (c) the instruction representing a function dispatch (e.g. direct `calls`). All of these steps are readily available from disassemblers, and step (a) has been shown to be learnable directly from binaries using a neural network architecture similar to ours [43]. Step (b) on architectures with fixed-length instructions (e.g. ARM) requires knowing only the instruction length. For variable-length architectures (e.g. x64/x86), it requires the knowledge of instruction encoding sufficient to recover instruction sizes (but nothing about their semantics). Step (c) is a minimalistic but simplifying assumption we have made; in concept, identifying which byte-sequences represent `call` instruction may be automatically learnable as well.

The input to our final model $\mathscr{M}$ is a *target* function for which we are recovering the type signature, and set of functions that call into it. Functions are represented in disassembled form, such that each function is a sequence of instructions, and each instruction is a sequence of bytes. The bytes do not carry any semantic meaning with them explicitly. We define this clearly before giving our precise problem definition.

Let T_a and $T_a[i]$ respectively denote the disassembled code and the ith bytes of a target function a. Then, the kth instruction of function a can be defined as:

$$I_a[k] :=< T_a[m], T_a[m+1], ..., T_a[m+l] >$$

where m is the index to the start byte of instruction $I_a[k]$ and l is the number of bytes in $I_a[k]$. The disassembled form of function a consisting of p instructions is defined as:

$$T_a :=< I_a[1], I_a[2], ..., I_a[p] >$$

With the knowledge of a `call` instruction, we determine the set of functions that call the target function a. If a function b has a direct call to function a, we take all[2] the instructions in b preceding the `call` instruction. We call this a *caller snippet* $C_{b,a}[j]$, defined as:

$$C_{b,a}[j] :=< I_b[0], I_b[1] ... I_b[j-1] >$$

where $I_b[j]$ is a direct `call` to a. If $I_b[j]$ is not a direct `call` to a, $C_{b,a}[j] := \emptyset$. We collect all caller snippets calling a, and thus the input $\mathscr{D}_a$ is defined as:

$$\mathscr{D}_a := T_a \cup \Big(\bigcup_{b \in S_a} \Big(\bigcup_{0 \le j \le |T_b|} C_{a,b}[j] \Big) \Big)$$

where S_a is the set of functions that call a.

[2] In our implementation, we limit the number of instructions to 500 for large functions.

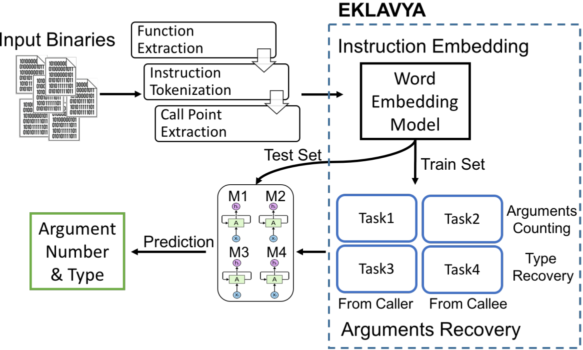

Figure 2: EKLAVYA Architecture. It takes in the binaries as input and performs a pre-processing step on it. Then it performs instruction embedding to produce embedded vectors for train and test dataset. The argument recovery module trains 4 RNN models $M_1, M_2, M_3, M_4$to recover the function argument count and types.

With the above definitions, we are now ready to state our problem definition. Our goal is to learn a model $\mathscr{M}$, which is used to decide two properties for a target function a, from given data $\mathscr{D}_a$, stated below:

Definition. (**Arguments Counts**) The number of arguments passed to function a.

Definition. (**Argument Types**) For each argument of function a, the C-style types defined as:

$$\tau ::= \texttt{int}|\texttt{char}|\texttt{float}|\texttt{void*}|\texttt{enum}|\texttt{union}|\texttt{struct}$$

Note that the above definition gives the inputs and outputs of the model $\mathscr{M}$, which can be queried for a target function. This is called the *test* set. For training the model $\mathscr{M}$, the training set has a similar representation. It consists of the disassembled functions input $\mathscr{D}_a$ as well as labels (the desired outputs) that represent the ground truth, namely the true number and types of each argument. For the training set, we extract the ground truth from the debug symbols generated from source code.

3 Design

EKLAVYA employs neural network to recover argument counts and types from binaries. The overall architecture is shown in Figure 2. EKLAVYA has two primary modules: a) instruction embedding module and an b) argument recovery module. The instruction embedding module learns the *semantics* of instructions by observing their use in our dataset of binaries (from one instruction set). It is possible to have one neural network that does not treat these as two separate substeps. However, in this case, the instruction semantics learnt may well be very specialized to the task of argument recovery. In our design, we train to extract semantics of the instruction set from binaries separately, independent to the task of further analysis at hand. This makes the design modular and allows reusing the embedding module in multiple binary analysis tasks. In addition, instead of keeping the semantics as an implicit internal state, explicitly outputting the semantics allows us to verify the correctness of each step independently. This makes the process of designing and debugging the architecture easier, thus motivating our choice of two modules.

The instruction embedding module takes as input a stream of instructions, represented as symbols. It outputs a vector representation of each instruction in a 256-dimensional space, hence *embedding* the instructions in a vector space. The objective is to map symbol into vectors, such that distances between vectors capture inter-instruction relationships.

Given the instructions represented as vectors, EKLAVYA trains a recurrent neural network (RNN) over the sequence of vectors corresponding to the function body. This is done in the argument recovery module. In some cases, EKLAVYA may only have the target of the function body to analyze, and in others it may have access to a set of callers to the target function. For generality, EKLAVYA trains models for four *tasks* defined below:

(a) **Task1**: Counting arguments for each function based on instructions from the caller;
(b) **Task2**: Counting arguments for each function based on instructions from the callee;
(c) **Task3**: Recovering the type of arguments based on instructions from the caller;
(d) **Task4**: Recovering the type of arguments based on instructions from the callee;

We train one model for each task, over the same outputs of the instruction embedding module. For each instruction set, we learn a different instruction embedding and RNN set. For a function to be tested, the user can use the predictions of any or all of these tasks; our default is to report the output of Task2 for argument counts and Task4 for types since this is analyzable from just the callee's function body (without knowing callers).

3.1 Instruction Embedding Module

The first key step in EKLAVYA is to uncover the semantic information of each instruction through learning. Note that the inputs to our learning algorithm are functions represented as raw binaries, with known boundaries of functions and instructions. In this representation, the

learning algorithm does not have access to any high-level semantics of an instruction. Intuitively, the goal is to infer the semantics of instructions from their *contextual use* in the binary, such as by analyzing which group appears sequentially together or in certain contexts relative to other groups. One general approach to extracting contextual relationships is to employ a technique called *word embedding* [8]. Word embedding in EKLAVYA converts each instruction's raw symbol into a vector. All instructions are thus represented in a high-dimensional space (256 dimensions in our case). Intuitively, the distance between instructions encodes relationships. For instance, the relative distance between the vectors for `push %edi` and `pop %edi` is similar to distance between `push %esi` and `pop %esi`. We demonstrate the kinds of relationships this module learns in Section 5 through examples. In summary, the output of this module is a map from instructions to a 256-dimensional vector.

There are other alternatives to word embedding, which we have considered. One can employ one-hot encoding analogous to a previous work on identifying function boundaries [43]. One could represent the ith instruction by a vector with its ith element as 1 and all other elements set to 0. For example, if there are 5 different instructions, the second instruction is represented as $[0,1,0,0,0]$. However, this technique is computationally inefficient if we expect to learn instruction semantics usable for many different binary analysis tasks, since a separate sub-network will likely be needed to re-learn the relationship between one-hot-encoded vectors for each new analysis task.

For word embedding, we use the skip-gram negative sampling method outlined in the paper that introduces `word2vec` technique for computing word embeddings [27]. The skip-gram is a shallow neural network using the current instruction to predict the instructions around it. Compared to other approaches like continuous bag-of-words (CBOW) technique [27], skip-gram shows better performance on the large-scale dataset and extracts more semantics for each instruction in our experience. To train the word embedding model, we tokenize the hexadecimal value of each instruction and use them as the training input to the embedding model. For example, the symbol or token for the instruction `push %ebp` is its hexadecimal opcode `0x55`. Note that the hexadecimal opcode is used just as a name much like 'john' or 'apple' and bears no numerical effects on the embedding. We train the embedding model for 100 epochs with the learning rate of 0.001.

3.2 Arguments Recovery Module

The function arguments recovery module trains four neural networks, one for each task related to count and type inference. To achieve each task outlined, we train a recurrent neural network (RNN). The input for training the model is the sequence of vectors (each representing an instruction) produced by word embedding, together with labels denoting the number of arguments and types (the ground truth). For argument type recovery, we have several design choices. We could learn one RNN for the first argument, one RNN for the second argument, and so on. Alternatively, we can have one RNN that predicts the type tuple for all the arguments of a function. Presently, we have implemented the first choice, since it alleviates any dependency on counting the number of arguments.

Recurrent Neural Networks. To design the arguments recovery module, we have considered various architectures, like a multilayer perceptron (MLP), a convolutional neural network (CNN) and a recurrent neural network (RNN). We find that an RNN is a suitable choice because it handles variable-length inputs gracefully, and has a notion of "memory". A key difference between feedforward neural networks like a multi-layer perceptron (MLP) and a recurrent neural network (RNN) is that an RNN incorporates the state of the previous input as an additional input to the current time. Effectively, this input represents an internal state that can accumulate the effects of the past inputs, forming a memory for the network. The recurrent structure of the network allows it to handle variable-length input sequences naturally.

In order to deal with the exploding and vanishing gradients during training [9], there are few commonly design options. One could use an LSTM network or use an RNN model with gated recurrent units (GRUs). We use GRUs since it has the control of whether to save or discard previous information and may train faster due to the fewer parameters. We find that an RNN with 3 layers using GRUs is sufficient for our problem.

To avoid overfitting, we use the dropout mechanism, which de-activates the output of a set of randomly chosen RNN cells [48]. This mechanism acts as a stochastic regularization technique. In our design, we experimented with various dropout rates between 0.1 to 0.8. We experimentally find the dropout rate of 0.8, corresponding to randomly dropping 20% of the cell's output, leads to a good result. Our models appeared to overfit with higher dropout rates.

3.3 Data Preprocessing & Implementation

We briefly discuss the remaining details related to preparation of the inputs to EKLAVYA, and its implementation.

The input for EKLAVYA is the disassembly binary code of the target function. To obtain this data, the first step is to identify the function boundaries. Function boundaries identification with minimal reliance of

instruction set semantics is an independent problem of interest. Previous approaches range from traditional machine learning techniques [7] to neural networks [43] to applying function interface verification [35]. In this work, we assume the availability and the correctness of function boundaries for recovering function arguments. To implement this step, we downloaded the dataset Linux packages and compiled them with both `clang` and `gcc` with debugging symbols. The function boundaries, argument counts and types are obtained by parsing the DWARF entries from the binary. Our implementation uses the `pyelftools` which parses the DWARF information [2]; additionally, to extract the argument counts and types, we implemented a Python module with 179 lines of code. We extract the start and end of function boundaries using the standard Linux `objdump` utility [1]. According to Dennis et al. [6], modern disassemblers are highly accurate at performing instruction level recovery for non-obfuscated binaries, especially for binaries generated by `gcc` and `clang`. Thus we use this as the ground truth, ignoring the marginal noise that errors may create in the dataset. After disassembly, we identify call sites and the caller snippets. Our total additional code implementation to perform these steps consists of 1273 lines of Python code.

To train the instruction embedding model and RNNs, we use Google Tensorflow [4]. Our implementation for the instruction embedding and RNN learning is a total of 714 lines of Python code.

4 Explicability of Models

Our guiding principle is to create models that exhibit learning of reasonable decision criteria. To explain what the models learn, we use a different set of techniques for the two parts of EKLAVYA: the instruction embedding model and the learnt RNNs.

4.1 Instruction Embedding

Recall the instruction embedding module learns a mapping between instructions of an architecture to a high-dimensional vector space. Visualizing such large dimensionality vector space is a difficult challenge. To understand these vectors, two common techniques are used — t-SNE [25] plots and analogical reasoning of vectors.

t-SNE Plots. t-SNE is a way to project high-dimensional vectors into a lower dimension one while preserving any neighborhood structures that might exist in the original vector space. Once projected, these can be visualized with scatter plots. Methods such as principal component analysis (PCA) [19] and classical multidimensional scaling [50] use linear transformations to project onto the low dimension space. Though powerful, these techniques often miss important non-linear structure in the data. The primary advantage of t-SNE is that it captures non-linear relationships in the local and global structure of the dataset.[3] For example, if word embedding learns that two instructions are similar, then they will be nearby in the high-dimensional space. t-SNE is expected to preserve this structure in low-dimensional plots, which we can visually analyze to check if it matches our knowledge of instruction semantics and their similarity. Note that t-SNE does not necessarily exhibit all the neighborhood structures that may exist in high- dimensional space, but is a best-effort tool at visualizing relationships.

Analogical Reasoning. Another way to infer relationships between instructions represented as vectors is by *analogical reasoning*. To understand the idea intuitively, we point to how this technique is used in natural language processing tasks. In natural language, analogy question tests the ability to define relationships between words and the understanding of the vocabulary. An analogical question typically consist of two pairs of word, e.g., (“man”, “king”) (“woman”, “queen”). To answer how related the two pairs are, the analogy “man is to king as woman is to queen” is formed of which the validity is tested. The vector offset method proposed by Mikolov et al. [29] frames this using vector arithmetic. The analogical question can be represented as $I_1 - I_2 \approx I_3 - I_4$ where I_1, I_2, I_3 and I_4 are the embedding vectors. Specifically, given the analogical question (“man”, “king”), (“woman”, ?), we can formulate it as $I_3 - I_1 + I_2 \approx I_4$. To get the approximated result, we first compute $d = I_3 - I_1 + I_2$. I_4 is the vector that has the greatest cosine similarity with d. Applying the idea to our problem setting, we can find similar analogies between one pairs of instructions and others. If such analogies match our prior knowledge of certain conventions or idioms that we expect in binary code, we can confirm that EKLAVYA is able to infer these similarities in its instruction embedding representation.

4.2 RNNs for Argument Recovery

We wish to determine for a given test function to an RNN, which instructions the RNN considers as important towards the prediction. If these instruction intuitively correspond to our domain knowledge of instructions that access arguments, then it increases our confidence in the RNN learning the desired decision criteria.

[3] A short primer on its design is presented in the Appendix B for the interested reader.

One way to analyze such properties is to employ saliency maps.

Saliency Map. Saliency maps for trained networks provide a visualization of which parts of an input the network considers important in a prediction. Intuitively, the important part of an input is one for which a minimal change results in a different prediction. This is commonly obtained by computing the gradient of the network's output with respect to the input. In our work, we chose the approach described by Simonyan et al. to obtain the gradient by back-propagation [44]. Specifically, we calculate the derivative of the output of the penultimate layer with respect to each input instruction (which is a vector). This results in a Jacobian matrix. Intuitively, each element in a Jacobian matrix tells us how each dimension of the instruction vector will affect the output of a specific class (a single dimension of the output). In this case, we just want to know how much effect a particular dimension has over the entire output, so we sum the partial derivatives for all elements of the output with respect to the particular input dimension. The result is a 256-dimension vector which tells us the magnitude of change each dimension have over the input. In order for us to visualize our saliency map, we need a scalar representation of the gradient vector. This scalar should represent the relative *magnitude* of change the entire input over the output. As such, we choose to calculate the L2-norm of the gradient vector of each instruction in the function. To keep the value between 0 to 1, we divide each L2-norm with the largest one ($\texttt{max}(L2-norms)$) in the function.

5 Evaluation

Our goal is to experimentally analyze the following:

1. The accuracy in identifying function argument counts and types (Section 5.2); and
2. Whether the trained models learn semantics that match our domain-specific knowledge (Section 5.3).

Our experiments are performed on a server containing 2, 14-core Intel Xeon 2GHz CPUs with 64GB of RAM. The neural network and data processing routines are written in Python, using the Tensorflow platform [4].

5.1 Dataset

We evaluated EKLAVYA with two datasets. The binaries for each dataset is obtained by using two commonly used compilers: *gcc* and *clang*, with different optimization levels ranging from `O0` to `O3` for both x86 and x64. We obtained the ground truth for the function arguments by parsing the `DWARF` debug information [3].

Following the dataset creation procedure used in previous work [43], our first dataset consists of binaries from 3 popular Linux packages: *binutils*, *coreutils* and *findutils* making up 2000 different binaries, resulting from compiling each program with 4 optimization levels (`O0-O3`) using both compilers targeting both instruction sets. For x86 binaries, there are 1,237,798 distinct instructions which make up 274,285 functions. Similarly for x64, there are 1,402,220 distinct instructions which make up 274,288 functions. This dataset has several duplicate functions, and we do not use it to report our final results directly. However, an earlier version of the paper reported on this dataset; for full disclosure, we report results on this dataset in the Appendix.

For our second dataset, we extended the first dataset with 5 more packages, leading to a total of 8 packages: *binutils*, *coreutils*, *findutils*, *sg3utils*, *utillinux*, *inetutils*, *diffutils*, and *usbutils*. This dataset contains 5168 different binaries, resulting from compiling each program with 4 optimization levels (`O0-O3`) using both compilers targeting both instruction sets. For x86 binaries, there are 1,598,937 distinct instructions which constitute 370,317 functions while for x64, there are a total of 1,907,694 distinct instructions which make up 370,145 functions.

Sanitization. For our full (second) dataset, we removed functions which are duplicates of other functions in the dataset. Given that the same piece of code compiled with different binaries will result in different offsets generated, naively hashing the function body is insufficient to identify duplicates. To work around this, we chose to remove all direct addresses used by instructions found in the function. For example, the instruction '`je 0x98`' are represented as '`je `'. After the substitution, we hash the function and remove functions with the same hashes. Other than duplicates, we removed functions with less than four instructions as these small functions typically do not have any operation on arguments.

After sanitation, for x86 binaries, there are 60,061 unique functions in our second dataset. Similarly for x64, there are 59,291 functions. All our final results report on this dataset.

We use separate parts of these datasets for *training* and *testing*. We randomly sample 80% binaries of each package and designate it as the training set; the remaining 20% binaries are used for testing. Note that the training set contains all binaries of one instruction set, compiled with multiple optimization levels from both compilers. EKLAVYA is tasked to generalize from these collectively. The test results are reported on different categories of optimizations within each instruction set, to see the impact of compiler and optimization on EKLAVYA's accuracy.

Imbalanced classes. Our dataset has a different number of samples for different labels or classes. For instance, the pointer datatype is several hundred times more frequent than unions; similarly, functions with less than 3 arguments are much more frequent that those with 9 arguments. We point out that this is a natural distribution of labels in real-world binaries, not an artifact of our choice. Since training and testing on labels with very few samples is meaningless, we do not report our test results on functions with more than 9 arguments for arguments counts recovery, and the "union" and "struct" datatypes here. The overall ratio of these unreported labels totals less than 0.8% of the entire dataset. The label distributions of the training dataset are reported in the rows labeled "data distribution" in Table 1 and Table 2.

5.2 Accuracy

Our first goal is to evaluate the precision, recall, and accuracy of prediction for each of the four tasks mentioned in Section 3. Precision Pc_i and recall Rc_i are used to measure the performance of EKLAVYA for class i and are defined as:

$$Pc_i = \frac{TP_i}{TP_i + FP_i}; Rc_i = \frac{TP_i}{TP_i + FN_i}$$

where TP_i, FP_i and FN_i are the true positive prediction, false positive prediction and false negative prediction of class i respectively.

We evaluate the accuracy of EKLAVYA by measuring the fraction of test inputs with correctly predicted labels in the test set. Readers can check that accuracy Acc can alternatively be defined as:

$$Acc = \sum_{i=1}^{n} P_i \times Rc_i$$

where n is the number of labels in testing set and P_i is the fraction of samples belonging to label i in the test runs. P_i can be seen as an estimate of the occurrence of label i in the real-world dataset and Rc_i is the probability of EKLAVYA labelling a sample as i given that its ground truth is label i.

Given that our training and testing datasets have imbalanced classes, it is helpful to understand EKLAVYA's accuracy w.r.t to the background distribution of labels in the dataset. For instance, a naive classifier that always predicts one particular label i irrespective of the given test input, will have accuracy p_i if the underlying label occurs p_i naturally in the test run. However, such a classifier will have a precision and recall of zero on labels other than i. Therefore, we report both the background data distribution of each label as well as precision and recall to highlight EKLAVYA's efficiency as a classifier.

Findings. Table 1 and Table 2 show the final results over some classes in the test dataset for each task. We have five key findings from these two tables:

(a) EKLAVYA has accuracy of around 84% for count recovery and 81% for type recovery tasks on average, with higher accuracy of over 90% and 80% respectively for these tasks on unoptimized binaries;
(b) EKLAVYA generalizes well across both compilers, `gcc` and `clang`;
(c) EKLAVYA performs well even on classes that occur less frequently, which includes samples with labels occuring as low as 2% times in the training dataset;
(d) In comparison to x86, codename has higher accuracy on x64 for count and type recovery; and,
(e) With increase in optimization levels, the accuracy of EKLAVYA drops on count recovery tasks but stays the same on type recovery tasks.

First, EKLAVYA has higher accuracy on unoptimized functions compared with previous work. The reported accuracy of previous work that uses principled use-def analysis and liveness analysis to count arguments is 78% for callers and 83% for callees [51]. It uses domain-specific heuristics about the calling convention to identify number of arguments — for example, their work mentions that if `r9` is used by a function then the function takes 6 arguments or more. However, EKLAVYA does not need such domain knowledge and obtain higher accuracy for count recovery. For example, the accuracy of EKLAVYA on x86 and x64 are 91.13% and 92.03% respectively from callers, while 92.70% and 97.48% separately from callees. For the task of type recovery, the accuracy of EKLAVYA, averaged for the first three arguments, on x86 and x64 are 77.20% and 84.55% respectively from callers, and 78.18% and 86.77% correspondingly from callees. A previous work on retargetable compilation recovers types without using machine learning techniques; however, a direct comparison is not possible since the reported results therein adopt a different measure of accuracy called conservativeness rate which cannot be translated directly to accuracy [14].

Second, EKLAVYA generalizes well over the choice of two compilers, namely `clang` and `gcc`. The accuracy of count recovery for x86 from callers and callees are 86.22% and 75.49% respectively for `gcc` binaries, and 85.30% and 80.05% for `clang` binaries. Similarly, the accuracy of type recovery (averaged for the first three arguments) on x86 from callers and callees is 80.92% and 79.04% respectively for `gcc` binaries, whereas it is 75.58% and 73.91% respectively for `clang` binaries. Though the average accuracy of `gcc` is slightly higher than `clang`, this advantage does not consistently exhibit across all classes.

Table 1: Evaluation result for argument count recovery from callers and callees for different optimization levels given different architectures. Columns 3-50 report the evaluation result of EKLAVYA on test dataset with different instruction set ranging from O0 to O3. "-" denotes that the specific metric cannot be calculated.

Third, EKLAVYA has high precision and recall on categories that occur relatively less frequently in our dataset. For example, the inputs with 4 arguments only count for around 6% in our training set, whereas the precision and recall of count recovery from callers are around 67% and 78% separately on x86. Similarly, inputs whose first argument is "enum" data type only occupy around 2% over our training set. However, the precision and recall of type recovery are around 76% and 69% from callers on x86.

Fourth, the accuracy of EKLAVYA on x64 is higher than x84. As shown in Table 1, the average accuracy of EKLAVYA for counts recovery task are 1.4% (from callers) and 9.0% (from callees) higher for x64 binaries than x86. Type recovery tasks exhibit a similar finding. Table 2 shows that the accuracy averaged for the task of recovering types for the first, second, and third arguments. EKLAVYA has an average accuracy $3-9\%$ higher for a given task on x64 than of the same task on x86 binaries. This is possibly because x86 has fewer registers, and most argument passing is stack-based in x86. EKLAVYA likely recognizes registers better than stack offsets.

Finally, the accuracy of the model with respect to the optimization levels is dependent on type of task. Optimization levels do *not* have a significant effect on the accuracy of the predictions in type recovery tasks , whereas the EKLAVYA performs better on `O0` than on `O1 - O3` for arguments counts recovery. For example, the accuracy of type recovery for the first argument from callers on `O0 - O3` are nearly the same, which is around 85% on x86. But, the accuracy for count recovery from callers on `x86`, for instance, is 91.13%, which drops to 83.48% when we consider binaries compiled with `O1`. The accuracy for count recovery does not change significantly for optimization levels `O1` to `O3`.

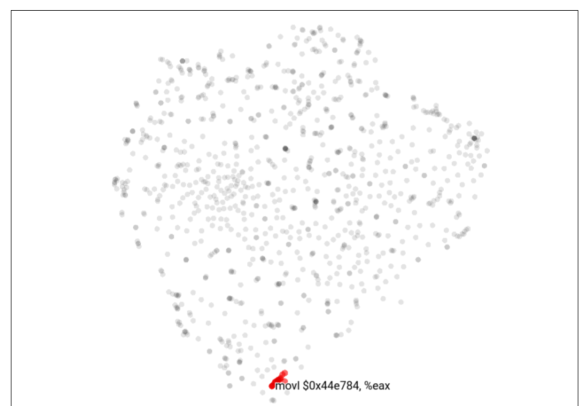

Figure 3: t-SNE visualization of `mov` instructions on x64. Each dot represent one `mov` instruction. Red dots are where Figure 4 is.

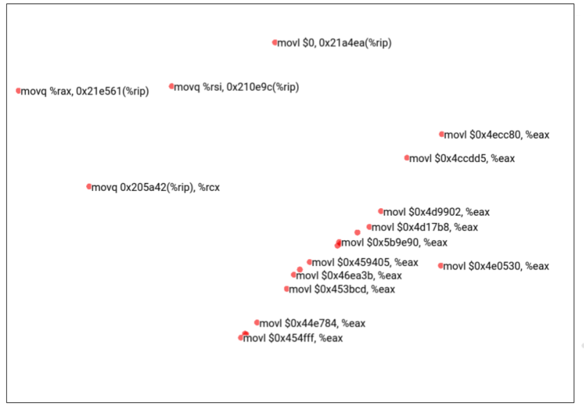

Figure 4: t-SNE visualization of a cluster of `mov $constant, %register` instructions on x64.

5.3 Explicability of Models

Our guiding principle in selecting the final architecture is its explicability. In this section, we present our results from qualitatively analyzing what EKLAVYA learns. We find that EKLAVYA automatically learns the semantics and similarity between instructions or instruction set, the common compiler conventions or idioms, and instruction patterns that differentiate the use of different values. This strengthens our belief that the model learns information that matches our intuitive understanding.

5.3.1 Instruction Semantics Extraction

In this analysis, we employ t-SNE plots and analogical reasoning to understand the relations learned by the word embedding model between instructions.

Semantic clustering of instructions. t-SNE plots allow us to project the points on the 256 dimension space to that of a two-dimensional image giving us a visualization of the clustering. Figure 3 shows one cluster corresponding to `mov` family of instructions, which EKLAVYA learns to have similarity. Due to a large amount of instructions (over a million), a complete t-SNE plot is difficult to analyze. Therefore, we randomly sampled 1000 instructions from the complete set of instructions, and select all instructions belonging to the `mov` family. This family consists of 472 distinct instruction vectors which we project onto a two-dimension space using t-SNE.

Then we "zoom-in" Figure 3 and show two interesting findings. These two findings are shown in Figure 4 and Figure 5. In Figure 4, we recognize `mov $constant, %register` instructions, which indicates that EKLAVYA recognizes the similarity between

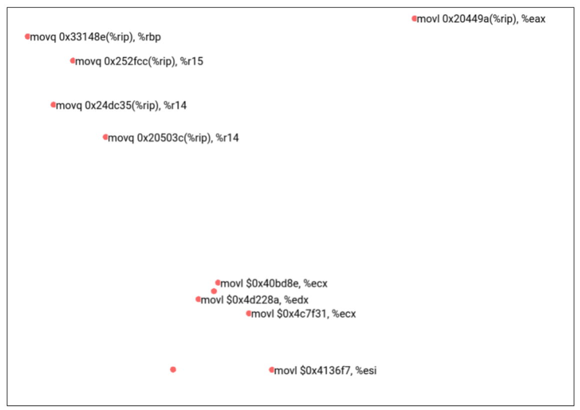

Figure 5: t-SNE visualization of `mov constant(%rip), %register` and `mov $constant, %register` instructions on x64.

all instructions that assign constant values to registers, and abstract out the register. Figure 5 shows that EKLAVYA learns the similar representation for `mov constant(%rip), %register` instructions. These two findings show the local structures that embedding model learned within "mov" family.

Relation between instructions. We use analogical reasoning techniques to find similarity between sets of instructions. In this paper, we show two analogies that our embedding model learned. The first example is that cosine distance between the instructions in the pair (`push %edi`, `pop %edi`) is nearly the same as the distance between instructions in the pair (`push %esi`, `pop %esi`). This finding corresponds to the fact that the use of `push-pop` sequences on one register is analogous to the use of `push-pop` sequences on another register. In essence, this finding shows that the model abstracts away the operand register from the use of `push-pop` (stack operation) instructions on x86/x64. As another example, we find that the distance between the instructions in the pair (`sub $0x30,%rsp`, `add $0x30,%rsp`) and the distance between the pair (`sub $0x20,%rsp`, `add $0x20,%rsp`) is nearly the same. This analysis exhibits that EKLAVYA recognizes that the integer operand can be abstracted away from such sequences (as long the same integer value is used). These instruction pairs are often used to allocate / deallocate the local frame in a function, so we find that EKLAVYA correctly recognizes their analogical use across functions. Due to space reasons, we limit the presented examples to three. In our manual investigation, we find several such semantic analogies that are auto-learned.

Table 3: The relative score of importance generated by saliency map for each instruction from four distinct functions to determine the number of arguments given the whole function.

5.3.2 Auto-learning Conventions

Next, we analyze which input features are considered important by EKLAVYA towards making a decision on a given input. We use the saliency map to score the relative importance of each instruction in the input function. Below, we present our qualitative analysis to identify the conventions and idioms that EKLAVYA auto-learns. For each case below, we compute saliency maps for 20 randomly chosen functions for which EKLAVYA correctly predicts signatures, and inspect them manually.

We find that instructions that are marked as high in relative importance for classification suggest that EKLAVYA auto-learns several important things. We find consistent evidence that EKLAVYA learns calling conventions and idioms, such as the argument passing conventions, "use-before-write" instructions, stack frame allocation instructions, and setup instructions for stack-based arguments to predict the number of arguments accepted by the function. EKLAVYA consistently identifies instructions that differentiate types (e.g. `pointers` from `char`) as important.

Identification of argument registers. We find that the RNN model for counting arguments discovers the specific registers used to pass the arguments. We selected 20 sample functions for which types were correctly predicted, and we consistently find that the saliency map marks instructions processing caller-save and callee-save registers as most important. Consider the function `parse_stab_struct_fields` shown in Table 3

as example, wherein the RNN model considers the instruction `movq %r8, %r13`; `movq %rcx, %r15`; `movq %rdx, %rbx`; `movq %rsi, 0x10(%rsp)` and `movq %rdi, 0x28(%rsp)` as the relatively most important instructions for determining the number of arguments, given the whole function body. This matches our manual analysis which shows that `rdi`, `rsi`, `rdx`, `rcx`, `r8` are used to pass arguments. We show 4 different functions taking different number of arguments as parameters in Table 3. In each example, one can see that the RNN identifies the instructions that first use the incoming arguments as relatively important compared to other instructions.

Further, EKLAVYA seems to correctly place emphasis on the instruction which reads a particular register before writing to it. This matches our intuitive way of finding arguments by identifying "use-before-write" instructions (with liveness analysis). For example, in the function `check_sorted` (Table 3(d)), the register `rcx` is used in a number of instructions. The saliency map marks the most important instruction to be the correct one that uses the register before write. Finally, the function `EmptyTerminal` also shows evidence EKLAVYA is not blindly memorizing register names (e.g. `rcx`) universally for all functions. It correctly de-emphasizes that the instruction `movq %ecx, %eax` is not related to argument passing. In this example, `rcx` has been clobbered before in the instruction `movl $0x10, %ecx` on `rcx` before reaching the `movq` instruction, and EKLAVYA accurately recognizes that `rcx` is not used as an argument here. We have manually analyzed this finding consistently on 20 random samples we analyzed.

Argument accesses after local frame creation. In our analyzed samples, EKLAVYA marks the arithmetic instruction that allocates the local stack frame as relatively important. This is because in the compilers we tested, the access to arguments begins after the stack frame pointer has been adjusted to allocate the local frame. EKLAVYA learns this convention and emphasizes its importance in locating instructions that access arguments (see Table 3).

We highlight two other findings we have confirmed manually. First, EKLAVYA correctly identifies arguments passed on the stack as well. This is evident in 20 functions we sampled from the set of functions that accept arguments on stack, which is a much more common phenomenon in x86 binaries that have fewer registers. Second, the analysis of instructions passing arguments from the body of the caller is nearly as accurate as that from that of callees. A similar saliency map based analysis of the caller's body identifies the right registers and setup of stack-based arguments are consistently marked as relatively high in importance. Due to space reasons, we have not shown the salience maps for these examples here.

(d) "print_icmp_header" compiled with clang-64-O1 (2nd argument - pointer)

Operations to type. With a similar analysis of saliency maps, we find that EKLAVYA learns instruction patterns to identify types. For instance, as shown in examples of Table 4, the saliency map highlights the relative importance of instructions. One can see that instructions that use byte-wide registers (e.g. `dl`) are given importance when EKLAVYA predicts the type to be `char`. This matches our semantic understanding that the `char` type is one byte and will often be used in operands of the corresponding bit-width. Similarly, we find that in cases where EKLAVYA predicts the type to be a `pointer`, the instructions marked as important have indirect register base addressing with the right registers carrying the pointer values. Where `float` is correctly predicted, the instructions highlighted involve XMM registers or floating point instructions. These findings consistently exhibit in our sampled sets, showing that EKLAVYA mirrors our intuitive understanding of the semantics.

5.3.3 Network Mispredictions

We provide a few concrete examples of EKLAVYA mispredictions. These examples show that principled program analysis techniques would likely discern such errors; therefore, EKLAVYA does *not* mimic a full liveness tracking function yet. To perform this analysis, we inspect a random subset of the mispredictions for each of the tasks using the saliency map. In some cases, we can speculate the reasons for mispredictions, though there are best-effort estimates. Our findings are presented in the form of 2 case studies below.

As shown in Table 5, the second argument is mis-

Table 5: x86 multiple type mispredictions for second arguments.

...	

(b) "prompt" compiled with gcc and O0 (number of arguments is 6 but predicted as 7)

predicted as an `integer` in the first example, while in the second case study, the second argument is mispredicted as a `pointer`. From these two examples, it is easy to see how the model has identified instructions which provide hints to what the types are. In both cases, the highlighted instructions suggest possibilities of multiple types and the mispredictions corresponds to one of it. The exact reasons for mispredictions are unclear but this seems to suggest that the model is not robust against situations where there can be multiple type predictions for different argument positions. We speculate that this is due to the design choice of training for each specific argument position a separate sub-network which potentially requires the network to infer calling conventions from just type information.

In the same example as above, the first argument is mispredicted as well. The ground truth states that the first argument is a `pointer`, whereas EKLAVYA predicts an `integer`. This shows another situation where the model makes a wrong prediction, namely when the usage of the argument within the function body provides insufficient hints for the type usage.

We group all mispredictions we have analyzed into three categories: insufficient information, high argument counts and off-by-one errors. A typical example of a misprediction due to lack of information is when the function takes in more arguments than it actually uses. The first example in Table 6 shows an example of it.

Typically, for a functions with high argument counts (greater than 6), the model will highlight the use of `%r9` and some subsequent stack uses. However in example 2 of Table 6, it shows how the model focuses on `%r9` but still made the prediction of an argument count of 7. The lack of training data for such high argument counts may be a reason for lack of robustness.

Off-by-one errors are those in which the network is able to identify instructions which indicate the number of arguments but the prediction is off by one. For example, the network may identify the use of `%rcx` as important but make the prediction that there are 5 arguments instead of 4 arguments. No discernible reason for these has emerged in our analysis.

6 Related Work

Machine Learning on Binaries. Extensive literature exists on applying machine learning for other binaries analysis tasks. Such tasks include malware classification [42, 5, 30, 20, 36, 15] and function identification [37, 7, 43]. The closest related work to ours is by Shin et al. [43], which apply RNNs to the task of function boundary identification. These results have high accuracy, and such techniques can be used to create the inputs for EKLAVYA. At a technical level, our work employs word-embedding techniques and we perform in-depth analysis of the model using dimensionality reduction, analogical reasoning and saliency maps. These analysis techniques have not been used in studying the learnt models for binary analysis tasks. For function identification, Bao et al. [7] utilize weighted prefix trees to improve the efficiency of function identification. Many other works use traditional machine learning techniques such as n-grams analysis [42], SVMs [36], and conditional random fields [37] for binary analysis tasks (different from ours).

Word embedding is a commonly used technique in such tasks, since these tasks require a way to represent words as vectors. These word embeddings can generally be categorized into two approaches, count-based [13, 32] and prediction-based [24, 28]. Neural networks are also frequently used for tasks like language translation [11, 49], parsing [46, 45].

Function Arguments Recovery. In binary analysis, recovery of function arguments [51, 23, 14] is an important component used in multiple problems. Some examples of the tasks include hot patching [33] and fine-grained control-flow integrity enforcement [51]. To summarize, there are two main approaches used to recover the function argument: liveness analysis and heuristic methods based on calling convention and idioms. Veen et. al. [51] in their work make use of both these methods

to obtain the function argument counts. Lee et. al. [23] formulate the usage of different data types in binaries to do type reconstruction. In addition, ElWazeer et al.[14] apply liveness analysis to provide a fine-grained recovery of arguments, variables and their types. A direct comparison to this work is difficult because their work considers a different type syntax than our work. At a high level, EKLAVYA provides a comparable level of accuracy, albeit on more coarse-grained types.

7 Conclusion

In this paper, we present a neural-network-based system called EKLAVYA for addressing function arguments recovery problem. EKLAVYA is compiler and instruction-set agnostic system with comparable accuracy. In addition, we find that EKLAVYA indeed learns the calling conventions and idioms that match our domain knowledge.

A Evaluation on the First Dataset

In this section, we will highlight the importance of having a good dataset. To do this, we will look at the accuracy evaluation using the dataset consisting of only *coreutils*, *binutils* and *findutils*. Table 7 depicts the results of the evaluation. Qualitative analysis of the results remains largely the same. For example, the high median and low minimum F1 indicates that EKLAVYA mis-predicts for some cases of which we have verified that these mis-predicted classes correspond to classes that are under-represented in our training set. However, a key difference we observed is the actual accuracy of the results. The accuracy of the smaller, unsanitized dataset is consistently high even in cases where we expect otherwise. For example, the F1 score for argument counting task is consistently over 0.90 even across optimization levels. We speculate that the difference in the accuracy is due to the presence of similar functions across the binaries. Manual inspection into the dataset confirms that there is indeed significant shared code amongst the binaries skewing the results. We find that it is not uncommon for programs within the same package, or even across packages to share the same static libraries or code. This problem is especially pronounced in binaries within the same package as these binaries typically share common internal routines. Note that this problem exists for binaries between packages too. There have been examples of functions of binaries from different packages having different names but is nearly identical in terms of the binary code. In our paper, we propose a simple method to remove similar functions but a better way of quantifying the similarities can be utilized to generate a more robust dataset. Finally, we hope that this can be built upon into a high quality, publicly available binary dataset where future binary learning approaches can be evaluated on.

B Short Primer on t-SNE

To maintain the neighborhood identity, t-SNE first use the conditional probabilities to represent the euclidean distance between high-dimension dataset. For instance, the similarity between two distinct instruction I_i and I_j is represented as the conditional probability p_{ij}. The conditional probability has following definition:

$$p_{j|i} = \frac{exp(-\left\|I_i - I_j\right\|^2/(2\sigma_i^2))}{\sum_{k\neq i} exp(-\left\|I_i - I_k\right\|^2/(2\sigma_i^2))}$$

$$p_{ij} = \frac{p_{j|i} + p_{i|j}}{2n}$$

where n is the number of data points and σ is the variance of distribution which is centered at each data point x_i. Here, t-SNE determines the value of σ_i by binary search with the given perplexity value.

The perplexity can be considered as the measurement of valid number of neighbors, which is defined as:

$$perplexity(p_i) = x^{H(p_i)}$$

$$H(p_i) == \sum_j p_{j|i} log_2 p_{j|i}$$

The second step is to minimize the difference between the conditional probability between high-dimensional dataset and low-dimensional dataset. For the conditional probability q_{ij} of low-dimensional data point y_i and y_j, t-SNE applies similar method:

$$q_{ij} = \frac{(1 + \left\|y_i - y_j\right\|^2)^{-1}}{\sum_{k\neq m}(1 + \left\|y_k - y_m\right\|^2)^{-1}}$$

Given the conditional probabilities, we can apply gradient descent method to do the minimization task.

Table 7: Evaluation result on the first dataset for count recovery and type recovery tasks from callers and callees for different optimization levels given different architectures.Columns 3-18 report the evaluation result of EKLAVYA on test dataset with different optimization level ranging from O0 to O3. The median, max, and min F1 are calculated over the reported labels, whereas the accuracy is calculated over the whole test set.

Abstract

Rowhammer is a hardware bug that can be exploited to implement privilege escalation and remote code execution attacks. Previous proposals on rowhammer mitigations either require hardware changes or follow heuristic-based approaches (based on CPU performance counters). To date, there exists no instant protection against rowhammer attacks on legacy systems.

In this paper, we present the design and implementation of a practical and efficient software-only defense against rowhammer attacks. Our defense, called CATT, prevents the attacker from leveraging rowhammer to corrupt kernel memory from user mode. To do so, we extend the physical memory allocator of the OS to physically isolate the memory of the kernel and user space. We implemented CATT on x86 and ARM to mitigate rowhammer-based kernel exploits. Our extensive evaluation shows that our mitigation (i) can stop available real-world rowhammer attacks, (ii) imposes virtually no runtime overhead for common user and kernel benchmarks as well as commonly used applications, and (iii) does not affect the stability of the overall system.

1 Introduction

CPU-enforced memory protection is fundamental to modern computer security: for each memory access request, the CPU verifies whether this request meets the memory access policy. However, the infamous rowhammer attack [11] undermines this access control model by exploiting a hardware fault (triggered through software) to flip targeted bits in memory. The cause for this hardware fault is due to the tremendous density increase of memory cells in modern DRAM chips, allowing electrical charge (or the change thereof) of one memory cell to affect that of an adjacent memory cell. Unfortunately, increased refresh rates of DRAM modules – as suggested by some hardware manufacturers – cannot eliminate this effect [3]. In fact, the fault appeared as a surprise to hardware manufacturers, simply because it does not appear during normal system operation, due to caches. Rowhammer attacks repetitively read (*hammer*) from the same physical memory address in very short time intervals which eventually leads to a bit flip in a physically co-located memory cell.

Rowhammer Attack Diversity. Although it might seem that single bit flips are not per-se dangerous, recent attacks demonstrate that rowhammer can be used to undermine access control policies and manipulate data in various ways. In particular, it allows for tampering with the isolation between user and kernel mode [20]. For this, a malicious user-mode application locates vulnerable memory cells and forces the operating system to fill the physical memory with page-table entries (PTEs), i.e., entries that define access policies to memory pages. Manipulating one PTE by means of a bit flip allows the malicious application to alter memory access policies, building a custom page table hierarchy, and finally assigning kernel permissions to a user-mode memory page. Rowhammer attacks have made use of specific CPU instructions to force DRAM access and avoid cache effects. However, prohibiting applications from executing these instructions, as suggested in [20], is ineffective because recent rowhammer attacks do no longer depend on special instructions [3]. As such, rowhammer has become a versatile attack technique allowing compromise of co-located virtual machines [18, 26], and enabling sophisticated control-flow hijacking attacks [6, 19, 22] without requiring memory corruption bugs [4, 7, 20]. Lastly, a recent attack, called Drammer [24], demonstrates that rowhammer is not limited to x86-based systems but also applies to mobile devices running ARM processors.

Rowhammer Mitigation. The common belief is that the rowhammer fault cannot be fixed by means of any

software update, but requires production and deployment of redesigned DRAM modules. Hence, existing legacy systems will remain vulnerable for many years, if not forever. An initial defense approach performed through a BIOS update to increase the DRAM refresh rate was unsuccessful as it only slightly increased the difficulty to conduct the attack [20]. The only other software-based mitigation of rowhammer, we are aware of, is a heuristic-based approach that relies on hardware performance counters [3]. However, it induces a worst-case overhead of 8% and suffers from false positives which impedes its deployment in practice.

Goals and Contributions. The goal of this paper is to develop the first practical software-based defense against rowhammer attacks that can instantly protect existing vulnerable legacy systems without suffering from any performance overhead and false positives. From all the presented rowhammer attacks [4, 7, 17, 18, 20, 24, 26], those which compromise the kernel memory to achieve privilege escalation are the most practical attacks and most challenging to mitigate. Other attacks can be either mitigated by disabling certain system features, or are impractical for real-world attacks: rowhammer attacks on virtual machines [18, 26] heavily depend on *memory deduplication* which is disabled in most production environments by default. Further, the browser attacks shown by Bosman et al. [4] require 15 to 225 minutes. As such, they are too slow for browser attacks in practice. Hence, we focus in this paper on practical kernel-based rowhammer attacks.

We present the design and implementation of a practical mitigation scheme, called CATT, that does not aim to prevent bit flips but rather remove the dangerous effects (i.e., exploitation) of bit flips. This is achieved by limiting bit flips to memory pages that are already in the address space of the malicious application, i.e., memory pages that are per-se untrusted. For this, we extend the operating system kernel to enforce a strong physical isolation of user and kernel space.

In detail, our main contributions are:

- We present a practical software-based defense against rowhammer. In contrast to existing solutions, our defense requires no hardware changes [11], does not deploy unreliable heuristics [3], and still allows legacy applications to execute instructions that are believed to alleviate rowhammer attacks [20].
- We propose a novel enforcement-based mechanism for operating system kernels to mitigate rowhammer attacks. Our design isolates the user and kernel space in physical memory to ensure that the attacker cannot exploit rowhammer to flip bits in kernel memory.
- We present our prototype implementation for the Linux kernel version 4.6, and demonstrate its effectiveness in mitigating all previously presented rowhammer attacks [7, 20].
- We successfully applied our Linux kernel patch for CATT to the Android version 4.4 for Google's Nexus devices. This allows us to also mitigate Drammer [24], a recent rowhammer-based privilege escalation exploit targeting ARM.
- We extensively evaluate the performance, robustness and security of our defense against rowhammer attacks to demonstrate the effectiveness and high practicality of CATT. In particular, our performance measurements indicate no computational overhead for common user and kernel benchmarks.

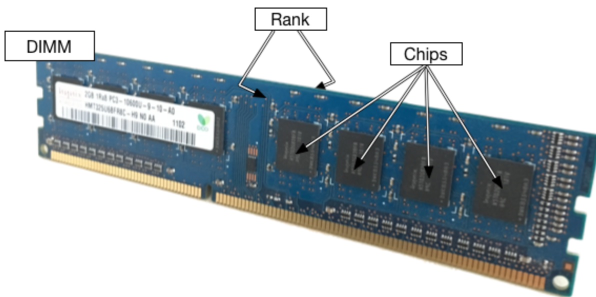

Figure 1: Organization of a DRAM module.

For a more comprehensive version of this paper with other rowhammer defense solutions, options and more technical details we refer to our full technical report available online [5].

2 Background

In this section, we provide the basic background knowledge necessary for understanding the remainder of this paper.

2.1 Dynamic Random Access Memory (DRAM)

A DRAM module, as shown in Figure 1, is structured hierarchically. The hardware module is called Dual Inline Memory Module (DIMM), which is physically connected through a channel to the memory controller. Modern desktop systems usually feature two channels facilitating parallel accesses to memory. The DIMM can be divided into one or two ranks corresponding to its front-

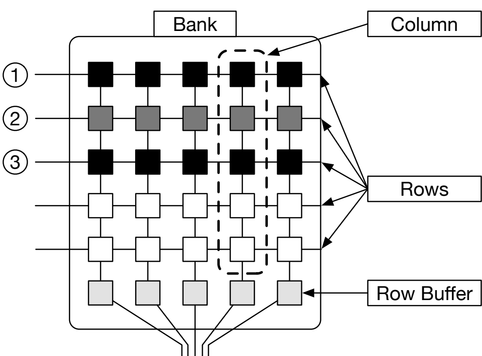

Figure 2: Organization of a Bank.

and backside. Each rank contains multiple chips which are comprised of one or multiple banks that contain the memory cells. Each bank is organized in columns and rows, as shown in Figure 2.

An individual memory cell consists of a capacitor and a transistor. To store a bit in a memory cell, the capacitor is electrically charged. By reading a bit from a memory cell, the cell is discharged, i.e., read operations are destructive. To prevent information loss, read operations also trigger a process that writes the bit back to the cell. A read operation always reads out the bits from a whole row, and the result is first saved in the row buffer before it is then transferred to the memory controller. The row buffer is also used to write back the content into the row of memory cells to restore their content.

It is noteworthy to mention that there exists the mapping between physical memory address and the rank-, bank- and row-index on the hardware module is non-linear. Consequently, two consecutive physical memory addresses can be mapped to memory cells that are located on different ranks, banks, or rows. For example, on Intel Ivy Bridge CPUs the 20th bit of the physical address determines the rank. As such, the consecutive physical addresses 0x2FFFFF and 0x300000 can be located on front and back side of the DIMM for this architecture. The knowledge of the physical memory location on the DIMM is important for both rowhammer attacks and defenses, since bit flips can only occur on the same bank. For Intel processors, the exact mapping is not officially documented, but has been reverse engineered [15, 26].

2.2 Rowhammer Overview and Challenges

As mentioned before, memory access control is an essential building block of modern computer security, e.g., to achieve process isolation, isolation of kernel code and data, and manage read-write-execute permission on memory pages. Modern systems feature a variety of mechanisms to isolate memory, e.g., paging [10], virtualization [1, 9], IOMMU [2], and special execution modes like SGX [10] and SMM [10]. However, these mechanisms enforce their isolation through hardware that mediates the physical memory accesses (in most cases the CPU). Hence, memory assigned to isolated entities can potentially be co-located in physical memory on the same bank. Since a rowhammer attack induces bit flips in co-located memory cells, it provides a subtle way to launch a remote attack to undermine memory isolation.

Recently, various rowhammer-based attacks have been presented [4, 7, 17, 18, 20, 24, 26]. Specifically, rowhammer was utilized to undermine isolation of operating system and hypervisor code, and escape from application sandboxes leveraged in web browsers. As discussed before, only the attacks that perform privilege escalation from user to kernel mode are considered as practical. In the following, we describe the challenges and workflow of rowhammer attacks. A more elaborated discussion on real-world, rowhammer-based exploits will be provided in Section 9.

The rowhammer fault allows an attacker to influence the electrical charge of individual memory cells by activating neighboring memory cells. Kim et al. [11] demonstrate that repeatedly activating two rows separated by only one row, called *aggressor rows* (① and ③ in Figure 2), lead to a bit flip in the enclosed row ②, called *victim row*.[1] To do so, the attacker has to overcome the following challenges: (i) undermine memory caches to directly perform repetitive reads on physical DRAM memory, and (ii) gain access to memory co-located to data critical to memory isolation.

Overcoming challenge (i) is complicated because modern CPUs feature different levels of memory caches which mediate read and write access to physical memory. Caches are important as processors are orders of magnitude faster than current DRAM hardware, turning memory accesses into a bottleneck for applications [25]. Usually, caches are transparent to software, but many systems feature special instructions, e.g., `clflush` or `movnti` for x86 [17, 20], to undermine the cache. Further, caches can be undermined by using certain read-access patterns that force the cache to reload data from physical memory [3]. Such patterns exist, because CPU caches are much smaller than physical memory, and system engineers have to adopt an eviction strategy to effectively utilize caches. Through alternating accesses to addresses which reside in the same cache line, the attacker can force the memory contents to be fetched from physical memory.

The attacker's second challenge (ii) is to achieve the physical memory constellation shown in Figure 2. For this, the attacker needs access to the aggressor rows in

[1] This rowhammer approach is called *double-sided* hammering. Other rowhammer techniques are discussed in Section 8

order to activate (*hammer*) them (rows ① and ③ in Figure 2). In addition, the victim row must contain data which is vulnerable to a bit flip (② in Figure 2). Both conditions cannot be enforced by the attacker. However, this memory constellation can be achieved with high probability using the following approaches. First, the attacker allocates memory hoping that the aggressor rows are contained in the allocated memory. If the operating system maps the attacker's allocated memory to the physical memory containing the aggressor rows, the attacker has satisfied the first condition. Since the attacker has no influence on the mapping between virtual memory and physical memory, she cannot directly influence this step, but she can increase her probability by repeatedly allocating large amounts of memory. Once control over the aggressor rows is achieved, the attacker releases all allocated memory except the parts which contain the aggressor rows. Next, victim data that should be manipulated has to be placed on the victim row. Again, the attacker cannot influence which data is stored in the physical memory and needs to resort to a probabilistic approach. The attacker induces the creation of many copies of the victim data with the goal that one copy of the victim data will be placed in the victim row. The attacker cannot directly verify whether the second step was successful, but can simply execute the rowhammer attack and validate whether the attack was successful. If not, the second step is repeated until the rowhammer successfully executes.

Seaborn et al. [20] successfully implemented this approach to compromise the kernel from an unprivileged user process. They gain control over the aggressor rows and then let the OS create huge amounts of page table entries with the goal of placing one page table entry in the victim row. By flipping a bit in a page table entry, they gained control over a subtree of the page tables allowing them to manipulate memory access control policies.

3 Threat Model and Assumptions

Our threat model is in line with related work [4, 7, 17, 18, 20, 26]:

- We assume that the operating system kernel is not vulnerable to software attacks. While this is hard to implement in practice it is a common assumption in the context of rowhammer attacks.
- The attacker controls a low-privileged user mode process, and hence, can execute arbitrary code but has only limited access to other system resources which are protected by the kernel through mandatory and discretionary access control.
- We assume that the system's RAM is vulnerable to rowhammer attacks. Many commonly used systems (see Table 1) include vulnerable RAM.

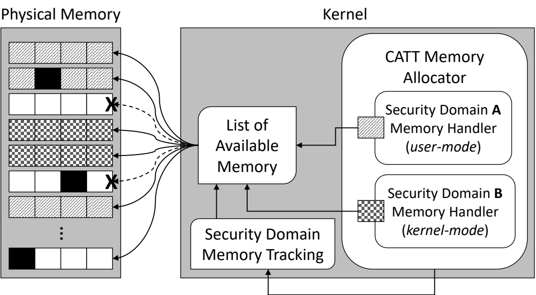

Figure 3: CATT constrains bit flips to the process' security domain.

4 Design of CATT

In this section, we present the high-level idea and design of our practical software-based defense against rowhammer attacks. Our defense, called CATT,[2] tackles the malicious *effect* of rowhammer-induced bit flips by instrumenting the operating system's memory allocator to constrain bit flips to the boundary where the attacker's malicious code executes. CATT is completely transparent to applications, and does not require any hardware changes.

Overview. The general idea of CATT is to tolerate bit flips by confining the attacker to memory that is already under her control. This is fundamentally different from all previously proposed defense approaches that aimed to prevent bit flips (cf. Section 9). In particular, CATT prevents bit flips from affecting memory belonging to higher-privileged *security domains*, e.g., the operating system kernel or co-located virtual machines. As discussed in Section 2.2, a rowhammer attack requires the adversary to bypass the CPU cache. Further, the attacker must arrange the physical memory layout such that the targeted data is stored in a row that is physically adjacent to rows that are under the control of the attacker. Hence, CATT ensures that memory between these two entities is physically separated by at least one row.[3]

To do so, CATT extends the physical memory allocator to partition the physical memory into security domains.

Figure 3 illustrates the concept. Without CATT, the attacker is able to craft a memory layout, where two ag-

[2] CAn't Touch This

[3] Kim et al. [11] mention that the rowhammer fault does not only affect memory cells of directly adjacent rows, but also memory cells of rows that are next to the adjacent row. Although we did not encounter such cases in our experiments, CATT supports multiple row separation between adversary and victim data memory. Further detailed discussion can be found in Section 8.

gressor rows enclose a victim row of a higher-privileged domain such as row ② in Figure 2. With CATT in place, the rows which are controlled by the attacker are grouped into the security domain A, whereas memory belonging to higher-privileged entities resides with their own security domain (e.g., the security domain B). Both domains are physically separated by at least one row which will not be assigned to any security domain.

Security Domains. Privilege escalation attacks are popular and pose a severe threat to modern systems. In particular, the isolation of kernel and user-mode is critical and the most appealing attack target. If a user-space application gains kernel privileges, the adversary can typically compromise the entire system. We define and maintain two security domains: a security domain for kernel memory allocations, and one security domain for user-mode memory allocations (see also Figure 3).

Challenges. The physical isolation of data raises the challenge of how to effectively isolate the memory of different system entities. To tackle this challenge, we first require knowledge of the mapping between physical addresses and memory banks. Since an attacker can only corrupt data within one bank, but not across banks, CATT only has to ensure that security domains of different system entities are isolated within each bank. However, as mentioned in Section 2.1, hardware vendors do not specify the exact mapping between physical address and banks. Fortunately, Pessl et al. [15] and Xiao et al. [26] provide a methodology to reverse engineer the mapping. For CATT, we use this methodology to discover the physical addresses of rows.

We need to ensure that the physical memory management component is aware of the isolation policy. This is vital as the memory management components have to ensure that newly allocated memory is adjacent only to memory belonging to the same security domain. To tackle this challenge, we instrumented the memory allocator to keep track of the domain association of physical memory and serve memory requests by selecting free memory from different pools depending on the security domain of the requested memory.

5 Implementation

Our software-based defense is based on modifications to low-level system software components, i.e., the physical memory allocator of the operating system kernel. In our proof-of-concept implementation of CATT, we focus on hardening Linux against rowhammer-based attacks. We successfully applied the mentioned changes to the x86-kernel version 4.6 and the Android kernel for Nexus devices in version 4.4. We chose Linux as our target OS for our proof-of-concept implementations for two reasons: (1) its source code is freely available, and (2) it is widely used on workstations and mobile devices. In the following we will explain the implementation of CATT's policy enforcement mechanism in the Linux kernel which allows for the partitioning of physical memory into isolated security domains. We note that CATT targets both x86 and ARM-based systems. Until today, rowhammer attacks have only been demonstrated for these two prominent architectures. However, our concept can be applied to other architectures, as well.

The basic idea underlying our software-based rowhammer defense is to physically separate rows that belong to different security domains. Operating systems are not per-se aware of the notions of cells and rows, but rather build memory management based on paging. Commodity operating systems use paging to map virtual addresses to physical addresses. The size of a page varies among architectures. On x86 and ARM, the page size is typically 4096 bytes (4K). As we described in Section 2.1, DRAM hardware consists of much smaller units of memory, i.e., individual memory cells storing single bits. Eight consecutive memory cells represent a byte, 4096 consecutive bytes a page frame, two to four page frames a row. Hence, our implementation of CATT changes low-level components of the kernel to make the operating system aware of the concept of memory rows.

In the following, we describe how we map individual memory pages to domains, keep track of different domains, modify the physical memory allocator, and define partitioning policies for the system's DRAM hardware.

5.1 Mapping Page Frames to Domains

To be able to decide whether two pages belong to the same security domain we need to keep track of the security domain for each page frame. Fortunately, the kernel already maintains meta data about each individual page frame. More specifically, each individual page frame is associated with exactly one meta data object (`struct page`). The kernel keeps a large array of these objects in memory. Although these objects describe physical pages, this array is referred to as *virtual memory map*, or `vmemmap`. The Page Frame Number (PFN) of a physical page is used as an offset into this array to determine the corresponding `struct page` object. To be able to associate a page frame with a security domain, we extend the definition of `struct page` to include a field that encodes the security domain. Since our prototype implementation targets rowhammer attacks that aim at violating the separation of kernel and user-space, we encode security domain 0 for kernel-space, and 1 for user-space.

5.2 Tracking Security Domains

The extension of the page frame meta data objects enables us to assign pages to security domains. However, this assignment is dynamic and changes over time. In particular, a page frame may be requested, allocated, and used by one domain, after it has been freed by another domain. Note that this does not violate our security guarantees, but is necessary for the system to manage physical memory dynamically. Yet, we need to ensure that page frames being reallocated continue to obey our security policy. Therefore, we reset the security domain upon freeing a page.

Upon memory allocation, CATT needs to correctly set the security domain of the new page. To do so, we require information about the requesting domain. For our case, where we aim at separating kernel and user-space domains, CATT utilizes the call site information, which is propagated to the memory allocator by default. Specifically, each allocation request passes a set of flags to the page allocator. These flags encode whether an allocation is intended for the kernel or the user-space. We leverage this information and separate the two domains by setting the domain field of the respective page frame.

When processes request memory, the kernel initially only creates a virtual mapping without providing actual physical page frames for the process. Instead, it only assigns physical memory on demand, i.e., when the requesting process accesses the virtual mapping a page fault is triggered. Thereafter, the kernel invokes the physical page allocator to search for usable pages and installs them under the virtual address the process attempted to access. We modified the page fault handler, which initiates the allocation of a new page, to pass information about the security domain to the page allocator. Next, the page is allocated according to our policy and sets the domain field of the page frame's meta data object to the security domain of the interrupted process.

5.3 Modifying the Physical Page Allocator

The Linux kernel uses different levels of abstraction for different memory allocation tasks. The physical page allocator, called *zoned buddy allocator*, is the main low-level facility handling physical page allocations. It exports its interfaces through functions such as `alloc_pages` which can be used by other kernel components to request physical pages. In contrast to higher-level allocators, the buddy allocator only allows for allocating sets of memory pages with a cardinality which can be expressed as a power of two (this is referred to as the *order* of the allocation). Hence, the buddy allocator's smallest level of granularity is a single memory page. The buddy allocator already partitions the system RAM into different *zones*. We modify the implementation of the physical page allocator in the kernel to include a dedicated memory zone for the kernel. This enables CATT to separate kernel from user pages according to the security domain of the origin of the allocation request. Hence, any requests for kernel pages will be served from the dedicated memory zone. We additionally instrument a range of maintenance checks to make them aware of our partitioning policy before the allocator returns a physical page. If any of these checks fail, the page allocator is not allowed to return the page in question.

5.4 Defining DRAM Partitioning Policies

Separating and isolating different security domains is essential to our proposed mitigation. For this reason, we incorporate detailed knowledge about the platform and its DRAM hardware configuration into our policy implementation. While our policy implementation for a target system largely depends on its architecture and memory configuration, this does not represent a fundamental limitation. Indeed, independent research [15, 26] has provided the architectural details for the most prevalent architectures, i.e., it shows that the physical address to DRAM mapping can be reverse engineered automatically for undocumented architectures. Hence, it is possible to develop similar policy implementations for architectures and memory configurations beyond x86 and ARM. We build on this prior research and leverage the physical address to DRAM mapping information to enforce strict physical isolation. In the following, we describe our implementation of the partitioning strategy for isolating kernel and user-space.

Kernel-User Isolation. To achieve physical separation of user and kernel space we adopt the following strategy: we divide each bank into a top and a bottom part, with a separating row in-between. Page frames for one domain are exclusively allocated from the part that was assigned to that domain. The part belonging to the kernel domain is determined by the physical location of the kernel image.[4] As a result, user and kernel space allocations may be co-located within one bank, but never within adjacent rows.[5] Due to this design memory allocated to the kernel during early boot is allocated from a memory region which is part of the kernel's security domain, hence, the isolation covers *all* kernel memory. Different partitioning policies would be possible in theory: for instance, we could confine the kernel to a certain DRAM

[4] This is usually at 1MB, although Kernel Address Space Layout Randomization (KASLR) may slightly modify this address according to a limited offset.

[5] The exact location for the split can be chosen at compile time. Hence, the partitioning is not fixed but can be chosen arbitrarily (e.g., 20-80, 50-50, 75-25, etc.).

System	Operating System	System Model
S1	Ubuntu 14.04.4 LTS	Dell OptiPlex 7010
S2	Debian 8.2	Dell OptiPlex 990
S3	Kali Linux 2.0	Lenovo ThinkPad x220

Table 1: Model numbers of the vulnerable systems used for our evaluation.

bank to avoid co-location of user domains within a single bank. However, this would likely result in a severe increase of memory latency, since reads and writes to a specific memory bank are served by the bank's row buffer. The benefit of our partitioning policy stems from the fact that we distribute memory belonging to the kernel security domain over multiple banks thereby not negatively impacting performance. Additionally, the bank split between top and bottom could be handled at run time, e.g., by dynamically keeping track of the individual bank-split locations similar to the watermark handling already implemented for different zones in the buddy allocator. In our current prototype, we only need to calculate the row index of a page frame for each allocation request. More specifically, we calculate this index from the physical address (PA) in the following way:

$$Row(PA) := \frac{PA}{PageSize \cdot PagesPerDIMM \cdot DIMMs}$$

Here, we calculate the number of pages per DIMM as $PagesPerDIMM := PagesPerRow \cdot BanksPerRank \cdot RanksPerDIMM$. Because all possible row indices are present once per bank, this equation determines the row index of the given physical address.[6] We note that this computation is in line with the available rowhammer exploits [20] and the reported physical to DRAM mapping recently reverse engineered [15, 26]. Since the row size is the same for all Intel architectures prior to Skylake [7], our implementation for this policy is applicable to a wide range of system setups, and can be adjusted without introducing major changes to fit other configurations as well.

6 Security Evaluation

The main goal of our software-based defense is to protect legacy systems from rowhammer attacks. We tested the effectiveness of CATT on diverse hardware configurations. Among these, we identified three hardware configurations, where we observed many reproducible bit flips. Table 1 and Table 2 lists the exact configurations of the three platforms we use for our evaluation. Our effectiveness evaluation of CATT is based on two attack scenarios. For the first scenario, we systematically search for reproducible bit flips based on a tool published by Gruss et al.[7] Our second attack scenario leverages a real-world rowhammer exploit published by Google's Project Zero.[8] We compared the outcome of both attacks on our vulnerable systems before and after applying CATT. Next, we elaborate on the two attack scenarios and their mitigation in more detail.

6.1 Rowhammer Testing Tool

We use a slightly modified version of the double-sided rowhammering tool, which is based on the original test by Google's Project Zero [20]. Specifically, we extended the tool to also report the aggressor physical addresses, and adjusted the default size of the fraction of physical memory that is allocated for the test. The tool scans the allocated memory for memory cells that are vulnerable to the rowhammer attack. To provide comprehensive results, the tool needs to scan the entire memory of the system. However, investigating the entire memory is hard to achieve in practice since some parts of memory are always allocated by other system components. These parts are therefore not available to the testing tool, i.e., memory reserved by operating system. To achieve maximum coverage, the tool allocates a huge fraction of the available memory areas. However, due to the lazy allocation of Linux the allocated memory is initially not mapped to physical memory. Hence, each mapped virtual page is accessed at least once, to ensure that the kernel assigns physical pages. Because user space only has access to the virtual addresses of these mappings, the tool exploits the `/proc/pagemap` kernel interface to retrieve the physical addresses. As a result, most of the systems physical memory is allocated to the rowhammering tool.

Afterwards, the tool analyzes the memory in order to identify potential victim and aggressor pages in the physical memory. As the test uses the double-sided rowhammering approach two aggressor pages must be identified for every potential victim page. Next, all potential victim pages are challenged for vulnerable bit flips. For this, the potential victim page is initialized with a fixed bit pattern and "hammered" by accessing and flushing the two associated aggressor pages. This ensures that all of the

[6] The default values for DDR3 on x86 are 4K for the page size, 2 pages per row, 8 banks per rank, 2 ranks per DIMM and between 1 and 4 DIMMs per machine. For DDR4 the number of banks per rank was doubled. DDR4 is supported on x86 starting with Intel's Skylake and AMD's Zen architecture.

accesses activate a row in the respective DRAM module. This process is repeated 10^6 times.[9] Lastly, the potential victim address can be checked for bit flips by comparing its memory content with the fixed pattern bit. The test outputs a list of addresses for which bit flips have been observed, i.e., a list of victim addresses.

Preliminary Tests for Vulnerable Systems. Using the rowhammering testing tool we evaluated our target systems. In particular, we were interested in systems that yield reproducible bit flips, as only those are relevant for practical rowhammer attacks. This is because the attack requires two steps. First, the attacker needs to allocate chunks of memory, and test each chunk to identify vulnerable memory. Second, the attacker needs to exploit the vulnerable memory. Since the attacker cannot force the system to allocate page tables at a certain physical position in RAM, the attacker has to repeatedly spray the memory with page tables to increase the chances of hitting the desired memory location. Both steps relay on reproducible bit flips.

Hence, we configured the rowhammering tool to only report memory addresses where bit flips can be triggered repeatedly. We successively confirmed that this list indeed yields reliable bit flips by individually triggering the reported addresses and checking for bit flips within an interval of 10 seconds. Additionally, we tested the bit flips across reboots through random sampling.

The three systems mentioned in Table 1 and Table 2 are highly susceptible to reproducible bit flips. Executing the rowhammer test on these three times and rebooting the system after each test run, we found 133 pages with exploitable bit flips for S1, 31 pages for S2, and 23 pages for S3.

To install CATT, we patched the Linux kernel of each system to use our modified memory allocator. Recall that CATT does not aim to prevent bit flips but rather constrain them to a security domain. Hence, executing the rowhammer test on CATT-hardened systems still locates vulnerable pages. However, in the following, we demonstrate based on a real-world exploit that the vulnerable pages are not exploitable.

6.2 Real-world Rowhammer Exploit

To further demonstrate the effectiveness of our mitigation, we tested CATT against a real-world rowhammer exploit. The goal of the exploit is to escalate the privileges of the attacker to kernel privileges (i.e., gain root access). To do so, the exploit leverages rowhammer to manipulate the page tables. Specifically, it aims to manipulate the access permission bits for kernel memory, i.e., reconfigure its access permission policy. A second option is to manipulate page table entries in such a way that they point to attacker controlled memory thereby allowing the attacker to install new arbitrary memory mappings.[10]

To launch the exploit, two conditions need to be satisfied: (1) a page table entry must be present in a vulnerable row, and (2) the enclosing aggressor pages must be allocated in attacker-controlled memory.

Since both conditions are not directly controllable by the attacker, the attack proceeds as follows: the attacker allocates large memory areas. As a result, the operating system needs to create large page tables to maintain the newly allocated memory. This in turn increases the probability to satisfy the aforementioned conditions, i.e., a page table entry will eventually be allocated to a victim

[9] This value is the hardcoded default value. Prior research [11, 12] reported similar numbers.

[10] The details of this attack option are described by Seaborn et al. [20].

page. Due to vast allocation of memory, the attacker also increases her chances that aggressor pages are co-located to the victim page.

Once the preconditions are satisfied, the attacker launches the rowhammer attack to induce a bit flip in victim page. Specifically, the bit flip modifies the page table entry such that a subtree of the paging hierarchy is under the attacker's control. Lastly, the attacker modifies the kernel structure that holds the attacker-controlled user process privileges to elevate her privileges to the superuser root. Since the exploit is probabilistic, it only succeeds in five out of hundred runs (5%). Nevertheless, a single successful run allows the attacker to compromise the entire system.

Effectiveness of CATT. Our defense mechanism does not prevent the occurrence of bit flips on a system. Hence, we have to verify that bit flips cannot affect data of another security domain. Rowhammer exploits rely on the fact that such a cross domain bit flip is possible, i.e., in the case of our exploit it aims to induce a bit flip in the kernel's page table entries.

However, since the exploit by itself is probabilistic, an unsuccessful attempt does not imply the effectiveness of CATT. As described above, the success rate of the attack is about 5%. After deploying CATT on our test systems, we repeatedly executed the exploit to minimize the probability of the exploit failing due to the random memory layout rather than due to our protection mechanism. We automated the process of continuously executing the exploit and ran this test for 48 h, on all three test systems. In this time frame the exploit made on average 3500 attempts of which on average 175 should have succeeded. However, with CATT, none of the attempts was successful. Hence, as expected, CATT effectively prevents rowhammer-based exploits.

As we have demonstrated, CATT successfully prevents the original attack developed on x86 by physically isolating pages belonging to the kernel from the user-space domain. In addition to that, the authors of the Drammer exploit [24] confirm that CATT prevents their exploit on ARM. The reason is, that they follow the same strategy as in the original kernel exploit developed by Project Zero, i.e., corrupting page table entries in the kernel from neighboring pages in user space. Hence, CATT effectively prevents rowhammer exploits on ARM-based mobile platforms as well.

7 Performance Evaluation

One of our main goals is practicability, i.e., inducing negligible performance overhead. To demonstrate practicability of our defense, we thoroughly evaluated the performance and stability impact of CATT on different benchmark and testing suites. In particular, we used the SPEC CPU2006 benchmark suite [8] to measure the impact on CPU-intensive applications, LMBench3 [14] for measuring the overhead of system operations, and the Phoronix test suite [16] to measure the overhead for common applications. We use the Linux Test Project, which aims at stress testing the Linux kernel, to evaluate the stability of our test system after deploying CATT. We performed all of our performance evaluation on system S2 (cf. Table 2).

7.1 Run-time Overhead

Table 4 summarizes the results of our performance benchmarks. In general, the SPEC CPU2006 benchmarks measure the impact of system modifications on CPU intensive applications. Since our mitigation mainly affects the physical memory management, we did not expect a major impact on these benchmarks. However, since these benchmarks are widely used and well established we included them in our evaluation. In fact, we observe a minimal performance improvement for CATT by 0.49% which we attribute to measuring inaccuracy. Such results have been reported before when executing a set of benchmarks for the same system with the exact same configuration and settings. Hence, we conclude that CATT does not incur any performance penalty.

LMBench3 is comprised of a number of micro benchmarks which target very specific performance parameters, e.g., memory latency. For our evaluation, we focused on micro benchmarks that are related to memory performance and excluded networking benchmarks. Similar to the previous benchmarks, the results fluctuate on average between −0.4% and 0.11%. Hence, we conclude that our mitigation has no measurable impact on specific memory operations.

Finally, we tested the impact of our modifications on the Phoronix benchmarks. In particular, we selected a subset of benchmarks[11] that, on one hand, aim to measure memory performance (IOZone and Stream), and, on the other hand, test the performance of common server applications which usually rely on good memory performance.

To summarize, our rigorous performance evaluation with the help of different benchmarking suites did not yield any measurable overhead. This makes CATT a highly practical mitigation against rowhammer attacks.

[11] The Phoronix benchmarking suite features a large number of tests which cover different aspects of a system. By selecting a subset of the available tests we do not intend to improve our performance evaluation. On the contrary, we choose a subset of tests that is likely to yield measurable performance overhead, and excluded tests which are unrelated to our modification, e.g., GPU or machine learning benchmarks.

Table 4: The benchmarking results for SPEC CPU2006, Phoronix, and LMBench3 indicate that CATT induce no measurable performance overhead. In some cases we observed negative overhead, hence, performance improvements. However, we attribute such results to measuring inaccuracy.

7.2 Memory Overhead

CATT prevents the operating system from allocating certain physical memory.

The memory overhead of CATT is constant and depends solely on number of memory rows per bank. Per bank, CATT omits one row to provide isolation between the security domains. Hence, the memory overhead is $1/\#rows$ ($\#rows$ being rows per bank). While the number of rows per bank is dependent on the system architecture, it is commonly in the order of 2^{15} rows per bank, i.e., the overhead is $2^{-15} \triangleq 0,003\%$.[12]

7.3 Robustness

Our mitigation restricts the operating system's access to the physical memory. To ensure that this has no effect on the overall stability, we performed numerous stress tests with the help of the Linux Test Project (LTP) [13]. These tests are designed to stress the operating system to identify problems. We first run these tests on a vanilla Debian 8.2 installation to receive a baseline for the evaluation of CATT. We summarize our results in Table 5, and report no deviations for our mitigation compared to the baseline. Further, we also did not encounter any problems during the execution of the other benchmarks. Thus, we conclude that CATT does not affect the stability of the protected system.

8 Discussion

Our prototype implementation targets Linux-based systems. Linux is open-source allowing us to implement our defense. Further, all publicly available rowhammer attacks target this operating system. CATT can be easily ported to memory allocators deployed in other operating systems. In this section, we discuss in detail the generality of our software-based defense against rowhammer. For a detailed discussion of possible extensions and additional policies we refer to our technical report [5].

8.1 Applying CATT to Mobile Systems

The rowhammer attack is not limited to x86-based systems, but has been recently shown to also affect the ARM platform [24]. The ARM architecture is predominant in mobile systems, and used in many smartphones and tablets. As CATT is not dependent on any x86 specific properties, it can be easily adapted for ARM based systems. We demonstrate this by applying our extended physical memory allocator to the Android kernel for Nexus devices in version 4.4. Since there are no major deviations in the implementation of the physical page allocator of the kernel between Android and stock Linux kernel, we did not encounter any obstacles during the port.

8.2 Single-sided Rowhammer Attacks

From our detailed description in Section 4 one can easily follow that our proposed solution can defeat all known rowhammer-based privilege escalation attacks in general, and single-sided rowhammer attacks [24] in particular. In contrast to double-sided rowhammer attacks (see Figure 2), single-sided rowhammer attacks relax the adversary's capabilities by requiring that the attacker has control over only one row adjacent to the victim memory row. As described in more detail in Section 4, CATT isolates different security domains in the physical memory. In particular, it ensures that different security domains are separated by at least one buffer row that is never used by the system. This means that the single-sided rowhammer adversary can only flip bits in own memory (that it already controls), or flip bits in buffer rows.

8.3 Benchmarks Selection

We selected our benchmarks to be comparable to the related literature. Moreover, we have done evaluations that go beyond those in the existing work to provide additional insight. Hereby, we considered different evaluation aspects: We executed SPEC CPU2006 to verify that our changes to the operating system impose no overhead of user-mode applications. Further, SPEC CPU2006 is the most common benchmark in the field of memory-corruption defenses, hence, our solutions can be compared to the related work. LMBench3 is specifically designed to evaluate the performance of common system operations, and used by the Linux kernel developers to test whether changes to the kernel affect the performance. As such LMBench3 includes many tests. For our evaluation, we included those benchmarks that perform memory operations and are relevant for our defense. Finally, we selected a number of common applications from the Phoronix test suite as macro benchmarks, as well as the *pts/memory* tests which are designed to measure the RAM and cache performance. For all our benchmarks, we did not observe any measurable overhead (see Table 4).

8.4 Vicinity-less Rowhammering

All previous Rowhammer attacks exploit rows which are physically co-located [4, 7, 20, 24]. However, while Kim et al. [11] suggested that physical adjacency accounts for the majority of possible bit flips, they also noted that this was not always the case. More specifically, they attributed potential aggressor rows with a greater row distance to the *re-mapping* of faulty rows: DRAM manufacturers typically equip their modules with around 2% of spare rows, which can be used to physically replace failing rows by re-mapping them to a spare row [23]. This means, that physically adjacent spare rows can be assigned to arbitrary row indices, potentially undermining our isolation policy. For this, an adversary requires a way of determining pairs of defunct rows, which are re-mapped to physically adjacent spare rows. We note that such a methodology can also be used to adjust our policy implementation, e.g., by disallowing any spare rows to be assigned to kernel allocations. Hence, re-mapping of rows does not affect the security guarantees provided by CATT.

9 Related Work

In this section, we provide an overview of existing rowhammer attack techniques, their evolution, and proposed defenses. Thereafter, we discuss the shortcomings

of existing work on mitigating rowhammer attacks and compare them to our software-based defense.

9.1 Rowhammer Attacks

Kim et al. [11] were the first to conduct experiments and analyze the effect of bit flipping due to repeated memory reads. They found that this vulnerability can be exploited on Intel and AMD-based systems. Their results show that over 85% of the analyzed DRAM modules are vulnerable. The authors highlight the impact on memory isolation, but they do not provide any practical attack. Seaborn and Dullien [20] published the first practical rowhammer-based privilege-escalation attacks using the x86 `clflush` instruction. In their first attack, they use rowhammer to escape the Native Client (NaCl) [27] sandbox. NaCl aims to safely execute native applications by 3rd-party developers in the browser. Using rowhammer malicious developers can escape the sandbox, and achieve remote code execution on the target system. With their second attack, Seaborn and Dullien utilize rowhammer to compromise the kernel from an unprivileged user-mode application. Combined with the first attack, the attacker can remotely compromise the kernel without exploiting any software vulnerabilities. To compromise the kernel, the attacker first fills the physical memory with page-table entries by allocating a large amount of memory. Next, the attacker uses rowhammer to flip a bit in memory. Since the physical memory is filled with page-table entries, there is a high probability that an individual page-table entry is modified by the bit flip in a way that enables the attacker to access other page-table entries, modify arbitrary (kernel) memory, and eventually completely compromise the system. Qiao and Seaborn [17] implemented a rowhammer attack with the x86 `movnti` instruction. Since the `memcpy` function of `libc` – which is linked to nearly all C programs – utilizes the `movnti` instruction, the attacker can exploit the rowhammer bug with code-reuse attack techniques [21]. Hence, the attacker is not required to inject her own code but can reuse existing code to conduct the attack. Aweke et al. [3] showed how to execute the rowhammer attack without using any special instruction (e.g., `clflush` and `movnti`). The authors use a specific memory-access pattern that forces the CPU to evict certain cache sets in a fast and reliable way. They also concluded that a higher refresh rate for the memory would not stop rowhammer attacks. Gruss et al. [7] demonstrated that rowhammer can be launched from JavaScript. Specifically, they were able to launch an attack against the page tables in a recent Firefox version. Similar to Seaborn and Dullien's exploit this attack is mitigated by CATT. Later, Bosman et al. [4] extended this work by exploiting the memory deduplication feature of Windows 10 to create counterfeit JavaScript objects, and corrupting these objects through rowhammer to gain arbitrary read/write access within the browser. In their follow-up work, Razavi et al. [18] applied the same attack technique to compromise cryptographic (private) keys of co-located virtual machines. Concurrently, Xiao et al. [26] presented another cross virtual machine attack where they use rowhammer to manipulate page-table entries of Xen. Further, they presented a methodology to automatically reverse engineer the relationship between physical addresses and rows and banks. Independently, Pessl et al. [15] also presented a methodology to reverse engineer this relationship. Based on their findings, they demonstrated cross-CPU rowhammer attacks, and practical attacks on DDR4. Van der Veen et al. [24] recently demonstrated how to adapt the rowhammer exploit to escalate privileges in Android on smartphones. Since the authors use the same exploitation strategy of Seaborn and Dullien, CATT can successfully prevent this privilege escalation attack. While the authors conclude that it is challenging to mitigate rowhammer in software, we present a viable implementation that can mitigate practical user-land privilege escalation rowhammer attacks.

Note that all these attacks require memory belonging to a higher-privileged domain (e.g., kernel) to be physically co-located to memory that is under the attacker's control. Since our defense prevents direct co-location, we mitigate these rowhammer attacks.

9.2 Defenses against Rowhammer

Kim et al. [11] present a number of possible mitigation strategies. Most of their solutions involve changes to the hardware, i.e., improved chips, refreshing rows more frequently, or error-correcting code memory. However, these solutions are not very practical: the production of improved chips requires an improved design, and a new manufacturing process which would be costly, and hence, is unlikely to be implemented. The idea behind refreshing the rows more frequently (every 32ms instead of 64ms) is that the attacker needs to hammer rows many times to destabilize an adjacent memory cell which eventually causes the bit flip. Hence, refreshing (stabilizing) rows more frequently could prevent attacks because the attacker would not have enough time to destabilize individual memory cells. Nevertheless, Aweke et al. [3] were able to conduct a rowhammer attack within 32ms. Therefore, a higher refresh rate alone cannot be considered as an effective countermeasure against rowhammer. Error-correcting code (ECC) memory is able to detect and correct single-bit errors. As observed by Kim et al. [11] rowhammer can induce multiple bit flips which cannot be detected by ECC memory. Further, ECC memory has an additional space overhead of around 12% and is more

expensive than usual DRAM, therefore it is rarely used.

Kim et al. [11] suggest to use probabilistic adjacent row activation (PARA) to mitigate rowhammer attacks. As the name suggests, reading from a row will trigger an activation of adjacent rows with a low probability. During the attack, the malicious rows are activated many times. Hence, with high probability the victim row gets refreshed (stabilized) during the attack. The main advantage of this approach is its low performance overhead. However, it requires changes to the memory controller. Thus, PARA is not suited to protect legacy systems.

To the best of our knowledge Aweke et al. [3] proposed the only other software-based mitigation against rowhammer. Their mitigation, coined ANVIL, uses performance counters to detect high cache-eviction rates which serves as an indicator of rowhammer attacks [3]. However, this defense strategy has three disadvantages: (1) it requires the CPU to feature performance counters. In contrast, our defense does not rely on any special hardware features. (2) ANVIL's worst-case run-time overhead for SPEC CPU2006 is 8%, whereas our worst-case overhead is 0.29% (see Table 4). (3) ANVIL is a heuristic-based approach. Hence, it naturally suffers from false positives (although the FP rate is below 1% on average). In contrast, we provide a deterministic approach that is guaranteed to stop rowhammer-based kernel-privilege escalation attacks.

10 Conclusion

Rowhammer is a hardware fault, triggered by software, allowing the attacker to flip bits in physical memory and undermine CPU-enforced memory access control. Recently, researchers have demonstrated the power and consequences of rowhammer attacks by breaking the isolation between virtual machines, user and kernel mode, and even enabling traditional memory-corruption attacks in the browser. In particular, rowhammer attacks that undermine the separation of user and kernel mode are highly practical and critical for end-user systems and devices.

Contrary to the common belief that rowhammer requires hardware changes, we show the first defense strategy that is purely based on software. CATT is a practical mitigation that tolerates rowhammer attacks by dividing the physical memory into security domains, and limiting rowhammer-induced bit flips to the attacker-controlled security domain. To this end, we implemented a modified memory allocator that strictly separates memory rows of user and kernel mode. Our detailed evaluation of CATT demonstrates that our defense mechanism prevents all known rowhammer-based kernel privilege escalation attacks while neither affecting the run-time performance nor the stability of the system.

Abstract

Control-Flow Integrity (CFI), as a means to prevent control-flow hijacking attacks, enforces that each instruction transfers control to an address in a set of valid targets. The security guarantee of CFI thus depends on the definition of valid targets, which conventionally are defined as the result of a static analysis. Unfortunately, previous research has demonstrated that such a definition, and thus any implementation that enforces it, still allows practical control-flow attacks.

In this work, we present a path-sensitive variation of CFI that utilizes runtime path-sensitive point-to analysis to compute the legitimate control transfer targets. We have designed and implemented a runtime environment, PittyPat, that enforces path-sensitive CFI efficiently by combining commodity, low-overhead hardware monitoring and a novel runtime points-to analysis. Our formal analysis and empirical evaluation demonstrate that, compared to CFI based on static analysis, PittyPat ensures that applications satisfy stronger security guarantees, with acceptable overhead for security-critical contexts.

1 Introduction

Attacks that compromise the control-flow of a program, such as return-oriented programming [33], have critical consequences for the security of a computer system. Control-Flow Integrity (CFI) [1] has been proposed as a restriction on the control-flow transfers that a program should be allowed to take at runtime, with the goals of both ruling out control-flow hijacking attacks and being enforced efficiently.

A CFI implementation can be modeled as program rewriter that (1) before a target program P is executed, determines feasible targets for each indirect control transfer location in P, typically done by performing an analysis that computes a sound over-approximation of the set of all memory cells that may be stored in each code pointer (i.e., a static *points-to analysis* [2, 34]). The rewriter then (2) rewrites P to check at runtime before performing each indirect control transfer that the target is allowed by the static analysis performed in step (1).

A significant body of work [1, 21, 41] has introduced approaches to implement step (2) for a variety of execution platforms and perform it more efficiently. Unfortunately, the end-to-end security guarantees of such approaches are founded on the assumption that if an attacker can only cause a program to execute control branches determined to be feasible by step (1), then critical application security will be preserved. However, recent work has introduced new attacks that demonstrate that such an assumption does not hold in practice [5, 12, 32]. The limitations of existing CFI solutions in blocking such attacks are inherent to *any* defense that uses static points-to information computed per control location in a program. Currently, if a developer wants to ensure that a program only chooses valid control targets, they must resort to ensure that the program satisfies *data integrity*, a significantly stronger property whose enforcement typically incurs prohibitively large overhead and/or has deployment issues, such as requiring the protected program being recompiled together with all dependent libraries and cannot be applied to programs that perform particular combinations of memory operations [17, 22–24].

In this work, we propose a novel, *path-sensitive* variation of CFI that is stronger than conventional CFI (i.e., CFI that relies on static points-to analysis). A program satisfies path-sensitive CFI if each control transfer taken by the program is consistent with the program's *entire* executed control path. Path-sensitive CFI is a stronger security property than conventional CFI, both in principle and in practice. However, because it does not place any requirements on the correctness of data operations, which happen much more frequently, it can be enforced much more efficiently than data integrity. To demonstrate this, we present a runtime environment, named PittyPat, that enforces path-sensitive efficiently using a combination of

commodity, low-overhead hardware-based monitoring and a new runtime points-to analysis.

PITTYPAT addressed two key challenges in building an efficient path-sensitive CFI solution. The first challenge is how to efficiently collect the path information about a program's execution so as to perform the analysis and determine if the program has taken only valid control targets. Collecting such information is not straightforward for dynamic analysis. An approach that maintains information inside the same process address space of the monitored program (e.g., [17]) must carefully protect the information; otherwise it would be vulnerable to attacks [11]. On the other hand, an approach that maintains information in a separate process address space must efficiently replicate genuine and sufficient data from the monitored program.

The second key challenge is how to use collected information to precisely and efficiently compute the points-to relationship. Niu et al. [26] have proposed leveraging execution history to dynamically activate control transfer targets. However, since the activation is still performed over the statically computed control-flow graph, its accuracy can degrade to the same as pure static-analysis-based approach. We compare PITTYPAT to such approaches in detail in §6.

PITTYPAT applies two key techniques in addressing these two challenges. First, PITTYPAT uses an event-driven kernel module that collects all chosen control-transfer targets from the *Processor Tracing (PT)* feature available on recent Intel processors [31]. PT is a hardware feature that efficiently records conditional and indirect branches taken by a program. While PT was originally introduced to enable detailed debugging through complete tracing, our work demonstrates that it can also be applied as an effective tool for performing precise, efficient program analysis for security.

The second technique is an abstract-interpretation-based incremental points-to analysis. Our analysis embodies two key innovations. First, raw PT trace is highly compressed (see §3 for details). As a result, reconstructing the control-flow (i.e., source address to destination address) itself is time consuming and previous work has utilized multiple threads to reduce the decoding latency [13]. Our insight to solve this problem is to sync up our analysis with the execution, so that our analysis only needs to know what basic blocks being executed, not the control transfer history. Therefore, we can directly map the PT trace to basic blocks using the control-flow graph (CFG). The second optimization is based on the observation that static points-to analyses collect and solve a system of constraints over *all pairs* of pointer variables in the program [2, 15]. While this approach has good throughput, it introduces unacceptable latency for online analysis. At the same time, to enforce CFI, we only need to know the points-to information of code pointers. Based on this observation, our analysis eagerly evaluates control relevant points-to constraints as they are generated.

We implemented PITTYPAT as an instrumenting compiler for the LLVM compiler [20] and a tool for Linux; the instrumenting compiler is an artifact of the current version of our prototype: PITTYPAT does not fundamentally rely on the ability to compile and instrument a target program. To evaluate PITTYPAT, we used it to enforce path-sensitive CFI for a set of security benchmarks developed in independent work. The results demonstrate that PITTYPAT can detect recent attacks on the control flow of benign benchmarks [5], as well as subversion of control flow in programs explicitly crafted to contain control vulnerabilities that are difficult to detect [12, 32]. In common cases where CFI allows a program to choose from tens of control transfer targets, PITTYPAT typically determines that only a *single* target is valid, based on the program's executed control path. On even compute-intensive benchmarks, PITTYPAT incurs reasonable performance overhead: a geometric mean of 12.73% over all SPEC CPU2006 benchmarks, whereas techniques that enforce data integrity incur 122.60%.

The rest of this paper is organized as follows. In §2, we illustrate PITTYPAT by example. In §3, we review previous work on which PITTYPAT is based. In §4, we present the security guarantees that PITTYPAT establishes, and describe the design of PITTYPAT. In §5, we describe the implementation of PITTYPAT in detail. In §6, we present an empirical evaluation of PITTYPAT. In §7, we compare PITTYPAT to related work. In §8, we conclude our work.

2 Overview

In this section, we present PITTYPAT by introducing a running example. In §2.1, we present a program `dispatch` that contains a control-flow vulnerability. In §2.2, we use `dispatch` to illustrate that any defense that enforces conventional CFI allows effective attacks on control-flow. In §2.3, we illustrate that *path-sensitive CFI* enforced by PITTYPAT does not allow the attack introduced in §2.2. In §2.4, we illustrate how PITTYPAT enforces path-sensitive CFI.

2.1 Subverting control flow

Figure 1 contains a C program, named `dispatch`, that we will use to illustrate PITTYPAT. `dispatch` declares a pointer `handler` (line `L7`) to a function that takes an argument of a struct `request` (defined at line `L1`–`L4`), which has two fields: `auth_user` represents a user's identity, and `args` stores the arguments. `dispatch` contains a loop (line `L10`–`L23`) that continuously accepts requests from users,

```
1  struct request {
2   int auth_user;
3   char args[100];
4  };
5
6  void dispatch() {
7   void (*handler)(struct request *) = 0;
8   struct request req;
9
10  while(1) {
11    // parse the next request
12    parse_request(&req);
13    if (req.auth_user == ADMIN) {
14      handler = priv;
15    } else {
16      handler = unpriv;
17      // NOTE. buffer overflow, which can overwrite
18      //  the handler variable
19      strip_args(req.args);
20    }
21    // invoke the hanlder
22    handler(&req);
23  }
24 }
```

Figure 1: A motivating example that illustrates the advantages of control-path validity.

and calls `parse_request` (line `12`) to parse the next request. If the request is an administrator (line `L13`), the function pointer `handler` will be assigned with `priv`. Otherwise, `handler` is assigned to `unpriv` (line `L16`), and `dispatch` will call `strip_args` (line `L19`) to strip the request's arguments. At last, `dispatch` calls `handler` to perform relevant behaviors.

However, the procedure `strip_args` contains a buffer-overflow vulnerability, which allows an attacker with control over input to `strip_args` to potentially subvert the control flow of a run of `dispatch` by using well-known techniques [28]. In particular, the attacker can provide inputs that overwrite memory outside of the fixed-size buffer pointed to by `req.args` in order to overwrite the address stored in `handler` to be the address of a function of their choosing, such as `execve`.

2.2 Limitations of existing CFI

Protecting `dispatch` so that it satisfies conventional control-flow integrity (CFI) [1] does not provide strong end-to-end security guarantees. An implementation of CFI attempts to protect a given program P in two steps. In the first step, the CFI implementation computes possible targets of each indirect control transfer in P by running a flow-sensitive points-to analysis[1] [2, 15, 34]. Such an approach, when protecting `dispatch`, would determine that when the execution reaches each of the following control locations L, the variable `handler` may store the following addresses $p(\texttt{L})$:

$$p(\texttt{L7}) = \{0\} \qquad p(\texttt{L14}) = \{\texttt{priv}\}$$
$$p(\texttt{L16}) = \{\texttt{unpriv}\} \qquad p(\texttt{L22}) = \{\texttt{priv}, \texttt{unpriv}\}$$

While flow-sensitive points-to analysis may implement various algorithms, the key property of each such analysis is that it computes points-to information per control location. If there is any run of the program that may reach control location L with a pointer variable `p` storing a particular address `a`, then the result of the points-to analysis must reflect that `p` may point to `a` at L. In the case of `dispatch`, any flow-sensitive points-to analysis can only determine that at line `L22`, `handler` may point to either `priv` or `unpriv`.

After computing points-to sets p for program P, the second step of a CFI implementation rewrites P so that at each indirect control-transfer instruction in each run, the rewritten P can only transfer control to a control location that is a points-to target in the target register according to p. Various implementations have been proposed for encoding points-to sets and validating control transfers efficiently [1, 9, 41].

However, all such schemes are fundamentally limited by the fact that they can only validate if a transfer target is allowed by checking its membership in a flow-sensitive points-to set, computed per control location. `dispatch` and the points-to sets p illustrate a case in which any such scheme *must* allow an attacker to subvert control flow. In particular, an attacker can send a request with the identity of anonymous user. When `dispatch` accepts such a request, it will store `unpriv` in `handler`, and then strip the arguments. The attacker can provide arguments crafted to overwrite `handler` to store `priv`, and allow execution to continue. When `dispatch` calls the function stored in `handler` (line `L22`), it will attempt to transfer control to `priv`, a member of the points-to set for `L22`. Thus, `dispatch` rewritten to enforce CFI must allow the call. Let the sequence of key control locations visited in the above attack be denoted $p_0 = [\texttt{L7}, \texttt{L16}, \texttt{L22}]$.

Although PathArmor [37] enforces context-sensitive CFI by inspecting the history of branches taken at runtime before allowing the monitored execution to perform a security-sensitive operation, it decides to allow execution to continue if the path contains a sequence of control transfers that are feasible according to a static, flow-sensitive points-to analysis computed before the program is run. As a result, PathArmor is susceptible to a similar attack.

Per-input CFI (denoted π-CFI) [26] avoids some of the vulnerabilities in CFI inherent to its use of flow-sensitive points-to sets, such as the vulnerability described above for `dispatch`. π-CFI updates the set of valid targets of control transfers of each instruction dynamically, based on operations performed during the current program execution. For example, π-CFI only allows a program to

[1] Some implementations of CFI [25, 41, 42] use a type-based alias analysis to compute valid targets, but such approaches are even less precise.

perform an indirect call to a function whose address was taken during an earlier program operation. In particular, if `dispatch` were rewritten to enforce π-CFI, then it would block the attack described above: in the execution of π-CFI described, the only instruction that takes the address of `handler` (line `L14`) is never executed, but the indirect call at `L22` uses `priv` as the target of an indirect call.

However, in order for π-CFI to enforce per-input CFI efficiently, it updates valid points-to targets dynamically using simple, approximate heuristics, rather than a precise program analysis that accurately models the semantics of instructions executed. For example, if a function f appears in the static points-to set of a given control location L and has its address taken at any point in an execution, then f remains in the points-to set of L for the rest of the execution, even if f is no longer a valid target as the result of program operations executed later. In the case of `dispatch`, once `dispatch` takes the address of `priv`, `priv` remains in the points-to set of control location `L22` for the remainder of the execution.

An attacker can thus subvert the control flow of `dispatch` rewritten to enforce π-CFI by performing the following steps. **(1)** An administrator sends a request, which causes `dispatch` to store `priv` in `handler`, call it, and complete an iteration of its loop. **(2)** The attacker sends an anonymous request, which causes `dispatch` to set `unpriv` in `handler`. **(3)** The attacker provides arguments that, when handled by `strip_args`, overwrite the address in `handler` to be `priv`, which causes `dispatch` to call `priv` with arguments provided by the attacker.

Because `priv` will be enabled as a control target as a result of the operations performed in step (1), `priv` will be a valid transfer target at line `L22` in step (3). Thus, the attacker will successfully subvert control flow. Let the key control locations in the control path along which the above attack is performed be denoted $p_1 = [\texttt{L7}, \texttt{L14}, \texttt{L22}, \texttt{L16}, \texttt{L22}]$.

2.3 Path-sensitive CFI

In this paper, we introduce a path-sensitive version of CFI that addresses the limitations of conventional CFI illustrated in §2.2. A program satisfies path-sensitive CFI if at each indirect control transfer, the program only transfers control to an instruction address that is in the points-to set of the target register according to a points-to analysis of the whole executed control *path*.

`dispatch` rewritten to satisfy path-sensitive CFI would successfully detect the attacks given in §2.2 on existing CFI. One collection of valid points-to sets for `handler` for each control location in subpath p_0 (§2.2) are the following:

$$(\texttt{L7}, \{0\}), (\texttt{16}, \{\texttt{unpriv}\}), (\texttt{L22}, \{\texttt{unpriv}\})$$

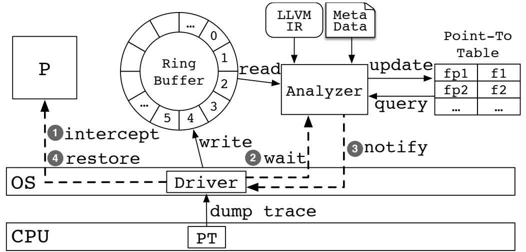

Figure 2: The architecture of PITTYPAT. P denotes a target program. The *analyzer* and *driver* modules of PITTYPAT are described in §2.4.

When execution reaches `L22`, `priv` is not in the points-to set of `handler`, and the program halts.

Furthermore, `dispatch` rewritten to satisfy path-sensitive CFI would block the attack given in §2.2 on π-CFI. One collection of valid points-to sets for `handler` for each control location in subpath p_1 are the following:

$$(\texttt{L7}, \{0\}) \quad (\texttt{L14}, \{\texttt{priv}\}) \quad (\texttt{L22}, \{\texttt{priv}\})$$
$$(\texttt{L16}, \{\texttt{unpriv}\}) \quad (\texttt{L22}, \{\texttt{unpriv}\})$$

When execution reaches `L22` in the second iteration of the loop in `dispatch`, `priv` is not in the points-to set of `handler`, and the program determines that the control-flow has been subverted.

2.4 Enforcing path-sensitive CFI efficiently

The points-to sets for control paths considered in §2.3 illustrate that if a program can be rewritten to satisfy path-sensitive CFI, it can potentially satisfy a strong security guarantee. However, ensuring that a program satisfies path-sensitive CFI is non-trivial, because the program must be extended to dynamically compute the results of sophisticated semantic constraints [2] over the exact control path that it has executed.

A key contribution of our work is the design of a run-time environment, PITTYPAT, that enforces path-sensitive CFI efficiently. PITTYPAT's architecture is depicted in Figure 2. For program P, the state and code of PITTYPAT consist of the following modules, which execute concurrently: **(1)** a user-space process in which P executes, **(2)** a user-space *analysis module* that maintains points-to information for the control-path executed by P, and **(3)** a kernel-space *driver* that sends control branches taken by P to the analyzer and validates system calls invoked by P using the analyzer's results.

Before a program P is monitored, the analysis module is given (1) an intermediate representation of P and (2) meta data including a map from each instruction address in the binary representation of P to the instruction in the intermediate representation of P. We believe that it would also be feasible to implement PITTYPAT to protect

a program given only as a binary, given that the analyzer module only must perform points-to analysis on the sequence of executed instructions, as opposed to inferring the program's complete control-flow graph.

As P executes a sequence of binary instructions, the driver module copies the targets of control branches taken by P from PT's storage to a ring buffer shared with the analyzer. PT's storage is privileged: it can only be written by hardware and flushed by privileged code, and cannot be tampered with by P or any other malicious user-space process. The analyzer module reads taken branches from the ring buffer, uses them to reconstruct the sequence of IR instructions executed by P since the last branch received, and updates the points-to information in a table that it maintains for P's current state by running a points-to analysis on the reconstructed sequence.

When P invokes a system call, the driver first intercepts P (❶), while waiting for the analyzer module to determine in parallel if P has taken a valid sequence of control targets over the *entire* execution up to the current invocation (❷ and ❸). The analyzer validates the invocation only if P has taken a valid sequence, and the driver allows execution of P to continue only if the invocation is validated (❹).

There are two key challenges we must address to make PittyPat efficient. First, trace information generated by PT is highly compressed; e.g., for each conditional branch that a program executes, PT provides only a single bit denoting the value of the condition tested in the branch. Therefore additional post-processing is necessary to recover transfer targets from such information. The approach used by the `perf` tool of Linux is to parse the next branch instruction, extract the offset information, then calculate the target by adding the offset (if the branch is taken) or the length of instruction (if branch is not taken). However, because parsing x86 instructions is non-trivial, such an approach is too slow to reconstruct a path online.

Our insight to solve this problem is that, to reconstruct the executed path, an analysis only needs to know the basic blocks executed. We have applied this insight by designing the analysis to maintain the current basic block executed by the program. The analysis can maintain such information using the compressed information that PT provides. E.g., if PT provides only a bit denoting the value of a condition tested in a branch, then the analysis inspects the conditional branch at the end of the maintained block, and from the branch, updates its information about the current block executed.

The second key challenge in designing PittyPat is to design a points-to analysis that can compute accurate points-to information while imposing sufficiently low overhead. Precise points-to analyses solve a system of constraints over all pairs of pointer variables in the program [2, 15]; solving such constraints uses a significant amount of time that is often acceptable in the context of an offline static analysis, but would impose unacceptable overhead if used by PittyPat's online analysis process. Other analyses bound analysis time to be nearly linear with increasing number of pointer variables, but generate results that are often too imprecise to provide strong security guarantees if used to enforce CFI [34].

To address the limitations of conventional points-to analysis, we have designed an online points-to analysis that achieves the precision of precise analysis at high performance. The analysis eagerly evaluates control relevant points-to constraints as they are generated, while updating the points-to relations table used for future control transfer validation. The analysis enables PittyPat, when analyzing runs of `dispatch` that execute paths p_0 and p_1, to compute the accurate points-to information given in §2.3. On practical benchmarks, it allows significantly smaller sets of control targets to be taken at each control branch, and detects attacks on control flow not detected by state-of-the-art defenses. Combined with our efficient path-reconstruction process, it also enables PittyPat to execute with an average of 12.73% overhead (geometric mean) on even compute-intensive benchmarks, such as SPEC CPU2006 (see §6).

Packet	Description
TIP.PGE	IP at which the tracing begin
TIP.PGD	Marks the ending of tracing
TNT	Taken/non-taken decisions of conditional branches
TIP	Target addresses of indirect branches
FUP	The source addresses of asynchronous events

Table 1: Control-relevant trace packets from Intel PT.

3 Background

3.1 Intel Processor Trace

Intel PT is a commodity, low-overhead hardware designed for debugging by collecting *complete* execution traces of monitored programs. PT captures information about program execution on each hardware thread using dedicated hardware facilities so that after execution completes, the captured trace data can be reconstructed to represent the exact program flow.

The captured control flow information from PT is presented in encoded data packets. The control relevant packet types are shown in Table 1. PT records the beginning and the end of tracing through `TIP.PGE` and `TIP.PGD` packets, respectively. Because the recorded control flow needs to be highly compressed in order to achieve the efficiency, PT employs several techniques to achieve this goal. In particular, PT only records the taken/non-taken decision of each conditional branches through `TNT`, along with the target of each indirect branches through `TIP`. A direct branch does not trigger a PT packet because the

control target of a direct branch is fixed.

Besides the limited packet types necessary for recovering *complete* execution traces, PT also adopts compact packet format to reduce the data throughput aggressively. For instance, `TNT` packets use one bit to indicate the direction of each conditional branches. `TIP` packets, on the other hand, contain compressed target address if the upper address bytes match the previous address logged. Thus on average, PT tracing incurs less than 5% overhead [13].

When configured appropriately, PT monitors a single program as well as its descendants based on CR3 filtering, and outputs all collected packets to physical memory allocated by its kernel driver. In the current implementation of PITTYPAT, a ring buffer is allocated so that it can be reused throughout execution. The details of its implementation are described in §5.1.

3.2 Conventional CFI

A control analysis, given program P, computes a sound over-approximation of the instruction pointers that may be stored in each pointer when P executes each instruction. An abstract domain D [8] consists of a set of abstract states, a concretization relation from abstract states to the program states that they represent, and for each program instruction `i`, an abstract transformer $\tau_D[\mathtt{i}] : D \rightarrow D$ that describes how each abstract state is updated by a program. Each abstract domain defines a transition relation ρ_D of steps valid according to D. In particular, for each instruction `i`, domain element D, and all states σ and σ', if σ represented by D and σ' is represented by $\tau_D[\mathtt{i}](D)$, then $(\sigma, \mathtt{i}, \sigma') \in \rho_D$. A control-analysis domain D is an abstract domain extended with a relation from each abstract domain element and instruction pointer to code pointers in states represented by D.

A valid flow-sensitive description in D of a program P is a map from each program point in P to an element in D that is consistent with the semantics of program instructions. There is always a most-precise valid flow-sensitive description in D, denoted $\mu[D]$.

Definition 1 *For control domain D, program P satisfies* (conventional) CFI *modulo D if, in each run of P, at each indirect branch point* `L`*, P transfers control to a control target in* $\mu[D](\mathtt{L})$.

We provide a complete formal definition of conventional CFI in §C.1.

An analysis that computes such a description is a *control analysis*. Control analyses conventionally are implemented as *points-to* analyses, such as Andersen's analysis [2] or Steensgard's analysis [34].

4 Design

A program P satisfies path-sensitive CFI under control domain D if each step of P is valid according to D (as described in §3.2).

Definition 2 *For control domain D, program P satisfies* path-sensitive CFI *modulo D if, in each run of P consisting of states* $\sigma_0, \ldots, \sigma_n$*, for each* $0 \leq j < n$ *where* σ_j *steps to* σ_{j+1} *on instruction* `i`*,* $(\sigma_j, \mathtt{i}, \sigma_{j+1}) \in \rho_D$*.*

A formal definition of path-sensitive CFI, along with results establishing that path-sensitive CFI is strictly stronger than conventional CFI, are given in §C.2.

PITTYPAT enforces path-sensitive CFI by maintaining a shadow execution/analysis that only examines control relevant data, while running concurrently with the monitored process. Using the complete traces reconstructed from Intel PT, only control-relevant data are computed and maintained as points-to relations throughout the execution, using an online points-to analysis. Analyzing only control-relevant data satisfies the need to validate control-transfer targets but significantly optimizes the analysis, because only parts of the program will be examined in the shadow execution/analysis. Such an analysis, along with the low overhead incurred by commodity hardware, allow PITTYPAT to achieve path-sensitive CFI with practical runtime overhead.

The architecture of PITTYPAT is depicted in §2.4, Figure 2. PITTYPAT consists of two modules. The first module executes a given program P in a designated monitor process and collects the targets of control transfers taken by P. We describe the operation of this module in §4.1 and give the details of its implementation in §5.1. The second module receives control-branch targets taken by P from the first module, reconstructs the control path executed by P from the received targets, and performs a points-to analysis along the reconstructed control path of P. We describe the operation of the analysis module in §4.2 and describe details of its implementation in §5.2.

4.1 Sharing taken branches efficiently

PITTYPAT uses the PT extension for Intel processors [31] to collect the control branches taken by P. A naive implementation of PITTYPAT would receive from the monitoring module the complete target address of each branch taken by P in encoded packets and decode the traces offline for analysis. PITTYPAT, given only Boolean flags from PT, decodes complete branch targets on the fly.

To do so, PITTYPAT maintains a copy of the current control location of P. For example, in Figure 1, when `dispatch` steps through the path [`L10`,`L16`,`L22`], the relevant PT trace contains only two `TNT` packets and one `TIP` packet. A `TNT` packet is a two-bit stream: 10. The first

bit, 1, represents the conditional branch at `L10` is taken (i.e., the execution enters into the loop). The second bit, 0, indicates the conditional branch at `L13` is not taken, and the executed location is now in the else branch. The `TIP` packet contains the address of function `unpriv`, which shows an indirect jump to `unpriv`.

PITTYPAT uses the Linux `perf` infrastructure to extract the execution trace of *P*. In particular, PITTYPAT uses the `perf` kernel driver to **(1)** allocate a ring buffer shared by the hardware and itself and **(2)** mark the process in which the target program executes (and any descendant process and thread) as traced so as to enable tracing when context switching into a descendant and disable tracing when context switching out of a descendant. The driver then transfers the recorded PT packets, together with thread ID and process ID, to the analyzer module through the shared buffer. This sharing mechanism has proved to be efficient on all performance benchmarks on which we evaluated PITTYPAT, typically incurring less than 5% overhead.

PITTYPAT intercepts the execution of a program at security-sensitive system calls in the kernel and does not allow the program to proceed until the analyzer validates all control branches taken by the program. The list of intercepted system calls can be easily configured; the current implementation checks `write`, `mmap`, `mprotect`, `mremap`, `sendmsg`, `sendto`, `execve`, `remap_file_pages`, `sendmmsg`, and `execveat`. The above system calls are intercepted because they can either disable DEP/W⊕X, directly execute an unintended command, write to files on the local host, or send traffic over a network.

4.2 Online points-to analysis

The analyzer module executes in a process distinct from the process in which the monitored process executes. Before monitoring a run of the program, the analyzer is given the monitored program's LLVM IR and meta information about mapping between IR and binary code. At runtime, the analyzer receives the next control-transfer target taken by the protected program from the monitor module, and either chooses to raise an alarm signaling that the control transfer taken would violate path-sensitive CFI, or updates its state and allows the original program to take its next step of execution.

The updated states contain two components: (1) the callstack of instructions being executed (i.e., the `pc`'s) and (2) points-to relations over models of memory cells that are control relevant only. The online points-to analysis addresses the limitations of conventional points-to analyses. In particular, it reasons precisely about the calling context of the monitored program by maintaining a stack of register frames. It avoids maintaining constraints over pairs of pointer variables by eagerly evaluating the sets of cells and instruction addresses that may be stored in each register and cell. It updates this information efficiently in response to program actions by performing updates on a single register frame and removing register frames when variables leave scope on return from a function call.

In general, a program may store function pointers in arbitrarily, dynamically allocated data structures before eventually loading the pointer and using it as the target of an indirect control transfer. If the analyzer were to maintain precise information about the points-to relation of all heap cells, then it would maintain a large amount of information never used and incur a significant cost to performance. We have significantly optimized PITTYPAT by performing aggressive analyses of a given program *P* offline, before monitoring the execution of *P* on a given input. PITTYPAT runs an analyzer developed in previous work on *code-pointer integrity* (CPI) [17] to collect a sound over-approximation of the instructions in a program that may affect a code pointer used as the target of a control transfer. At runtime, the analyzer only analyzes instructions that are control relevant as determined by its offline phase.

A program may contain many functions that perform no operations on data structures that indirectly contain code pointers, and do not call any functions that perform such operations. We optimized PITTYPAT by applying an offline analysis based on a sound approximation of the program's call graph to identify all such functions. At runtime, PITTYPAT only analyzes functions that may indirectly perform relevant operations.

To illustrate the analyzer's workflow, consider the execution path [`L10`, `L12`, `L16`, `19`, `L22`] in Figure 1 as an example. Initially, the analyzer knows that the current instruction being executed is `L10`, and the points-to table is empty. The analyzer then receives a taken `TNT` packet, and so it updates the `pc` to `L12`, which calls a non-sensitive function `parse_request`. However instead of tracing instructions in `parse_request`, the analyzer waits until receiving a `TIP` packet signaling the return from `parse_request` before continue its analysis. Next, it updates the `pc` to `L16` after receiving a non-taken `TNT` packet, which indicates that the else branch is taken. Here, the analyzer updates the points-to table to allow `handler` to point to `unpriv` when it handles `L16`. Because the program also calls a non-sensitive function at `L19`, the analyzer waits again and updates the `pc` to `L22` only after receiving another `TIP` packet. Finally, at `L22`, the analyzer waits for a `TIP` packet at the indirect call, and checks whether the target address collected by the monitor module is consistent with the value pointed by `handler` in the points-to table. In this case, if the address in the received `TIP` packet is not `unpriv`, the analyzer throws an alarm.

We have described the analyzer as validating taken control branches and eagerly throwing alarms when it detects an incorrect branch in order to simplify its description.

The actual implementation of the analyzer only provides such an alarm in response to a request from PITTYPAT's kernel module when a monitored process attempts to invoke a system call, as described in §5.1.

5 Implementation

5.1 Monitor module

PITTYPAT controls the Intel PT extension and collects an execution trace from a monitored program by adapting the Linux v4.4 `perf` infrastructure. Because `perf` was originally designed to aid debugging, the original version provided with Linux 4.4 only supports decoding and processing traces offline. In the original implementation, the `perf` kernel module continuously outputs packets of PT trace information to the file system in user space as a log file to be consumed later by a userspace program. Such a mechanism obviously cannot be used directly within PITTYPAT, which must share branch information at a speed that allows it to be run as an online monitor.

We modified the kernel module of `perf`, which begins and ends collection of control targets taken after setting a target process to trace, allocates a ring buffer in which it shares control branches taken with the analyzer, and monitors the amount of space remaining in the shared buffer. The module also notifies the analyzer when taken branches are available in its buffer, along with how many chosen control targets are available. The notification mechanism reuses the pseudo-file interface of the `perf` kernel module. The analyzer creates one thread to wait (i.e., poll) on this file handler for new trace data. Once woken up by the kernel, it fetches branches from the shared ring buffer with minimal latency.

System calls are intercepted by a modified version of the system-call mechanism provided by the Linux kernel. When the monitored process is created, it—along with each of its sub-processes and threads created later—is flagged with a true value in a `PT_CPV` field of its `task_struct` in kernel space. When the kernel receives a request for a system call, the kernel checks if the requesting process is flagged. If so, the kernel inspects the value in register `rax` to determine if it belongs to the configured list of marked system calls as described in §4.1. The interception mechanism is implemented as a semaphore, which blocks the system call from executing further code in kernel space until the analyzer validates all branches taken by the monitored process and signals the kernel.

The driver module and modifications to the kernel consist of approximately 400 lines of C code.

5.2 Analyzer module

PITTYPAT's analyzer module is implemented as two core components. The first component consists of a LLVM compiler pass, implemented in 500 lines, that inserts an instruction at the beginning of each basic block before the IR is translated to binary instructions. Such instructions are used to generate a map from binary basic blocks to LLVM IR basic blocks. Thus when PITTYPAT receives a `TNT` packet for certain conditional branch, it knows the corresponding IR basic block that is the target of the control transfer. The inserted instructions are removed when generating binary instructions; therefore no extra overhead is introduced to the running program.

The second component, implemented in 5,800 lines C++ code, performs a path-sensitive points-to analysis over the control path taken by the monitored process, and raises an error if the monitored process ever attempts to transfer control to a branch not allowed by path-sensitive CFI. Although the analysis inspects only low-level code, it directly addresses several challenges in analyzing code compiled from high-level languages. First, to analyze exception-handling by a C++ program, which unwinds stack frames without explicit calls to return instructions, the analyzer simply consumes the received `TNT` packets generated when the program compares the exception type and updates the `pc` to the relevant exception handler.

To analyze a dynamic dispatch performed by a C++ program, the analyzer uses its points-to analysis to determine the set of possible objects that contain the vtable at each dynamic-dispatch callsite. The analyzer validates the dispatch if the requested control target stored in a given `TIP` packet is one of the members of the object from which the call target is loaded. At each call to `setjmp`, the analyzer stores all possible `setjmp` buffer cells that may be used as arguments to `setjmp`, along with the instruction pointer at which `setjmp` is called, in the top stack frame. At each call to `longjmp`, the analyzer inspects the target `T` of the indirect call and unwinds its stack until it finds a frame in which `setjmp` was called at `T`, with the argument buffer of `longjmp` may have been the buffer passed as an argument to `setjmp`.

6 Evaluation

We performed an empirical evaluation to answer the following experimental questions. **(1)** Are benign applications transformed to satisfy path-sensitive CFI less susceptible to an attack that subverts their control security? **(2)** Do applications that are explicitly written to perform malicious actions that satisfy weaker versions of CFI fail to satisfy path-sensitive CFI? **(3)** Can PITTYPAT enforce path-sensitive CFI efficiently?

To answer these questions, we used PITTYPAT to en-

force path-sensitive CFI on a set of benchmark programs and workloads, including both standard benign applications and applications written explicitly to conceal malicious behavior from conventional CFI frameworks. In summary, our results indicate that path-sensitive CFI provides a stronger security guarantee than state-of-the-art CFI mechanisms, and that PITTYPAT can enforce path-sensitive CFI while incurring overhead that is acceptable in security-critical contexts.

6.1 Methodology

We collected a set of benchmarks, each described in detail in §6.2. We compiled each benchmark with LLVM 3.6.0, and ran them on a set of standard workloads. During each run of the benchmark, we measured the time used by the program to process the workload. If a program contained a known vulnerability that subverted conventional CFI, then we ran the program on inputs that triggered such a vulnerability as well, and observed if PITTYPAT determined that control-flow was subverted along the execution. Over a separate run, at each control branch taken by the program, we measured the size of the points-to set of the register that stored the target of the control transfer.

We then built each benchmark to run under a state-of-the-art CFI framework implemented in previous work, π-CFI [26]. While π-CFI validates control targets per control location, it instruments a subject program so that control edges of the program are disabled by default, and are only enabled as the program executes particular triggering actions (e.g., a function can only be called after its address is taken). It thus allows sets of transfer targets that are no larger than those allowed by conventional implementations of CFI, and are often significantly smaller [26]. For each benchmark program and workload, we observed whether π-CFI determined that the control-flow integrity of the program was subverted while executing the workload and measured the runtime of the program while executed under π-CFI. We compared PITTYPAT to π-CFI because it is the framework most similar to PITTYPAT in concept: it validates control-transfer targets based not only on the results of a static points-to analysis, but collecting information about the program's dynamic trace.

6.2 Benchmarks

To evaluate the ability of PITTYPAT to protect long-running, benign applications, and to evaluate the overhead that it incurs at runtime, we evaluated it on the SPEC CPU2006 benchmark suite, which consists of 16[2] C/C++ benchmarks. We ran each benchmark three times over its provided reference workload. For each run, we measured the runtime overhead imposed by PITTYPAT and the number of control targets allowed at each indirect control transfer, including both indirect calls and returns. We also evaluated PITTYPAT on the NGINX server—a common performance macro benchmark, configured to run with multiple processes.

To evaluate PITTYPAT's ability to enforce end-to-end control security, we evaluated it on a set of programs explicitly crafted to contain control vulnerabilities, both as analysis benchmarks and in order to mount attacks on critical applications. In particular, we evaluated PITTYPAT on programs in the RIPE benchmark suite [39], each of which contains various vulnerabilities that can be exploited to subvert correct control flow (e.g. *Return-Oriented Programming* (ROP) or *Jump-oriented Programming* (JOP)). We compiled 264 of its benchmarks in our x64 Linux test environment and evaluated PITTYPAT on each. We also evaluated PITTYPAT on a program that implements a proof-of-concept COOP attack [32], a novel class of attacks on the control-flow of programs written in object-oriented languages that has been used to successfully mount attacks on the Internet Explorer and Firefox browsers. We determined if PITTYPAT could block the attack that the program attempted to perform.

6.3 Results

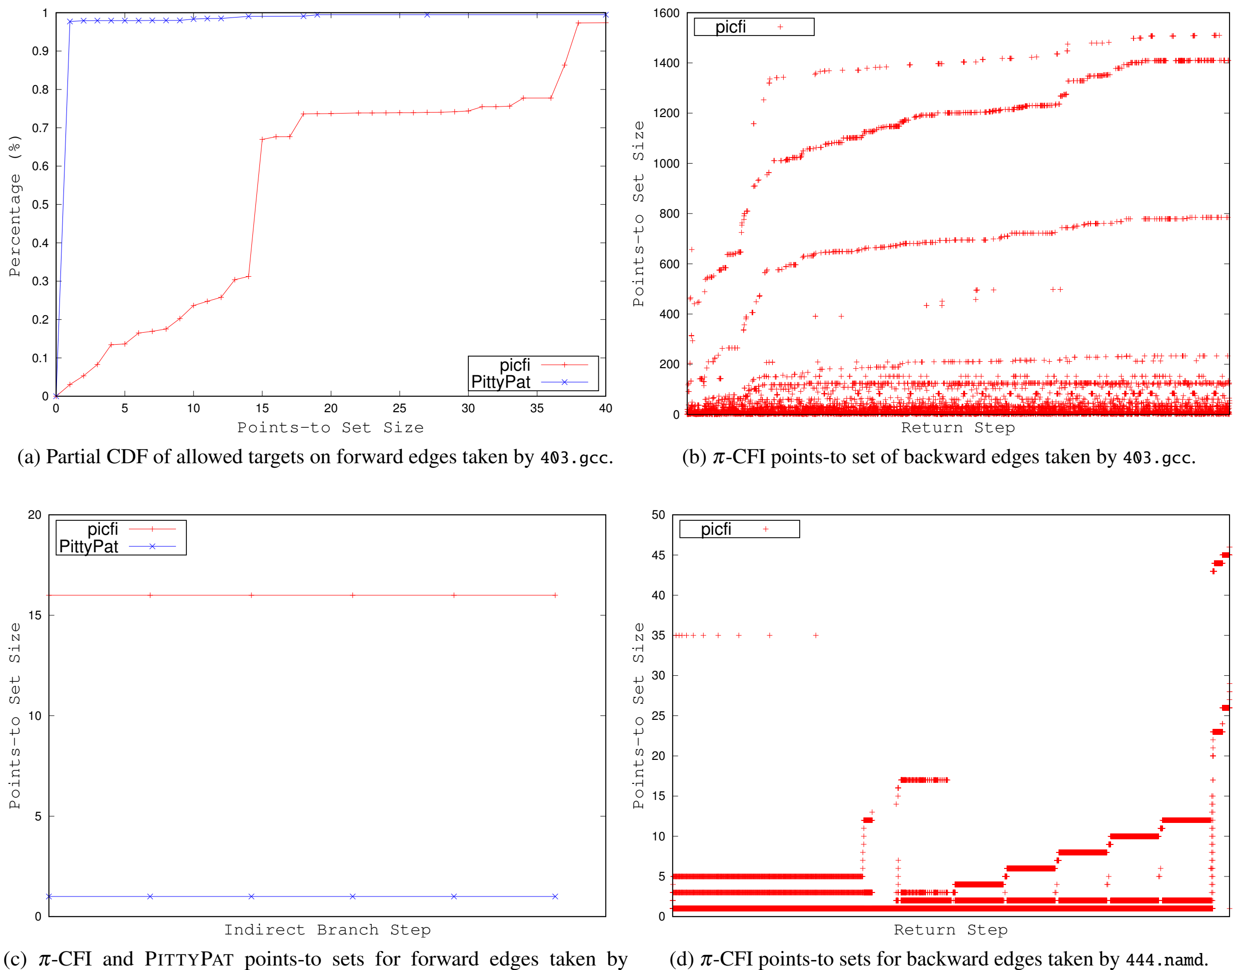
6.3.1 Protecting benign applications

Figure 3 contains plots of the control-transfer targets allowed by π-CFI and PITTYPAT over runs of example benchmarks selected from §6.2. In the plots, each point on the x-axis corresponds to an indirect control transfer in the run. The corresponding value on the y-axis contains the number of control targets allowed for the transfer.

Previous work on CFI typically reports the average indirect-target reduction (AIR) of a CFI implementation; we computed the AIR of PITTYPAT. However, the resulting data does not clearly illustrate the difference between PITTYPAT and alternative approaches, because all achieve a reduction in branch targets greater than 99% out of all branch targets in the program. This is consistent with issues with AIR as a metric established in previous work [4]. Figure 3, instead, provides the absolute magnitudes of points-to sets at each indirect control transfer over an execution.

Figure 3a contains a Cumulative Distribution Graph (CDF) of all points-to sets at *forward* (i.e., jumps and calls) indirect control transfers of size no greater than 40 when running `403.gcc` under π-CFI and PITTYPAT. We used a CDF over a portion of the points-to sets in order to display the difference between the two approaches in the presence of a small number of large points-to sets,

[2] We don't include `447.dealII`, `471.omnetpp`, and `483.xalancbmk` because their LLVM IR cannot be completely mapped to the binary code.



(a) Partial CDF of allowed targets on forward edges taken by `403.gcc`.

(b) π-CFI points-to set of backward edges taken by `403.gcc`.

(c) π-CFI and PittyPat points-to sets for forward edges taken by `444.namd`.

(d) π-CFI points-to sets for backward edges taken by `444.namd`.

Figure 3: Control-transfer targets allowed by π-CFI and PittyPat over `403.gcc` and `444.namd`.

explained below. Figure 3a shows that PittyPat can consistently maintain significantly smaller points-to sets for forward edges than that of π-CFI, leading to a stronger security guarantee. Figure 3a indicates that when protecting practical programs, an approach such as π-CFI that validates per location allows a significant number of transfer targets at each indirect callsite, even using dynamic information. In comparison, PittyPat uses the entire history of branches taken to determine that at the vast majority of callsites, only a *single* address is a valid target. The difference in the number of allowed targets can be explained by the different heuristics adopted in π-CFI, which monotonically accumulates allowed points-to targets without any disabling schemes once targets are taken, and the precise, context-sensitive points-to analysis implemented in PittyPat. Similar difference between π-CFI and PittyPat can also be found in all other C benchmarks from SPEC CPU2006.

For the remaining 4% of transfers not included in Figure 3a, both π-CFI and PittyPat allowed up to 218 transfer targets; for each callsite, PittyPat allowed no more targets than π-CFI. The targets at such callsites are loaded from vectors and arrays of function pointers, which PittyPat's current points-to analysis does not reason about precisely. It is possible that future work on a points-to analysis specifically designed for reasoning precisely about such data structures over a single path of execution—a context not introduced by any previous work on program analysis for security—could produce significantly smaller points-to sets.

A similar difference between π-CFI and PittyPat is demonstrated by the number of transfer targets allowed for other benchmarks. In particular, Figure 3c contains similar data for the `444.namd` benchmark. `444.namd`, a C++ program, contains many calls to functions loaded from vtables, a source of imprecision for implementations of CFI that can be exploited by attackers [32]. PittyPat allows a *single* transfer target for *all* forward edges as

a result of its online points-to analysis. The difference between π-CFI and PITTYPAT are also found for other C++ benchmarks, such as 450.soplex, 453.povray and 473.astar.

π-CFI and PITTYPAT consistently allow dramatically different numbers of transfer targets for return instructions. While monitoring 403.gcc, π-CFI allows, for some return instructions, over 1,400 return targets (Figure 3b). While monitoring 444.namd, π-CFI allows, for some return instructions, more than 46 transfer targets (Figure 3d). Because PITTYPAT maintains a stack of points-to information during its analysis, it will *always* allow only a single transfer target for each return instruction, over all programs and workloads. PITTYPAT thus significantly improves defense against ROP attacks, which are still one of the most popular attacks software.

6.3.2 Mitigating malicious applications

To determine if PITTYPAT can detect common attacks on control, we used it to monitor selected RIPE benchmarks [39]. For each of the 264 benchmarks that ran in our experimental setup, PITTYPAT was able to successfully detect attacks on the benchmark's control security.

We constructed a proof-of-concept program vulnerable to a COOP [32] attack that corrupts virtual-function pointers to perform a sequence of method calls not possible by a well-defined run of the program. In Figure 4, the program defines two derived classes of SchoolMember (line L1–L4), Student (line L5–L10) and Teacher (line L11–L16). Both Student and Teacher define their own implementation of the virtual function registration() (lines L7–9 and L13–15, respectively). set_buf() (line L17–L21) allocates a buffer buf on the stack of size 4 (line L18), but does not bound the amount of data that it reads into buf (line L20). The main function (line L22–L37) constructs instances of Student and Teacher (lines L23 and L24, respectively), and stores them in SchoolMember pointers (lines L26 and 27 respectively). main then calls the registration() method of each instance (lines L29–L31), reads input from a user by calling set_buf() (line L33), and calls Student::registration() a second time (line L35). A malicious user can subvert control flow of the program by exploiting the buffer overflow vulnerability in set_buf to overwrite the vptr of Student to that of Teacher and run Teacher::registration() at line L35.

Previous work introducing COOP attacks [32] established such an attack cannot be detected by CFI. π-CFI was not able to detect an attack on the above program because it allows a dynamic method as a call target once its address is taken. However, PITTYPAT detected the attack because its analyzer module accurately models the effect of each load of a function pointer used to implement the dynamic calls over the program's well-defined runs.

```
1  class SchoolMember {
2    public:
3      virtual void registration(void){}
4  };
5  class Student : public SchoolMember{
6    public:
7      void registration(void){
8        cout << "I am a Student\n";
9      }
10 };
11 class Teacher : public SchoolMember{
12   public:
13     void registration(void){
14       cout << "This is sensitive!\n";
15     }
16 };
17 void set_buf(void){
18   char buf[4];
19   //change vptr to that of Teacher's sensitive func
20   gets(buf);
21 }
22 int main(int argc, char *argv[]){
23   Student st;
24   Teacher te;
25   SchoolMember *member_1, *member_2;
26   member_1 = &te;
27   member_2 = &st;
28   //Teacher calling its virtual functions
29   member_1->registration();
30   //Student calling its virtual functions
31   member_2->registration();
32   //buffer overflow to overwrite the vptr
33   set_buf();
34   //Student calling its virtual functions again
35   member_2->registration();
36   return 0;
37 }
```

Figure 4: A program vulnerable to a COOP attack.

6.3.3 Enforcing path-sensitive CFI efficiently

Table 2 contains measurements of our experiments that evaluate performance of PITTYPAT when monitoring benchmarks from SPEC CPU2006 and NGINX server, along with the performance results replicated from the paper that presented π-CFI [26]. A key feature observable from Table 2 is that PITTYPAT induces overhead that is consistently larger than, but often comparable to, the overhead induced by π-CFI. The results show that PITTYPAT incurs a geometric mean of 12.73% overhead across the 16 SPEC CPU2006 benchmarks, along with a 11.9% increased response time for NGINX server over one million requests with concurrency level of 50. Overhead of sharing branch targets taken is consistently less than 5%. The remaining overhead, incurred by the analysis module, is proportional to the number of memory operations (e.g., loads, stores, and copies) performed on memory cells that transitively point to a target of an indirect call, as well as the number of child processes/threads spawned during execution of multi-process/-threading benchmarks.

Another key observation from Table 2 is that PITTYPAT induces much smaller overhead than CETS [23] and SoftBound [22], which can only be applied to a small selection of the SPEC CPU2006 benchmarks. CETS provides

Table 2: "Name" contains the name of the benchmark. "KLoC" contains the number of lines of code in the benchmark. Under "Payload Features," "Exp" shows if the benchmark contains an exploit and "Tm (sec)" contains the amount of time used by the program, when given the payload. Under "π-CFI Featues", "PITTYPAT Features," and "CETS+SB Features," "Alarm" contains a flag denoting if a given framework determined that the payload was an attack and aborted; "Overhd (%)" contains the time taken by the framework, expressed as the ratio over the baseline time.

temporal memory safety and SoftBound provides spatial memory safety; both enforce full data integrity for C benchmarks, which entails control security. However, both approaches induce significant overhead, and cannot be applied to programs that perform particular combinations of memory-unsafe operation [17]. Our results thus indicate a continuous tradeoff between security and performance among exisiting CFI solution, PITTYPAT, and data protection. PITTYPAT offers control security that is close to ideal, i.e. what would result from data integrity, but with a small percentage of the overhead of data-integrity protection.

7 Related Work

The original work on CFI [1] defined control-flow integrity in terms of the results of a static, flow-sensitive points-to analysis. A significant body of work has adapted the original definition for complex language features and developed sophisticated implementations that enforce it. While CFI is conventionally enforced by validating the target of a control transfer before the transfer, control-flow locking [3] validates the target after the transfer to enable more efficient use of system caches. Compact Control Flow Integrity and Randomization (CCFIR) [41] optimizes the performance of validating a transfer target by randomizing the layout of allowable transfer targets at each jump. Opaque CFI (O-CFI) [21] ensures that an attacker who can inspect the rewritten code cannot learn additional information about the targets of control jumps that are admitted as valid by the rewritten code. All of the above approaches enforce security defined by the results of a flow-sensitive points-to analysis; previous work has produced attacks [5, 12, 32] that are allowed by any approach that relies on such information. PITTYPAT is distinct from all of the above approaches because it computes and uses the results of a points-to analysis computed for the exact control path executed. As a result, it successfully detects known attacks, such as COOP [32] (see §6.3.2).

Previous work has explored the tradeoffs of implementing CFI at distinct points in a program's lifecycle. CF restrictor [30] performs CFI analysis and instrumentation completely at the source level in an instrumenting compiler, and further work developed CFI integrated into production compilers [36]. BinCFI [42] implements CFI without access to the program source, but only access to a stripped binary. Modular CFI [25] implements CFI for programs constructed from separate compilation units. Unlike each of the above approaches, PITTYPAT consists of a background process that performs an online analysis of the program path executed.

Recent work on *control-flow bending* has established limitations on the security of any framework that enforces only conventional CFI [5], and proposes that future work explore CFI frameworks that validate branch targets using an auxiliary structure, such as a shadow stack. The conclusions of work on control-flow bending are strongly consistent with the motivation of PITTYPAT: the key contribution of PITTYPAT is that it enforces path-sensitive CFI, provably stronger than conventional CFI, and does so not only by maintaining a shadow stack of points-to infor-

mation, but by validating the targets of indirect branches using *path*-sensitive points-to analysis. Per-input CFI (π-CFI) [26] only enables control transfers to targets that are enabled depending on previous operations taken by a program in a given run; §6 contains a detailed comparison of π-CFI to PITTYPAT.

Several implementations of CFI use hardware features that efficiently record control targets chosen by a program. CFIMon [40] collects the transfer targets chosen by the program from the processor's branch tracing store, and validates the chosen target against the results of a flow-sensitive points-to analysis. Previous work has also proposed customized architectures with extended instruction sets that directly implement primitive operations required in order to enforce CFI [9]. Such approaches are thus distinct from our approach for the same reason as all approaches that use the results of a flow-sensitive analysis. kBouncer [29] interposes when a program attempts to execute a system call and inspects the Last Branch Record (LBR) provided on Intel processors to detect patterns of transfer targets that indicate an ROP attack. ROPecker [7] similarly interposes at key security events and inspects the LBR, but combines information from inspecting the history of chosen branches with a forward analysis. PathArmor [37] interposes key system calls, collects the last transfer targets collected in the LBR, and determines if there is a feasible path through the program's control-flow graph that reaches each transfer target. Further work [6] introduced counterattacks against such defenses that exploit the fact that each of the defenses only inspects the LBR to analyze a bounded number of transfer targets chosen immediately before a system call.

The above approaches are similar to PITTYPAT in that they inspect the results of hardware features that collect some subset of the control targets taken by a program at runtime. However, they are all distinct from PITTYPAT because PITTYPAT uses hardware features to maintain accurate points-to information by inspecting *all* branch targets chosen by a program over its execution. Recent work has proposed approaches that leverage Intel PT. Most such approaches use PT to debug programs [16, 35], whereas PITTYPAT uses PT to protect their control security. Some approaches [13, 14, 19] use PT to enforce that an application satisfies CFI as defined by a static flow-sensitive analysis; PITTYPAT uses PT to ensure that a program satisfies a stronger, path-sensitive variation of CFI.

Points-to analysis is a classic problem in static program analysis, with different approaches that achieve distinct tradeoffs in either higher precision [2] or scalability [34]. Points-to analyses are characterized on multiple dimensions, including flow-sensitivity [2, 34] and context-sensitivity [10, 18, 27, 38, 43]. However, a key property of all such analyses is that they are performed statically, and thus compute information either per program point or per group of stack configurations [15]. PITTYPAT uses a points-to analysis to compute points-to information based on the exact program path executed. As a result, PITTYPAT does not merge points-to information over multiple paths that reach a given control location or stack configuration, which heavily influenced the design of the novel points-to analysis that it uses. Recent work [17] has introduced *Code-Pointer Integrity (CPI)*, which protects the integrity of all addresses that indirectly affect the value of a function pointer used as the target of an indirect branch. A key finding of the original work on CPI is that CPI is relatively expensive to enforce for programs that contain a large number of code pointers, such as binaries compiled from programs in object-oriented languages. As a result, CPI was proposed along with *code-pointer separation* (CPS), in which the values of code pointers are protected, but pointers to cells containing code pointers are left unprotected. Subsequent work on *counterfeit object-oriented programming* [32] demonstrated that CPS is insufficiently strong to block code-reuse attacks on object-oriented programs.

PITTYPAT, along with all approaches for enforcing various versions of CFI, differs fundamentally from CPI in that it does not attempt to protect any segment of a program's data at runtime. Instead, PITTYPAT validates candidate targets of indirect control transfers based only on the history of control branches taken. CPI and PITTYPAT have complementary strengths and should be applied in complementary security settings. In particular, CPI often incurs slightly lower overhead, but can only be applied in scenarios in which the source code of the entire program to be protected is available to be analyzed and instrumented. Such conditions are not satisfied in cases in which a program relies on large, untrusted third-party or shared libraries. PITTYPAT can potentially incur larger performance overhead than CPI. However, because it performs an points-to analysis that can be easily run on sequences of low-level instructions, it can be applied to protect program modules that are only available as binaries. It also need not instrument any code of a protected application. Our current implementation of PITTYPAT uses an analysis proposed in the work on CPI only to optimize the points-to analysis performed at runtime to validate branch targets.

8 Conclusion

We introduced a path-sensitive variation of CFI and an efficient runtime enforcement system, PITTYPAT. Our formal analysis and empirical evaluation demonstrate that, PITTYPAT provides strictly stronger security guarantees than conventional CFI, while incurring an acceptable amount of runtime overhead.

Appendix

A Language definition

In this section, we define the syntax (§A.1) and semantics (§A.2) of programs in PITTYPAT's target language.

A.1 Syntax

Figure 5 contains the syntax of a space of program instructions, Instrs. An instruction may compute the value of an operation in `ops` over values stored in registers and store the result in a register, may allocate a fresh memory cell (Eqn. 1), may load a value stored in the address in one operand register into a target register, may store a value in an operand register at the address stored in a target register (Eqn. 2), may test if the value in a register is non-zero and if so transfer control to an instruction at the address stored in an operand register, may perform an indirect call to a target address stored in an operand, or may return from a call (Eqn. 3). Although all operations are assumed to be binary, when convenient we will depict operations as using fewer registers (e.g., a copy instruction `copy r0,r1` in §4.2).

A program is a map from instruction addresses to instructions. That is, for space of instruction addresses IAddrs containing a designated *initial* address $\iota \in \mathsf{IAddrs}$, the language of programs is $\mathsf{Lang} = \mathsf{IAddrs} \to \mathsf{Instrs}$.

Instrs does not contain instructions similar to those in an architecture with a complex instruction-set, which may, e.g., perform operations directly on memory. The design of PITTYPAT directly generalizes to analyze programs that use such an instruction set. In particular, the actual implementation of PITTYPAT monitors programs compiled for `x86`.

A.2 Semantics

Each program $P \in \mathsf{Lang}$ defines a language of sequences of program states, called runs, that are generated by executing a sequence of instructions in P from an initial state. In particular, each program P defines two languages of runs. The first is the language of *well-defined* runs, in which each step from the current state is defined by the semantics of the next instruction in P. The second is the language of *feasible* runs contain some state q from which P executes an instruction that is not defined at q (e.g., dereferencing an invalid address). When the successive state of q is not defined and the program takes a step of execution, the program may potentially perform an operation that subverts security.

A state is a stack of assignments from registers to values and a memory, which maps each memory cell to a value. Let Words be a space of data words and let Cells be a space of memory cells. A value is an instruction address (§A.1), a data word, or a memory cell; i.e., $\mathsf{Values} = \mathsf{IAddrs} \cup \mathsf{Words} \cup \mathsf{Cells}$. Let the space of *registers* be denoted Regs. A *register frame* is the address of the current instruction and a map from each register to a value; i.e., the space of register frames, for $\mathsf{RegMaps} = \mathsf{Regs} \to \mathsf{Values}$, is denoted

$$\mathsf{Frames} = \mathsf{IAddrs} \times \mathsf{RegMaps}$$

For each register frame $f \in \mathsf{Frames}$, the instruction address of f is denoted as $\mathsf{ip}[f]$.

A *cell memory* is a map from each memory cell to a value; i.e., the space of cell memories is $\mathsf{Mems} = \mathsf{Cells} \to \mathsf{Values}$. A *state* is a pair of a non-empty stack of register frames and a cell memory; i.e., the space of states is denoted

$$\mathsf{States} = \mathsf{Frames}^{+} \times \mathsf{Mems}$$

For each state q, the instruction address of the top frame of q is denoted $\mathsf{ip}[q]$. For each sequence of states $r \in \mathsf{States}^*$, the sequence of corresponding instruction pointers of each state in r is denoted $\mathsf{IPs}(r) \in \mathsf{IAddrs}^*$. The states consisting of a single stack frame whose instruction pointer is ι are the *initial* states, denoted $\mathsf{States}_0 \subseteq \mathsf{States}$.

A transition relation relates each pre-state and instruction to their resulting post-states. I.e., the space of transition relations is $\mathsf{TransRels} = (\mathsf{States} \times \mathsf{Instrs}) \times \mathsf{States}$. The semantics of Lang is defined by the *well-defined* transition relation of Lang, denoted $\rho[\mathsf{WellDef}] \in \mathsf{TransRels}$. Each step of execution that is safe is a step in $\rho[\mathsf{WellDef}]$. The definition of $\rho[\mathsf{WellDef}]$ is standard, and we omit a complete definition.

For each transition relation $\rho \in \mathsf{TransRels}$, the *runs* of ρ in P are the sequences of states r in which each state in r steps to the successive state in r under ρ in P; the language of all such runs is denoted $\mathsf{Runs}[\rho, P]$. The runs of P under $\rho[\mathsf{WellDef}]$ are the *well-defined* runs of P, denoted

$$\mathsf{Runs}[\mathsf{WellDef}, P] = \mathsf{Runs}[\rho[\mathsf{WellDef}], P]$$

The feasible transition relation of Lang is $\rho[\mathsf{WellDef}]$ extended to relate each pre-state and instruction undefined in $\rho[\mathsf{WellDef}]$ to each post-state. The feasible transition relation thus includes safe steps of execution that a program may take, along with unsafe steps taken when the program executes an instruction from a state in which the instruction is not defined (i.e., loading from an address that does not point to allocated memory). The feasible transition relation of Lang is denoted

$$\rho[\mathsf{Feasible}] = \rho[\mathsf{WellDef}] \cup ((\mathsf{States} \times \mathsf{Instrs}) \setminus \mathsf{Dom}(\rho[\mathsf{WellDef}])) \times \mathsf{States}$$

where $\mathsf{Dom}(\rho[\mathsf{WellDef}])$ denotes the domain of $\rho[\mathsf{WellDef}]$.

The runs of P under $\rho[\mathsf{Feasible}]$ are the *feasible* runs of P, denoted $\mathsf{Runs}[\mathsf{Feasible}, P] = \mathsf{Runs}[\rho[\mathsf{Feasible}], P]$.

B Formal definition of points-to analysis

A control analysis takes a program P and computes a sound over-approximation of the instruction pointers that may be stored in each register when P executes a given instruction over a well-defined run. A control-analysis domain is an abstract domain [8] consisting of a set of abstract states, a concretization relation from abstract states to the program states that they represent, and an abstract transformer that describes how each abstract state is updated by a program.

Definition 3 *A* control-analysis domain *is a triple* (A, γ, τ)*, with:* ***(1)*** *An* abstract domain *A.* ***(2)****A* concretization relation *$\gamma \subseteq A \times \mathsf{States}$. There must be* initial *and* empty *elements $\mathsf{Init}, \mathsf{Empty} \in A$ such that* ***(a)*** *$\{\mathsf{Init}\} \times \mathsf{States}_0 \subseteq \gamma$ and* ***(b)*** *$\{\mathsf{Empty}\} \times \mathsf{States} \cap \gamma = \emptyset$.* ***(3)*** *An* abstract transformer *$\tau : A \times \mathsf{Instrs} \times \mathsf{IAddrs} \to A$, where for each abstract state $a \in A$, each state $q \in \mathsf{States}$ such that $(a, q) \in \gamma$, and each instruction $\mathtt{i} \in \mathsf{Instrs}$ and state $q' \in \mathsf{States}$ such that $(q, \mathtt{i}, q') \in \rho[\mathsf{WellDef}]$, it holds that $(\tau(a, \mathtt{i}, \mathsf{ip}[q']), q') \in \gamma$.*

For each control domain D, we refer to the abstract states, concretization relation, and abstract transformer of D as $A[D]$, $\gamma[D]$, and $\tau[D]$, respectively. The space of control-analysis domains is denoted Doms.

The initial and empty elements in $A[D]$ are denoted $\mathsf{Init}[D]$ and $\mathsf{None}[D]$. The binary relation $\sqsubseteq^D \subseteq A[D] \times A[D]$ is defined as follows. For all abstract states $a_0, a_1 \in A[D]$, if for each concrete state $q \in \mathsf{States}$ such that $(a_0, q) \in \gamma[D]$ it holds that $(a_1, q) \in \gamma[D]$, then $a_0 \sqsubseteq^D a_1$.

C Formal definitions of control security

C.1 Conventional CFI

For each control domain D and program P, a valid description of P in D over-approximates the control targets stored bound to registers and memory when control reaches each of instruction address of P. In particular, a valid description δ maps each instruction address to an abstract state of D that such that (1) δ maps ι to $\mathsf{Init}[D]$ and (2) δ is consistent with the abstract transformers of each instruction over D.

Definition 4 *For each control domain $D \in \mathsf{Doms}$ and program $P \in \mathsf{Lang}$, let $\delta : \mathsf{IAddrs} \to A[D]$ be such that* ***(1)*** *$\delta(\iota) = \mathsf{Init}[D]$;* ***(2)*** *for all instruction addresses $a_0, a_1 \in \mathsf{IAddrs}$ and instruction $\mathtt{i} \in \mathsf{Instrs}$, it holds that $\tau[D](\delta(a_0), \mathtt{i}, a_1) \sqsubseteq^D \delta(a_1)$. Then δ is a* valid description *of P in D.*

For each control domain $D \in \mathsf{Doms}$ and program $P \in \mathsf{Lang}$, the space of valid descriptions of P in D is denoted $\mathsf{ValidDescs}[D, P]$.

For each control domain $D \in \mathsf{Doms}$ and program $P \in \mathsf{Lang}$ the *most precise* description of P in D, denoted $\mu[D, P] \in \mathsf{ValidDescs}[D, P]$, is the valid description of P in D such that for all valid descriptions $\delta' \in \mathsf{ValidDescs}[D, P]$ and each instruction address $a \in \mathsf{IAddrs}$, $\mu[D, P](a) \sqsubseteq^D \delta'(a)$. Under well-understood conditions [8], D has a most-precise description for each program P that can be computed efficiently [2, 34].

Example 1 *For program `dispatch` (§2.1) and any control domain D that maps each instruction pointer to a set of instruction addresses, the most precise description of `dispatch` restricted to function pointers is given in §2.2.*

Each program P and domain D define a transition relation in which at each step from each instruction address a, the program only transfers control to an instruction address that is feasible in the most precise description of P under D at a.

Definition 5 *For each program* $P \in \mathsf{Lang}$ *and control domain* $D \in \mathsf{Doms}$*, let* $\rho \in \mathsf{TransRels}$ *be such that for all instruction addresses* $a, a' \in \mathsf{Addrs}$*, each instruction* $\mathtt{i} \in \mathsf{Instrs}$ *with* $\tau[D](\mu[D,P](a), \mathtt{i}, a') \neq \mathsf{None}[D]$ *and all states* $q, q' \in \mathsf{States}$ *with* $(\mu[D,P](a), q)$ *and* $(\mu[D,P](a'), q')$*, it holds that* $((q, \mathtt{i}), q') \in \rho$*. Then* ρ *is the* flow-sensitive transition relation *of* D *and* P*.*

For each domain D and program P, the flow-sensitive transition relation of D and P is denoted $\mathsf{FS}[D,P]$.

For each control domain D and program P, the most precise flow-sensitive description of P in D (Appendix D) defines an instance of generalized control security that is equivalent to CFI [1].

Definition 6 *For all programs* $P, P' \in \mathsf{Lang}$ *and each control-analysis domain* $D \in \mathsf{Doms}$*, if* P' *satisfies generalized control security under* $\mathsf{FS}[D,P]$ *(Appendix D, Defn. 5) with respect to* P*, then* P' *satisfies* CFI modulo D *with respect to* P*.*

Defn. 6 is equivalent to "ideal" CFI as defined in previous work to establish fundamental limitations on CFI [5].

C.2 Path-sensitive CFI

The problem of enforcing CFI is typically expressed as instrumenting a given program P to form a new program P' that allows each indirect control transfer in each of its executions only if the target of the transfer is valid according to a flow-sensitive description of the control-flow graph of P. To present our definition of path-sensitive CFI, we will introduce a general definition of control security parameterized on a given transition relation ρ. P' satisfies generalized control security under ρ with respect to P if **(1)** P' preserves each well-defined run of P and **(2)** each feasible run of P' has instruction addresses identical to the instruction addresses of some run of P under ρ.

Definition 7 *For each transition relation* $\rho \in \mathsf{TransRels}$*, let programs* $P, P' \in \mathsf{Lang}$ *be such that* ***(1)*** $\mathsf{Runs}[\mathsf{WellDef}, P] \subseteq \mathsf{Runs}[\mathsf{WellDef}, P']$*;* ***(2)*** *for each run* $r' \in \mathsf{Runs}[\mathsf{Feasible}, P']$*, there is some run* $r \in \mathsf{Runs}[\rho, P]$ *such that* $\mathsf{IPs}(r) = \mathsf{IPs}(r')$*. Then* P' *satisfies* generalized control security *under* ρ *with respect to* P*.*

We now define path-sensitive CFI, an instance of generalized control security that is strictly stronger than CFI. Each control domain D defines a transition relation over program states that are described by abstract states of D connected by the abstract transformer of D.

Definition 8 *For each control domain* $D \in \mathsf{Doms}$ *(§3.2, Defn. 3), let* $\rho[D] \in \mathsf{TransRels}$*, be such that for each abstract state* $a \in A[D]$*, each state* $q \in \mathsf{States}$ *such that* $(a, q) \in \gamma[D]$*, and each instruction* $\mathtt{i} \in \mathsf{Instrs}$ *and state* $q' \in \mathsf{States}$ *such that* $(\tau[D](a, \mathtt{i}, \mathsf{ip}[q']), q') \in \gamma[D]$*, it holds that* $(q, \mathtt{i}, q') \in \rho[D]$*. Then* $\rho[D]$ *is the* transition relation modulo D*.*

For all programs P and P' and each control domain D, P' satisfies path-sensitive CFI modulo D with respect to P if each step of each run of P' corresponds to a step of P over states with the same description under D.

Definition 9 *For all programs* $P, P' \in \mathsf{Lang}$ *and each control domain* $D \in \mathsf{Doms}$*, if* P' *satisfies control security under* $\rho[D]$ *(Defn. 8) with respect to* P*, then* P' *satisfies* path-sensitive CFI modulo D *with respect to* P*.*

Path-sensitive CFI is conceptually similar to, but stronger than, context-sensitive CFI [37], which places a condition on only bounded suffixes of a program's control path before the program attempts to execute a critical security event, such as a system call.

Path-sensitive CFI is as strong as CFI.

Lemma 1 *For each control domain* D *and all programs* $P, P' \in \mathsf{Lang}$ *such that* P' *satisfies path-sensitive CFI modulo* D *with respect to* P*,* P' *satisfies CFI modulo* D *with respect to* P*.*

Lemma 1 follows immediately from the fact that any control-transfer target that is along a given control path must be a valid target in a meet-over-all-paths solution.

Path-sensitive CFI is in fact *strictly* stronger than CFI.

Lemma 2 *For some control domain* D *and programs* $P, P' \in \mathsf{Lang}$*,* P' *satisfies CFI with respect to* P *modulo* D *but* P' *does not satisfy path-sensitive CFI with modulo* D *respect to* P*.*

Lemma 2 is immediately proven using any domain D that is sufficiently accurate between two control states and a program P that generates state with either control configuration at a particular program point.

D Formal definition of online analysis

The behavior of the analyzer module is determined by a fixed control-analysis domain D (§3.2, Defn. 3). We refer to PITTYPAT instantiated to use control domain D for points-to analysis as PITTYPAT$[D]$.

As the analyzer module executes, it maintains a control-domain abstract state $d \in A[D]$. In each step of execution, the analyzer module receives from the monitor process the next control-transfer target taken by the monitored program P, and either chooses to raise an alarm that transferring control to the target would cause P to break path-sensitive CFI modulo D, or updates its state and allows P to take its next step of execution.

In each step of execution, the analyzer module receives the next control target $a \in \mathsf{IAddrs}$ taken by the monitored program, and either raises an alarm or updates its maintained control description d as a result. If a is not a feasible target from d over the next sequence of non-branch instructions, then the analyzer module throws an alarm signaling that control flow has been subverted, and aborts.

Theorem 1 *For* $D \in \mathsf{Doms}$ *and* $P \in \mathsf{Lang}$*, the program* P' *simulated by running* P *in* PITTYPAT$[D]$ *satisfies path-sensitive CFI modulo* D *with respect to* P *(Defn. 9).*

We have given the design of an analyzer module that uses an arbitrary control domain generically; i.e., the analyzer can use any control-analysis domain that satisfies the definition given in §3.2, Defn. 3. However, we have found that the performance of the analyzer module can be improved significantly by using a control domain that takes advantage of the particular context of online path-sensitive analysis by maintaining points-to information about exactly the variables that are live in each live stack frame in the program state. We now define in detail the control domain used by our analysis, $\mathsf{OnlinePtsTo} = (A, \gamma, \tau)$.

Each element in the space A is either $\mathsf{None}[A]$, which represents no states, or a tuple consisting of **(1)** a stack in which each entry is a map from each register `r` to a set of memory cells and instruction pointer that `r` may store and **(2)** a map from each cell to the cells and instruction pointers that it may store. I.e., for

$$\begin{aligned}\mathsf{Addrs} &= \mathsf{IAddrs} \cup \mathsf{Cells}\\ \mathsf{RegPtsMaps} &= \mathsf{Regs} \to \mathscr{P}(\mathsf{Addrs})\\ \mathsf{FramePtsTo} &= \mathsf{IAddrs} \times \mathsf{RegPtsMaps}\\ \mathsf{CellPtsTo} &= \mathsf{Cells} \to \mathscr{P}(\mathsf{Addrs})\end{aligned}$$

with $\mathscr{P}(\mathsf{Addrs})$ the powerset of addresses, the abstract states are $A = \mathsf{FramePtsTo}^+ \times \mathsf{CellPtsTo}$. The stack containing a single frame that maps each register to the empty set of addresses, paired with an empty memory map, is the initial element of A.

Example 2 *§2.3 contains examples of elements of A. In order to simplify the presentation, in §2.3, only bindings to the function pointer* `handler` *are shown, because these bindings are the only ones that need to be inspected to determine the security of a given run of* `dispatch`*.*

Concretization relation $\gamma \subseteq A \times \mathsf{States}$ relates each stack and memory of points-to information to each concrete state with a similarly structured stack and heap. For each $n \in \mathbb{N}$, let $\mathsf{a}_0, \ldots, \mathsf{a}_n \in \mathsf{IAddrs}$, $R_0, \ldots, R_n \in \mathsf{RegMaps}$, and $R'_0, \ldots, R'_n \in \mathsf{RegPtsMaps}$ be such that for each $i \leq n$ and each register $\mathtt{r} \in \mathsf{Regs}$, if $R_i(\mathtt{r}) \in \mathsf{Addrs}$, then $R_i(\mathtt{r}) \in R'_i(\mathtt{r})$. Let $m \in \mathsf{Mems}$ and $m' \in \mathsf{CellPtsTo}$ be such that for each cell $c \in \mathsf{Cells}$, $m(c) \in m'(c)$. Then:

$$\begin{aligned}&(([(\mathtt{i}_0, R'_0), \ldots, (\mathtt{i}_n, R'_n)], m'),\\ &\ ([(\mathtt{i}_0, R_0), \ldots, (\mathtt{i}_n, R_n)], m)) \in \gamma\end{aligned}$$

The abstract transformer $\tau : A \times \mathsf{Instrs} \times \mathsf{IAddrs} \to A$ is defined as follows. For each set of memory cells $C \subseteq \mathsf{Cells}$, let $\mathsf{fresh}(C) \in \mathsf{Cells} \setminus C$ be a fresh memory cell not in C. For all register frames $f_0, \ldots, f_n \in \mathsf{FramePtsTo}$, each register map $m \in \mathsf{RegPtsTo}$, each cell points-to map $c \in \mathsf{CellPtsTo}$, all registers $\mathtt{r0}, \mathtt{r1}, \mathtt{r2} \in \mathsf{Regs}$, and all instruction addresses $a, a' \in \mathsf{IAddrs}$, a store instruction `store r0, r1` updates the cell map so that each cell bound to `r1` points to each cell points to each cell bound to `r0`. I.e., for $c_0, \ldots, c_n \in R(\mathtt{r1})$,

$$\begin{aligned}&\tau(((a,R) :: F, m), \mathtt{store\ r0,\ r1}, a') =\\ &\quad ((a',R) :: F, m[c_0 \mapsto R(\mathtt{r0}), \ldots, c_n \mapsto R(\mathtt{r0})])\end{aligned}$$

A branch instruction requires that the target instruction address is in the points-to set of the target register of the branch. I.e., if $a' \in R(\mathtt{r0})$, then

$$\tau(((a,R) :: F, m), \mathtt{br\ r0}, a') = ((a',R) :: F, m)$$

Otherwise, τ maps the abstract state to $\mathsf{None}[A]$. A call instruction increments the instruction pointer in the top frame and pushes onto the stack a frame with an empty register map. I.e., if $a' \in R(\mathtt{r})$,

$$\begin{aligned}&\tau(((a,R) :: F, m), \mathtt{call\ r0}, a') =\\ &\quad ((a', \emptyset) :: (a+1, R) :: F, m)\end{aligned}$$

Otherwise, τ maps the abstract state to $\mathsf{None}[A]$. A return instruction pops the top register frame from the stack. I.e., $\tau(((a,R) :: F, m), \mathtt{return}, a') = (F, m)$ A data operation updates only the instruction address:

$$\tau(((a,R) :: F, m), \mathtt{op\ r0,r1,r2}, a') = ((a',R) :: F, m)$$

An allocation `alloc r0` updates the register map in the top frame of the stack so that `r0` points to a fresh memory cell. I.e.,

$$\begin{aligned}&\tau(((a,R) :: F, m), \mathtt{alloc\ r0}, a') =\\ &\quad ((a', R[\mathtt{r0} \mapsto \mathsf{fresh}(\mathsf{Rng}(m))]) :: F, m)\end{aligned}$$

where $(a,R) :: F$ denotes (a,R) prepended to F and $\mathsf{Rng}(m)$ denotes the range of m. A copy instruction `copy r0, r1` updates the register map so that each cell that may be stored in `r0` may be stored in `r1`. I.e.,

$$\begin{aligned}&\tau(((a,R) :: F, m), \mathtt{copy\ r0,\ r1}, a') =\\ &\quad ((a', R[\mathtt{r1} \mapsto R(\mathtt{r0})]) :: F, m)\end{aligned}$$

A load instruction `load r0, r1` updates the register map in the top frame so that each cell that may be pointed to by a cell bound to `r0` is bound to `r1`:

$$\begin{aligned}&\tau(((a,R) :: F, m), \mathtt{ld\ r0,\ r1}, a') =\\ &\quad ((a', R[\mathtt{r1} \mapsto \bigcup_{c \in R(\mathtt{r0})} m(c)]) :: F, m)\end{aligned}$$

The abstract transformers for other instructions, such as data operations that perform pointer arithmetic, are defined similarly, and we do not give explicit definitions here in order to simplify the presentation.

Example 3 *Consider descriptions of states of* `dispatch` *and its instruction* `call handler` *(§2.1). For abstract state*

$$A_0 = ([(\mathit{L22}, [\mathit{handler} \mapsto \{\mathit{priv}\}])], \emptyset)$$

$\tau(A_0, \mathit{call\ handler}, \mathit{priv})$ *consists of a fresh stack frame for* priv *pushed onto the stack* $[(\mathit{L22}, \mathit{handler} \mapsto \mathit{priv})]$*. For abstract state*

$$A_1 = ([(\mathit{L22}, [\mathit{handler} \mapsto \{\mathit{unpriv}\}]), \emptyset)$$

$\tau(A_1, \mathit{call\ handler}, \mathit{priv})$ *is* $\mathsf{None}[A]$*.*

We have given an online points-to analysis for a simple language with only calls and returns. Practical languages typically support additional interprocedural control instructions that, e.g., resolve calls targets through dynamic dispatch or unwind the callstack. Our complete implementation handles each such instruction using an appropriate abstract transformer.

The fact that (D, γ, τ) defines a sound analysis can be proven using standard techniques from abstract interpretation [8].

Digtool: A Virtualization-Based Framework for Detecting Kernel Vulnerabilities

Jianfeng Pan, Guanglu Yan, Xiaocao Fan
IceSword Lab, 360 Internet Security Center

Abstract

Discovering vulnerabilities in operating system (OS) kernels and patching them is crucial for OS security. However, there is a lack of effective kernel vulnerability detection tools, especially for closed-source OSes such as Microsoft Windows. In this paper, we present Digtool, an effective, binary-code-only, kernel vulnerability detection framework. Built atop a virtualization monitor we designed, Digtool successfully captures various dynamic behaviors of kernel execution, such as kernel object allocation, kernel memory access, thread scheduling, and function invoking. With these behaviors, Digtool has identified 45 zero-day vulnerabilities such as out-of-bounds access, use-after-free, and time-of-check-to-time-of-use among both kernel code and device drivers of recent versions of Microsoft Windows, including Windows 7 and Windows 10.

1 Introduction

Software vulnerabilities have been well studied over the years, but they still remain a significant threat to computer security today. For instance, improper use of parameters or memory data can lead to program bugs, some of which can become vulnerabilities, such as time-of-check-to-time-of-use (TOCTTOU), use-after-free (UAF), and out-of-bounds (OOB) vulnerabilities. These vulnerabilities are often the root cause of successful cyberattacks. However, symptoms resulting from these vulnerabilities tend to be delayed and non-deterministic, which makes them difficult to discover by regular testing. Therefore, dedicated vulnerability identification tools that can systematically find software vulnerabilities are urgently needed.

There are usually two aspects in detecting vulnerabilities: path exploration and vulnerability identification. Combining path exploration with vulnerability identification tools is an effective way to detect vulnerabilities. Most fuzzing tools, such as AFLFast [12] and SYMFUZZ [16], only adopt path exploration to probe code branches. As a typical example of a path explorer, S2E [17], based on virtualization technology, combines virtual machine monitoring with symbolic execution to automatically explore paths. Vulnerability identification tools are used for recording exceptions (e.g., the abuse of parameters or illegal memory access) in the paths that have been probed. While we could have also investigated path exploration, the main focus of Digtool is vulnerability detection.

Depending on the detection targets, vulnerability identification tools can be classified into two categories: (1) tools for checking applications in user mode, and (2) tools for detecting programs in kernel mode. However, most of the current vulnerability identification tools, such as DESERVE [29], Boundless [15], and LBC [21], have been designed for applications in user mode. They cannot be directly used to detect kernel vulnerabilities. However, vulnerabilities in OS kernels or third-party drivers have a far more severe threat than user-level vulnerabilities. Thus, there is still a need for effective detection of kernel vulnerabilities.

Several Linux kernel vulnerability identification tools, such as Kmemcheck [32], Kmemleak [6], and KEDR [35], have been developed. They can effectively capture kernel vulnerabilities. However, since they rely on the implementation details and the source code of the OS, it is difficult to port these tools to other OSes, especially to a closed-source OS such as Windows.

In Windows OS, a notable tool for checking kernel vulnerabilities is Driver Verifier [28], which is used to detect illegal function calls or actions that might corrupt the system. While Driver Verifier is able to detect many potential bugs, it is an integrated system, but not a dedicated tool for detecting kernel vulnerabilities. For instance, it cannot be used to identify certain vulnerabilities, such as TOCTTOU vulnerabilities.

Vulnerability identification tools based on virtualization are much more portable to support different OSes, including closed-source ones. However, the current vulnerability identification tools based on virtualization, such as VirtualVAE [18] and PHUKO [38], are dedicated to detecting a single, specific type of vulnerabilities. Moreover, they have not been evaluated in detecting zero-day kernel vulnerabilities. It is worth noting that the virtualization-based tool Xenpwn [41] makes use of Libvmi [34] to discover vulnerabilities in para-virtualized devices of Xen (not for the Windows OS). It traces guest physical addresses through extended page tables (EPTs). However, it is not appropriate for monitoring guest virtual addresses.

For closed-source OSes such as Windows, it is even more difficult to build a vulnerability identification tool. We are neither able to insert detection code at compile-time to detect program errors like those tools for Linux, nor able to rewrite or modify the OS source code like Driver Verifier. Under these constraints, we adopt virtualization to hide the internal details of the Windows OS, and carry out the detection at a lower level, i.e., at the hypervisor. Therefore, a novel vulnerability identification framework named *Digtool* is proposed, which captures dynamic behavior characteristics to discover kernel vulnerabilities in the Windows OS by using virtualization technology.

Contributions. In short, we make the following contributions in this paper:

- A virtualization-based vulnerability identification framework, *Digtool*, is proposed to detect different types of kernel-level vulnerabilities in the Windows OS. It does not need to crash the OS, and thus it can *capture multiple vulnerabilities and provide the exact context of kernel execution*. It is designed to *be independent of kernel source code*, which enlarges its applicable scope. In addition, it does not depend on any current virtualization platform (e.g., Xen) or emulator (e.g., bochs).

- Based on the framework, virtualization-based detection algorithms are designed to discover four types of vulnerabilities, including *UNPROBE* (no probe, i.e., no checking on the user pointer to the input buffer), *TOCTTOU, UAF*, and *OOB*. These algorithms can effectively detect kernel vulnerabilities by accurately capturing their dynamic characteristics.

- With Digtool, we found *45 zero-day kernel vulnerabilities* from both Windows kernel code and third-party device driver code. These vulnerabilities had never been published before. We have made responsible disclosure and have helped the corresponding vendors fix the vulnerabilities. The root cause of some of the vulnerabilities is also analyzed in this paper.

The rest of this paper is organized as follows. In Section 2, we describe the background. In Section 3, we provide the overall design of the framework. In Section 4, we detail the implementation of Digtool, and, in Section 5, evaluate its effectiveness and efficiency. In Section 6, we discuss its limitations and directions for future research. In Section 7, we review the related work, and in Section 8 we conclude.

2 Background

UNPROBE, TOCTTOU, UAF, and OOB vulnerabilities have widely appeared in various programs including OS kernels. They can lead to denial-of-service attacks, local privilege escalation, and even remote code execution, which directly affect the stability and security of the victim program.

No checking of a user pointer to an input buffer could lead to a vulnerability that is denoted *UNPROBE* in this paper. Many kernel modules omit the checking for user pointers (especially when the user pointers are nested in a complex structure). According to the historical data of common vulnerabilities and exposures (CVEs), there have been many UNPROBE vulnerabilities in the Windows kernels, and there are also many such vulnerabilities in third-party drivers (e.g., the vulnerabilities in the experiment described herein). An UNPROBE vulnerability could result in an invalid memory reference, an arbitrary memory read, or even an arbitrary memory overwrite. Therefore, detection of UNPROBE is necessary. While fuzzing based on path exploration can help solve some problems, it is difficult to test all pointer arguments nested in complicated structures.

A *TOCTTOU* vulnerability stems from fetching a value from user memory more than once. Usually, a brittle system-call handler fetches a parameter for the first time to check it and for the second time to use it. Thus, an attacker has a chance to tamper with the parameter in the user space between the two steps. Consequently, the system-call handler will fetch and use the compromised parameter, which will lead to a TOCTTOU vulnerability. Similar to UNPROBE above, TOCTTOU could also result in an invalid memory reference, an arbitrary memory read, or an arbitrary memory overwrite. It is difficult to detect this type of vulnerability through fuzzing based only on path exploration. Bochspwn [24] was developed to identify many TOCTTOU vulnerabilities in the Windows kernel. However, its application is extremely restricted by the disappointing performance of the bochs emulator [25]. In addition, the bochs emulator

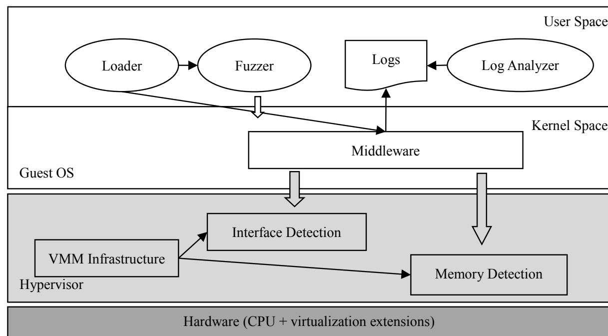

Figure 1: Digtool architecture.

cannot simulate all actual operations and functionalities of a real-world machine (e.g., inability to emulate certain real, hardware-specific kernel modules, such as modern video card drivers). As a result, Bochspwn cannot cover all of the kernel modules.

A *UAF* vulnerability stems from reuse of freed memory. An *OOB* vulnerability results from accessing memory that is beyond the bounds of allocated heaps or memory objects. In many cases, these vulnerabilities could lead to local privilege escalation. For the Linux OS, tools such as AddressSanitizer [36] have been released to detect these vulnerabilities. For the closed-source Windows OS, it is difficult for a third party to build such detection tools. Driver Verifier [28] proposed by Microsoft can be used to discover these types of vulnerabilities. However, it is much more likely to miss a vulnerability in some scenarios (e.g., the UAF detection scenario described in Section 4.3.1).

Digtool adopts virtualization technology to detect the above four types of vulnerabilities in Windows kernels and device drivers with better detection results. As a framework, it could also be used to detect some other types of vulnerabilities, such as double-free and information leakage, by expanding its detection algorithms.

3 Overview

The overall architecture of Digtool is illustrated in Figure 1. The subsystems and logic modules of the Digtool are distributed across user space, kernel space, and the hypervisor. The thin arrows in the figure indicate that there are direct invoking relationships or direct channels for passing messages between modules. The thick arrows illuminate that two modules act on each other indirectly via some event-triggering mechanisms.

One of the most important tasks for the hypervisor is to *monitor virtual memory access*. This is the basis for interface detection and memory detection. However, the memory monitor methods in current vulnerability identification tools are unsuitable for our scenario. Without source code, we cannot monitor memory access through patching source code like Driver Verifier [28], or through configuring compile-time instrumentation like AddressSanitizer [36]. Patching the system exception handler to intercept memory references by using page access rights is an alternative, but it will introduce significant, internal modifications in the kernel that may impact the stability of the OS and be the least portable. Binary rewriting could help to solve part of the problem. However, tools such as Pin [27] and DynamoRIO [13] work well in user mode, but it is difficult for these tools to work in kernel mode. Drk [5] tried to port the DynamoRIO to the kernel space for Linux, but it has not been updated for years, and there are few special tools for the Windows kernel. As an alternative, QEMU [11] or the recent extension PEMU [42] could be used to implement kernel program instrumentation for the Windows OS, but it is complicated and has a heavier effect on performance even without monitoring memory access.

Therefore, there is a clear need to develop an efficient alternative mechanism for tracing memory access outside a guest OS. As most programs run in virtual address space, we should focus more on the virtual address than on the physical address. Thus, the method of using EPT to trace *physical addresses*, like Xenpwn [41], cannot be directly used in our scenario, especially for the Windows OS, whose memory mapping between virtual and physical addresses is nonlinear. In view of the poor performance of Bochspwn [24], we did not adopt a full-stack emulator. In order to build a practical framework that focuses on the virtual address space, a *shadow page table (SPT)* based on hardware virtualization technology is employed to *monitor virtual memory access*, which is very different from Xenpwn and Bochspwn in both design and implementation.

In kernel space, the major work includes setting the monitored memory area, communicating with the hypervisor, and intercepting specified kernel functions. The monitored memory area depends on the type of vulnerability to be detected. It will be changed along with the occurrence of some kernel events (e.g., allocating or releasing memory). Hence, it is necessary to trace these events in kernel space. For communication, the service interfaces are exported by Digtool. Kernel code invokes these interfaces to request services from the hypervisor. In addition, some kernel functions of the OS should be hooked to trace some particular events. All of these tasks that should be reserved in kernel space make up the middleware.

The loader, fuzzer, and log analyzer are placed in user space to simplify the code and make the entire system more stable. The loader activates the hypervisor and loads the fuzzer that is used to probe program paths.

Thus, the behavior characteristics in the probed paths can be recorded for the log analyzer.

Unlike emulator-based tools (e.g., Bochspwn [24]), Digtool is able to run in a physical machine with this architecture design. *It is widely applicable to almost all main kernels and third-party drivers.*

3.1 Hypervisor Components

Digtool does not rely on any current hypervisor such as Xen or KVM, and we implemented our own hypervisor that contains three important components, including VMM infrastructure (VMM, i.e., virtual machine monitor, which is equivalent to a hypervisor), interface detection, and memory detection.

To begin with, VMM infrastructure checks the hardware environment and the OS version to ensure compatibility. It then initializes the hypervisor and loads the original OS into a VM. The initialization of the hypervisor mainly consists of the following tasks: (1) building SPTs to monitor virtual memory access in the guest OS, (2) initializing modules for tracing thread scheduling, and (3) establishing communication between the OS kernel and the hypervisor. As such, the interface detection and memory detection components can monitor and handle some special events.

Interface detection monitors the parameters passed from user-mode programs during the system-call execution. It traces the *use* and the *check* of these parameters to discover potential vulnerabilities. The SPTs are needed to monitor the *user memory space* during the system-call execution. As system calls are always invoked in kernel mode, we do not need to monitor user memory when the processor runs in user mode. Otherwise, many VMEXIT events will be triggered, which will bring a substantial decrease in performance. In order to focus on vulnerabilities in a limited scope of system calls, interface detection is able to configure the detection scope of system calls through correlative service interfaces. Thus, it can obtain the potential vulnerabilities in specified system calls.

Memory detection monitors the use of *kernel memory* in the guest OS to detect illegal memory access. The SPTs are used to monitor the kernel memory. To detect some specified types of vulnerabilities in different detection targets (e.g., the multi-user Win32 driver: `Win32k`), memory detection is able to set monitored memory area and configure detection targets. It also dynamically calibrates the monitored memory area when capturing events of memory allocation or deallocation. All of these are implemented through corresponding service interfaces. Thus, it will obtain the exact characteristics of potential vulnerabilities during the memory access process.

3.2 Kernel-Space Components

The middleware locates in the kernel space of the guest OS. It is used to connect the subsystems in the hypervisor and the programs in the user space. For example, before loading the fuzzer, we can set the detection scope of system calls through the configuration file. Then, the middleware transfers the configuration information and the fuzzer process information from the loader to the hypervisor. Thus, the hypervisor can detect vulnerabilities in the environment of the fuzzer process.

For interface detection, the middleware records all behavior events in log files through a work thread. The recorded data include system call number, event type, event time, instruction address, and accessed memory of the event. Thus, the log analyzer can detect potential UNPROBE and TOCTTOU vulnerabilities from the log files. Note that only the system calls in the detection scope are recorded, which is meaningful when the system calls are invoked frequently. The number of frequent system calls could be limited to reduce the performance cost and alleviate the stress on the log analyzer. We can then obtain more effective data with less performance overhead.

For memory detection, the middleware helps dynamically calibrate the monitored memory by hooking some specified memory functions. In order to obtain more relevant data and reduce performance cost, it also limits the areas of monitored memory and the scope of kernel code (e.g., the code segment of `Win32k`) through invoking the service interfaces. If a potential vulnerability is found, the middleware records it and interrupts the guest OS through single-step mode or a software interruption. Thus, the guest OS is able to be connected with a debug tool such as `Windbg`, and the exact context is obtained to analyze the vulnerability.

3.3 User-Space Components

There are three modules in the user space: loader, fuzzer, and log analyzer. The loader is used for loading the target process, after which Digtool provides a process environment for detecting vulnerabilities. The loader can also limit the detection scope of system calls and set the virtual addresses of the boundary for ProbeAccess events (which will be described in Section 4.2) through the configuration file.

The fuzzer is responsible for discovering code branches. It is loaded by the loader. In Digtool, the fuzzer needs to invoke the system calls in the detection scope, and discovers as many branches as possible in the code of a system call by adjusting the corresponding parameters. A higher path-coverage rate can certainly help achieve a more comprehensive test. However, as this

paper mainly focuses on the *vulnerability identification tool*, not path exploration, we will not go into much detail regarding the fuzzer or the path coverage.

The log analyzer is designed to discover potential vulnerabilities from log files. It extracts valuable information from the large amount of recorded data according to the characteristics of vulnerabilities. The log analyzer's vulnerability detection algorithm needs to be changed depending on the types of vulnerabilities (e.g., UNPROBE or TOCTTOU) to be detected, since we use different policy to detect them.

4 Implementation

In this section, we provide the implementation details of how we implement Digtool, especially its hypervisor components, including VMM infrastructure, interface detection, and memory detection. The implementation of other components, such as the middleware, loader, fuzzer, and log analyzer, is also described in this section.

4.1 VMM Infrastructure

The main task of VMM infrastructure is to initialize the hypervisor and provide some basic facilities. After initializing the hypervisor, it loads the original OS into a VM. Then, the hypervisor is able to monitor the OS through the facilities.

The initialization process runs as follows. In the beginning, Digtool is loaded into the OS kernel space as a driver that checks whether processors support hardware virtualization through `CPUID` instruction. If they support it, VMM infrastructure builds some facilities for the hypervisor. Then, it starts the hypervisor for every processor by initializing some data structures (e.g., `VMCS`) and registers (e.g., `CR4`). Finally, it sets the state of guest CPUs according to the state of the original OS. Thus, the original OS becomes a guest OS running in a VM.

The Intel developer's manual [23] can be referenced to obtain the implementation details of hardware virtualization. This paper mainly focuses on the modules that help to identify vulnerabilities. These modules include the virtual page monitor, thread scheduling monitor, CPU emulator, communication between kernel and hypervisor, and the events monitor. Among these, the CPU emulator and events monitor are associated with particular types of vulnerabilities, so these two parts will be described in corresponding subsections.

4.1.1 Virtual Page Monitor

Digtool adopts SPTs to monitor virtual memory access. To reduce performance cost, SPTs are only employed for the monitored threads (i.e., the fuzzer threads). For non-monitored threads, the original page tables in the guest OS are used. When thread scheduling occurs, the virtual page monitor needs to judge whether the new thread that will get control is a monitored thread. Only when it is a monitored thread, will a SPT be built for it. Thus, performance is optimized.

Figure 2 shows the workflow of the virtual page monitor for a monitored thread. Digtool adopts a sparse BitMap that traces virtual pages in a process space. Each bit in the BitMap represents a virtual page. If a bit is set to 1, the corresponding page needs to be monitored, and the P flag in its page table entry (PTE) of the SPT should be clear [note that the SPT is constructed according to the guest page table (GPT)]. Thus, access to the monitored virtual page will trigger a `#PF` (i.e., page fault) exception that will be captured by the hypervisor.

When the `#PF` exception is captured, the page-fault handler in the hypervisor will search for the BitMap. If the bit for the page that causes the `#PF` exception is 0, the page is not monitored. The SPT will be updated through GPT. Then, the instruction that causes the exception will re-execute successfully. If the bit is 1, it is a monitored page. Then, the Handle module will be used to handle this exception. It will (1) record the exception, or (2) inject a private interrupt (0x1c interrupt, which has not been used) into the guest OS. The recording process for the exception is described in the following (i.e., the part of shared memory described in Section 4.1.3). The private interrupt handler stores some information (e.g., the memory address that is accessed, and the instruction that causes the `#PF`) about the `#PF` exception, and then it connects to a debug tool by triggering another exception, such as software interruption, in the guest OS. After that, Digtool *"single steps"* the instructions in the guest OS by setting a `MTF` (monitor trap flag, which can be used in new version of processors) or `TF` (trap flag, which is used in old versions of processors) in the hypervisor. Meanwhile, the SPT is updated through GPT to make the instruction that causes the exception re-execute successfully. Because of `MTF` or `TF`, a `VMEXIT` will be triggered after executing one instruction in the guest OS, and then the hypervisor will get control again. Thus, the handler of `MTF` or `TF` in the hypervisor has a chance to clear the P flag, and the page will be monitored once again. Finally, it disables the `MTF` or `TF` to cancel the single-stepping operation.

We have noticed that, in most cases, we need to monitor a *memory region* rather than an entire memory page. A memory region covers only one part of a memory page or contains several pages. All of the memory pages owned by a monitored memory region should be traced. When a `#PF` exception is triggered, its handler needs to

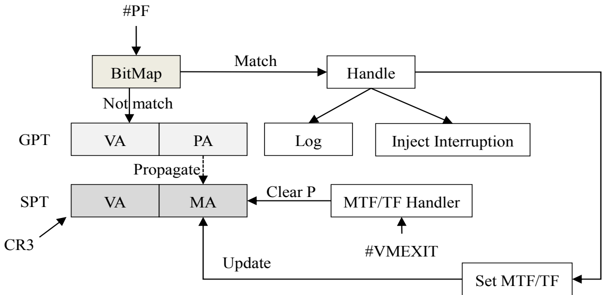

Figure 2: Workflow of virtual page monitor.

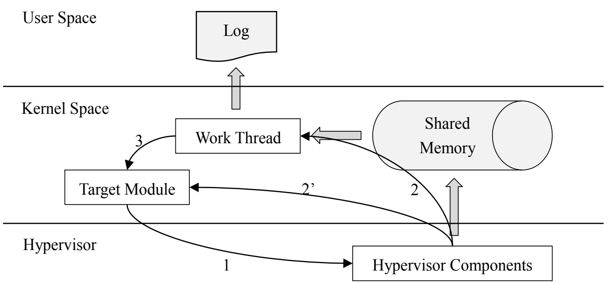

Figure 3: Communication between kernel and hypervisor via shared memory.

further recognize whether the address causing the #PF exception is in the monitored memory region.

4.1.2 Thread Scheduling Monitor

As discussed above, Digtool only focuses on the monitored threads. It needs to trace thread scheduling to enable detection for monitored threads and disable detection for non-monitored threads. Thus, it achieves better performance with more effective data. The method of the thread scheduling monitor is shown below.

In the Windows OS, the _KPRCB structure contains the running thread information for its corresponding processor. The _KPRCB is referenced by the _KPCR structure whose address can be obtained through the FS register (for x64 architecture, the GS register). The running thread of the current processor can be obtained through the following relationship:

FS->_KPCR->_KPRCB->CurrentThread.

With respect to how to acquire _KPRCB, the methods described in ARGOS [43] could be leveraged to uncover this data structure, though currently we use manual reverse engineering and internal Windows kernel knowledge to get it. Note that there are also other data structure agnostics approaches to detect kernel threads, such as using kernel stack pointer (e.g., [20]). After obtaining the _KPRCB structure, the CurrentThread member in the _KPRCB is monitored. Any write operation to the CurrentThread means a new thread will become the running state, and this will be captured by the hypervisor. If the new thread is a monitored thread, the virtual page monitor will be activated to detect vulnerabilities.

4.1.3 Communication Between Kernel and Hypervisor

The communication between kernel and hypervisor includes two main aspects. One is that the kernel component makes a request to the hypervisor, and the hypervisor provides service. The other is that the hypervisor sends messages to the kernel component, and the kernel component handles the messages. The former is mainly implemented by the service interfaces, and the latter is carried out through the shared memory.

Digtool exports some service interfaces for the kernel-space components. They can be directly invoked by kernel code. The service interfaces are implemented through a VMCALL instruction, which will trigger a VMEXIT to trap into the hypervisor. Thus, the service routines in the hypervisor can handle the requests.

The shared memory is applied to exchange data between the hypervisor and kernel code. The hypervisor writes the captured behavior information to the shared memory and notifies the kernel space components. Then, the kernel space components read and deal with the data in the shared memory. The workflow of the shared memory is shown in Figure 3.

The main data flow is represented by the thick arrows in the figure. When the hypervisor captures some behavior characteristics, it records them into shared memory. The middleware in the kernel space uses a work thread to read the data in the shared memory. It also records characteristic information into log files.

The following stream of instructions is shown by the thin arrows in Figure 3: (1) When the target module (which is being detected) triggers an event monitored by the hypervisor, a VMEXIT will be captured by the hypervisor. (2) The hypervisor records the event information into shared memory. If the shared memory is full, it will inject a piece of code into the guest OS. The code will notify the work thread to handle the data in shared memory (i.e., read them from shared memory and write them into log files). If the shared memory is not full, it will jump back to the target module (the arrow represented by 2'). (3) After notifying the work thread, the injected code will return to the target module and re-execute the instruction that causes the VMEXIT.

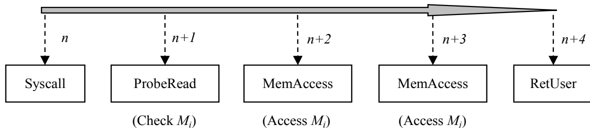

Figure 4: Example of recorded events during a system call.

4.2 Detecting Vulnerabilities at System Call Interface

Interface detection traces the execution process of system calls and monitors their parameters passed from user-mode programs. It then decides whether the *check* or the *use* of these parameters will create potential hazards.

Interface detection monitors the entire execution process of system calls from the point of *entering into kernel mode* to the point of *returning to user mode*. During this process, it monitors how the kernel code handles the user memory. Then, it records the behavior characteristics to analyze potential vulnerabilities. Interface detection is implemented by defining and intercepting different *behavior events* during the execution of system calls. These behavior events and their interception methods make up the events monitor.

Ten types of behavior events are defined in the event monitor: Syscall, Trap2b, Trap2e, RetUser, MemAccess, ProbeAccess, ProbeRead, ProbeWrite, GetPebTeb, and AllocVirtualMemory events. Particular combinations of these events can help locate potential vulnerabilities in the large amount of log data (e.g., two continuous MemAccess events suggest a potential TOCTTOU vulnerability). The behavior events recorded in the execution of a system call are shown in Figure 4. The boxes denote recorded events. The values (e.g., n and $n+1$) above the boxes are the event time (which only records order but not the actual intervals). The M_i and M_j under the boxes represent the user memory addresses accessed by the event.

In the Windows OS, fast system call, interruption of `0x2b`, and interruption of `0x2e` are the three entry points that allow user-mode code to invoke kernel functions. The fast system call adopts the `sysenter/syscall` instruction to go into kernel mode. The interruption of `0x2b` is used to return from a user-mode callout to the kernel-mode caller of a callback function. The interruption of `0x2e` is responsible for entering into kernel mode in older Windows OSes. In Digtool, the three entry points are traced by intercepting corresponding entries in the interrupt descriptor table (IDT) or MSR register. They are defined as three types of behavior events, which are marked as Syscall event, Trap2b event, and Trap2e event, respectively.

The return point is obtained by another way. When the control flow returns to the user mode, the processor will prefetch the user-mode instructions. Thus, Digtool obtains the point of returning to user mode by monitoring the user-mode pages access. This behavior event is marked as RetUser event.

After obtaining the two key points (i.e., the Syscall/-Trap2b/Trap2e event and RetUser event), interface detection will record the instructions that manipulate user memory between the two points. To achieve this, one important function is to monitor access to the user memory through SPTs. This behavior event is marked as a MemAccess event. It is noticed that, the user-mode pages are monitored only if the processor runs in kernel mode, and this will significantly reduce the performance cost.

To improve the efficiency of discovering and analyzing vulnerabilities, interface detection also defines and intercepts some other behavior events, including ProbeAccess, ProbeRead, ProbeWrite, GetPebTeb, and AllocVirtualMemory. Among the five events, the first three are used to record whether the user memory address has been checked by the kernel code, while the last two events suggest that the user memory address is legal; that is, there is no need to check it again and thus false positives can be reduced. These events are intercepted by hooking corresponding kernel functions, except for the ProbeAccess event.

GetPebTeb and AllocVirtualMemory events are used to reduce false positives. In order to improve the detection accuracy, we should focus on the user memory that is passed as parameters from the user-mode program, rather than on the memory that has been checked or that will be deliberately accessed by kernel code. For example, kernel code sometimes accesses a user memory region returned by a `PsGetProcessPeb` function or allocated by a `NtAllocateVirtualMemory` function during a system call. In these cases, the user memory is not a parameter passed from a user-mode program, and it has less of a chance of causing a vulnerability. Digtool defines GetPebTeb and AllocVirtualMemory events, respectively, to handle these cases. These events inform the log analyzer that the access to user memory is legal and that no bug exists.

In addition to invoking the `ProbeForRead` (i.e., ProbeRead event) or `ProbeForWrite` (i.e., ProbeWrite event) function, kernel code can also adopt direct comparison to check the legitimacy of the user memory address; for example, "`cmp esi, dword ptr [nt!MmUserProbeAddress (83fa271c)]`" where the `esi` register stores the user memory address to be checked, and the exported variable `nt!MmUserProbeAddress` stores the boundary of the user memory space. This kind of behavior event is

marked as a ProbeAccess event. We cannot intercept it by hooking a kernel function as this event is not handled by any kernel function. Moreover, there is no access to user memory space. Hence, we cannot intercept it through monitoring a MemAccess event either. For this particular type of event, the CPU emulator is proposed.

The CPU emulator is placed in the hypervisor to help obtain behavior characteristics that are difficult to obtain through regular methods. The CPU emulator is implemented by interpreting and executing a piece of code of the guest OS. Its workflow is shown in Figure 5. The DR registers are used to monitor the target memory. For the ProbeAccess event, the target memory stores the boundary that is used for checking the user-mode address. Usually, the exported variable, `nt!MmUserProbeAddress`, is one of the target memory. Kernel code can reference this variable directly or restore its value into another variable, such as `win32k!W32UserProbeAddress`. All of these variables are target memory. The address of target memory can be set by the configuration file of the loader, and then the hypervisor obtains the target memory through the middleware and monitor the memory access through DR registers. When the guest OS accesses target memory, the debug exception handler (DR handler) in the hypervisor will capture it. The handler updates the processor state of the CPU emulator (i.e., *Virtual CPU*) through that of the VM (i.e., *Guest CPU*). Thus, the CPU emulator is activated to interpret and execute the code of the guest OS around the instruction that causes the debug exception. Since the debug exception is a trap event, the start address for the CPU emulator is the instruction directly before the guest EIP register.

As the ProbeAccess event adopts direct comparison to check pointer parameters for a system call, the CPU emulator should focus on `cmp` instructions when it interprets and executes the code of the guest OS. The user-mode virtual address (UVA) for a pointer passed from a user-mode program is obtained by analyzing `cmp` instructions. Then, the ProbeAccess event is recorded in log files via shared memory.

There may be more than one UVA to be checked in a system call. The device driver may restore the value from target memory to a register and then check the UVAs by comparing them to the register separately. The maximum number of UVAs (represented by the letter N in Figure 5) could be set through the configuration file. After finishing N `cmp` instructions or a fixed number of instructions, the hypervisor will stop interpreting and executing, and return to the guest OS to continue executing the following instructions.

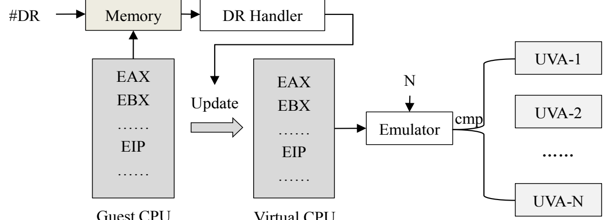

Figure 5: Workflow of CPU emulator.

4.2.1 Detecting UNPROBE Vulnerabilities

For the Windows kernel and device drivers, user memory (pointed by a user pointer) can be accessed under the protection of structured exception handling (SEH) at any time. It is safe to de-reference a user pointer if it points into the user space. Otherwise, it will bring on a serious vulnerability that is called UNPROBE in this paper. Theoretically, before using a pointer passed from a user-mode program, a system-call handler should check it to ensure that it points into the user-mode space. As a consequence, it will cause a ProbeAccess, ProbeRead, or ProbeWrite event before a MemAccess event under normal circumstances. If there is no such type of checking event before a MemAccess event, there may be an UNPROBE vulnerability in the kernel code.

To detect an UNPROBE vulnerability, we focus on whether there is a checking event before a MemAccess event, and whether the virtual addresses in the two events are the same. As discussed above, the ProbeRead and ProbeWrite events are directly obtained by hooking the checking functions in the kernel. The difficulty lies in the ProbeAccess event. In the Windows kernel, there is much code that checks parameters via direct comparison. Only intercepting ProbeRead and ProbeWrite events will result in a large number of false positives. A significant number of false positives will create more workload and make it more complicated to perform reverse analysis. Hence, monitoring a ProbeAccess event through the CPU emulator is of significant importance. We therefore propose the use of CPU emulator to detect UNPROBE vulnerabilities.

Take Figure 4 as an example, at the event time of "$n+3$", the kernel code triggers a MemAccess event by accessing user memory. If there is no ProbeAccess/ProbeRead/ProbeWrite event to check the user address beforehand, or no AllocVirtualMemory/GetPebTeb event to imply the legitimacy of the address, an UNPROBE vulnerability may exist in the kernel code. In contrast, if there is a ProbeAccess/ProbeRead/ProbeWrite event or GetPebTeb/AllocVirtualMemory event to suggest that the user address is legal, and the event is trig-

gered in the same system call as the MemAccess event, the code is safe.

To detect an UNPROBE vulnerability, the fuzzer invokes the test system calls and tries to discover as many branches as possible by adjusting their parameters. Furthermore, the log analyzer looks for MemAccess events in which the user addresses have not been verified by a ProbeAccess/ProbeRead/ProbeWrite or GetPebTeb/AllocVirtualMemory event during a system-call execution.

4.2.2 Detecting TOCTTOU Vulnerabilities

There are two key factors in a TOCTTOU vulnerability. One is that the parameter passed from a user-mode program should be a pointer. The other is that the system-call handler fetches the parameter from user memory more than once. Thus, the user-mode code has a chance to change the parameter referenced by the pointer.

Take Figure 4 again for instance, if a piece of kernel code accesses the same user memory at the time of "$n+2$" and "$n+3$," there may be a TOCTTOU vulnerability in the kernel code. To discover this type of vulnerability, the key point is to look for the user memory that has been accessed more than once in the log files. The event time could help to improve the accuracy. If there are two MemAccess events that fetch from the same user memory, we can judge whether they are triggered in the same system call by comparing the two events' times with the Syscall/Trap2b/Trap2e event time and the RetUser event time. Only when they are in the same system-call execution, may a TOCTTOU vulnerability exist.

The fuzzer needs to invoke the test system calls, and it should discover as many branches as possible by adjusting parameters. At the same time, interface detection records the dynamic characteristics via the middleware. Then, the log analyzer is used to look for the user memory addresses that have been accessed more than once during a system-call execution.

4.3 Detecting Vulnerabilities via Memory Footprints

Memory-footprint-based detection is used to detect illegal use of kernel memory by tracing the behavior of memory allocation, release, and access. In this paper, we will focus on two aspects of illegal memory use: accessing beyond the bounds of allocated heaps and referencing to freed memory. These can lead to *OOB* and *UAF* vulnerabilities.

To capture the dynamic characteristics of vulnerabilities, we need to monitor the allocated, unallocated, and freed memory. Accessing allocated memory is allowed, but using unallocated or freed memory is illegal. Digtool monitors the kernel memory through the virtual page monitor. Illegal memory access will be captured by its page-fault handler in the hypervisor. Then, it records the memory access error or submits it to a kernel debug tool like `Windbg` [8]. Thus, the exact context of kernel execution can be provided for the vulnerability detection.

In order to obtain more relevant data and reduce performance overhead, the monitored memory pages can be restricted. The middleware helps to limit the scope of monitored pages, and passes the scope to the memory detection by invoking our exported service interfaces of Digtool. For instance, when detecting UAF vulnerabilities, we are only concerned with freed memory, so we need to limit the scope to freed pages. Furthermore, to put more emphasis on the kernel code under test, Digtool can also specify target modules to define a scope of kernel code. Only the instructions in the target modules that cause illegal memory access are recorded. Thus, we can concentrate on the target code tested by the fuzzer.

For tracing the allocated and freed memory, Digtool hooks memory functions such as `ExAllocatePoolWithTag` and `ExFreePoolWithTag`. These functions are used to allocate or free kernel memory in the guest OS. Thus, we can determine which memory region is allocated and which is freed. As the size of freed memory cannot be directly obtained through the arguments of the free functions, Digtool records the memory address and the memory size via the parameters of allocation functions. Thus, when a free function is called, the memory size can be obtained by searching for the record.

Memory allocations before Digtool is loaded cannot be captured. Therefore, Digtool should be loaded as early as possible to achieve more precise detection. It is feasible to load Digtool during boot time by setting the registry. Thus, there are only a few modules loaded before Digtool and the unmonitored memory allocations are few, which largely limits the attack surfaces. To summarize, the memory allocations before loading Digtool have a negligible impact on precision. Built atop virtualization technology, our memory-footprint-based approach can be applied to various kernels and device drivers without any compile-time requirements.

4.3.1 Detecting UAF Vulnerabilities

UAF results from reusing the freed memory. To detect it, memory detection needs to trace the freed memory pages until they are allocated again. Any access to the freed memory will be marked as a UAF vulnerability.

In order to trace freed memory, memory functions such as `ExAllocatePoolWithTag`, `ExFreePoolWithTag`, `RtlAllocateHeap`, and `RtlFreeHeap` (as discussed above, hooking mem-

ory allocation functions is done to record the size of freed memory) need to be hooked. Note that the Windows OS implements some wrapper functions for these. For instance, both `ExAllocatePool` and `ExAllocatePoolEx` are the wrapper functions for `ExAllocatePoolWithTag`. To avoid multiple monitoring and repetitive records, Digtool only hooks underlying memory functions such as `ExAllocatePoolWithTag` rather than wrapper functions. Inappropriate use of lookaside lists will also cause UAF vulnerabilities. Digtool hooks the corresponding functions, including `InterlockedPushEntrySList` and `InterlockedPopEntrySList`, to monitor the freed memory blocks in the lookaside lists.

Any instruction operating on the freed memory (or blocks) is regarded as the "*use*" instruction of a UAF vulnerability. It is obtained through the virtual page monitor. The "*free*" instruction of a UAF vulnerability is obtained by recording the free function when it is invoked, and its call-stack information is recorded through a *backtrace* of the stack to facilitate analysis.

A UAF vulnerability may be missed in some scenarios. Considering such situations, there is a memory block `A` referenced by pointer `P`. After freeing block `A`, another program allocates a memory block `B` that covers the entire memory of block `A`. Then, the first program tries to manipulate block `A` through the pointer `P`. Obviously, there is a UAF vulnerability in the first program. However, as the memory region of block `A` is allocated again, it is difficult to detect the vulnerability. This is the reason that Driver Verifier may miss a UAF vulnerability. In order to solve this problem, Digtool delays the release of the freed memory to extend the detection time window. The freed memory will be released until it reaches a certain size.

4.3.2 Detecting OOB Vulnerabilities

An OOB vulnerability can be caused by accessing memory that is beyond the bounds of allocated heaps. To detect it, the monitored memory space should be limited to the unallocated memory areas. Any access to the unallocated memory areas will prompt an OOB vulnerability.

Digtool calibrates the unallocated memory areas through the help of the middleware. In general, except for the memory areas occupied by kernel modules and stacks, the rest of the memory pools are defined as initial unallocated memory areas. As the kernel memory state keeps changing, memory functions that allocate or free memory need to be hooked. Thus, it can adjust the unallocated memory areas dynamically. During the detection process, Digtool needs to search the records of allocated or unallocated memory areas. An AVL tree (i.e., a self-balancing binary search tree) is employed to improve the performance of the memory search. It adds a node when a memory area is allocated, and deletes the node if the memory is freed. Thus, when a monitored page (not a memory area) is accessed (note that the monitoring granularity of memory virtualization is a page, but the size of a memory area may be less than a page; the monitored pages are recorded via the BitMap, while the monitored memory areas are stored in the AVL tree.), Digtool searches the AVL tree for the accessed memory area. If no related node is found, an OOB vulnerability may exist.

Note that, as unallocated memory contains freed memory in the detection, an "OOB" may be caused by accessing a freed memory area. Some reverse-engineering effort is needed to further distinguish between OOB and UAF vulnerabilities.

An OOB vulnerability may be missed in some scenarios. Considering such situations, two memory blocks `A` and `B` are allocated and they are adjacent. A brittle program tries to access block `A` with a pointer and an offset, but the offset is so large that the accessed address locates in block `B`. This is an obvious OOB vulnerability. However, block `B` is also in the AVL tree, so it is difficult to detect this error. To solve this problem, Digtool will allocate an extra memory area with `M` bytes when a hooked memory allocation function is invoked. As a result, the total size of block `A` is `sizeof(A)+M`, and the start address of block `B` will be backward for `M` bytes. However, the size of block `A` recorded in the AVL tree is still defined as `sizeof(A)` bytes. As a consequence, the extra memory area with `M` bytes is not in the AVL tree. Thus, instead of block `B`, the brittle program will access the extra memory area, and an OOB vulnerability will be then captured by Digtool.

5 Evaluation

5.1 Effectiveness

We checked the detection capability of Digtool by testing the programs of different products, including the Windows OS and some anti-virus software (all of the products were the latest version at the time of the experiments). The experimental environments included Windows 7 and Windows 10. (Digtool can support Windows XP/Vista/7/8/10, etc.) We chose some *zero-day* vulnerabilities that had been responded to and fixed by the responsible vendors as examples to illustrate the experimental results. *All of the vulnerabilities discussed below were first discovered by Digtool* (all have been reported to the corresponding vendors, among which Microsoft, Avast, and Dr. Web have confirmed and fixed their vulnerabilities).

Table 1: List of UNPROBE vulnerabilities.

Software products	Unsafe system calls
Avast Free Antivirus 11.2.2262	NtAllocateVirtualMemory NtCreateSection
Dr. Web 11.0	NONE
AhnLab 8.0	NtQueryValueKey NtCreateKey NtDeleteValueKey NtLoadKey NtOpenKey NtSetValueKey NtUnloadKey
Norman Security Suite 11.0.0	NtCreateMutant NtCreateEvent NtCreateFile NtCreateSemaphore
Spyware Detector 2.0.0.3	NtCreateFile NtCreateKey NtDeleteFile NtDeleteValueKey NtOpenFile NtOpenKey NtOpenSection NtSetInformationFile NtSetValueKey NtWriteVirtualMemory

5.1.1 Detecting Vulnerabilities via Interface

We chose five anti-virus software products as test targets since they intercept many system calls that could be invoked by user-mode applications. The test was mainly carried out on Avast for its strength of complexity. The other four anti-virus software products included Dr. Web, Ahnlab, Norman, and Spyware Detector. We used some zero-day vulnerabilities discovered through Digtool to verify its ability to detect UNPROBE and TOCTTOU vulnerabilities. The middleware recorded the behavior characteristics into log files to help locate vulnerabilities.

Detecting UNPROBE. Taking a vulnerability in Avast 11.2.2262 as an example, through the log analyzer, the following data were obtained from the Digtool's log file for Avast 11.2.2262:

```
NtAllocateVirtualMemory:
Eip: 89993f3d, Address: 0023f304, rw: R
Eip: 84082ed9, Address: 0023f304, PROBE!
KiFastSystemCallRet
```

`aswSP.sys`, the Avast driver program, used the instruction at the address `0x89993f3d` to fetch the value from the user address (i.e., `0x23f304`) without checking. The subsequent checking instruction at the address `0x84082ed9` belonged to the `NtAllocateVirtualMemory` function. Therefore, there was a typical UNPROBE vulnerability in `aswSP.sys`.

Using Digtool, 23 similar vulnerabilities were found in the five anti-virus software programs tested. The results are shown in Table 1. For security reasons, we only give the system calls for which vulnerabilities exist.

When the log analyzer points out a potential UNPROBE vulnerability, and the tested driver only uses the `ProbeForRead` and `ProbeForWrite` functions to check a user pointer (this is a common scenario in third-party drivers), no human effort is needed for further confirmation as the detection is precise due to the facts that the start address and length information of the input buffer can be obtained through the corresponding kernel function. If the driver uses direct comparison to check a user pointer, Digtool may produce false positives or false negatives. This results from a lack of accurate address ranges in the ProbeAccess event as we cannot obtain the "size" of the input buffer. We must assume the length for the input user-mode buffer. If the assumed length is larger then the real one, false negatives may be produced. Otherwise, false positives may be generated.

In the case of ProbeAccess, Digtool only helps point out a potential vulnerability. Human effort is still needed to obtain the exact length of the input user-mode buffer through reverse analysis so that we can determine whether the instruction (given by the log analyzer) could really cause an UNPROBE vulnerability.

Detecting TOCTTOU. Taking a vulnerability in Dr. Web 11.0 as an example, through the `log analyzer` the following dynamic characteristics were distilled from Digtool's log file for Dr. Web 11.0:

```
NtCreateSection:
Count:3 ==============
Eip: 83f0907f Address:3b963c Sequence:398 rw: R
Eip: 89370d54 Address:3b963c Sequence:399 rw: R
Eip: 89370d7b Address:3b963c Sequence:401 rw: R
KiFastSystemCallRet
```

The user address `0x3b963c` was accessed by the kernel instructions more than once, so there may be a TOCTTOU vulnerability. `dwprot.sys`, the Dr. Web driver program, used the instruction at the address `0x89370d54` to fetch the value from the user address (i.e., `0x3b963c`), and then it invoked the `ProbeForRead` function to check it. At the address `0x89370d7b`, the `dwprot.sys` fetched the value again to use it. Therefore, there was a typical TOCTTOU vulnerability in `dwprot.sys`.

With the help of Digtool, 18 kernel-level TOCTTOU vulnerabilities were found in the five anti-virus software programs tested. The results are shown in Table 2. For security reasons, we only give the system calls for which vulnerabilities exist.

Digtool may produce false positives that originate from the fact that it detects TOCTTOU vulnerabilities through double-fetch. Further manual analysis is needed to confirm that double-fetch is a TOCTTOU vulnerability.

5.1.2 Detecting Vulnerabilities via Memory Footprints

We chose 32-bit Windows 10 as a test target. Some zero-day vulnerabilities discovered by Digtool were selected

Table 2: List of TOCTTOU vulnerabilities.

Software products	Unsafe system calls
Avast Free Antivirus 11.2.2262	NtUserOpenDesktop NtQueryObject NtUserBuildNameList NtOpenSection NtCreateEvent NtCreateEventPair NtCreateIoCompletion NtCreateMutant NtCreateSection NtCreateSemaphore NtCreateTimer NtOpenEvent NtOpenEventPair NtOpenIoCompletion NtOpenMutant NtOpenSemaphore NtOpenTimer
Dr. Web 11.0	NtCreateSection
AhnLab 8.0	NONE
Norman Security Suite 11.0.0	NONE
Spyware Detector 2.0.0.3	NONE

to verify its effectiveness in detecting UAF and OOB vulnerabilities. Instead of logging, the middleware was set to interrupt the guest OS and connect to `Windbg` when a program error was captured. Thus, an exact context can be provided for analysis.

Detecting UAF. The following content is shown by `Windbg` when the UAF vulnerability (`MS16-123/CVE-2016-7211` [3]) is captured in `win32kfull.sys`; this vulnerability was first discovered through Digtool:

```
Single step exception - code 80000004
win32k!_ScrollDC+0x21:
96b50f3e  83ff01 cmp edi,1
```

The "Single-step exception" is triggered by Digtool. As it is a trap event, the instruction that triggers the exception has already been finished, and the guest OS is interrupted at the address of the next instruction to be executed. The instruction just before `0x96b50f3e` is the exact instruction that tries to access a freed memory area and causes the UAF vulnerability. We can obtain it by `Windbg` as follows and its address is `0x96b50f3b`. The `esi` register (at the address of `0x96b50f3b`) stores the address of the freed heap:

```
96b50f3b 8b7e68 mov edi,dword ptr [esi+68h]
96b50f3e 83ff01 cmp edi,1//win32k!_ScrollDC+0x21
```

Detecting OOB. Vulnerabilities including `MS16-090/CVE-2016-3252` [2], `MS16-034/CVE-2016-0096` [1], and `MS16-151/CVE-2016-7260` [4] were first discovered by Digtool. Taking `MS16-090/CVE-2016-3252` as an example to illustrate the detection result, the following content was shown when the vulnerability was captured in `win32kbase`:

```
Single step exception - code 80000004
win32kbase!RGNMEMOBJ::bFastFill+0x385:
93e34bf9 895304      mov dword ptr [ebx+4],edx
```

This is similar to the content of the above UAF, and `0x93e34bf9` is the address of the next instruction to be executed. The instruction just before `0x93e34bf9` is the exact instruction that tries to access an unallocated memory area and causes the OOB vulnerability.

Note that there is no false positive in the UAF/OOB detection, and no human effort is needed for locating or confirming the vulnerability. Whenever an exception is captured, it is always a vulnerability.

5.2 Efficiency

Owing to the fact that Bochspwn [24], which is based on the bochs emulator [25], only detects TOCTTOU vulnerabilities among the four types of vulnerabilities by now, we tested Digtool's performance cost in detecting TOCTTOU vulnerabilities, and compared its performance with that of the bochs emulator in the same environment (i.e., the same hardware platform, OS version, parameters of system calls, and arguments of the test program). We chose ten common system calls that are the most widely used and hooked by anti-virus software to test the efficiency. In order to obtain a more comprehensive result, we also chose a frequently used program, WinRAR 5.40 [7], for an efficiency test. The performance cost is shown in Figure 6 (the result may be affected by some factors, such as the parameters of system calls and the WinRAR input file).

The performance cost of Digtool is divided into two categories: "unrecorded" and "recorded." "Unrecorded" means that the system calls are not included in the configuration file, and thus no page is monitored and no log is recorded for them. However, the other modules in interface detection are activated. This class of performance cost can provide a comprehensive comparison with the bochs emulator since the bochs emulator records nothing. In addition, it also reflects the state of the entire system since most of system calls and threads are unmonitored when detecting TOCTTOU. "Recorded" indicates that the system calls are put into the configuration file and their behaviors are recorded. It describes the performance cost of the related system calls in the specified monitored thread, but has nothing to do with the performance of the other system calls and threads. "Windows" denotes the performance of a clean OS without any tools, and "bochs" represents the performance cost of the OS running into bochs emulator.

In the case of "unrecorded," the result of system calls showed that Digtool is from 2.18 to 5.03 times slower than "Windows," but 45.4 to 156.5 times faster than "bochs." From the WinRAR result, Digtool is 2.25

	NtCreateMutant	NtCreateSection	NtMapViewOfSection	NtLoadDriver	NtWriteVirtualMemory	NtFreeVirtualMemory	NtAlpcConnectPort	NtOpenEvent	NtCreateTimer	NtCreateKey	WinRAR
Windows	112.4	109.5	128.2	125	156	469	719	115.4	112.4	300.2	147
Digtool(unrecorded)	565.4	547	584.4	575.2	609.4	1578	1565.4	562.6	565.6	750	331.4
Digtool(recorded)	9893.2	9226.7	20398.3	2052	16771	10101.7	24969	8987	8187.2	22997.7	1977.8
bochs	34398.3	31844.2	48943.6	36572.5	53940.2	71573	244921.8	33296.8	32573	103036.5	142104.3

Figure 6: Performance overhead.

times slower than "Windows," but 428.8 times faster than "bochs." In the case of "recorded," most of the monitored system calls are from 70 to 90 times (which depends on the arguments and system calls) slower than "Windows," but still much faster than "bochs." From the WinRAR result (all of the system calls in the `NT` kernel are recorded), the "recorded" case is 13.45 times slower than "Windows." This finding offers another perspective on the average performance cost of an application under the situation of monitoring all system calls. In this extreme case, Digtool is still 71.8 times faster than the bochs emulator. Thus, Digtool achieves an acceptable level of performance.

5.3 Comparison and Analysis

Next, we illustrate Digtool's advantages by comparison with Driver Verifier [28], which is a notable tool for checking Windows kernels.

Crash resilient. Digtool is able to capture dynamic characteristics of potential vulnerabilities without needing a "Blue Screen of Death" (BSOD). As the analysis process only requires the recorded data containing accessed memory address, event type, and event time, there is no need for triggering a BSOD to locate a program error. The fuzzer only needs to discover as many code branches as possible, and it does not have to crash the OS. During this process, Digtool will record all dynamic characteristics. Without a BSOD, it keeps recording, which will help find more vulnerabilities.

However, it is inevitable that Driver Verifier will cause a BSOD to locate and analyze a vulnerability. It does not stop crashing the OS at the address of the same program error until the error is fixed. This will make it difficult to test other vulnerabilities. For example, when we test Avast with Driver Verifier, the cause of a BSOD is always the same:

```
Arg1:f6, Referencing user handle as KernelMode.
Arg2:0c, Handle value being referenced.
```

The BSOD results from using a user-mode handle under the `KernelMode` flag. If the problem is not solved, Driver Verifier cannot further test Avast.

Interrupting the OS with an exact context. Through the middleware, Digtool can be set to interrupt the guest OS when a program error happens. Thus, it can provide an exact context for the vulnerability by connecting to a debug tool.

Driver Verifier has to crash the OS to locate and analyze a program error. However, the context has been changed since the OS is not stopped at the moment the program error occurs (usually, the OS will keep running for a moment to trigger the program error). Much more human effort is needed to locate the error.

Taking `MS16-090/CVE-2016-3252` [2] as an example, Digtool exactly locates the instruction (just before `0x93e34bf9`) that causes the vulnerability:

```
win32kbase!RGNMEMOBJ::bFastFill+0x385:
93e34bf9 895304      mov dword ptr[ebx+4],edx
```

However, from Driver Verifier, the captured context is as follows:

```
BAD_POOL_HEADER (19)
FOLLOWUP_IP:
win32kfull!NSInstrumentation::PlatformFree+10
a0efaade 5d      pop ebp
```

Driver Verifier only points out a "bad pool" (OOB) error, but does not provide an exact context for the vulnerability. Much more reverse-engineering effort is required to locate the vulnerability from the above information.

Capturing more vulnerabilities. Digtool can effectively detect UNPROBE and TOCTTOU vulnerabilities. However, as no similar detection rule is designed, Driver Verifier cannot be used to detect them. Moreover, Driver

Verifier may sometimes miss a UAF or OOB vulnerability because the vulnerability may happen to access a valid memory page, and does not cause a BSOD. Thus, Driver Verifier cannot find it.

The above UAF vulnerability (`MS16-123/CVE-2016-7211`) discovered by Digtool is an example. It accesses a freed memory block that is almost immediately reallocated again under normal circumstances. As a consequence, the physical page of the freed memory block is valid, and it does not violate the rule of Driver Verifier, no BSOD is caused, and no bug is found. However, the vulnerability can be captured by Digtool due to the fact that it delays the release of freed memory. Thus, Digtool is more powerful in this regard.

To summarize, Digtool discovers *45 zero-day* kernel vulnerabilities, and effectively detects the four types of program errors: *UNPROBE, TOCTTOU, UAF*, and *OOB*. In terms of efficiency, it achieves significantly better performance than Bochspwn. Compared to Driver Verifier, it can *capture multiple vulnerabilitie with an exact execution context*. As such, Digtool can be considered a complement to Driver Verifier.

6 Discussion

Digtool has a number of limitations. First, the performance cost could be optimized. Although it is much faster than an emulator, the performance overhead is still costly in the monitored threads. The performance cost mainly comes from the frequent switches between the hypervisor and guest OS. How to reduce the switches and the performance cost could be a research topic.

Second, the supported platforms could be extended. Digtool currently only supports the Windows OS. Via virtualization technology, the hypervisor runs outside of the guest OS, which tends to be more portable and has the potential of supporting other OSes. However, the middleware in the kernel space is platform-specific. The main work of supporting various platforms (e.g., MacOS) is adapting the middleware.

Third, there is still room for extension in the detection algorithms. Currently, Digtool is able to detect UNPROBE, TOCTTOU, UAF, and OOB vulnerabilities. As it can almost monitor any memory page, it could be used to detect some other types of vulnerabilities, such as race conditions, by extending the detection algorithms.

7 Related Work

7.1 Static Analysis

Static analysis is to detect potential vulnerabilities from programming language literature. Unlike other detection methods, it does not depend on executable binary files. Wagner *et al*. [39] proposed an automated detection method of finding program bugs in C code that can discover potential buffer overrun vulnerabilities by analyzing source code. Grosso *et al*. [19] also presented a method of detecting buffer overflows for C code that does not need human intervention to define and tune genetic algorithm weights, and therefore it becomes completely automated.

Static analysis achieves a high rate of code coverage, but its precision may be insufficient when dealing with difficult language constructs and concepts. In addition, it cannot detect program bugs without source code.

7.2 Source Instrumentation

Source instrumentation is also called compile-time instrumentation; it inserts detection code at compile-time to detect program bugs. CCured [30] is used to detect unsafe pointers for C programs. It combines instrumentation with static analysis to eliminate redundant checks. AddressSanitizer [36] creates poisoned redzones around heaps, stacks, and global objects to detect overflows and underflows. Compared to other methods, it can detect errors not only in heaps, but also in stacks and global variables.

Source instrumentation has higher precision, but its code coverage may be less comprehensive than static analysis. In addition, it has the same limitation as static analysis; that is, it cannot detect program bugs without source code.

7.3 Binary Instrumentation

Binary instrumentation inserts detection code into executable binary files and detects program bugs at runtime. Purify [22] is an older tool for checking program bugs based on binary instrumentation that can detect memory leaks and memory access errors. Valgrind [31] is a dynamic binary instrumentation framework designed to build heavyweight binary analysis tools like Memcheck [37]. Dr. Memory [14] is a memory-checking tool that operates on applications under both Windows and Linux environments.

These tools do not rely on source code, and exhibit an ability to effectively detect program errors. However, many of them only detect bugs for applications in user mode and cannot operate on programs in kernel mode, especially on the Windows kernel. Some Qemu-based tools support the instrumentation of Windows OS kernel, but these tools cannot be used to detect vulnerabilities in a physical machine and their average performance overhead is quite high.

7.4 Specialized Memory Allocator

Another class of vulnerability identification tool uses a specialized memory allocator and does not change the rest of the executable binary files. It analyzes the legality of memory access by replacing or patching memory functions.

Some tools make use of the page-protection mechanism of processors. Each allocated region is placed into a dedicated page (or a set of pages). One extra page at the right (or/and the left) is allocated and marked as inaccessible. A page fault will be reported as an OOB error when instructions access the inaccessible page. Duma [9] and GuardMalloc [26] are in this category.

Some other tools add redzones around the allocated memory. In addition to the redzones, they also populate the newly allocated memory or freed memory with special "magic" values. If a magic value is read, the program may have accessed an out-of-bounds or uninitialized memory. If a magic value in a redzone is overwritten, it will be detected later, when the redzone is examined for freed memory. Therefore, there is no immediate detection of the memory access error. Tools in this category include DieHarder [33] and Dmalloc [40].

These tools do not depend on source code either and are well suited for discovering memory errors, but they share the limitation encountered in other tools, namely that many of them cannot operate on the Windows kernel. Moreover, it is difficult for them to check for UNPROBE or TOCTTOU vulnerabilities.

7.5 Kernel-Level Analysis Tools

There are only a few vulnerability identification tools for programs in kernel mode, and most of them are aimed at Linux. Kmemcheck [32] and Kmemleak [6] are memory-checking tools for the Linux kernel. Kmemcheck monitors the legality of memory access by tracing read and write operations. Kmemleak is used to detect memory leaks by checking allocated memory blocks and their pointers. Both tools can help discover memory errors in the Linux kernel. However, all of the similar tools need to expand the source code of Linux or insert detection code at compile-time, and thus it is difficult to port them to a closed-source OS like Windows.

Driver Verifier [28] is the major tool for detecting bugs in the Windows kernel. It can find program bugs that are difficult to discover during regular testing. These bugs include illegal function calls, memory corruption, bad I/O packets, deadlocks, and so on. Driver Verifier is an integrated system for detecting illegal actions that might corrupt the OS, but not a dedicated tool for detecting vulnerabilities (see Section 5.3 for a discussion of Driver Verifier's ability to detect vulnerabilities). As part of the kernel, in fact, Driver Verifier also relies on the source code of the OS.

Although the above tools can be applied to detect kernel vulnerabilities, they are too tightly coupled with implementation details and the source code of OSes, so they cannot work when no source code is available. Moreover, it is difficult to port them to another type of OS.

7.6 Virtualization/Emulator-Based Methods

Virtualization/emulator-based vulnerability identification tools detect potential vulnerabilities by tracing function calls and monitoring memory access. Through virtualization or emulator technology, they can overcome most OS differences and easily support various OSes.

Among the more common virtualization-based tools and methods are the following. VirtualVAE [18] is a vulnerability analysis environment that is based on QEMU [11]. In [18], it is claimed that it can detect bugs for programs in both kernel mode and user mode. PHUKO [38], based on Xen [10], detects buffer overflow attack, and it checks return addresses for dangerous functions to determine vulnerabilities. These virtualization-based methods only focus on a single type of program error. They are not built as a framework for detecting various vulnerabilities. Moreover, the implementation details for some of them are not exhaustive, and the detection effects have not been illustrated through detection of vulnerabilities in the real world. Their performance may be influenced by a full-stack virtualization framework.

Bochspwn [24] is a notable emulator-based vulnerability identification tool. Dozens of TOCTTOU vulnerabilities have been found in the Windows kernel using Bochspwn. However, its scope of application is limited by the bochs emulator.

8 Conclusions

In this paper, a virtualization-based vulnerability identification framework called Digtool is proposed. It can detect different types of kernel vulnerabilities including *UNPROBE, TOCTTOU, UAF*, and *OOB* in the Windows OS. It successfully captures various dynamic behaviors of kernel execution such as kernel object allocation, kernel memory access, thread scheduling, and function invoking. With these behaviors, Digtool has identified 45 *zero-day* vulnerabilities among both kernel code and device drivers. It can help effectively improve the security of kernel code in the Windows OS.

Abstract

Many kinds of memory safety vulnerabilities have been endangering software systems for decades. Amongst other approaches, fuzzing is a promising technique to unveil various software faults. Recently, feedback-guided fuzzing demonstrated its power, producing a steady stream of security-critical software bugs. Most fuzzing efforts—especially feedback fuzzing—are limited to *user space components* of an operating system (OS), although bugs in *kernel components* are more severe, because they allow an attacker to gain access to a system with full privileges. Unfortunately, kernel components are difficult to fuzz as feedback mechanisms (i.e., guided code coverage) cannot be easily applied. Additionally, non-determinism due to interrupts, kernel threads, statefulness, and similar mechanisms poses problems. Furthermore, if a process fuzzes its own kernel, a kernel crash highly impacts the performance of the fuzzer as the OS needs to reboot.

In this paper, we approach the problem of coverage-guided kernel fuzzing in an *OS-independent* and *hardware-assisted* way: We utilize a hypervisor and Intel's *Processor Trace* (PT) technology. This allows us to remain independent of the target OS as we just require a small user space component that interacts with the targeted OS. As a result, our approach introduces almost no performance overhead, even in cases where the OS crashes, and performs up to 17,000 executions per second on an off-the-shelf laptop. We developed a framework called *kernel-AFL* (kAFL) to assess the security of Linux, macOS, and Windows kernel components. Among many crashes, we uncovered several flaws in the *ext4* driver for Linux, the *HFS* and *APFS* file system of macOS, and the *NTFS* driver of Windows.

1 Introduction

Several vulnerability classes such as memory corruptions, race-conditional memory accesses, and use-after-free vulnerabilities, are known threats for programs running in user mode as well as for the operating system (OS) core itself. Past experience has shown that attackers typically focus on user mode applications. This is likely because vulnerabilities in user mode programs are notoriously easier and more reliable to exploit. However, with the appearance of different kinds of exploit defense mechanisms – especially in user mode, it has become much harder nowadays to exploit known vulnerabilities. Due to those advanced defense mechanisms in user mode, the kernel has become even more appealing to an attacker since most kernel defense mechanisms are not widely deployed in practice. This is due to more complex implementations, which may affect the system performance. Furthermore, some of them are not part of the official mainline code base or even require support for the latest CPU extension (e.g., SMAP / SMEP on x86-64). Additionally, when compromising the OS, an attacker typically gains full access to the system resources (except for virtualized systems). Kernel-level vulnerabilities are usually used for privilege escalation or to gain persistence for kernel-based rootkits.

For a long time, fuzzing has been a critical component in testing and establishing the quality of software. However, with the development of American Fuzzy Lop (AFL), smarter fuzzers have gained significant traction in the industry [1] as well as in research [8, 14, 35, 37]. This trend was further amplified by Google's *OSS Fuzz* project that successfully found—and continues to find—a significant number of critical bugs in highly security-relevant software. Finally, DARPA's Cyber Grand Challenge showed that fuzzing remains highly relevant for the state-of-the-art in bug finding. The latest generation of feedback-driven fuzzers generally uses mechanisms to learn which inputs are interesting and which are not. Interesting inputs are used to produce more inputs that may trigger new execution paths in the target. Inputs that did not trigger interesting behavior in the program are discarded. Thus, the fuzzer is able to "learn" the input

format. This greatly improves efficiency and usability of fuzzers, especially by reducing the need for an oracle which generates semi-valid inputs or an extensive corpus that covers most paths in the target.

Unfortunately, AFL is limited to user space applications and lacks kernel support. Fuzzing kernels has a set of additional challenges when compared to userland (or *ring 3*) fuzzing: First, crashes and timeouts mandate the use of virtualization to be able to catch faults and continue gracefully. Second, kernel-level code has significantly more non-determinism than the average ring 3 program—mostly due to interrupts, kernel threads, statefulness, and similar mechanisms. This makes fuzzing kernel code challenging. Furthermore, there is no equivalent to command line arguments or `stdin` to interact with kernels or drivers in a generic way except for plain interrupt or `sysenter` instructions. In addition, the Windows kernel and many relevant drivers and core components (for Windows, macOS and even Linux) are closed source and cannot be instrumented by common techniques without a significant performance overhead.

Previous approaches to kernel fuzzing were not portable because they relied on certain drivers or recompilation [10, 34], were very slow due to emulation to gather feedback [7], or simply were not feedback-driven at all [11].

In this paper, we introduce a new technique that allows applying feedback fuzzing to arbitrary (even closed source) x86-64 based kernels, without any custom ring 0 target code or even OS-specific code at all. We discuss the design and implementation of *kernel-AFL* (kAFL), our prototype implementation of the proposed techniques. The overhead for feedback generation is very small (less than 5%) due to a new CPU feature: Intel's *Processor Trace* (PT) technology provides control flow information on running code. We use this information to construct a feedback mechanism similar to AFL's instrumentation. This allows us to obtain up to 17,000 executions per second on an off-the-shelf laptop (Thinkpad T460p, i7-6700HQ and 32 GB RAM) for simple target drivers. Additionally, we describe an efficient way for dealing with the non-determinisms that occur during kernel fuzzing. Due to the modular design, kAFL is extensible to fuzz *any* x86/x86-64 OS. We have applied kAFL to Linux, macOS, and Windows and found multiple previously unknown bugs in kernel drivers in those OSs.

In summary, our contributions in this paper are:

- **OS independence**: We show that feedback-driven fuzzing of closed-source kernel mode components is possible in an (almost) OS-independent manner by harnessing the hypervisor (VMM) to produce coverage. This allows targeting any x86 operating system kernel or user space component of interest.
- **Hardware-assisted feedback**: Our fuzzing approach utilizes Intel's Processor Trace (PT) technology, and thus has a very small performance overhead. Additionally, our PT-decoder is up to 30 times faster than Intel's `ptxed` decoder. Thereby, we obtain complete trace information that we use to guide our evolutionary fuzzing algorithm to maximize test coverage.
- **Extensible and modular design**: Our modular design separates the fuzzer, the tracing engine, and the target to fuzz. This allows to support additional x86 operating systems' kernel space and user space components, without the need to develop a system driver for the target OS.
- **kernel-AFL**: We incorporated our design concepts and developed a prototype called *kernel-AFL* (kAFL) which was able to find several vulnerabilities in kernel components of different operating systems. To foster research on this topic, we make the source code of our prototype implementation available at `https://github.com/RUB-SysSec/kAFL`.

2 Technical Background

We use the Intel Processor Trace (*Intel PT*) extension of *IA-32* CPUs to obtain coverage information for ring 0 execution of arbitrary (even closed-source) OS code. To facilitate efficient and OS-independent fuzzing, we also make use of Intel's hardware virtualization features (Intel VT-x). Hence, our approach requires a CPU that supports both *Intel VT-x* and *Intel PT*. This section provides a brief overview of these hardware features and establishes the technical foundation for the later sections.

2.1 x86-64 Virtual Memory Layouts

Every commonly used x86-64 OS uses a *split virtual memory layout*: The kernel is commonly located at the upper half of each virtual memory space, whereas each user mode process memory is located in the lower half. For example, the virtual memory space of Linux is typically split into kernel space (upper half) and user space (lower half) each with a size of 2^{47} due to the 48-bit virtual address limit of current x86-64 CPUs. Hence, the kernel memory is mapped to any virtual address space and therefore it is located *always* at the same virtual address. If an user mode process executes the `syscall`/`sysenter` instruction for kernel interaction or causes an exception that has to be handled by the OS, the OS will keep the current CR3 value and thus does not switch the virtual memory address space. Instead, the current virtual memory address space is reused and the kernel handles the current user mode process related task within the same address space.

2.2 Intel VT-x

The kernel fuzzing approach introduced in this paper relies on modern x86-64 hardware virtualization technology. Hence, we provide a brief overview of Intel's hardware virtualization technology, Intel VT-x.

We differentiate between three kinds of CPUs: physical CPUs, logical CPUs, and virtual CPUs (vCPUs). A physical CPU is a CPU that is implemented in hardware. Most modern CPUs support mechanisms to increase multithreading performance without additional physical CPU cores on the die (e.g., *Intel Hyper-Threading*). In this case, there are multiple logical CPUs on one physical CPU. These different logical CPUs share the physical CPU and, thus, only one of them can be active at a time. However, the execution of the different logical CPUs is interleaved by the hardware and therefore the available resources can be utilized more efficiently (e.g., one logical CPU uses the arithmetic logic unit while another logical CPU waits for a data fetch) and the operating system can reduce the scheduling overhead. Each logical CPU is usually treated like a whole CPU by the operating system. Finally, it is possible to create multiple hardware-supported virtual machines (VMs) on a single logical CPU. In this case, each VM has a set of its own vCPUs.

The virtualization role model is divided into two components: the virtual machine monitor (VMM) and the VM. The VMM, also named *hypervisor* or *host*, is privileged software that has full control over the physical CPU and provides virtualized guests with restricted access to physical resources. The VM, also termed *guest*, is a piece of software that is transparently executed within the virtualized context provided by the VMM.

To provide full hardware-assisted virtualization support, Intel VT-x adds two additional execution modes to the well-known protection ring based standard mode of execution. The default mode of executions is called *VMX OFF*. It does not implement any hardware virtualization support. When using hardware-supported virtualization, the CPU switches into the *VMX ON* state and distinguishes between two different execution modes: the higher-privileged mode of the hypervisor (VMX root or VMM), and the lower privileged execution mode of the virtual machine guest (VMX non-root or VM).

When running in guest mode, several privileged actions or reasons (execution of restricted instructions, expired VMX-preemption timer, or access to certain emulated devices) in the VM guest will trigger a VM-Exit event and transfer control to the hypervisor. This way, it is possible to run arbitrary software that expects privileged access to the hardware (such as an OS) inside a VM. At the same time, a higher authority can meditate and control the operations performed with a small performance overhead.

To create, launch, and control a VM, the VMM has to use a virtual machine control structure (VMCS) for each vCPU [28]. The VMCS contains all essential information about the current state and how to perform VMX transitions of the vCPU.

2.3 Intel Processor Trace

With the fifth generation of Intel Core processors (Broadwell architecture), Intel has introduced a new processor feature called *Intel Processor Trace (Intel PT)* to provide execution and branch tracing information. Unlike other branch tracing technologies such as *Intel Last Branch Record (LBR)*, the size of the output buffer is no longer strictly limited by special registers. Instead, it is only limited by the size of the main memory. If the output target is repeatedly and timely emptied, we can create traces of arbitrary length. The processor's output format is packet-oriented and separated into two different types: general execution information and control flow information packets. Intel PT produces various types of control flow related packet types during runtime. To obtain control-flow information from the trace data, we require a decoder. The decoder needs the traced software to interpret the packets that contain the addresses of conditional branches.

Intel specifies five types of control flow affecting instructions called *Change of Flow Instruction (CoFI)*. The execution of different CoFI types results in different sequences of flow information packets. The three CoFI types relevant to our work are:

1. **Taken-Not-Taken (TNT):** If the processor executes any conditional jump, the decision whether this jump was taken or not is encoded in a TNT packet.

2. **Target IP (TIP):** If the processor executes an indirect jump or transfer instruction, the decoder will not be able to recover the control flow. Therefore, the processor produces a TIP packet upon the execution of an instruction of the type `indirect branch`, `near ret` or `far transfer`. These TIP packets store the corresponding target instruction pointer executed by the processor after the transfer or jump has occurred.

3. **Flow Update Packets (FUP):** Another case where the processor must produce a hint packet for the software decoder are asynchronous events such as interrupts or traps. These events are recorded as FUPs and usually followed by a TIP to indicate the following instruction.

To limit the amount of trace data generated, Intel PT provides multiple options for runtime filtering. Depending on the given processor, it might be possible to configure multiple ranges for instruction-pointer filtering (*IP Filter*). In general, these filter ranges only affect virtual addresses if paging is enabled; this is always the case in x86-64 long-mode. Therefore, it is possible to limit trace generation to selected ranges and thus avoid huge amounts of superfluous trace data. In accordance to the IP filtering mechanism, it is possible to filter traces by the current privilege level (CPL) of the protection ring model (e.g ring 0 or ring 3). This filter allows us to select only the user mode ($CPL > 0$) or kernel mode ($CPL = 0$) activity. kAFL utilizes this filter option to limit tracing explicitly to kernel mode execution. In most cases, the focus of tracing is not the whole OS within all user mode processes and their kernel interactions. To limit trace data generation to one specific virtual memory address space, software can use the *CR3 Filter*. Intel PT will only produce trace data if the CR3 value matches the configured filter value. The CR3 register contains the pointer to the current page table. The value of the CR3 register can thus be used to filter code executed on behalf of a certain ring 3 process, even in ring 0 mode.

Intel PT supports various configurable target domains for output data. kAFL focuses on the Table of Physical Addresses (ToPA) mechanism that enables us to specify multiple output regions: Every ToPA table contains multiple *ToPA entries*, which in turn contain the physical address of the associated memory chunk used to store trace data. Each ToPA entry contains the physical address, a size specifier for the referred memory chunk in physical memory, and multiple type bits. These type bits specify the CPU's behavior on access of the ToPA entry and how to deal with filled output regions.

3 System Overview

We now provide a high-level overview of the design of an OS-independent and hardware-assisted feedback fuzzer before presenting the implementation details of our tool called kAFL in Section 4.

Our system is split into three components: the fuzzing logic, the VM infrastructure (modified versions of QEMU and KVM denoted by QEMU-PT and KVM-PT), and the user mode agent. The fuzzing logic runs as a ring 3 process on the host OS. This logic is also referred to as kAFL. The VM infrastructure consists of a ring 3 component (QEMU-PT) and a ring 0 component (KVM-PT). This facilitates communication between the other two components and makes the Intel PT trace data available to the fuzzing logic. In general, the guest only communicates with the host via hypercalls. The host can then read and write guest memory and continues VM execution once the request has been handled. A overview of the architecture can be seen in Figure 1.

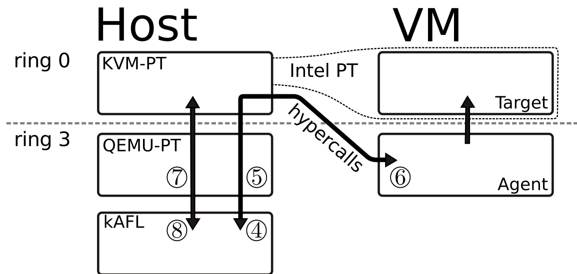

Figure 1: High-level overview of the kAFL architecture. The setup process (①-③) is not shown.

We now outline the events and communication that take place during a fuzz run, as depicted in Figure 2. When the VM is started, the first part of the user mode agent (the loader) uses the hypercall `HC_SUBMIT_PANIC` to submit the address of the kernel panic handler (or the *BugCheck* kernel address in Windows) to QEMU-PT ①. QEMU-PT then patches a hypercall calling routine at the address of the panic handler. This allows us to get notified and react fast to crashes in the VM (instead of waiting for timeouts / reboots).

Then the loader uses the hypercall `HC_GET_PROGRAM` to request the actual user mode agent and starts it ②. Now the loader setup is complete and the fuzzer begins its initialization. The agent triggers a `HC_SUBMIT_CR3` hypercall that will be handled by KVM-PT. The hypervisor extracts the CR3 value of the currently running process and hands it over to QEMU-PT for filtering ③. Finally, the agent uses the hypercall `HC_SUBMIT_BUFFER` to inform the host at which address it expects its inputs. The fuzzer setup is now finished and the main fuzzing loop starts.

During the main loop, the agent requests a new input using the `HC_GET_INPUT` hypercall ④. The fuzzing logic produces a new input and sends it to QEMU-PT. Since QEMU-PT has full access to the guest's memory space, it can simply copy the input into the buffer specified by the agent. Then it performs a VM-Entry to continue executing the VM ⑤. At the same time, this VM-Entry event enables the PT tracing mechanism. The agent now consumes the input and interacts with the kernel (e.g., it interprets the input as a file system image and tries to mount it ⑥). While the kernel is being fuzzed, QEMU-PT decodes the trace data and updates the bitmap on demand. Once the interaction is finished and the kernel handed control back to the agent, the agent notifies the hypervisor via a `HC_FINISHED` hypercall. The resulting VM-Exit stops the tracing and QEMU-PT decodes the remaining trace data ⑦. The resulting bitmap is passed

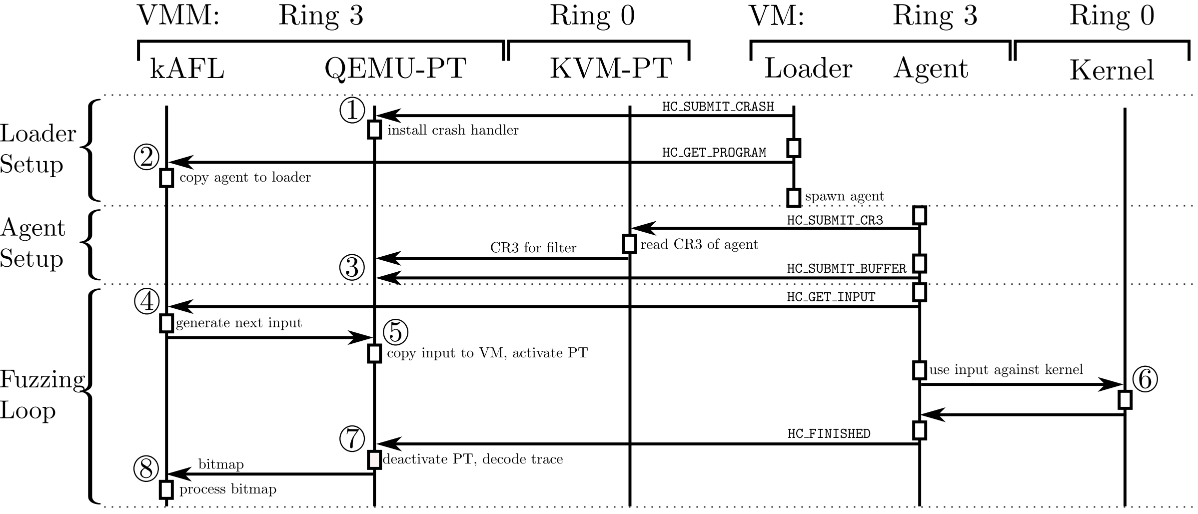

Figure 2: Overview of the kAFL hypercall interaction.

to the logic for further processing ⑧. Afterwards, the agent can continue to run any untraced clean-up routines before issuing another HC_GET_INPUT to start the next loop iteration.

3.1 Fuzzing Logic

The fuzzing logic is the command and controlling component of kAFL. It manages the queue of interesting inputs, creates mutated inputs, and schedules them for evaluation. In most aspects, it is based on the algorithms used by AFL. Similarly to AFL, we use a bitmap to store basic block transitions. We gather the AFL bitmap from the VMs through an interface to QEMU-PT and decide which inputs triggered interesting behaviour. The fuzzing logic also coordinates the number of VMs spawned in parallel. One of the bigger design differences to AFL is that kAFL makes extensive use of multiprocessing and parallelism, where AFL simply spawns multiple independent fuzzers which synchronize their input queues sporadically[1]. In contrast, kAFL executes the deterministic stage in parallel, and all threads work on the most interesting input. A significant amount of time is spent in tasks that are not CPU-bound (such as guests that delay execution). Therefore, using many parallel processes (upto 5-6 per CPU core) drastically improves performance of the fuzzing process due to a higher CPU load per core. Lastly, the fuzzing logic communicates with the user interface to display current statistics in regular intervals.

[1]AFL recently added experimental support for distributing the deterministic stage, see https://github.com/mirrorer/afl/blob/master/docs/parallel_fuzzing.txt#L60-L66.

3.2 User Mode Agent

We expect a user mode agent to run inside the virtualized target OS. In principle, this component only has to synchronize and gather new inputs by the fuzzing logic via the hypercall interface and use it to interact with the guest's kernel. Example agents are programs that try to mount inputs as file system images, pass specific files such as certificates to kernel parser or even execute a chain of various syscalls.

In theory, we only need one such component. In practice, we use two different components: The first program is the *loader component*. Its job is to accept an arbitrary binary via the hypercall interface. This binary represents the *user mode agent* and is executed by the loader component. Additionally, the loader component will check if the agent has crashed (which happens often in case of syscall fuzzing) and restarts it if necessary. This setup has the advantage that we can pass any binary to the VM and reuse VM snapshots for different fuzzing components.

3.3 Virtualization Infrastructure

The fuzzing logic uses QEMU-PT to interact with KVM-PT to spawn the target VMs. KVM-PT allows us to trace individual vCPUs instead of logical CPUs. This component configures and enables Intel PT on the respective logical CPU before the CPU switches to guest execution and disables tracing during the VM-Exit transition. This way, the associated CPU will only provide trace data of the virtualized kernel itself. QEMU-PT is used to interact with the KVM-PT interface to configure and toggle Intel PT from user space and access the output buffer to decode the trace data. The

decoded trace data is directly translated into a stream of addresses of executed *conditional branch instructions*. Moreover, QEMU-PT also filters the stream of executed addresses—based on previous knowledge of non-deterministic basic blocks—to prevent false-positive fuzzing results, and makes those available to the fuzzing logic as AFL-compatible bitmaps. We use our own custom Intel PT decoder to cache disassembly results, which leads to significant performance gains compared to the off-the-shelf solution provided by Intel.

3.4 Stateful and Non-Deterministic Code

Tracing operating systems results in a significant amount of non-determinism. The largest source of non-deterministic basic block transitions are interrupts, which can occur at any point in time. Additionally, our implementation does not reset the whole state after each execution since reloading the VM from a memory snapshot is costly. Thus we have to deal with the stateful and asynchronous aspects of the kernel. An example for stateful code might be a simple call to `kmalloc()`: Depending on the number of previous allocations, `kmalloc()` might simply return a fresh pointer or map a whole range of pages and update a significant amount of metadata. We use two techniques to deal with these challenges.

The first one is to filter out interrupts and the transition caused while handling interrupts. This is possible using the Intel PT trace data. If an interrupt occurs, the processor emits a TIP instruction since the transfer is not visible in the code. To avoid confusion during an interrupt occurring at an indirect control flow instruction, the TIP packet is marked with FUP (flow update packet) to indicate an asynchronous event. After identifying such a signature, the decoder will drop all basic blocks visited until the corresponding `iret` instruction is encountered. To link the interrupts with their corresponding `iret`, we track all interrupts on a simple call stack. This mechanism is necessary since the interrupt handler may itself be interrupted by another interrupt.

The second mechanism is to blacklist any basic block that occurs non-deterministically. Each time we encounter a new bit in the AFL bitmap, we re-run the input several times in a row. Every basic block that does not show up in all of the trials will be marked as non-deterministic and filtered from further processing. For fast access, the results are stored in a bitmap of blacklisted basic block addresses. During the AFL bitmap translation, any transition hash value—which combines the current basic block address and the previous basic block address—involving a blacklisted block will be skipped.

3.5 Hypercalls

Hypercalls are a feature introduced by virtualization. On Intel platforms, hypercalls are triggered by the `vmcall` instruction. Hypercalls are to VMMs as syscalls are to kernels. If any ring 3 process or the kernel in the VM executes a `vmcall` instruction, a VM-Exit event is triggered and the VMM can decide how to process the hypercall. We patched KVM-PT to pass through our own set of hypercalls to the fuzzing logic if a magic value is passed in `rax` and the appropriate hypercall-ID is set in `rbx`. Additionally, we also patched KVM-PT to accept hypercalls from ring 3. Arguments for specific hypercalls are passed through `rcx`. We use this mechanism to define an interface that user mode agent can use to communicate with the fuzzing logic. One example hypercall is `HC_SUBMIT_BUFFER`. Its argument is a guest pointer that is stored in `rcx`. Upon executing the `vmcall` instruction, a VM-Exit is triggered and QEMU-PT stores the buffer pointer that was passed. It will later copy the new input data into this buffer (see step ⑤ in Figure 2). Finally, the execution of the VM is continued.

```
cli
mov rax, KAFL_MAGIC_VALUE
mov rbx, HC_CRASH
mov rcx, 0x0
vmcall
```

Listing 1: Hypercall crash notifier.

Another use case for this interface is to notify the fuzzing logic when a crash occurs in the target OS kernel. In order to do so, we overwrite the kernel crash handler of the OS with a simple hypercall routine. The injected code is shown in Listing 1 and displays how the hypercall interface is used on the assembly level. The `cli` instruction disables all interrupts to avoid any kind of asynchronous interference during the hypercall routine.

4 Implementation Details

Based on the design outlined in the previous section, we built a prototype of our approach called kAFL. In the following, we describe several implementation details. The source code of our reference implementation is available at `https://github.com/RUB-SysSec/kAFL`.

4.1 KVM-PT

Intel PT allows us to trace branch transitions without patching or recompiling the targeted kernel. To the best of our knowledge, no publicly available driver is able to trace only guest executions of a single vCPU using Intel PT for long periods of time. For instance, Simple-PT [29] does not support long-term tracing by design. The

perf-subsystem [5] supports tracing of VM guest operations and long-term tracing. However, it is designed to trace logical CPUs, not vCPUs. Even if VMX execution is traced, the data would be associated with logical CPUs and not with vCPUs. Hence, the VMX context must be reassembled, which is a costly task.

To address these shortcomings, we developed KVM-PT. It allows us to trace vCPUs for an indefinite amount of time without any scheduling side effects or any loss of trace data due to overflowing output regions. The extension provides a fast and reliable trace mechanism for KVM vCPUs. Moreover, this extension exposes, much like KVM, an extensive user mode interface to access this tracing feature from user space. QEMU-PT utilizes this novel interface to interact with KVM-PT and to access the resulting trace data.

4.1.1 vCPU Specific Traces

To enable Intel PT, software that runs within ring 0 (in our case KVM-PT) has to set the corresponding bit of a model specific register (MSR) (IA32_RTIT_CTL_MSR.TraceEn) [28]. After tracing is enabled, the logical CPU will trace any executed code if it satisfies the configured filter options. The modification has to be done before the CPU switches from the host context to the VM operation; otherwise the CPU will execute guest code and is technically unable to modify any host MSRs. The inverse procedure is required after the CPU has left the guest context. However, enabling or disabling Intel PT manually will also yield a trace containing the manual MSR modification. To prevent the collection of unwanted trace data within the VMM, we use the MSR autoload capabilities of Intel VT-x. MSR autoloading can be enabled by modifying the corresponding entries in the VMCS (e.g., *VM_ENTRY_CONTROL_MSR* for VM-entries). This forces the CPU to load a list of preconfigured values for defined MSRs after either a VM-entry or VM-exit has occurred. By enabling tracing via MSR autoloading, we only gather Intel PT trace data for one specific vCPU.

4.1.2 Continuous Tracing

Once we have enabled Intel PT, the CPU will write the resulting trace data into a memory buffer until it is full. The physical addresses of this buffer and how to handle full buffers is specified by an array of data structures called Table of Physical Addresses (ToPA) entries.

The array can contain multiple entries and has to be terminated by a single END entry ③. There are two different ways the CPU can handle an overflow: It can stop the tracing (while continuing the execution—thus resulting in incomplete traces) or it can raise an interrupt. This interrupt causes a VM-exit since it is not maskable. We catch the interrupt on the host and consume the trace data. Finally, we reset the buffers and continue with the VM execution. Unfortunately, this interrupt might be raised at an unspecified time after the buffer was filled[2]. Our configuration of the ToPA entries can be seen in Figure 3. To avoid losing trace data, we use two different ToPA entries. The first one is the main buffer ①. Its overflow behavior is to trigger the interrupt. Once the main buffer is filled, a second entry is used until the interrupt is actually delivered. The ToPA specifies another smaller buffer ②. Overflowing the second buffer would lead to the stop of the tracing. To avoid the resulting data loss, we chose the second buffer to be about four times larger than the largest overflowing trace we have ever seen in our tests (4 KB).

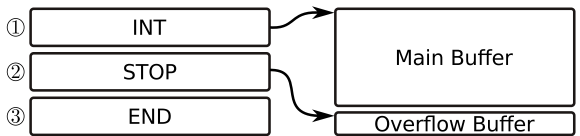

Figure 3: KVM-PT ToPA configuration.

In case the second buffer also overflows, the following trace will contain a packet indicating that some data is missing. In that case the size of the second buffer can simply be increased. This way, we manage to obtain precise traces for any amount of trace data.

4.2 QEMU-PT

To make use of the KVM extension KVM-PT, an user space counterpart is required. QEMU-PT is an extension of QEMU and provides full support for KVM-PT's user space interface. This interface provides mechanisms to enable, disable, and configure Intel PT at runtime as well as a periodic ToPA status check to avoid overruns. KVM-PT is accessible from user mode via ioctl() commands and an mmap() interface.

In addition to being a userland interface to KVM-PT, QEMU-PT includes a component that decodes trace data into a form more suitable for the fuzzing logic: We decode the Intel PT packets and turn them into an AFL-like bitmap.

4.2.1 PT Decoder

Extensive kernel fuzzing may generate several hundreds of megabytes of trace data per second. To deal with

[2]This is due to the current implementation of this interrupt. Intel specifies the interrupt as *not precise*, which means it is likely that further data will be written to the next buffer or tracing will be terminated and data will be discarded.

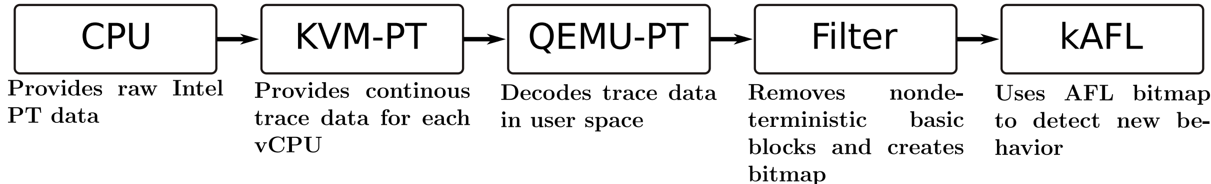

Figure 4: Overview of the pipeline that converts Intel PT traces to kAFL bitmaps.

such large amounts of incoming data, the decoder must be implemented with a focus on efficiency. Otherwise, the decoder may become the major bottleneck during the fuzzing process. Nevertheless, the decoder must also be precise, as inaccuracies during the decoding process would result in further errors. This is due to the nature of Intel PT decoding since the decoding process is sequential and is affected by previously decoded packets.

To ease efforts to implement an Intel PT software decoder, Intel provides its own decoding engine called `libipt` [4]. `libipt` is a general-purpose Intel PT decoding engine. However, it does not fit our purposes very well because `libipt` decodes trace data in order to provide execution data and flow information. Furthermore, `libipt` does not cache disassembled instructions and has performed poorly in our use cases.

Since kAFL only relies on flow information and the fuzzing process is repeatedly applied to the same code, it is possible to optimize the decoding process. Our Intel PT software decoder acts like a *just-in-time decoder*, which means that code sections are only considered if they are executed according to the decoded trace data. To optimize further look-ups, all disassembled code sections are cached. In addition, we simply ignore packets that are not relevant for our use case.

Since our PT decoder is part of QEMU-PT, trace data is directly processed if the ToPA base region is filled. The decoding process is applied in-place since the buffer is directly accessible from user space via `mmap()`. Unlike other Intel PT drivers, we do not need to store large amounts of trace data in memory or on storage devices for post-mortem decoding. Eventually, the decoded trace data is translated to the AFL bitmap format.

4.3 AFL Fuzzing Logic

We give a brief description of the fuzzing parts of AFL because the logic we use to perform scheduling and mutations closely follows that of AFL. The most important aspect of AFL is the bitmap used to trace which basic block transitions where encountered. Each basic block has a randomly assigned ID, and each transition from basic block A to another basic block B is assigned an offset into the bitmap according to the following formula:

$$(id(A)/2 \oplus id(B))\ \%\ \texttt{SIZE_OF_BITMAP}$$

Instead of the compile-time random, kAFL uses the addresses of the basic blocks. Each time the transition is observed, the corresponding byte in the bitmap is incremented. After finishing the fuzzing iteration, each entry of the bitmap is rounded such that only the highest bit remains set. Then the bitmap is compared with the global static bitmap to see if any new bit was found. If a new bit was found, it is added to the global bitmap and the input that triggered the new bit is added to the queue. When a new interesting input is found, a deterministic stage is executed that tries to mutate each byte individually.

Once the deterministic stage is finished, the non-deterministic phase is started. During this non-deterministic phase, multiple mutations are performed at random locations. If the deterministic phase finds new inputs, the non-deterministic phase will be delayed until all deterministic phases of all interesting inputs have been performed. If an input triggers an entirely new transition (as opposed to a change in the number of times the transition was taken), it will be favored and fuzzed with a higher priority.

5 Evaluation

Based on our implementation, we now describe the different fuzzing campaigns we performed to evaluate kAFL. We evaluate kAFL's fuzzing performance across different platforms. Section 5.5 provides an overview of all reported vulnerabilities, crashes, and bugs that were found during the development process of kAFL. We also evaluate kAFL's ability to find a previously known vulnerability. Finally, in Section 5.6 the overall fuzzing performance of kAFL is compared to *ProjectTriforce*, the only other OS-independent feedback fuzzer available. TriforceAFL is based on the emulation backend of QEMU instead of hardware-assisted virtualization and Intel PT. The performance overhead of KVM-PT is discussed in Section 5.7. Additionally, a performance comparison of our PT decoder and an Intel implementation of a software decoder is given in Section 5.8.

If not stated otherwise, the benchmarks were performed on a desktop system with an Intel i7-6700 processor and 32GB DDR4 RAM. To avoid distortions due

to poor I/O performance, all benchmarks are performed on a RAM disk. Similar to AFL, we consider a crashing input to be *unique* if it triggered at least one basic block transition which has not been triggered by any previous crash (i.e., the bitmap contains at least one new bit). Note this does not imply that the underlying bugs are truly unique.

5.1 Fuzzing Windows

We implemented a small Windows 10 specific user mode agent that mounts any data chunk (fuzzed payload) as NTFS-partitioned volume (289 lines of C code). We used the *Virtual Hard Disk* (VHD) API and various IOCTLS to mount and unmount volumes programmatically [31, 32]. Unfortunately, mounting volumes is a slow operation under Windows and we only managed to achieve a throughput of 20 executions per second. Nonetheless, kAFL managed to find a crash in the NTFS driver. The fuzzer ran for 4 days and 14 hours and reported 59 unique crashes, all of which were division by zero crashes. After manual investigation we suspect that there is only one unique bug. While it does not allow code execution, it is still a denial-of-service vulnerability, as for example, a USB stick with that malicious NTFS volume plugged into a critical system will crash that system with a blue screen. It seems that we only scratched the surface and NTFS was not thoroughly fuzzed yet. Hence, we assume that the NTFS driver under Windows is a valuable target for coverage-based feedback fuzzing.

Furthermore, we implemented a generic system call (syscall) fuzzing agent that simply passes a block of data to a syscall by setting all registers and the top stack region (55 lines of C and 46 lines of assembly code). This allows to set parameters for a syscall with a fuzzing payload *independent* of the OS ABI. The same fuzzer can be used to attack syscalls on different operation systems such as Linux or macOS. However, we evaluated it against the Windows kernel given the proprietary nature of this OS. We did not find any bugs in 13 hours of fuzzing with approx 6.3M executions since many syscalls cause the userspace agent to terminate: Due to the coverage-guided feedback, kAFL quickly learned how to generate payloads to execute valid syscalls, and this led to the unexpected execution of user mode callbacks via the kernel within the fuzzing agent. These crashes require rather expensive restarts of the agent and therefore we only achieved approx. 134 executions per second, while normally kAFL achieves a throughput of 1,000 to 4,000 tests per second (see Section 5.2). Additionally, the Windows syscall interface has already received much attention by the security community.

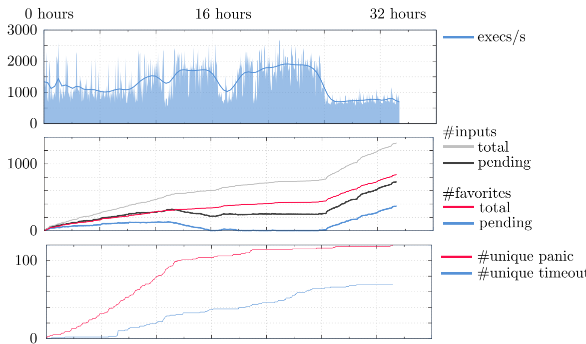

Figure 5: Fuzzing the ext4 kernel module for 32 hours.

5.2 Fuzzing Linux

We implemented a similar agent for Linux, which mounts data as ext4 volumes (66 lines of C code). We started the fuzz campaign with a minimal 64KB ext4 image as initial input. However, we configured the fuzzer such that it only fuzzes the first two kilobytes during the deterministic phase. In contrast to Windows, the Linux mount process is very fast, and we reached 1,000 to 2,000 tests per second on a Thinkpad laptop with a i7-6700HQ@2.6GHz CPU and 32GB RAM. Due to this high performance, we obtained significantly better coverage and managed to discover 160 unique crashes and multiple (confirmed) bugs in the ext4 driver during a twelve-day fuzzing campaign. Figure 5 shows the first 32 hours of another fuzzing run. The fuzzing process was still finding new paths and crashes on a fairly regular basis after 32 hours. An interesting observation is that there was no new coverage produced between hours 16 and 25, yet the number of inputs increased due a higher number of loop iterations. After hour 25, a truly new input was found that unlocked significant parts of the codebase.

5.3 Fuzzing macOS

Similarly to Windows and Linux, we targeted multiple file systems for macOS. So far, we found approximately 150 crashes in the HFS driver and manually confirmed that at least three of them are unique bugs that lead to a kernel panic. Those bugs can be triggered by unprivileged users and, therefore, could very well be abused for local denial-of-service attacks. One of these bugs seems to be a use-after-free vulnerability that leads to full control of the `rip` register. Additionally, kAFL found 220 unique crashes in the APFS kernel extension. All 3 HFS vulnerabilities and multiple APFS flaws have been reported to Apple.

5.4 Rediscovery of Known Bugs

We evaluated kAFL on the `keyctl` interface, which allows a user space program to store and manage various kinds of key material in the kernel. More specifically, it features a DER (see RFC5280) parser to load certificates. This functionality had a known bug (CVE-2016-0758[3]). We tested kAFL against the same interface on a vulnerable kernel (version 4.3.2). kAFL was able to uncover the same problem and one additional previously unknown bug that was assigned CVE-2016-8650[4]. kAFL managed to trigger 17 unique KASan reports and 15 unique panics in just one hour of execution time. During this experiment, kAFL generated over 34 million inputs, found 295 interesting inputs, and performed nearly 9,000 executions per second. This experiment was performed while running 8 processes in parallel.

5.5 Detected Vulnerabilities

During the evaluation, kAFL found more than a thousand unique crashes. We evaluated some manually and found multiple security vulnerabilities in all tested operating systems such as Linux, Windows, and macOS. So far, eight bugs were reported and three of them were confirmed by the maintainers:

- Linux: keyctl Null Pointer Dereference[5] (CVE-2016-8650[6])
- Linux: ext4 Memory Corruption[7]
- Linux: ext4 Error Handling[8]
- Windows: NTFS Div-by-Zero[9]
- macOS: HFS Div-by-Zero[10]
- macOS: HFS Assertion Fail[10]
- macOS: HFS Use-After-Free[10]
- macOS: APFS Memory Corruption[10]

Red Hat has assigned a CVE number for the first reported security flaw, which triggers a null pointer deference and a partial memory corruption in the kernel ASN.1 parser if an RSA certificate with a zero exponent is presented. For the second reported vulnerability, which triggers a memory corruption in the ext4 file system, a mainline patch was proposed. The last reported Linux vulnerability, which calls in the ext4 error handling routine `panic()` and hence results in a kernel panic, was at the time of writing not investigated any further. The NTFS bug in Windows 10 is a non-recoverable error condition which leads to a blue screen. This bug was reported to Microsoft, but has not been confirmed yet. Similarly, Apple has not yet verified or confirmed our reported macOS bugs.

5.6 Fuzzing Performance

We compare the overall performance of kAFL across different operating systems. To ensure comparable results, we created a simple driver that contains a JSON parser based on `jsmn`[11] for each aforementioned operating system and used it to decode user input (see Listing 2). If the user input is a JSON string starting with `"KAFL"`, a crash is triggered. We traced both the JSON parser as well as the final check. This way kAFL was able to learn correct JSON syntax. We measured the time used to find the crash, the number of executions per second, and the speed for new paths to be discovered on all three target operating systems.

```
1  jsmn_parser parser;
2  jsmntok_t tokens[5];
3  jsmn_init(&parser);
4
5  int res=jsmn_parse(&parser, input, size, tokens, 5);
6  if(res >= 2){
7      if(tokens[0].type == JSMN_STRING){
8          int json_len = tokens[0].end - tokens[0].
               start;
9          int s = tokens[0].start;
10         if(json_len > 0 && input[s+0] == 'K'){
11         if(json_len > 1 && input[s+1] == 'A'){
12         if(json_len > 2 && input[s+2] == 'F'){
13         if(json_len > 3 && input[s+3] == 'L'){
14             panic(KERN_INFO "KAFL...\n");
15     }}}}}
16 }
```

Listing 2: The JSON parser kernel module used for the coverage benchmarks.

We performed five repeated experiments for each operating system. Additionally we tested TriforceAFL with the Linux target driver. TriforceAFL is unable to fuzz Windows and macOS. To compare TriforceAFL with kAFL, the associated *TriforceLinuxSyscallFuzzer* was slightly modified to work with our vulnerable Linux kernel module. Unfortunately, it was not possible to compare kAFL against Oracle's file system fuzzer [34] due to technical issues with its setup.

During each run, we fuzzed the JSON parser for 30 minutes. The averaged and rounded results are displayed in Table 1. As we can see, the performance of kAFL is very similar across different systems. It should be remarked that the variance in this experiment is rather high

[11] http://zserge.com/jsmn.html

	Execs/Sec (1 Process)	Execs/Sec (8 Processes)	Time to Crash (1 Process)	Time to Crash (8 Processes)	Paths/Min (1 Process)	Paths/Min (8 Processes)
TriforceAFL	150	320	-[a]	-[a]	10.08	-[b]
Linux (initramfs)	3000	5700	7:50	6:00	15.84	15.62
Debian 8	3000	5700	4:55	6:30	16.20	16.00
Debian 8 (KASan)	4300	5700	9:20	6:00	16.22	15.90
macOS (10.12.4)	5100	8100	7:43	5:10	14.50	15.06
Windows 10	4300	8700	4:14	4:50	11.50	12.02

[a] Not found during 30-minute experiments.

[b] This value cannot be obtained since TriforceAFL does not synchronize in such short time frames.

Table 1: kAFL and TriforceAFL fuzzing performance on the JSON sample driver.

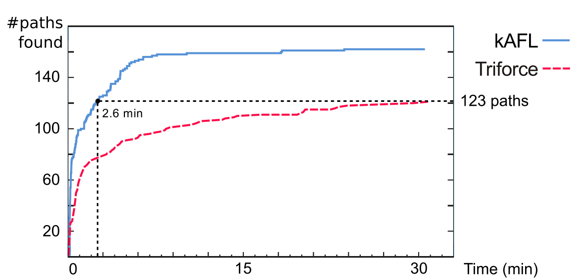

Figure 6: Coverage comparison of kAFL (initramfs) and TriforceAFL. kAFL takes less than 3 minutes to find the same number of paths as TriforceAFL does in 30 minutes (each running 1 process).

and explains some of the surprising results. This is due to the stochastic nature of fuzzing, since each fuzzer finds vastly different paths, some of which may take significantly longer to process, especially crashing paths and loops. One example for high variance is the fact that on Debian 8 (initramfs), the multiprocessing configuration on average needed more time to find the crash than one process.

TriforceAFL We used the JSON driver to compare kAFL and TriforceAFL with respect to execution speed and code coverage. However, the results where biased heavily in two ways: TriforceAFL did not manage to find a path that triggers the crash within 30 minutes (usually it takes approximately 2 hours), making it very hard to compare the code coverage of kAFL and TriforceAFL. The number of discovered paths is not a good indicator for the amount of coverage: With increasing running time, it becomes more difficult to discover new paths. Secondly, the number of executions per second is also biased by slower and harder to reach paths and especially crashing inputs. The coverage reached over time can be seen in Figure 6. It is obvious from the figure that kAFL found a significant number of paths that are very hard to

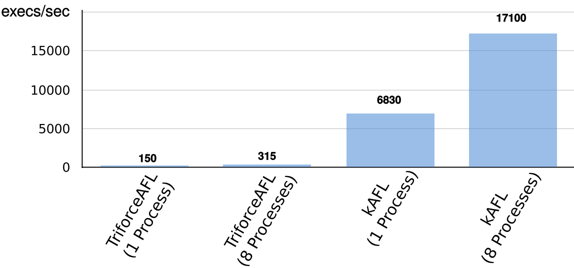

Figure 7: Raw execution performance comparison.

reach for TriforceAFL. kAFL mostly stops finding new paths around the 10-15 minute mark, because the target driver simply doesn't contain any more paths to be uncovered. Therefore, the coverage value in Table 1 (stated as *Paths/Min*) is limited to the first 10 minutes of each 30-minute run.

We also compare raw execution performance instead of overall fuzzing performance, which is biased because of the execution of different paths, the sampling process for the non-determinism-filter, and various synchronization mechanisms. Especially on smaller inputs, these factors disproportionately affect the overall fuzzing performance. To avoid this, we compared the performance during the first havoc stage. Figure 7 shows the raw execution performance of kAFL compared to TriforceAFL during this havoc phase. kAFL provides up to 54 times better performance compared to TriforceAFL's QEMU CPU emulation. Slightly lower performance boosts are seen in single-process execution (48 times faster).

syzkaller We did not perform a performance comparison against syzkaller [10]. This has two reasons: First of all, syzkaller is a highly specific syscall fuzzer that encodes a significant amount of domain knowledge and is therefore not applicable to other domains such as filesystem images. On the other hand, syzkaller would most likely generate a significantly higher code coverage even without any feedback since it knows how to generate

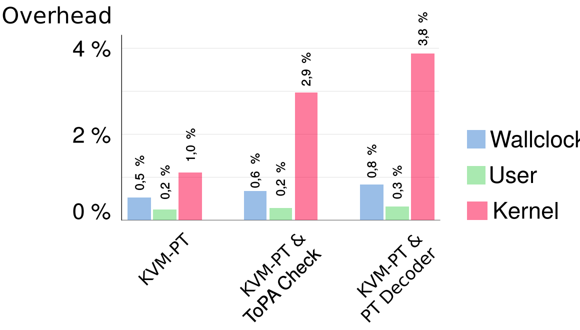

Figure 8: Overhead for compiling QEMU-2.6.0 in a traced VM.

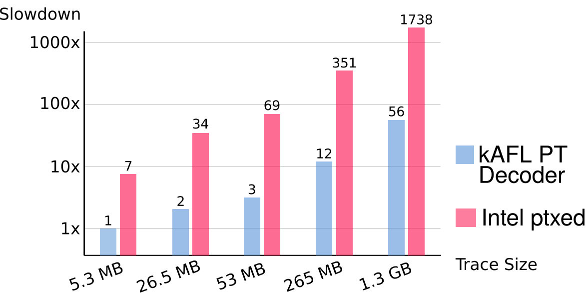

Figure 9: kAFL and ptxed decoding time on multiple copies of the same trace (kAFL is up to 30 times faster).

valid syscalls and hence is able to trigger valid paths without any learning. Therefore, the coverage comparison would be highly misleading unless we implement the same syscall logic; a task that is out of the scope of this paper. Additionally, the coverage collection via kcov is highly specific to Linux and not applicable to closed-source targets.

5.7 KVM-PT Overhead

Our KVM extension KVM-PT adds overhead to the raw execution of KVM. Therefore, the performance overhead was compared with several KVM-PT setups on an i5-6500@3.2Ghz desktop system with 8GB DDR4 RAM. This includes KVM-PT in combination with the PT decoder, KVM-PT without the PT decoder but processing frequent ToPA state checks, and KVM-PT without any ToPA consideration. For this benchmark, a 13MB kernel code range was configured via IP filtering ranges and traced with one of the aforementioned setups of KVM-PT. These benchmarks consider only the kernel core, but neither considers any kernel module. During KVM-PT execution only supervisor mode was traced.

To generate Intel PT load, `QEMU-2.6.0` was compiled within a traced VM using the `./configure` option `--target-list=x86_64-softmmu`. We restricted tracing to the whole kernel address space. This benchmark was executed on a single vCPU. The resulting compile time was measured and compared. The following figure illustrates the relative overhead compared to KVM execution without KVM-PT (see Figure 8). We ran three experiments to determine the overhead of the different components. In each experiment, we measured three different overheads: wall-clock time, user, and kernel. The difference in overall time is denoted by the wall-clock overhead. Additionally, we measured how much more time is spent in the kernel and how much time is spend only in user space. Since we only trace the kernel, we expect the users space overhead to be insignificant. Intel describes a performance penalty of < 5 % compared to execution without enabled Intel PT [30]. Accordingly, we expect approximately 5% of kernel overhead. In the first experiment, the traces were discarded without further analysis (KVM-PT). In the second experiment (KVM-PT & ToPA Check), we enabled repeated checking and clearing of the ToPA buffers. In the final experiment (KVM-PT & PT decoder), we tested the whole pipeline including our own decoder and conversion to an AFL bitmap.

During our benchmarks, an overhead between 1% – 4% was measured empirically. Since the resulting overhead is small, we do not expect it to have a major influence on the overall fuzzing performance.

5.8 Decoder Engine

In contrast to KVM-PT, the decoder has significant influence on the overall performance of the fuzzing process since the decoding process is—other than Intel PT and hence KVM-PT—not hardware-accelerated. Therefore, this process is costly and has to be as efficient as possible. Consequently, the performance of our developed PT decoder was compared to that of `ptxed`. This decoder is Intel's example implementation of an Intel PT software decoder and is based on `libipt`. To compare both decoder engines, a small Intel PT trace sample was generated by executing

```
find / > /dev/null 2> /dev/null
```

within a Linux VM (`Linux debian 4.8.0-1-amd64`) traced by KVM-PT. This performance benchmark was processed on an i5-6500@3.2Ghz desktop system with 8GB DDR4 RAM. Only code execution in supervisor mode was traced. The generated sample is 9.4MB in size and contains over 431,650 TNT packets, each representing up to 7 branch transitions. The sample also contains over 100,045 TIPs. We sanitized the sample by removing anything but *flow information packets* (see Section 2.3) to avoid any influence of decoding large amount

of *execution information packets*, since those are not considered by our PT decoder. The result is a 5.3*MB* trace file. To test the effectiveness of the caching approach of our PT decoder, we created cases containing 1, 5, 10, 50, and 250 copies of the trace. This is a realistic test case, since during fuzzing we see the same (or very similar) paths repeatedly. Figure 9 illustrates the measured speedup of our PT decoder compared to `ptxed`.

The figure also shows that our PT decoder easily outperforms the Intel decoder implementation, even if the PT decoder processes data for the very first time. This is most likely due to the fact that even a single trace already contains a significant amount of loops. Another possible factor is the use of Capstone [2] as the instruction decoding backend. As we decode more and more copies of the same trace, it can be seen that our decoder becomes increasingly faster (only using 56 times as much time to decode 250 times that amount of data). The *caching* approach outperforms Intel's implementation and is up to 25 to 30 times faster.

6 Related Work

Fuzzers are often classified according to the amount of interaction with the target program. For black-box fuzzers, the fuzzer does not use any information about the target program at all. White-box fuzzers typically use advanced program analysis techniques to uncover interesting properties of the target. Somewhere in the middle are so called gray-box fuzzers that will typically use some kind of feedback from the target (such as coverage information) to guide their search, without analyzing the logic of the target program itself. In this section, we provide a brief overview of the work performed in the corresponding areas of fuzzing.

6.1 Black-Box Fuzzers

The oldest class of fuzzers are black-box fuzzers. These fuzzers typically have no interaction with the target program beyond executing it on newly generated inputs. To increase effectiveness, a number of assumptions are usually made: Either a large corpus of good coverage inputs get mutated and recombined repeatedly. Examples for this class are Radamsa [3] or zzuf [12]. Or, the programmer needs to specify how to generate new semi-valid input files that almost look like real files. Examples including tools like Peach [6] or Sulley [9]. Both approaches have one very important drawback: It is a time-consuming task to use these tools.

To improve the performance of black-box fuzzers, many techniques have been proposed. Holler et al. [27] introduced learning interesting parts of the input grammar from old crashing inputs. Others even sought to infer the whole input grammar from program traces [13, 24, 38]. The selection of more interesting inputs was optimized by Rebert et al. [36]. Similar approaches have been used to optimize the mutation rate [17, 40].

6.2 White-Box fuzzers

To reduce the burden on the tester, techniques where introduced that apply insights from program analysis to find more interesting inputs. Tools like SAGE [23], DART [22], KLEE [15], SmartFuzz [33], or Mayhem [16] try to enumerate complex paths by using techniques such as symbolic execution and constraint solving. Tools like TaintScope [39], BuzzFuzz [21] and Vuzzer [35] utilize taint tracing and similar dynamic analysis techniques to uncover new paths. These tools are often able to find very complicated code paths that are hidden behind checksums, magic constants, and other constraints that are very unlikely to be satisfied by random inputs. Another approach is to use the same kind of information to bias the search towards dangerous behavior instead of new code paths [26].

The downside is that these techniques are often significantly harder to implement, scale to large programs, and parallelize. To the best of our knowledge, there are no such tools for operating system fuzzing.

6.3 Gray-Box Fuzzers

Gray-box fuzzers try to retain the high throughput and simplicity of black-box fuzzers while gaining some of the additional coverage provided by the advanced mechanics in white-box fuzzing. The prime example for gray-box fuzzing is AFL, which uses coverage information to guide its search. This way, AFL voids spending additional time on inputs that do not trigger new behaviors. Similar techniques are used by many other fuzzers [8, 25].

To further increase the effectiveness of gray-box fuzzing, many of the tricks already used in black-box fuzzing can be applied. Böhme et al. [14] showed how to use the insight gained from modelling gray-box fuzzing as a walk on a Markov chain to increase the performance of gray-box fuzzing by up to an order of magnitude.

6.4 Coverage-Guided Kernel Fuzzers

A project called syzkaller was released by Vyukov; it is the first publicly available gray-box coverage-guided kernel fuzzer [10]. Nossum and Casanovas demonstrate that most Linux file system drivers are vulnerable to feedback-driven fuzzing by using an adapted version of AFL [34]. This modified AFL version is based on glue code to the kernel consisting of a driver interface to

measure feedback during fuzzing file system drivers of the kernel and expose this data to the user space. This fuzzer runs inside the targeted OS; a crash terminates the fuzzing session.

In 2016, Hertz and Newsham released a modified version of AFL called TriforceAFL [7]. Their work is based on a modification of QEMU and utilizes the corresponding emulation backend to measure fuzzing progress by determining the current instruction pointer after a control flow altering instruction has been executed. In theory, their fuzzer is able to fuzz any OS emulated in QEMU. In practice, the TriforceAFL fuzzer is limited to operating systems that are able to boot from read-only file systems, which narrows down the candidates to classic UNIX-like operating systems such as Linux, FreeBSD, NetBSD, or OpenBSD. Therefore, TriforceAFL is currently not able to fuzz closed-source operating systems such as macOS or Windows.

7 Discussion

Even though our approach is general, fast and mostly independent of the underlying OS, there are some limitations we want to discuss in this section.

OS-Specific Code. We use a small amount (usually less than 150 lines) of OS-dependent ring 3 code that performs three tasks. First, it interacts with the OS to translate the inputs from the fuzzing engine to interactions with the OS (e.g., mount the data as a partition). Second, it obtains the address of the crash handler of the OS such that we can detect crashes faster than it would take to wait for the timeout. Third, it can return the addresses of certain drivers. These addresses can be used to limit tracing to the activity of said drivers, which improves performance when only fuzzing individual drivers.

None of these functions are necessary and only improve performance in some cases. The first use case can be avoided by using generic syscall fuzzing. In that case a single standard C program which does not use any platform-specific API would suffice to trigger `sysenter`/`syscall` instructions. We do not strictly need the address of the crash handler, since there are numerous other ways to detect whether the VM crashed. It would also be quite easy to obtain crash handlers dynamically by introducing faults and analyzing the obtained traces. Finally, we can always trace the whole kernel, taking a slight performance hit (mostly introduced by the increased amount of non-determinism). In cases such as syscall fuzzing, we need to trace the whole kernel, therefore syscall fuzzing would not be impacted if this ability was missing. In summary, this is the first approach that can fuzz arbitrary x86-64 kernels without any customization and a near-native performance.

Supported CPUs. Due to the usage of *Intel PT* and *Intel VT-x*, our approach is limited to certain Intel CPUs supporting these extensions. Virtually all modern Intel CPUs support *Intel VT-x*. Unfortunately, Intel is rather vague as to which CPUs exactly support process trace inside of VMs and various other extensions (such as IP filtering and multi-entry ToPA). We tested our system on the following CPU models: Intel Core i5-6500, Intel Core i7-6700HQ, and Intel Core i5-6600. We believe that at the time of writing, most Skylake and Kabylake CPUs have the necessary hardware support.

Just-In-Time Code. Intel PT does not provide a complete list of executed instruction pointers. Instead, Intel PT generates as little information as necessary to reduce the amount of data produced by the processor. Consequently, the Intel PT software decoder does not only require control flow information to reconstruct the control flow but also needs the program that was executed during tracing. If the program is modified during runtime, as often done by just-in-time (JIT) compilers in user and kernel mode, the decoder is unable to exactly restore the runtime control flow. To bypass this limitation, the decoder requires information about all modifications applied to the program instead of an ordinary memory dump or the executable file. As Deng et al. [18] have shown, this is possible by making use of EPT violations when executing written pages. Another, somewhat more old-fashioned, method to achieve the same is to use shadow page tables [19]. Once one it is possible to hook the execution of modified code, self-modifying code can be dumped. Reimplementing this technique was out of the scope of this work. It should be noted though that fuzzing kernel JIT code is a very interesting topic since kernel JIT components, such as the BPF JIT in Linux, have often been part of serious vulnerabilities.

Multibyte Compares. Similar to AFL, we are unable to effectively bypass checks for large magic values in the inputs. However, we support specifying dictionaries of interesting constants to improve performance if such magic values are known in advance (e.g., from RFCs, source code, or disassembly). Some solutions involving techniques such as concolic execution (e.g., Driller [37]) or taint tracking (e.g., Vuzzer [35]) have been proposed. However, none of these techniques can easily be adapted to closed-source operating system kernels. Therefore it remains an open research problem how to deal with those situations on the kernel level.

Ring 3 Fuzzing. We only demonstrated this technique against kernel-level code. However, the exact same technique can be used to fuzz closed-source ring 3 code as

well. Since our approach has a very modest tracing overhead, we expect that this technique will outperform current dynamic binary instrumentation based techniques for feedback fuzzing of closed-source ring 3 programs such as *winAFL* [20].

8 Conclusion

The latest generation of feedback-driven fuzzing methods has proven to be an effective approach to find vulnerabilities in an automated and comprehensive fashion. Recent work has also demonstrated that such techniques can be applied to kernel space. While previous feedback-driven kernel fuzzers were able to find a large amount of security flaws in certain operating systems, their benefit was either limited by poor performance due to CPU emulation or a lack of portability due to the need for compile-time instrumentations.

In this paper, we presented a novel mechanism to utilize the latest CPU features for a feedback-driven kernel fuzzer. As shown in the evaluation, combining all components provides the ability to apply kernel fuzz testing to any target OS with significantly better performance than the alternative approaches.

Acknowledgment

This work was supported by the German Federal Ministry of Education and Research (BMBF Grant 16KIS0592K HWSec). We would like to thank our shepherd Suman Jana for his support in finalizing this paper and the anonymous reviewers for their constructive and valuable comments. Furthermore, we would also like to thank Ralf Spenneberg and Hendrik Schwartke from OpenSource Security for supporting this research. Finally, we would like to thank Ali Abbasi, Tim Blazytko, Teemu Rytilahti and Christine Utz for their valuable feedback.

Abstract

Programming languages such as C and C++ support variadic functions, i.e., functions that accept a variable number of arguments (e.g., `printf`). While variadic functions are flexible, they are inherently not type-safe. In fact, the semantics and parameters of variadic functions are defined implicitly by their implementation. It is left to the programmer to ensure that the caller and callee follow this implicit specification, without the help of a static type checker. An adversary can take advantage of a mismatch between the argument types used by the caller of a variadic function and the types expected by the callee to violate the language semantics and to tamper with memory. Format string attacks are the most popular example of such a mismatch.

Indirect function calls can be exploited by an adversary to divert execution through illegal paths. CFI restricts call targets according to the function prototype which, for variadic functions, does not include all the actual parameters. However, as shown by our case study, current CFI implementations are mainly limited to non-variadic functions and fail to address this potential attack vector. Defending against such an attack requires a stateful dynamic check.

We present HexVASAN, a compiler based sanitizer to effectively type-check and thus prevent any attack via variadic functions (when called directly or indirectly). The key idea is to record metadata at the call site and verify parameters and their types at the callee whenever they are used at runtime. Our evaluation shows that HexVASAN is (i) practically deployable as the measured overhead is negligible (0.45%) and (ii) effective as we show in several case studies.

1 Introduction

C and C++ are popular languages in systems programming. This is mainly due to their low overhead abstractions and high degree of control left to the developer. However, these languages guarantee neither type nor memory safety, and bugs may lead to memory corruption. Memory corruption attacks allow adversaries to take control of vulnerable applications or to extract sensitive information.

Modern operating systems and compilers implement several defense mechanisms to combat memory corruption attacks. The most prominent defenses are Address Space Layout Randomization (ASLR) [47], stack canaries [13], and Data Execution Prevention (DEP) [48]. While these defenses raise the bar against exploitation, sophisticated attacks are still feasible. In fact, even the combination of these defenses can be circumvented through information leakage and code-reuse attacks.

Stronger defense mechanisms such as Control Flow Integrity (CFI) [6], protect applications by restricting their control flow to a predetermined control-flow graph (CFG). While CFI allows the adversary to corrupt non-control data, it will terminate the process whenever the control-flow deviates from the predetermined CFG. The strength of any CFI scheme hinges on its ability to statically create a precise CFG for indirect control-flow edges (e.g., calls through function pointers in C or virtual calls in C++). Due to ambiguity and imprecision in the analysis, CFI restricts adversaries to an over-approximation of the possible targets of individual indirect call sites.

We present a new attack against widely deployed mitigations through a frequently used feature in C/C++ that has so far been overlooked: variadic functions. Variadic functions (such as `printf`) accept a varying number of arguments with varying argument types. To implement variadic functions, the programmer implicitly encodes the argument list in the semantics of the function and has to make sure the caller and callee adhere to this implicit contract. In `printf`, the expected number of arguments and their types are encoded implicitly in the format string, the first argument to the function. Another frequently used scheme iterates through parameters until

a condition is reached (e.g., a parameter is NULL). Listing 1 shows an example of a variadic function. If an adversary can violate the implicit contract between caller and callee, an attack may be possible.

In the general case, it is impossible to enumerate the arguments of a variadic function through static analysis techniques. In fact, their number and types are intrinsic in how the function is defined. This limitation enables (or facilitates) two attack vectors against variadic functions. First, attackers can hijack indirect calls and thereby call variadic functions over control-flow edges that are never taken during any legitimate execution of the program. Variadic functions that are called in this way may interpret the variadic arguments differently than the function for which these arguments were intended, and thus violate the implicit caller-callee contract. CFI countermeasures specifically prevent illegal calls over indirect call edges. However, even the most precise implementations of CFI, which verify the type signature of the targets of indirect calls, are unable to fully stop illegal calls to variadic functions.

A second attack vector involves overwriting a variadic function's arguments directly. Such attacks do not violate the intended control flow of a program and thus bypass all of the widely deployed defense mechanisms. Format string attacks are a prime example of such attacks. If an adversary can control the format string passed to, e.g., `printf`, she can control how all of the following parameters are interpreted, and can potentially leak information from the stack, or read/write to arbitrary memory locations.

The attack surface exposed by variadic functions is significant. We analyzed popular software packages, such as Firefox, Chromium, Apache, CPython, nginx, OpenSSL, Wireshark, the SPEC CPU2006 benchmarks, and the FreeBSD base system, and found that variadic functions are ubiquitous. We also found that many of the variadic function calls in these packages are indirect. We therefore conclude that both attack vectors are realistic threats. The underlying problem that enables attacks on variadic functions is the lack of type checking. Variadic functions generally do not (and cannot) verify that the number and type of arguments they expect matches the number and type of arguments passed by the caller. We present HexVASAN, a compiler-based, dynamic sanitizer that tackles this problem by enforcing type checks for variadic functions at run-time. Each argument that is retrieved in a variadic function is type checked, enforcing a strict contract between caller and callee so that (i) a maximum of the passed arguments can be retrieved and (ii) the type of the arguments used at the callee are compatible with the types passed by the caller. Our mechanism can be used in two operation modes: as a runtime monitor to protect programs against attacks and as sanitizer to detect type mismatches during program testing.

We have implemented HexVASAN on top of the LLVM compiler framework, instrumenting the compiled code to record the types of each argument of a variadic function at the call site and to check the types whenever they are retrieved. Our prototype implementation is light-weight, resulting in negligible (0.45%) overhead for SPEC CPU2006. Our approach is general as we show by recompiling the FreeBSD base system and effective as shown through several exploit case studies (e.g., a format string vulnerability in sudo).

We present the following contributions:

- Design and implementation of a variadic function sanitizer on top of LLVM;
- A case study on large programs to show the prevalence of direct and indirect calls to variadic functions;
- Several exploit case studies and CFI bypasses using variadic functions.

2 Background

Variadic functions are used ubiquitously in C/C++ programs. Here we introduce details about their use and implementation on current systems, the attack surface they provide, and how adversaries can abuse them.

```c
#include <stdio.h>
#include <stdarg.h>

int add(int start, ...) {
    int next, total = start;
    va_list list;
    va_start(list, start);
    do {
        next = va_arg(list, int);
        total += next;
    } while (next != 0);
    va_end(list);
    return total;
}

int main(int argc, const char *argv[]) {
    printf("%d\n", add(5, 1, 2, 0));
    return 0;
}
```

Listing 1: Example of a variadic function in C. The function `add` takes a non-variadic argument `start` (to initialize an accumulator variable) and a series of variadic `int` arguments that are added until the terminator value `0` is met. The final value is returned.

2.1 Variadic functions

Variadic functions (such as the printf function in the C standard library) are used in C to maximize the flexibility in the interface of a function, allowing it to accept a number of arguments unknown at compile-time. These functions accept a variable number of arguments, which do not necessarily have fixed types. An example of a variadic function is shown in Listing 1. The function add accepts one mandatory argument (start) and a varying number of additional arguments, which are marked by the ellipsis (...) in the function definition.

The C standard defines several macros that portable programs may use to access variadic arguments [33]. stdarg.h, the header that declares these macros, defines an opaque type, va_list, which stores all information required to retrieve and iterate through variadic arguments. In our example, the variable list of type va_list is initialized using the va_start macro. The va_arg macro retrieves the next variadic argument from the va_list, updating va_list to point to the next argument as a side effect. Note that, although the programmer must specify the expected type of the variadic argument in the call to va_arg, the C standard does not require the compiler to verify that the retrieved variable is indeed of that type. va_list variables must be released using a call to the va_end macro so that all of the resources assigned to the list are deallocated.

printf is an example of a more complex variadic function which takes a format string as its first argument. This format string implicitly encodes information about the number of arguments and their type. Implementations of printf scan through this format string several times to identify all format arguments and to recover the necessary space in the output string for the specified types and formats. Interestingly, arguments do not have to be encoded sequentially but format strings allow out-of-order access to arbitrary arguments. This flexibility is often abused in format string attacks to access arbitrary stack locations.

2.2 Variadic functions ABI

The C standard does not define the calling convention for variadic functions, nor the exact representation of the va_list structure. This information is instead part of the ABI of the target platform.

x86-64 ABI. The AMD64 System V ABI [36], which is implemented by x86-64 GNU/Linux platforms, dictates that the caller of a variadic function must adhere to the normal calling conventions when passing arguments. Specifically, the first six non-floating point arguments and the first eight floating point arguments are passed through CPU registers. The remaining arguments, if any, are passed on the stack. If a variadic function accepts five mandatory arguments and a variable number of variadic arguments, then all but one of these variadic arguments will be passed on the stack. The variadic function itself moves the arguments into a va_list variable using the va_start macro. The va_list type is defined as follows:

```
typedef struct {
  unsigned int gp_offset;
  unsigned int fp_offset;
  void *overflow_arg_area;
  void *reg_save_area;
} va_list[1];
```

va_start allocates on the stack a reg_save_area to store copies of all variadic arguments that were passed in registers. va_start initializes the overflow_arg_area field to point to the first variadic argument that was passed on the stack. The gp_offset and fp_offset fields are the offsets into the reg_save_area. They represent the first unused variadic argument that was passed in a general purpose register or floating point register respectively.

The va_arg macro retrieves the first unused variadic argument from either the reg_save_area or the overflow_arg_area, and either it increases the gp_offset/fp_offset field or moves the overflow_arg_area pointer forward, to point to the next variadic argument.

Other architectures. Other architectures may implement variadic functions differently. On 32-bit x86, for example, all variadic arguments must be passed on the stack (pushed right to left), following the cdecl calling convention used on GNU/Linux. The variadic function itself retrieves the first unused variadic argument directly from the stack. This simplifies the implementation of the va_start, va_arg, and va_end macros, but it generally makes it easier for adversaries to overwrite the variadic arguments.

2.3 Variadic attack surface

When calling a variadic function, the compiler statically type checks all non-variadic arguments but does not enforce any restriction on the type or number of variadic arguments. The programmer must follow the implicit contract between caller and callee that is only present in the code but never enforced explicitly. Due to this high flexibility, the compiler cannot check arguments statically. This lack of safety can lead to bugs where an adversary achieves control over the callee by modifying the arguments, thereby influencing the interpretation of the passed variadic arguments.

Modifying the argument or arguments that control the interpretation of variadic arguments allows an adversary

to change the behavior of the variadic function, causing the callee to access additional or fewer arguments than specified and to change the interpretation of their types.

An adversary can influence variadic functions in several ways. First, if the programmer forgot to validate the input, the adversary may directly control the arguments to the variadic function that controls the interpretation of arguments. Second, the adversary may use an arbitrary memory corruption elsewhere in the program to influence the argument of a variadic function.

Variadic functions can be called statically or dynamically. Direct calls would, in theory, allow some static checking. Indirect calls (e.g., through a function pointer), where the target of the variadic function is not known, do not allow any static checking. Therefore, variadic functions can only be protected through some form of runtime checker that considers the constraints of the call site and enforces them at the callee side.

2.4 Format string exploits

Format string exploits are a perfect example of corrupted variadic functions. An adversary that gains control over the format string used in `printf` can abuse the `printf` function to leak arbitrary data on the stack or even resort to arbitrary memory corruption (if the pointer to the target location is on the stack). For example, a format string vulnerability in the smbclient utility (CVE-2009-1886) [40] allows an attacker to gain control over the Samba file system by treating a filename as format string. Also, in PHP 7.x before 7.0.1, an error handling function in zend_execute_API.c allows an attacker to execute arbitrary code by using format string specifiers as class name (CVE-2015-8617) [1].

Information leaks are simple: an adversary changes the format string to print the desired information that resides somewhere higher up on the stack by employing the desired format string specifiers. For arbitrary memory modification, an adversary must have the target address encoded somewhere on the stack and then reference the target through the `%n` modifier, writing the number of already written bytes to that memory location.

The GNU C standard library (*glibc*) enforces some protection against format string attacks by checking if a format string is in a writable memory area [29]. For format strings, the *glibc* `printf` implementation opens `/proc/self/maps` and scans for the memory area of the format string to verify correct permissions. Moreover, a check is performed to ensure that all arguments are consumed, so that no out-of-context stack slots can be used in the format string exploit. These defenses stop some attacks but do not mitigate the underlying problem that an adversary can gain control over the format string. Note that this heavyweight check is only used if the format string argument *may* point to a writable memory area at compile time. An attacker may use memory corruption to redirect the format string pointer to an attacker-controlled area and fall back to a regular format string exploit.

3 Threat model

Programs frequently use variadic functions, either in the program itself or as part of a shared library (e.g., `printf` in the C standard library). We assume that the program contains an arbitrary memory corruption, allowing the adversary to modify the arguments to a variadic function and/or the target of an indirect function call, targeting a variadic function.

Our target system deploys existing defense mechanisms like DEP, ASLR, and a strong implementation of CFI, protecting the program against code injection and control-flow hijacking. We assume that the adversary cannot modify the metadata of our runtime monitor. Protecting metadata is an orthogonal engineering problem and can be solved through, e.g., masking (`and`-ing every memory access), segmentation (for x86-32), protecting the memory region [9], or randomizing the location of sensitive data. Our threat model is a realistic scenario for current attacks and defenses.

4 HexVASAN design

HexVASAN monitors calls to variadic functions and checks for type violations. Since the semantics of how arguments should be interpreted by the function are intrinsic in the logic of the function itself, it is, in general, impossible to determine the number and type of arguments a certain variadic function accepts. For this reason, HexVASAN instruments the code generated by the compiler so that a check is performed at runtime. This check ensures that the arguments consumed by the variadic function match those passed by the caller.

The high level idea is the following: HexVASAN records metadata about the supplied argument types at the call site and verifies that the extracted arguments match in the callee. The number of arguments and their types is always known at the call site and can be encoded efficiently. In the callee this information can then be used to verify individual arguments when they are accessed. To implement such a sanitizer, we must design a metadata store, a pass that instruments call sites, a pass that instruments callers, and a runtime library that manages the metadata store and performs the run-time type verification. Our runtime library aborts the program whenever a mismatch is detected and generates detailed information about the call site and the mismatched arguments.

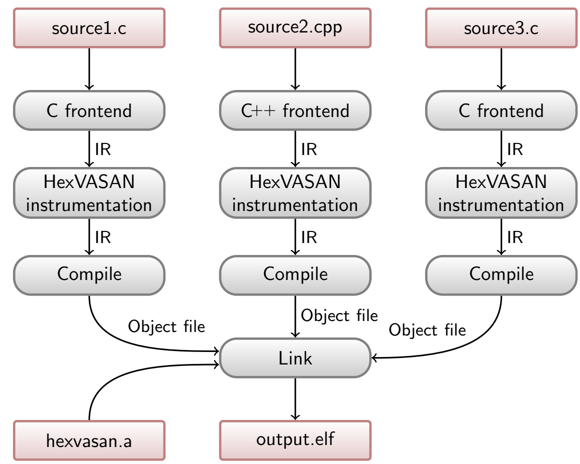

Figure 1: Overview of the HexVASAN compilation pipeline. The HexVASAN instrumentation runs right after the C/C++ frontend, while its runtime library, `hexvasan.a`, is merged into the final executable at link time.

4.1 Analysis and Instrumentation

We designed HexVASAN as a compiler pass to be run in the compilation pipeline right after the C/C++ frontend. The instrumentation collects a set of statically available information about the call sites, encodes it in the LLVM module, and injects calls to our runtime to perform checks during program execution.

Figure 1 provides an overview of the compilation pipeline when HexVASAN is enabled. Source files are first parsed by the C/C++ frontend which generates the intermediate representation on which our instrumentation runs. The normal compilation then proceeds, generating instrumented object files. These object files, along with the HexVASAN runtime library, are then passed to the linker, which creates the instrumented program binary.

4.2 Runtime support

The HexVASAN runtime augments every `va_list` in the original program with the type information generated by our instrumentation pass, and uses this type information to perform run-time type checking on any variadic argument accessed through `va_arg`. By managing the type information in a metadata store, and by maintaining a mapping between `va_lists` and their associated type information, HexVASAN remains fully compatible with the platform ABI. This design also supports interfacing between instrumented programs and non-instrumented libraries.

The HexVASAN runtime manages the type information in two data structures. The core data structure, called the *variadic list map* (VLM), associates `va_list` structures with the type information produced by our instrumentation, and with a counter to track the index of the last argument that was read from the list. A second data structure, the *variadic call stack* (VCS), allows callers of variadic functions to store type information of variadic arguments until the callee initializes the `va_list`.

Each variadic call site is instrumented with a call to `pre_call`, that prepares the information about the call site (a *variadic call site descriptor* or VCSD), and a call to `post_call`, that cleans it up. For each variadic function, the `va_start` calls are instrumented with `list_init`, while `va_copy`, whose purpose is to clone a `va_list`, is instrumented through `list_copy`. The two run-time functions will allocate the necessary data structures to validate individual arguments. Calls to `va_end` are instrumented through `list_end` to free up the corresponding data structures.

Algorithm 1 summarizes the two phases of our analysis and instrumentation pass. The first phase identifies all the calls to variadic functions (both direct and indirect). Note that identifying indirect calls to variadic functions is straight-forward in a compiler framework since, even if the target function is not statically known, its type is. Then, all the parameters passed by that specific call

```
input: a module m
/* Phase 1                                            */
foreach function f in module m do
    foreach variadic call c with n arguments in f do
        vcsd.count ← n;
        foreach argument a of type t do
            vcsd.args.push(t);
        end
        emit call to pre_call(vcsd) before c;
        emit call to post_call() after c;
    end
end
/* Phase 2                                            */
foreach function f in module m do
    foreach call c to va_start(list) do
        emit call to list_init(&list) after c;
    end
    foreach call c to va_copy(dst,src) do
        emit call to list_copy(&dst,&src) after c;
    end
    foreach call c to va_end(list) do
        emit call to list_free(&list) after c;
    end
    foreach call c to va_arg(list,type) do
        emit call to check_arg(&list,type) before c;
    end
end
```

Algorithm 1: The instrumentation process.

site are inspected and recorded, along with their type in a dedicated VCSD which is stored in read-only global data. At this point, a call to `pre_call` is injected before the variadic function call (with the newly created VCSD as a parameter) and, symmetrically, a call to `post_call` is inserted after the call site.

The second phase identifies all calls to `va_start` and `va_copy`, and consequently, the `va_list` variables in the program. Uses of each `va_list` variable are inspected in an architecture-specific way. Once all uses are identified, we inject a call to `check_arg` before dereferencing the argument (which always resides in memory).

4.3 Challenges and Discussion

When designing a variadic function call sanitizer, several issues have to be considered. We highlight details about the key challenges we encountered.

Multiple `va_lists`. Functions are allowed to create multiple `va_lists` to access the same variadic arguments, either through `va_start` or `va_copy` operations. HexVASAN handles this by storing a VLM entry for each individual `va_list`.

Passing `va_lists` as function arguments. While uncommon, variadic functions are allowed to pass the `va_lists` they create as arguments to non-variadic functions. This allows non-variadic functions to access variadic arguments of functions higher in the call stack. Our design takes this into account by maintaining a list map (VLM) and by instrumenting all `va_arg` operations, regardless of whether or not they are in a variadic function.

Multi-threading support. Multiple threads are supported by storing our per-thread runtime state in a thread-local variable as supported on major operating systems.

Metadata format. We use a constant data structure per variadic call site, the VCSD, to hold the number of arguments and a pointer to an array of integers identifying their type. The `check_arg` function therefore only performs two memory accesses, the first to load the number of arguments and the second for the type of the argument currently being checked.

To uniquely identify the data types with an integer, we decided to build a hashing function (described in Algorithm 2) using a set of fixed identifiers for primitive data types and hashing them in different ways depending on how they are aggregated (pointers, `union`, or `struct`). The last hash acts as a terminator marker for aggregate types, which allows us to, e.g., distinguish between {`struct{ int }, int`} and {`struct {struct{ int, int }}`}. Note that an (unlikely) hash collision only results in two different types being accepted as equal. Such a hashing mechanism has the advantage of being deterministic across compilation units, removing the need for

```
input  : a type t and an initial hash value h
output: the final hash value h
h = hash(h, typeID(t));
switch typeID(t) do
    case AggregateType
        /* union, struct and pointer          */
        foreach c in componentTypes(t) do
            h = hashType(c, h);
        end
    case FunctionType
        h = hashType(returnType(t), h);
        foreach a in argTypes(t) do
            h = hashType(a, h);
        end
    end
endsw
h = hash(h, typeID(t));
return h
```

Algorithm 2: Algorithm describing the type hashing function *hashType*. *typeID* returns an unique identifier for each basic type (e.g., 32-bit integer, `double`), type of aggregate type (e.g., `struct`, `union`...) and functions. *hash* is a simple hashing function combining two integers. *componentTypes* returns the components of an aggregate type, *returnType* the return type of a function prototype and *argTypes* the type of its arguments.

keeping a global map of type-unique id pairs. Due to the information loss during the translation from C/C++ to LLVM IR, our type system does not distinguish between signed and unsigned types. The required metadata is static and immutable and we mark it as read-only, protecting it from modification. However, the VCS still needs to be protected through other mechanisms.

Handling floating point arguments. In x86-64 ABI, floating point and non-floating point arguments are handled differently. In case of floating point arguments, the first eight arguments are passed in the floating point registers whereas in case of non-floating point the first six are passed in general-purpose registers. HexVASAN handles both argument types.

Support for aggregate data types. According to AMD64 System V ABI, the caller unpacks the fields of the aggregate data types (structs and unions) if the arguments fit into registers. This makes it hard to distinguish between composite types and regular types – if unpacked they are indistinguishable on the callee side from arguments of these types. HexVASAN supports aggregate data types even if the caller unpacks them.

Attacks preserving number and type of arguments. Our mechanism prevents attacks that change the number of arguments or the types of individual arguments.

Format string attacks that only change one modifier can therefore be detected through the type mismatch even if the total number of arguments remains unchanged.

Non-variadic calls to variadic functions. Consider the following code snippet:

```
typedef void (*non_variadic)(int, int);

void variadic(int, ...) { /* ... */ }

int main() {
  non_variadic function_ptr = variadic;
  function_ptr(1, 2);
}
```

In this case, the function call in `main` to `function_ptr` appears to the compiler as a non-variadic function call, since the type of the function pointer is not variadic. Therefore, our pass will not instrument the call site, leading to potential errors.

To handle such (rare) situations appropriately, we would have to instrument all non-variadic call sites too, leading to an unjustified overhead. Moreover, the code above represents *undefined behavior* in C [27, 6.3.2.3p8] and C++ [26, 5.2.10p6], and might not work on certain architectures where the calling convention for variadic and non-variadic function calls are not compatible. The GNU C compiler emits a warning when a function pointer is cast to a different type, therefore we require the developer to correct the code before applying HexVASAN.

Central management of the global state. To allow the HexVASAN runtime to be linked into the base system libraries, such as the C standard library, we made it a static library. Turning the runtime into a shared library is possible, but would prohibit its use during the early process initialization – until the dynamic linker has processed all of the necessary relocations. Our runtime therefore either needs to be added solely to the C standard library (so that it is initialized early in the startup process) or the runtime library must carefully use weak symbols to ensure that each symbol is only defined once if multiple libraries are compiled with our countermeasure.

C++ exceptions and `longjmp`. If an exception is raised while executing a variadic function (or one of its callees), the variadic function may not get a chance to clean up the metadata for any `va_lists` it has initialized, nor may the caller of this variadic function get the chance to clean up the type information it has pushed onto the VCS. Other functions manipulating the thread's stack directly, such as `longjmp`, present similar issues.

C++ exceptions can be handled by modifying the LLVM C++ frontend (i.e., `clang`) to inject an object with a lifetime spanning from immediately before a variadic function call to immediately after. Such an object would call `pre_call` in its constructor and `post_call` in the destructor, leveraging the exception handling mechanism to make HexVASAN exception-safe. Functions like `longjmp` can be instrumented to purge the portions of HexVASAN's data structures that correspond to the discarded stack area. We did not observe any such calls in practice and leave the implementation of handling exceptions and `longjump` across variadic functions as future engineering work.

5 Implementation

We implemented HexVASAN as a sanitizer for the LLVM compiler framework [31], version 3.9.1. We have chosen LLVM for its robust features on analyzing and transforming arbitrary programs as well as extracting reliable type information. The sanitizer can be enabled from the C/C++ frontend (`clang`) by providing the `-fsanitize=vasan` parameter at compile-time. No annotations or other source code changes are required for HexVASAN. Our sanitizer does not require visibility of whole source code (see Section 4.3), but works on individual compilation units. Therefore link-time optimization (LTO) is not required and thus fits readily into existing build systems. In addition, HexVASAN also supports signal handlers.

HexVASAN consists of two components: a static instrumentation pass and a runtime library. The static instrumentation pass works on LLVM IR, adding the necessary instrumentation code to all variadic functions and their callees. The support library is statically linked to the program and, at run-time, checks the number and type of variadic arguments as they are used by the program. In the following we describe the two components in detail.

Static instrumentation. The implementation of the static instrumentation pass follows the description in Section 4. We first iterate through all functions, looking for `CallInst` instructions targeting a variadic function (either directly or indirectly), then we inspect them and create for each one of them a read-only `GlobalVariable` of type `vcsd_t`. As shown in Listing 2, `vcsd_t` is composed by an unsigned integer representing the number of arguments of the considered call site and a pointer to an array (another `GlobalVariable`) with an integer element for each argument of `type_t`. `type_t` is an integer uniquely identifying a data type obtained using the *hashType* function presented in Algorithm 2. At this point a call to `pre_call` is injected before the call site, with the newly create VCSD as a parameter, and a call to `post_call` is injected after the call site.

During the second phase, we first identify all `va_start`, `va_copy`, and `va_end` operations in the program. In the IR code, these operations appear as calls to the LLVM in-

```
struct vcsd_t {
  unsigned count;
  type_t *args;
};

thread_local stack<vcsd_t *> vcs;
thread_local map<va_list *,
                 pair<vcsd_t *, unsigned>> vlm;

void pre_call(vcsd_t *arguments) {
  vcs.push_back(arguments);
}
void post_call() {
  vcs.pop_back();
}
void list_init(va_list *list_ptr) {
  vlm[list_ptr] = { vcs.top(), 0 };
}

void list_free(va_list *list_ptr) {
  vlm.erase(list_ptr);
}

void check_arg(va_list *list_ptr, type_t type) {
  pair<vcsd_t *, unsigned> &args = vlm[list_ptr];
  unsigned index = args.second++;
  assert(index < args.first->count);
  assert(args.first->args[index] == type);
}

Listing 2: Simplified C++ representation of the instrumented code for Listing 1.

trinsics `llvm.va_start`, `llvm.va_copy`, and `va_end`. We instrument the operations with calls to our runtime's `list_init`, `list_copy`, and `list_free` functions respectively. We then proceed to identify `va_arg` operations. Although the LLVM IR has a dedicated `va_arg` instruction, it is not used on any of the platforms we tested. The `va_list` is instead accessed directly. Our identification of `va_arg` is therefore platform-specific. On x86-64, our primary target, we identify `va_arg` by recognizing accesses to the `gp_offset` and `fp_offset` fields in the x86-64 version of the `va_list` structure (see Section 2.2). The `fp_offset` field is accessed whenever the program attempts to retrieve a floating point argument from the list. The `gp_offset` field is accessed to retrieve any other types of variadic arguments. We insert a call to our runtime's `check_arg` function before the instruction that accesses this field.

Listing 2 shows (in simplified C) how the code in Listing 1 would be instrumented by our sanitizer.

Dynamic variadic type checking. The entire runtime is implemented in plain C code, as this allows it to be linked into the standard C library without introducing a dependency to the standard C++ library. The VCS is implemented as a thread-local stack, and the VLM as a thread-local hash map. The `pre_call` and `post_call` functions push and pop type information onto and from the VCS. The `list_init` function inserts a new entry into the VLM, using the top element on the stack as the entry's type information and initializing the counter for consumed arguments to 0.

`check_arg` looks up the type information for the `va_list` being accessed in the VLM and checks if the requested argument exists (based on the counter of consumed arguments), and if its type matches the one provided by the caller. If either of these checks fails, execution is aborted, and the runtime will generate an error message such as the one shown in Listing 3. As a consequence, the pointer to the argument is never read or written, since the pointer to it is never dereferenced.

6 Evaluation

In this section we present a case study on variadic function based attacks against state-of-the-art CFI implementations. Next, we evaluate the effectiveness of HexVASAN as an exploit mitigation technique. Then, we evaluate the overhead introduced by our HexVASAN prototype implementation on the SPEC CPU2006 integer (CINT2006) benchmarks, on Firefox using standard JavaScript benchmarks, and on micro-benchmarks. We also evaluate how widespread the usage of variadic functions is in SPEC CPU2006 and in Firefox 51.0.1, Chromium 58.0.3007.0, Apache 2.4.23, CPython 3.7.0, nginx 1.11.5, OpenSSL 1.1.1, Wireshark 2.2.1, and the FreeBSD 11.0 base system.

Note that, along with testing the aforementioned software, we also developed an internal set of regression tests. Our regression tests allow us to verify that our sanitizer correctly catches problematic variadic function calls, and does not raise false alarms for benign calls. The test suite explores corner cases, including trying to access arguments that have not been passed and trying to access them using a type different from the one used at the call site.

6.1 Case study: CFI effectiveness

One of the attack scenarios we envision is that an attacker controls the target of an indirect call site. If the intended target of the call site was a variadic function, the attacker could illegally call a different variadic function that expects different variadic arguments than the intended target (yet shares the types for all non-variadic arguments). If the intended target of the call site was a non-variadic function, the attacker could call a variadic function that interprets some of the intended target's arguments as variadic arguments.

All existing CFI mechanisms allow such attacks to some extent. The most precise CFI mechanisms, which rely on function prototypes to classify target sets (e.g., LLVM-CFI, piCFI, or VTV) will allow all targets with the same prototype, possibly restricting to the subset of functions whose addresses are taken in the program. This is problematic for variadic functions, as only non-variadic types are known statically. For example, if a function of type `int (*)(int, ...)` is expected to be called from an indirect call site, then precise CFI schemes allow calls to all other variadic functions of that type, even if those other functions expect different types for the variadic arguments.

A second way to attack variadic functions is to overwrite their arguments directly. This happens, for example, in format string attacks, where an attacker can overwrite the format string to cause misinterpretation of the variadic arguments. HexVASAN detects both of these attacks when the callee attempts to retrieve the variadic arguments using the `va_arg` macro described in Section 2.1. Checking and enforcing the correct types for variadic functions is only possible at runtime and any sanitizer must resort to run-time checks to do so. CFI mechanisms must therefore be extended with a HexVASAN-like mechanism to detect violations. To show that our tool can complement CFI, we create test programs containing several variadic functions and one non-variadic function. The definitions of these functions are shown below.

```
int sum_ints(int n, ...);
int avg_longs(int n, ...);
int avg_doubles(int n, ...);
void print_longs(int n, ...);
void print_doubles(int n, ...);
int square(int n);
```

This program contains one indirect call site from which only the `sum_ints` function can be called legally, and one indirect call site from which only the `square` function can be legally called. We also introduce a memory corruption vulnerability which allows us to override the target of both indirect calls.

We constructed the program such that `sum_ints`, `avg_longs`, `print_longs`, and `square` are all address-taken functions. The `avg_doubles` and `print_doubles` functions are not address-taken.

Functions `avg_longs`, `avg_doubles`, `print_longs`, and `print_doubles` all expect different variadic argument types than function `sum_ints`. Functions `sum_ints`, `avg_longs`, `avg_doubles`, and `square` do, however, all have the same non-variadic prototype (`int (*)(int)`).

We compiled six versions of the test program, instrumenting them with, respectively, HexVASAN, LLVM 3.9 Forward-Edge CFI [59], Per-Input CFI [44], CCFI [35], GCC 6.2's VTV [59] and Visual C++ Control Flow Guard [37]. In each version, we first built an attack involving a variadic function, by overriding the indirect call sites with a call to each of the variadic functions described above. We then also tested overwriting the arguments of the `sum_ints` function, without overwriting the indirect call target. Table 1 shows the detection results.

LLVM Forward-Edge CFI allows calls to `avg_longs` and `avg_doubles` from the `sum_ints` indirect call site because these functions have the same static type signature as the intended call target. This implementation of CFI does not allow calls to variadic functions from non-variadic call sites, however.

CCFI only detects calls to `print_doubles`, a function that is not address-taken and has a different non-variadic prototype than `square`, from the `square` call site. It allows all of the other illegal calls.

Intended target	Actual target: Prototype	Actual target: A.T.?	LLVM-CFI	pi-CFI	CCFI	VTV	CFG	HexVASAN
Variadic	Same	Yes	✗	✗	✗	✗	✗	✓
		No	✗	✓	✗	✗	✗	✓
	Different	Yes	✓	✓	✗	✗	✗	✓
		No	✓	✓	✗	✗	✗	✓
Non-variadic	Same	Yes	✓	✓	✗	✗	✗	✓
		No	✓	✓	✗	✗	✗	✓
	Different	Yes	✓	✓	✗	✗	✗	✓
		No	✓	✓	✓	✗	✗	✓
Original	Overwritten Arguments		✗	✗	✗	✗	✗	✓

Table 1: Detection coverage for several types of illegal calls to variadic functions. ✓ indicates detection, ✗ indicates non-detection. "A.T." stands for *address taken*.

GCC VTV, and Visual C++ CFG allow all of the illegal calls, even if the non-variadic type signature does not match that of the intended call target.

pi-CFI allows calls to the `avg_longs` function from the `sum_ints` indirect call site. `avg_longs` is address-taken and it has the same static type signature as the intended call target. pi-CFI does not allow illegal calls to non-address-taken functions or functions with different static type signatures. pi-CFI also does not allow calls to variadic functions from non-variadic call sites.

All implementations of CFI allow direct overwrites of variadic arguments, as long as the original control flow of the program is not violated.

6.2 Exploit Detection

To evaluate the effectiveness of our tool as a real-world exploit detector, we built a HexVASAN-hardened version of sudo 1.8.3. sudo allows authorized users to execute shell commands as another user, often one with a high privilege level on the system. If compromised, sudo can escalate the privileges of non-authorized users, making it a popular target for attackers. Versions 1.8.0 through 1.8.3p1 of sudo contained a format string vulnerability (CVE-2012-0809) that allowed exactly such a compromise. This vulnerability could be exploited by passing a format string as the first argument (`argv[0]`) of the sudo program. One such exploit was shown to bypass ASLR, DEP, and glibc's FORTIFY_SOURCE protection [20]. In addition, we were able to verify that GCC 5.4.0 and clang 3.8.0 fail to catch this exploit, even when annotating the vulnerable function with the `format` function attribute [5] and setting the compiler's format string checking (`-Wformat`) to the highest level.

Although it is sudo itself that calls the format string function (`fprintf`), HexVASAN can only detect the violation on the callee side. We therefore had to build hardened versions of not just the sudo binary itself, but also the C library. We chose to do this on the FreeBSD platform, as its standard C library can be easily built using LLVM, and HexVASAN therefore readily fits into the FreeBSD build process. As expected, HexVASAN does detect any exploit that triggers the vulnerability, producing the error message shown in Listing 4.

6.3 Prevalence of variadic functions

To collect variadic function usage in real software, we extended our instrumentation mechanism to collect statistics about variadic functions and their calls. As shown in Table 2, for each program, we collect:

	Call sites			Func.			Ratio	
Program	Tot.	Ind.	%	Tot.	A.T.	Proto	Tot.	A.T.
Firefox	30225	1664	5.5	421	18	241	1.75	0.07
Chromium	83792	1728	2.1	794	44	396	2.01	0.11
FreeBSD	189908	7508	3.9	1368	197	367	3.73	0.53
Apache	7121	0	0	94	29	41	2.29	0.71
CPython	4183	0	0	382	0	38	10.05	0.00
nginx	1085	0	0	26	0	14	1.86	0.00

xalancbmk	19	0	0	4	2	4	1.00	0.50

Table 2: Statistics of Variadic Functions for Different Benchmarks. The second and third columns are variadic call sites broken into "Tot." (total) and "Ind." (indirect); % shows the percentage of variadic call sites. The fifth and sixth columns are for variadic functions. "A.T." stands for *address taken*. "Proto." is the number of distinct variadic function prototypes. "Ratio" indicates the *function-per-prototypes* ratio for variadic functions.

Call sites. The number of function calls targeting variadic functions. We report the total number and how many of them are indirect, since they are of particular interest for an attack scenario where the adversary can override a function pointer.

Variadic functions. The number of variadic functions. We report their total number and how many of them have their address taken, since CFI mechanism cannot prevent functions with their address taken from being reachable from indirect call sites.

Variadic prototypes. The number of distinct variadic function prototypes in the program.

Functions-per-prototype. The average number of variadic functions sharing the same prototype. This measures how many targets are available, on average, for each indirect call sites targeting a specific prototype. In practice, this the average number of permitted destinations for an indirect call site in the case of a perfect CFI implementation. We report this value both considering all the variadic functions and only those whose address is taken.

Interestingly, each benchmark we analyzed contains calls to variadic functions and several programs (Firefox, OpenSSL, perlbench, gcc, povray, and hmmer) even contain indirect calls to variadic functions. In addition to *calling* variadic functions, each benchmark also *defines* numerous variadic functions (421 for Firefox, 794 for Chromium, 1368 for FreeBSD, 469 for Wireshark, and 382 for CPython). Variadic functions are therefore prevalent and used ubiquitously in software. Adversaries have plenty of opportunities to modify these calls and to attack the implicit contract between caller and callee. The compiler is unable to enforce any static safety guarantees when calling these functions, either for the number of arguments, nor their types. In addition, many of the benchmarks have variadic functions that are called indirectly, often with their address being taken. Looking at Firefox, a large piece of software, the numbers are even more staggering with several thousand indirect call sites that target variadic functions and 241 different variadic prototypes.

The prevalence of variadic functions leaves both a large attack surface for attackers to either redirect variadic calls to alternate locations (even if defense mechanisms like CFI are present) or to modify the arguments so that callees misinterpret the supplied arguments (similar to extended format string attacks).

In addition, the compiler has no insight into these functions and cannot statically check if the programmer supplied the correct parameters. Our sanitizer identified three interesting cases in `omnetpp`, one of the SPEC CPU2006 benchmarks that implements a discrete event simulator. The benchmark calls a variadic functions with a mismatched type, where it expects a `char *` but receives a NULL, which has type `void *`. Listing 5 shows the offending code.

We also identified a bug in SPEC CPU2006's `perlbench`. This benchmark passes the result of a subtraction of two character pointers as an argument to a

```
static sEnumBuilder _EtherMessageKind(
     "EtherMessageKind",
    JAM_SIGNAL, "JAM_SIGNAL",
    ETH_FRAME, "ETH_FRAME",
    ETH_PAUSE, "ETH_PAUSE",
    ETHCTRL_DATA, "ETHCTRL_DATA",
    ETHCTRL_REGISTER_DSAP,
         "ETHCTRL_REGISTER_DSAP",
    ETHCTRL_DEREGISTER_DSAP,
         "ETHCTRL_DEREGISTER_DSAP",
    ETHCTRL_SENDPAUSE, "ETHCTRL_SENDPAUSE",
    0, NULL
);
```

Listing 5: Variadic violation in omnetpp.

variadic function. At the call site, this argument is a machine word-sized integer (i.e., 64-bits integer on our test platform). The callee truncates this argument to a 32-bit integer by calling `va_arg(list, int)`. HexVASAN reports this (likely unintended) truncation as a violation.

6.4 Firefox

We evaluate the performance of HexVASAN by instrumenting Firefox (51.0.1) and using three different browser benchmark suites: Octane, JetStream, and Kraken. Table 3 shows the comparison between the HexVASAN instrumented Firefox and native Firefox. To reduce variance between individual runs, we averaged fifteen runs for each benchmark (after one warmup run). For each run we started Firefox, ran the benchmark, and closed the browser. HexVASAN incurs only 1.08% and 1.01% overhead for Octane and JetStream respectively and speeds up around 0.01% for Kraken. These numbers are indistinguishable from measurement noise. Octane [4] and JetStream measure the time a test takes to complete and then assign a score that is inversely proportional to the runtime, whereas Kraken [3] measures the speed of test cases gathered from different real-world applications and libraries.

Benchmark		Native	HexVASAN
Octane	AVERAGE	31241.80	30907.73
	STDDEV	2449.82	2442.82
	OVERHEAD		-1.08%
JetStream	AVERAGE	200.76	198.75
	STDDEV	0.66	1.68
	OVERHEAD		-1.01%
Kraken	AVERAGE [ms]	832.48	832.41
	STDDEV [ms]	7.41	12.71
	OVERHEAD		0.01%

Table 3: Performance overhead on Firefox benchmarks. For Octane and JetStream higher is better, while for Kraken lower is better.

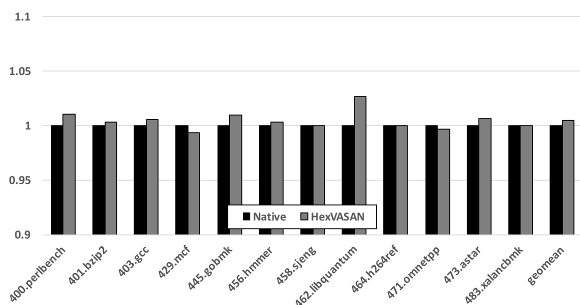

Figure 2: Run-time overhead of HexVASAN in the SPECint CPU2006 benchmarks, compared to baseline LLVM 3.9.1 performance.

6.5 SPEC CPU2006

We measured HexVASAN's run-time overhead by running the SPEC CPU2006 integer (CINT2006) benchmarks on an Ubuntu 14.04.5 LTS machine with an Intel Xeon E5-2660 CPU and 64 GiB of RAM. We ran each benchmark program on its reference inputs and measured the average run-time over three runs. Figure 2 shows the results of these tests. We compiled each benchmark with a vanilla clang/LLVM 3.9.1 compiler and optimization level `-O3` to establish a baseline. We then compiled the benchmarks with our modified clang/LLVM 3.9.1 compiler to generate the HexVASAN results.

The geometric mean overhead in these benchmarks was just 0.45%, indistinguishable from measurement noise. The only individual benchmark result that stands out is that of `libquantum`. This benchmark program performed 880M variadic function calls in a run of just 433 seconds.

6.6 Micro-benchmarks

Besides evaluating large benchmarks, we have also measured HexVASAN's runtime overhead on a set of micro-benchmarks. We have written test cases for variadic functions with different number of arguments, in which we repeatedly invoke the variadic functions. Table 4 shows the comparison between the native and HexVASAN-instrumented micro-benchmarks. Overall, HexVASAN incurs runtime overheads of 4-6x for variadic function calls due to the additional security checks. In real-world programs, however, variadic functions are invoked rarely, so HexVASAN has little impact on the overall runtime performance.

	# calls	Native [μs]	HexVASAN [μs]
Variadic function argument count: 3	1	0	0
	100	2	12
	1000	20	125
Variadic function argument count: 12	1	0	0
	100	6	22
	1000	55	198

Table 4: Performance overhead in micro-benchmarks.

7 Related work

HexVASAN can either be used as an always-on runtime monitor to mitigate exploits or as a sanitizer to detect bugs, sharing similarities with the sanitizers that exist primarily in the LLVM compiler. Similar to HexVASAN, these sanitizers embed run-time checks into a program by instrumenting potentially dangerous program instructions.

AddressSanitizer [54] (ASan), instruments memory accesses and allocation sites to detect spatial memory errors, such as out-of-bounds accesses, as well as temporal memory errors, such as use-after-free bugs. Undefined Behavior Sanitizer [52] (UBSan) instruments various types of instructions to detect operations whose semantics are not strictly defined by the C and C++ standards, e.g., increments that cause signed integers to overflow, or null-pointer dereferences. Thread Sanitizer [55] (TSAN) instruments memory accesses and atomic operations to detect data races, deadlocks, and various misuses of synchronization primitives. Memory Sanitizer [58] (MSAN) detects uses of uninitialized memory.

CaVer [32] is a sanitizer targeted at verifying correctness of downcasts in C++. Downcasting converts a base class pointer to a derived class pointer. This operation may be unsafe as it cannot be statically determined, in general, if the pointed-to object is of the derived class type. TypeSan [25] is a refinement of CaVer that reduces overhead and improves the sanitizer coverage.

UniSan [34] sanitizes information leaks from the kernel. It ensures that data is initialized before leaving the kernel, preventing reads of uninitialized memory.

All of these sanitizers are highly effective at finding specific types of bugs, but, unlike HexVASAN, they do not address misuses of variadic functions. The aforementioned sanitizers also differ from HexVASAN in that they typically incur significant run-time and memory overhead.

Different control-flow hijacking mitigations offer partial protection against variadic function attacks by preventing adversaries from calling variadic functions through control-flow edges that do not appear in legitimate executions of the program. Among these mitigations, we find Code Pointer Integrity (CPI) [30], a mitigation that prevents attackers from overwriting code pointers in the program, and various implementations of Control-Flow Integrity (CFI), a technique that does not prevent code pointer overwrites, but rather verifies the integrity of control-flow transfers in the program [6, 7, 11, 14–16, 21, 22, 28, 35, 37, 38, 41–44, 46, 49–51, 59, 61–66].

Control-flow hijacking mitigations *cannot* prevent attackers from overwriting variadic arguments directly. At best, they can prevent variadic functions from being called through control-flow edges that do not appear in legitimate executions of the program. We therefore argue that HexVASAN and these mitigations are orthogonal. Moreover, prior research has shown that many of the aforementioned implementations fail to fully prevent control-flow hijacking as they are too imprecise [8, 17, 19, 23], too limited in scope [53, 57], vulnerable to information leakage attacks [18], or vulnerable to spraying attacks [24, 45]. We further showed in Section 6.1 that variadic functions exacerbate CFI's imprecision problems, allowing additional leeway for adversaries to attack variadic functions.

Defenses that protect against direct overwrites or misuse of variadic arguments have thus far only focused on format string attacks, which are a subset of the possible attacks on variadic functions. LibSafe detects potentially dangerous calls to known format string functions such as `printf` and `sprintf` [60]. A call is considered dangerous if a `%n` specifier is used to overwrite the frame pointer or return address, or if the argument list for the `printf` function is not contained within a single stack frame. FormatGuard [12] instruments calls to `printf` and checks if the number of arguments passed to `printf` matches the number of format specifiers used in the format string.

Shankar et al. proposed to use static taint analysis to detect calls to format string functions where the format string originates from an untrustworthy source [56]. This approach was later refined by Chen and Wagner [10] and used to analyze thousands of packages in the Debian 3.1 Linux distribution. TaintCheck [39] also detects untrustworthy format strings, but relies on dynamic taint analysis to do so.

`_FORTIFY_SOURCE` of *glibc* provides some lightweight checks to ensure all the arguments are consumed. However, it can be bypassed [2] and does not check for type-mismatch. Hence, none of these aforementioned solutions provide comprehensive protection against variadic argument overwrites or misuse.

8 Conclusions

Variadic functions introduce an implicitly defined contract between the caller and callee. When the programmer fails to enforce this contract correctly, the violation leads to runtime crashes or opens up a vulnerability to an attacker. Current tools, including static type checkers and CFI implementations, do not find variadic function type errors or prevent attackers from exploiting calls to variadic functions. Unfortunately, variadic functions are prevalent. Programs such as SPEC CPU2006, Firefox, Apache, CPython, nginx, wireshark and libraries frequently leverage variadic functions to offer flexibility and abundantly call these functions.

We have designed a sanitizer, HexVASAN, that addresses this attack vector. HexVASAN is a light weight runtime monitor that detects bugs in variadic functions and prevents the bugs from being exploited. It imposes negligible overhead (0.45%) on the SPEC CPU2006 benchmarks and is effective at detecting type violations when calling variadic arguments. Download HexVASAN at `https://github.com/HexHive/HexVASAN`.

Towards Practical Tools for Side Channel Aware Software Engineering: 'Grey Box' Modelling for Instruction Leakages

David McCann

Carolyn Whitnall
University of Bristol

Abstract

Power (along with EM, cache and timing) leaks are of considerable concern for developers who have to deal with cryptographic components as part of their overall software implementation, in particular in the context of embedded devices. Whilst there exist some compiler tools to detect timing leaks, similar progress towards pinpointing power and EM leaks has been hampered by limits on the amount of information available about the physical components from which such leaks originate.

We suggest a novel modelling technique capable of producing high-quality instruction-level power (and/or EM) models without requiring a detailed hardware description of a processor nor information about the used process technology (access to both of which is typically restricted). We show that our methodology is effective at capturing differential data-dependent effects as neighbouring instructions in a sequence vary. We also explore register effects, and verify our models across several measurement boards to comment on board effects and portability. We confirm its versatility by demonstrating the basic technique on two processors (the ARM Cortex-M0 and M4), and use the M0 models to develop ELMO, the first leakage simulator for the ARM Cortex M0.

1 Introduction

Early evaluation of the leakage properties of security-critical code is an essential step in the design of secure technology. A developer in possession of a good quality explanatory model for (e.g.) the power consumption or electromagnetic radiation of a particular device can use this to predict the leakage traces arising from a particular code sequence and so identify (and address) possible points of weakness. Whilst the smart-card community is accustomed to support from side-channel testing facilities (either in-house or via external evaluation labs), there is a distinct lack of equivalent dedicated expertise in the fast-growing realm of the Internet-of-Things (IoT). This new market is rife with small start-ups whose limited budgets and rapid pace of advancement are incompatible with the prices and typical workflow of independent evaluators. Thus there arises a pressing need for user-friendly tools which easily integrate with established software development practice—typically in C and/or assembly, depending on the performance requirements of a given application—to assist in making that practice more security-aware.

Whilst there are tools to identify timing leaks such as `ctgrind` [16], there are no such easy tools for detecting power or EM leaks in programs. The reason for this is easily explained: timing information for instructions is readily available, however, accurate models for the instantaneous power consumption or EM emanations are not available.

The challenge of *acquiring* a good quality power model is in **choosing what to include** far more than it is in choosing between particular statistical techniques. The power consumption of a device bears a complex relationship with its various components and processes, necessitating a trade-off between precisely capturing as many details as possible and keeping within reasonable computational and sampling bounds. Transistor (respectively cell) netlists can be used to derive accurate gate-level models [17, Ch. 3], but for the purposes of development-stage side-channel testing in software, we require assembly level models.

Earlier efforts focused on assembly instructions to ensure covering vulnerabilities which might be introduced at compilation time, but (over-) simplified the modelling aspect by relying on Hamming weight and distance assumptions [7, 26]. A more recent, higher-level proposal based on C++ code representation also uses simplified leakage assumptions, although the author does acknowledge the potential for more sophisticated profiling [28]. Among the existing works only Debande et al. [6] em-

phasise the importance of (and the complexities involved in) deriving realistic leakage models empirically. They fit linear models in function of the state bits and state transitions using the techniques of linear regression.

However, such models are still considerably simplified relative to what is known about the complex factors driving device power consumption. For instance, much earlier efforts to model *total energy consumption* for the purposes of optimising code for constrained devices [27] showed clearly that the power consumed by a particular instruction varies according to the instructions previous in the sequence.

Another important aspect of power model construction, as emphasised by recent contributions in the template building literature [5, 11, 20], is **portability** between different devices of the same design.

1.1 Our Contributions

We present a strategy for building refined assembly code instruction-level power trace simulators and show that it is applicable to two processors relevant to the IoT context: the ARM Cortex M0 and M4. We develop the tool fully for the M0 and verify its utility for side-channel early evaluation.

The first part of our contribution is a side-channel modelling procedure novel for the thoroughness it attains by incorporating established linear regression model-selection techniques. We combine *a priori* knowledge about the M0 and the M4 with power (respectively EM) leakage samples obtained in carefully designed experiments, and use ordinary least squares (OLS) estimation and joint F-tests to decide between candidate explanatory variables in pursuit of models which account well for the exploitable aspects of the side-channel leakage whilst avoiding redundant complexity. The effects that we explore include instruction operands, bit-flips between consecutive operands, data-dependent interactions with previous and subsequent instructions in a sequence, register interactions, and higher-order operand and transition interactions. We verify portability by testing for board effects, which show no evidence of varying differentially with the processed data. We also show (via clustering analysis) that a set of 21 key M0 instructions can be meaningfully reduced to just five similarly-leaking classes, thereby greatly reducing the complexity of the modelling task. As well as enhancing the accuracy and nuance of our predicted traces relative to previous work, our systematic method of selecting and testing potential explanatory variables provides valuable insights into the leakage features of the ARM Cortex devices examined, which are of independent interest.

The second part of our contribution is a procedure to extract the data flows of arbitrary code sequences which can subsequently be mapped to trace predictions via our carefully refined models. We do this for the M0 by adapting an open-source instruction set simulator, chosen to enable us to eventually release a full open-source version of our own tool. We then demonstrate the utility of the simulator for flagging up even unexpected leaks in cryptographic implementations, by performing leakage detection tests against simulated and real measurements associated with an imperfectly-protected code sequence.

The remainder of the paper proceeds as follows: in Section 2 we review the previous work on leakage modelling, and provide a very brief overview of the key features of the ARM Cortex architecture and the Thumb instruction set, alongside some information about our tailored acquisition procedure. In Section 3 we outline our methodology for leakage characterisation and for testing for significant contributory effects. In Section 4 we explore the data-dependent leakage characteristics of each considered instruction taken individually, and empirically confirm the natural clustering of like instructions. In Section 5 we build complex models for the M0, allowing for the effects of neighbouring instructions and higher-order interactions and testing for the possibility of board and register effects. In Section 6 we explain how to use the models to simulate power traces, analyse them, and draw conclusions about leaking instructions. Closing remarks and open questions follow in Section 7.

2 Background

In this section we aim to provide enough context for our paper to be reasonably self-contained for a reader not familiar with the tasks of leakage modelling and model evaluation (Sect. 2.1), the ARM Cortex-M processor family (Sect. 2.2), assembly code instructions (Sect. 2.3) and/or typical side-channel measurement setups (Sect. 2.4).

2.1 Leakage Modelling Techniques

Modelling power consumption always involves a trade-off between precision and economy (with respect to time, memory usage and input data required). The most detailed ('white box') efforts take place at the analog or logic level and aim to characterise the power consumed by every component in (part of) a circuit. For the purposes of side-channel analysis, simpler, targeted ('black box') models can be estimated from sampled traces for particular intermediate values. Instruction-level models of the type we propose represent a ('grey box') middle ground, combining some relatively detailed knowledge of the implementation with empirical analysis of carefully sampled leakage traces. We briefly overview these three research directions below, followed by a summary

of some typical approaches to the difficult task of model quality evaluation.

2.1.1 Model Building Utilising Processor/Implementation Specific Information

Netlists describing all the transistor connections in a circuit, along with their parasitic capacitances, can be used to perform analog simulations of the whole or a part of the circuit. This process involves solving numerous difference equations and is highly resource intensive. A less costly (but also less precise) logic-level alternative uses cell-level netlists, back-annotated with information about signal delays and rise and fall times. These are used to simulate the *transitions* occurring in the circuit, which are subsequently mapped to a power trace according to knowledge of the capacitive loads of the cell outputs. Alternatively, the *number* of transitions occurring can be taken as a simplified approximation of the power consumption, which implicitly amounts to the assumption that all $0 \rightarrow 1$ transitions contribute equally to $1 \rightarrow 0$ transitions (and similarly for $0 \rightarrow 0$ and $1 \rightarrow 1$ transitions). See Chapter 3 of [17] for more details. Note that even these most exhaustive of strategies, which may be collectively classed as 'white box' modelling due to their reliance on comprehensive implementation details, fail to account for influences on the leakage outside the information provided by the netlist (for instance crosstalk) and therefore represent simplifications of varying imperfection.

2.1.2 Model Building for Intermediate Instructions

For the purposes of side-channel analysis and evaluation, it suffices to build models only for power consumption which (potentially) bears a relationship to the processing of security-sensitive data or operations. These strategies bypass the requirement for detailed knowledge of the implementation and may be thought of as 'black box' modelling. A typical approach has been to focus on (searchably small) target intermediate values of interest (for example, the output of an S-box). By measuring large numbers of leakage traces as the output of the target function varies in a known way, it is possible to estimate the parameters of (for example) a multivariate Gaussian distribution associated with each possible value taken by the intermediate. Traces acquired from an equivalent device with an unknown key (and therefore unknown intermediates) can then be compared against these fitted models ('templates') for the purposes of classification [3, 5]. Linear regression techniques can be used to reduce the complexity of the leakage characterisation [23, 29]; the assumption of normality can be avoided, for example by building models using machine learning classification techniques [14].

2.1.3 Model Building for Processor Instructions

In order to simulate leakage of arbitrary code sequences on a given device we opt for ('grey box') instruction-level characterisation. Previous instruction-level (and higher code-level) simulations for the purposes of side-channel analysis have settled for Hamming weight or Hamming distance assumptions [26, 28] or have estimated simple models constrained to be close to such approximations [7, 6]. However, much earlier work by Tiwari et al. [27] explores more complex model configurations for the purposes of simulating and minimising the *total power cost* of software to be run on resource-constrained devices. The authors find that not only do instructions have different costs, but that those costs are influenced by preceding instructions in a circuit. Their models are thus comprised of instruction-specific average base costs additively combined with instruction-pair-specific average circuit state overheads. This methodology is not adequate for our purposes, as it essentially averages over all possible data inputs—precisely the source of variation that most needs to be captured and understood in a side-channel context. Hence, we combine similar instruction and instruction-interaction terms with data-state, -transition and -interaction terms, drawing on modern approaches to linear regression-based profiling [4, 29] to handle the considerable added complexity.

2.1.4 Evaluating Model Quality

To build a model is to attempt to capture the most important features of an underlying reality which is (at least in the cases where such an exercise is useful and interesting) *unknown*. For this reason it is generally not possible to definitively establish the quality of any model (i.e., the extent to which it matches reality). However, there *do* exist methods, depending on the various model-fitting strategies adopted, for indicating whether the output result is suitable for its desired purpose. An approach popular in the side-channel evaluation literature is to estimate the amount of information (in bits) in the true leakage which is successfully captured by an evaluator's model for that leakage with a metric called the *perceived information* (PI) [21, 8]. This retains the usual shortfalling in that the question of how *good* the model is essentially corresponds to the one of how close the PI is to the true (as always, unknown) mutual information. However, in [8] the authors show how to combine cross-correlation and distance sampling to increase confidence (or highlight problems) in models used for evaluation.

Nevertheless, for our purposes, the established tools traditionally associated with linear regression model

building are better suited as they allow disentangling the contributions of component parts of the model as well as commenting on overall model quality. The coefficient of determination, or R^2, is a popular goodness-of-fit measure which can be thought of as the proportion of the total variation in the sample which is explained by (i.e. can be predicted by) the model. However, the R^2 is notoriously difficult to interpret as it always increases with the number of explanatory variables, hampering attempts to compare models of different sizes. It can be adjusted by penalising for the number of variables, but it is normally recommended to compute the F-statistic (see Sect. 3.1) to test for the statistically significant improvement of one model over another. The F-test can also be used to test *overall* model significance, which is useful in our case where the exploitable (i.e. data dependent) variation may only represent a small fraction of the total variation in the traces (which includes noise and unrelated processes). That is, a low R^2 need not imply that a model is unfit for purpose, as long as it represents a statistically significant data-dependent component of the leakage; conversely, a high R^2 need not indicate a model as more fit for purpose if the extra variation explained is irrelevant to the data-dependent side-channel leakage or is a result of over-fit.

However, F-tests offer no reassurance that other important contributory factors have not been *omitted* from the model. In the context of modelling for side-channel detection, it is established practice to verify the *adequacy* of the trace simulations by demonstrating that they reliably reveal the same vulnerabilities as real trace measurements. Previously, this has largely been attempted by performing DPA attacks [7, 26]; for the purposes of rigour, we propose to also utilise the leakage detection framework of [10] (see Sect. 6.3).

2.2 ARM Cortex-M Processor Family

The ARM Cortex-M processor family[19] was first introduced by ARM in 2004 to be used specifically within small microcontrollers, unlike the Cortex-A and Cortex-R families which, although introduced at the same time, are aimed at higher-end applications. Within the family there are six variants of processor: the M0, M0+, M1, M3, M4 and M7, where the M0 provides the lowest cost, size and power device, the M7 the highest performing device, and the M0+, M3 and M4 processors sit in-between. The M1 is much the same as the M0 however it has been designed as a “soft core” to run inside a Field Programmable Gate Array (FPGA). The M0 and M3 share the same architecture as the M0+ and M4 respectively, though the M0+ and M4 have additional features on top of the basic processor architecture to provide them with greater performance. The M7 processor is the most recent (2014) and high performing of the Cortex-M family.

Whilst the exact CPU architecture of the Cortex-M devices is not publicly available, it can be assumed to resemble the basic architecture of ARM cores, as detailed in [9]. Figure 1 shows a simplified version of the basic architectural components: besides the arithmetic-logic unit (ALU), there exists a hardware multiplier, and a (barrel) shifter. The register banks feed into the ALU via two buses, one of which is also connected to some data in/out registers. There is a third bus that connects the output of the ALU back into the register banks.

We select the Cortex-M0 and M4 processors (see Tab. 2 in the Appendix for comparison) to evaluate using our clustering profiling methodology and go on to further analyse and produce a leakage emulator for the Cortex-M0. The reason for the selection of these two processors is that they represent either ends of the spectrum for the older, more widely used, of the Cortex-M family, allowing us to demonstrate that our methodology can be applied to a range of processors.

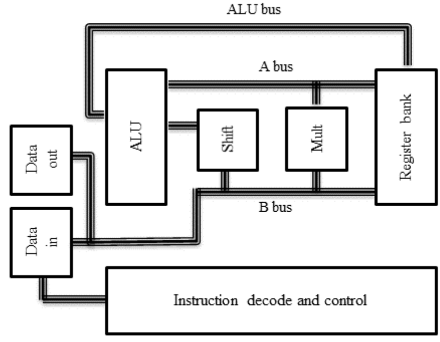

Figure 1: Simplified ARM CPU architecture (redrawn from [9]) for a 3-stage pipeline architecture.

2.3 Instructions

In this work we focus on profiling a select number (21) of Thumb instructions that are highly relevant for implementing symmetric cryptography, which run on both the Cortex-M0 and M4 processors: `ldr`, `ldrb`, `ldrh`, `str`, `strb`, `strh`, `lsls`, `lsrs`, `rors`, `muls`, `eors`, `ands`, `adds`, `adds` *#imm*, `subs`, `subs` *#imm*, `orrs`, `cmp`, `cmp` *#imm*, `movs` and `movs` *#imm*. Note that `adds` #imm and `subs` #imm use 3-bit immediate values rather than 8-bit values. All non-memory instructions use the `s` suffix and so update the conditional flags and, in the case of the Cortex-M0, can only use low registers. The implementation of the `muls` instruction takes a single cycle to execute on both processors. We made this selection to include core instructions with particular use within (symmetric key) cryptographic algorithms, which tend to per-

form operations on the set of unsigned integers. We also focus on the instructions which contain the `s` suffix to comply with restrictions required for many of the Cortex-M0 instructions and, where there is the option to use the non-suffixed instruction with higher registers (as with the `adds`, `subs` and `movs` instructions), we chose the suffixed version to maintain consistency with the other instructions.

Understanding and interpreting the input format of the instructions is necessary in order to correctly model them and the interactions between them. From Fig. 1 we would expect three buses to be used for the ALU instructions, as well as for shift and multiply instructions where the barrel shifter and hardware multiplier are present: the A bus for operand 1, the B bus for operand 2 and the output of the operation on the ALU bus. In our analysis we do not consider the effects of ALU outputs, as we assume the output of an instruction to be used as an input to a following instruction; we focus on the two operands of the operation which we would expect to leak via the A and B buses. We therefore take these to correspond to operands 1 and 2 respectively. For memory instructions we expect the data being loaded or stored to leak on bus B, as well as the data bus. To include this leakage and any interactions it may have with the previous data value that was on this bus, we set the data to be loaded or stored as the value of operand 2 for all memory instructions. How we model these operands based on the register selection of the instructions is described below.

For the majority of non-memory instructions (i.e. those other than `ldr`, `ldrb`, `ldrh`, `str`, `strb`, `strh`), three different registers may be selected for use in the format "`inst` r_d, r_n, r_m/#*imm*", where r_d is the destination register for the output, r_n the register holding the first operand and r_m the register containing the second operand. However, `mov` and `cmp` instructions each have only two registers: r_d, r_n and r_n, r_m respectively.

To simplify our configuration for modelling instructions, and to ensure enough registers for the analysis of three instructions (where each register must be fixed beforehand), r_d was the same as r_n for all of these, limiting the number of registers required for each instruction to 2. This method also allowed us to more easily assess switching effects in the destination register. We therefore took operand 1 to be r_d/r_n and operand 2 to be r_m.

Memory instructions have a slightly different configuration as the second operand needs to be a valid memory address. They typically have the form "`inst` $r_t, [r_n, r_m/\#imm]$" where r_t is the register to which the data is to be stored or from which it is to be loaded (according to the functionality of the instruction), r_n is the memory address and r_m/#*imm* is the offset to this memory address which can either be in a register r_m or input as an immediate value (#*imm*). The `ldr` instruction analysed was of this form rather than the alternative form which loads the memory address of a label. For our analysis we did not consider the leakage of memory addresses and so the value of the offset was simply set to 0 for all memory instructions with the memory address of r_n fixed beforehand. We therefore have one main operand for memory instructions which is the data in r_t for store instructions and the value in the memory address of r_n ($data[r_n]$) for load instructions which we set to operand 2 in both instances. For store instructions, we set the data in memory which is to be overwritten ($data[r_n]$) and for load instructions the register into which the data is to be loaded (r_t) to be random data which we model as operand 1 in both cases. This is to include any potential leaks that could come from either of these sources, however we would do expect this to include bit interactions with operand 1 of the previous instructions as we do not expect either of these data values to be transmitted on bus A in Fig. 1.

2.4 Measurement Setups

We work with implementations of the two processors by ST Microelectronics on STM Discovery Boards, with the ARM Cortex-M0 being implemented on an STM32F0 (30R8T6) Discovery Board and the ARM Cotex-M4 on the STM32F4 (07VGT6). These boards both feature an ST-Link to flash programs to the processor and provide on-chip debugging capabilities as well as on-board RC oscillator clock signals (8Mhz and 16Mhz for the STM32F0 and STM32F4 respectively). Further details about the devices can be found in datasheets [24] and [25].

In order to get accurate power measurements for the Cortex-M0, we modified the STM32F0 board by extracting the power pins of the processor, and passing the power supply through a 360Ω resistor over which a differential probe was connected. This was to minimise the potential for board and setup effects. We also verified the stability of our power supply. To measure the EM emissions on the Cortex-M4 processor we placed a small EM probe over the output of one of the capacitors leading to one of the power supply pins of the processor.

We used a Lecroy Waverunner 700 Zi scope at a sampling rate of 500 MS/S for both the power and EM analyses. The sampling rate was selected by observing DPA outcomes on the Cortex-M0 across different sampling rates: 500 MS/S was the lowest sampling rate at which the best DPA outcomes were achieved. The clock speed of the Cortex-M0 was set to 8Mhz and the Cortex-M4 set to 16 Mhz. To lower the independent noise, we averaged over five acquisitions per input for the power measurements for the M0 (as this was found to be the lowest number that brought the most signal gain) and 10 for the

EM measurements for the M4 (to further reduce the additional noise associated with this method of taking traces). No filtering or further signal processing took place for the Cortex-M0 power measurements, however a 48Mhz low-pass filter was used before amplifying the EM signal for the Cortex-M4.

We note that our measurement of EM uses only one probe over one of multiple power inputs to the processor (for the M0 we reduced the number of power inputs to a single one over which to measure) and that, whilst we have applied *some* pre-processing to the (noisier) EM measurements, we could have attempted more thorough techniques to enhance the signal. We view, therefore, our two measurement setups for the different boards to represent different ends of the spectrum in terms of the time and effort invested to get improved measurements. In this way we aim to gain an understanding of how our profiling methodology adapts to different setup scenarios as well as for different processors.

3 A Novel Methodology to Characterise a Modern Microprocessor

In principle all components (i.e. on the lowest level of gates and interconnects) contribute to the side channel leakage in the form of power or EM and so could be modelled as predictor variables. The skill and challenge in model building is then to select and test (and possibly discard) potential predictors in a systematic manner, manoeuvring the trade-off between infeasible complexity and oversimplification. We opt for a 'grey box' approach which does not require detailed hardware descriptions but *does* assume access to assembly code in order to construct models at the instruction level. We concentrate on predictor variables that can be derived from assembly sequences (i.e. input data, register locations), but we also want to potentially account for board-specific effects.

Linear regression model-fitting techniques have been used by the research community for some years already to profile side-channel leakage [23]. We refine the adopted procedures according to well-established statistical hypothesis testing strategies, in order to better understand the true functional form of the leakage and to make informed judgements about candidate explanatory variables. Specifically, we perform F-tests for the joint significance of groups of related variables, and include or exclude them accordingly, thus producing meaningful explanatory models which are not unnecessarily complex.

3.1 Model Building

We fit models of the following form (written in matrix notation) to the measured leakage of different instructions via OLS estimation (see, e.g., Chapter 3 of [12]):

$$\mathbf{y} = \delta + [\,\mathbf{O_1}\,|\,\mathbf{O_2}\,|\,\mathbf{T_1}\,|\,\mathbf{T_2}\,]\,\boldsymbol{\beta} + \boldsymbol{\varepsilon} \tag{1}$$

where $\mathbf{O_i} = [\mathbf{x_i}[0]\,|\,\mathbf{x_i}[1]\,|\,\ldots\,|\,\mathbf{x_i}[31]]$ is the matrix of operand bits across bus $i = 1,2$, $\mathbf{T_i} = [\mathbf{x_i}[0] \oplus \mathbf{z_i}[0]|\ldots|\mathbf{x_i}[31] \oplus \mathbf{z_i}[31]]$ is the matrix of bit transitions across bus $i = 1,2$ (i.e., $[b]$ denotes the bth-bit, $\mathbf{x_i}$ denotes the ith operand to a given instruction, $\mathbf{z_i}$ denotes the ith operand to the previous instruction, and '$|$' denotes matrix concatenation). The scalar intercept δ and the vector of coefficients $\boldsymbol{\beta}$ are the model parameters to be estimated, and $\boldsymbol{\varepsilon}$ is the vector of error terms (noise), assumed for inference to have constant, uncorrelated variance across all observations.[1] If the noise can additionally be assumed to be normally distributed then the validity of the hypothesis tests holds without need of recourse to asymptotic properties of the test statistics.

3.2 Selecting Explanatory Variables

The innovations we propose over previous uses of linear regression for modelling side-channel leakage are with respect to informed model selection. The task of selecting a meaningful subset from a large number of candidate explanatory variables is well-recognised as non-trivial. Techniques such as stepwise regression [15] fully automate the procedure by iteratively adding and removing individual terms according to their contribution to the current configuration of the model. This approach is sensitive to the order in which terms are introduced and prone to over-fitting, and has attracted criticism for greatly understating the uncertainty of the finalised models as typically reported. Stepwise regression has been used to achieve so-called 'generic-emulating' DPA [30]; it is effective in this context because attack success does not derive from the actual construction of the produced models but requires only that the proportion of variance accounted for is greater under the correct key hypothesis than under the alternatives. However, we require our models to be *meaningful*, not just (artificially) close-fitting. Thus we adopt a more conservative and traditional approach towards model building by which informed intuition about likely (jointly) contributing factors precedes formal statistical testing for inclusion or exclusion.

The criterion for model inclusion is based on the F-test. Consider two models, A and B, such that A is 'nested' within B—that is, it has $p_A < p_B$ parameters associated with a subset of model B's fitted terms (e.g. $\mathbf{y} = \delta' + [\,\mathbf{O_2}\,|\,\mathbf{T_1}\,|\,\mathbf{T_2}\,]\,\boldsymbol{\beta'} + \boldsymbol{\varepsilon'}$ versus (1) above). We are interested in the joint significance of the terms omitted

[1] By mean-centering each trace prior to analysis we remove drift, which could otherwise introduce auto-correlation.

from A (in our example case, the bits of the first operand). The test statistic is computed via the residual sums of squares (RSS) of each model, along with their respective numbers of parameters p_A, p_B and the sample size n as follows:

$$F = \frac{\left(\frac{\text{RSS}_A - \text{RSS}_B}{p_B - p_A}\right)}{\left(\frac{\text{RSS}_B}{n - p_B}\right)} \quad (2)$$

Under the *null hypothesis* that the terms have no effect, F has an F-distribution with $(p_B - p_A, n - p_B)$ degrees of freedom. If then, for a given significance level (usually $\alpha = 5\%$, as we opt for throughout)[2], F is larger than the 'critical value' of the $F_{p_B - p_A, n-p_B}$ distribution[3] we reject the null hypothesis and conclude that the tested terms *do* have an effect. If F is smaller than the critical value, we say that there is no evidence to reject the null hypothesis.

In the same way, we can add other terms to model (1) and test appropriate subsets in order to rigorously explore which factors influence the form of the leakage and should therefore be taken into account in the final model. We are especially concerned with sources of variation that have a *differential* impact on the *data-dependent* contributions, as these will determine how well we are able to proportionally approximate the exploitable part of the leakage (whereas 'level' (average) effects will simply shift the model by an additive constant). In particular, we test (in Sect. 5) for register, board and adjacent instruction effects on the operand and bit-flip contributions by computing F-statistics for the associated sets of interaction terms.

4 Identifying Basic Leakage Characteristics

We first investigate the instruction-dependent form of the leakage in a simple setting, where differential effects from other factors do not yet play a role. For this purpose, we perform the same fixed sequence `mov-instr-mov` 5,000 times for each selected instruction, as the two 32-bit operands vary. We measure the power consumption (or EM, in the case of the M4) associated with each sequence, and identify as a suitable point the maximum peak[4] in the clock cycle during which the instruction leaks. We fit the model (1) to the (drift-adjusted) vector of measurements at this point.

Table 3 in the Appendix confirms the overall significance of the model for each M0 instruction. This supports our point selection and the intuition that the leakage depends in part on the data being operated on. However, some differences can be observed in the contributing factors:

- The load instructions depend only on the bits of the operands (operand 2 or both for `ldrh`) and not the bit flips.
- The store instructions depend only on the bits and the bit transitions of the second operands.
- The operations on immediate values essentially have *no* second operand on which to depend.
- For all the other instructions all tested sets of explanatory variables are judged significant at the 5% level, which the exception of the second operand bit transitions for the `mul`.[5]

4.1 Further observations and indicators for model quality

Although we caution in the background section that over-interpreting the 'raw' value of resulting R-squareds is not advisable, their relative values can provide some evidence about the relative quality between (same-type) models obtained via e.g. different setups and devices.

Hence we now discuss same-type models for the M4, which we obtained using traces from a deliberately weaker measurement setup. Table 4, also in the Appendix, shows the model results for the M4. The model for the `mov` instruction is not found to be significant, implying that there is insufficient evidence to conclude that the EM radiation of `mov` depends on its data operands and bus transitions. The models for other instructions are overall significant, but fewer of the data-dependent terms are identified as contributing.

- Both operands to the ALU instructions contribute, except in the case of those involving immediate values (which, again, essentially have no second operand).
- Only the second operand to the load and store instructions contributes significantly.
- Bus transitions contribute to the instructions on immediate values, and also to `cmp`.

Whilst we again advise against over-interpreting the R-squareds (see Section 2.1), a comparison between the first rows of 3 and 4 indicates that, in the case of the ALU and shift instructions, model (1) accounts for substantially less of the variation in the M4 EM traces than it does of the variation in the M0 power traces. Although this could be taken as evidence that the instructions in question leak more in the case of the M0 and less in

[2]The significance level should be understood as the probability of rejecting the null hypothesis when it is in fact true.

[3]The number large enough to imply inconsistency with the distributional assumption fixing the probability of error at α.

[4]This choice is specific to our measurements and is by no means the only option.

[5]'Significant at the 5% level' is a shorthand way of saying that the null hypothesis of 'no effect' is *rejected* by the F-test when the probability of a false rejection (Type I error) is fixed at 5%.

the case of the M4, it is more likely that the M4 model is weaker because of the weaker setup as discussed in Sect. 2.4). We take this as further evidence that statistical measures that we suggest as part of our methodology are suitable to judge model quality.

4.2 Clustering Analysis to Identify Like Instructions

We eventually want to allow for possible differences in the leakage behaviours of instructions depending on adjacent activity in sequences of code (as per [27]). This will be much easier to achieve if we can reduce the number of distinct instructions requiring consideration. For instance, we might expect instructions invoking the same processor components (as visualised in Fig. 1) to leak similarly: ALU instructions as one group (i.e. `adds`, `adds` #*imm*, `ands`, `eors`, `movs`, `movs` #*imm*, `orrs`, `subs`, `subs` #*imm*, `cmp`, `cmp` #*imm*), shifts as another, albeit closely-related group (`lsls`, `lsrs`, `rors`), loads (`ldr`, `ldrb`, `ldrh`) and stores (`str`, `strb`, `strh`) that interact with the data in/out registers as two more groups, and the multiply instruction (`muls`) as a group on its own with a distinct profile due to its single cycle implementation.

We compare this intuitive grouping with that which is empirically suggested by the data by performing clustering analysis (see, e.g., Chapter 14 of [12]) on the per-instruction data term coefficients $\boldsymbol{\beta}$ obtained by fitting model (1) for both the M0 and the M4. We use the average Euclidean distance between instruction models to form a hierarchy of clusters (represented by the dendrograms in Fig. 6). Adjusting the inconsistency threshold[6] between 0.7 and 1.2 produces the groupings reported in Tables 5 and 6. In the case of the M0, these align nicely with our intuitive grouping: at threshold 0.9 the match is exact; at a threshold of 1.1 the shifts join the ALU instructions; at a threshold of 1.2 the instructions form a single cluster. In the case of the M4, the intuition is confirmed to a degree: at threshold 0.8, the ALU instructions are spread out over four groups, and the store operations over two; but the shift operations cluster together, as do the loads, and the `mul` is again identified as distinct. There is no overlap between the nine groups until they form a single cluster at threshold 1.0.

A 'good' cluster arrangement will achieve high similarity within groups and high dissimilarity between groups. The *silhouette value* is a useful measure to gauge this, defined for the ith object as $S_i = \frac{b_i - a_i}{\max(a_i, b_i)}$, where a_i is the average distance from the ith object to the other objects in the same cluster, and b_i is the minimum (over all clusters) average distance from the ith object to the objects in a different cluster [22]. Fig. 2 plots the M0 cluster silhouettes for a selection of the arrangements in Tab. 5. The consistency threshold of 0.9 is associated with the highest median silhouette value (0.56), supporting our *a priori* intuition.

[6] The *inconsistency coefficient* is defined as the height of the individual link minus the mean height of all links at the same hierarchical level, all divided by the standard deviation of all the heights on that level (see Matlab's `cluster` command: `http://uk.mathworks.com/help/stats/cluster.html`).

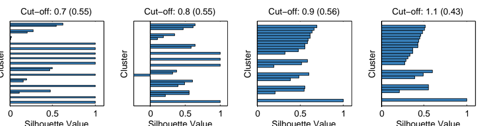

Figure 2: Silhouette plots for each M0 cluster arrangement (numbers in parentheses report median silhouette indices).

4.3 Functional Form of the Leakage

We next look more closely at the form of the estimated leakage models. Fig. 3 plots the mean data-dependent coefficients associated with the different terms in the model equations, for each of the five M0 groups suggested by the clustering analysis with a threshold of 0.9.

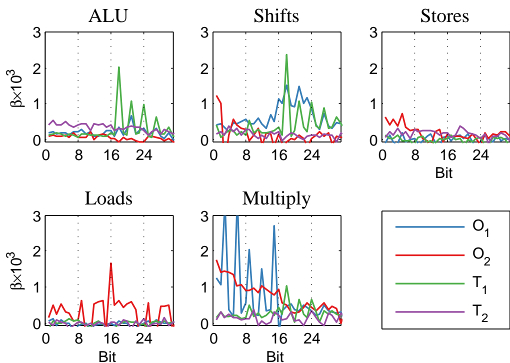

Figure 3: Average estimated coefficients on the model terms for each 'found' M0 instruction cluster

The differences between the groups are immediately clear. We make the following observations for the M0:

- ALU instructions (`adds`, `ands`, `cmps`, `eors`, `movs`, `orrs` and `subs`, and their immediate value equivalents where relevant) leak primarily in the transition between the first operands given to the current and previous instruction. However, not all the bits of this transition contribute; most of the explained leakage is in three bits of the third operand byte and one in the fourth.
- Shifts (`lsls`, `lsrs`, `rors`) appear to leak in the first operand (which contains the data being shifted)

and the transition between that and the first operand for the preceding instruction. The coefficients are largest for the third and (to a lesser extent) the fourth bytes. The transition leakage applies only to a few bits, while the operand leakage is more spread out between the bits. There is some evidence of leakage from the first three bits of the second operand.

- Stores (`str`, `strb`, `strh`) leak primarily in the first byte of the second operand.
- Loads (`ldr`, `ldrb`, `ldrh`) leak across most bits of the second operand. This shape is closest to the typically-made Hamming weight assumption.
- Multiply (`muls`) leaks mostly in the first two bytes of the first and second operand. The coefficients on the first operand are large for just six of the bits while the second operand coefficients are medium-sized across all bits of the first two bytes.

In summary, our exploratory analysis of the data-dependent form of the instruction leakages confirms many of our *a priori* intuitions about the architecture and supports our model building approach as sensible and meaningful. It also indicates that we can lessen the burden of the task by reducing the number of distinct instructions to be modelled to a meaningfully representative subset of the initial 21. Reducing *unnecessary* complexity in the instruction set increases the scope for adding meaningfully explanatory complexity to the models themselves, which we proceed to do in the next section for the power consumption of the M0.

5 Building Complex Models for the M0

From this point forward we concentrate on the M0 and seek to build more complex, sequence-dependent models for five instructions chosen to represent the groups identified by the clustering analysis of Sect. 4.2: `eors`, `lsls`, `str`, `ldr` and `muls`. The model coefficients for each of these are shown in Fig. 7 (see Appendix). As we would hope, they can be observed (by comparing with Fig. 3) to match well the mean coefficients for the groups that they represent, with the possible exception of `str`, which has smaller coefficients on the first byte than the average within its group.

We are confident that these five are adequate for understanding the leakage behaviour of all 21. Restricting the analysis in this way enables exhaustive exploration of the effects of preceding and subsequent operations when instructions are performed in sequence.[7]

[7]Such an approach implicitly makes the further assumption that instructions within each identified cluster are affected similarly by the sequence of which they are a part.

5.1 Exploring Board Effects

To understand if we need to account for variation between boards we replicate the M0 acquisition described at the start of Section 4 for a further 7 boards. We find the leaking point for each acquisition and pool the data. We then fit model (1) with the addition of a dummy for (level) board effects and we compare this against a model with the further addition of board/data interaction dummies, in order to test the joint significance of the latter.

We find a remarkable degree of consistency in the data-dependent leakage of the different boards. F-tests for the joint interaction between board and data effects do *not* reject the null hypothesis of 'no effect' for *any* of the instructions This also implies that our setup has minimised (or even removed) any measurable impact on the processor's power consumption.

5.2 Exploring Register Effects

The ARM Cortex-M0 architecture distinguishes between low (r0–r7) and high (r8–r15) registers. The latter, which can only be accessed by the `mov` instruction, are used for fast temporary storage. These were observed by inspection to have different leakage characteristics to the low registers. However, due to their singular usage we consider them outside of the scope of this particular analysis and focus only on the low registers. For the purposes of future extensions to our methodology, we propose modelling high register `movs` as an additional distinct instruction.

We test for variation between the eight low registers by collecting 5,000 traces for each source register (r_n) and destination register (r_d) (evenly distributed over the possible source/destination pairs, making 625 per pair) as `movs` are performed on random inputs. We then fit model (1) with the addition of dummy variables for source register and for destination register, and compare this against a model with the further addition of register/-data interaction dummies, in order to test the significance of the latter.

We find that the registers *do* have a jointly significant effect on the leakage data-dependency (see LHS of Tab. 7 in Appendix A). Considered separately, only the source register effect remains significant; at the 5% level we do not reject the null hypothesis that the destination register has no effect. Moreover, the effect can be isolated (by testing one 'source register interaction' at a time relative to the model with no source register interactions) to just half the source registers (`r0`, `r1`, `r4` and `r7`).

This analysis suggests that the inclusion of (some) source register effects would increase the ability of the model to accurately approximate the data-dependent leakage. However, such an extension would add consid-

erable complexity; it is important to examine the *practical* significance of the effects as well as the *statistical* significance which, in large sample sizes (such as we deal with here), will eventually be detected even for very small differences. The figure on the right of Tab. 7 (Appendix A) shows the estimated coefficients on the data terms as the source register varies. The 'significant' effect is at least small enough that it cannot be easily visualised—a legitimate criteria for assessing practical significance according to [2], although we have not carried out the formal visual inspection there proposed. We judge it acceptable, for now, to exclude it from the model in order to incorporate more important factors such as the effect of previous and subsequent instructions, which we consider in Sect. 5.3.

5.3 Allowing For Sequence Dependency

In this section we work towards extending our instruction level models to control (and test) for the possible effects of the previous and subsequent instructions in a given sequence.

To achieve this we acquired 1,000 traces for each of the possible 125 combinations of three out of the five instructions, with random data inputs. We alternated the sequences within a single acquisition to minimise the possibility of conflating instruction sequence effects with drift or acquisition effects, and mean-centered them to adjust for any overall drift. We compressed the traces to a single point (the maximum power peak) in each clock cycle, and selected the clock cycle most strongly associated with the data inputs to the target (middle) instruction. For the `ldr` instruction (which is two cycles long) the relevant point was one cycle ahead of that of the `muls`, `lsls` and `eors`; for `str`, the relevant point was three clock cycles ahead, implying that the data leaked during the subsequent instruction.

Using these relevant points, we then built models for each target instruction in function of its operands, as in model (1), with the addition of dummy variables for previous and subsequent instructions. We further allow for the data-dependent component to vary via four sets of interaction terms: the product of the instruction dummies with the Hamming weights of each operand and also with the corresponding Hamming distances (the sum of bitflips). This enables a degree of flexibility in estimating the form of the data dependency whilst avoiding the introduction of an infeasible number of instruction/data bit interaction terms into the model equation.

For ease of presentation consider the following groups of variables which together comprise the full set of explanatory variables:

- $\mathbf{I_p}$: The previous instruction in the sequence, fitted as a dummy variable (with `eors` as baseline to preserve linear independence).
- $\mathbf{I_s}$: The subsequent instruction in the sequence, fitted similarly to I_p.
- $\mathbf{D} = [\mathbf{O_1} \,|\, \mathbf{O_2} \,|\, \mathbf{T_1} \,|\, \mathbf{T_2}]$: All 128 operand bit and transition dummies.
- $\mathbf{DxI_p} = [\mathbf{O_1xI_p} \,|\, \mathbf{O_2xI_p} \,|\, \mathbf{T_1xI_p} \,|\, \mathbf{T_2xI_p}]$: The Hamming weights of the two 32-bit operands and their Hamming distances from the previous two inputs, interacted with the 'previous instruction' dummies (i.e. the products of the four summarised data terms with each of the four instruction dummies).
- $\mathbf{DxI_s} = [\mathbf{O_1xI_s} \,|\, \mathbf{O_2xI_s} \,|\, \mathbf{T_1xI_s} \,|\, \mathbf{T_2xI_s}]$: The Hamming weights of the two 32-bit operands and their Hamming distances from the previous two inputs, interacted with the 'subsequent instruction' dummies, as above.

The extended model, in our matrix notation, is therefore:

$$\mathbf{y} = \delta + [\mathbf{I_p} \,|\, \mathbf{I_s} \,|\, \mathbf{D} \,|\, \mathbf{DxI_p} \,|\, \mathbf{DxI_s}]\, \boldsymbol{\beta} + \boldsymbol{\varepsilon} \qquad (3)$$

For the purposes of building comprehensive instruction-level models we are especially interested in confirming (or otherwise) the presence of sequence-varying data-dependency, which we again achieve by performing F-tests for the contribution of the interaction terms. Table 8, in the Appendix, shows that the full set of interaction terms are jointly significant (at the 5% level) in all cases, as are the previous and subsequent instruction interactions considered separately. We also divide the interaction terms into four groups according to the operand or transition with which they are each associated, in order to test whether the varying data-dependency arises from all or just a subset (in which case we could reduce the complexity of the model). Only for the `str` model do we fail to find evidence of significant effects for all four, suggesting (in that case) the possibility of removing operand 1 and transition 2 terms without cost to the model.

We thus conclude that the form of the data-dependent leakage depends significantly on the previous and subsequent instructions within a sequence, and recommend that they be taken into account (as we have done here) when seeking to build comprehensive instruction-level models.

5.4 Exploring Higher-Order Effects

An obvious limitation of model (3) is that it restricts the relationship between the bits/transitions and the leakage to be linear. In practice, it is reasonable to suppose (for example) that bits carried on adjacent wires may produce

some sort of interaction. Previous analyses fitting linear regression models to target values [13, 29] have allowed for these and for other higher-order interactions, increasing the possibility of accounting for even more exploitable variation in the leakage. However, they have failed to investigate if such effects are in fact present.

We therefore test for the inclusion of adjacent and non-adjacent bit interactions in model (3). Table 9, in the Appendix, shows that we find significant effects precisely (and only) where we would expect to: in the leakages of `lsls` and `muls`, instructions which explicitly involve the joint manipulation of bits within the operands. We also test for adjacent bit flip interactions, which are not found to contribute significantly towards any of the instruction leakages. For the purposes of simulation, we therefore elect to use model (3) in the case of `eors`, `str` and `ldr`, and model (3) with the addition of input bit interactions in the case of `lsls` and `muls`.

6 Using and Evaluating our Grey Box Models in a Practical Context

Up until know we have considered short instruction sequences. We have shown that our novel approach produces models which, when evaluated in the context of an instruction triplet, include statistically relevant and architecturally justified terms. Furthermore, our methodology clearly indicates model quality: the models derived from a dedicated setup for monitoring the power consumption showed much better statistics then the models derived from the much less sophisticated EM setup.

However, to make the final argument that our approach results in models that are useful in the context of arbitrary instruction sequences, we need to consider code that is longer and more varied then the triplets that we used for model building. We also need to define a measure that allows us to judge how good the 'match' between model-simulated and real power traces is. We could consider randomly generating arbitrary code sequences (of some predefined length), and defining some distance measure. However, because we have a very clear application for these models in mind, we opt for a more decisive and targeted evaluation strategy. The ultimate test, arguably, is to utilise our models for the M0 to evaluate the security different implementation of a cryptographic algorithm (e.g. AES). To conduct such a test, we build an **E**mulator for power **L**eakages for the **M0** (short: ELMO, elaborated on in the next section). In this context we expect that leakage simulations based our newly constructed models enable to detect leaks that relate to the modelled instructions, but also (maybe more simply) that our models correlate well to measured traces.

6.1 ELMO

As follows from Sect. 3, our instruction-level models work with code that has been compiled down to assembly level, easily obtained via the ARM toolchain. Computing model predictions requires knowledge of the inputs to instructions, which entails emulating a given piece of code in order to extract the data flow. There are a number of instruction-level emulators available for the ARM, Thumb and Thumb2 instruction sets due to the popularity of these processors.

We choose an open source (programmed in C) emulator called Thumbulator[8]. We choose this over more well-known emulators[9] for its simplicity and ease of adaptivity for our purposes. One disadvantage of this choice is that it is inevitably less well-tested than its more popular rivals; it also omits the handful of Thumb-2 instructions which are available in the ARMv6-M instruction set, although we did not profile any of these. Of course, any of the other emulators could be equally incorporated within our methodology.

The Thumbulator takes as input a binary program in Thumb assembly, and decodes and executes each instruction sequentially, using a number of inbuilt functions to handle loads and stores to memory and reads and writes to registers. It provides the capability to trace the instruction and memory flow of a program for the purpose of debugging. Our data flow adaptation is built around a linked list data structure: in addition to the instruction type, the values of the two operands and the associated bit-flips from the preceding operands are stored in 32-element binary arrays.

The operand values, and associated bit-flips from the preceding operations, are then used as input to the model equations (as derived in Sect. 5; see Eqn. (1)), one for each profiled instruction group. Summarising, simulating the power consumption requires deriving, from the data flow information, the variables corresponding to the terms in the equations: the previous and subsequent instructions, the bits and the bit-flips of each operand, the Hamming weight and Hamming distances, and the adjacent bit interactions where relevant (i.e. for `lsls` and `muls`). The variables are then weighted by the appropriate coefficient vector and summed to give a leakage value, which is written to a trace file and saved.

6.2 Evaluating Model Correlation to Real Leakages

A simple way to check how well a model corresponds to real leakage behaviour is to compute the (Pearson) correlation between the model predictions for a particular instruction (operating on a set of known inputs) and the measured traces corresponding to a code sequence containing that same instruction (operating on the same inputs). This procedure can be used to demonstrate the improvement of our derived models over weaker, assumed models, such as the Hamming weight.

Figure 4 juxtaposes the correlation traces produced by the Hamming weight prediction of the leakage associated with the first round output as the M0 performs AES (top), and by the ELMO prediction corresponding to the same intermediate being loaded into the register (middle). It can be clearly seen that the ELMO model generates larger peaks, and more of them. The bottom of Figure 4 shows, for comparison, the peaks which are exhibited when the model predictions are correlated with an equivalent set of ELMO-emulated traces. These indicate the same leakage points as displayed in the measured traces, with the advantage of enhanced definition thanks to the lack of (data-independent) noise in the simulations. It thus emerges that Hamming weight-based simulations do not give a full picture of the true leakage of an implementation on an M0, and should not be relied upon for pre-empting data sensitivities. The same picture emerges for the other instructions but we do not include an exhaustive analysis for the sake of brevity. In conclusion, our models represent a marked improvement over simply using the Hamming weight.

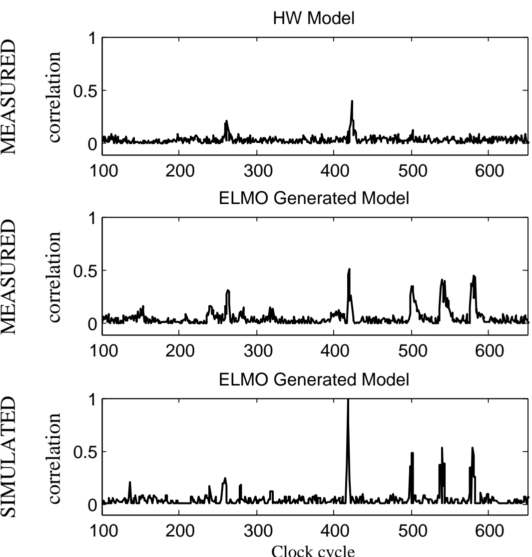

Figure 4: Correlation traces for ELMO-predicted intermediate values (top) and Hamming weight model predictions (middle) in 500 real M0 traces; correlation trace for ELMO-predicted intermediate values in the equivalent set of ELMO-emulated traces (bottom).

6.3 Evaluating Models via Leakage Detection

Further to the capability of our models to improve correlation analysis, we now show that they can also be applied to the task of (automated) leakage detection on assembly implementations. They can thereby be used to spot 'subtle' leaks – that is, leaks that would be difficult for non-specialist software engineers to understand and pinpoint.

To aid readability we briefly overview the leakage detection procedures proposed by Goodwill et al. [10]. These are based on classical statistical hypothesis tests, and can be categorised as *specific* or *non-specific*. Specific tests divide the traces into two subsets based on some known intermediate value such as an output bit of an S-box or the equality (or otherwise) of a round output byte to a particular value. The non-specific 'fixed-versus-random' test acquires traces associated with a particular fixed data input and compares them against traces associated with random inputs. In all cases the Welch's two-sample t-test for equality of means is then performed; results that are larger than a defined threshold, which we indicate via a dotted line in our figures, are taken as evidence for a leak.

6.3.1 Detecting 'Subtle' Leaks

We now choose a code sequence relating to a supposedly protected AES operation. The code sequence implements a standard countermeasure called masking [1]. Masking essentially distributes all intermediate variables into shares which are *statistically independent*, but whose composition (typically by way of exclusive-or) results in the (unmasked) variables. Consequently, standard DPA attacks [18] no longer succeed. The ease of implementation in software and ability to provide some sort of proof of leakage resilience has made masking a popular side channel attack countermeasure, on the receiving end of considerable attention from academia and industry alike. However, it is also well-known that implementations of masking schemes can produce subtle unanticipated leakages [17].

We faithfully implemented a masking scheme for AES (as described in [17]) in Thumb assembly to avoid the potential introduction of masking flaws by the compiler (from C to assembly). The code sequence, which we will analyse and discuss, relates to an operation called

ShiftRows which takes place as part of the AES round function. In a masked implementation, this results in a masked row (i.e. which would typically be stored within a register) being rotated and then written back into memory. Table 1 shows the assembly code for ShiftRows. An experienced and side-channel aware implementer who has detailed leakage information about the M0 would now be able to spot a problem with this code: because the `ror` instruction also leaks a function of the Hamming distance to its predecessor, there could be problem if the prior instruction is protected by the same mask. Clearly an inexperienced implementer, or somebody who does not have the necessary profiling information, would not be able to make this inference.

We now show that ELMO traces (for this same code sequence) can be used for the purposes of (pre-emptive) leakage detection. Since we do not expect any specific, simple leaks to be detectable under masking, we configured a 'fixed-versus-random' test to check instead for *arbitrary leaks*. Figure 5 shows that the analysis of our model-simulated traces indicates the presence of leaks in several instructions (see also Tab. 1 where they are colour-coded in red). These leaks are precisely due to the `ror` leakage properties that we discussed in the previous paragraph. The figure shows that all real-measurement leaks can be identified from the simulations, with the exception of some lingering leakage in the cycles after the final `ldr`. We believe this results from the fact that our models are constructed at instruction level rather than clock-cycle level—so the leakage arising from a particular instruction is tied to the cycle in which it is performed. Whilst this degrades the *visual* similarity of our simulations, it has the big advantage that we can easily track back to the 'offending' instruction.

In short, our grey box approach to modelling side-channel leakage proves highly successful at capturing and replicating potentially vulnerable data-dependency in arbitrary sequences of assembly code.

Cycle No.	Address	Machine Code	Assembly Code
1-2	0x08000206	0x684C	ldr r4,[r1,#0x4]
3	0x08000208	0x41EC	ror r4,r5
4-5	0x0800020A	0x604C	str r4,[r1,#0x4]

Table 1: Thumb assembly implementation of ShiftRows showing (colour-coded in red) leaky instructions as indicated by the model-simulated power consumption.

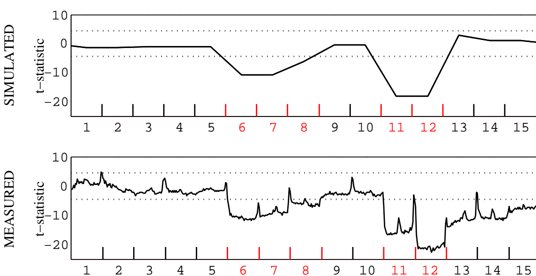

Figure 5: Fixed vs random t-tests against the (simulated and real) power consumption of masked ShiftRows. (Dotted lines indicate the ± 4.5 threshold for t-test significance).

7 Conclusion

We have shown how to combine a 'grey box' view of a cryptographic device with well-understood statistical techniques for model construction and evaluation in order to profile and simulate instruction-level side-channel leakage traces. Our methodology enables informed and statistically-testable decisions between candidate predictor variables, as well as empirically-verified clustering of like instructions. In this way, *redundant* complexity can be removed to increase the scope for additional *explanatory* complexity in our models. The procedure is appropriate for use with different devices and side-channels, and is self-equipped with the capability to identify scenarios where the measurements in question contain little of interest (i.e. minimal data-dependency). In addition to the valuable insights this methodology provides into leakage behaviours, which are of immediate interest to the side channel experts, it has considerable practical application via the integration of our models into a side-channel simulator (ELMO). We are thereby able to produce leakage traces for arbitrary sequences of code which demonstrably exhibit the same vulnerabilities as the same code sequences running on a real device. This capability suggests a variety of highly beneficial possible uses, such as the automated detection of leakages in the software development stage and the automated insertion (and testing) of countermeasures, as well as hugely promising prospects for optimisation with respect to protection level and energy efficiency.

Strong and Efficient Cache Side-Channel Protection using Hardware Transactional Memory

Daniel Gruss*, Julian Lettner†, Felix Schuster, Olga Ohrimenko, Istvan Haller, Manuel Costa
Microsoft Research

Abstract

Cache-based side-channel attacks are a serious problem in multi-tenant environments, for example, modern cloud data centers. We address this problem with Cloak, a new technique that uses hardware transactional memory to prevent adversarial observation of cache misses on sensitive code and data. We show that Cloak provides strong protection against all known cache-based side-channel attacks with low performance overhead. We demonstrate the efficacy of our approach by retrofitting vulnerable code with Cloak and experimentally confirming immunity against state-of-the-art attacks. We also show that by applying Cloak to code running inside Intel SGX enclaves we can effectively block information leakage through cache side channels from enclaves, thus addressing one of the main weaknesses of SGX.

1 Introduction

Hardware-enforced isolation of virtual machines and containers is a pillar of modern cloud computing. While the hardware provides isolation at a logical level, physical resources such as caches are still shared amongst isolated domains, to support efficient multiplexing of workloads. This enables different forms of side-channel attacks across isolation boundaries. Particularly worrisome are cache-based attacks, which have been shown to be potent enough to allow for the extraction of sensitive information in realistic scenarios, e.g., between colocated cloud tenants [56].

In the past 20 years cache attacks have evolved from theoretical attacks [38] on implementations of cryptographic algorithms [4] to highly practical generic attack primitives [43,62]. Today, attacks can be performed in an automated fashion on a wide range of algorithms [24].

Many countermeasures have been proposed to mitigate cache side-channel attacks. Most of these countermeasures either try to eliminate resource sharing [12, 18, 42, 52, 58, 68, 69], or they try to mitigate attacks after detecting them [9, 53, 65]. However, it is difficult to identify all possible leakage through shared resources [34, 55] and eliminating sharing always comes at the cost of efficiency. Similarly, the detection of cache side-channel attacks is not always sufficient, as recently demonstrated attacks may, for example, recover the entire secret after a single run of a vulnerable cryptographic algorithm [17, 43, 62]. Furthermore, attacks on singular sensitive events are in general difficult to detect, as these can operate at low attack frequencies [23].

In this paper, we present Cloak, a new efficient defensive approach against cache side-channel attacks that allows resource sharing. At its core, our approach prevents cache misses on sensitive code and data. This effectively conceals cache access-patterns from attackers and keeps the performance impact low. We ensure permanent cache residency of sensitive code and data using widely available hardware transactional memory (HTM), which was originally designed for high-performance concurrency.

HTM allows potentially conflicting threads to execute *transactions* optimistically in parallel: for the duration of a transaction, a thread works on a private memory snapshot. In the event of conflicting concurrent memory accesses, the transaction aborts and all corresponding changes are rolled back. Otherwise, changes become visible atomically when the transaction completes. Typically, HTM implementations use the CPU caches to keep track of transactional changes. Thus, current implementations like Intel TSX require that all accessed memory remains in the CPU caches for the duration of a transaction. Hence, transactions abort not only on real conflicts but also whenever transactional memory is evicted prematurely to DRAM. This behavior makes HTM a powerful tool to mitigate cache-based side channels.

The core idea of Cloak is to execute leaky algorithms in HTM-backed transactions while ensuring that *all* sensitive data and code reside in transactional memory for the duration of the execution. If a transaction succeeds, secret-dependent control flows and data accesses are guaranteed to stay within the CPU caches. Otherwise, the corresponding transaction would abort. As we show and discuss, this simple property can greatly raise the bar for contemporary cache side-channel attacks or even prevent them completely. The Cloak approach can be implemented on top of any HTM that provides the aforementioned basic properties. Hence, compared to other approaches [11, 42, 69] that aim to provide isola-

*Work done during internship at Microsoft Research; affiliated with Graz University of Technology.
†Work done during internship at Microsoft Research; affiliated with University of California, Irvine.

tion, Cloak does not require any changes to the operating system (OS) or kernel. In this paper, we focus on Intel TSX as HTM implementation for Cloak. This choice is natural, as TSX is available in many recent professional and consumer Intel CPUs. Moreover, we show that we can design a highly secure execution environment by using Cloak inside Intel SGX enclaves. SGX enclaves provide a secure execution environment that aims to protect against hardware attackers and attacks from malicious OSs. However, code inside SGX enclaves is as much vulnerable to cache attacks as normal code [7,20,46,57] and, when running in a malicious OS, is prone to other memory access-based leakage including page faults [10, 61]. We demonstrate and discuss how Cloak can reliably defend against such side-channel attacks on enclave code.

We provide a detailed evaluation of Intel TSX as available in recent CPUs and investigate how different implementation specifics in TSX lead to practical challenges which we then overcome. For a range of proof-of-concept applications, we show that Cloak's runtime overhead is small—between -0.8% and $+1.2\%$ for low-memory tasks and up to $+248\%$ for memory-intense tasks in SGX—while state-of-the-art cache attacks are effectively mitigated. Finally, we also discuss limitations of Intel TSX, specifically negative side effects of the aggressive and sparsely documented hardware prefetcher.

The key contributions of this work are:

- We describe Cloak, a universal HTM-based approach for the effective mitigation of cache attacks.
- We investigate the peculiarities of Intel TSX and show how Cloak can be implemented securely and efficiently on top of it.
- We propose variants of Cloak as a countermeasure against cache attacks in realistic environments.
- We discuss how SGX and TSX in concert can provide very high security in hostile environments.

Outline. The remainder of this paper is organized as follows. In Section 2, we provide background on software-based side-channel attacks and hardware transactional memory. In Section 3, we define the attacker model. In Section 4, we describe the fundamental idea of Cloak. In Section 5, we show how Cloak can be instantiated with Intel TSX. In Section 6, we provide an evaluation of Cloak on state-of-the-art attacks in local and cloud environments. In Section 7, we show how Cloak makes SGX a highly secure execution environment. In Section 8, we discuss limitations of Intel TSX with respect to Cloak. In Section 9, we discuss related work. Finally, we provide conclusions in Section 10.

2 Background

We now provide background on cache side-channel attacks and hardware transactional memory.

2.1 Caches

Modern CPUs have a hierarchy of caches that store and efficiently retrieve frequently used instructions and data, thereby, often avoiding the latency of main memory accesses. The first-level cache is the usually the smallest and fastest cache, limited to several KB. It is typically a private cache which cannot be accessed by other cores. The last-level cache (LLC), is typically unified and shared among all cores. Its size is usually limited to several MBs. On modern architectures, the LLC is typically inclusive to the lower-level caches like the L1 caches. That is, a cache line can only be in an L1 cache if it is in the LLC as well. Each cache is organized in *cache sets* and each cache set consists of multiple *cache lines* or *cache ways*. Since more addresses map to the same cache set than there are ways, the CPU employs a cache replacement policy to decide which way to replace. Whether data is cached or not is visible through the memory access latency. This is a root cause of the side channel introduced by caches.

2.2 Cache Side-Channel Attacks

Cache attacks have been studied for two decades with an initial focus on cryptographic algorithms [4, 38, 51]. More recently, cache attacks have been demonstrated in realistic cross-core scenarios that can deduce information about single memory accesses performed in other programs (*i.e.*, access-driven attacks). We distinguish between the following access-driven cache attacks: Evict+Time, Prime+Probe, Flush+Reload. While most attacks directly apply one of these techniques, there are many variations to match specific capabilities of the hardware and software environment.

In Evict+Time, the victim computation is invoked repeatedly by the attacker. In each run, the attacker selectively evicts a cache set and measures the victim's execution time. If the eviction of a cache set results in longer execution time, the attacker learns that the victim likely accessed it. Evict+Time attacks have been extensively studied on different cache levels and exploited in various scenarios [51, 60]. Similarly, in Prime+Probe, the attacker fills a cache set with their own lines. After waiting for a certain period, the attacker measures if all their lines are still cached. The attacker learns whether another process—possibly the victim—accessed the selected cache set in the meantime. While the first Prime+Probe attacks targeted the L1 cache [51, 54], more recent

attacks have also been demonstrated on the LLC [43, 50, 56]. Flush+Reload [62] is a powerful but also constrained technique; it requires attacker and victim to share memory pages. The attacker selectively flushes a shared line from the cache and, after some waiting, checks if it was brought back through the victim's execution. Flush+Reload attacks have been studied extensively in different variations [2, 41, 66]. Apart from the CPU caches, the shared nature of other system resources has also been exploited in side-channel attacks. This includes different parts of the CPU's branch-prediction facility [1, 15, 40], the DRAM row buffer [5, 55], the page-translation caches [21, 28, 36] and other microarchitectural elements [14].

This paper focuses on mitigating Prime+Probe and Flush+Reload. However, Cloak conceptually also thwarts other memory-based side-channel attacks such as those that exploit the shared nature of the DRAM.

2.3 Hardware Transactional Memory

HTM allows for the efficient implementation of parallel algorithms [27]. It is commonly used to elide expensive software synchronization mechanisms [16, 63]. Informally, for a CPU thread executing a hardware transaction, all other threads appear to be halted; whereas, from the outside, a transaction appears as an atomic operation. A transaction fails if the CPU cannot provide this atomicity due to resource limitations or conflicting concurrent memory accesses. In this case, all transactional changes need to be rolled back. To be able to detect conflicts and revert transactions, the CPU needs to keep track of transactional memory accesses. Therefore, transactional memory is typically divided into a *read set* and a *write set*. A transaction's read set contains all read memory locations. Concurrent read accesses by other threads to the read set are generally allowed; however, concurrent writes are problematic and—depending on the actual HTM implementation and circumstances—likely lead to transactional aborts. Further, any concurrent accesses to the write set necessarily lead to a transactional abort. Figure 1 visualizes this exemplarily for a simple transaction with one conflicting concurrent thread.

Commercial Implementations. Implementations of HTM can be found in different commercial CPUs, among others, in many recent professional and consumer Intel CPUs. Nakaike et al. [48] investigated four commercial HTM implementations from Intel and other vendors. They found that all processors provide comparable functionality to begin, end, and abort transactions and that all implement HTM within the existing CPU cache hierarchy. The reason for this is that only caches can be held in a consistent state by the CPU itself. If data is

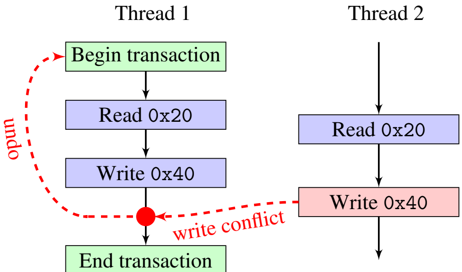

Figure 1: HTM ensures that no concurrent modifications influence the transaction, either by preserving the old value or by aborting and reverting the transaction.

evicted to DRAM, transactions necessarily abort in these implementations. Nakaike et al. [48] found that all four implementations detected access conflicts at cache-line granularity and that failed transactions were reverted by invalidating the cache lines of the corresponding write sets. Depending on the implementation, read and write set can have different sizes, and set sizes range from multiple KB to multiple MB of HTM space.

Due to HTM usually being implemented within the CPU cache hierarchy, HTM has been proposed as a means for optimizing cache maintenance and for performing security-critical on-chip computations: Zacharopoulos [64] uses HTM combined with prefetching to reduce the system energy consumption. Guan et al. [25] designed a system that uses HTM to keep RSA private keys encrypted in memory and only decrypt them temporarily inside transactions. Jang et al. [36] used hardware transaction aborts upon page faults to defeat kernel address-space layout randomization.

3 Attacker Model

We consider multi-tenant environments where tenants do not trust each other, including local and cloud environments, where malicious tenants can use shared resources to extract information about other tenants. For example, they can influence and measure the state of caches via the attacks described in Section 2.2. In particular, an attacker can obtain a high-resolution trace of its own memory access timings, which are influenced by operations of the victim process. More abstractly, the attacker can obtain a trace where at each time frame the attacker learns whether the victim has accessed a particular memory location. We consider the above attacker in three realistic environments which give her different capabilities:

Cloud We assume that the processor, the OS and the hypervisor are trusted in this scenario while other cloud tenants are not. This enables the attacker to launch cross-VM Prime+Probe attacks.

Local This scenario is similar to the Cloud scenario, but we assume the machine is not hosted in a cloud environment. Therefore, the tenants share the machine in a traditional time-sharing fashion and the OS is trusted to provide isolation between tenants. Furthermore, we assume that there are shared libraries between the victim and the attacker, since this is a common optimization performed by OSs. This enables the attacker to launch Flush+Reload attacks, in addition to Prime+Probe attacks.

SGX In this scenario, the processor is trusted but the adversary has full control over the OS, the hypervisor, and all other code running on the system, except the victim's code. This scenario models an SGX-enabled environment, where the victim's code runs inside an enclave. While the attacker has more control over the software running on the machine, the SGX protections prevent sharing of memory pages between the enclave and untrusted processes, which renders Flush+Reload attacks ineffective in this setting.

All other side-channels, including power analysis, and channels based on shared microarchitectural elements other than caches are outside our scope.

4 Hardware Transactional Memory as a Side-Channel Countermeasure

The foundation of all cache side-channel attacks are the timing differences between cache hits and misses, which an attacker tries to measure. The central idea behind Cloak is to instrument HTM to prevent any cache misses on the victim's sensitive code and data. In Cloak, all sensitive computation is performed in HTM. Crucially, in Cloak, all security-critical code and data is deterministically *preloaded* into the caches at the beginning of a transaction. This way, security-critical memory locations become part of the read or write set and all subsequent, possibly secret-dependent, accesses are guaranteed to be served from the CPU caches. Otherwise, in case any preloaded code or data is evicted from the cache, the transaction necessarily aborts and is reverted. (See Listing 1 for an example that uses the TSX instructions `xbegin` and `xend` to start and end a transaction.)

Given an *ideal* HTM implementation, Cloak thus prevents that an attacker can obtain a trace that shows whether the victim has accessed a particular memory location. More precisely, in the sense of Cloak, ideal HTM has the following properties:

R1 Both data and code can be added to a transaction as transactional memory and thus are included in the HTM atomicity guarantees.

Listing 1: A vulnerable crypto operation protected by Cloak instantiated with Intel TSX; the `AES_encrypt` function makes accesses into `lookup_tables` that depend on `key`. Preloading the tables and running the encryption code within a HTM transaction ensures that eviction of table entries from LLC will terminate the code before it may cause a cache miss.

```
if ((status = _xbegin()) == _XBEGIN_STARTED) {
  for (auto p : lookup_tables)
    *(volatile size_t*)p;
  AES_encrypt(plaintext, ciphertext, &key);
  _xend();
}
```

R2 A transaction aborts immediately when any part of transactional memory leaves the cache hierarchy.

R3 All pending transactional memory accesses are purged during a transactional abort.

R4 Prefetching decisions outside of transactions are not influenced by transactional memory accesses.

R1 ensures that all sensitive code and data can be added to the transactional memory in a deterministic and leakage-free manner. **R2** ensures that any cache line evictions are detected implicitly by the HTM and the transaction aborts before any non-cached access is performed. **R3** and **R4** ensure that there is no leakage after a transaction has succeeded or aborted.

Unfortunately, commercially available HTM implementations and specifically Intel TSX do not precisely provide **R1–R4**. In the following Section 5 we discuss how Cloak can be instantiated on commercially available (and not ideal) HTM, what leakage remains in practice, and how this can be minimized.

5 Cloak based on Intel TSX

Cloak can be built using an HTM that satisfies **R1–R4** established in the previous section. We propose Intel TSX as an instantiation of HTM for Cloak to mitigate the cache side channel. In this section, we evaluate how far Intel TSX meets **R1–R4** and devise strategies to address those cases where it falls short. All experiments we report on in this section were executed on Intel Core i7 CPUs of the Skylake generation (i7-6600U, i7-6700, i7-6700K) with 4MB or 8MB of LLC. The source code of these experiments will be made available at http://aka.ms/msr-cloak.

5.1 Meeting Requirements with Intel TSX

We summarize our findings and then describe the methodology.

R1 and **R2** hold for data. It supports read-only data that does not exceed the size of the LLC (several MB) and write data that does not exceed the size of the L1 cache (several KB);

R1 and **R2** hold for code that does not exceed the size of the LLC;

R3 and **R4** hold in the *cloud* and *SGX* attacker scenarios from Section 3, but not in general for *local* attacker scenarios.

5.1.1 Requirements 1&2 for Data

Our experiments and previous work [19] find the read set size to be ultimately constrained by the size of the LLC: Figure 2 shows the failure rate of a simple TSX transaction depending on the size of the read set. The abort rate reaches 100% as the read set size approaches the limits of the LLC (4MB in this case). In a similar experiment, we observed 100% aborts when the size of data written in a transaction exceeded the capacity of the L1 data cache (32 KB per core). This result is also confirmed in Intel's *Optimization Reference Manual* [30] and in previous work [19, 44, 64].

Conflicts and Aborts. We always observed aborts when read or write set cache lines were actively evicted from the caches by concurrent threads. That is, evictions of write set cache lines from the L1 cache and read set cache lines from the LLC are sufficient to cause aborts. We also confirmed that transactions abort shortly after cache line evictions: using concurrent `clflush` instructions on the read set, we measured abort latencies in the order of a few hundred cycles (typically with an upper bound of around 500 cycles). In case varying abort times should prove to be an issue, the attacker's ability to measure them, e.g., via Prime+Probe on the abort handler, could be thwarted by *randomly* choosing one out of many possible abort handlers and rewriting the `xbegin` instruction accordingly,[1] before starting a transaction.

Tracking of the Read Set. We note that the data structure that is used to track the read set in the LLC is unknown. The Intel manual states that "an implementation-specific second level structure" may be available, which probabilistically keeps track of the addresses of read-set

[1]The 16-bit relative offset to a transaction's abort handler is part of the `xbegin` instruction. Hence, for each xbegin instruction, there is a region of 1 024 cache lines that can contain the abort handler code.

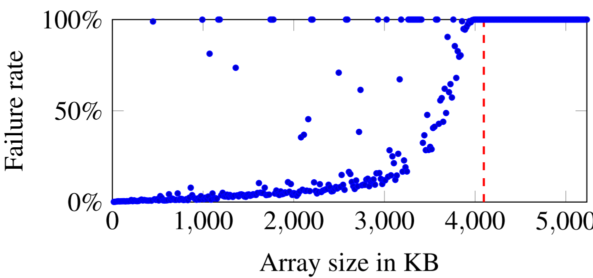

Figure 2: A TSX transaction over a loop reading an array of increasing size. The failure rate reveals how much data can be read in a transaction. Measured on an i7-6600U with 4 MB LLC.

cache lines that were evicted from the L1 cache. This structure is possibly an on-chip bloom filter, which tracks the read-set membership of cache lines in a probabilistic manner that may give false positives but no false negatives.[2] There may exist so far unknown leaks through this data structure. If this is a concern, all sensitive data (including read-only data) can be kept in the write set in L1. However, this limits the working set to the L1 and also requires all data to be stored in writable memory.

L1 Cache vs. LLC. By adding all data to the write set, we can make **R1** and **R2** hold for data with respect to the L1 cache. This is important in cases where victim and attacker potentially share the L1 cache through hyper-threading.[3] Shared L1 caches are not a concern in the *cloud* setting, where it is usually ensured by the hypervisor that corresponding hyper-threads are not scheduled across different tenants. The same can be ensured by the OS in the *local* setting. However, in the *SGX* setting a malicious OS may misuse hyper-threading for an L1-based attack. To be not constrained to the small L1 in SGX nonetheless, we propose solutions to detect and prevent such attacks later on in Section 7.2.

We conclude that Intel TSX sufficiently fulfills **R1** and **R2** for data if the read and write sets are used appropriately.

5.1.2 Requirements 1&2 for Code

We observed that the amount of code that can be executed in a transaction seems not to be constrained by the sizes of the caches. Within a transaction with strictly no reads and writes we were reliably able to execute more

[2]In Intel's *Software Development Emulator* [29] the read set is tracked probabilistically using bloom filters.

[3]Context switches may also allow the attacker to examine the victim's L1 cache state "postmortem". While such attacks may be possible, they are outside our scope. TSX transactions abort on context switches.

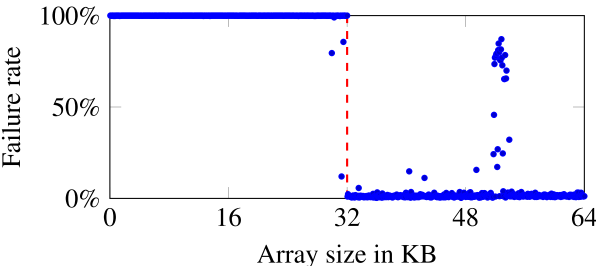

Figure 3: A TSX transaction over a nop-sled with increasing length. A second thread waits and then flushes the first cache line once before the transaction ends. The failure rate starts at 100% for small transaction sizes. If the transaction self-evicts the L1 instruction cache line, e.g., when executing more than 32 KB of instructions, the transaction succeeds despite of the flush. Measured on an i7-6600U with 32 KB L1 cache.

than 20 MB of nop instructions or more than 13 MB of arithmetic instructions (average success rate ˜10%) on a CPU with 8 MB LLC. This result strongly suggests that executed code does not become part of the read set and is in general not explicitly tracked by the CPU.

To still achieve **R1** and **R2** for code, we attempted to make code part of the read or write set by accessing it through load/store operations. This led to mixed results: even with considerable effort, it does not seem possible to reliably execute cache lines in the write set without aborting the transaction.[4] In contrast, it is generally possible to make code part of the read set through explicit loads. This gives the same benefits and limitations as using the read set for data.

Code in the L1 Cache. Still, as discussed in the previous Section 5.1.1, it can be desirable to achieve **R1** and **R2** for the L1 cache depending on the attack scenario. Fortunately, we discovered undocumented microarchitectural effects that reliably cause transactional aborts in case a recently executed cache line is evicted from the cache hierarchy. Figure 3 shows how the transactional abort rate relates to the amount of code that is executed inside a transaction. This experiment suggests that a concurrent (hyper-) thread can cause a transactional abort by evicting a transactional code cache line currently in the L1 instruction cache. We verified that this effect exists for direct evictions through the `clflush` instruction as well as indirect evictions through cache set conflicts. However, self-evictions of L1 code cache lines (that is, when a transactional code cache line is replaced by another one) do not cause transactional aborts. Hence, forms of **R1** and **R2** can also be ensured for code in the L1 instruction cache without it being part of the write set.

In summary, we can fulfill requirements **R1** and **R2** by moving code into the read set or, using undocumented microarchitectural effects, by limiting the amount of code to the L1 instruction cache and preloading it via execution.

5.1.3 Requirements 3&4

As modern processors are highly parallelized, it is difficult to guarantee that memory fetches outside a transaction are not influenced by memory fetches inside a transaction. For precisely timed evictions, the CPU may still enqueue a fetch in the memory controller, *i.e.*, a race condition. Furthermore, the hardware prefetcher is triggered if multiple cache misses occur on the same physical page within a relatively short time. This is known to introduce noise in cache attacks [24,62], but also to introduce side-channel leakage [6].

In an experiment with shared memory and a cycle-accurate alignment between attacker and victim, we investigated the potential leakage of Cloak instantiated with Intel TSX. To make the observable leakage as strong as possible, we opted to use Flush+Reload for the attack primitive. We investigated how a delay between the transaction start and the flush operation and a delay between the flush and the reload operations influence the probability that an attacker can observe a cache hit against code or data placed into transactional memory. The victim in this experiment starts the transaction, by placing data and code into transactional memory in a uniform manner (using either reads, writes or execution). The victim then simulates meaningful program flow, followed by an access to one of the sensitive cache lines and terminating the transaction. The attacker "guesses" which cache line the victim accessed and probes it. Ideally, the attacker should not be able to distinguish between correct and wrong guesses.

Figure 4 shows two regions where an attacker could observe cache hits on a correct guess. The left region corresponds to the preloading of sensitive code/data at the beginning of the transaction. As expected, cache hits in this region were observed to be identical to runs where the attacker had the wrong guess. On the other hand, the right region is unique to instances where the attacker made a correct guess. This region thus corresponds to a window of around 250 cycles, where an attacker could potentially obtain side-channel information. We explain the existence of this window by the fact that Intel did not design TSX to be a side-channel free primitive, thus **R3** and **R4** are not guaranteed to hold and a limited amount of leakage remains. We observed identical high-level re-

[4] In line with our observation, Intel's documentation [31] states that "executing self-modifying code transactionally may also cause transactional aborts".

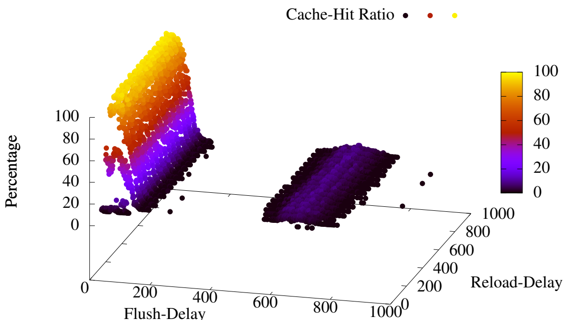

Figure 4: Cache hits observed by a Flush+Reload attacker with the ability to overlap the attack with different segments of the victim's transaction. Cache hits can be observed both in the region where the victim tries to prepare its transactional memory, as well as in a small window around a secret access. The Z axis represents the success rate of the attacker observing a cache hit.

sults for all forms of preloading (reading, writing, executing) and all forms of secret accesses (reading, writing, executing).

To exploit the leakage we found, the attacker has to be able to determine whether the CPU reloaded a secret-dependent memory location. This is only possible if the attacker shares the memory location with the victim, *i.e.*, only in *local* attacks but not in other scenarios. Furthermore, it is necessary to align execution between attacker and victim to trigger the eviction in exactly the right cycle range in the transaction. While these properties might be met in a Flush+Reload attack with fast eviction using `clflush` and shared memory, it is rather unlikely that an attack is possible using Prime+Probe, due to the low frequency of the attack [22] and the cache replacement policy. Thus, we conclude that requirements **R3** and **R4** are likely fulfilled in all scenarios where the attacker can only perform Prime+Probe, but not Flush+Reload, *i.e.*, cloud and SGX scenarios. Furthermore, requirements **R3** and **R4** are likely to be fulfilled in scenarios where an attacker can perform Flush+Reload, but not align with a victim on a cycle base nor measure the exact execution time of a TSX transaction, *i.e.*, the local scenario.

5.2 Memory Preloading

Using right the memory preloading strategy is crucial for the effectiveness of Cloak when instantiated on top of TSX. In the following, we describe preloading techniques for various scenarios. The different behavior for read-only data, writable data, and code, makes it necessary to preload these memory types differently.

5.2.1 Data Preloading

As discussed, exclusively using the write set for preloading has the benefit that sensitive data is guaranteed to stay within the small L1 cache, which is the most secure option. To extend the working set beyond L1, sensitive read-only data can also be kept in the LLC as described in Section 5.1.1. However, when doing so, special care has to be taken. For example, naïvely preloading a large (> 32 KB) sequential read set after the write set leads to assured abortion during preloading, as some write set cache-lines are inevitably evicted from L1. Reversing the preloading order, *i.e.*, read set before write set, partly alleviates this problem, but, depending on the concrete read set access patterns, one is still likely to suffer from aborts during execution caused by read/write set conflicts in the L1 cache. In the worst case, such self-eviction aborts may leak information.

To prevent such conflicts, in Cloak, we reserve certain cache sets in L1 entirely for the write set. This is possible as the L1 cache-set index only depends on the virtual address, which is known at runtime. For example, reserving the L1 cache sets with indexes 0 and 1 gives a conflict-free write set of size $2 \cdot 8 \cdot 64B = 1KB$. For this allocation, it needs to be ensured that the same 64 B cache lines of *any* 4 KB page are not part of the read set (see Figure 5 for an illustration). Conversely, the write set is placed in the same 64 B cache lines in up to eight different 4 KB pages. (Recall that an L1 cache set comprises eight ways.) Each reserved L1 cache set thus blocks $1/64^{th}$ of the entire virtual memory from being used in the read set.

While this allocation strategy plays out nicely in theory, we observed that apparently the CPU's data prefetcher [30] often optimistically pulled-in unwanted cache lines that were conflicting with our write set. This can be mitigated by ensuring that sequentially accessed read cache lines are separated by a page boundary from write cache lines and by adding "safety margins" between read and write cache lines on the same page.

In general, we observed benefits from performing preloading similar to recent Prime+Probe attacks [22, 45], where a target address is accessed multiple times and interleaved with accesses to other addresses. Further, we observed that periodic "refreshing" of the write set, e.g., using the `prefetchw` instruction, reduced the chances of write set evictions in longer transactions.

5.2.2 Code Preloading

As described in Section 5.1.2, we preload code into the read set and optionally into the L1 instruction cache. To preload it into the read set, we use the same approach as for data. However, to preload the code into the L1 instruction cache we cannot simply execute the function,

Figure 6: Cache lines are augmented with a multi-byte `nop` instruction. The `nop` contains a byte `c3` which is the opcode of `retq`. By jumping directly to the `retq` byte, we preload each cache line into the L1 instruction cache.

as this would have unwanted side effects. Instead, we insert a multi-byte `nop` instruction into every cache line, as shown in Figure 6. This `nop` instruction does not change the behavior of the code during actual function execution and only has a negligible effect on execution time. However, the multi-byte `nop` instruction allows us to incorporate a byte `c3` which is the opcode of `retq`. Cloak jumps to this return instruction, loading the cache line into the instruction L1 cache but not executing the actual function. In the preloading phase, we perform a call to each such `retq` instruction in order to load the corresponding cache lines into the L1 instruction cache. The `retq` instruction immediately returns to the preloading function. Instead of `retq` instructions, equivalent `jmp reg` instructions can be inserted to avoid touching the stack.

5.2.3 Splitting Transactions

In case a sensitive function has greater capacity requirements than those provided by TSX, the function needs to be split into a series of smaller transactional units. To prevent leakage, the control flow between these units and their respective working sets needs to be input-independent. For example, consider a function `f()` that iterates over a fixed-size array, e.g., in order to update certain elements. By reducing the number of loop iterations in `f()` and invoking it separately on fixed parts of the target array, the working set for each individual transaction is reduced and chances for transactional aborts decrease. Ideally, the splitting would be done in an automated manner by a compiler. In a context similar to ours though not directly applicable to Cloak, Shih et al. [59] report on an extension of the Clang compiler that automatically splits transactions into smaller units with TSX-compatible working sets. Their approach is discussed in more detail in Section 9.

5.3 Toolset

We implemented the read-set preloading strategy from Section 5.2.1 in a small C++ container template library. The library provides generic read-only and writable arrays, which are allocated in "read" or "write" cache lines respectively. The programmer is responsible for arranging data in the specialized containers before invoking a Cloak-protected function. Further, the programmer decides which containers to preload. Most local variables and input and output data should reside in the containers. Further, all sub-function calls should be inlined, because each `call` instruction performs an implicit write of a return address. Avoiding this is important for large read sets, as even a single unexpected cache line in the write set can greatly increase the chances for aborts.

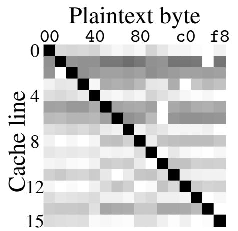
We also extended the Microsoft C++ compiler version 19.00. For programmer-annotated functions on Windows, the compiler adds code for starting and ending transactions, ensures that all code cache lines are preloaded (via read or execution according to Section 5.2.2) and, to not pollute the write set, refrains from unnecessarily spilling registers onto the stack after preloading. Both library and compiler are used in the SGX experiments in Section 7.1.

6 Retrofitting Leaky Algorithms

To evaluate Cloak, we apply it to existing weak implementations of different algorithms. We demonstrate that in all cases, in the *local* setting (Flush+Reload) as well as the *cloud* setting (Prime+Probe), Cloak is a practical countermeasure to prevent state-of-the-art attacks. All experiments in this section were performed on a mostly idle system equipped with a Intel i7-6700K CPU with 16 GB DDR4 RAM, running a default-configured Ubuntu Linux 16.10. The applications were run as regular user programs, not pinned to CPU cores, but sharing CPU cores with other threads in the system.

6.1 OpenSSL AES T-Tables

As a first application of Cloak, we use the AES T-table implementation of OpenSSL which is known to be sus-



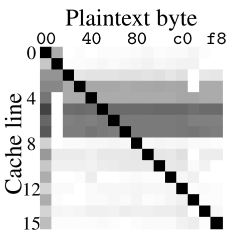


Figure 7: Color matrix showing cache hits on an AES T-table. Darker means more cache hits. Measurement performed over roughly 2 billion encryptions. Prime+Probe depicted on the left, Flush+Reload on the right.

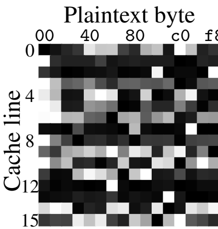

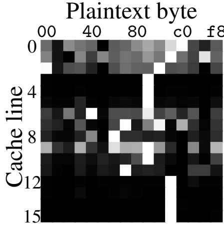

Figure 8: Color matrix showing cache hits on an AES T-table. The implementation is protected by Cloak. Darker means more cache hits. Measurement performed over roughly 3 billion transactions (500 million encryptions) for Prime+Probe (left) and 4.9 billion transactions (1.5 million encryptions) for Flush+Reload (right). The side-channel leakage is not visible in both cases.

ceptible to cache attacks [4, 24, 26, 33, 35, 51]. In this implementation, AES performs 16 lookups to 4 different T-tables for each of the 10 rounds and combines the values using `xor`. The table lookups in the first round of AES are $T_j[x_i = p_i \oplus k_i]$ where p_i is a plaintext byte, k_i a key byte, and $i \equiv j \mod 4$. A typical attack scenario is a known-plaintext attack. By learning the cache line of the lookup index x_i an attacker learns the upper 4 bits of the secret key byte $x_i \oplus p_i = k_i$. We wrap the entire AES computation together with the preloading step into a single TSX transaction. The preloading step fetches the 4 T-Tables, *i.e.*, it adds 4 KB of data to the read set.

We performed roughly 2 billion encryptions in an asynchronous attack and measured the cache hits on the T-table cache lines using Prime+Probe and Flush+Reload. Figure 7 is a color matrix showing the number of cache hits per cache line and plaintext-byte value. When protecting the T-tables with Cloak (cf. Figure 8), the leakage from Figure 7 is not present anymore.

We fixed the time for which the fully-asynchronous known-plaintext attack is run. The amount of time corresponds to roughly 2 billion encryptions in the baseline implementation. For the AES T-Table implementation protected with Cloak we observed a significant performance difference based on whether or not an attack is running simultaneously. This is due to the TSX transaction failing more often if under attack.

While not under attack the implementation protected with Cloak started 0.8% more encryptions than the baseline implementation (*i.e.*, with preloading) and less than 0.1% of the transactions failed. This is not surprising, as the execution time of the protected algorithm is typically below 500 cycles. Hence, preemption or interruption of the transaction is very unlikely. Furthermore, cache evictions are unlikely because of the small read set size and optimized preloading (cf. Section 5.2.1). Taking the execution time into account, the implementation protected with Cloak was 0.8% faster than the baseline implementation. This is not unexpected, as Zacharopoulos [64] already found that TSX can improve performance.

Next, we measured the number of transactions failing under Prime+Probe and Flush+Reload. We observed 82.7% and 99.97% of the transactions failing for each attack, respectively. Failing transactions do not consume the full amount of time that one encryption would take as they abort earlier in the function execution. Thus, the protected implementation started over 37% more encryptions as compared to the baseline implementation when under attack using Prime+Probe and 2.53 times the encryptions when under attack using Flush+Reload. However, out of these almost 3 billion transactions only 500 million transactions succeeded in the case of Prime+Probe. In the case of Flush+Reload only 1.4 million out of 4.9 billion transactions succeeded. Thus, in total the performance of our protected implementation under a Prime+Probe attack is only 23.7% of the performance of the baseline implementation and only 0.06% in the case of a Flush+Reload attack.

The slight performance gain of Cloak while not being actively attacked shows that deploying our countermeasure for this use case does not only eliminate cache side-channel leakage but it can also be beneficial. The lower performance while being attacked is still sufficient given that leakage is eliminated, especially as the attacker has to keep one whole CPU core busy to perform the attack and this uses up a significant amount of hardware resources whether or not Cloak is deployed.

6.2 Secret-dependent execution paths

Powerful attacks allow to recover cryptographic keys [62] and generated random numbers by monitoring execution paths in libraries [67]. In this example, we model such a scenario by executing one of 16 functions based on a secret value that the attacker tries to learn—adapted from the AES example. Like in previous Flush+Reload attacks [62, 67], the attacker

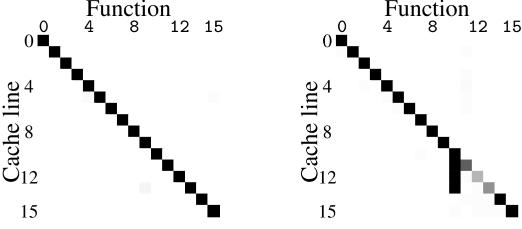

Figure 9: Color matrix showing cache hits on function code. Darker means more cache hits. Measurement performed over roughly 100 million function executions for Prime+Probe (left) and 10 million function executions for Flush+Reload (right).

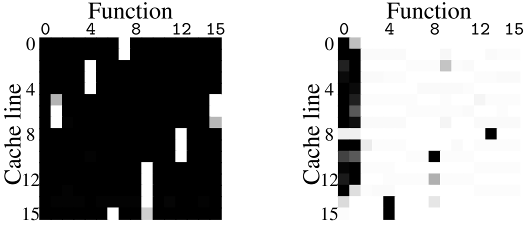

Figure 10: Color matrix showing cache hits on function code protected using Cloak. Darker means more cache hits. Measurement performed over roughly 1.5 billion transactions (77 314 function executions) for Prime+Probe (left) and 2 billion transactions (135 211 function executions) for Flush+Reload (right). Side-channel leakage is not visible in both cases.

monitors the function addresses for cache hits and thus derives which function has been called. Each of the 16 functions runs only a small code snippet consisting of a loop counting from 0 to 10 000. We wrap the entire switch-case together with the preloading step into a single TSX transaction. The preloading step fetches the 16 functions, each spanning two cache lines, *i.e.*, 2 KB of code are added to the read set.

As in the previous example, Cloak eliminates all leakage (cf. Figure 10). While not under attack the victim program protected with Cloak started 0.7% more function executions than the baseline implementation. Less than 0.1% of the transactions failed, leading to an overall performance penalty of 1.2%. When under attack using Prime+Probe, 11.8 times as many function executions were started and with Flush+Reload, 19 times as many. However, only 0.005% of the transactions succeeded in the case of Prime+Probe and only 0.0006% in the case of Flush+Reload. Thus, overall the performance is reduced to 0.03% of the baseline performance when under a Prime+Probe attack and 0.14% when under a Flush+Reload attack. The functions are 20 times slower than

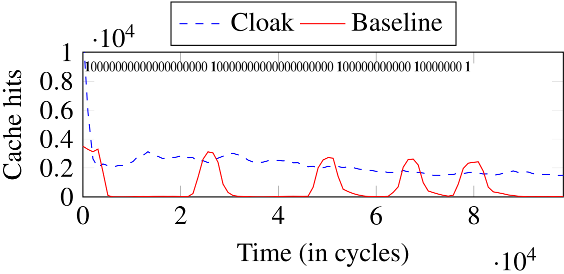

Figure 11: Cache traces for the multiply routine (as used in RSA) over 10 000 exponentiations. The secret exponent is depicted as a bit sequence. Measurement performed over 10 000 exponentiations. The variant protected with Cloak does not have visual patterns that correspond to the secret exponent.

the AES encryptions from the previous example. Thus, the high failure rate is not unexpected, as there is more time for cache evictions caused by other processes.

It is important to note that the performance under attack is not essential as the attacker simultaneously keeps one or more CPU cores on full load, accounting for a significant performance loss with and without Cloak.

6.3 RSA Square-and-Multiply example

We now demonstrate an attack against a square-and-multiply exponentiation and how Cloak allows to protect it against cache side-channel attacks. Square-and-multiply is commonly used in cryptographic implementations of algorithms such as RSA and is known to be vulnerable to side-channel attacks [54, 62]. Though cryptographic libraries move to constant-time exponentiations that are intended to not leak any information through the cache, we demonstrate our attack and protection on a very vulnerable schoolbook implementation. A square-and-multiply algorithm takes 100 000 cycles to complete. Thus, wrapping the whole algorithm in one TSX transaction has only a very low chance of success by itself. Instead we split the loop of the square-and-multiply algorithm into one small TSX transaction per exponent bit, *i.e.*, adding the `xbegin` and `xend` instructions and the preloading step to the loop. This way, we increase the success rate of the TSX transactions significantly, while still leaking no information on the secret exponent bits. The preloading step fetches 1 cache line per function, *i.e.*, 128 B of code are added to the read set.

Figure 11 shows a Flush+Reload cache trace for the multiply routine as used in RSA. The plot is generated over 10 000 exponentiation traces. Each trace is aligned by the first cache hit on the multiply routine that was measured per trace. The traces are then summed to produce the functions that are plotted. The baseline imple-

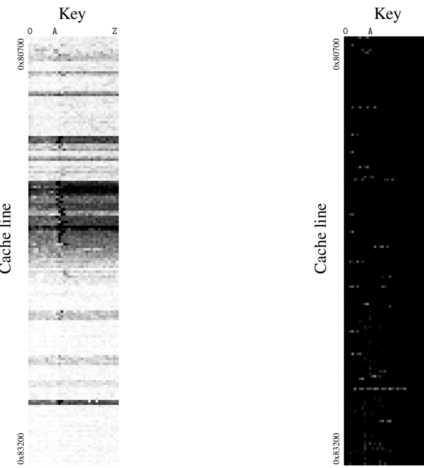

Figure 12: Cache template matrix showing cache hits on the binary search in _gdk_keyval_from_name without protection (left) and with Cloak (right). Darker means more cache hits. All measurements were performed with Flush+Reload. The pattern of the binary search is clearly visible for the unprotected implementation and not visible anymore when protected with Cloak.

mentation has a clear peak for each 1 bit in the secret exponent. The same implementation protected with Cloak shows no significant changes in the cache hits over the full execution time.

While not under attack, the performance of the implementation protected with Cloak is only slightly lower than the performance of the unprotected baseline implementation. To evaluate the performance in this case we performed 1 million exponentiations. During these 1 million exponentiations, only 0.5% of the transactions failed. The total runtime overhead we observed while not under attack was 1.1%. Unsurprisingly, while under attack we observed a significantly higher overhead of factor 982. This is because 99.95% of the transactions failed, *i.e.*, the transactions for almost every single bit failed and had to be repeated.

6.4 GTK keystroke example

We investigated leakage in the GTK framework, which performs a binary search to translate raw keyboard inputs to platform-independent key names and key values. Gruss et al. [24] demonstrated that this leaks significant information on single keys typed by a user, in an automated cache template attack. Their attack on GDK library version 3.10.8 has partially been resolved on current Linux systems with GDK library version 3.18.9. Instead of multiple binary searches that leak information we only identified one binary search that is still performed upon every keystroke.

In order to demonstrate the general applicability of Cloak, we reproduced the attack by Gruss et al. [24] on a recent version of the GDK library (3.18.9) which comes with Ubuntu 16.10. We attack the binary search in _gdk_keyval_from_name which is executed upon every keystroke in a GTK window. As shown in Figure 12, the cache template matrix of the unprotected binary search reveals the search pattern, narrowing down on the darker area where the letter keys are and thus the search ends. In case of the implementation protected by Cloak, the search pattern is disguised. With the keystroke information protected by Cloak, we could neither measure a difference in the perceived latency when typing through a keyboard, nor measure and overall increase of the system load or execution time of processes. The reason for this is that keystroke processing involves hundreds of thousands of CPU cycles spent in drivers and other functions. Furthermore, keystrokes are rate-limited by the OS and constrained by the speed of the user typing. Thus, the overhead we introduce is negligible for the overall latency and performance.

We conclude that Cloak can be used as a practical countermeasure to prevent cache template attacks on fine-grained information such as keystrokes.

7 Side-Channel Protection for SGX

Intel SGX provides an isolated execution environment called *enclave*. All code and data inside an enclave is shielded from the rest of the system and is even protected against hardware attacks by means of strong memory encryption. However, SGX enclaves use the regular cache hierarchy and are thus vulnerable to cache side-channel attacks. Further, as enclaves are meant to be run on untrusted hosts, they are also susceptible to a range of other side-channel attacks such as OS-induced page faults [61] and hardware attacks on the memory bus. In this section, we first retrofit a common machine learning algorithm with Cloak and evaluate its performance in SGX. Afterwards, we explore the special challenges that enclave code faces with regard to side channels and design extended countermeasures on top of Cloak. Specifically, we augment sensitive enclave code with Cloak and require that the potentially malicious OS honors a special *service contract* while this code is running.

7.1 Secure Decision Tree Classification

To demonstrate Cloak's applicability to the SGX environment and its capability to support larger working sets, we adapted an existing C++ implementation of a *decision tree classification* algorithm [49] using the toolset described in Section 5.3. The algorithm traverses a decision tree for an input record. Each node of the tree

contains a predicate which is evaluated on features of the input record. As a result, observations of unprotected tree traversal can leak information about the tree and the input record. In this particular case, several trees in a so-called *decision forest* are traversed for each input record.

Our Cloak-enhanced implementation of the algorithm contains three programmer-annotated functions, which translates into three independent transactions. The most complex of these traverses a preloaded tree for a batch of preloaded input records. The batching of input records is crucial here for performance, as it amortizes the cost of preloading a tree. We give a detailed explanation and a code sample of tree traversal with Cloak in Appendix A.

Evaluation. We compiled our implementation for SGX enclaves using the extended compiler and a custom SGX software stack. We used a pre-trained decision forest for the *Covertype* data set from the *UCI Machine Learning Repository*[5]. Each tree in the forest consists of 30 497—32 663 nodes and has a size of 426 KB–457 KB. Each input record is a vector of 54 floating point values. We chose the *Covertype* data set because it produces large trees and was also used in previous work by Ohrimenko et al. [49], which also mitigates side channel leakage for enclave code.

We report on experiments executed on a mostly idle system equipped with a TSX and SGX-enabled Intel Core i7-6700 CPU and 16 GB DDR4 RAM running Windows Server 2016 Datacenter. In our container library, we reserved eight L1 cache sets for writable arrays, resulting in an overall write set size of 4 KB. Figure 13 shows the cycles spent inside the enclave (including entering and leaving the enclave) per input record averaged over ten runs for differently sized input batches. These batches were randomly drawn from the data set. The sizes of the batches ranged from 5 to 260. For batches larger than 260, we observed capacity aborts with high probability. Nonetheless, seemingly random capacity aborts could also be observed frequently even for small batch sizes. The number of aborts also increased with higher system load. The cost for restarting transactions on aborts is included in Figure 13.

As baseline, we ran inside SGX the same algorithm without special containers and preloading and without transactions. The baseline was compiled with the unmodified version of the Microsoft C++ compiler at the highest optimization level. As can be seen, the number of cycles per query greatly decreases with the batch size. Batching is particularly important for Cloak, because it enables the amortization of cache preloading costs. Overall, the overhead ranges between +79% (batch size 5) and +248% (batch size 260). The overhead increases

[5]https://archive.ics.uci.edu/ml

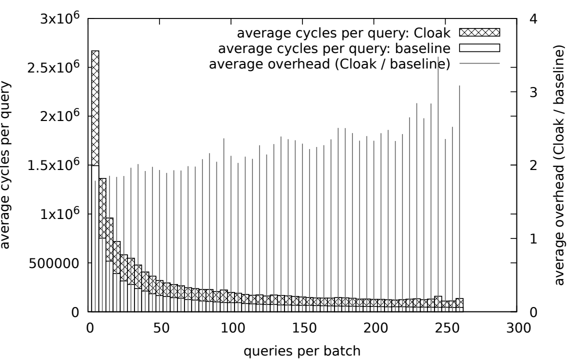

Figure 13: Average number of cycles per query for decision forest batch runs of different sizes.

with the batch size, because the baseline also profits from batching (*i.e.*, "cache warming" effects and amortization of costs for entering/leaving the enclave), while the protected version experiences more transactional aborts for larger batches. We also ran a similar micro-benchmark outside SGX with more precise timings. Here, the effect of batching was even clearer: for a batch size of 5, we observed a very high overhead of +3 078%, which gradually decreased to +216% for a batch size of 260.

Even though the experimental setting in Ohrimenko et al. [49] is not the same as ours (for instance they used the official Intel SGX SDK, an older version of the compiler, and their input data was encrypted) and they provide different guarantees, we believe that their reported overhead of circa +6 200% for a single query to SGX highlights the potential efficiency of Cloak.

7.2 Service Contracts with the OS

Applying the basic Cloak techniques to sensitive enclave code reduces the risk of side-channel attacks. However, enclave code is especially vulnerable as the corresponding attacker model (see Section 3) includes malicious system software and hardware attacks. In particular, malicious system software, *i.e.*, the OS, can amplify side-channel attacks by concurrently (**A1**) interrupting and resuming enclave threads [40], (**A2**) unmapping enclave pages [61], (**A3**) taking control of an enclave thread's sibling hyper-thread (HT) [11], or (**A4**) repeatedly resetting an enclave. **A3** is of particular concern in Cloak as TSX provides requirement **R2** (see Section 4) only for the LLC. Hence, code and data in the read set are not protected against a malicious HT which can perform attacks over the L1 and L2 caches from outside the enclave. In the following, we describe how Cloak-protected enclave code can ensure that the OS is honest and does not mount attacks **A1**–**A4**.

7.2.1 Checking the Honesty of the OS

While SGX does not provide functionality to directly check for **A1** and **A2** or to prevent them, it is simple with Cloak: our experiments showed in line with Intel's documentation [31] that transactions abort with code OTHER (no bits set in the abort code) in case of interrupts or exceptions. In case unexpected aborts of this type occur, the enclave may terminate itself as a countermeasure.

Preventing **A3** is more involved and requires several steps: before executing a transaction, we demand that (i) both HTs of a CPU core enter the enclave and (ii) remain there. To enforce (ii), the two threads write a unique marker to each thread's *State Save Area* (SSA) [32] inside the enclave. Whenever a thread leaves an enclave asynchronously (e.g., because of an interrupt), its registers are saved in its SSA [32]. Hence, every unexpected exception or interrupt necessarily overwrites our markers in the SSAs. By inspecting the markers, we can thus ensure that neither of the threads was interrupted (and potentially maliciously migrated to a different core by the OS). One thread now enters a Cloak transaction and verifies the two markers, making them part of its read set. Thus, as we confirmed experimentally, any interruption of the threads would overwrite an SSA marker in the read set and cause an immediate transactional abort with code CONFLICT (bit three set in the abort code).

Unfortunately, for (i), there is no direct way for enclave code to tell if two threads are indeed two corresponding HTs. However, after writing the SSA markers, before starting the SSA transaction, the enclave code can initially conduct a series of experiments to check that, with a certain confidence, the two threads indeed share an L1 cache. One way of doing so is to transmit a secret (derived using the `rdrand` instruction inside the enclave) over a timing-less L1-based TSX *covert channel*: for each bit in the secret, the receiver starts a transaction and fills a certain L1 cache set with write-set cache lines and busy-waits within the transaction for a certain time; if the current bit is 1, the sender aborts the receiver's transaction by touching conflicting cache lines of the same cache set. Otherwise, it touches non-conflicting cache lines. After the transmission, both threads compare their versions of the secret. In case bit-errors are below a certain threshold, the two threads are assumed to be corresponding HTs. In our experiments, the covert channel achieved a raw capacity of 1 MB/s at an error rate of 1.6% between two HTs. For non-HTs, the error rate was close to 50% in both cases, showing that no cross-core transmission is possible.[6] While a malicious OS could attempt to eavesdrop on the sender and replay for the receiver to spoil the check, a range of additional countermeasures exists that would mitigate this attack. For example, the two threads could randomly choose a different L1 cache set (out of the 64 available) for each bit to transmit.

To protect against **A4**, the enclave may use SGX's trusted monotonic counters [3] or require an online connection to its owner on restart.

Finally, the enclave may demand a private LLC partition, which could be provided by the OS via Intel's recent *Cache Allocation Technology* (CAT) feature [32] or "cache coloring" [11,37,58]. A contract violation would become evident to the enclave through increased numbers of aborts with code CONFLICT.

[6] Using the read set instead yields a timing-less cross-core covert channel with a raw capacity of 335 KB/s at an error rate of 0.4%.

8 Limitations and Future Work

Cache attacks are just one of many types of side-channel attacks and Cloak naturally does not mitigate all of them. Especially an adversary able to measure the execution time of a transaction might still derive secret information. Beyond this, Cloak instantiated with Intel TSX may be vulnerable to additional side channels that have not yet been explored. We identified five potential side channels that should be investigated in more detail: First, the interaction of the read set and the "second level structure" (*i.e.*, the bloom filter) is not documented. Second, other caches, such as translation-lookaside buffers and branch-prediction tables, may still leak information. Third, the Intel TSX abort codes may provide side-channel information if accessible to an attacker. Fourth, variants of Prime+Probe that deliberately evict read set cache lines from L1 to the LLC but not to DRAM could potentially obtain side-channel information without causing transaction aborts. Fifth, the execution time of transactions including in particular the timings of aborts may leak information. Finally, it is important to note that Cloak is limited by the size of the CPU's caches, since code and data that have secret-dependent accesses must fit in the caches. TSX runtime behavior can also be difficult to predict and control for the programmer.

9 Related Work

Using HTM for Security and Safety. The Mimosa system [25] uses TSX to protect cryptographic keys in the Linux kernel against different forms of memory disclosure attacks. Mimosa builds upon the existing TRESOR system [47], which ensures that a symmetric master key is always kept in the CPU's debug registers. Mimosa extends this protection to an arbitrary number of (asymmetric) keys. Mimosa always only writes protected keys to memory within TSX transactions. It ensures that these keys are wiped before the correspond-

ing transaction commits. This way, the protected keys are never written to RAM. However, Mimosa does not prevent cache side-channel attacks. Instead, for AES computations it uses AES-NI, which does not leak information through the cache. However, a cache attack on the square-and-multiply routine of RSA in the presence of Mimosa would still be possible. To detect hardware faults, the HAFT system [39] inserts redundant instructions into programs and compares their behavior at runtime. HAFT uses TSX to efficiently roll-back state in case a fault was encountered.

Probably closest related to Cloak is the recent T-SGX approach [59]. It employs TSX to protect SGX enclave code against the page-fault side channel [61], which can be exploited by a malicious OS that unmaps an enclave's memory pages (cf. Section 7). At its core, T-SGX leverages the property that exceptions within TSX transactions cause transactional aborts and are not delivered to the OS. T-SGX ensures that virtually all enclave code is executed in transactions. To minimize transactional aborts, e.g., due to cache-line evictions, T-SGX's extension of the Clang compiler automatically splits enclave code into small *execution blocks* according to a static over-approximation of L1 usage. At runtime, a *springboard* dispatches control flow between execution blocks, wrapping each into a separate TSX transaction. Thus, only page faults related to the springboard can be (directly) observed from the outside. All transactional aborts are handled by the springboard, which may terminate the enclave when an attack is suspected. For T-SGX, Shih et al. [59] reported performance overheads of 4%–108% across a range of algorithms and, due to the strategy of splitting code into small execution blocks, caused only very low rates of transactional aborts.

The strategy employed by T-SGX cannot be generally transferred to Cloak, as—for security—one would need to reload the code and data of a sensitive function whenever a new block is executed. Hence, this strategy is not likely to reduce cache conflicts, which is the main reason for transactional aborts in Cloak, but rather increase performance overhead. Like T-SGX, the recent Déjà Vu [8] approach also attempts to detect page-fault side-channel attacks from within SGX enclaves using TSX: an enclave thread emulates an non-interruptible clock through busy waiting within a TSX transaction and periodically updating a counter variable. Other enclave threads use this counter for approximate measuring of their execution timings along certain control-flow paths. In case these timings exceed certain thresholds, an attack is assumed. Both T-SGX and Déjà Vu conceptually do not protect against common cache side-channel attacks.

Prevention of Resource Sharing. One branch of defenses against cache attacks tries to reduce resource sharing in multi-tenant systems. This can either be implemented through hardware modifications [12, 52], or by dynamically separating resources. Shi et al. [58] and Kim et al. [37] propose to use cache coloring to isolate different tenants in cloud environments. Zhang et al. [68] propose cache cleansing as a technique to remove information leakage from time-shared caches. Godfrey et al. [18] propose temporal isolation through scheduling and resource isolation through cache coloring. More recently Zhou et al. [69] propose a more dynamic approach where pages are duplicated when multiple processes access them simultaneously. Their approach can make attacks significantly more difficult to mount, but not impossible. Liu et al. [42] propose to use Intel CAT to split the LLC, avoiding the fundamental resource sharing that is exploited in many attacks. In contrast to Cloak, all these approaches require changes on the OS level.

Detecting Cache Side-Channel Leakage. Other defenses aim at detecting potential side-channel leakage and attacks, e.g., by means of static source code analysis [13] or by performing dynamic anomaly detection using CPU performance counters. Gruss et al. [23] explore the latter approach and devise a variant of Flush+Reload that evades it. Chiappetta et al. [9] combine performance counter-based detection with machine learning to detect yet unknown attacks. Zhang et al. [65] show how performance counters can be used in cloud environments to detect cross-VM side-channel attacks. In contrast, Cloak follows the arguably stronger approach of mitigating attacks before they happen. Many attacks require only a small number of traces or even work with single measurements [17, 43, 62]. Thus, Cloak can provide protection where detection mechanisms fail due to the inherent detection delays or too coarse heuristics. Further, reliable performance counters are not available in SGX enclaves.

10 Conclusions

We presented Cloak, a new technique that defends against cache side-channel attacks using hardware transactional memory. Cloak enables the efficient retrofitting of existing algorithms with strong cache side-channel protection. We demonstrated the efficacy of our approach by running state-of-the-art cache side-channel attacks on existing vulnerable implementations of algorithms. Cloak successfully blocked all attacks in every attack scenario. We investigated the imperfections of Intel TSX and discussed the potentially remaining leakage. Finally, we showed that one of the main limitations of Intel SGX, the lack of side-channel protections, can be overcome by using Cloak inside Intel SGX enclaves.

19       left = node.left;
20       right = node.right_or_leafid;
21       if (left == node) {
22         leafids[q] = right;
23         break;
24       }
25       if (queries.item(q, node.fdim) <=
     node.fthresh)
26         idx = left;
27       else
28         idx = right;
29     }
30   }
31 }
```

A Cloak Code Example

Listing 2 gives an example of the original code for tree traversal and its Cloak-protected counterpart. In the original code, a tree is stored in a `Nodes` array where each node contains a feature, `fdim`, and a threshold, `fthres`. Access to a node determines which feature is used to make a split and its threshold on the value of this feature indicates whether the traversal continues left or right. For every record batched in `Queries`, the code traverses the tree according to feature values in the record. Once a leaf is reached its value is written as the output of this query in `LeafIds`. The following features of Cloak are used to protect code and data accesses of the tree traversal. First, it uses Cloak data types to allocate `Nodes` and `Queries` in the read set and `LeafIds` in the write sets. This ensures that data is allocated as described in Section 5.2.1, oblivious from the programmer. The parameters `NCS_R` and `NCS_W` indicate the number of cache sets to be used for the read and write sets. Second, the programmer indicates to the compiler which function should be run within a transaction by using `_tsx_protected` annotation. The programmer calls preload (lines 11, 12, and 15) on sensitive data structures. The repeated preloading of the writable array `leafids` in line 15 refreshes the write set to prevent premature evictions.

CacheD: Identifying Cache-Based Timing Channels in Production Software

Abstract

Side-channel attacks recover secret information by analyzing the physical implementation of cryptosystems based on non-functional computational characteristics, e.g. time, power, and memory usage. Among all well-known side channels, cache-based timing channels are notoriously severe, leading to practical attacks against certain implementations of theoretically secure crypto algorithms, such as RSA, ElGamal and AES. Such attacks target the hierarchical design of the modern computer memory system, where different memory access patterns of a program can bring observable timing difference.

In this work, we propose a novel technique to help software developers identify potential vulnerabilities that can lead to cache-based timing attacks. Our technique leverages symbolic execution and constraint solving to detect potential cache differences at each program point. We adopt a cache model that is general enough to capture various threat models that are employed in practical timing attacks. Our modeling and analysis are based on the formulation of cache access at different program locations along execution traces. We have implemented the proposed technique as a practical tool named CacheD (Cache Difference), and evaluated CacheD towards multiple real-world cryptosystems. CacheD takes less than 17 CPU hours to analyze 9 widely used cryptographic algorithm implementations with over 120 million instructions in total. The evaluation results show that our technique can accurately identify vulnerabilities reported by previous research. Moreover, we have successfully discovered previously unknown issues in two widely used cryptosystems, OpenSSL and Botan.

1 Introduction

Side-channel attacks recover secret information by analyzing the physical implementation of crypto and other systems based on non-functional computational characteristics. Typical attributes exploited in such attacks include time [30], power [37], memory consumption [28], network traffic [16], and electromagnetic [46].

Among all side-channel attacks, cache-based timing attacks steal confidential information based on the program's runtime cache behaviors. Cache-based timing attacks are perhaps the most practical and important ones, since those attacks does not require any physical access to the confidential computation, yet the timing signal carries enough information to break RSA [3, 45, 59], AES [8, 11, 42, 53, 27] and ElGamal [63, 34]. Other than cryptosystems, research has also shown that cache-based timing channels may leak other confidential information [47, 57, 62, 58].

The mitigation mechanisms towards cache-based timing channels can be categorized into hardware and software based solutions. Hardware-based solutions focus on new cache designs such as partitioned cache [43, 54, 31, 61], randomized/remapping cache [54, 55, 33], and line-locking cache [54]. But such secure hardware assumes that crucial memory accesses are identified (by security experts) in the first place. Most software-based solutions only consider cache-based timing channels due to secret-dependent control flow [4, 25, 38, 7, 17, 44] and hence, cannot prevent subtle leakage found in source code without any secret-dependent control flow (see §2.2.2). More advanced program analyses [6, 19, 20, 60] can detect the subtle leakage missed by those solutions, but they only provide an upper-bound on timing-based information leakage; it is unclear what/where the vulnerability is when those tools report a non-zero upper bound.

We focus on cache-based timing analysis. Cache attacks can be categorized into three models [51], time-driven, access-driven, and trace-driven attacks, each of which leverages a different approach to monitor the cache behavior. Time-driven attacks [8] observe the overall execution time of the cryptosystems and require many measure samples. Existing work has demonstrated the feasibility to launch the cache-based attack locally or

remotely towards the AES encryption algorithm [8, 42]. In contrast, access-driven attacks [24, 53] and trace-driven attacks [2] exploit more fine-grained cache behavior and require fewer measurement samples, but they are based on more sophisticated threat models and require deep knowledge about the hardware and software system under attack [53, 39, 45].

Given the complexity of the memory hierarchy in modern computer systems, it is difficult for developers to reason about the cache access behavior of a program or a particular memory access. For example, the Appendix A shows a large and complicated symbolic formula of a memory access address found in our experiment. It is quite obvious how complicated it is to reason its cache behavior, let alone take the context into consideration. Developers may be able to come up with better abstractions and reasoning, but it is easy to miss nuances and corner cases as demonstrated in our findings (see §7). Thus it is of great practical value to develop an automated tool that can help developers reason about the cache behavior of a memory access.

In this paper, we propose a general trace-based method with symbolic execution and constraint solving to detect potential cache variations at each program location. Our theory and cache modeling are independent of threat models that are employed in attacks to utilize the potential vulnerabilities detected. Our modeling and analysis are based on formulations of cache access at different program locations along the execution trace. More specifically, we record the execution trace, and use symbolic execution (with the secret as symbols) to formulate the cache access variations at each memory access. In other words, for each memory access in an execution trace, we check whether it is possible that this memory access can touch different cache lines given different secret inputs. Moreover, our method also provides two values that will cause such cache access variations at one memory access using a constraint solver. Once confirmed, such cache access variations can be leveraged, with various threat models, for cache-based side-channel attacks.

We have implemented the proposed technique as a practical tool named CacheD (Cache Difference), and evaluated CacheD towards multiple real-world cryptosystems. The evaluation results show that our technique can accurately identify vulnerabilities reported by previous research. Moreover, we have successfully discovered previously unknown issues in two widely used cryptosystems, OpenSSL (version 0.9.7c and 1.0.2f) and Botan (version 1.10.13).

We make the following contributions.

- We propose a novel trace-based analysis method that models the cache variations on every memory access. Our modeling is conceptually simple yet general enough to capture most adopted threat models. While existing research is designed to infer an "upper-bound" on timing-based information leakage, our technique can accurately point out what/where the vulnerability is, and provide concrete examples to trigger the issue. It becomes much simpler for developers to identify potential timing channels in their code.
- We have developed a practical tool called CacheD, which is precise and scalable enough to assist developers in identifying vulnerable program points in production cryptosystems.
- We applied CacheD to a set of widely used cryptosystems to search for timing channels in the implementations of well-known cryptographic algorithms. Within 17 CPU hours, CacheD identified 156 vulnerable program points along the analyzed execution traces of over 120 million instructions.
- By monitoring cache traffic of the test cases using a hardware simulator, we have confirmed the identified vulnerabilities as true positives: different secrets provided by CacheD lead to observable cache behavior difference, which further reveals potential timing channels.

2 Background

2.1 Memory Hierarchy and Set-Associative Cache

The storage system of modern computers adopts a hierarchical design. In the hierarchy, storage hardware in higher layers has faster response time but lower capacity due to hardware cost. When the CPU needs to retrieve the data, it will access the layers from the top to the bottom. In this way, the CPU can speed up data retrieval with limited hardware resources, based on the observation that memory accesses in computer programs are usually temporarily and spatially coalesced.

The topmost three layers of the hierarchy are processor registers, caches, and the main memory, the latter two of which share the same address space. Since caches are built with costly and fast on-chip devices, their latency is much lower than that of the main memory. When a data read misses the cache, the CPU will have to retrieve the data from the main memory, thus leading to a significant delay up to hundreds of CPU cycles. Therefore, minimizing cache misses is one of the most important objectives in processor design.

The organization of a cache refers to the policy that decides how the data are stored and replaced based on their addresses in the memory space. Modern processors usually have multiple levels of caches that form a structure isomorphic to the whole memory hierarchy. In most

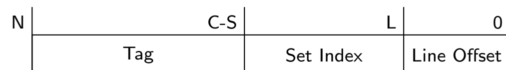

Figure 1: Cache indexing of S-way set-associative caches with the line size of 2^L bytes the capacity of 2^C bytes for a 2^N-byte address space.

cases, regardless of the levels on which the caches serve in the hierarchy, all of them are similarly organized, in a way called set-associative organization.

The minimal storage unit of set-associative caches is called a line and the cache is divided into sets consisting of the same number of lines. For set-associative caches, the organization is fully decided by three factors, i.e., the cache size, the line size, and the set size, where the set size is usually referred to as the number of ways the cache is associated in.

For a 2^K-way associative cache with the line size of 2^L bytes and a total capacity of 2^C bytes, it will be divided into 2^{C-K} sets. Bytes at each address can reside in any of lines of one particular set. Given an N-bit memory address, the cache looks up the data by dissecting the address into three parts, as shown in Fig. 1. The set index is used to locate the set in which the data may be stored, and the tag is used to confirm that the data is currently present in one of the lines in that set. If the tag matches, the line offset is used to locate the data inside the cache line; otherwise, accessing memory at that address leads to a cache miss, and the processor will have to retrieve the data from the lower layers of the memory hierarchy.

The low L bits of the address used to access the cache is irrelevant to timing, since the CPU always retrieve a whole cache line at a time. Only the high $N-L$ bits of the address indicate whether the memory access may hit the cache or not, based on the status of the cache. For most CPUs, one cache line holds 64 bytes of data, meaning the value of L is 6. Without losing generality, we will adopt this configuration in the rest of the paper unless noted otherwise.

2.2 Cache-Based Timing Channels

The cache is highly optimized, sophisticated, and inherently shared, in modern multicore and manycore architectures; even a small change in confidential data may bring drastic and subtle changes to the traffic to the cache. The consequence is that a dedicated attacker may reveal confidential data by measuring the latency introduce by the cache.

2.2.1 Leakage due to secret-dependent control flow

The confidential data may affect the traffic to the cache when there is secret-dependent control flow in the source code. Such leakage is best illustrated in the square-and-multiply implementation (shown below) of modular exponentiation, the core computation of cyphers such as RSA and ElGamal.

The pseudo-code computes $b^e \mod m$, where we assume the n-bit secret exponent e is in its binary representation and $e[i]$ is the i-th bit of e. Note that in this implementation, the branch condition at line 4 depends on one bit of e. Moreover, the real implementation of $r = r * b \mod m$ involves memory reads since b and e consist of multiple words in RSA and ElGamal. Consequently, an attacker that probes the cache usage of this victim program can recover the exponent, and hence, reveals the private key of RSA [1, 59] and ElGamal [63, 34].

```
1  r = 1;
2  for i from n−1 to 0 {
3      r = r*r mod m;
4      if (e[i] == 1) {
5          r = r*b mod m;
6      }
7  }
```

Previous work shows that secret-dependent control flow can be identified via information flow analysis, and be mitigated by removing secret-dependent branches or balancing branches conditioned on confidential data [4, 25, 38, 7, 17]. But these mechanisms cannot prevent leakages due to memory traffic as we discuss next. In fact, some tricks of removing secret-dependent control flow may introduce those new leakages in a program.

2.2.2 Leakage due to secret-dependent memory traffic

Cache-based timing attacks also work on implementations without any secret-dependent control flow, as illustrated in our running example (Fig. 2). This simple program iteratively accesses a table of size 128 stored in the memory. Note that the execution of this program follows the same control flow regardless of the secret since the loop body is executed exactly 200 times. Nevertheless, the memory address accessed at line 9 is key dependent, and hence, may result in memory requests to secret-dependent cache lines. Hence, a cache-probing attack (e.g., prime-and-probe attack [42, 53, 11, 63, 34]) may peek which cache line is accessed, and consequently, infer at least some bits of the secret in this example.

We emphasize that although we use this contrived running example in this paper for its simplicity, variants of the vulnerability illustrated in this example are found and exploited in real-world implementations of crypto systems, such as the AES implementation in OpenSSL, exploited in [24, 42, 53], the RSA and ElGamal implementations in Libgcrypt, exploited in [59, 34]. For example, the *sliding-window*-based modular exponential implementation [12] is vulnerable to cache-based timing attacks. With a parameter L (window size), the sliding-window implementation splits the secret expo-

```
1   void foo(int secret)
2   {
3     int table[128] = {0};
4     int i, t;
5     int index = 0;
6     for (i=0; i<200; i++)
7     {
8       index = (index+secret) % 128;
9       t = table[index];
10      t = table[(index) % 4];
11    }
12  }
```

Figure 2: CacheD running example.

nent e into a couple of *windows*, where each window holds a value (with at most L-bits) that is either a sequence of 0's, or bits that starts with a 1 and ends with a 1 (hence, an odd number). Given a non-zero window value, say v, this implementation computes b^v via a table lookup: $T[(v-1)/2]$, where T is a precomputed table such that $T[i] = b^{i*2+1} \mod N$. Note computing b^v involves no secret-dependent branch, but different cache lines are accessed given different values of v, hence, leading to practical cache-based timing attacks (e.g., [34]). CacheD successfully detects such vulnerabilities in Libgcrypt (§7.3).

2.3 Threat Model

We consider an attacker who shares the same hardware platform with the victim, a common scenario in the era of cloud computing. Hence, the attacker may observe cache accesses at different program locations along a program execution trace. That is, we assume an attacker can either directly or indirectly learn the trace of cache lines being accessed during the execution of the victim program. This strong threat model captures most cache-based timing attacks in the literature, such as an attacker who observes cache accesses by measuring the latency of the victim program (e.g., cache reuse attacks [43, 11, 10, 24] and evict-and-time attack [42]), or the latency of the attacker's program (e.g., prime-and-probe attacks [42, 53, 11, 63, 34]).

Compared with previously categorized threat models based on the abstraction of cache hit and miss (namely, the time-based, trace-based and access-based models [19, 51]), our more detailed model using the abstraction of cache lines has a couple of benefits. Firstly, our threat model is stronger than those based on cache hit/miss, since in most architectures, a trace of cache lines being accessed uniquely determines cache hit/miss at any program point. Secondly, working on the cache line abstraction makes the vulnerability analysis more general, since unlike cache hit/miss, the abstraction is independent of cache implementation details, such as cache-replacement policies, cache associativity and so on.

3 Method

3.1 Overview

In modern multicore and manycore architectures, the cache behavior may bring drastic difference in the latency of memory accesses (§2.1). Based on this observation, we propose a technique that detects potential timing channels caused by variant cache behavior. More specifically, we model cache lines being accessed as symbolic formulas where sensitive program data are treated as free variables during symbolic execution. In practice, sensitive data are typically the private keys used in cryptosystems and any data derived from those keys. With the help of constraint solvers, we can logically deduce whether sensitive data would affect the cache behavior of the program and hence, reveal potential timing channels.

Operationally, given a program point where a memory access occurs, we can model the memory address being accessed as a symbolic formula $F(\vec{k})$, where $\vec{k}$, as the only free variables in F, stands for program secrets. By substituting all occurrences of $\vec{k}$ in F with new free variables $\vec{k'}$, we can obtain another formula $F(\vec{k'})$. A satisfiable formula $F(\vec{k}) \neq F(\vec{k'})$ indicates that at this particular program point, the address used to access the memory depends on the values of the secrets.

We further refine the formulation above regarding two aspects. First, a difference in the memory address does not imply a difference in the cache line being accessed. That is, the low L bits (the line offset part in Fig. 1) of the address are irrelevant to cache behavior. Therefore, instead of trying to solve $F(\vec{k}) \neq F(\vec{k'})$, we construct F as a bit vector and solve $F(\vec{k}) \gg L \neq F(\vec{k'}) \gg L$, where $\gg$ is the right shift operation on bit vectors. Second, a solution of the refined formula may not be feasible along the trace under examination. For better precision, we augment the formula with the path condition (C) collected along the already processed trace. The path condition is the conjunction of all the branch conditions along the trace before this memory access (assuming an SSA transformation on the trace). The final formula for satisfiability checking is then $(F(\vec{k}) \gg L \neq F(\vec{k'}) \gg L) \wedge C$.

3.2 Example

Consider the running example shown in Fig. 2, in which the secret is used as the index of a table. By symbolizing the secret as k, a memory access formula can be build which presents the first table query (line 9) in the first iteration of the loop as:[1]

$$F(k) \equiv 10 + 4 \cdot k \mod 128$$

[1] Variable `index` is accumulated in the loop so further memory access formulas are different.

where 10 is assumed the base address of the table. This formula can be further refined into a cache line access formula as

$$F(k) \gg L \equiv 10 + 4 \cdot k \bmod 128 \gg L$$

where L equals to 6 regarding the cache configuration of most CPUs on the market (discussed in §2.1).

To find two secrets that result in different cache behaviors, we further replace symbol k in formula $F(k)$ with a fresh symbol, and check the satisfiability of $F(k) \gg 6 \neq F(k') \gg 6$ using a theory prover; a reasonable solver will answer yes, meaning the constraint is satisfiable, with a solution such as

$$[k = 1, k' = 30]$$

Hence, we have successfully identified that different secrets (e.g., 1 and 30) can lead to the access of different cache lines at line 9 of the sample code. Actually, by feeding different secrets (1 or 30) to this function, memory access in the above case hits cache line 0 or 1, which enables attackers to launch cache probing attacks (e.g., prime-and-probe attacks [42, 53, 11, 63, 34]) to infer the value of the secret.

Another obvious secret dependent memory access is at line 10, which holds the memory access formula (also for the first iteration of the loop) as:

$$G(k) \equiv 10 + 4 \cdot (k \bmod 128) \bmod 4$$

According to constraint solving, $G(k) \gg 6 \neq G(k') \gg 6$ is unsatisfiable at this time. That means, memory access at line 10 always access the same cache line, and hence, is immune to cache-probing attacks.

3.3 Scope and Limitations

Trace-based Analysis. CacheD is designed to analyze execution traces of program executables. In general, low-level analysis (such as analysis towards the execution trace) is capable of capturing pitfalls or vulnerabilities that are mostly ignored by analyzing the source code [5]. In addition, since the inputs to CacheD are execution traces generated from program executables, CacheD is also capable of identifying vulnerabilities introduced by compiler optimizations or even commonly used obfuscations without additional efforts. We take execution traces as the input for CacheD because whole-binary symbolic execution is mostly considered unscalable, even through trace-based analysis loses some generality for only analyzing one or several execution paths. Moreover, since we only keep symbols derived from the secret, pointers which do not contain symbols can be updated with concrete values acquired from the execution trace.

Main Audiences. The main audiences of our work are software developers: developers can use CacheD to "debug" their software (through execution traces) and identify vulnerable program points that may lead to cache-based timing attacks. Previously, finding such vulnerabilities are challenging—if possible at all—towards industrial-strength cryptosystems.

The trace-based analysis is usually unable to cover all program points; in other words, to produce execution traces that can cover the vulnerable code, it might require deliberate selection of proper program inputs to trigger the vulnerability. Although this coverage issue is unavoidable in general, we assume developers themselves would be able to construct proper program inputs and provide critical execution traces to CacheD. There are also techniques, such as concolic testing [49, 22, 23], developed in the software testing and verification community that can be leveraged.

On the other hand, considering the research objective in this paper (i.e., cryptosystems), most critical procedures (where vulnerabilities could exist) can indeed be triggered by following the standard routines defined by the cryptographic libraries. Evaluation details of our work are presented in §7.

Adoption of Constraint Solver. In practice, searching for different secret values that lead to different cache behaviors is very complex and thus difficult for developers without resort to rigorous tools. For example, the big and complex formula shown in Appendix A is almost impossible for developers to deduce a solution. Symbolic execution is considerably more precise than traditional data-flow analysis, and when constraint solver finds a solution for memory accessing formula, it naturally provides counter examples that lead to the variant cache accesses, making it easier for developers to reveal underling issues in their software.

Soundness vs. Precision. CacheD is not sound in the terminology of program analysis; that is, when CacheD reports no vulnerability, it does not mean the program under examination is free of cache-based side-channel attacks. On the other hand, CacheD is quite precise with few false positives. According to our threat model, false positives only occur in scenarios such as if the symbolic memory model is not precise enough. Constraint solving will not introduce false positives as a positive solution is really satisfiable for the formula, but it might miss positives. In practice, our evaluation also reports consistent findings that positive cases studied in the hardware simulator can surely lead to cache line access variance (details are given in §7.3). We actually have not encountered any false positives

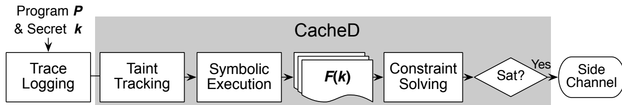

Figure 3: The architecture of CacheD.

in our evaluation. As previously discussed, existing research [19, 20] aims at reasoning the "upper-bound" of information leakage through abstract interpretation, but may not be precise enough due to over-approximation. Moreover, CacheD distinguishes itself by being able to point out where/what the vulnerability is, and provide examples that are likely to trigger the issue. Considering CacheD as a "debugging" or vulnerability detection tool, it is equally important to adopt its precise and practical techniques on side-channel detection.

4 Design

We present CacheD, a tool that delivers scalable detection of cache-based timing channels in real-world cryptosystems. Fig. 3 shows the architecture of CacheD. In general, given a binary executable with secrets as inputs, we first get a concrete execution trace by monitoring its execution (§4.1). The trace is then fed into CacheD to perform taint analysis; we mark the secret as the taint seed (§4.2) and propagate the taint information along the trace to identify instructions related to the usage of the secret.

CacheD then symbolizes the secret into one or several symbols (each symbol represents one word), and performs symbolic execution along the tainted instructions on the trace (§4.3). During the symbolic interpretation, CacheD builds symbolic formulas for each memory access along the trace. Symbolic memory access formulas are further analyzed using a constraint solver to check whether cache behavior variations exist. As aforementioned, we check the satisfiability of $(F(\vec{k}) \gg L \neq F(\vec{k}') \gg L) \ \wedge \ C$; if satisfiable, the solution to $\vec{k}$ and $\vec{k}'$ represent different secret values that can lead to different cache behavior of this program point. The only architecture-specific parameter to CacheD is the cache line size. As discussed in §2.1, we set L to be 6 throughout this paper since most CPUs on the market sets have a cache-line size of 64. Next, we elaborate on challenges and design of each step in the following sections.

4.1 Execution Trace Generation

CacheD takes a concrete program execution trace as its input. In general, the execution trace can be generated by employing dynamic instrumentation tools to monitor the execution of the target program and dump the execution trace. We assume the instrumentation tools also dump the context information (including the value of every register) of *every* executed instruction as well.

Locating Secrets in the Trace. Besides the dumped execution trace and the context information, another input of CacheD is the locations (e.g., a memory location or a register) of the secrets in a program. This information serves as the seed for the taint analysis and symbolic execution in later stages.

While the secrets (e.g., the private key or a random number) are usually obvious in the source code, it may not be straightforward to identify the location of the secret in an execution trace, since variable names are absent in the assembly code. Treating this as a typical (manual) reverse engineering task, our approach to searching for the secrets in the assembly is to "correlate" memory reads with the usage of the key in the source code. To do so, we identify the critical function in the source code where the key is initialized and then search for the function in the assembly code. The search space can be further reduced by cutting the assembly code into small regions according to the conditional jumps in the context. With further reverse engineering effort in small regions, we can eventually recognize the location of the secret in the assembly code, as a register, or a sequence of memory cells in the memory.

Although currently this step is largely manual, it is likely that it can be automated by a secret-aware compiler, which tracks the location of secrets throughout the compilation; however, we leave this as future work.

4.2 Taint Analysis

CacheD leverages symbolic execution to interpret each instruction along a trace to reason about memory accesses that are dependent on secrets. Our tentative tests show that the symbolic-level interpretation is one performance bottleneck of CacheD. However, we notice that only a subset of instructions in a trace is dependent on the secrets. Thus, a natural optimization in our context is to leverage taint analysis to rule out instructions that are irrelevant to the secret; the remaining instructions are the focus of the more heavy-weight symbolic execution.

After reading the execution trace, CacheD first parses the instructions into its internal representations. It then starts the taint analysis from the first usage of the secret. Following existing taint analyses (e.g., [48, 52]), we propagate the taint information along the trace following pre-defined tainting rules that we discuss shortly. After the taint analysis, we keep the instructions whose operands are tainted.

Taint propagation rules define how tainted information flows through instructions, memories and CPU flags, as

well as what operations introduce new taint or remove existing taint. Well-defined propagation rules should not miss needed taint propagation, while keeping the set of tainted memory cells as small as possible to reduce the overhead of further heavy-weight analysis (i.e., symbolic execution in our context). Considering the context of cryptosystems, we now propose our taint propagation rules as follows.

Taint Propagation for Registers. The propagation rules for register-level operations are very straightforward. In general, if a tainted variable flows to an untainted one, then the latter will be tainted. On the other hand, we delete the taint label on the information flow destination if the source is not tainted.

Taint Propagation for Memory-related Operations. We now define the tainting rules for memory operations. CacheD tracks the taint information for each memory cell. More specifically, the taint module of CacheD keeps a set, where each element is the address of tainted memory cell. Taint operation inserts new elements into this list, while untaint operation deletes the corresponding element. Recall that we dump the context information for each executed instruction (§4.1). For each memory access, we compute the address through the concrete register values recorded in the context information. Hence, the memory address is always a *concrete* value and memory-related taint propagation is considered accurate.

Memory addressing defined in the x86 instruction set can be divided into the base address and the memory offset, each of which is maintained by a register or a concrete value. Our tainting rule defines that whenever the registers representing either the base address or the offset are tainted, we would propagate the taint to the contents of the accessed memory cells. Our tainting rules are reasonable and avoid under-tainting, since in general the secret content can be used as memory pointers (representing base addresses) as well as memory offsets.

Taint Propagation for CPU Flags. In x86 instruction set, CPU flags participant in the computation of many instructions and are also used to select branches. To precisely track the secret information flow, CacheD record taint propagations towards CPU flags.

In general, CPU flags could be modified according to the computation results of certain instructions, for example, flag `ZF` will be set to one if the result of an `SUB` (subtraction) operation is zero. In case any operand of a given instruction is tainted, we taint all CPU flags that can be affected by the current computation. In addition, taint label can also be propagated from CPU flags to registers or memory cells; we taint registers or memory cells that hold the computation result of an instruction whenever tainted CPU flags participant the computation.

4.3 Symbolic Execution

We now introduce how we build the symbolic execution module of CacheD. As previously mentioned (§4.2), tainted instructions (i.e., instructions whose operands are tainted) are kept after taint analysis. These instructions, together with their associated context information, are passed to the symbolic execution module; the location of the secret is another input of symbolic execution. The symbolic execution engine starts the interpretation at the beginning of the first tainted instruction (i.e., the first usage of the secret) and interprets each instruction until the trace end.

Symbolization of the Secret. In general, secrets (e.g., private key) can be maintained as a variable (as shown in Fig. 2), an array, or a compound data structure. Note that only the *content* of the secret (e.g., the value of a private key) is considered as "secret" in our context.

If the secret is maintained as one variable (e.g., one register or a memory cell on the stack), it is straightforward for symbolization. On the other hand, if the secret is stored in a sequence of memory cells (e.g., one array, structure, or class instance), CacheD assigns the base address (provided by programmers in previous stage §4.1) to a special symbol. Further memory reads using this special symbol as the base address is considered to access the secret content. CacheD generates a fresh symbol (for simplicity's sake, we name such symbol as *key symbol*) each time when the memory read has a different offset (since it indicates a different part of the secret memory region is visited).

Design of the Symbolic Execution Engine. As aforementioned (§3.1), we collect all the conditions (i.e., some formulas evolving CPU flags) of the branches along the trace and conjunct them into the path condition. Since the program execution trace can be effectively viewed as the static single assignment (SSA) format, the path condition is accumulated along the trace and it must be always true at any execution point (otherwise the execution trace is invalid). Our side-channel checking is performed at every memory access. When encountering a memory access, CacheD pauses the symbolic execution engine and sends the memory access formula as well as the currently-collected path condition to the solver. Consistent with our taint propagation rules which captures information flow through memory accesses (§4.2), for a memory load operation whose addressing formula containing key symbols (i.e., either the base

address or the memory offset is computed from secrets), we would symbolize the memory cell with a fresh key symbol if it is visited for the first time.

Symbolic Execution Memory Model. Symbolic execution interprets programs with logical formulas instead of concrete values so that the semantics captured are not specific to a single input. However, some program semantics are difficult to analyze when the information flow is encoded symbolically, such as dereferencing a symbolic pointer. In general, when a symbolically executed program reads from the memory using an abstract (symbolized) address, the execution engine needs to decide the content read from the address. On the other hand, when the program writes to the memory using an abstract address, the engine needs to decide how to update the memory status. The policy that specifies those aspects is called a memory model.

When designing a symbolic execution engine, the trade-off between scalability and precision should be carefully considered. That is, we cannot employ a full-fledged memory model that features abstract memory chunks, since our tentative test shows that such memory model does not scale for the real-world applications. Instead, our current design develop a memory model that reasons symbolic pointers with their concrete values on the trace, which is conceptually the same as other commonly used binary analysis platforms (e.g., the trace-based analysis of BAP [14]).

5 Optimization

While taint analysis is efficient, symbolic execution and constraint solving are time consuming in general. Here we discuss several optimizations in CacheD.

Identify Independent Vulnerabilities. To capture information flow through memory operations in symbolic execution, we create a fresh key symbol for a memory load of unknown positions whenever the base or memory offset is computed from key symbols. In this section, we propose a finer-grained policy, which reveals "independent" vulnerable program points. The key motivation is that, by studying the underlying memory layout, attackers would be able to learn relations between the newly-created key symbol and the memory addressing formula (which contains one or several key symbols). Hence, we assume further vulnerabilities revealed through the usage of this new key symbol would mostly leak the same piece (or a subset) of secret information (we elaborate on this design choice shortly).

We now present an example to motivate this optimization. In general, for a memory load operation

$$load\ reg,\ [F(\vec{k})]$$

where $F(\vec{k})$ is the memory addressing formula through the secret $\vec{k}$, and *reg* stores the loaded content from the memory. There exist three different cases regarding the solution of our constraint solver:

- To test whether the array index, and hence the fetched content, may differ in two executions with different keys, CacheD checks the formula $(F(\vec{k}) \neq F(\vec{k}')) \wedge C$. If there is no satisfiable solution for this formula, we interpret this memory access is *independent* of the key. Thus, there is no need to create a fresh key symbol; we update the memory load output (i.e., *reg* in the above case) with concrete value from the trace.
- If there exist satisfiable solutions for $(F(\vec{k}) \gg L \neq F(\vec{k}') \gg L) \wedge C$, it means we find an *independent vulnerable program point*. As discussed above, further vulnerable program points discovered through the newly created key symbol (stored in *reg*) would likely leak the same piece of secret information as this vulnerability, thus "depending" on this point.
- The remaining case is that there is no satisfiable solution for $(F(\vec{k}) \gg L \neq F(\vec{k}') \gg L) \wedge C$ while there exists solutions for $(F(\vec{k}) \neq F(\vec{k}')) \wedge C$. In other words, while the current memory access does not reveal a vulnerability, still, different secrets would lead to the access of different memory cells, which constructs an information flow. Hence, we create a fresh key symbol and use it to update the memory load output.

In general, we consider independent vulnerabilities are highly informative to attackers; independent vulnerabilities probably indicate the most-likely attack surface of the victim, because stealing secret through "dependent" vulnerabilities need additional efforts to learn the program memory layout. On the other hand, memory layouts are feasible and likely to be learned as precomputed data structures are widely deployed in real-world cryptosystems to speed up the computation. Overall, "dependent" vulnerabilities reveal an additional attack surface which are commonly ignored by previous research.

Early Stop Criterion of Symbolic Execution. One vulnerable program point (e.g., a table query) can be executed for one or more times during the runtime (thus appearing more than once on the execution trace). On the other hand, a program point can be considered as "vulnerable" as long as one of its usage is

confirmed vulnerable. Hence, while in general CacheD symbolically interpret all the tainted instructions, one early stop criterion adopted in CacheD is that we have already identified at least one vulnerable memory access for *any* tainted access relating to the same program point.

Domain knowledge of RSA and ElGamal implementation. As previously discussed, our taint propagation rule would taint the visited memory cells whenever registers hold the base address or memory offset are tainted. While this rule reasonably captures the information flow through memory accesses, we terminate the taint propagation for one specific case, given the domain knowledge of cryptosystems being analyzed.

To speed up processing, the sliding-window based modular exponentiation algorithm leverages a two-level "precomputed table" to store the modular exponentiation values of the base regarding some predefined window-sized value. Additionally, a precomputed size table is deployed to store the length of each precomputed modular exponentiation value. Hence, most of the computation are substituted into two table lookups towards the precomputed table and the size table through the window size key. Appendix B presents the structure of a two-level precomputed table used in Libgcrypt 1.6.1. Each element in the first-level array stores a pointer referring to the second level, and each second level array stores a big integer (b^v for some window-sized value v).

Our study of such tables shows that for non-trivial decryptions (e.g., decrypt an encrypted message of one character), the lengths of all the second-level arrays are equal to N (we observed that N is fixed to 32 for RSA while 64 for ElGamal implementations evaluated in §7). Hence, elements in the precomputed size table are identical and the attacker would observe the same output regardless of the secret input. In other words, it is reasonable to assume secrets can hardly be leaked by observing the table query outputs. Given such observation, CacheD is optimized to terminate the taint propagation towards the precomputed size table.

Trace Cut. CacheD is designed to analyze any fragment of program execution trace, with a tradeoff of performance and coverage. Ideally, we would like to analyze the entire trace from the program entry point until the end. With taint analysis (§4.2), the analysis effectively starts from the beginning of the function where the key is used for the first time. Besides, for the RSA and ElGamal decryption, where the secret key is used for multiple operations, we choose only critical procedures (i.e., functions implemented the modular exponentiation operation and their callees) that have been the target for various timing attacks. Analyzing the same procedure which has been well-studied from different angles in the literature makes it easier to compare our experiment results (in terms of re-discover existing issue and identify unknown issue) with existing work. On the other hand, there is no issue for CacheD to analyze other standard computation procedures.

Table 1: Cryptosystems analyzed by CacheD.

Algorithm	Implementation	Versions
RSA	Libgcrypt [32]	1.6.1, 1.7.3
	OpenSSL [40]	0.9.7c, 1.0.2f
	Botan [35]	1.10.13
ElGamal	Libgcrypt [32]	1.6.1, 1.7.3
AES	OpenSSL [40]	0.9.7c, 1.0.2f

6 Implementation

CacheD is implemented in Scala, with over 4,800 lines of code. The program execution trace is generated by Pin [36], a widely-used dynamic binary instrumentation tool. Pin provides infrastructures to intercept and instrument the execution of a binary. During execution, Pin inserts the instrumentation code into the original code and recompiles the output leveraging a Just-In-Time (JIT) compiler. We develop a plugin of Pin (162 lines of C++ code) to log the executed instructions as well as the context information during the execution. While our current implementation (including CacheD and the Pin plugin) analyzes binaries on the 32-bit Linux platforms (i.e., binaries with the ELF format), we emphasize that the proposed technique is mostly independent with the underlying architecture details, and hence not difficult to port to other platforms (e.g., Windows or 64-bit Linux).

CacheD leverages the widely-used constraint solver Z3 [18] for constraint solving (Z3 provides Java API, which bridges Z3 solver to our Scala code). In addition, we leverage bit vectors provided by Z3 to represent the taint label of each general-purpose register as well as symbols used in symbolic execution. Note that x86 instructions can manipulate the subset of each register, and benefit from bit vectors, arbitrary operations on the subset of each general-purpose register are supported without additional effort. As aforementioned, we track the taint towards CPU flags; a vector of one bit is created to represent each CPU flag.

7 Evaluation

We evaluate CacheD on several real-world cryptographic libraries. The cryptosystems used in our evaluation are listed in Table 1. In sum, we evaluated CacheD on five real-world cryptosystems in total, including nine different implementations of three cryptographic algorithms, RSA, AES, and ElGamal.

Table 2: Evaluation results of different cryptographic algorithm implementations.

Algorithm	Implementation	Adopt the "Domain Knowledge of RSA and Elgamal" Optimization (§6)	Vulnerable Program Points (known/unknown)	Independent Vulnerable Points (known/unknown)	# of Instructions on the Traces	Processing Time (CPU Seconds)
RSA	Libgcrypt 1.6.1	✓	2/20	2/0	26,848,103	11542.3
RSA	Libgcrypt 1.7.3	✓	0/0	NA	27,775,053	10788.9
ElGamal	Libgcrypt 1.6.1	✓	2/19	2/0	31,077,760	17044.8
ElGamal	Libgcrypt 1.7.3	✓	0/0	NA	31,407,882	12463.1
RSA	OpenSSL 0.9.7c	×	0/2	0/1	674,797	199.3
RSA	OpenSSL 1.0.2f	×	0/2	0/1	473,392	165.6
AES	OpenSSL 0.9.7c	×	48/0	48/0	791	43.4
AES	OpenSSL 1.0.2f	×	32/0	32/0	2,410	48.5
RSA	Botan 1.10.13	✓	0/29	0/2	2,005,124	7527.0
Total			84/72	84/4	120,265,312	59822.9

Experiment setup. All the cryptosystems are C/C++ libraries. We write simple programs to invoke the test libraries for key generation, encryption as well as decryption. We generate keys of 128 bits for AES experiments, and keys of 2048 bits for other experiments. After generating the keys, for all test cryptographic algorithms, we first use their encryption routines to encrypt a plain text "hello world". The encrypted message is then fed into the decryption procedures. As previously introduced, the execution traces of those decryption procedures are logged for analysis. The programs are compiled into binary code on 32-bit Ubuntu 12.04, with gcc/g++ compiler (version 4.6.3).

7.1 Evaluation Result Overview

Vulnerability Identification. We present the breakdown of the positives reported by CacheD in Table 2. As shown in the table, most of the evaluated implementations are reported to contain vulnerabilities that can lead to cache-based side-channel attacks. Overall, CacheD reveal 156 (84 known and 72 unknown) vulnerable program points, among which 88 (84 known and 4 unknown) program points are independent. Considering the large number of issues discovered by CacheD, we interpret the evaluation result as promising.

In general, existing research has pointed out potential issues that can lead to the cache based side-channel attacks on the implementation of sliding-window based modular exponentiation [20], and such implementation is leveraged by both RSA and ElGamal decryption procedures. In this research CacheD has successfully confirmed such already-reported issues. We present a detailed study of two independent vulnerable program points found in RSA implementation of Libgcrypt 1.6.1 in §7.3, and also compare our findings of RSA and ElGamal with existing literatures in §7.4.1. Besides, considering its multiple rounds of table lookup, AES has also been pointed out as vulnerable in terms of cache-based side channel attacks by previous work [15]. CacheD reports consistent findings in §7.4.2.

Moreover, CacheD has also successfully identified a number of vulnerable program points in two widely-used cryptosystems (Botan and OpenSSL). Those vulnerabilities, to the best of our knowledge, are unknown to existing research (the "unknown" issues). We elaborate on these identified issues in §7.5.

We also evaluate CacheD towards the RSA and ElGamal implementations of Libgcrypt 1.7.3, which are considered as safe from information leakage since there is no secret-dependent memory access. CacheD reports no vulnerable program point in both the ElGamal and RSA implementations. Indeed, taint analysis of CacheD identifies **zero** secret-dependent memory access in both implementations. Although trace-based analysis is in general not sufficient to "prove" a cryptosystem as free of information leakage, considering related research as less scalable ([19]), CacheD presents a scalable and practical way to study such industrial strength cryptosystems.

Processing Time. We also report the processing time of CacheD in Table 2. The experiments use a machine with a 2.90GHz Intel Xeon(R) E5-2690 CPU and 128GB memory. Table 2 presents the number of processed instructions and the processing time for each experiment. In general, we evaluate CacheD regarding five industrial-strength cryptosystems, with over **120 million** instructions in total. Table 2 shows that all the experiments can be finished within 5 CPU hours. We interpret the processing time of CacheD as very promising, and this evaluation faithfully demonstrates the high scalability of CacheD in terms of real-world cryptosystems.

Our evaluation also shows the proposed optimizations (§5) are effective, which surely improve the overall scalability of CacheD. Indeed tentative implementation of CacheD (without optimizations) times out after 20 hours to process the ElGamal Libgcrypt 1.6.1 test case. On the other hand, we observed that CacheD becomes slower largely due to the nature of symbolic execution; with more symbolic variables and formulas carried on, every further reasoning can take more time. In addition, since symbolic formulas can grow larger during interpretation (e.g., variables are manipulated for iterations in a loop), solver could probably encounter more challenging problems during further constraint solving. Also, branch con-

Table 3: Gem5 configurations.

ISA	x86
Processor type	single core, out-of-order

AES	OpenSSL 0.9.7c	✓	✓
AES	OpenSSL 1.0.2f	✓	
RSA	Botan 1.10.13	✓	✓

ditions are accumulated along the trace; more constraints need to be solved, which leads to performance penalties as well.

7.2 Exploring the Positives

To study whether the positives can lead to real cache difference during execution, we employ a commonly-used computer architecture simulator—gem5 [9]—to check the identified vulnerable program points. As previously discussed (§5), independent vulnerable program points (88 in total) are considered as mostly informative; "dependent" vulnerable program points would mostly leak the same piece of information as independent ones. Hence in this step, we focus on the check of independent vulnerable program points. While CacheD identifies 8 independent vulnerabilities in the RSA and ElGamal implementations, 80 program points are reported as vulnerable in two AES implementations. Without losing generality, we check all the independent vulnerabilities for RSA and ElGamal, while only checking the first four vulnerabilities for these two AES implementations.

As aforementioned, for each vulnerable program point, the constraint solver provides at least one satisfiable solution (i.e., a pair of $\vec{k}$ and $\vec{k}'$) that leads to the access to different cache lines. Hence, for *each* vulnerable program point, we instrument the source code of the corresponding test program to modify secrets with $\vec{k}$ and $\vec{k}'$; we then compile the source code into two binaries. We monitor the execution of instrumented binaries using the full-system simulation mode of gem5, and intercept cache access from CPU to L1 Data Cache. The full-system simulation uses Ubuntu 12.04 with kernel version 3.2.1.[2] Table 3 presents the configurations.

[2]The full-system simulation mode of gem5 only supports 64-bit kernels. Also, we compiled the instrumented source code into 64-bit binaries since the simulated OS threw some TLB translation exceptions when executing 32-bit binaries.

Results. When executing each vulnerable program point (i.e., a memory access), we record the visited cache line as well as the cache status of this cache line. Table 4 present the results. By comparing cache traffic of executing binaries with secret $\vec{k}$ or $\vec{k}'$, we have confirmed that memory accesses at **all** vulnerable program points indeed visited different cache lines. We have also confirmed that cache statuses are different at the vulnerable program points for most of the test cases.

There are two test cases (row 5 and 7 in Table 4) that show identical cache status at the vulnerable program points. Note that we only record cache status at the memory access of these vulnerable points (some examples are given shortly in Fig. 4c); it is likely that the accesses to different cache lines actually lead to cache behavior variations during further program execution. On the other hand, given our current conservative observation, still, most of the test cases reveal noticeable cache difference. We will present detailed study of the RSA Libgcrypt 1.6.1 (row 2 in Table 4) in §7.3.

In general, we consider the evaluation results as quite promising; while previous work (e.g., [19]) performs overall reasoning of the program information leakage upper bound and lack of information on what/where the vulnerability is, CacheD fills the gap by providing concrete examples to trigger cache behavior variations at its discovered program points.

7.3 Case Study of RSA Vulnerabilities

In this section, we present a case study of two identified vulnerable program points, with detailed explanation in terms of the source code patterns as well as hardware simulation results.

As presented in Table 2, we identified two independent vulnerable program points in the RSA implementation of Libgcrypt 1.6.1. Source code shown in Fig. 4a is found in the sliding-window implementation of the modular exponentiation algorithm; we have confirmed that two identified independent vulnerable program points represent table queries at line 13 and 14. Indeed, `e` is an element of the secret array (line 5; thus `e` is secret), and `e0` is a sliding window of `e` (line 9). `e0` is used to access the first level of the precomputed table (line 13) and precomputed size table (line 14). Intuitively, different `e0` accesses different table entries, which potentially leads to different cache line and eventually leaks the secret (i.e., `e`).

When analyzing the execution trace, CacheD successfully identified two secret-dependent memory accesses (line 4-5 in Fig. 4b), and by inquiring the constraint solver, CacheD finds two pairs of `e` that can lead to the access of different cache lines for the first and second memory accesses, respectively (the "solutions" in

```

(c) Hardware simulation results for the first memory access (e is 0x10000016 and e' is 0x1000003e).

Figure 4: Case study of two independent RSA vulnerable program points in Libgcrypt 1.6.1. The vulnerable program points and the corresponding memory access instructions on the trace are **bold**. The tainted variable in source code and trace are red, and `e` is secret (line 5 in Fig. 4a). Note that `base_u_size` is not tainted regarding the optimization of RSA precomputed size table (§5).

Fig. 4b). To confirm the findings, we compile four program binaries with modified `e` regarding the solutions.

Fig. 4c shows the simulation outputs using gem5. Due to the limited space, we only provide the first eight records for the first vulnerable program point (there are 604 records in total). The first column of each output represents the program counters; the second column shows the accessed memory addresses and the last column is the cache statuses of the accessed cache lines. Note that program counter 0x44156a and 0x441572 represent the first and second vulnerable program points, respectively. Comparing these two results, we can observe that different cache lines are accessed (corresponding memory addresses are marked as red at line 1-2), which further leads to timing difference of three cache hit vs. miss (corresponding cache statuses are marked as red at line 5-7). Simulation results for the second memory access are omitted due to the limited space. We report to have similar observations.

Consistent with the existing findings, these two table queries are also reported as vulnerable by previous work [20]. According to our taint policy, the table query output (`base_u`) would be tainted since `e0` is tainted. Our study also shows that memory access through `base_u` would reveal another twenty vulnerable program points (row 2 in Table 2). Moreover, this modular exponentiation function is used by both RSA and ElGamal decryption procedures; two independent vulnerable program points found in the ElGamal implementation (row 4 in Table 2) are also due to these table queries.

7.4 Known Vulnerabilities

We also evaluate CacheD by confirming known side-channel vulnerabilities.

7.4.1 RSA and ElGamal in Libgcrypt

Function `_gcry_mpi_powm` (Fig. 4a) found in the Libgcrypt (1.6.1) sliding-window implementation of the modular exponentiation algorithm is vulnerable. Note that such implementation indeed is used by both RSA and ElGamal decryption procedures. We have already presented results and a case study in §7.3. Besides those two independent program points, CacheD finds 19 vulnerable program points in the ElGamal implementation and 20 points in the RSA implementation Table 2.

Consistent with previous work [20], CacheD confirms two vulnerable program points in the Libgcrypt (1.6.1) that can lead to cache-based timing attacks. On the other hand, while previous work [20] only reports potential timing channels through these two direct usage of secrets, CacheD can actually detect further unknown (to the best of our knowledge) pitfalls (around 20 unknown points for each). The results show that CacheD can provide developers with more comprehensive information regarding side-channel issues.

7.4.2 AES in OpenSSL

We also analyzed the positive results identified in AES implementations of OpenSSL (version 0.9.7c and 1.0.2f). In general, standard AES decryption undertakes

a three-step approach for decryption, in which the second and third steps consist of (multiple rounds) lookup table queries through blocks of secrets. Intuitively, such secret-dependent table queries could reveal considerable amount of timing-channel vulnerabilities.

Our evaluation has confirmed this intuition. CacheD successfully identifies 48 vulnerable program points for OpenSSL (0.9.7c). Indeed all of the identified program points are lookup table queries through secrets, which is consistent with previous research [15]. Analysis of another OpenSSL (1.0.2f) gave similar results: CacheD identifies 32 vulnerable program points of secret-dependent lookup table queries (Table 2).

7.5 Unknown Vulnerabilities

CacheD also successfully identifies several potential vulnerabilities that have not been reported in public, to the best of our knowledge.

7.5.1 RSA in OpenSSL

CacheD reported two positive results in each OpenSSL implementation (version 0.9.7c and version 1.0.2f) of the RSA decryption procedure. CacheD further identified one independent vulnerable point for each implementation. Appendix C presents the source code in which the independent positive is discovered. Before performing the modular exponentiation, function `BN_num_bits` calculates the length of the secret key by bit. The secret key information is represented by a `BIGNUM` structure pointed by `a`, with the key value stored in a byte buffer `a->d` and the length of the buffer stored in `a->top`, respectively. Since the key length by bit may not be a multiple of the key length by byte, the code uses a lookup table in `BN_num_bits_word` to determine the exact number of bits in the last entry of `a->d`. CacheD points out that accessing this lookup table will lead to a cache difference, thus leaking information about the most significant several bits of the secrete key which are stored in `a->d[a->top - 1]`. Results in §7.2 also support our finding. In addition, CacheD also identified another vulnerable program point which is derived from the output of this table query (row 6-7 in Table 2).

We also find the same implementation that could lead to timing channels in its most recent releases (released in late Sep. 2016): version 1.0.2j, version 1.1.0b, and version 1.0.1u.

7.5.2 RSA Implementation in Botan

Another vulnerability found by CacheD is in the Botan (1.10.13) implementation of RSA, whose source code is shown in Appendix D. The Montgomery exponentiator is an algorithm for modular exponentiation. Similar to the Libgcrypt (1.6.1) implementation of RSA (Fig. 4a), a precomputed table is employed to cache some intermediate results and a sliding window of the secret key is used to query the table (line 9). The queried output is maintained as a `BigInt` class instance and it is represented as a symbol of the key according to our taint propagation rules (§4.3). Later, when the class method `sig_words` is invoked (line 13), two memory accesses (line 19-20) through the key symbol are captured by CacheD (note that `reg` at line 19 is a private variable of class `BigInt`).

Our constraint solver has proved that there are multiple satisfiable solutions for both the first and the second memory access (line 19-20). Moreover, by employing different secrets provided by the solver, we report to observe cache behavior variations in the hardware simulator (§7.2). In addition, the memory query output (`x` at line 19) is used to access memories later, which results into 27 "dependent" vulnerable program points (row 10 in Table 2).

Besides the implementations evaluated in this work (version 1.10.13), we notice that this vulnerability affects several other versions of Botan, including 1.10.12, 1.10.11, and 1.11.33.

8 Related Work

8.1 Timing attacks

One major motivation for controlling timing channels is the protection of cryptographic keys against side-channels arising from timing attacks. Since the seminal paper of Kocher [30], attacks that exploit timing channels have been demonstrated on RSA [13, 30, 3, 45, 59], AES [24, 42, 53] and ElGamal [63].

Shared data cache is shown to be a rich source of timing channels. The potential risk of cache-based timing channels was first identified by Hu [26]. Around 2005, real cache-based timing attacks are demonstrated on AES [8, 42], and RSA [45]. Since then, more practical timing attacks are emerging. Previous work shows the practicality of various timing attacks utilizing the shared data: among VMs in multi-tenant cloud [50]. Timing attacks are shown to be a potential risk across VMs [57, 56, 47], and more evidence is emerging showing practical timing attacks that break crypto systems [63, 59, 34]. Recent work [41] presents a successful cache attack where the victim merely has to access a website owned by the attacker.

8.2 Mitigation of cache-based timing channels

Much prior application-level mitigation only handles timing leakage due to secret-dependent control flows [4, 25, 38, 7, 17, 44]. However, as shown in recent cache-based timing attacks [24, 42, 53, 59, 34], subtle timing leakage survives even with the absence of secret-dependent control flows. Recently, advanced program analyses are proposed to identify those subtle cache-based timing channels [6, 19, 20, 60], but they only provide an upper-bound on timing-based information leakage; it is unclear what/where the vulnerability is when those tools report a non-zero upper bound.

At the system level, Düppel [64] clears L1 and L2 cache before context switching; but it cannot mitigate the last-level cache-based attack, such as [34]. StealthMem [21, 29] manages a set of locked cache lines per core, which are never evicted from the cache. But its security relies on the assumption that "crucial" data was identified in the first place. But doing so nontrivial. For instance, the crucial data in AES is the lookup table, which only stores public data.

At the hardware level, one direction of mitigating cache-based timing channels is to either physically or logically partition the data cache [43, 54, 31, 61]. Line-locking cache was also implemented in hardware [54]. New hardware designs, such as RPCache [54], NewCache [55], and random fill cache [33], inject random noises to cache delay to confuse attackers. Common to those hardware-based mitigation mechanisms is the assumption that "crucial" data was identified by the software, where CacheD can be helpful.

9 Conclusion

To help developers improve the implementations of software that is sensitive to information leakage, we have developed a tool called CacheD to detect potential timing channels caused by the differences of cache behavior. With the help of symbolic execution techniques, CacheD models the memory addresses at each program point as logical formulas so that constraint solvers can check whether sensitive program data affects cache behavior, thus revealing potential timing channels. CacheD is scalable enough for analyzing real-world cryptosystems with decent accuracy. We have evaluated a prototype of CacheD with a set of widely used cryptographic algorithm implementations. CacheD is able to detect a considerable number of side-channel vulnerabilities, some of which are previously unknown to the public.

B Structure of Two-level Precomputed Table and Precomputed Size Table

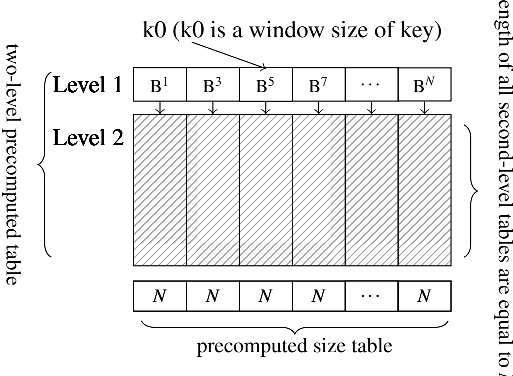

Figure 5: Two-level precomputed table and precomputed size table used in RSA and ElGamal. Our observation shows that the length of all the second-level precomputed tables are equal in non-trivial decryption processes of RSA and ElGamal. In other words, attackers can hardly infer `k0` by observing query outputs of the precomputed size table.

C Unknown RSA Vulnerabilities in OpenSSL

```
1  int BN_num_bits(const BIGNUM *a) {
2    BN_ULONG l;
3    int i;
4
5    bn_check_top(a);
6
7    if (a->top == 0) return(0);
8    l=a->d[a->top-1];
9    assert(l != 0);
10   i=(a->top-1)*BN_BITS2;
11   return(i+BN_num_bits_word(l));
12 }
13
14 int BN_num_bits_word(BN_ULONG l) {
15   static const char bits[256]={
16     0,1,2,2,3,3,3,3,4,4,4,4,4,4,4,4,
17     5,5,5,5,5,5,5,5,5,5,5,5,5,5,5,5,
18     ...
19     8,8,8,8,8,8,8,8,8,8,8,8,8,8,8,8,
20     8,8,8,8,8,8,8,8,8,8,8,8,8,8,8,8,
21   };
22   ....
23   return bits[l];
24 }
```

Figure 6: Unknown RSA vulnerabilities found in OpenSSL (version 0.9.7c and 1.0.2f). The tainted variable (i.e., secret) `l` is red and the vulnerable program point is **bold**.

D Unknown RSA Vulnerabilities in Botan

```
1  BigInt Montgomery_Exponentiator::execute() const {
2   ...
3   for(size_t i = exp_nibbles; i > 0; --i) {
4    ...
5    const u32bit nibble = exp.get_substring(
6    window_bits*(i-1), window_bits);
7
8    //note that the following code is not a mem access
9    const BigInt& y = g[nibble];
10
11   bigint_monty_mul(&z[0], z.size(),
12                x.data(), x.size(), x.sig_words(),
13                y.data(), y.size(), y.sig_words(),
14    ...
15   }
16 }
17
18 size_t sig_words() const {
19   const word* x = &reg[0];
20   size_t sig = reg.size();
21   ...
22 }
```

Figure 7: Unknown RSA vulnerabilities found in the Montgomery exponentiator of Botan (version 1.10.13). Tainted variables are marked as red and the vulnerable program points are **bold**. `sig` is not tainted according to the optimization of RSA precomputed size table (§5).

BinSim: Trace-based Semantic Binary Diffing via System Call Sliced Segment Equivalence Checking

Jiang Ming

Abstract

Detecting differences between two binary executables (binary diffing), first derived from patch analysis, have been widely employed in various software security analysis tasks, such as software plagiarism detection and malware lineage inference. Especially when analyzing malware variants, pervasive code obfuscation techniques have driven recent work towards determining semantic similarity in spite of ostensible difference in syntax. Existing ways rely on either comparing runtime behaviors or modeling code snippet semantics with symbolic execution. However, neither approach delivers the expected precision. In this paper, we propose *system call sliced segment equivalence checking*, a hybrid method to identify fine-grained semantic similarities or differences between two execution traces. We perform enhanced dynamic slicing and symbolic execution to compare the logic of instructions that impact on the observable behaviors. Our approach improves existing semantics-based binary diffing by 1) inferring whether two executable binaries' behaviors are conditionally equivalent; 2) detecting the similarities or differences, whose effects spread across multiple basic blocks. We have developed a prototype, called *BinSim*, and performed empirical evaluations against sophisticated obfuscation combinations and more than 1,000 recent malware samples, including now-infamous crypto ransomware. Our experimental results show that BinSim can successfully identify fine-grained relations between obfuscated binaries, and outperform existing binary diffing tools in terms of better resilience and accuracy.

1 Introduction

An inherent challenge for reverse engineering is the source code of the program under examination is typically absent. The binary executable becomes the only available resource to be analyzed. The techniques to detect the difference between two executables (binary diffing) have been applied to a broad range of reverse engineering tasks. For example, the difference between a pre-batched binary and its updated version reveals the fixed vulnerability [23, 54], and such information can be exploited by attackers to quickly generate "1-day" exploit [9, 50]. The similarity between an intellectual property protected binary and a suspicious binary indicates a potential case of software plagiarism [41, 73]. A more appealing application emerges in malware analysis. According to the latest Panda Security Labs study [53], many malware samples in circulation are not brand new but rather evolutions of previously known malware code. Relentless malware developers typically apply various obfuscation schemes (e.g., packer, polymorphism, metamorphism, and code virtualization) [51, 57] to camouflage arresting features, circumvent malware detection, and impede reverse engineering attempts. Therefore, an obfuscation-resilient binary diffing method is of great necessity.

Pervasive code obfuscation schemes have driven binary diffing methods towards detecting semantic similarity despite syntactical difference (e.g., different instruction sequences or byte N-grams). Existing semantics-aware binary diffing can be classified into two categories. The first one compares runtime execution behaviors rather than instruction bytes. Since dynamic analysis has good resilience against code obfuscation [48], there has been a notable amount of work to measure the similarities of program behavior features, such as system call sequences and dependency graphs [6, 12, 14]. However, the program of interest may not involve unique system call sequence [73]. Furthermore, dynamic-only methods neglect subtle differences that do not reflect on the behavior change. In that case, two matched system calls may carry different meanings.

The second category relies on measuring the semantics of two pieces of binary code [54, 41, 37, 25, 43], which is usually based on basic block semantics mod-

eling. At a high level, it represents the input-output relations of a basic block as a set of symbolic formulas, which are later proved by either a constraint solver [41, 15, 25, 43], random sampling [54] or hashing [37] for equivalence. Although these tools are effective against moderate obfuscation within a basic block, such as register swapping, instruction reordering, instruction substitution, and junk code insertion [51], they exhibit a common "block-centric" limitation [13, 37]; that is, it is insufficient to capture the similarities or differences that go beyond a single basic block boundary. This issue stems from the fact that the effect of code transformations spreads across basic blocks, such as return-oriented programming encoding [40, 55], virtualization obfuscation's decode-dispatch loop [61], covert computation [59], and different implementation algorithms [56].

In this paper, we propose a hybrid method, *BinSim*, to address the limitations of existing binary diffing approaches. We attempt to identify fine-grained relations between obfuscated binary code. BinSim leverages a novel concept and technique called *System Call Sliced Segments* and their *Equivalence Checking*. This new technique relies on system or API calls[1] to slice out corresponding code segments and then check their equivalence with symbolic execution and constraint solving. Starting from the observable behavior, our approach integrates symbolic execution with dynamic backward slicing to compare the behavior-related instruction segments. We find that two matched system calls together with their arguments may carry different meanings. Our approach can answer whether two matched API calls are *conditional equivalent* [31]. Note that the behavior-related instruction segments typically bypass the boundary of a basic block so that we are more likely to detect similarities or differences that spread across basic blocks.

More precisely, we run two executables in tandem under the same input and environment to record their detailed execution data. Then, we rely on an advanced bioinformatics-inspired approach [34] to perform system call sequence alignment. After that, we trace back from the arguments of the matched system calls to determine instructions that directly (data flow) or indirectly (control flow) impact on the argument values. However, the standard dynamic slicing algorithm [80] does not suffice to operate at the obfuscated binaries. Our enhanced backward slicing considers many tricky issues and deals with obfuscation schemes that cause undesired slice explosion. Next, we calculate weakest preconditions (WP) along the dynamic slice. The resulting WP formulas accumulated in the two slices are then submitted to a constraint solver to verify whether they are equivalent. Now determining whether two matched system calls are truly equivalent under current path conditions boils down to a query of equivalence checking.

We have developed a prototype of BinSim on top of the BitBlaze [66] binary analysis platform. Experimental results on a range of advanced obfuscation schemes are encouraging. Compared with a set of existing binary diffing tools, BinSim exhibits better resilience and accuracy. We also evaluate BinSim and existing tools on more than $1,000$ recent malware samples, including highly dangerous and destructive crypto-ransomware (e.g., CryptoWall) [32, 33, 58]. The results show that BinSim can successfully identify fine-grained relations between obfuscated malware variants. We believe BinSim is an appealing method to complement existing malware defenses.

Scope and Contributions BinSim is mainly designed for fine-grained individual binary diffing analysis. It is an ideal fit for security analysts who need further investigation on two suspicious binaries. The previous work on large-scale coarse-grained malware comparison [6, 28] is orthogonal and complementary to BinSim. In summary, the contributions of this paper are as follows.

- BinSim presents a novel concept, System Call Sliced Segment Equivalence Checking, that relies on system or API calls to slice out corresponding code segments and then checks their equivalence with symbolic execution and constraint solving.
- BinSim can detect the similarities or differences across multiple basic blocks. Therefore, BinSim overcomes the "block-centric" limitation (Existing Method 2) to a great extent. Compared to dynamic-only approaches (Existing Method 1), BinSim provides more precise results, such as whether two programs' behaviors are conditionally equivalent.
- Performing dynamic slicing on the obfuscated binaries is rather tricky and complicated. The redundant instructions introduced by indirect memory access and fake control/data dependency can poison the slicing output. We improve the standard algorithm to produce more precise result.
- Unlike previous work that evaluates the efficacy of binary diffing either on different program versions [7, 25, 49], different compiler optimization levels [21, 41] or considerably moderate obfuscation [37, 41], we evaluate BinSim rigorously against sophisticated obfuscation combinations and recent malware. To the best of our knowledge, this is the first work to evaluate binary diffing in such scale.

[1]The system calls in Windows are named as native API. We also consider part of Windows API calls as a proxy for system calls.

2 Motivation and Overview

In this section, we first discuss the drawbacks of current semantics-aware binary diffing approaches. This also inspires us to propose our method. We will show C code for understanding motivating examples even though BinSim works on binary code. At last, we introduce the architecture of BinSim.

2.1 Motivation

Binary diffing methods based on behavior features (e.g., system call sequence or dependency graph) are prevalent in comparing obfuscated programs, in which the accurate static analysis is typically not feasible [48]. However, such dynamic-only approaches may disregard some real different semantics, which are usually caused by instruction level execution differences. Figure 1 presents such a counterexample, which lists three similar programs in the view of source code and their system call dependencies. Given any input $x \geq 0$, the three system call sequences (`NtCreateFile` $\rightarrow$ `NtWriteFile` $\rightarrow$ `NtClose`) together with their arguments are identical. Besides, these three system calls preserve a data flow dependency as well: one's return value is passed to another's in-argument (as shown in Figure 1(d)). Therefore, no matter comparing system call sequences or dependency graphs, these three programs reveal the same behavior. However, if we take a closer look at line 3 and 4 in Figure 1(b), the two statements are used to calculate the absolute value of x. That means the input value y for `NtWriteFile` in Figure 1(a) and Figure 1(b) differs when $x < 0$. In another word, these two programs are only *conditionally equivalent*. Note that by random testing, there is only about half chance to find Figure 1(a) and Figure 1(b) are different. Recently, the "query-then-infect" pattern has become common in malware attacks [77], which only target specific systems instead of randomly attacking victim machines. When this kind of malware happens to reveal the same behavior, dynamic-only diffing methods may neglect such subtle conditional equivalence and blindly conclude that they are equivalent under all conditions.

Another type of semantics-aware binary diffing utilizes symbolic execution to measure the semantics of the binary code. The core of current approaches is matching semantically equivalent basic blocks [25, 37, 41, 43, 54]. The property of straight-line instructions with one entry and exit point makes a basic block a good fit for symbolic execution (e.g., no path explosion). In contrast, symbolic execution on a larger scope, such as a function, has two challenges: 1) recognizing function boundary in stripped binaries [5]; 2) performance bottleneck even on the moderate size of binary code [46]. Such block-centric methods are effective in defeating instruction obfuscation within a basic block. Figure 2 presents two equivalent basic blocks whose instructions are syntactically different. Their output symbolic formulas are verified as equivalent by a constraint solver (e.g., STP [24]). However, there are many cases that the semantic equivalence spread across the boundary of a basic block. Figure 3 presents such an example, which contains three different implementations to count the number of bits in an unsigned integer (`BitCount`). Figure 3(a) and Figure 3(b) exhibit different loop bodies, while Figure 3(c) has merely one basic block. Figure 3(c) implements `BitCount` with only bitwise operators. For the main bodies of these three examples, we cannot even find matched basic blocks, but they are indeed semantically equivalent. Unfortunately, current block-centric binary diffing methods fail to match these three cases. The disassembly code of these three `BitCount` algorithms are shown in Appendix Figure 11.

Figure 4 shows another counterexample, in which the semantic difference spreads across basic blocks. When a basic block produces multiple output variables, existing block-centric binary diffing approaches try all possible permutations [54, 41, 25] to find a bijective mapping between the output variables. In this way, the two basic block pairs in Figure 4 (BB1 vs. BB1' and BB2 vs. BB2') are matched. Please note that the input variables to BB2 and BB2' are switched. If we consider the two sequential executed basic blocks as a whole, they will produce different outputs. However, the current block-centric approach does not consider the context information such as the order of matched variables. Next, we summarize possible challenges that can defeat the block-centric binary diffing methods.

1. The lack of context information such as Figure 4.

2. Compiler optimizations such as loop unrolling and function inline, which eliminate conditional branches associated.

3. Return-oriented programming (ROP) is originally designed as an attack to bypass data execution prevention mechanisms [60]. The chain of ROP gadgets will result in a set of small basic blocks. ROP has been used as an effective obfuscation method [40, 55] to clutter control flow.

4. Covert computation [59] utilizes the side effects of microprocessors to hide instruction semantics across a set of basic blocks.

5. The same algorithm but with different implementations such as Figure 3, Figure 12, and Figure 13. More examples can be found in Hacker's

```
1: int x, y; // x is an input
2: HANDLE out = CreateFile("a.txt", ...);
3: y = x + x;
4: WriteFile(out, &y, sizeof y, ...);
5: CloseHandle(out);
```

(a)

```
1: int x, y, z; // x is an input
2: HANDLE out = CreateFile("a.txt", ...);
3: z = (x >> 31);
4: z = (x ^ z) - z; // z is the absolute value of x
5  y = 2 * z;
6: WriteFile(out, &y, sizeof y, ...);
7: CloseHandle(out);
```

(b)

```

(d) System call (Windows native API) sequence and dependency

Figure 1: Example: system calls are conditional equivalent.

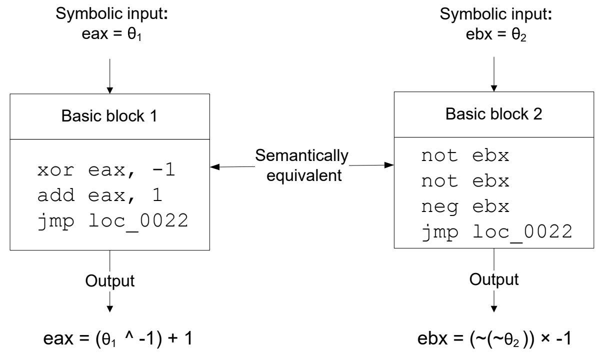

Figure 2: Semantically equivalent basic blocks with different instructions.

Delight [74], which is a collection of programming optimization tricks with bitwise operations.

6. Control flow obfuscation schemes, such as opaque predicates [17] and control flow flattening [71], can break up one basic block into multiple ones.

7. Virtualization obfuscation decode-dispatch loop [61, 79] generates a sequence of basic blocks to interpret one x86 instruction. This difficulty is further exacerbated by multi-level virtualization.

BinSim's hybrid approach can naturally break basic block boundaries and link related instructions. However, we have to take extra efforts to address the last two challenges. We will discuss them in Section 4.

2.2 Methodology

Figure 5 illustrates BinSim's core method. Given two programs P and P', our approach performs dynamic analysis as well as symbolic execution to compare how the matched system call arguments are calculated, instead of their exhibited values. We first run P and P' in tandem under the same input and environment to collect the logged traces together with their system call sequences. Then we do the system call sequences alignment to get a list of matched system call pairs (step 1). Another purpose of system call alignment is to fast identify programs exhibiting very different behaviors. After that, starting from the matched system calls arguments, we conduct backward slicing on each logged trace to identify instructions that affect the argument both directly (data flow) and indirectly (control flow). We extend the standard dynamic slicing algorithm to deal with the challenges when working on obfuscated binaries. Next, we compute the weakest precondition (WP) along each slice (step 2). In principle, WP is a symbolic formula that captures the data flow and control flow that affect the calculation of the argument. However, cryptographic functions typically generate complicated symbolic representations that could otherwise be hard to solve. To walk around this obstacle, we identify the possible cryptographic functions from the sliced segments and decom-

```

2: {
3:   unsigned int count = 0;
4:   for (count = 0; n; n >>= 1)
5:     count += n & 1 ;
6:   printf ("%d", count);
7: }
```

(a)

```
1: void BitCount2(unsigned int n)
2: {
3:   unsigned int count = 0;
4:   while (n != 0 ) {
5:       n = n & (n-1);
6:       count++;
7:     }
8:   printf ("%d", count);
9: }
```

(b)

```
1: void BitCount3(unsigned int n)
2: {
3:   n = (n & (0x55555555)) +
       ((n >> 1) & (0x55555555));
4:   n = (n & (0x33333333)) +
       ((n >> 2) & (0x33333333));
5:   n = (n & (0x0f0f0f0f)) +
       ((n >> 4) & (0x0f0f0f0f));
6:   n = (n & (0x00ff00ff)) +
       ((n >> 8) & (0x00ff00ff));
7:   n = (n & (0x0000ffff)) +
       ((n >> 16) & (0x0000ffff));
8:   printf ("%d", n);
9: }
```

(c)

Figure 3: Semantic equivalence spreads across basic blocks.

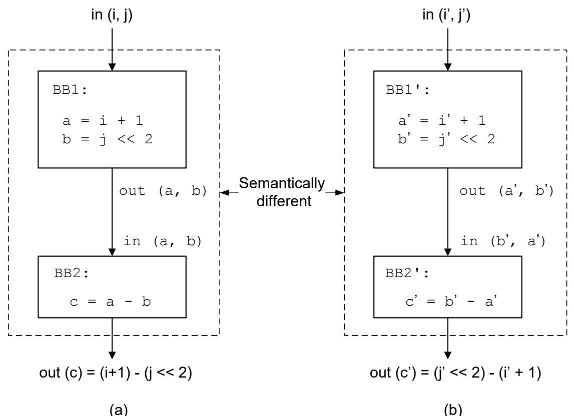

Figure 4: Semantic difference spreads across basic blocks.

pose them from equivalence checking (step 3). Then we utilize a constraint solver to verify whether two WP formulas are equivalent (step 4). Following the similar style, we compare the remaining system call pairs. At last, we perform an approximate matching on identified cryptographic functions (step 5) and calculate the finial similarity score.

Now we use the examples shown in Section 2.1 to describe how BinSim improves existing semantics-based binary diffing approaches. Assume we have got the aligned system call sequences shown in Figure 1(d). Starting from the address of the argument y in `NtWriteFile`, we do backward slicing and compute WP with respect to y. The results of the three programs are shown as follows.

$$\psi_{1a}:\ x+x$$
$$\psi_{1b}:\ 2\times((x\wedge(x>>31))-(x>>31))$$
$$\psi_{1c}:\ x<<1$$

To verify whether $\psi_{1a}=\psi_{1b}$, we check the equivalence of the following formula:

$$x+x\ =\ 2\times((x\wedge(x>>31))-(x>>31)) \qquad (1)$$

Similarly, we check whether $\psi_{1a}=\psi_{1c}$ by verifying the formula:

$$x+x\ =\ x<<1 \qquad (2)$$

The constraint solver will prove that Formula 2 is always true but Formula 1 is not. Apparently, we can find a counterexample (e.g., $x=-1$) to falsify Formula 1. Therefore, we have ground truth that the `NtWriteFile` in Figure 1(a) and Figure 1(c) are truly matched, while `NtWriteFile` in Figure 1(a) and Figure 1(b) are *conditionally equivalent* (when the input satisfies $x\geq 0$).

For the three different implementations shown in Figure 3, BinSim works on the execution traces under the same input (n). In this way, the loops in Figure 3 have been unrolled. Starting from the output argument, the resulting WP captures the semantics of "bits counting" across basic blocks. Therefore, we are able to verify that the three algorithms are equivalent when taking the same unsigned 32-bit integer as input. Similarly, we can verify that the two code snippets in Figure 4 are not semantically equivalent.

2.3 Architecture

Figure 6 illustrates the architecture of BinSim, which comprises two stages: online trace logging and offline comparison. The online stage, as shown in the left side of Figure 6, involves two plug-ins built on Temu [66], a whole-system emulator: *generic unpacking* and *on-demand trace logging*. Temu is also used as a malware execution sandbox in our evaluation. The recorded traces are passed to the offline stage of BinSim for comparison (right part of Figure 6). The offline stage consists of three components: preprocessing, slicing and WP calculation, and segment equivalence checker. Next, we will present each step of BinSim in the following two sections.

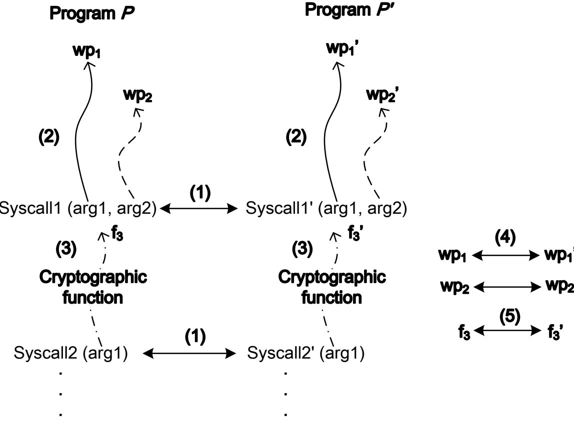

Figure 5: System call sliced segment equivalence checking steps: (1) system call alignment; (2) dynamic slicing and weakest precondition calculation; (3) cryptographic function detection; (4) equivalence checking; (5) cryptographic function approximate matching.

3 On-demand Trace Logging

BinSim's online logging stage records the needed information for the subsequent steps. The logged trace data consist of three parts: 1) instruction log contains each executed instruction's x86 opcode and values of operands; 2) memory log stores memory access addresses, which facilitate binary code slicing; 3) system calls invoked and their data flow dependencies. In general, not all of the trace data are of interest. For example, a common optimization adopted by the offline symbolic execution is "function summary" [10]. For some well-known library functions that have explicit semantics (e.g., string operation functions), we can turn off logging when executing them and generate a symbolic summary correspondingly in the offline analysis. Another example is many malware samples exhibit the malicious behavior only after the real payload is unpacked. Our generic unpacking plug-in, similar to the hidden code extractor [30], supports recording the execution trace that comes from real payload instead of various unpacking routines.

One common attack to system call recording is adding irrelevant system calls on purpose, which can also poison the system call sequences alignment. To remove system call noises, we leverage Temu's customizable multi-tag taint tracking feature to track data flow dependencies between system calls. Kolbitsch et al. [36] have observed three possible sources of a system call argument: 1) the output of a previous system call; 2) the initialized data section (e.g., `.bss` segment); 3) the immediate argument of an instruction (e.g., `push 0`). Except for the immediate argument, we label the system call outputs and the value read from the initialized data section as different taint tags. In this way, the irrelevant system calls without data dependency will be filtered out. The tainted arguments of aligned system call will be taken as the starting point of our backward slicing.

We also consider the parameter semantics. For example, although *NtClose* takes an integer as input, the source of the parameter should point to an already opened device rather than an instruction operand (see Figure 1). Therefore, the fake dependency such as "`xor eax, eax; NtClose(eax);`" will be removed. Another challenge is malware could invoke a different set of system calls to achieve the same effect. Recent work on "replacement attacks" [44] shows such threat is feasible. We will discuss possible workaround in Section 6.

4 Offline Analysis

4.1 Preprocessing

When the raw trace data arrive, BinSim first lifts x86 instructions to Vine IL. The static single assignment (SSA) style of Vine IL will facilitate tracking the use-def chain when performing backward slicing. Besides, Vine IL is also side effect free. It explicitly represents the setting of the `eflags` register bits, which favors us to identify instructions with implicit control flow and track ROP code. For example, the carry flag bit (cf) is frequently used by ROP to design conditional gadget [60].

Then we align the two collected system call sequences to locate the matched system call pairs. System call sequence alignment has been well studied in the previous literature [34, 76]. The latest work, MalGene [34], tailors Smith-Waterman local alignment algorithm [65] to the unique properties of system call sequence, such as limited alphabet and sequence branching caused by thread scheduling. Compared to the generic longest common subsequences (LCS) algorithm, MalGene delivers more accurate alignment results. There are two key scores in Smith-Waterman algorithm: *similarity function on the alphabet* and *gap penalty scheme*. MalGene customizes these two scores for better system call alignment.

Our system call alignment adopts a similar approach as MalGene [34] but extends the scope of *critical system calls*, whose alignments are more important than others. Since MalGene only considers the system call sequence deviation of the same binary under different runtime environments, the critical system calls are subject to process and thread operations. In contrast, BinSim focuses on system call sequence comparisons of polymorphic or metamorphic malware variants. Our critical system calls include more key system object operations. Appendix Table 7 lists some examples of critical system calls/Windows API we defined. Note that other system call comparison methods, such as dependency graph iso-

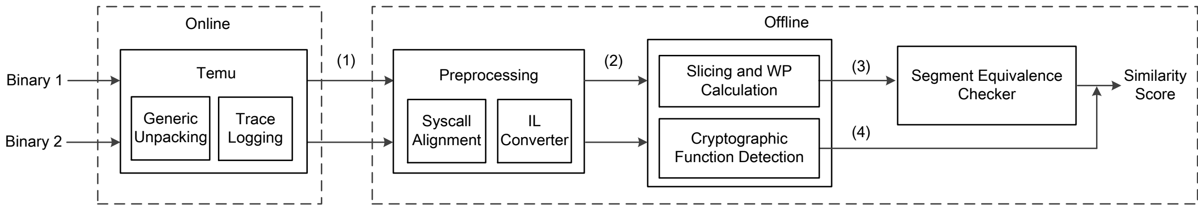

Figure 6: Schematic overview of BinSim. The output for each processing: (1) unpacked code, instruction log, memory log, and system call sequences; (2) IL traces and initial matched system call pairs; (3) weakest preconditions of system call sliced segments; (4) identified cryptographic functions.

morphism [14] and tree automata inference [3] are orthogonal to our approach.

4.2 Dynamic Slicing Binary Code

After system calls alignment, we will further examine the aligned system calls to determine whether they are truly equivalent. To this end, commencing at a tainted system call's argument, we perform dynamic slicing to backtrack a chain of instructions with data and control dependencies. The slice criterion is ⟨eip, argument⟩, while `eip` indicates the value of instruction pointer and `argument` denotes the argument taken as the beginning of backwards slicing. We terminate our backward slicing when the source of slice criterion is one of the following conditions: the output the previous system call, a constant value, or the value read from the initialized data section. Standard dynamic slicing algorithm [1, 80] relies on program dependence graph (PDG), which explicitly represents both data and control dependencies. However, compared to the source code slicing, dynamic slicing on the obfuscated binaries is never a textbook problem. The indirect memory access of binary code will pollute the conventional data flow tracking. Tracking control dependencies in the obfuscated binary code by following explicit conditional jump instructions is far from enough. Furthermore, the decode-dispatch loop of virtualization obfuscation will also introduce many fake control dependencies. As a result, conventional dynamic slicing algorithms [1, 80] will cause undesired slice explosion, which will further complicate weakest precondition calculation. Our solution is to split data dependencies and control dependencies tracking into three steps: 1) index and value based slicing that only consider data flow; 2) tracking control dependencies; 3) remove the fake control dependencies caused by virtualization obfuscation code dispatcher.

BinSim shares the similar idea as Coogan et al. [19] in that we both decouple tracing control flow from data flow when handling virtualization obfuscation. Coogan et al.'s approach is implemented through an equational reasoning system, while BinSim's dynamic slicing is built on an intermediate language (Vine IL). However, BinSim is different from Coogan et al.'s work in a number of ways, which we will discuss in Section 7.

4.2.1 Index and Value Based Slicing

We first trace the instructions with data dependencies by following the "use-def" chain (ud-chain). However, the conventional ud-chain calculation may result in the precision loss when dealing with indirect memory access, in which general registers are used to compute memory access index. There are two ways to track the ud-chain of indirect memory access, namely *index based* and *value based*. The index based slicing, like the conventional approach, follows the ud-chain related the memory index. For the example of `mov edx [4*eax+4]`, the instructions affecting the index `eax` will be added. Value based slicing, instead, considers the instructions related to the value stored in the memory slot. Therefore, the last instruction that writes to the memory location `[4*eax+4]` will be included. In most cases, the value based slicing is much more accurate. Figure 7 shows a comparison between index based slicing and value based slicing on the same trace. Figure 7(a) presents the C code of the trace. In Figure 7(b), index based slicing selects the instructions related to the computation of memory index `j = 2*i + 1`. In contrast, value based slicing in Figure 7(c) contains the instructions that is relevant to the computation of memory value `A[j] = a + b`, which is exactly the expected slicing result. However, there is an exception that we have to adopt index based slicing: when an indirect memory access is a valid index into a jump table. Jump tables typically locate at read-only data sections or code sections, and the jump table contents should not be modified by other instructions. Therefore, we switch to track the index ud-chain, like `eax` rather than the memory content.

4.2.2 Tracking Control Dependency

Next, we include the instructions that have control dependencies with the instructions in the last step. In addition to explicit conditional jump instructions (e.g., `je`

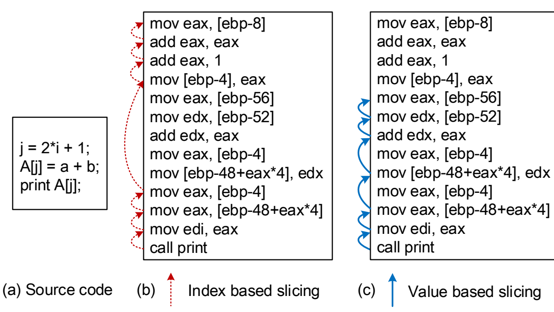

Figure 7: Index based vs. Value based slicing.

and `jne`), obfuscators may hide control flow into indirect jumps by using encoding function to calculate the real branch [78]. Our solution is to trace how the control transfer is calculated. We observe that most x86 conditional control transfers depend on certain bit value of the `eflags` register (e.g., `zf` and `cf`). Even obfuscators try to hide the conditional jumps, they still need to use arithmetic operations on certain `eflags` bits (e.g., ROP obfuscation [40, 55] and covert computation [59]). To identify these implicit control transfers, our approach trace the data flow of `eflags` bit value; that is, the instructions that calculate the bit value of the `eflags` are added into the slice. Note that in addition to the explicit conditional jump instructions, there are quite a number of instructions that have conditional jump semantics. For example, `cmovne ebx,edx` moves the value of `edx` to `ebx` according to `zf` flag. We also notice a case that the conditional logic is implemented without `eflags`: `jecxz` jumps if register `ecx` is zero. Currently BinSim supports all these special cases, which are summarized in Appendix Table 8.

4.2.3 Dispatcher Identification

Virtualization obfuscation, a great challenge to binary code slicing [61, 79], replaces the original binary code with new type of bytecode, and a specific interpreter is attached to interpret each bytecode. Due to the ease of implementing an instruction set emulator [64], current tools adopt decode-dispatch loop based interpretation [69, 52, 16]. Besides, the virtualization bytecode is designed as stack architecture style [62], which has a simple representation but requires more statements for a given computation. One instruction is typically translated to a sequence of bytecode operations on the stack values through the decode-dispatch loop. As a result, the collected slice from the above steps will contain a large number of redundant instructions caused by decode-dispatch loop iterations. We observe that each decode-dispatch loop iteration has the following common features.

1. It is a sequence of memory operations, ending with an indirect jump.
2. It has an input register `a` as virtual program counter (VPC) to fetch the next bytecode (e.g., `ptr[a]`). For example, VMProtect [69] takes `esi` as VPC while Code Virtualizer [52] chooses `al` register.
3. It ends with an indirect jump which dispatches to a bytecode handler table. The index into the jump table has a data dependency with the value of `ptr[a]`.

Our containment technique is to first identify possible decode-dispatch loop iterations in the backward slice according to the above common features. For each instruction sequence ending with an indirect jump, we mark the input registers as $a_1, a_2, ...a_n$ and output registers as $b_1, b_2, ...b_n$. Then we check whether there is an output register b_i meets the two heuristics:

1. b_i is tainted by the data located in `ptr[`a_j`]`.
2. The instruction sequence ends with `jmp ptr [`b_i`*(table stride) + table base]`.

After that, we will remove the fake control dependencies caused by virtualization obfuscation code dispatcher. In our preliminary testing, five virtualization obfuscation protected instructions produces as many as 3,163 instructions, and most of them are related to the decode-dispatch loop. After our processing, the number of instruction is reduced to only 109.

4.3 Handling Cryptographic Functions

Now-infamous crypto ransomware extort large ransom by encrypting the infected computer's files with standard cryptographic functions [33]. One ransomware archetype typically evolves from generation to generation to produce a large number of new strains. They may refine old versions incrementally to better support new criminal business models. In addition to the generic detection methods based on monitoring file system anomalies [32, 58], it is very interesting to investigate this emerging threat with BinSim, such as identifying ransomware variant relationships and investigate ransomware evolution. However, cryptographic functions have been known to be a barrier to SMT-based security analysis in general [11, 72] because of the complicated input-output dependencies. Our backward slicing step will produce a quite long instruction segment, and the corresponding equivalence checking will become hard to solve as well [67].

We observer that cryptographic function execution has almost no interaction with system calls except the ones are used for input and output. For example, crypto ransomware take the original user's file as input, and then

overwrite it with the encrypted version. Inspired by Caballero et al.'s work [11], we do a "stitched symbolic execution" to walk around this challenge. Specifically, we first make a forward pass over the sliced segments to identify the possible cryptographic functions between two system calls. We apply the advanced detection heuristics proposed by Gröbert et al. [27] (e.g., excessive use of bitwise operations, instruction chains, and mnemonic const values) to quickly match known cryptographic function features. If a known cryptographic function is detected, we will turn off the weakest precondition calculation and equivalence checking. In Section 4.5, we will discuss how to approximately measure the similarity of detected cryptographic functions.

4.4 Weakest Precondition Calculation

Let's assume the slice we collected (S) contains a sequence of instructions $[i_1, i_2, ..., i_n]$. Our weakest precondition (WP) calculation takes (S) as input, and the state of the execution to the given API call's argument as the postcondition (P). Inductively, we first calculate $\text{wp}(i_n, P) = P_{n-1}$, then $\text{wp}(i_{n-1}, P_{n-1}) = P_{n-2}$ and until $\text{wp}(i_1, P_1) = P_0$. The weakest precondition, denoted as $\text{wp}(S, P) = P_0$, is a boolean formula over the inputs that follow the same slice (S) and forces the execution to reach the given point satisfying P. We adopt a similar algorithm as Banerjee et al.'s [4] to compute the WP for every statement in the slice, following both data dependency and control dependency. The resultant WP formula for a program point can be viewed as a conjunction of predicates accumulated before that point, in the following form:

$$WP = F_1 \wedge F_2 \wedge ... \wedge F_k.$$

Opaque predicates [17], a popular control flow obfuscation scheme, can lead to a very complicated WP formula by adding infeasible branches. We apply recent opaque predicate detection method [45] to identify so called invariant, contextual, and dynamic opaque predicates. We remove the identified opaque predicate to reduce the size of the WP formula.

4.5 Segment Equivalence Checking

We identify whether two API calls are semantically equivalent by checking the equivalence of their arguments' weakest preconditions. To this end, we perform *validity checking* for the following formula.

$$wp_1 \equiv wp_2 \wedge arg_1 = arg_2 \tag{3}$$

Different from existing block-centric methods, whose equivalence checking is limited at a single basic block level, our WP calculation captures the logic of a segment of instructions that go across the boundaries of basic blocks. Our method can offer a logical explanation of whether syntactically different instruction segments contribute to the same observable behavior. Frequent invocation of constraint solver imposes a significant overhead. Therefore, we maintain a HashMap structure to cache the results of the previous comparisons for better performance.

To quantitatively represent different levels of similarity and facilitate our comparative evaluation, we assign different scores ($0.5 \sim 1.0$) based on the already aligned system call sequences. The similarity sore is tuned with our ground truth dataset (Section 5.2) by two metrics: *precision* and *recall*. The precision is to measure how well BinSim identifies different malware samples; while recall indicates how well BinSim recognizes the same malware samples but with various obfuscation schemes. An optimal similarity sore should provide high precision and recall at the same time. We summarize the selection of similarity score as follows.

1. 1.0: the arguments of two aligned system calls pass the equivalence checking. Since we have confidence these system calls should be perfectly matched, we represent their similarity with the highest score.

2. 0.7: the sliced segments of two aligned system calls are corresponding to the same cryptographic algorithm (e.g. AES vs. AES). We assign a slightly lower score to represent our approximate matching of cryptographic functions.

3. 0.5: the aligned system call pairs do not satisfy the above conditions. The score indicates their arguments are either conditionally equivalent or semantically different.

Assume the system call sequences collected from program a and b are T_a and T_b, and the number of aligned system calls is n. We define the similarity calculation as follows.

$$\text{Sim}(a,b) = \frac{\sum_{i=1}^{n} \textit{Similarity Score}}{\text{Avg}\{|T_a|, |T_b|\}} \tag{4}$$

$\sum_{i=1}^{n} \textit{Similarity Score}$ sums the similarity score of aligned system call pairs. To balance the different length of T_a and T_b and be sensitive to system call noises insertion, we use the average number of two system call sequences as the denominator. The value of $\text{Sim}(a,b)$ ranges from 0.0 to 1.0. The higher $\text{Sim}(a,b)$ value indicates two traces are more similar.

Table 1: Different obfuscation types and their examples.

	Type	Examples
1	Intra-basic-block	Register swapping, junk code, instructions substitution and reorder
2	Control flow	Loop unrolling, opaque predicates, control flow flatten, function inline
3	ROP	Synthetic benchmarks collected from the reference [79]
4	Different implementations	BitCount (Figure 3) isPowerOfTwo (Appendix Figure 12) flp2 (Appendix Figure 13)
5	Covert computation[59]	Synthetic benchmarks
6	Single-level virtualization	VMProtect [69]
7	Multi-level virtualization	Synthetic benchmarks collected from the reference [79]

5 Experimental Evaluation

We conduct our experiments with several objectives. First and foremost, we want to evaluate whether BinSim outperforms existing binary diffing tools in terms of better obfuscation resilience and accuracy. To accurately assess comparison results, we design a controlled dataset so that we have a ground truth. We also study the effectiveness of BinSim in analyzing a large set of malware variants with intra-family comparisons. Finally, performance data are reported.

5.1 Experiment Setup

Our first testbed consists of Intel Core i7-3770 processor (Quad Core with 3.40GHz) and 8GB memory, running Ubuntu 14.04. We integrate *FakeNet* [63] into Temu to simulate the real network connections, including DNS, HTTP, SSL, Email, FTP etc. We carry out the large-scale comparisons for malware variants in the second testbed, which is a private cloud containing six instances running simultaneously. Each instance is equipped with a duo core, 4GB memory, and 20GB disk space. The OS and network configurations are similar to the first testbed. Before running a malware sample, we reset Temu to a clean snapshot to eliminate the legacy effect caused by previous execution (e.g., modify registry configuration). To limit the possible time-related execution deviations, we utilize Windows Task Scheduler to run each test case at the same time.

5.2 Ground Truth Dataset

Table 1 lists obfuscation types that we plan to evaluate and their examples. Intra-basic-block obfuscation methods (Type 1) have been well handled by semantics-based binary diffing tools. In Section 2.1, we summarize possible challenges that can defeat the block-centric binary diffing methods, and Type 2 $\sim$ Type 7 are corresponding to such examples. We collect eight malware source code with different functionalities from VX Heavens[2]. We investigate the source code to make sure they are different, and each sample can fully exhibit its malicious behavior in the runtime. Besides, we also collect synthetic benchmarks from the previous work. The purpose is to evaluate some obfuscation effects that are hard to automate. Our controlled dataset statistics are shown in Table 2. The second column of Table 2 lists different obfuscation schemes and combinations we applied.

In addition to BinSim, we also test other six representative binary diffing tools. BinDiff [23] and DarunGrim [50] are two popular binary diffing products in industry. They rely on control flow graph and heuristics to measure similarities. CoP [41] and iBinHunt [43] represent "block-centric" approaches. Based on semantically equivalent basic blocks, iBinHunt compares two execution traces while CoP identifies longest common subsequence with static analysis. System call alignment and feature set are examples of dynamic-only approaches. "Feature set" indicates the method proposed by Bayer et al. [6] in their malware clustering work. They abstract system call sequence to a set of features (e.g., OS object, OS operations, and dependencies) and measure the similarities of two feature sets by Jaccard Index. For comparison, we have implemented the approaches of CoP [41], iBinHunt [43], and feature set [6]. The system call alignment is the same to the method adopted by BinSim.

5.3 Comparative Evaluation Results

Naively comparing these seven binary diffing tools with their similarity scores is not informative[3]. It is also very difficult to interpret precision and recall values because each tool adopts different similarity metrics and thresh-

Average								
"Right pairs" vs. "Obfuscation pairs"		0.50	0.48	0.34	0.46	0.10	0.15	0.09
"Right pairs" vs. "Wrong pairs"		0.65	0.65	0.66	0.55	0.71	0.63	0.76

old. What matters is that a tool can differentiate right-pair scores from wrong-pair scores. We first test how their similar scores change from right pairs to wrong pairs. For the right pair testing, we compare each sample in Table 2 with itself (no obfuscation). The average values are shown in "Right pairs" bar in Figure 8. Then we compare each sample with the other samples (no obfuscation) and calculate the average values, which are shown in "Wrong pairs" bar in Figure 8[4]. The comparison results reveal a similar pattern for all these seven binary diffing tools: a large absolute difference value between the right pair score and the wrong pair score.

Next, we figure out how the similarity score varies under different obfuscation schemes and combinations. We first calculate the similarity scores for "Right pairs" (self comparison) and "Obfuscation pairs" (the clean version vs. its obfuscated version). Table 3 shows the absolute difference values between "Right pairs" and "Obfuscation pairs". Since code obfuscation has to preserve semantics [17], the small and consistent difference values can indicate that a binary diffing tool is resilient to different obfuscation schemes and combinations. BinDiff, DarunGrim, iBinHunt and CoP do not achieve a consistent (good) result for all test cases, because their difference values fluctuate. The heuristics-based comparisons adopted by BinDiff and DarunGrim can only handle mild instructions obfuscation within a basic block. Since multiple obfuscation methods obfuscate the structure of control flow graph (e.g., ROP and control flow obfuscation), the effect of BinDiff and DarunGrim are limited. CoP and iBinHunt use symbolic execution and theorem proving techniques to match basic blocks, and therefore are resilient to intra-basic-block obfuscation (Type 1). However, they are insufficient to defeat the obfuscation that may break the boundaries of basic blocks (e.g., Type 2 $\sim$ Type 7 in Table 1). The last rows of Table 3 shows the average difference values for the "Right pairs" vs. "Obfuscation pairs" and "Right pairs" vs. "Wrong pairs". The closer for these two scores, the harder for a tool to set a threshold or cutoff line to give a meaningful information on the similarity score.

[4]It does not mean that higher is better on the similarity scores for the right pairs, and lower is better for the wrong pairs. What is important is how their similarity values change from right pairs to wrong pairs.

Table 4: Comparison of slice sizes (# instructions).

Sample	Obfuscation type	No-VMP	Conventional	BinSim

Clibo	1+6	156	16,860	238
Branko	1+2+6	472	31,154	520
Sasser	1+2+6	1,484	64,276	1,766
fibonacci	7	156	4,142	278

Table 5: Similarity score of four CryptoWall variants.

a vs. b	a vs. c	a vs. d	b vs. c	b vs. d	c vs. d
0.92	0.83	0.32	0.78	0.33	0.37

Regarding dynamic-only methods (system call alignment and feature set), their scores are consistent for most comparisons. The reason is dynamic-only approaches are effective to defeat most code obfuscation schemes. However, we notice a variant of `Hunatcha` worm exhibits the malicious behavior under the condition of *systime.Month* < 12. Without more detailed information such as path conditions, both system call alignment and feature set methods fail to identify such conditional equivalence. This disadvantage is further manifested by our large-scale malware comparisons, in which we find out 11% variants are conditionally equivalent.

5.4 Offline Analysis Evaluation

In this section, we first evaluate BinSim's dynamic slicing when handling obfuscated binaries. We test BinSim with VMProtect [69], an advanced commercial obfuscator. In addition to virtualization obfuscation, which can cause slice size explosion, VMProtect also performs intra-basic-block (Type 1) and control flow obfuscation (Type 2). As shown in Table 4, we obfuscate the test cases with multiple obfuscation combinations and multi-level virtualization (Type 7). "No-VMP" column indicates BinSim's result without obfuscation. The last two columns show the slice sizes of conventional dynamic slicing and BinSim. BinSim outperforms the conventional approach by reducing slice sizes significantly. Note that the sliced segment produced by BinSim contains many different instructions with "No-VMP" version. Directly comparing the syntax of instructions is not feasible. Our semantics-based equivalence checking can show that the new sliced segment is equivalent to the original instructions.

Next, we evaluate BinSim's cryptographic function approximate matching, which allows equivalence checking in the presence of cryptographic functions that could otherwise be hard to analyze. We collect four CryptoWall variants and apply BinSim to compare them pair by pair. CryptoWall is a representative ransomware family, and it is also continuously evolving. The similar scores are shown in Table 5. We notice three samples (a, b, and c) are quite similar, and one sample (CryptoWall.d) has relatively large differences with the others. After investigating BinSim's output, we find out that CryptoWall.d reveals three distinct behaviors: 1) "query-then-infect": it will terminate execution if the infected machine's UI languages are Russian, Ukrainian or other former Soviet Union country languages (via `GetSystemDefaultUILanguage`). This clearly shows that the adversaries want to exclude certain areas from attacking. 2) It uses AES for file encryption while the other three variants choose RSA. 3) It encrypts files with a new file name generation algorithm. Our "query-then-infect" findings coincide with the recent CryptoWall reverse engineering report [2].

5.5 Analyzing Wild Malware Variants

We report our experience of applying BinSim and other six binary diffing tools on $1,050$ active malware samples (uncontrolled dataset)[5]. The dataset is retrieved from VirusShare[6] and analyzed at February 2017. We leverage VirusTotal[7] to do an initial clustering by majority voting. The total $1,050$ samples are grouped into 112 families, and more than 80% samples are protected by different packers or virtualization obfuscation tools. For each binary diffing tool, we perform intra-family pairwise comparison on our private cloud. The distribution of similarity scores is shown in Table 6. Because BinDiff, DarunGrim, and CoP cannot directly work on the packed binary, we provide the unpacker binaries preprocessed by BinSim's generic unpacking.

In most cases, dynamic-only methods and BinSim are able to find small distances among intra-family samples. For example, over 86% of the pairs have a similarity score of 0.6 or greater. System call alignment has a better distribution than BinSim during the similarity score range $0.70 \sim 1.00$. We attribute the high score to the fact that system call alignment cannot detect *conditional equivalence*. Actually, we successfully identify that about 11% of malware samples have so-called "query-then-infect" behaviors [77], and BinSim is able to find whether two malware variants are conditionally equivalent. In these cases, BinSim's lower scores better fit the ground truth. Figure 9 shows a conditional equivalent behavior we find in `Trojan-Spy.Win32.Zbot` variants. Figure 10 presents a common compiler optimization that converts a high-level branch condition into a purely arithmetic sequence. This optimization can frustrate "block-centric" binary diffing methods, and we have

[5]The initial dataset is much larger, but we only consider the active samples that we can collect system calls.

seen such cases repeatedly in our dataset. By contrast, BinSim's hybrid approach naturally identifies the implicit control dependency in Figure 10 (b).

5.6 Performance

In Table 2, we also report the performance of BinSim when analyzing the controlled dataset. The fourth column lists the runtime overhead imposed by our online trace logging. On average, it incurs 8X slowdown, with a peak value 12X when executing KeyLogger. The fifth to seventh columns present the execution time of each component in our offline analysis stage. The number of instructions in the system call slice ranges from 5 to 138 and the average number is 22. The "STP" column presents average time spent on querying STP when comparing two programs. Here we show the time before and after the optimization of caching equivalence queries. On average, the HashMap speeds up STP processing time by a factor of 1.7. Considering that BinSim attempts to automatically detect obfuscated binary code similarity, which usually takes exhausting manual efforts from several hours to days, this degree of slowdown is acceptable. Performing the intra-family comparisons on 1,050 malware samples required approximately 3 CPU days.

6 Discussion

Like other malware dynamic analysis approaches, BinSim bears with the similar limitations: 1) incomplete path coverage; 2) environment-sensitive malware [34, 35] which can detect sandbox environment. Therefore, BinSim only detects the similarities/differences exhibiting during execution. The possible solutions are to explore more paths by automatic input generation [26, 47] and analyze malware in a transparent platform (e.g., VMRay Analyzer [70]). Our current generic unpacking is sufficient for our experiments. However, it can be defeated by more advanced packing methods such as multiple unpacking frames and parallel unpacking [68]. We plan to extend BinSim to deal with the advanced packing methods. Recent work proposes "replacement attacks" [44] to mutate system calls and their dependencies. As a result, similar malware variants turn out to have different behavior-based signatures. We regard this "replacement attacks" as a potential threat because it can reduce BinSim's similarity score. One possible solution is to design a layered architecture to capture alternative events that achieve the same high-level functionality.

BinSim's enhanced slicing algorithm handles the obfuscations that could break the block-centric binary comparisons. We have evaluated BinSim against a set of sophisticated commercial obfuscation tools and advanced academic obfuscation methods. However, determined adversaries may carefully add plenty of redundant dependencies to cause slice size explosion, and the resulting weakest preconditions could become too complicated to be solved. As an extreme case, the dependencies of a system call argument can be propagated to the entire program. To achieve this, it requires that future attackers have much deeper understanding about program analysis (e.g., inter-procedure data/control follow analysis) and take great engineering efforts. An attacker can also customize an unknown cryptographic algorithm to evade our cryptographic function approximate matching. However, correctly implementing a cryptographic algorithm is not a trivial task, and most cryptographic functions are reused from open cryptographic libraries, such as OpenSSL and Microsoft Cryptography API [75]. Therefore, BinSim raises the attacking bar significantly compared to existing techniques. On the other side, designing a worst case evaluation metric needs considerable insights into malicious software industry [39]. We leave it as our future work.

7 Related Work

7.1 Dynamic Slicing and Weakest Precondition Calculation

As dynamic slicing techniques [1, 80] can substantially reduce the massive program statements under investigation to a most relevant subset, they have been widely applied to the domain of program analysis and verification. Differential Slicing [29] produces a causal difference graph that captures the input differences leading to

Table 6: Similarity score distribution (%) of intra-family comparisons.

Score range	BinDiff	DarunGrim	iBinHunt	CoP	Syscall alignment	Feature set	BinSim
0.00–0.10	1	1	1	1	1	1	1
0.10–0.20	3	2	1	3	1	1	1
0.20–0.30	3	4	2	4	1	2	1
0.30–0.40	13	14	3	10	1	3	1
0.40–0.50	18	17	5	18	2	3	2
0.50–0.60	14	16	18	13	3	4	4
0.60–0.70	17	13	17	14	6	16	11
0.70–0.80	13	15	20	16	26	27	24
0.80–0.90	9	10	15	11	21	16	19
0.90–1.00	9	8	18	10	38	27	36

the execution differences. Weakest precondition (WP) calculation is firstly explored by Dijkstra [20] for formal program verification. Brumley et al. [8] compare WP to identify deviations in different binary implementations for the purpose of error detection and fingerprint generation. Ansuman et al. [4] calculate WP along the dynamic slicing to diagnose the root of an observable program error. BinSim's dynamic slicing and WP calculation are inspired by Ansuman et al.'s work. However, we customize our dynamic slicing algorithm to operate at the obfuscated binaries, which is more tricky than working on source code or benign programs. Another difference is we perform equivalence checking for WP while they do implication checking.

The most related backward slicing method to BinSim is Coogan et al.'s work [19]. We both attempt to identify the relevant instructions that affect system call arguments in an obfuscated execution trace, and the idea of value based slicing and tracking control dependency is similar. However, BinSim is different from Coogan et al.'s work in a number of ways. First, Coogan et al.'s approach is designed only for virtualization obfuscation. To evaluate the accuracy of backward slicing, they compare the x86 instruction slicing pairs by the syntax of the opcode (e.g., *mov*, *add*, and *lea*). It is quite easy to generate a syntactically different trace through instruction-level obfuscation [51]. Furthermore, the commercial virtualization obfuscators [52, 69] have already integrated code mutation functionality. Therefore, Coogan et al.'s approach has less resilience to other obfuscation methods. Second, we utilize taint analysis to identify virtualization bytecode dispatcher while Coogan et al. apply different heuristics. Third, Coogan et al. do not handle cryptographic functions. They state that the encryption/decryption routine could cripple their analysis. Fourth, Coogan et al. evaluate their method on only six tiny programs; while BinSim goes through an extensive evaluation. Last, but not the least, after the sub-traces or sliced segments are constructed, Coogan et al. compare them syntactically while BinSim uses weakest precondition to compare them semantically.

7.2 Binary Diffing

Hunting binary code difference have been widely applied in software security. BinDiff [23] and DarunGrim [50] compare two functions via the maximal control flow subgraph isomorphism and match the similar basic blocks with heuristics. BinSlayer [7] improves BinDiff by matching bipartite graphs. dicovRE [22] extracts a set of syntactical features to speed up control flow subgraph isomorphism. These approaches gear toward fast matching similar binary patches, but they are brittle to defeat the sophisticated obfuscation methods. Another line of work captures semantic equivalence between executables. BinHunt [25] first leverages symbolic execution and theorem proving to match the basic blocks with the same semantics. BinJuice [37] extracts the semantic abstraction for basic blocks. Exposé [49] combines function-level syntactic heuristics with semantics detection. iBinHunt [43] is an inter-procedural path diffing tool and relies on multi-tag taint analysis to reduce possible basic block matches. Pewny et al. [54] adopt basic block semantic representation sampling to search cross-architecture bugs. As we have demonstrated, these tools suffer from the so called "block-centric" limitation. In contrast, BinSim can find equivalent instruction sequences across the basic block boundary. Egele et al. [21] proposed blanket execution to match similar functions in binaries using dynamic testing. However, blanket execution requires a precise function scope identification, which is not always feasible for obfuscated binary code [42].

7.3 Malware Dynamic Analysis

Malware dynamic analysis techniques are characterized by analyzing the effects that the program brings to the operating system. Compared with static analysis, dynamic analysis is less vulnerable to various code obfuscation methods [48]. Christodorescu et al. [14] proposed to use data-flow dependencies among system calls as malware specifications, which are hard to be circum-

vented by random system calls injection. Since then, there has been a significant amount of work on dynamic malware analysis, e.g., malware clustering [6, 28] and detection [3, 12]. However, dynamic-only approaches may disregard the conditional equivalence or the subtle differences that do not affect system call arguments. Therefore, BinSim's hybrid approach is much more accurate. In addition, dynamic slicing is also actively employed by various malware analysis tasks. The notable examples include an efficient malware behavior-based detection that executes the extracted slice to match malicious behavior [36], extracting kernel malware behavior [38], generating vaccines for malware immunization [76], and identifying malware dormant functionality [18]. However, all these malware analysis tasks adopt the standard dynamic slicing algorithms [1, 80], which are not designed for tracking the data and control dependencies in a highly obfuscated binary, e.g., virtualization-obfuscated malware. As we have demonstrated in Section 4.2, performing dynamic slicing on an obfuscated binary is challenging. Therefore, our method is beneficial and complementary to existing malware defense.

8 Conclusion

We present a hybrid method combining dynamic analysis and symbolic execution to compare two binary execution traces for the purpose of detecting their fine-grained relations. We propose a new concept called *System Call Sliced Segments* and rely on their *Equivalence Checking* to detect fine-grained semantics similarity. By integrating system call alignment, enhanced dynamic slicing, symbolic execution, and theorem proving, our method compares the semantics of instruction segments that impact on the observable behaviors. Compared to existing semantics-based binary diffing methods, our approach can capture the similarities, or differences, across basic blocks and infer whether two programs' behaviors are conditionally equivalent. Our comparative evaluation demonstrates BinSim is a compelling complement to software security analysis tasks.

Desktop	CreateDesktop, SwitchDesktop, SetThreadDesktop
Other	LoadLibrary, GetProcAddress, GetModuleHandle

Table 8: Instructions with implicit branch logic.

Instructions	Meaning
CMOVcc	Conditional move
SETcc	Set operand to 1 on condition, or 0 otherwise
CMPXCHG	Compare and then swap
REP-prefixed	Repeated operations, the upper limit is stored in ecx
JECXZ	Jump if ecx register is 0
LOOP	Performs a loop operation using ecx as a counter

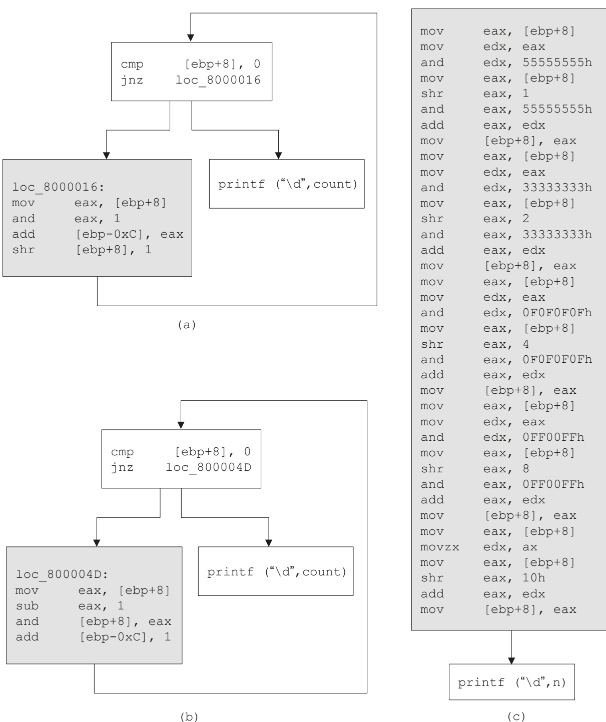

Figure 11: The disassembly code of three BitCount algorithms shown in Figure 3. The grey basic blocks represent the main loop bodies, which are not matched by "block-centric" binary diffing tools.

```
1  int isPowerOfTwo_1 (unsigned int x)
2  {
3     /* While x is even and > 1 */
4     while (((x % 2) == 0) && x > 1)
5        x /= 2;
6     return (x == 1);
7  }
8
9  int isPowerOfTwo_2 (unsigned int x)
10 {
11    unsigned int numberOfOneBits = 0;
12    while(x && numberOfOneBits <=1)
13    {
14       /* Is the least significant bit a 1? */
15       if ((x & 1) == 1)
16          numberOfOneBits++;
17       /* Shift number one bit to the right */
18       x >>= 1;
19    }
20    return (numberOfOneBits == 1);
21 }
```

Figure 12: Two different `isPowerOfTwo` algorithms check if an unsigned integer is a power of 2.

```
1  unsigned flp2_1 (unsigned x){
2     x=x|(x>>1);
3     x=x|(x>>2);
4     x=x|(x>>4);
5     x=x|(x>>8);
6     x=x|(x>>16);
7     return x-(x>>1);
8  }
9
10 unsigned flp2_2 (unsigned x){
11    unsigned y=0x80000000;
12    while(y>x){
13       y=y>>1;
14    }
15    return y;
16 }
17
18 unsigned flp2_3 (unsigned x){
19    unsigned y;
20    do{
21       y=x;
22       x=x&(x-1);
23    }while(x!=0);
24    return y;
25 }
```

Figure 13: Three different `flp2` algorithms find the largest number that is power of 2 and less than an given integer x.

PLATPAL: Detecting Malicious Documents with Platform Diversity

Meng Xu and Taesoo Kim
Georgia Institute of Technology

Abstract

Due to the continued exploitation of Adobe Reader, malicious document (maldoc) detection has become a pressing problem. Although many solutions have been proposed, recent works have highlighted some common drawbacks, such as parser-confusion and classifier-evasion attacks.

In response to this, we propose a new perspective for maldoc detection: platform diversity. In particular, we identify eight factors in OS design and implementation that could cause behavioral divergences under attack, ranging from syscall semantics (more obvious) to heap object metadata structure (more subtle) and further show how they can thwart attackers from finding bugs, exploiting bugs, or performing malicious activities.

We further prototype PLATPAL to systematically harvest platform diversity. PLATPAL hooks into Adobe Reader to trace internal PDF processing and also uses sandboxed execution to capture a maldoc's impact on the host system. Execution traces on different platforms are compared, and maldoc detection is based on the observation that a benign document behaves the same across platforms, while a maldoc behaves differently during exploitation. Evaluations show that PLATPAL raises no false alarms in benign samples, detects a variety of behavioral discrepancies in malicious samples, and is a scalable and practical solution.

1 Introduction

Cyber attackers are turning to document-based malware as users wise up to malicious email attachments and web links, as suggested by many anti-virus (AV) vendors [39, 50, 54, 57]. Users are generally warned more on the danger of executable files by browsers, email agents, or AV products, while documents such as PDFs are treated with much less caution and scrutiny because of the impression that they are static files and can do little harm.

However, over time, PDF specifications have changed. The added scripting capability makes it possible for documents to work in almost the same way as executables, including the ability to connect to the Internet, run processes, and interact with other files/programs. The growth of content complexity gives attackers more weapons to launch powerful attacks and more flexibility to hide malicious payload (e.g., encrypted, hidden as images, fonts or Flash contents) and evade detection.

A maldoc usually exploits one or more vulnerabilities in its interpreter to launch an attack. Fortunately (or unfortunately), given the increasing complexity of document readers and the wide library/system component dependencies, attackers are presented with a large attack surface. New vulnerabilities continue to be found, with 137 published CVEs in 2015 and 227 in 2016 for Adobe Acrobat Reader (AAR) alone. The popularity of AAR and its large attack surface make it among the top targets for attackers [25], next to browsers and OS kernels. After the introduction of a Chrome-like sandboxing mechanism [2], a single exploit can worth as high as $70k in pwn2own contest [21]. The collected malware samples have shown that many Adobe components have been exploited, including element parsers and decoders [37], font managers [28], and the JavaScript engine [22]. System-wide dependencies such as graphics libraries [23] are also on attackers' radar.

The continued exploitation of AAR along with the ubiquity of the PDF format makes maldoc detection a pressing problem, and many solutions have been proposed in recent years to detect documents bearing malicious payloads. These techniques can be classified into two broad categories: static and dynamic analysis.

Static analysis, or signature-based detection [14, 27, 31, 33, 34, 36, 46, 52, 59], parses the document and searches for indications of malicious content, such as shellcode or similarity with known malware samples. On the other hand, dynamic analysis, or execution-based detection [45, 48, 58], runs partial or the whole document and traces for malicious behaviors, such as vulnerable API calls or return-oriented programming (ROP).

However, recent works have highlighted some common drawbacks of these solutions. Carmony *et al*. [11] show that the PDF parsers used in these solutions might have overly simplified assumptions about the PDF specifications, leading to an incomplete extraction of malicious payloads and failed analysis. It has also been demonstrated that machine-learning-based detection could potentially be evaded in principled and automatic ways [35, 53, 65]. In addition, many solutions focus only on the JavaScript parts and ignore their synergy with other PDF components in launching attacks. Therefore, even though modern AV products support PDF-exploit detection, they cannot quickly adapt to novel obfuscation techniques even if the latter constitute only minor modifications of existing exploits [55]. AV products also exhibit problems providing protection against zero-day attacks, due to the lack of attack procedures and runtime traces.

In this paper, we propose PLATPAL, a maldoc detection scheme that analyzes the behavioral discrepancies of malicious document files on different platforms (e.g., Windows or Macintosh (Mac)). Unlike the static and dynamic detection schemes that rely on existing malware samples to construct heuristics, PLATPAL is based on a completely different set of insights: 1) a benign document behaves the same (in a certain level) across platforms, while 2) a malicious document causes diverged behaviors when launching exploits on different platforms.

The first assumption can be empirically verified by opening many benign samples that use a variety of PDF features across platforms. To support the second assumption, we investigated the factors in OS implementation that could cause behavioral divergences when under attack and identified eight such factors, ranging from syscall semantics (more obvious) to heap object metadata structure (more subtle). We further show how they can be used to thwart attackers in finding bugs, exploiting bugs, or performing malicious activities.

PLATPAL is based on these insights. To detect whether a document has malicious payload, PLATPAL opens it with the same version of AAR instances, but running on top of different operating systems. PLATPAL records the runtime traces of AAR while processing the document and subsequently compares them across platforms. Consensus in execution traces and outputs indicates the health of the document, while divergences signal an attack.

Although the process sounds simple and intuitive, two practical questions need to be addressed to make PLATPAL work: 1) what "behaviors" could be potentially different on different platforms? and 2) how can they be universally traced? PLATPAL traces and compares two types of behaviors. Internal behaviors include critical functions executed by AAR in the PDF processing cycle, such as loading, parsing, rendering, and script execution. External behaviors include filesystem operations, network activities, and program launches. This aligns with typical malware analysis tools such as Cuckoo sandbox [44].

It is worth highlighting that PLATPAL should not be considered as a competitor to current malware analysis tools such as Cuckoo [44] as they rely on different assumptions. Current tools rely heavily on the availability of a blacklist (or whitelist) of OS-wide activities are already available such that a sample's behaviors can be vetted against the list. This approach works well for known malware but might lost its advantage against 0-day PDF exploits. On the other hand, PLATPAL does not require the such a list to function and only relies on the fact that it is difficult for an attacker to craft a malicious PDF that exploits AAR in exactly the same way in both Windows and Mac platforms.

PLATPAL is evaluated against 1030 benign samples that use various features in the PDF specifications and reports no discrepancies in their traces, i.e., no false alarms. For a collection of 320 maldoc samples exploiting 16 different CVEs, PLATPAL can detect divergences in 209 of them with an additional 34 samples crashing both AAR instances. The remainder are undetected for various reasons, such as targeting an old and specific version of AAR or failure to trigger malicious activities. PLATPAL can finish a scan of the document in no more than 24 seconds per platform and requires no manual driving.

Paper contribution. In summary, this paper makes the following contributions:

- We propose to execute a document across different platforms and use behavioral discrepancies as an indicator for maldoc detection.
- We perform in-depth analysis and categorization of platform diversities and show how they can be used to detect maldoc attacks.
- We prototype PLATPAL based on these insights. Evaluations prove that PLATPAL is scalable, does not raise false alarms, and detects a variety of behavioral discrepancies in malicious samples.

We plan to open source PLATPAL to prompt using platform diversity for maldoc detection and also launch a PDF maldoc scanning service for public use.

2 Maldoc Detection: A Survey

Existing maldoc detection methods can be classified broadly into two categories: 1) dynamic analysis, in which malicious code is executed and examined in a specially instrumented environment; and 2) static analysis, in which the detection is carried out without code execution. A summary of existing methods is presented in Table 1.

Category	Focus	Detection Technique	Parser ?	ML ?	Pattern ?	Evasion / Drawbacks
Static	JavaScript	Lexical analysis [27]	Yes	Yes	Yes	Heavy obfuscation, Code loading
	JavaScript	Token clustering [59]	Yes	Yes	Yes	
	JavaScript	API reference classification [14]	Yes	Yes	Yes	
	JavaScript	Shellcode and opcode signature [31]	No	No	Yes	
	Metadata	Linearized object path [36]	Yes	Yes	Yes	Mimicry [53], Reverse mimicry [35]
	Metadata	Hierarchical structure [33, 52]	Yes	Yes	Yes	
	Metadata	Content meta-features [46]	Yes	Yes	Yes	
	Both	Many above-mentioned heuristics [34]	Yes	Yes	Yes	
Dynamic	JavaScript	Shellcode and opcode signature [58]	Yes	No	Yes	Incompatible JS engine, Non-script based attacks
	JavaScript	Known attack patterns [45]	Yes	No	Yes	
	JavaScript	Memory access patterns [48]	Yes	No	Yes	
	JavaScript	Common maldoc behaviors [29]	No	No	Yes	Zero-day exploits
	Document	Violation of memory access invariants [62]	No	No	No	ROP and JIT-Spraying

Table 1: A taxonomy of malicious PDF document detection techniques. This taxonomy is partially based on a systematic survey paper [40] with the addition of works after 2013 as well as summaries parser, machine learning, and pattern dependencies and evasion techniques.

2.1 Static Techniques

One line of static analysis work focuses on JavaScript content for its importance in exploitation, e.g., a majority (over 90% according to [58]) of maldocs use JavaScript to complete an attack. PJScan [27] relies on lexical coding styles like the number of variable names, parenthesis, and operators to differentiate benign and malicious JavaScript code. Vatamanu *et al.* [59] tokenizes JavaScript code into variables types, function names, operators, etc. and constructs clusters of tokens as signatures for benign and malicious documents. Similarly, Lux0r [14] constructs two sets of API reference patterns found in benign and malicious documents, respectively, and uses this to classify maldocs. MPScan [31] differs from other JavaScript static analyzers in a way that it hooks AAR and dynamically extracts the JavaScript code. However, given that code analysis is still statically performed, we consider it a static analysis technique.

A common drawback of these approaches is that they can be evaded with heavy obfuscation and dynamic code loading (except for [31] as it hooks into AAR at runtime). Static parsers extract JavaScript based on pre-defined rules on where JavaScript code can be placed/hidden. However, given the flexibility of PDF specifications, it is up to an attacker's creativity to hide the code.

The other line of work focuses on examining PDF file metadata rather than its actual content. This is partially inspired by the fact that obfuscation techniques tend to abuse the flexibility in PDF specifications and hide malicious code by altering the normal PDF structure. PDF Malware Slayer [36] uses the linearized path to specific PDF elements (e.g., `/JS`, `/Page`, etc) to build maldoc classifiers. Srndic *et al.* [52] and Maiorca *et al.* [33] go one step further and also use the hierarchical structure for classification. PDFrate [46] includes another set of features such as the number of fonts, the average length of streams, etc. to improve detection. Maiorca *et al.* [34] focuses on both JavaScript and metadata and fuses many of the above-mentioned heuristics into one procedure to improve evasion resiliency.

All methods are based on the assumption that the normal PDF element hierarchy is distorted during obfuscation and new paths are created that could not normally exist in benign documents. However, this assumption is challenged by two attacks. Mimicus [53] implements mimicry attacks and modifies existing maldocs to appear more like benign ones by adding empty structural and metadata items to the documents with no actual impact on rendering. Reverse mimicry [35] attack, on the contrary, attempts to embed malicious content into a benign PDF by taking care to modify it as little as possible.

2.2 Dynamic Techniques

All surveyed dynamic analysis techniques focus on embedded JavaScript code only instead of the entire document. MDScan [58] executes the extracted JavaScript code on a customized `SpiderMonkey` interpreter and the interpreter's memory space is constantly scanned for known forms of shellcode or malicious opcode sequences. PDF Scrutinizer [45] takes a similar approach by hooking the `Rhino` interpreter and scans for known malicious code patterns such as heap spray, shellcode, and vulnerable method calls. ShellOS [48] is a lightweight OS designed to run JavaScript code and record its memory access patterns. During execution, if the memory access sequences match a known malicious pattern (e.g., ROP, critical syscalls or function calls, etc), the script is considered malicious.

Although these techniques are accurate in detecting malicious payload, they suffer from a common problem:

an incompatible scripting environment. AAR's JavaScript engine follows not only the ECMA standard [18], but also the Acrobat PDF standard [1] (e.g., Adobe DOM elements). Therefore, without emulation, objects like `doc`, `app`, or even `this` (which are very common in both benign and malicious documents) will not function correctly. In addition, malicious payload can be encoded as a font or an image object in the document [37], which will neither be extracted nor detected. Certain attacks might also exploit the memory layout knowledge such as the presence of ROP gadgets or functions available in AAR and its dependent libraries, which is hard to emulate in an external analysis environment.

Instead of emulating the JavaScript execution environment, Liu *et al*. [29] instruments the PDF document with context monitoring code and uses AAR's own runtime to execute JavaScript code and hence is not affected by the incompatibility problem. However, the instrumented code only monitors common and known patterns of malicious behavior such as network accesses, heap-spraying, and DLL-injection, etc, which are not fully generic and have to be extended when new anti-detection measures of malicious code come up. CWXDetector [62] proposes a W⊕X-like approach to detect illegitimate code injected by maldocs during execution. But similar to W⊕X, its effectiveness is compromised in the presence of ROP and JIT-spraying.

2.3 Summary and Motivations

Surveying the maldoc detection techniques yields several interesting observations:

Parser reliance. Since a document consists of both data (e.g., text) and executable (e.g., script) components, a common pattern is to first extract the executable components and further examine them with either static or dynamic analysis. To this end, a parser that is capable of parsing PDF documents the same way as AAR does is generally assumed. As shown in Table 1, all but three methods use either open-sourced or their home-grown parsers and assume their capability. However, Carmony *et al*. [11] shows that these parsers are typically incomplete and have oversimplified assumptions in regard to where JavaScript can be embedded, therefore, *parser confusion attacks* can be launched to easily evade their detection.

Machine learning reliance. Machine learning techniques are heavily used in maldoc detection, especially in static analysis, because of their ability in classification/clustering without prior knowledge of the pattern. As shown in Table 1, seven out of 13 methods use machine learning to differentiate benign and malicious documents, while another four methods can also be converted to use machine learning for heuristics mining. However, recently proposed adversarial machine learning techniques [20, 42, 65] raise serious doubts about the effectiveness of classifiers based on superficial features in the presence of adversaries. For example, Xu *et al*. [65] is capable of automatically producing evasive maldoc variants without knowledge about the classifier, in a way similar to genetic programming.

Structural/behavioral discrepancy. An implicit assumption in the surveyed methods is that structural/behavioral discrepancies exist between benign and malicious documents and such discrepancies can be observed. Since the document must follow a public format specification, commonalities (structural or behavioral) are expected in benign documents. If a document deviates largely from the specification or the common patterns of benign samples, it is more likely to be a malicious document. However, such an assumption is challenged by the Mimicus [53] and reverse mimicry [35] attacks in a way that a maldoc can systematically evades detection if an attacker knows the patterns used to distinguish benign and malicious documents. In addition, deriving the discrepancy patterns requires known malware samples. Therefore, all but one methods in Table 1 require known malware samples either to learn patterns automatically or to manually define patterns based on heuristics, expectations, or experience. This restricts their capabilities in detecting zero-day attacks where no prior knowledge can be obtained.

Full dynamic analysis. It is worth noting that only one dynamic detection method performs analysis on the entire file; instead, the rest of the methods perform analysis on the extracted JavaScript code only. This is in contrast with traditional sandboxed malware analysis such as Cuckoo [44] or CWSandbox [63], which executes the malware and examines its behavior and influence on the host operating system during runtime. One reason could be because the maldoc runs on top of AAR, which itself is a complex software and leaves a large footprint on the host system. The traces of maldoc execution are hidden in the large footprint, making analysis much harder.

Motivation. The development of PLATPAL is motivated by the above-mentioned problems in maldoc detection research. We design PLATPAL to: 1) share the same view of the document as the intended interpreter (i.e., AAR in this paper); 2) use simple heuristics that do not rely on machine learning; 3) detect zero-day attacks without prior knowledge; 4) capture the maldoc's influence on the host system; and 5) be complementary to the surveyed techniques to further raise the bar for maldoc attackers.

3 Platform Diversity

This section focuses on understanding why platform diversity can be an effective approach in detecting maldoc

attacks. We first present a motivating example and then list the identified factors that are important in launching attacks, but are different on Windows and Mac platforms. We further show how to use them to thwart attackers and concretize it with four case studies. We end by discussing platform-detection techniques that a maldoc can use and the precautions PLATPAL should take.

3.1 A Motivating Example

In December 2012, researchers published a public proof-of-concept exploit for AAR [37]. This exploit attacks a heap overflow vulnerability found in the PDF parser module when parsing an embedded BMP RLE encoded image (CVE-2013-2729). By simply opening the maldoc, the AAR instance on Windows platform (including Windows 7, 8 and 10) is compromised and the attacker can run arbitrary code with the privileges of the compromised process. During our experiment, we ran this exploit on the Windows version of AAR 10.1.4 and reproduced the attack. However, when we opened the same sample with the Mac version of AAR 10.1.4, the attack failed and no malicious activities were observed.

In fact, in the malware history, Windows has drawn more attraction from attackers than Mac, and the same applies to maldocs. The Windows platform tends to be more profitable because of its market share, especially with enterprise users [38], who heavily use and exchange PDF documents. Therefore, it is reasonable to expect that the majority of maldocs target primarily the Windows platform, as cross-platform exploits are much harder to develop due to the factors discussed later.

The mindset of maldoc attackers and the discrepancy in reacting to malicious payload among different platforms inspire us to use platform diversity as the heuristic for maldoc detection: a benign document "behaves" the same when opened on different platforms while a maldoc could have different "behaviors" when launching exploits on different platforms. In other words, cross-platform support, the power used to make the PDF format and AAR popular, can now be used to defend against maldoc attacks.

3.2 Diversified Factors

We identified eight factors related to launching maldoc attacks but are implemented differently on Windows and Mac platforms.

Syscall semantics. Both syscall numbers and the register set used to hold syscall parameters are different between Windows and Mac platforms. In particular, file, socket, memory, process, and executable operations all have non-overlapping syscall semantics. Therefore, crafting shellcode that executes meaningfully on both platforms is extremely difficult in practice.

Calling conventions. Besides syscalls, the calling convention (i.e., argument passing registers) for userspace function differs, too. While Windows platforms use `rcx`, `rdx`, and `r8` to hold the first three parameters, Mac platforms use `rdi`, `rsi`, and `rdx`. This makes ROP-like attacks almost impossible, as the gadgets to construct these attacks are completely different.

Library dependencies. The different sets of libraries loaded by AAR block two types of exploits: 1) exploits that depend on the existence of vulnerabilities in the loaded libraries, e.g., graphics libraries, font manager, or `libc`, as they are all implemented differently on Windows and Mac platforms; and 2) exploits that depend on the existence of certain functions in the loaded libraries, e.g., `LoadLibraryA`, or `dlopen`.

Memory layout. The offset from the attack point (e.g., the address of the overflowed buffer or the integer value controlled by an attacker) to the target point, be it a return address, GOT/PLT entry, vtable entry, or even control data, is unlikely to be the same across platforms. In other words, directing control-flow over to the sprayed code can often be blocked by the discrepancies in memory layouts across platforms.

Heap management. Given the wide deployment of ASLR and DEP, a successful heap buffer overflow usually leads first to heap metadata corruption and later exploits the heap management algorithm to obtain access to control data (e.g., vtable). However, heap management techniques are fundamentally different between Windows and Mac platforms. Therefore, the tricks to corrupt metadata structures maintained by `segment heap` [67] (Windows allocator) will not work in the `magazine malloc` [5] (Mac allocator) case and vice versa.

Executable format. While Windows platforms generally recognize COM, NE, and PE formats, Mac platforms recognize only the Mach-O format. Therefore, maldocs that attempt to load an executable after exploitation will fail. Although "fat binaries" that can run on multiple CPU architectures exist, we are not aware of an executable format (or any wrapper tools) that is capable of running on multiple platforms.

Filesystem semantics. Windows uses backslashes (`\`) as path separators, while Mac uses forward slashes (`/`). In addition, Windows has a prefixed drive letter (e.g., `C:\`) while Mac has a mount point (e.g., the root `/`). Therefore, hard-coded path names, regardless of whether they are in JavaScript or attacker-controlled shellcode, will break on at least one platform. Dynamically generated filenames rely on the fact that certain files exist at a given path, which is unlikely to hold true across platforms.

Expected programs/services. This is heavily relied upon by the dropper or phishing type of maldocs, for example, dropping a malformed MS Office document

that exploits MS Office bugs, or redirecting the user to a malicious website that attacks the Internet Explorer browser. As Mac platforms are not expected to have these programs, such attacks will fail on Mac platforms.

3.3 Attack Categorization

As shown in Figure 1, a typical maldoc attack consists of three steps: 1) finding vulnerabilities, 2) exploiting them to inject attacker-controlled program logic, and 3) profiting by performing malicious activities such as stealing information, dropping backdoors, C&C, etc. The identified diversity factors in §3.2 can help detect maldocs at different stages.

In terms of finding vulnerabilities, exploiting vulnerabilities on platform-specific components can obviously be detected by PLATPAL, as the vulnerable components do not exist on the other platform.

The exploitation techniques can be divided into two subcategories, based on whether an attack exploits memory errors (e.g., buffer overflow, integer overflow, etc) to hijack control-flow or exploits logic bugs (e.g., JavaScript API design flaws).

Memory-error based control-flow hijacking puts a high requirement on the memory content during exploitation. For example, ROP attacks, which are commonly found in maldoc samples, require specific gadgets and precise information on where to find them in order to make powerful attacks. However, these gadgets and their addresses in memory can be easily distorted by the discrepancies in loaded libraries and memory layouts.

On the other hand, exploiting features that are naturally cross-platform supported, e.g., JavaScript hidden API attacks or abusing the structure of PDF document to obfuscate malicious payload, are not subject to the intricacies of runtime memory contents and are more likely to succeed.

Finally, even if an attacker succeeds in the first two steps, the attack can be detected while the maldoc is performing malicious activities, such as executing a syscall, loading a PE-format executable on Mac platforms, or accessing a file that exists only on Windows platforms.

3.4 Case Studies

We use representative examples to show how platform diversity can be used to detect maldoc attacks in each step shown in Figure 1.

Platform-specific bug. One source of platform-specific bugs comes from system libraries that are used by AAR. An example is CVE-2015-2426, an integer overflow bug in the Windows Adobe Type Manager Library. A detailed study can be found at [28]. In this case, opening the maldoc sample on Windows platforms will trigger the exploitation, while nothing will happen when opening it on Mac platforms. In other words, maldocs that exploit bugs in dependent libraries will surely fail on other platforms.

Another source of bugs comes from the AAR implementation itself, and we also found a few cases where the implementation of the same function can be vulnerable on one platform but safe on the other. For example, CVE-2016-4119 is a use-after-free vulnerability in the `zlib` deflating algorithm used by AAR to decompress embedded images [30]. The Mac version of AAR is able to walk through the document and exit gracefully, while AAR on Windows crashes during the rendering stage. A closer look at their execution shows that the decoded image objects are different on these platforms.

Memory error. Due to the deployment of ASLR and DEP in modern operating systems, direct shellcode injection cannot succeed. As a result, attackers exploiting memory errors generally require some form of heap preparation to obtain read/write accesses to control data, and the most common target we observed is vtable.

In the case of [37], the maldoc sample exploits CVE-2013-2729, an integer overflow bug in AAR itself, to prepare the heap to obtain access to a vtable associated with an image object. In particular, it starts by allocating 1000 consecutive memory chunks, each of 300 bytes, a value carefully selected to match the size of the vtable, and subsequently free one in every 10 chunks to create a few holes. It then uses a malformed BMP image of 300 bytes to trigger the integer overflow bug and manages to override the heap metadata, which resides in an attacker-controlled slot (although the attacker does not know which slot before hand). The malformed BMP image is freed from memory, but what is actually freed is the attacker-controlled slot, because of the heap metadata corruption. Later, when the struct containing a vtable is allocated in the same slot (almost guaranteed because of heap defragmentation), the attacker gains access and hijacks control-flow by overriding vtable entries.

However, this carefully constructed attack has two assumptions, which do not hold across platforms: 1) the size of the vtable on Windows and Mac platforms is different; and 2) the heap object metadata structures are different. As a result, overriding the heap metadata on Mac platform yields no observable behaviors.

Logic bugs. Another common attack vector of AAR is the logic bugs, especially JavaScript API design flaws. Unlike attacks that exploit memory errors, JavaScript API attacks generally require neither heap constructions nor ROP-style operations. Instead, they can be launched with as little as 19 lines of JavaScript code, as shown in Figure 2. Gorenc *et al.* [22] further extends this technique to complete remote code execution attacks by abusing hidden JavaScript APIs.

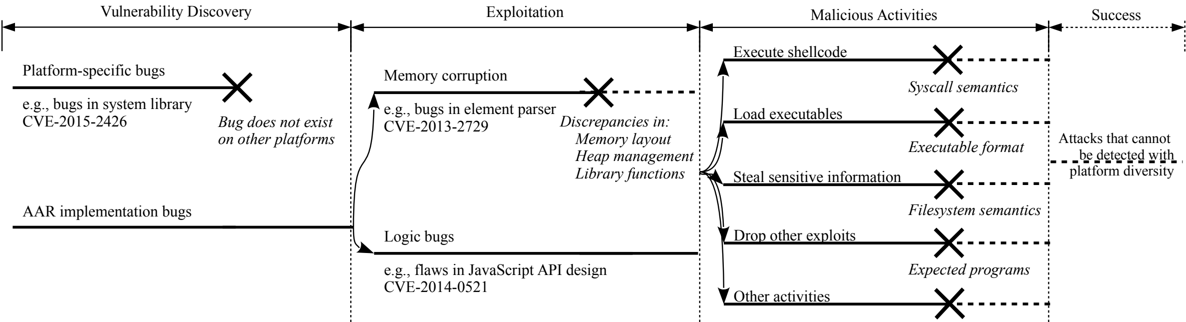

Figure 1: Using platform diversity to detect maldocs throughout the attack cycle. *Italic texts* near × refers to the factors identified in §3.2 that can be used to detect such attacks. A dash line means that certain attacks might survive after the detection.

```
1  var t = {};
2  t.__defineSetter__('doc', app.beginPriv);
3  t.__defineSetter__('user', app.trustedFunction);
4  t.__defineSetter__('settings', function() { throw 1; });
5  t.__proto__ = app;
6  try {
7    DynamicAnnotStore.call(t, null, f);
8  } catch(e) {}
9
10 f();
11 function f() {
12   app.beginPriv();
13   var file = '/c/notes/passwords.txt';
14   var secret = util.stringFromStream(
15       util.readFileIntoStream(file, 0)
16       );
17   app.alert(secret);
18   app.endPriv();
19 }
```

Figure 2: CVE-2014-0521 proof-of-concept exploitation

Besides being simple to construct, these attacks are generally available on both Windows and Mac platforms because of the cross-platform support of the JavaScript. Therefore, the key to detecting these attacks via platform diversity is to leverage differences system components such as filesystem semantics, expected installed programs, etc., and search for execution divergences when they are performing malicious activities. For example, line 15 will fail on Mac platforms in the example of Figure 2, as such a file path does not exist on Mac.

3.5 Platform-aware Exploitation

Given the difficulties of launching maldoc attacks on different platforms with the same payload, what an attacker can do is to first detect which platform the maldoc is running on through explicit or implicit channels and then launch attacks with platform-specific payload.

In particular, the Adobe JavaScript API contains publicly accessible functions and object fields that could return different values when executed on different platforms. For example, `app.platform` returns `WIN` and `MAC` on respective platforms. `Doc.path` returns file path to the document opened, which can be used to check whether the document is opened on Windows or Mac by testing whether the returned path is prefixed with `/c/`.

Another way to launch platform-aware attacks is to embed exploits on two platform-specific vulnerabilities, each targeting one platform. In this way, regardless of on which platform the maldoc is opened, one exploit will be triggered and malicious activities can occur.

In fact, although platform-aware maldocs are rare in our sample collection, PLATPAL must be aware of these attack methods and exercises precautions to detect them. In particular, the possibility that an attacker can probe the platform first before launching the exploit implies that merely comparing external behaviors (e.g., filesystem operations or network activities) might not be sufficient as the same external behaviors might be due to the result of different attacks. Without tracing the internal PDF processing, maldocs can easily evade PLATPAL's detection using platform-specific exploits, for example, by carrying multiple ROP payloads and dynamically deciding which payload to use based on the return value of `app.platform`, or even generating ROP payload dynamically using techniques like JIT-ROP [49].

However, we do acknowledge that, given the complexity of the PDF specification, PLATPAL does not enumerate all possible platform-probing techniques. Therefore, PLATPAL could potentially be evaded through implicit channels we have not discovered (e.g., timing side-channel).

3.6 Platform-agnostic Exploitation

We also identified several techniques that can help "neutralize" the uncertainties caused by platform diversity, including but not limited to heap feng-shui, heap spray, and polyglot shellcode.

Heap feng-shui. By making consecutive heap allocations and de-allocations of carefully selected sizes, an attacker can systematically manipulate the layout of the heap and predict the address of the next allocation or

de-allocation [51]. This increases the chance of obtaining access to critical data such as vtables even without knowing every detail of the system memory allocator.

Heap spray and NOP sled. By repeatedly allocating the attack payload and NOP sled in heap [13], an attacker is alleviated from using precise memory locations for control-flow hijacking; instead, an attacker only needs to ensure that control-flow is redirected to the sprayed area.

Ployglot shellcode trampoline. Although not seen in the wild, it is possible to construct OS-agnostic shellcode in a similar manner as CPU architecture-agnostic shellcode [17, 64]. The key idea is to find operations that are meaningful in one platform and NOP on the other and use these operations to jump to different code for platform-specific activities.

Although these operations can succeed on both platforms, attacks using these techniques can still be detected by platform diversity. This is because these operations have to be paired with other procedures to complete an end-to-end attack. For example, heap manipulation can succeed but the resulting memory layout might not be suitable for both platforms to land the critical data in attacker-controlled memory because of the discrepancies in heap management, while ployglot shellcode trampolines can run without crashing AAR, but the attack can still be detected by the malicious activities performed.

4 The PlatPal Approach

This section presents the challenges and their solutions in designing PlatPal that harvests platform diversity for maldoc detection.

4.1 Dual-level Tracing

Although the platform diversity heuristic sounds intuitive, two natural questions arise: 1) What "behaviors" could be potentially different across different platforms? and 2) How can they be universally traced and compared?

To answer the first question, "behaviors" must satisfy two requirements: 1) they are available and do not change across platforms and 2) they are the same for benign documents and could be different for maldocs. To this end, we identified two sets of "behaviors" that match these requirements: AAR's internal PDF processing functions (*internal behaviors*) and external impact on the host system while executing the document (*external behaviors*).

For *internal behaviors*, in AAR, PDF documents pass through the PDF processing functions in a deterministic order and trigger pre-defined callbacks sequentially. For example, a callback is issued when an object is resembled or rendered. When comparing execution across platforms, for a benign document, both function execution order and results are the same because of the cross-platform support of AAR, while for a maldoc, the execution trace could be different at many places, depending on how the attack is carried out.

In terms of *external behaviors*, because of the cross-platform nature of PDF specifications, if some legitimate actions impact the host system in one platform, it is expected that the same actions will be shown when opening the document on the other platform. For example, if a benign document connects to a remote host (e.g., for content downloading or form submission), the same behavior is expected on other platforms. However, if the Internet connection is triggered only upon successful exploitation, it will not be shown on the failing platform.

The architecture of PlatPal is described in Figure 3. PlatPal traces both internal and external behaviors, and we argue that tracing both types of behaviors is necessary. Tracing external behaviors is crucial to catch the behavioral discrepancy after a successful exploitation, i.e., the malicious activity step in Figure 1. For example, after a successful JavaScript hidden API attack [22], the attacker might want to execute shellcode, which will fail on Mac because of discrepancies in syscall semantics. The internal behaviors, however, all show the same thing: execution of JavaScript code stops at the same place.

The most compelling reason to have an internal behavior tracer is to defeat platform probing attempts, without which PlatPal can be easily evaded by launching platform-aware attacks, as described in §3.5. Another reason to trace internal behaviors is to provide some insights on which AAR component is exploited or where the attack occurs, which helps the analysis of maldoc samples, especially for proof-of-concept (PoC) samples that simply crash AAR without any external activities.

4.2 Internal PDF Processing

PlatPal's internal behavior tracer closely follows how AAR processes PDF documents. PDF processing inside AAR can be divided into two stages.

In the *parsing* stage, the underlying document is opened and the header is scanned to quickly locate the trailer and cross reference table (XRT). Upon locating the XRT, basic elements of the PDF document, called COS objects, are enumerated and parsed. Note that COS objects are only data with a type label (e.g., integer, string, keyword, array, dictionary, or stream). One or more COS objects are then assembled into PDF-specific components such as text, image, font, form, page, JavaScript code, etc. according to AAR's interpretation of PDF specifications. The hierarchical structure (e.g., which texts appear in a particular page) of the PDF document is also constructed along this process. The output, called PD tree, is then passed to the rendering engine for display.

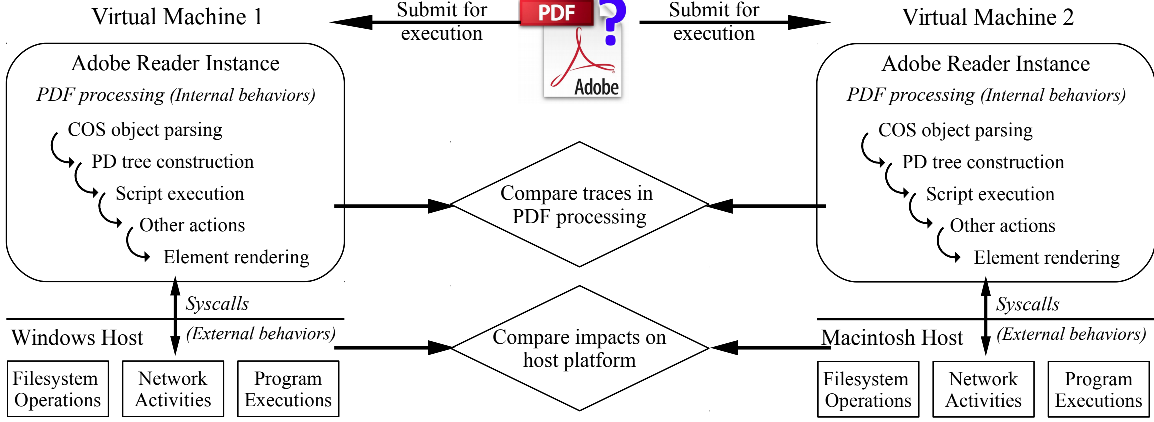

Figure 3: PLATPAL architecture. The suspicious file is submitted to two VMs with different platforms. During execution, both internal and external behaviors are traced and compared. Divergence in any behavior is considered a malicious signal.

The *drawing* stage starts by performing `OpenActions` specified by the document, if any. Almost all maldocs will register anything that could trigger their malicious payload in `OpenActions` for immediate exploitation upon document open. Subsequent drawing activities depend on user's inputs, such as scrolling down to the next page triggers the rendering of that page. Therefore, in this stage, PLATPAL not only hooks the functions but also actively drives the document rendering component by component. Note that displaying content to screen is a platform-dependent procedure and hence, will not be hooked by PLATPAL, but the callbacks (e.g., an object is rendered) are platform-independent and will be traced.

In addition, for AAR, when the rendering engine performs a JavaScript action or draws a JavaScript-embedded form, the whole block of JavaScript code is executed. However, this also enables the platform detection attempts described in §3.5 and an easy escape of PLATPAL's detection. To avoid this, PLATPAL is designed to suppress the automatic block execution of JavaScript code. Instead, the code is tokenized to a series of statements that are executed one by one, and the results from each execution are recorded and subsequently compared. If the statement calls a user-defined function, that function is also executed step-wise.

Following is a summary of recorded traces at each step:

COS object parsing: PLATPAL outputs the parsing results of COS objects (both type and content).

PD tree construction: PLATPAL outputs every PD component with type and hierarchical position in the PD tree.

Script execution: PLATPAL outputs every executed statement and the corresponding result.

Other actions: PLATPAL outputs every callback triggered during the execution of this action, such as change of page views or visited URLs.

Element rendering: PLATPAL outputs every callback triggered during the rendering of the PDF element.

4.3 External System Impact

As syscalls are the main mechanisms for a program to interact with the host platform, PLATPAL hooks syscalls and records both arguments and return values in order to capture the impact of executing a maldoc on the host system. However, for PLATPAL, a unique problem arises when comparing syscalls across platforms, as the syscall semantics on Windows and Mac are drastically different.

To ease the comparison of external behaviors across platforms, PLATPAL abstracts the high-level activities from the raw syscall dumps. In particular, PLATPAL is interested in three categories of activities:

Filesystem operations: including files opened/created during the execution of the document, as well as file deletions, renames, linkings, etc.

Network activities: including domain, IP address, and port of the remote socket.

External executable launches: including execution of any programs after opening the document.

Besides behaviors constructed from syscall trace, PLATPAL additionally monitors whether AAR exits gracefully or crashes during the opening of the document. We (empirically) believe that many typical malware activities such as stealing information, C&C, dropping backdoors, etc, can be captured in these high-level behavior abstractions. This practice also aligns with many automated malware analysis tools like Cuckoo [44] and CWSandbox [63], which also automatically generate a summary that sorts and organizes the behaviors of malware into a few categories. However, unlike these dynamic malware analysis tools that infer maliciousness of the sample based on the sequence or hierarchy of these activities, the only indication of maliciousness for PLATPAL is that the set of captured activities differs across platforms. Another difference is that the summary generated by Cuckoo and CWSandbox usually requires manual interpretation to

judge maliciousness, while the summary from PlatPal requires no human effort in comparing behaviors across platforms.

5 Implementation

PlatPal consists of three components: 1) an internal behavior tracer in the form of AAR plugin; 2) an external behavior tracer in the form of syscall tracer; and 3) a sandboxed environment for dynamic document examination based on VMware. We prototype PlatPal to work on recent Windows (versions 7, 8 and 10) and Mac (versions Yosemite, El Capitan, and Sierra) platforms, and is compatible with all AAR versions from Adobe Reader X 10.0 to the latest version of Adobe Acrobat DC.

5.1 Internal Behavior Tracer

Given that AAR is closed-source software, it is not viable to hook AAR's PDF processing functions through source code instrumentation. Initially, we used dynamic binary instrumentation tools (i.e., Intel Pin [32] and DynamoRio [7]) to hook the execution of AAR and examine function calls at runtime. However, such an approach has two significant drawbacks: 1) These tools introduce a 16-20 times slowdown, which is not tolerable for practical maldoc detection. For example, executing a two-page document could take up to five minutes, and sometimes is even halted by the system; 2) The PDF processing logic is hidden in over 15000 functions (latest version of AAR) with no name or symbol information. It is difficult if not impossible to identify the critical functions as well as to construct the whole cycle.

To this end, PlatPal chooses to develop an AAR plugin as the internal behavior tracer. The AAR plugin technology [3] is designed to extend AAR with more functionalities such as database interaction, online collaboration, etc. The compiled plugin takes the form of a loadable DLL on Windows and an app bundle on Mac, which is loaded by AAR upon initialization and has significant control over AAR at runtime. The AAR plugin provides a few nice features that suit PlatPal's needs: 1) Its cross-platform support abstracts the platform-specific operations to a higher level; 2) It uses the internal logic of AAR in PDF processing and summarizes the logic into 782 functions and callbacks (nicely categorized and labeled), which enables PlatPal to both passively monitor the execution of these functions and actively drive the document, including executing JavaScript code and rendering elements; 3) It is stable across AAR versions (only two functions are added since version 10, which are not used by PlatPal); 4) Since the AAR plugin is in the form of a loadable module, it shortens the total document analysis time to an average of 24 seconds.

In recording behaviors discussed in §4.2, the COS objects and PD hierarchical information are extracted using the enumeration methods provided by the `CosDoc`, `PDDoc`, and `PDF_Consultant` classes. JavaScript code is first tokenized by a lexer adapted from `SpiderMonkey` and executed statement-by-statement with `AFExecuteThisScript` method from `AcroForm` class. The rest of the PDF-supported actions are launched with the `AVDocPerformAction` method. The PDF processing functions exposed to the AAR plugin can be hooked by the simple JMP-Trampoline hot-patching technique as summarized in [6].

5.2 External Behavior Tracer

As illustrated in §4.3, PlatPal's external behavior tracer records syscall arguments and return values during document execution. On Windows, the tracer is implemented based on `NtTrace` [41]; on Mac, the tracer is a `Dscript` utilizing the `DTrace` [9] mechanism available on BSD systems. Both techniques are mature on respective platforms and incur small execution overhead: 15% to 35% compared to launching AAR without the tracer attached, which helps to control the total execution time per document. Constructing the high-level behaviors is performed in a similar manner as Cuckoo guest agent [44].

In PlatPal, syscall tracing starts only after the document is opened by AAR. The AAR initialization process is not traced (as AAR itself is not a malware) and PlatPal is free of the messy filesystem activities (e.g., loading libraries, initializing directory structures, etc) during the start-up, leaving the execution trace in a very short and clean state. In fact, a benign document typically has around 20 entries of filesystem traces and no network activities or external program launches. AAR uses a single thread for loading and parsing the document and spawns one helper thread during document rendering. Syscalls of both threads are traced and compared.

To compare file paths, PlatPal further aggregates and labels filesystem operation traces into a few categories that have mappings on both platforms, including AAR program logic, AAR support file, AAR working caches, system library/framework dependencies, system fonts, and temporary files. Files outside these labels will go to the unknown category and will be compared based on filenames.

5.3 Automated Execution Sandbox

For PlatPal, the purpose of having an automated execution sandbox is twofold: 1) to confine the malicious activities within a proper boundary and 2) to provide a clean execution environment for each document examination that is free from side effects by prior executions.

The virtual machine (VM) is initialized with a clean-slate operating system and subsequently provisioned with the necessary tools and settings, including AAR, the plugin, and the syscall tracer. The memory and disk snapshot is taken after the provision, and each subsequent document execution restores the states from this snapshot. PLATPAL uses VMware for the management of VMs and snapshots.

Workflow. PLATPAL can be started like `PlatPal <file-to-check>`. After that, PLATPAL populates a Windows VM and a Mac VM and restores the memory and disk snapshots. The suspicious document is then uploaded to these VMs and AAR is started with the syscall tracer attached. After AAR is done with initialization, the control is transferred to the plugin (internal tracer), which opens the document for examination. After the examination finishes (or AAR crashes), logs from internal and external tracing are pulled from the respective VMs and compared on the host. PLATPAL reports whether discrepancies are detected among these logs.

6 Evaluation

In this section, we validate the fundamental assumption of PLATPAL: benign documents behave the same when opened across different platforms, while maldocs behave differently when doing exploitation on different platforms. We also evaluate PLATPAL's performance in terms of total time taken to finish a complete analysis.

Experiment setup. The experiments were conducted on a MacBook Pro (2016 model) with Intel Core i7 2.9GHz CPU and 16GB RAM running macOS Sierra. One VM is provisioned with Windows 7 Professional SP1 and the other VM is provisioned with OSX Yosemite 10.10.1. Each VM is further provisioned with 6 different versions of AAR instances[1] listed in Table 2. Each document sample is forced to be closed after one minute execution.

6.1 Benign Samples

The benign sample set consists of three parts: 1000 samples are collected by searching Google with file type PDF and no keywords. However, a majority of these samples do not use features that are typically exploited by maldocs. For example, only 28 files contain embedded fonts and 6 files contain JavaScript code. Therefore, we further collected 30 samples from PDF learning sites[2] that use advanced features in the PDF standard, including embedded JavaScript (26 samples), AcroForm (17), self-defined font (6), and 3D objects (2). All of the samples are submitted to VirusTotal and scanned by 48 AV products and none of them are flagged as malicious by any of the AV engine.

The samples are submitted to PLATPAL for analysis. In particular, each document is opened by all six versions of AAR instances on both platforms. This is to empirically verify that all AAR reader instances do not introduce non-determinism during the document executions. Pairwise behavior comparison is conducted per AAR version and no discrepancy is observed, for any AAR version tested. More importantly, the experiment results support the first part of PLATPAL's assumption: benign documents behave the same across platforms.

6.2 Maldoc Detection

The maldoc samples are all collected from VirusTotal. In particular, we collected samples with identified CVE numbers (i.e., the sample exploits a particular CVE) [3] as of Dec. 31, 2016. As a prototype, we restrict the scope by analyzing CVEs published after 2013 and further filter the samples that are obviously mislabeled (e.g., a 2011 sample exploiting a 2016 CVE) or of wrong types (e.g., a zip file or an image file) and obtained a 320-sample dataset.

The samples are submitted to PLATPAL for analysis. In addition, we select the AAR versions that are most popular based on the time when the CVE was published. In other words, each exploit is a zero-day attack to the AAR version tested. The per-CVE detection results are presented in Table 2 and the breakdown in terms of which behavior factor causes the discrepancy is listed in Table 3.

Interpretation. For any sample submitted to PLATPAL, only three outcomes are possible:

1) *Malicious*: At least one behavioral discrepancy is observed, including the case in which AAR crashes on both platforms but the internal behavior is different, i.e., they crash at different PDF processing stages.

2) *Suspicious*: AAR crashes on both platforms but no difference is observed in internal behaviors. Given that a benign document has no reason to crash AAR, PLATPAL considers these samples as suspicious.

3) *Benign*: No behavioral discrepancy can be observed and AAR exits gracefully on both platforms.

Overall result. Out of 320 samples, PLATPAL detected 209 (65.3%) *malicious* samples, 34 (10.6%) *suspicious* samples, and 77 (24.1%) *benign* samples.

Suspicious samples. Among the 34 suspicious samples, we are able to confirm that 16 are PoC samples, including 7 released on Exploit-DB [19], 3 in public blogs, and 6 inferred by their original filenames recorded by VirusTotal. These samples are likely obtained by fuzzing and upon

[1] Previous versions of AAR can be obtained from ftp://ftp.adobe.com/pub/adobe/reader

[2] The samples are mainly obtained from http://www.pdfscripting.com and http://www.planetpdf.com/

[3] VirusTotal labels a sample with CVE number as long as one of the hosted AV products flag the sample with the CVE label.

CVE	AAR Version	Num. Samples	Result	
			Both crash	Divergence
2016-6946	DC.16.45	51	8	40
2016-4204	DC.16.45	78	7	37
2016-4119	DC.10.60	1	0	1
2016-1091	DC.10.60	63	6	31
2016-1077	DC.10.60	1	0	1
2016-1046	DC.10.60	4	0	4
2015-5097	11.0.10	4	0	4
2015-2426	11.0.10	14	6	8
2015-0090	11.0.10	1	0	1
2014-0521	11.0.00	2	0	2
2014-0495	11.0.00	2	0	2
2013-3353	10.1.4	16	4	10
2013-3346	10.1.4	7	0	7
2013-2729	10.1.4	23	3	19
2013-0640	10.1.0	30	0	22
2013-0641	10.1.0	23	0	20
Total		320	34	209

Table 2: PLATPAL maldoc detection results grouped by CVE number. *Both crash* means AAR crashes on both platforms while executing the maldoc sample with no divergence on internal behaviors; *Divergence* means at least one behavioral discrepancy (either internal or external) is observed.

execution, will simply crash AAR. We expect it to apply to the rest of the suspicious samples as well.

Benign samples. We identified several reasons for the failed detection of these samples.

1) The maldoc targets old and specific AAR versions. Although a majority of maldoc samples exploit a wide range of AAR versions, we do find samples that target old AAR versions only, i.e., 9.X and 8.X, including 8 CVE-2013-0640 samples, 3 CVE-2013-0641 samples, and 1 CVE-2013-2729 sample. We also found that 13 CVE-2016-4204 samples and 10 CVE-2016-1091 samples seems to be exploiting AAR version 11.0.X and the exploits do not work on the AAR DC version used in the experiment. This is based on manual inspection of the JavaScript dump from these samples.

In total, they account for 36 out of the 77 samples classified as benign. This is also shows the drawback of PLATPAL, being a dynamic analysis approach, it requires proper setup of the execution environment to entice the malicious behaviors.

2) The maldoc sample could be mis-classified by AV vendor on VirusTotal. This could be true for 11 CVE-2016-4204 and 8 CVE-2016-1091 samples, as out of the 48 AV products hosted on VirusTotal, only one AV vendor flags them as malicious. In total, this accounts for 19 out of the 77 samples classified as benign.

3) The maldoc does not perform malicious activity. Not all malicious activities in the maldoc can be triggered. In particular, we observed two CVE-2013-3353 samples attempted to connect to a C&C server in JavaScript but did nothing afterwards because of the lack of responses, which results in no divergences in execution trace.

In the end, for the rest of the samples classified as benign (20 in total), we are unable to confirm a reason why no behavioral discrepancies are observed. It could be because of any of the aforementioned reasons (but we are unable to confirm) and we do not preclude the possibility that some samples could evade PLATPAL's detection. Given the scope and flexibility of PDF specification, it is possible that PLATPAL needs to hook more functions (e.g., per glyph to host encoding transformation performed a font) to capture finer-grained internal behaviors.

Behavior effectiveness. Table 3 also shows the effectiveness of various behaviors in detecting maldocs.

1) By the first row, it is possible to have only external behavior divergences, while internal behaviors are the same (e.g., due to pure JavaScript attacks). By the first column, it is also possible to have only internal behavior divergences, while external behaviors are the same (due to the powerful error-correction capability of AAR).

2) Crash/no crash is the most effective external indicator, as memory-error exploitation is the dominating technique for maldoc attacks among the samples. JavaScript execution is the most effective internal indicator, as almost all attacks involve JavaScript; even memory error exploits use it to prepare the heap.

Pinpointing attacks by internal tracer. One supplementary goal of the internal tracer is to provide insights on which AAR component is exploited or where the attack occurs given a maldoc sample. To evaluate how this goal is achieved, we performed a cross-check on where the internal behavior divergence occurs and the targeted AAR component of each CVE[4]. The result is shown in Table 4.

In four out of 7 cases, PLATPAL's internal tracer finds divergence during the invocation of the vulnerable components. In the CVE-2015-2426 case, since the vulnerable component is a font library, the divergence is first detected during the rendering process. In the CVE-2013-3346 case, the vulnerable component (ToolButton callback) is triggered through JavaScript code and hence, the first divergence occurs in the script engine. In the CVE-2013-2729 case, although the bug is in the parser component, the divergence is detected when the maldoc is playing heap feng-shui to arrange heap objects.

Resilience against automated maldoc generation. We test PLATPAL's resilience against state-of-the-art maldoc generation tool, EvadeML [65], which automatically produce evasive maldoc variants against ML-depended approaches in Table 1 given a malicious seed file. To do this, we selected 30 samples out of the 209 malicious samples which are also detected as malicious by PDFrate [46],

[4] Only CVEs which full details are publicly disclosed are considered

Internal Behavior	External Behavior						Total
	No difference	Both crash	One crash	Filesystem	Network	Executable	
No difference	77	34	0	6	3	0	120
COS object parsing	4	8	23	0	0	0	35
PD tree construction	0	0	2	4	2	0	8
JavaScript execution	5	5	47	18	12	4	91
Other actions	0	0	0	2	0	2	4
Element rendering	3	10	35	9	5	0	62
Total	89	57	107	39	22	6	320

Table 3: PLATPAL maldoc detection results grouped by the factor causing divergences. Note that for each sample, only one internal and one external factor is counted as the cause of divergence. E.g., if a sample crashes on Mac and does not crash on Windows, even their filesystem activities are different, it is counted in the crash/no crash category. The same rule applies to internal behaviors.

CVE	Targeted component	Divergence first occurs	Detects
2016-4119	Parser	Parser	Vuln. component
2016-1077	Parser	Parser	Vuln. component
2016-1046	Script engine	Script engine	Vuln. component
2015-2426	Library	Render	Exploit carrier
2014-0521	Script engine	Script engine	Vuln. component
2013-3346	Render	Script engine	Exploit carrier
2013-2729	Parser	Script engine	Exploit carrier

Table 4: Divergence detected by PLATPAL's internal tracer vs the actual buggy AAR component.

Item	Windows		Mac	
	Ave.	Std.	Ave.	Std.
Snapshot restore	9.7	1.1	12.6	1.1
Document parsing	0.5	0.2	0.6	0.2
Script execution	10.5	13.0	5.1	3.3
Element rendering	7.3	8.9	6.2	6.0
Total	23.7	8.5	22.1	6.3

Table 5: Breakdown of PLATPAL's analysis time per document (unit: seconds).

the default PDF classifier that works with EvadeML[5]. We then uses EvadeML to mutate these samples until all variants are considered benign. Finally, we send these evasive variants to PLATPAL for analysis and all of them are again marked as malicious, i.e., behavioral discrepancies are still observed. This experiment empirically verifies PLATPAL's resilience on automated maldoc generation tools. The main reason for the resilience is that EvadeML mainly focuses on altering the structural feature of the maldoc while preserves its exploitation logic and also the internal and external behaviors when launching the attack.

6.3 Performance

In PLATPAL, the total analysis time consists of two parts: 1) time to restore disk and memory snapshots and 2) time to execute the document sample. The latter can be further broken down into document parsing, script execution, and element rendering time. Table 5 shows the time per item and the overall execution time.

On average, document execution on both VMs can finish at approximately the same time (23.7 vs 22.1 seconds). Given that the VMs can run in parallel, a complete analysis can finish within 25 seconds. A notable difference is that script execution on the Windows platform takes significantly longer than on the Mac platform. This is because almost all maldoc samples target Windows platforms and use JavaScript to launch the attack. The attack quickly fails on Mac (e.g., wrong address for ROP gadgets) and crashes AAR but succeeds on Windows and therefore takes longer to finish. The same reason also explains why the standard deviation on script execution time is larger on the Windows platform.

[5] It is worthnoting that PLATPAL cannot be used as the PDF classifier for EvadeML as EvadeML requires a maliciousness score which has to be continuous between 0 and 1 while PLATPAL can only produce discrete scores of either 0 or 1. Therefore, we use PDFrate, the PDF classifier used in the EvadeML paper [65], for this experiment.

7 Discussion

7.1 Limitations

User-interaction driven attacks. Although PLATPAL is capable of simulating simple users' interactions (e.g., scrolling, button clicking, etc), PLATPAL does not attempt to explore all potential actions (e.g., key press, form filling, etc) or explore all branches of the JavaScript code. Similarly, PLATPAL cannot detect attacks that intentionally delay their execution (e.g., start exploitation two minutes after document open). These are common limitations for any dynamic analysis tool. However, we believe this is not a serious problem for maldoc detection, as hiding malicious activities after complex user interactions limits its effectiveness in compromising the victim's system.

Social engineering attacks. PLATPAL is not capable of detecting maldocs that aim to perform social engineering

attacks, such as faking password prompt with a JavaScript window or enticing the user to download a file and execute it. This is because these maldocs neither exploit bugs in AAR nor inject malicious payload, (in fact they are legit documents structural-wise) and hence will have exactly the same behaviors on both platforms.

Targeted AAR version. If a maldoc targets a specific version of AAR, its behaviors in PLATPAL will likely be either crashing both AAR instances (i.e., exploited the bug but used the wrong payload), or the document is rendered and closed gracefully because of error correction by AAR. In the latter case, PLATPAL will not be able to detect a behavioral discrepancy. This is usually not a problem for PLATPAL in practice, as PLATPAL will mainly be used to detect maldocs against the latest version of AAR. However, PLATPAL can also have a document tested on many AAR versions and flag it as suspicious as long as a discrepancy is observed in any single version.

Non-determinism. Another potential problem for PLATPAL is that non-deterministic factors in document execution could cause false alerts. Examples include return value of `gettime` functions or random number generators available through JavaScript code. Although PLATPAL does not suffer from such a problem during the experiment, a complete solution would require a thorough examination of the PDF JavaScript specification and identify all non-determinism. These non-deterministic factors need to be recorded during the execution of a document on one platform and replayed on the other platform.

7.2 Deployment

As PLATPAL requires at least two VMs, a large amount of image and memory needs to be committed to support the operation of PLATPAL. Our current implementation uses 60GB disk space to host the snapshots for six versions of AAR and 2GB memory per each running VM.

To this end, we believe that PLATPAL is best suited for cloud storage providers (e.g., Dropbox, Google Docs, Facebook, etc.) which can use PLATPAL to periodically scan for maldocs among existing files or new uploads. These providers can afford the disk and memory required to set up VMs with diverse platforms as well as enjoy economy of scale. Similarly, PLATPAL also fits the model of online malware scanning services like VirusTotal or the cloud versions of anti-virus products.

In addition, as a complementary scheme, PLATPAL can be easily integrated with previous works (Table 1) to improve their detection accuracy. In particular, PLATPAL's internal behavior tracer can be used to replace parsers in these techniques to mitigate the parser-confusion attack [11]. COS object and PD tree information can be fed to metadata-based techniques [33, 36, 46, 52], while the JavaScript code dump can be fed to JavaScript-oriented techniques [14, 27, 31, 45, 48, 58, 59] for analysis.

7.3 Future Works

We believe that PLATPAL is a flexible framework that is suitable not only for PDF-based maldoc detection but also for systematically approaching security-through-diversity.

Support more document types. MS Office programs share many features with AAR products, such as 1) supporting both Windows and Mac platforms; 2) supporting a plugin architecture which allows efficient hooking of document processing functions and action driving; 3) executing documents based on a standard specification that consists of static components (e.g., text) and programmable components (e.g., macros). Therefore, we do not see fundamental difficulties in porting PLATPAL to support maldoc detection that targets MS Office suites.

As another example, given that websites can also be viewed as HTML documents with embedded JavaScript, malicious website detection also fits into PLATPAL's framework. Furthermore, given that Chrome and Firefox browsers and their scripting engines are open-sourced, PLATPAL is capable of performing finer-grained behavior tracing and comparison with source code instrumentation.

Explore architecture diversity. Apart from platform diversity, CPU architecture diversity can also be harvested for maldoc detection, which we expect to have a similar effect in stopping maldoc attacks. To verify this, we plan to extend PLATPAL to support the Android version of AAR, which has both ARM and x86 variants.

8 Additional Related Work

In addition to the maldoc detection work, being an N-version system, PLATPAL is also related to the N-version research. The concept of the N-version system was initially introduced as a software fault-tolerance technique [12] and was later applied to enhance system and software security. For example, Frost [60] instruments a program with complementary scheduling algorithms to survive concurrency errors; Crane *et al*. [16] applies dynamic control-flow diversity and noise injection to thwart cache side-channel attacks; Tightlip [68] and Capizzi *et al*. [10] randomize sensitive data in program variants to mitigate privacy leaks; Mx [24] uses multiple versions of the same program to survive update bugs; Cocktail [66] uses multiple web browser implementations to survive vendor-specific attacks; and Nvariant [15], Replicae [8], and GHUMVEE [61] run program variants in disjoint memory layouts to mitigate code reuse attacks. Similarly, Orchestra [43] synchronizes two program variants which grow the stack in opposite directions for intrusion detec-

tion. In particular, Smutz *et al*. [47] attempts to identify and prevent detection evasions by constructing diversified classifiers, ensembling them into a single system, and comparing their classification outputs with mutual agreement analysis.

Although PLATPAL is designed for a completely different goal (i.e., maldoc detection), it shares the insights with N-version systems: an attacker is forced to simultaneously compromise all variants with the same input in order to take down or mislead the whole system.

Another line of related work is introducing diversity to the execution environment in order to entice and detect malicious behaviors. For example, HoneyClient [56], caches and resembles potentially malicious objects from the network stream (e.g., PDF files) and then send it to multiple emulated environments for analysis. Balzarotti *et al*. [4] detects "split personality" in malware, i.e., malware that shows diverging behaviors in emulated environment and bare-metal machines, by comparing the runtime behaviors across runs. Rozzle [26] uses symbolic execution to emulate different environment values malware typically checks and hence, entice environment-specific behaviors from the malware. to show diverging behaviors.

PLATPAL shares the same belief as these works: diversified execution environment leads to diversified behaviors, and focuses on harvesting platform diversity for maldoc detection.

9 Conclusion

Due to the continued exploitation of AAR, maldoc detection has become a pressing problem. A survey of existing techniques reveals that they are vulnerable to recent attacks such as parser-confusion and ML-evasion attacks. In response to this, we propose a new perspective: platform diversity, and prototype PLATPAL for maldoc detection. PLATPAL hooks into AAR to trace internal PDF processing and also uses full dynamic analysis to capture a maldoc's external impact on the host system. Both internal and external traces are compared, and the only heuristic to detect maldoc is based on the observation that a benign document behaves the same across platforms, while a maldoc behaves differently during exploitation, because of the diversified implementations of syscalls, memory management, etc. across platforms. Such a heuristic does not require known maldoc samples to derive patterns that differentiate maldocs from benign documents, which also enables PLATPAL to detect zero-day attacks without prior knowledge of the attack. Evaluations show that PLATPAL raises no false alarms in benign samples, detects a variety of behavioral discrepancies in malicious samples, and is a scalable and practical solution.

Abstract

It's an essential step to understand malware's behaviors for developing effective solutions. Though a number of systems have been proposed to analyze Android malware, they have been limited by incomplete view of inspection on a single layer. What's worse, various new techniques (e.g., packing, anti-emulator, etc.) employed by the latest malware samples further make these systems ineffective. In this paper, we propose `Malton`, a novel on-device non-invasive analysis platform for the new Android runtime (i.e., the ART runtime). As a dynamic analysis tool, `Malton` runs on real mobile devices and provides a comprehensive view of malware's behaviors by conducting multi-layer monitoring and information flow tracking, as well as efficient path exploration. We have carefully evaluated `Malton` using real-world malware samples. The experimental results showed that `Malton` is more effective than existing tools, with the capability to analyze sophisticated malware samples and provide a comprehensive view of malicious behaviors of these samples.

1 Introduction

To propose effective solutions, it is essential for malware analysts to fully understand malicious behaviors of Android malware. Though many systems have been proposed, malware authors have quickly adopted advanced techniques to evade the analysis. For instance, since the majority of static analysis tools inspect the Dalvik bytecode [2], malware circumvent them by using various obfuscation techniques to raise the bar of code comprehension [61], implementing malicious activities in native libraries to evade the inspection [13, 59, 70, 92], and leveraging packing techniques to hide malicious payloads [82, 85, 88]. For example, the percentage of packed Android malware has increased from 10% to 25% [36], and 37.0% of the Android apps execute native code [11].

These sophisticated techniques employed by the latest malware also make the dynamic analysis systems ineffective. First, malicious behaviors usually cross several system layers (e.g., the Android runtime, the Android framework, and native libraries, etc.). However, the majority of dynamic analysis systems [34, 46, 73, 91] lack of the capability of cross-layer inspection, and thus provide incomplete view of malicious behaviors. For example, CopperDroid [73] monitors malware behaviors mainly through the trace of system calls (e.g., *sys_sendto()* and *sys_write()*). Thus, it is hard to expose the execution details in the Android framework layer and the runtime layer, due to the well-known semantic gap challenge. Second, the anti-debug and anti-emulator techniques employed by malware [44, 47, 56, 74] as well as the new Android runtime (i.e., the ART runtime) further limit the usage of many dynamic analysis systems. For example, in [14], 98.6% malware samples were successfully analyzed on the real smartphone, whereas only 76.84% malware samples were successfully inspected using the emulator. Most of the existing tools either rely on emulators (e.g., DroidScope [83]) or modify the old Android runtime (i.e., Dalvik Virtual Machine, or DVM for short) to monitor malware behaviors (e.g., TaintDroid [38]). Third, it is a common practice that malware executes different payloads according to the commands from the remote command and control (i.e., C&C) servers. However, existing systems are not effective in capturing the execution of all malicious payloads, because they are impaired by the inherent limitation of dynamic analysis (i.e., low code coverage) and the lack of efficient code path exploration technique.

In this paper, we propose `Malton`, a novel on-device non-invasive analysis platform for the ART runtime. Compared with other systems, `Malton` employs two important capabilities, namely, a) multi-layer monitoring and information flow tracking, and b) efficient path ex-

*The corresponding author.

ploration, to provide a comprehensive view of malware behaviors. Moreover, Malton does not need to modify malware's bytecode for conducting static instrumentation. To our best knowledge, Malton is the *first* system with such capabilities. Table 7 in Section 6 illustrates the key differences between Malton and other systems.

Malton inspects Android malware on different layers. It records the invocations of Java methods, including sensitive framework APIs and the concerned methods of the malware, in the *framework layer*, and captures stealthy behaviors, such as dynamic code loading and JNI reflection, in the *runtime layer*. Moreover, it monitors library APIs and system calls in the *system layer*, and propagates taint tags and explores different code paths in the *instruction layer*. However, multi-layer monitoring is not enough to provide a comprehensive view of malware behaviors, because malicious payloads could be conditionally executed. We deal with this challenge with the capability to efficiently explore code paths. First, to trigger as many malicious payloads as possible, we propose a multi-path exploration engine based on the concolic execution [27] to generate concrete inputs for exploring different code paths. Second, to conduct efficient path exploration on mobile devices with limited computational resources, we propose an offloading mechanism to move heavy-weight tasks (e.g., solving constraints) to resourceful desktop computers, and an in-memory optimization mechanism that makes the execution flow return to the entry point of the interested code region immediately after exiting the code region. Third, in case the constraint solver fails to find a solution to explore a code path, we equip Malton with a direction execution engine to forcibly execute a specified code path. Since Malton requires the necessary human annotations of the interested code regions, it is most useful in the human-guided detailed exploration of Android malware.

We have implemented a prototype of Malton based on the binary instrumentation framework Valgrind [53]. Since both the app's code and the framework APIs are compiled into native code in the ART runtime, we leverage the instrumentation mechanism of Valgrind to introspect apps and the Android framework. We evaluated Malton with real-world malware samples. The experimental results show that Malton can analyze sophisticated malware samples and provide a comprehensive view of their malicious behaviors.

In summary, we make the following contributions.

- We propose a novel Android malware analysis system with the capability to provide a comprehensive view of malicious behaviors. It has two major capabilities, including multi-layer monitoring and information flow tracking, and efficient path exploration.
- We implement the system named Malton by solving several technical challenges (e.g., cross-layer taint propagation, on-device Java method tracking, execution path exploration, etc.). To the best of our knowledge, it is the *first* system having such capabilities. To engage the whole community, we plan to release Malton to the community.
- We carefully evaluate Malton with real-world malware samples. The results demonstrated the effectiveness of Malton in analyzing sophisticated malware.

The rest of this paper is organized as follows. Section 2 introduces background knowledge and describes a motivating example. Section 3 details the system design and implementation. Section 4 reports the evaluation results. Then, we discuss Malton's limitations and possible solutions in Section 5. After presenting the related work in Section 6, we conclude the paper in Section 7.

2 Background

2.1 The ART Runtime

ART is the new runtime introduced in Android version 4.4, and becomes the default runtime from version 5.0. When an app is being installed, its Dalvik bytecode in the Dex file is compiled to native code[1] by the `dex2oat` tool, and a new file in the OAT format is generated including both the Dalvik bytecode and native code. The OAT format is a special ELF format with some extensions.

The OAT file has an `oatdata` section, which contains the information of each class that has been compiled into native code. The native code resides in a special section with the offset indicated by the `oatexec` symbol. Hence, we can find the information of a Java class in the `oatdata` section and its compiled native code through the `oatexec` symbol.

When an app is launched, the ART runtime parses the OAT file and loads the file into memory. For each Java class object, the ART runtime has a corresponding instance of the C++ class `Object` to represent it. The first member of this instance points to an instance of the C++ class `Class`, which contains the detailed information of the Java class, including the fields, methods, etc. Each Java method is represented by an instance of the C++ class `ArtMethod`, which contains the method's address, access permissions, the class to which this method belongs, etc. The C++ class `ArtField` is used to represent a class field, including the class to which this field belongs, the index of this field in its class, access rights, etc. We can leverage the C++ `Object`, `Class`, `ArtMethod` and `ArtField` to find the detailed information of the Java class, methods and fields of the Java class.

[1]Native code denotes the native instructions that could directly run with a particular processor.

Listing 1: A motivating example

```
1  public static native void readContact();
2  public static native void parseMSG(String msg);
3  private void readIMSI(){
4    TelephonyManager telephonyManager =
5      (TelephonyManager) getSystemService(
6        Context.TELEPHONY_SERVICE);
7    String imsi = telephonyManager.getSubscriberId();
8    // Send back data through SMTP protocol
9    smtpReply(imis);
10 }
11 private void procCMD(int cmd, String msg){
12   if(cmd == 1) {
13     readSMS();  // Read SMS content
14   } else if(cmd == 2) {
15     readContact();  // Read Contact content
16   } else if(cmd == 3) {
17     readIMSI();  // Read device IMSI information
18   } else if(cmd == 4) {
19     rebootDevice();  // Reboot the device
20   } else if(cmd == 5) {
21     parseMSG(msg);  // Parse msg in native code
22   } else { // The command is unrconginized.
23     reply("Unknown command!");
24   }
25 }
26 public boolean equals(String s1, String s2) {
27   if(s1.count != s2.count)
28     return false;
29   if(s1.hashCode() != s2.hashCode())
30     return false;
31   for(int i = 0; i < count; ++i)
32     if (s1.charAt(i) != s2.charAt(i))
33       return false;
34   return true;
35 }
36 public void onReceiver(Context context, Intent intent){
37   String body = smsMessage.getMessageBody();
38   // Get the telephone of the sender
39   String sender = smsMessage.getOriginatingAddress();
40   // Check if the SMS is sent form the controller
41   if(equals(sender, "6223**60")) {
42     procCMD(Interger.parseInt(body), body);
43   }
44   ...
45 }
```

The Android framework is compiled into an OAT file named "*system@framework@boot.oat*". This file is loaded to the fixed memory range for all apps running on the device without ASLR enabled [69].

2.2 Motivating Example

We use the example in Listing 1 to illustrate the usage of `Malton`. In this example, the method *onReceiver()* is an SMS listener and it is invoked when an SMS arrives. In this method, the telephone number of the sender is first acquired (Line 39) for checking whether the SMS is sent from the controller (Tel: 6223**60). Only the SMS from the controller will be processed by the method *procCMD()* (Line 42). There are 5 types of commands, each of which leads to a special malicious behavior (i.e., Line 13, 15, 17, 19 and 21). Reading contact and parsing SMS are implemented in the JNI methods *readContact()* (Line 1) and *parseMSG()* (Line 2), respectively.

Existing malware analysis tools could not construct a complete view of the malicious behaviors. For example, when *cmd* equals 3 (Line 16), IMSI is obtained by invoking the framework API *getSubscriberId()* (Line 7), and then leaked through SMTP protocol (Line 9). Although existing tools (e.g., CopperDroid [73]) can find that the malware reads IMSI and leaks the information by system call *sys_sendto()*, they cannot locate the method used to get IMSI and how the IMSI is leaked in detail, because *sys_sendto()* can be called by many functions (e.g., JavaMail APIs, Java Socket methods and C/C++ Socket methods) from both the framework layer and the native layer. `Malton` can solve this problem because it performs multi-layer monitoring.

When *cmd* equals 5, the content of SMS, which is obtained from the framework layer (Line 37), will be parsed in the JNI method *parseMSG()* (Line 2) by native code. Although taint analysis could identify this information flow, existing static instrumentation based tools (e.g., TaintART [71] and ARTist [21]) cannot track the information flow in the native code. `Malton` can tackle this issue since it offers cross-layer taint analysis.

Moreover, as shown in the method *procCMD()* (Line 11), the malware performs different activities according to the parameter *cmd*. Due to the low code coverage of dynamic analysis, how to efficiently explore all the malicious behaviors with the corresponding inputs is challenging. `Malton` approaches this challenge by conducting concolic execution with in-memory optimization and direct execution. Furthermore, we propose a new offloading mechanism to avoid overloading the mobile devices with limited computational resources. Since some constraints may not be solved (e.g., the hash functions at Line 29), we develop a direct execution engine to cover specified branches forcibly.

3 Design and Implementation

In this section, we first illustrate the design of our approach, and then detail the implementation of `Malton`.

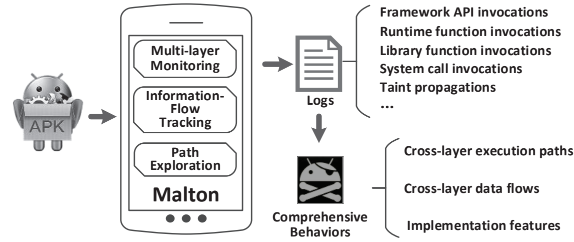

Figure 1: The scenario of `Malton`.

3.1 Overview

`Malton` helps security analysts obtain a complete view of malware samples under examination. To achieve this goal, `Malton` supports three major functionalities. First, due to the multi-layer nature of Android system, `Malton` can capture malware behaviors at different layers. For instance, malware may conduct malicious activities by

invoking native code from Java methods, and such behaviors involve method invocations and data transmission at multiple layers. The challenging issue is how to effectively bridge the semantic gap when monitoring the ARM instructions.

Second, malware could leak private information by passing the data across multiple layers back and forth. Note that many framework APIs are JNI methods (e.g., *String.concat()*, *String.toCharArray()*, etc.), whose real implementations are in native code. `Malton` can detect such privacy leakage because it supports cross-layer information flow tracking (Section 3.5).

Third, since malware may conduct diverse malicious activities according to different commands and contexts, `Malton` can trigger these activities by exploring the paths automatically (Section 3.6). It is non-trivial to achieve this goal because dynamic analysis systems usually have limited code coverage.

Figure 1 illustrates a use scenario of `Malton`. `Malton` runs in real Android devices and conducts multi-layer monitoring, information flow tracking, and path exploring. After running a malware sample, `Malton` generates logs containing the information of method invocations and taint propagations at different layers and the result of concolic executions. Based on the logs, we can reconstruct the execution paths and the information flows for characterizing malware behaviors.

Though `Malton` performs the analysis in multiple layers as shown in Figure 2, the implementation of `Malton` in each layer is not independent. Instead, different layers share the information with each other. For example, the taint propagation module in the instruction layer needs the information about the Java methods that are parsed and processed in the framework layer.

`Malton` is built upon Valgrind [53] (V3.11.0) with around 25k lines of C/C++ codes calculated by CLOC [1]. Next, we will detail the implementation at each layer.

3.2 Android Framework Layer

To monitor the invocations of privacy-concerned Java methods of the Android framework and the app itself, `Malton` instruments the native code of the framework and the app. Since the Dalvik code has been compiled into native instructions, we leverage Valgrind for the instrumentation. The challenge here is how to recover and understand the semantic information of Java methods from the ARM instructions, including the method name, parameters, call stacks, etc. For instance, if a malware sample uses the Android framework API to retrieve user contacts, `Malton` should capture this behavior from the ARM instructions and recover the context of the API invocation. To address this challenge, we propose an efficient way to bridge the semantic gaps between the low level

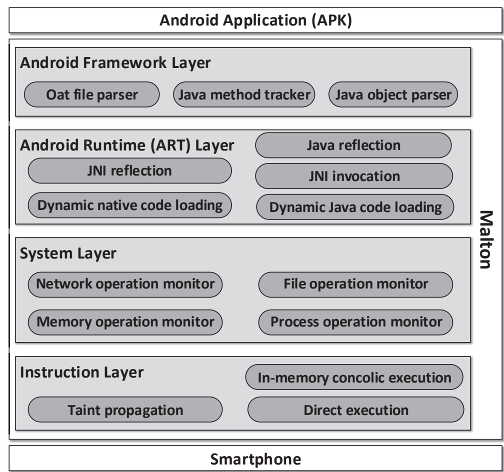

Figure 2: The overview of `Malton`.

native instructions and upper layer Java methods.

Java Method Tracker To track the Java method invocations, we need to identify the entry point and exit points of each Java method from the ARM instructions dynamically. Note that the ARM instructions resulted from the Dalvik bytecode are further translated into multiple IR blocks by `Malton`. An IR block is a collection of IR statements with one entry point and multiple exit points. One exit point of an IR block could be either the conditional exit statement (i.e., `Ist_Exit`) or the next statement (i.e., `Ist_Next`). We leverage the APIs from Valgrind to add instrumentation at the beginning, before any IR instruction, after any IR instruction, or at the end of the selected IR block. The instrumentation statements will invoke our helper functions.

To obtain the entry point of a Java method, we use the method information in the OAT file. Specifically, the OAT file contains the information of each compiled Java method (`ArtMethod`), including the method name, offset of the ARM instructions, access flags, etc. `Malton` parses the OAT files of both the Android framework and the app itself to retrieve such information, and keeps it in a hash table. When the native code is translated into the IR blocks, `Malton` looks up the beginning address of each IR block in the hash table to decide whether it is the entry of a Java method. If so, `Malton` inserts the helper function (i.e., *callTrack()*) at the beginning of the block to record the method invocation and parse arguments when it is executed.

To identify the exit point of a Java method, `Malton` leverages the method calling convention of the ARM architecture[2]. Specifically, the return address of a method is stored in the link register (i.e., the *lr* register) when the method is invoked. Hence, in *callTrack()*, `Malton` pushes

[2]Comments in file /art/compiler/dex/quick/arm/arm_lir.h

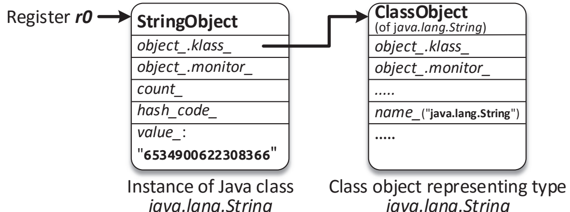

Figure 3: The example of parsing the Java object of the result of *TelephonyManager.getDeviceId()*

the value of *lr* into the method call stack since *lr* could be changed during the execution of the method. `Malton` also inserts the helper function (i.e., *retTrack()*) before each exit point (i.e., `Ist_Exit` and `Ist_Next`) of the IR block. In *retTrack()*, `Malton` compares the jump target of the IR block with the method's return address stored at the top of the method call stack. If they are equal, an exit point of the method is found, and this return address is popped from the method call stack.

`Malton` parses the arguments and the return value of the method after the entry point and the exits point of the method are identified, respectively. According to the method calling convention, the register *r0* points to the `ArtMethod` object of current method, and registers $r1 - r3$ contain the first three arguments. Other arguments beyond the first three words are pushed into the stack by the caller. For example, when the framework method *sendMessageAtTime(Message msg, long uptimeMillis)* of class *android/os/Handler* is invoked, *r0* points to the `ArtMethod` instance of the method *sendMessageAtTime()*, *r1* stores the *this* object and *r2* represents the argument *msg*. For the argument *uptimeMillis*, the high 32 bits are stored in the register *r3* and the low 32 bits are pushed into the stack. When the method returns, the return value is stored in the register *r0* if the return value is 32 bits, and in registers *r0* and *r1* if the return value is 64 bits.

Java Object Parser After getting the method arguments and the return value, we need to further parse the value if it is not the primitive data. There are two major data types [42] in Java, including primitive data types and reference/object data types (objects). For the primitive types, which include byte, char, short, int, long, float, double and boolean, we can directly get the value from registers and the stack. For the object, the value that we obtain from the register or the stack is a pointer that points to a data structure containing the detailed information of this object. Following this pointer, we get the class information of this object, and then parse the memory of this object to determine the concrete value.

Figure 3 illustrates the process of parsing the Java object of the result of *TelephonyManager.getDeviceId()*. According to its method shorty, we know that the return value of this API is a Java object represented by an *Object* instance, of which the memory address is stored in the register *r0*. Then, we can decide that the concrete type of this object is *java.lang.String*. By parsing the results according to the memory layout of *String* object, which is represented by the *StringObject* data structure, we can obtain the concrete string "6534900622308366". Currently, `Malton` can parse the Java objects related to String and Array. To handle new objects, users just need to implement the corresponding parsers for `Malton`.

3.3 Android Runtime Layer

To capture stealthy behaviors that cannot be monitored by the Java method tracker in the Android framework layer, `Malton` further instruments the ART runtime (i.e., *libart.so*). For example, the packed malware may use the internal functions of the ART runtime to load and execute the decrypted bytecode directly from the memory [85,88]. Malicious payloads could also be implemented in native code, and then invoke the privacy-concerned Java methods from native code through the JNI reflection mechanism. While the invoked Java method could be tracked by the Java method tracker in the Android framework layer, `Malton` tracks the JNI reflection to provide a comprehensive view of malicious behaviors, such as, the context when privacy-concerned Java methods are invoked from the native code. This is one advantage of `Malton` over other tools.

Table 1: Runtime behaviors related functions.

Behavior	Functions
Native code loading	*JavaVMExt::LoadNativeLibrary()*
Java code loading	*DexFile::DexFile()* *DexFile::OpenMemory()* *ClassLinker::DefineClass()*
JNI invocation	*artFindNativeMethod()* *ArtMehod::invoke()*
JNI reflection	*InvokeWithVarArgs()* *InvokeWithJValues()* *InvokeVirtualOrInterfaceWithJValues()* *InvokeVirtualOrInterfaceWithVarArgs()*
Java reflection	*InvokeMethod()*

Table 1 enumerates the runtime behaviors and the corresponding functions in the ART runtime that `Malton` instruments. Native code loading means that malicious code could be implemented in native code and loaded into memory, where Java code loading refers to loading the Dalvik bytecode. Note that Android packers usually exploit these APIs to directly load the decrypted bytecode from memory. JNI invocation refers to all the function calls from Java methods to native methods. This includes

the JNI calls in the app and the Android framework. JNI reflection, on the other hand, refers to calling Java methods from native code. For instance, malicious payloads implemented in native code could invoke framework APIs using JNI reflection. Java reflection is commonly used by malware to modify the runtime behavior for evading the static analysis [61]. For example, framework APIs could be invoked by decrypting the method names and class names at runtime using Java reflection.

3.4 System Layer

`Malton` tracks system calls and system library functions at the system layer. To track system calls, `Malton` registers callback handlers before and after the system call invocation through Valgrind APIs. For system library functions, `Malton` wraps them using the function wrapper mechanism of Valgrind. In the current prototype, `Malton` focuses on four types of behaviors at the system lever.

- Network operations. Since malware usually receives the control commands and sends private data through network, `Malton` inspects these behaviors by wrapping network related system calls, such as, *sys_connect()*, *sys_sendto()*, *recvfrom()*, etc.
- File operations. As malware often accesses sensitive information in files and/or dynamically loads malicious payloads from the file system, `Malton` records file operations to identify such behaviors.
- Memory operations. Since packed malware usually dynamically modifies its own codes through memory operations, like *sys_mmap()*, *sys_protect()*, etc., `Malton` monitors such memory operations.
- Process operations. As malware often needs to fork new process, or exits when the emulator or the debug environment is detected, `Malton` captures such behaviors by monitoring system calls relevant to the process operations, including *sys_execve()*, *sys_exit()*, etc.

Moreover, `Malton` may need to modify the arguments and/or the return values of system calls to explore code paths. For example, the C&C server may have been shut down when malware samples are being analyzed. In this case, `Malton` replaces the results of the system call *sys_connect()* to success, or replaces the address of C&C with a bogus one controlled by the analyst to trigger malicious payloads. We will discuss the techniques used to explore code paths in Section 3.6.

3.5 Instruction Layer: *Taint Propagation*

At the instruction layer, `Malton` performs two major tasks, namely, taint propagation and path exploration. Note that accomplishing these tasks needs the semantic information in the upper layers, such as the method invocations for identifying the information flow, etc.

Table 2: The taint propagation related IR Statements.

IR Statement	Representation
`Ist_WrTmp`	Assign a value (i.e., IR Expression) to a temporary.
`Ist_LoadG`	Load a value to a temporary with guard.
`Ist_CAS`	Do an atomic compare-and-swap operation.
`Ist_LLSC`	Do an either load-linked or store-conditional operation.
`Ist_Put`	Write a value to a guest register.
`Ist_PutI`	Write a value to a guest register at a non-fixed offset in the guest state.
`Ist_Store`	Write a value to memory.
`Ist_StoreG`	Write a value to memory with guard.
`Ist_Dirty`	Call a C function.

To propagate taint tags across different layers, `Malton` works at the instruction layer because the codes of all upper layers become ARM instructions during execution. Since these ARM instructions will be translated into IR statements [53], `Malton` performs taint propagation on IR statements with byte precision by inserting helper functions before selected IR statements.

Table 3: Taint propagation related IR expressions.

IR Expression	Representation
`Iex_Const`	A constant-valued expression.
`Iex_RdTmp`	The value held by a VEX temporary.
`Iex_ITE`	A ternary if-then-else operation.
`Iex_Get`	Get the value held by a guest register at a fixed offset.
`Iex_GetI`	Get the value held by a guest register at a non-fixed offset.
`Iex_Unop`	A unary operation.
`Iex_Binop`	A binary operation.
`Iex_Triop`	A ternary operation.
`Iex_Qop`	A quaternary operation.
`Iex_Load`	Load the value stored in memory.
`Iex_CCall`	A call to a pure (no side-effects) helper C function.

For `Malton`, there are 9 types IR statements related to the taint propagation, which are listed in Table 2. For the `Ist_WrTmp` statement, since the source value may be the result of an IR expression, we also need to parse the logic of the IR expression for taint propagation. The IR expressions that can affect the taint propagation are summarized in Table 3. During the execution of the target app, `Malton` parses the IR statements and expressions in the helper functions, and propagates the taint tags according to the logic of the IR statements and expressions.

`Malton` supports taint sources/sinks in different layers (i.e., the framework layer and the system layer). For example, `Malton` can take the arguments and results of both Java methods and C/C++ methods as the taint sources, and check the taint tags of the arguments and the results of sink methods. By default, at the framework layer, 11 types of information are specified as taint sources, including device information (i.e., IMSI, IMEI, SN and phone number), location information (i.e., GPS location, network location and last seen location) and personal information (i.e., SMS, MMS, contacts and call logs). `Malton` also checks the taint tags of the arguments and results when each framework method is invoked. In the system layer, `Malton` takes system calls *sys_write()* and

sys_sendto() as taint sinks by default, because the sensitive information is usually stored to files or leaked out of the device through these system calls. As malware can receive commands from network, `Malton` takes system call *sys_recvfrom()* as the taint source by default. Note that `Malton` can be easily extended to support other methods as taint sources and sinks in both the framework layer and the system layer.

3.6 Instruction Layer: *Path Exploration*

Advanced malware samples usually execute malicious payloads according to the commands received from the C&C server or the special context (e.g., date, locations, etc.). To trigger as many malicious behaviors as possible for analysis, `Malton` employs the efficient path exploration technique, which consists of taint analysis, in-memory concolic execution with an offloading mechanism, and direct execution engine. Specifically, taint analysis helps the analyst identify the code paths depending on the inputs, such as network commands, and the concolic execution module can generate the required inputs to explore the interested code paths. When the inputs cannot be generated, we rely on the direct execution engine to forcibly execute certain code paths. Since concolic execution [27] is a well-known technique in the community, we will not introduce it in the following. Instead, we detail the offloading mechanism and the in-memory optimization used in the concolic execution module, and explain how the direct execution engine works.

Concolic Execution: Offloading Mechanism It is non-trivial to apply concolic execution in analyzing Android malware on real devices, because concolic execution requires considerable computational resources, resulting in unacceptable overhead on the mobile devices. To alleviate this limitation, `Malton` utilizes an offloading mechanism that moves the task of solving constraints to the resourceful desktop computers, and then sends back the satisfying results to the mobile devices as inputs. Our approach is motivated by the fact that the time consumption for solving constraints occupies the overall runtime of concolic execution. For example, the percentage of time used to solve constraints is nearly 41% of the KLEE system, even after optimizations [25].

More precisely, when the malware sample is running in our system, `Malton` redirects all the constraints to the logcat messages [4], which could be retrieved by the desktop computer using the ADB (Android Debug Bridge) tool. Then, the constraint solver, which is implemented based on Z3 [33], generates the satisfying inputs and feeds the inputs back to `Malton` through a file. Since we may have multiple code paths that need to be explored, this process could be repeated several times until the constraint solver pushes an empty input file to the device for notifying `Malton` to finish path exploring.

Concolic Execution: In-memory Optimization To speed up the analysis, especially when there are multiple execution paths, each of which depends on the special input, we propose in-memory optimization to restrict concolic execution within the interested code region specified by the analyst without repeatably running from the beginning of the program. By default, the analyst is required to specify the arguments or variables as the input of the concolic execution, which will be represented as symbolic values during concolic execution. For example, the analyst can select the SMS content acquired from the method *getMessageBody()* (Line 37 in Listing 1) as the input. Moreover, the analyst can select the IR statement that lets the input have concrete values as the entry point of the code region, and choose the exit statement (i.e., `Ist_Exit`) or the next statement (i.e., `Ist_Next`) of the subroutine as the exit point of the code region.

`Malton` runs the malware sample until the exit point of the interested code region for collecting constraints and generating new inputs for different code paths through an SMT solver. Then, it forces the execution to return to the entry point of the code region through modifying the program counter and feeds the inputs by writing the new inputs directly into the corresponding locations (i.e., memories or registers). Moreover, `Malton` needs to recover the execution context and the memory state at the entry point of the code region.

To recover the execution context, `Malton` conducts instrumentation at the beginning of the code region, and inserts a helper function to save the execution context (i.e., register states at the first iteration). After that, the saved register states will be recovered in the later iterations. As Valgrind uses the structure `VexGuestArchState` to represent the register states, we save and recover the register states by reading and writing the `VexGuestArchState` data in the memory.

To recover the memory states, `Malton` replaces the system's memory allocation/free functions with our customized implementations to monitor all the memory allocation/free operations. `Malton` can also free the allocated memory or re-allocate the freed memory. Besides, `Malton` inserts a helper function before each memory store (i.e., `Ist_Store` and `Ist_StoreG`) statement to track the memory modifications, so that all the modified memory could be restored.

Alternatively, the analyst can choose the target code region according to the method call graph, or first use static analysis tool to identify code paths and then select a portion of the path as the interested code region.

Direct Execution The concolic execution may not be able to explore all the code paths of the interested code region, because the constraint solver may not find satis-

fying inputs for complex constraints, such as float-point operations and encryption routines. For the conditional branches with unresolved constraints, `Malton` has the capability to directly execute certain code paths.

The direct execution engine of `Malton` is implemented through two techniques: a) modifying the arguments and the results of methods, including library functions, system calls and Java methods; b) setting the guard value of the conditional exit statement (i.e., `Ist_Exit`). The guard value is the expression used in the `Ist_Exit` statement to determine whether the branch should be taken.

It's straightforward to modify arguments and the return values of library functions and system calls by leveraging Valgrind APIs. However, it's challenging to deal with the Java methods because there is no interface in Valgrind to wrap Java methods. Fortunately, we have obtained the entry point and exit points of the compiled Java method in the framework layer (Section 3.2). Hence, we could wrap the Java method by adding instrumentation at its entry point and exit points. For example, to change the source telephone number of a received SMS to explore certain code path (Line 41 in Listing 1), `Malton` can wrap the framework API *SmsMessage.getOriginatingAddress()* and modify its return value to a desired number at the exit points.

To set the guard value of the `Ist_Exit` statement, we insert a helper function before each `Ist_Exit` statement and specify the guard value to the result of the helper function. In an IR block, the program can only conventionally jump out of the IR block at the location of the `Ist_Exit` statement (e.g., an if-branch in the program). The `Ist_Exit` statement is defined with the format "`if(t) goto <dst>`" in Valgrind, where *t* and *dst* represent the guard value and destination address, respectively. By returning "1" or "0" in the helper function, we can let *t* satisfy or dissatisfy the condition for exploring different code paths.

Table 4: Comparison of the capability of capturing the sensitive behaviors of malware samples.

Behavior	CopperDroid	DroidBox	Malton
Personal Info	435 (85.0%)	135 (26.4%)	511 (99.8%)
Network access	351 (68.5%)	211 (41.2%)	445 (86.9%)
File access	438 (85.5%)	509 (99.4%)	512 (100%)
Phone call	52 (10.1%)	1 (0.2%)	59 (11.5%)
Send SMS	26 (5.1%)	15 (2.9%)	28 (5.5%)
Java code loading	NA	509 (99.4%)	512 (100%)
Anti-debugging	4 (0.8%)	NA	4 (0.8%)
Native code loading	NA	NA	160 (31.2%)

4 Evaluation

We evaluate `Malton` using real-world Android malware samples to answer the following questions.

Q1: Can `Malton` capture more sensitive operations than other systems?

Q2: Can `Malton` analyze sophisticated malware samples (e.g., packed malware) to provide a comprehensive view of malicious behaviors?

Q3: Is the path exploration mechanism effective and efficient?

4.1 Sensitive Behavior Monitoring

To answer **Q1**, we compare `Malton`'s capability of capturing sensitive behaviors with CopperDroid [73] and DroidBox [34]. These two systems are implemented by instrumenting Android emulator and modifying the Android system, respectively. Since CopperDroid's website[3] has just queued all our uploaded malware samples, we cannot obtain the corresponding analysis results. Therefore, we downloaded the analysis reports of $1,362$ malware samples that have been analyzed by CopperDroid. According to their md5s, we collected 512 samples, and run them using `Malton` and DroidBox, respectively. The comparison results are listed in Table 4. The first column shows the type of sensitive behaviors, and the following columns list the numbers and percentages of malware samples that have been detected by each system due to the corresponding sensitive behaviors . We can see that for all the sensitive behaviors `Malton` detected more samples than the other two systems.

We further manually analyze the malware samples to understand why `Malton` detects more sensitive behaviors in those samples than the other two systems. First, `Malton` monitors malware's behaviors in multiple layers, and thus it can capture more behaviors than the systems focusing on one layer. For instance, the malware sample[4] retrieves the serial number and operator information of the SIM card through the framework APIs *TelephonyManager.getSimSerialNumber()* and *TelephonyManager.getSimOperator()*, respectively. However, CopperDroid does not support reconstructing such behaviors from system calls and DroidBox does not monitor these framework APIs. Second, `Malton` runs on real devices, and hence it could circumvent many anti-emulator techniques. For instance, the malware sample[5] detects the existence of emulator based on the value of *android_id* and *Build.DEVICE*. If the obtained value indicates that it is running in an emulator, the malicious behaviors will not be triggered.

Note that these samples were analyzed by CopperDroid before 2015 and it is likely that their C&C servers were active at that time. However, not all C&C servers

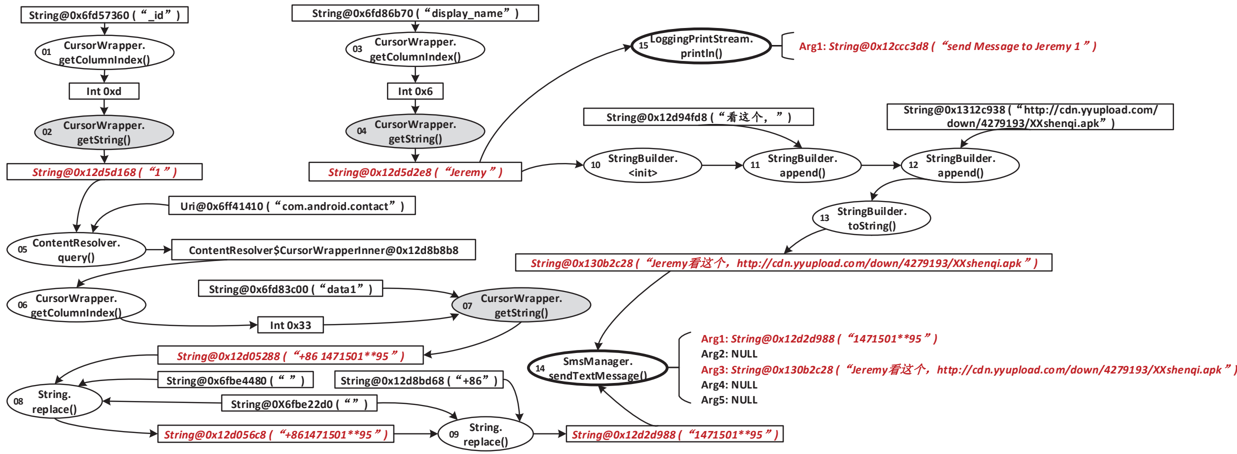

Figure 4: `Malton` can help the analyst construct the complete flow of information leakage in the *XXshenqi* malware. The ellipses refer to function invocations, where the grey ellipses represent taint sources and the ellipses with bold lines denote taint sinks. The rectangles indicate data and red italics strings highlight the tainted information.

were still active when `Malton` inspects the same samples. Hence, in the worst case, `Malton`'s results may be penalized since the malware cannot receive commands.

Summary Compared with existing tools running in the emulator and monitoring malware behaviors in a single layer, `Malton` can capture more sensitive behaviors thanks to its on-device and cross-layer inspection.

4.2 Malware Analysis

To answer **Q2**, we evaluate `Malton` with sophisticated malware samples by constructing the complete flow of information leakage across different layers, detecting stealthy behaviors with Java/JNI reflection, dissecting the behaviors of packed Android malware, and identifying the malicious behaviors of hidden code.

4.2.1 Identify Cross-Layer Information Leakage

This experiment uses the sample in the XXShenqi [3] malware family, which is an SMS phishing malware with package name *com.example.xxshenqi*. When the malware is launched, it reads the contact information and creates a phishing SMS message that will be sent to all the contacts collected. In this inspection, we focused on the behavior of creating and sending the phishing SMS message to the retrieved contacts by letting the contacts be the taint source and the methods for sending SMS messages be the taint sink. The detailed flow is illustrated in Figure 4.

To retrieve the information of each contact, the malware first obtains the column index and the value of the field *_id* in step 1 and step 2 in Figure 4[6], respectively. Then, a new instance of the class *CursorWrapper* is created based on *_id* and *uri* (*com.android.contact*), and this contact's phone number is acquired through this instance. After that, blank characters and the national number ("+86") are removed from the retrieved phone number in steps 8 and 9. In the method *String.replace()*[7], *StringFactory.newStringFromString()* and *String.setCharAt()* are invoked to create a new string according to the current string and set the specified character(s) of the new string, respectively. These two methods are JNI functions and implemented in the system layer. For *String.setCharAt()*, `Malton` can further determine the tainted portion of the string at the byte granularity. By contrast, TaintDroid does not support this functionality because for JNI methods it lets the taint tag of the whole return value be the union of the function arguments' taint tags. After that, a phishing SMS message is constructed according to the *display_name* of a retrieved contact and the phishing URL through steps 10-13. Finally, the phishing SMS is sent to the contact in step 14 and a message "send Message to Jeremy 1" is printed in step 15.

Summary By conducting the cross-layer taint propagation, `Malton` can help the analyst construct the complete flow of information leakage.

4.2.2 Detect Stealthy Malicious Behaviors

Some malware adopts Java/JNI reflection to hide their malicious behaviors. We use the sample in the *photo3*[8] malware family to evaluate `Malton`'s capability of detecting such stealthy behaviors. Figure 5 demonstrates the identified stealthy behaviors, which are completed in two different threads. The number in the ellipse and rectangle is the step index, and we use different colours (i.e.,

[6]The number in each ellipse denotes the step index.

[7]in /libcore/libart/src/main/java/java/lang/String.java

[8]md5:8bd9f5970afec4b8e8a978f70d5e87ab

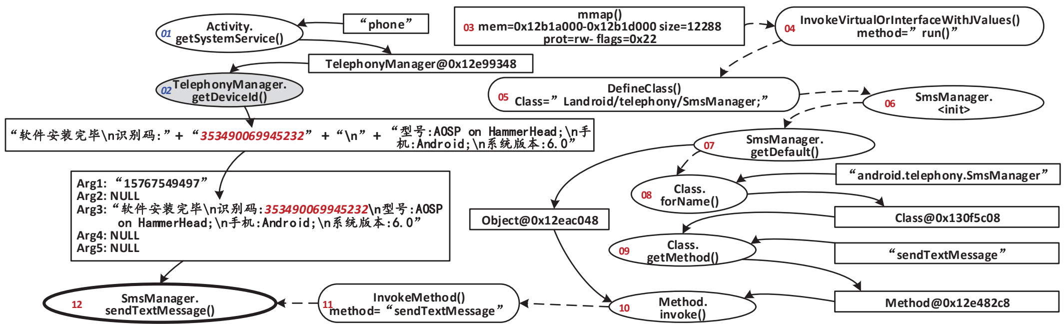

Figure 5: `Malton` can detect stealthy behaviors through the Java/JNI reflection of the *photo3* malware. The ellipses refer to function invocations in the framework layer, where the grey ellipses represent taint sources and the ellipses with bold lines denote taint sinks. The round corner rectangles stand for function invocations at the runtime layer. Other rectangles indicate data and red italics strings highlight the tainted information.

blue and red) for the numbers to distinguish two threads. The execution paths are denoted by both the solid lines and dashed lines, and the solid lines further indicate how the information is leaked. We describe the identified malicious behaviors as follows.

- The device ID is returned by the method *TelephonyManager.getDeviceId()* in step 1 and step 2.
- A new thread is created to send the collected information to the malware author. In step 3, a memory area is allocated by the system call *sys_mmap()*, and the thread method *run()* is invoked by the runtime through the JNI reflection function *InvokeVirualOrInterfaceWithJValues()* in step 4. Next, the class *android/telephony/SmsManager* is defined and initialized in step 5 and step 6. In step 7, the *SmsManager* object is obtained through the static method *SmsManager.getDefault()*.
- The malware sends SMS messages through Java reflection. Specifically, in step 8, the malware obtains the object of the *android.telephony.SmsManager* class through the Java reflection method *Class.forName()*. Then, it retrieves the method object of *sendTextMessage()* using the Java reflection method *Class.getMethod()* in step 9. Finally, it calls the Java method *sendTextMessage()* in step 10. This invocation goes to the method *InvokeMethod()* in the ART runtime layer in step 11.

Summary `Malton` can identify malware's stealthy behaviors through Java/JNI reflection in different layers.

4.2.3 Dissect Packed Android Malware's Behaviors

Since `Malton` stores the collected information into log files, we can dissect the behaviors of packed Android malware by analyzing the log files. As an example, Figure 6 shows partial log file of analyzing the packed malware sample[9], and Figure 7 illustrates the identified malicious behaviors of this sample. Such behaviors can be divided into two parts. One is related to the original packed malware (Lines 1-21), and the other one is relevant to the hidden payloads of the malware (Lines 22-30).

Once the malware is started, the class *com.netease.nis.wrapper.MyApplication* is loaded for preparing the real payload (Line 2). Then, the Android framework API *Application.attach()* is invoked (Line 4) to set the property of the app context. After that, the malware calls the Java method *System.loadLibrary()* to load its native component `libnesec.so` at Line 7. `Malton` empowers us to observe that the ART runtime invokes the function *FindClass()* (Line 8) and the function *LoadNativeLibrary()* (Line 9) to locate the class *com.netease.nis.wrapper.MyJni* and load the library `libnesec.so`, respectively.

After initialization, the malware calls the JNI method *MyJni.load()* to release and load the hidden Dalvik bytecode into memory. More precisely, the package name is first obtained through JNI reflection (Line 11 and 12). Then, the hidden bytecode is written into the file "*.cache/classes.dex*" under the app's directory (Line 13 and 14). After that, a new `DexFile` object is initialized based on the newly created Dex file through the runtime function *DexFile::OpenMemory()* (Line 16).

We also find that the packed malware registers an Intent receiver to handle the Intent `com.zjdroid.invoke` at Line 19 and 21. Note that ZjDroid [9] is a dynamic unpacking tool based on the Xposed framework and is started by the Intent `com.zjdroid.invoke`. By registering the Intent receiver, the malware can detect the existence of ZjDroid.

Finally, the app loads and initializes the class *v.v.v.MainActivity* in Line 23 to 26, and the hidden malicious payloads are executed at Line 29. To hide itself, the

24         DefineClass()                         // args: DexFileObj=0x06d541c8  Class="Lv/v/v/MainActivity;"
25     Class.newInstance()
26         Activity.init()
27 Instrumentation.callActivityOnCreate()        // Create and display an activity
28         Activity.performCreate()              // Create activity "v.v.v.MainActivity"
29             ...;                              // Malicious behaviors 2
30         Activity.finish()                     // Close the activity for hiding
```

Behaviors of "v.v.v.MainActivity"

Figure 6: The major information collected by `Malton` on function level. The names of Android runtime functions and system calls are in black italics. We omit the information of method arguments due to the space limitation).

malware also calls the framework method *Activity.finish()* to destroy its activity (Line 30).

Summary `Malton` can analyze sophisticated packed malware samples, and help the analyst identify the behaviors of both the malware and its hidden code.

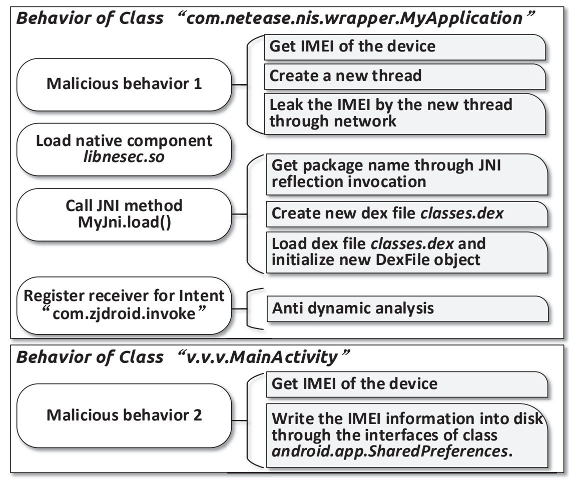

Figure 7: `Malton` can reconstruct the behaviors of the packed malware and its hidden code.

4.3 Path Exploration

To answer **Q3**, we first employ `Malton` to analyze the SMS handler of the packed malware *com.nai.ke*. From the logs, we find that its SMS handler *handleReceiver()* processes each incoming SMS by obtaining its address and content through methods *getOriginatingAddress()* and *getMessageBody()*, respectively. If the SMS is not from the controller (i.e., Tel: 1851130**14), it calls the method *abortBroadcast()* to abort the current broadcast.

Effectiveness To explore all the malicious payloads controlled by the received SMS message, we specify the code region between the return of the function *getMessageBody()* and the return of *handleReceiver()* to perform in-memory concolic execution. We set the result of *getMessageBody()* (i.e., SMS content) as the input of the concolic execution. To circumvent the checking of the phone number of the received SMS message, we trigger the malware to execute the satisfied code path by changing the result of *getOriginatingAddress()* to the number of the controller.

However, we find that the constraint resolver cannot always find the satisfying input due to the comparison of two strings' hash values. Therefore, we use the direct execution engine to force the malware to execute the selected code path. Eventually, we identify 14 different code paths (or behaviors) that depend on the content of the received SMS. The generated inputs and their corresponding behaviors are listed in Table 5. This result demonstrated the effectiveness of `Malton` to explore different code paths.

Efficiency Thanks to the in-memory optimization, when exploring code paths in the interested code region, `Malton` just needs one SMS and then iteratively executes the specified code region for 14 times without the need of restarting the app for 14 times. To evaluate the ef-

Table 5: The commands and the related behaviors explored by `Malton` (The 3rd column lists the number of IR blocks to be executed for exploring the code paths with/without in-memory optimization).

Command	Detected behavior	Number of executed blocks
"cq"	Read information SMS contents, contacts, device model and system version, then send to 292019159c@fcvh77f.com with password "aAaccvv11" through SMTP protocol.	32k/20443k
"qf"	Send SMS to all contacts with no SMS content.	7k/20537k
"df"	Send SMS to specified number, and both the number and content are specified by the command SMS.	5k/22970k
"zy"	Set unconditional call forwarding through making call to "**21**targetNum*%23", and the *targetNum* is read from the command SMS.	8k/22848k
"by"	Set call forwarding when the phone is busy through making call to "%23%23*targetNum*%23", and the *targetNum* is read from the control SMS.	15k/20639k
"ld","fd","dh","cz", "fx","sx","dc", "bc"	Modify the its configuration file zzxx.xml.	5k-18k/20403k-20452k
Others	Tell the controller the command format is error by replying an SMS.	15k/20443k

ficiency of the in-memory optimization, we record the number of IR blocks to be executed for exploring each code path with/without in-memory optimization, and list them in Table 5 (the last column). The result shows that the in-memory optimization can avoid executing a large number of IR blocks. For example, when exploring the paths decided by the command "df", `Malton` only needs to execute 5k IR blocks with in-memory optimization. Otherwise, it has to execute 22,970k IR blocks.

Table 6: The number of IR blocks to be executed for path exploration with and without in-memory optimization.

Malware	With Optimization	Without Optimization
0710*ef*0*ee*60*e*1*acfd*2817988672*bf*01*b*	203k	26237k
0*ced*776*e*0*f*18*ddf*02785704*a*72*f*97*aac*	203k	26010k
0*e*69*af*88*dcbb*469*e*30*f*16609*b*10*c*926*c*	4k	16826k
336602990*b*176*cf*381*d*288*b*79680*e*4*f*6	13k	1908k
8*e*1*c*7909*aed*92*eea*89*f*6*a*14*e*0*f*41503*d*	7k	69968k

We also use five other malware samples, which have the SMS handler, to further evaluate the efficiency of the path exploration module. The average number of IR blocks to be executed with and without in-memory optimization are listed in Table 6. The in-memory optimization can obviously reduce the number of IR blocks to be executed.

Summary The path exploration module of `Malton` can explore code paths of malicious payloads effectively and efficiently. The concolic execution engine generates the satisfying inputs to execute certain code paths, and the direct execution engine forcibly executes selected code paths when the constraint resolver fails.

4.4 Performance Overhead

To understand the overhead introduced by `Malton`, we run the benchmark tool CF-Bench [8] 30 times on a Nexus 5 smartphone running Android 6.0 under four different environments, including Android without Valgrind, Android with Valgrind, and `Malton` with and

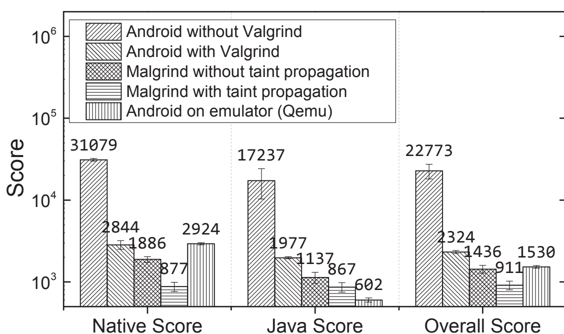

Figure 8: Performance measured by CF-Bench.

without the taint propagation. To compare with the dynamic analysis tools based on the Qemu emulator, we also execute CF-Bench in Qemu, which runs on a Ubuntu 14.04 desktop equipped with Core(TM) i7 CPU and 32G memory.

The results are shown in Figure 8. There are three types of scores. The Java score denotes the performance of Java operations, and the native score indicates the performance of naive code operation. The overall scores are calculated based on the Java and the native score. A higher score means a better performance.

Figure 8 illustrates that `Malton` introduces around 16x and 36x slowdown to the Java operations without and with taint propagation. However, when the app runs with only Valgrind, there is also 11x slowdown. It means that `Malton` brings 1.5x-3.2x additional slowdown to Valgrind. Similarly, for the native operations, `Malton` introduces 1.7x-2.3x additional slowdown when running Valgrind is taken as the baseline. Overall, `Malton` introduces around 25x slowdown (with taint propagation). Since the Qemu [57] emulator incurs around 15x overall slowdown, and the Qemu-based tools (e.g., the taint tracker of DroidScope [83]) may incur 11x-34x additional slowdown, `Malton` could be more efficient than the existing tools based on Qemu.

Summary As a dynamic analysis tool, `Malton` has a reasonable performance and could be more efficient than the existing tools based on the Qemu emulator.

5 Discussion

In this section, we discuss the limitations of Malton and potential solutions to be investigated in future work.

First, Malton is based on the Valgrind framework. Similar to the anti-emulator techniques, malware samples may detect the existence of Malton and then stop executing malicious payloads or confuse the Java method tracker of Malton. For example, the malware could check the app starting command or the time used to finish some operations. To address this challenge, we could leverage Malton's path exploration mechanism to explore and trigger conditionally executed payloads. Nevertheless, it's an arm race between the analysis tool and anti-analysis techniques.

Second, though the in-memory optimization significantly reduces the code required to be executed, it is semi-automated because the analysts have to specify the entry point and the exit point of the interested code region. How to fully automate this process is an interesting research direction that we will pursue. Moreover, the direct execution needs analysts to specify the branches to be executed directly. Our current prototype ignores all possible crashes because the directly executed code path may access invalid memory. Advanced malware may exploit this weakness to evade Malton. In future work, we will borrow some ideas from the X-Force [55] system to recover the execution from crashes automatically.

Third, the code coverage is a concern for all dynamic analysis platforms, including ours. We leverage the monkey tool to generate events, and use the path exploration module to explore code paths. Even using the simple monkey tool, Malton has demonstrated better results than existing tools in Section 4.1. In future work, we will equip Malton with UI automation frameworks (e.g., [41]) to generate more directive events. Moreover, as Malton only defines the default sensitive APIs, users can add more sensitive APIs to Malton.

Last but not least, though Malton uses taint analysis to track sensitive information propagation, it cannot track implicit information flow and propagate taint tags over indirect flows.We will enhance it by leveraging the ideas in [45]. For example, we can track the indirect flows like Binder IPC/RPC by hooking the related framework methods and runtime functions. Moreover, since the major purpose of Malton is to provide a comprehensive view of the target apps instead of finding unknown malware, it requires users to specify the malicious patterns for employing Malton to identify potential malware.

6 Related Work

Android malware analysis techniques can be generally divided into static analysis, dynamic analysis, and the hybrid of static and dynamic analysis. Since Malton is a dynamic analysis system, this section introduces the related dynamic and hybrid approaches. Interested readers please refer to [18,51,58,63,72,80] for more information on static analysis of Android apps.

6.1 Dynamic or Hybrid Analysis

According to the implementation techniques, the existing (dynamic or hybrid) Android malware analysis tools can be roughly divided into five types: tailoring Android system [34, 39, 71, 89], customizing Android emulator (e.g., Qemu) [73, 83], modifying (repackaging) app implementation [37], employing system tracking tools [84], or leveraging an app sandbox [20, 24].

We compare Malton with popular (dynamic or hybrid) Android malware analysis tools, and enumerate the major differences in Table 7. Please note that ◔, ◑, and ◕ indicate that the tool can capture malware behaviors in the framework layer, the runtime layer and the native layer, respectively. Besides, the shadow sector means partial support. For example, ◔ of TaintART suggests that it can monitor partial framework behaviors.

TaintDroid [39] conducts dynamic taint analysis to detect information leakage by modifying DVM. It does not capture the behaviors in native layer because it trusts the native libraries loaded from firmware and does not consider third-party native libraries. While only a small percent of apps used native libraries when TaintDroid was designed, recent studies showed that native libraries have been heavily used by apps and malware [19, 59]. At the runtime layer, although TaintDroid can track taint propagation in DVM, it neither monitor the runtime behaviors nor support ART. Though many studies [34, 62, 65, 68, 77, 89, 90] enhanced TaintDroid from different aspects, they cannot achieve the same capability as Malton. For example, AppsPlayground [62] combines TaintDroid and fuzzing to conduct multi-path taint analysis. Mobile-Sandbox [68] uses TaintDroid to monitor framework behaviors and employs ltrace [5] to capture native behaviors.

To avoid modifying Android system (including the framework, native libraries, Linux kernel etc.), a number of studies [10, 12, 22, 23, 31, 32, 43, 60, 61, 67, 78, 81, 87] propose inserting the logics of monitoring behaviors or security policies into the Dalvik bytecode of the malware under inspection and then repacking it into a new APK. Those studies have three common drawbacks. First, they can only monitor the framework layer behaviors by manipulating Dalvik bytecode. Second, those approaches are invasive that can be detected by malware. Third, malware may use packing techniques to prevent such approaches from repacking it [85, 88].

Based on QEMU, DroidScope [83] reconstructs the

Table 7: Comparison of `Malton` with the popular existing Android malware analysis tools.

OS-level and Java-level semantics, and exports APIs for building specific analysis tools, such as dynamic information tracer. Hence, there is a semantic gap between the VMI observations and the reconstructed Android specific behaviors. Since it monitors the Java-level behaviors by tracing the execution of Dalvik instructions, it cannot monitor the Java methods that are compiled into native code and running on ART (i.e, partial support of framework layer). Moreover, DroidScope does not monitor JNI and therefore it cannot capture the complete behaviors at runtime layer. CopperDroid [73] is also built on top of Qemu and records system call invocations by instrumenting Qemu. Since it performs binder analysis to reconstruct the high-level Android-specific behaviors, only a limited number of behaviors can be monitored. Moreover, it cannot identify the invocations of framework methods. ANDRUBIS [50] and MARVIN [49] (which is built on top of ANDRUBIS) monitor the behaviors at the framework layer by instrumenting DVM and log system calls through VMI.

Monitoring system calls [17, 35, 46, 48, 54, 68, 75, 76, 84, 91] is widely used in Android malware analysis because considerable APIs in upper layers eventually invoke systems calls. For instance, Dagger [84] collects system calls through strace [6], recodes binder transactions via sysfs [7], and accesses process details from */proc* file system. One common drawback of system-call-based techniques is the semantic gap between system calls with the behaviors of upper layers, even though several studies [54, 84, 91] try to reconstruct high-level semantics from system calls. Besides tracing system calls, MADAM [35] and ProfileDroid [76] monitor the interactions between user and smartphone. However, they cannot capture the behaviors in the runtime layer.

Both TaintART [71] and ARTist [21] are new frameworks to propagate the taint information in ART. They modify the tool `dex2oat`, which is provided along with ART runtime to turn Dalvik bytecode into native code during app's installation. The taint propagation instructions will be inserted into the compiled code by the modified `dex2oat`. However, they only propagate taint at the runtime layer, and do not support the taint propagation through JNI or in native codes. Moreover, they cannot handle the packed malware, because such malware usually dynamically load the Dalvik bytecode into runtime directly without triggering the invocation of `dex2oat`. CRePE [29] and DroidTrack [64] track apps' behaviors at the framework layer by modifying Android framework.

Boxify [20] and NJAS [24] are app sandboxes that encapsulate untrusted apps in a restricted execution environment within the context of another trusted sandbox app. Since they behave as a proxy for all system calls and binder channels of the isolated apps, they support the analysis of native code and could reconstruct partial framework layer behaviors.

ARTDroid [30] traces framework methods by hooking the virtual framework methods and supports ART. Since the boot image boot.art contains both the vtable_ and virtual_methods_ arrays that store the pointers to virtual methods, ARTDroid hijacks vtable_ and virtual_methods_ to monitor the APIs invoked by malware.

HARVESTER and GroddDroid [10, 61] support multipath analysis. The former [61] covers interested code forcibly by replacing conditionals with simple Boolean variables, while the latter [10] uses a similar method to jump to interested code by replacing conditional jumps with unconditional jumps. Different from `Malton`, they need to modify the bytecode of malware.

6.2 Multi-path analysis for Android

There are a few studies about multi-path analysis for Android. TriggerScope [40] is a static symbolic executor that handles Dalvik bytecode. Similar to other static analysis tools, it may run into trouble when handling reflections, native code, dynamic Dex loading etc. Anand et al. [15] proposed ACTEve that uses concolic execution to generate input events for testing apps and offloads constraint solving to the host. There are three major differences between ACTEve and the path exploration module of `Malton`. First, since ACTEve instruments the analyzed app and the SDK, this invasive approach may be detected by malware. Second, ACTEve does not support native code. Third, it does not apply the in-memory optimization. ConDroid [66] also depends on the static instrumentation, and therefore has the same limitations.

Two recent studies [52, 86] propose converting Dalvik bytecode into Java bytecode and then using Java PathFinder [16] to conduct symbolic execution in a customized JVM. However, JVM cannot properly emulate the real device. Moreover, they do not support the analysis of native code.

To make concolic execution applicable for testing embedded software, Chen et al. [28] and MAYHEM [26] adopt similar offloading method. However, they do not apply the in-memory optimization and cannot be used to analyze Android malware. For example, Chen et al. coordinates the part on device and the part on host through the Wind River Tool Exchange protocol for VxWorks.

7 Conclusion

We propose a novel on-device non-invasive analysis system named `Malton` for inspecting Android malware running on ART. `Malton` provides a comprehensive view of the Android malware behaviors, by conducting multi-layer monitoring and information flow tracking and efficient path exploration without the need of modifying the malware. We have developed a prototype of `Malton` and the evaluation with real-world sophisticated malware samples demonstrated the effectiveness of our system.

Abstract

Despite the pervasive nature of Internet censorship and the continuous evolution of how and where censorship is applied, measurements of censorship remain comparatively sparse. Understanding the scope, scale, and evolution of Internet censorship requires global measurements, performed at regular intervals. Unfortunately, the state of the art relies on techniques that, by and large, require users to directly participate in gathering these measurements, drastically limiting their coverage and inhibiting regular data collection. To facilitate large-scale measurements that can fill this gap in understanding, we develop Iris, a scalable, accurate, and ethical method to measure global manipulation of DNS resolutions. Iris reveals widespread DNS manipulation of many domain names; our findings both confirm anecdotal or limited results from previous work and reveal new patterns in DNS manipulation.

1 Introduction

Anecdotes and reports indicate that Internet censorship is widespread, affecting at least 60 countries [29, 39]. Despite its pervasive nature, empirical Internet measurements revealing the scope and evolution of Internet censorship remain relatively sparse. A more complete understanding of Internet censorship around the world requires *diverse* measurements from a wide range of geographic regions and ISPs, not only across countries but also within regions of a single country. Diversity is important even within countries, because political dynamics can vary internally, and because different ISPs may implement filtering policies differently.

Unfortunately, most mechanisms for measuring Internet censorship currently rely on volunteers who run measurement software deployed on their own Internet-connected devices (e.g., laptops, phones, tablets) [43, 49]. Because these tools rely on people to install software and perform measurements, it is unlikely that they can ever achieve the scale required to gather continuous and diverse measurements about Internet censorship. Performing measurements of the scale and frequency necessary to understand the scope and evolution of Internet censorship calls for fundamentally new techniques that do not require human involvement or intervention.

We aim to develop techniques that can perform widespread, longitudinal measurements of global Internet manipulation without requiring the participation of individual users in the countries of interest. Organizations may implement censorship at many layers of the Internet protocol stack; they might, for example, block traffic based on IP address, or they might block individual web requests based on keywords. Recent work has developed techniques to continuously measure widespread manipulation at the transport [23,42] and HTTP [45] layers, yet a significant gap remains in our understanding of global information control concerning the manipulation of the Internet's Domain Name System (DNS). Towards this goal, we develop and deploy a method and system to detect, measure, and characterize the manipulation of DNS responses in countries across the entire world.

Developing a technique to *accurately* detect DNS manipulation poses major challenges. Although previous work has studied inconsistent or otherwise anomalous DNS responses [32, 34], these methods have focused mainly on identifying DNS responses that could reflect a variety of underlying causes, including misconfigurations. In contrast, our work aims to develop methods for accurately identifying DNS manipulation indicative of an intent to restrict user access to content. To achieve high detection accuracy, we rely on a collection of metrics that we base on the underlying properties of DNS domains, resolutions, and infrastructure.

One set of detection metrics focuses on *consistency*—intuitively, when we query a domain from different locations, the IP addresses contained in DNS responses should reflect hosting from either a common server (i.e., the same IP address) or the same autonomous system.

Another set of detection metrics focuses on *independent verifiability*, by comparison to independent information such as the identity in the TLS certificate for the website corresponding to the domain. Each of these metrics naturally lends itself to exceptions: for example, queries from different locations utilizing a content distribution network (CDN) will often receive different IP addresses (and sometimes even different CDNs). However, we can use violations of *all* of the metrics as a strong indicator of DNS manipulation.

In addition to achieving accurate results, another significant design challenge concerns *ethics*. In contrast to systems that explicitly involve volunteers in collecting measurements, methods that send DNS queries through open DNS resolvers deployed across the Internet raise the issue of potentially implicating third parties who did not in fact agree to participate in the measurement. Using "open resolvers" is potentially problematic, as most of these are not actual resolvers but instead DNS forwarders in home routers and other devices [46]. A censor may misattribute requests from these resources as individual citizens attempting to access censored resources.

Reasoning about the risks of implicating individual citizens requires detailed knowledge of how censors in different countries monitor access to censored material and how they penalize such actions. These policies and behaviors may be complex, varying across time, region, individuals involved, and the nature of the censored content; such risks are likely intractable to accurately deduce. To this end, our design takes steps to ensure that, to the extent possible, we only query open DNS resolvers hosted in Internet *infrastructure* (e.g., within Internet service providers or cloud hosting providers), in an attempt to eliminate any use of resolvers or forwarders in the home networks of individual users. This step reduces the set of DNS resolvers that we can use for our measurements from tens of millions to only a few thousand. However, we find that the resulting coverage still suffices to achieve a global view of DNS manipulation, and—importantly—in a safer way than previous studies that exploit open DNS resolvers.

Our work makes the following contributions. First, we design, implement, and deploy Iris, a scalable, ethical system for measuring DNS manipulation. Second, we develop analysis metrics for disambiguating natural variation in DNS responses for a domain from nefarious manipulation. Third, we perform a global measurement study that highlights the heterogeneity of DNS manipulation, across countries, resolvers, and domains. We find that manipulation varies across DNS resolvers even within a single country.

2 Related Work

Country-specific censorship studies. In recent years many researchers have investigated the whats, hows, and whys of censorship in particular countries. These studies often span a short period of time and reflect a single vantage point within a target country, such as by renting virtual private servers. For example, studies have specifically focused on censorship practices in China [55], Iran [7], Pakistan [38], Syria [12], and Egypt [8]. Studies have also explored the employment of various censorship methods, e.g., injection of fake DNS replies [5, 36], blocking of TCP/IP connections [54], and application-level blocking [19, 33, 41]. A number of studies suggest that countries sometimes change their blocking policies and methods in times surrounding political events. For example, Freedom House reports 15 instances of Internet shutdowns—where the government cut off access to Internet entirely—in 2016 alone [29]. Most of these were apparently intended to prevent citizens from reaching social media to spread unwanted information.

Other studies have demonstrated that government censorship covers a broad variety of services and topics, including video portals (e.g.,`youtube.com`) [51], blogs (e.g., `livejournal.com`) [3], and news sites (e.g., `bbc.com`) [9]. Censors also target circumvention and anonymity tools; most famously, the Great Firewall of China has engaged in a decade-long cat-and-mouse game with Tor [24, 53]. Although these studies provide important data points, each reflects a snapshot at a single point in time and thus cannot capture ongoing trends and variations in censorship practices.

Global censorship measurement tools. Several research efforts developed platforms to measure censorship by running experiments from diverse vantage points. For instance, CensMon [48] used PlanetLab nodes in different countries, and UBICA [1] aimed to increase vantage points by running censorship measurement software on home gateway devices and user desktops. In practice, as far as we know, neither of these frameworks are still deployed and collecting data. The OpenNet Initiative [39] has used its public profile to recruit volunteers around the world who have performed one-off measurements from home networks each year for the past ten years. OONI [49] and ICLab [30], two ongoing data collection projects, use volunteers to run both custom software and custom embedded devices (such as Raspberry Pis [26]).

Although each of these frameworks can perform a extensive set of tests, they rely on volunteers who run measurement software on their Internet-connected devices. These human involvements make it more challenging—if not impossible—to gather continuous and diverse measurements.

Pearce et al. recently developed Augur, a method to perform longitudinal global measurement using TCP/IP side channels [42]. Although Augur examines a similar set of domains and countries as Iris, it focuses on identifying IP-based disruption rather than DNS-based manipulation.

Measuring DNS manipulation. The DNS protocol's lack of authentication and integrity checking makes it a prime target for attacks. Jones et al. presented techniques for detecting unauthorized DNS root servers, though found little such manipulation in practice [32]. Jiang et al. identified a vulnerability in DNS cache update policies that allows malicious domains to stay in the cache even if removed from the zone file [31].

Several projects have explored DNS manipulation using a limited number of vantage points. Weaver et al. explored DNS manipulation with respect to DNS redirection for advertisement purposes [52]. The authors also observed incidents in which DNS resolvers redirected end hosts to malware download pages. There are many country-specific studies that show how different countries use a variety of DNS manipulation techniques to exercise Internet censorship. For example, in Iran the government expects ISPs to configure their DNS resolvers to redirect contentious domains to a censorship page [7]. In Pakistan, ISPs return NXDOMAIN responses [38]. In China, the Great Firewall injects forged DNS packets with seemingly arbitrary IP addresses [5]. These studies however all drew upon a small or geographically limited set of vantage points, and for short periods of time.

Using open resolvers. A number of studies have explored DNS manipulation at a larger scale by probing the IPv4 address space to find open resolvers. In 2008, Dagon et al. found corrupt DNS resolvers by running measurements using 200,000 open resolvers [18]; they do not analyze the results for potential censorship. A similar scan by anonymous authors [4] in 2012 showed evidence of Chinese DNS censorship affecting non-Chinese systems.

Follow-on work in 2015 by Kührer et al. tackled a much larger scope: billions of lookups for 155 domain names by millions of open resolvers [34]. The study examined a broad range of potentially tampered results, which in addition to censorship included malware, phishing, domain parking, ad injection, captive portals, search redirection, and email delivery. They detected DNS manipulation by comparing DNS responses from open resolvers with ground truth resolutions gathered by querying control resolvers. They then identified legitimate unmanipulated answers using a number of heuristic filtering stages, such as treating a differing response as legitimate if its returned IP address lies within the same AS the ground truth IP address.

We tried to use their method for conducting global measurements specifically for detecting censorship. However, censorship detection was not a focus of their work, and the paper does not explicitly describe the details of its detection process. In particular, other than examining HTTP pages for "blocked by the order of ..." phrasing, the paper does not present a decision process for determining whether a given instance of apparent manipulation reflects censorship or some other phenomenon. In addition, their measurements leverage open resolvers *en masse*, which raises ethical concerns for end users who may be wrongly implicated for attempting to access banned content. In contrast, we frame an explicit, reproducible method for globally measuring DNS-based manipulation in an ethically responsible manner.

In 2016, Scott et al. introduced Satellite [47], a system which leverages open resolvers to identify CDN deployments and network interference using collected resolutions. Given a bipartite graph linking domains queried with IP address answers collected from the open resolvers, Satellite identifies strongly connected components, which represent domains hosted by the same servers. Using metrics for domain similarity based on the overlap in IP addresses observed for two domains, Satellite distinguishes CDNs from network interference as components with highly similar domains (additionally, other heuristics help refine this classification).

3 Method

In this section we describe Iris, a scalable, lightweight system to detect DNS manipulation. We begin by scoping the problem space, identifying the capabilities and limitations of various measurement building blocks, and stating our assumptions about the threat model. We explain the process by which we select (1) which domain names to measure, and (2) the vantage points to measure them from, taking into consideration questions of ethics and scalability. We then describe, given a set of measurement vantage points and DNS domain names, how we characterize the results of our measurements and use them to draw conclusions about whether DNS manipulation is taking place, based on either the *consistency* or the *independent verifiability* of the responses that we receive. Next, we consider our technical approach in light of existing ethical norms and guidelines, and explain how various design decisions help us adhere to those principles as much as possible. Finally, we discuss the implicit and technical limitations of Iris.

3.1 Overview

We aim to identify DNS manipulation, which we define as the instance of a DNS response both (1) having attributes (e.g., IP addresses, autonomous systems, web

content) that are not consistent with respect to a well-defined control set; and (2) returning information that is demonstrably incorrect when compared against independent information sources (e.g., TLS certificates).

Approach. Detecting DNS manipulation is conceptually simple: At a high-level, the idea entails performing DNS queries through geographically distributed DNS resolvers and analyzing the responses for activity that suggests that the responses for a DNS domain might be manipulated. Despite its apparent simplicity, however, realizing a system to scalably collect DNS data and analyze it for manipulation poses both ethical and technical challenges. The ethical challenges concern selecting DNS resolvers that do not implicate innocent citizens, as well as ensuring that Iris does not induce undue load on the DNS resolution infrastructure; §3.2 explains the ethical guidelines we use to reason about design choices. §3.3 describes how Iris selects a "safe" set of open DNS resolvers; The technical challenges center around developing sound methods for detecting manipulation, which we describe in §3.4 and §3.5.

Identifying DNS names to query. Iris queries a list of sensitive URLs compiled by Citizen Lab [14]. We call this list the Citizen Lab Block List (CLBL). This list of URLs is compiled by experts based on known censorship around the world, divided by category. We distill the URLs down to domain names and use this list as the basis of our dataset. We then supplement this list by adding additional domain names selected at random from the Alexa Top 10,000 [2]. These additional domain names help address geographic or content biases in the the CLBL while not drastically increasing the total number of queries.

Assumptions and focus. First, Iris aims to identify widespread manipulation at the scale of Internet service providers and countries. We cannot identify manipulation that is targeted at specific individuals or populations or manipulation activities that exploit high-value resources such as valid but stolen certificates. Second, we focus on manipulation tactics that do not rely on stealth; we assume that adversaries will use DNS resolvers to manipulate the responses to DNS queries. We assume that adversaries do not return IP addresses that are incorrect but within the same IP prefix as a correct answer [5, 7, 38]. Finally, when attributing DNS manipulation to a particular country or dependent territory, we rely on the country information available from Censys [21] supplemented with MaxMind's [37] dataset to map a resolver to a specific country (or dependent territory).

3.2 Ethics

The design of Iris incorporates many considerations regarding ethics. Our primary ethical concern is the risks associated with the measurements that Iris conducts, as issuing DNS queries for potentially censored or manipulated DNS domains through resolvers that we do not own could potentially implicate otherwise innocent users. A second concern is whether the DNS queries that we generate introduce undue query load on authoritative DNS nameservers for domains that we do not own. With these concerns in mind, we consider the ethics of performing measurements with Iris, using the ethical guidelines of the Belmont Report [10] and Menlo Report [20] to frame our discussion.

One important ethical principle is *respect for persons*; essentially, this principle states that an experiment should respect the rights of humans as autonomous decision-makers. Sometimes this principle is misconstrued as a requirement for informed consent for all experiments. In many cases, however, informed consent is neither practical nor necessary; accordingly, Salganik [44] characterizes this principle instead as "some consent for most things". In the case of Iris, obtaining the consent of all open DNS resolver operators is impractical.

In lieu of attempting to obtain informed consent, we turn to the principle of *beneficence*, which weighs the benefits of conducting an experiment against the risks associated with the experiment. Note that the goal of beneficence is not to *eliminate* risk, but merely to *reduce* it to the extent possible. Iris's design relies heavily on this principle: Specifically, we note that the benefit of issuing DNS queries through tens of millions of resolvers has rapidly diminishing returns, and that using only open resolvers that we can determine are unlikely to correspond to individual users greatly reduces the risk to any individual without dramatically reducing the benefits of our experiment. We note that our consideration of ethics in this regard is a significant departure from previous work that has issued queries through open DNS resolver infrastructure but has not considered ethics.

The principle of *justice* states that the beneficiaries of an experiment should be the same population that bears the risk of that experiment. On this front, we envision that the beneficiaries of the kinds of measurements that we collect using Iris will be wide-ranging: designers of circumvention tools, as well as policymakers, researchers, and activists who are improving communications and connectivity for citizens in oppressive regimes all need better data about the extent and scope of Internet censorship. In short, even in the event that some entity in a country that hosts an open DNS resolver might bear some risk as a result of the measurements we conduct, we envision that those same entities may ultimately benefit from the research, policy-making, and tool development

that Iris facilitates.

A final guideline concerns *respect for law and public interest*, which essentially extends the principle of beneficence to all relevant stakeholders, not only the experiment participants. This principle is useful for reasoning about the externalities that our DNS queries create by increasing DNS query load on the nameservers for various DNS domains. To abide by this principle, we rate-limit our DNS queries for each DNS domain to ensure that the owners of these domains do not face large expenses as a result of the queries that we issue. This rate limit is necessary because some DNS service providers charge based on the peak or near peak query rate.

3.3 Open DNS Resolvers

To obtain a wide range of measurement vantage points, we use *open DNS resolvers* deployed around the world; such resolvers will resolve queries for any client.

Measurement using open DNS resolvers is an ethically complex issue. Previous work has identified tens of millions of these resolvers around the world [34]. Given their prevalence and global diversity, open resolvers are a compelling resource, providing researchers with considerable volume and reach. Unfortunately, open resolvers also pose a risk not only to the Internet but to individual users.

Open resolvers can be the result of configuration errors, frequently on end-user devices such as home routers [34]. Using these devices for measurement can incur monetary cost, and if the measurement involves sensitive content or hosts, can expose the owner to harm. Furthermore, open resolvers are also a common tool in various online attacks such as Distributed Denial-of-Service (DDoS) amplification attacks [35]. Despite efforts to reduce both the prevalence of open resolvers and their potential impact [40], they remain commonplace.

Due to these and the ethics considerations that we discussed in §3.2, we restrict the set of open resolvers that we use to the few thousand resolvers that we are reasonably certain are part of the Internet infrastructure (e.g., belonging to Internet service providers, online cloud hosting providers), as opposed to attributable to any single individual. Figure 1 illustrates the process by which Iris finds safe open DNS resolvers. We now explain this process in more detail. Conceptually, the process comprises two steps: (1) scanning the Internet for open DNS resolvers; or (2) pruning the list of open DNS resolvers that we identify to limit the resolvers to a set that we can reasonably attribute to Internet infrastructure.

By using DNS resolvers we do not control, we cannot differentiate between country-wide or state-mandated censorship and localized manipulation (e.g., captive portals, malware [34]) at individual resolvers. Therefore

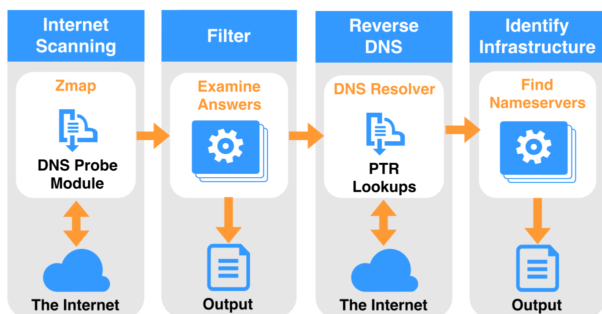

Figure 1: *Overview of Iris's DNS resolver identification and selection pipeline. Iris begins with a global scan of the entire IPv4 address space, followed by reverse DNS PTR lookups for all open resolvers, and finally filtering resolvers to only include DNS infrastructure.*

we must aggregate and analyze results at ISP or country scale.

Step 1: Scanning the Internet's IPv4 space for open DNS resolvers. Scanning the IPv4 address space provides us with a global perspective on all open resolvers. To do so, we developed an extension to the ZMap [22] network scanner to enable Internet-wide DNS resolutions[1]. This module queries port 53 of all IPv4 addresses with a recursive DNS A record query. We use a purpose-registered domain name we control for these queries to ensure there is a known correct answer. We conduct measurements and scans from IP addresses having a `PTR` record identifying the machine as a "research scanner." These IP addresses also host a webpage identifying our academic institution and offering the ability to opt-out of scans. From these scans, we select all IP addresses that return the correct answer to this query and classify them as open resolvers. In §4.1, we explore the population of open DNS resolvers that we use for our study.

Step 2: Identifying Infrastructure DNS Resolvers. Given a list of all open DNS resolvers on the Internet, we prune this list to include only DNS resolvers that can likely be attributed to Internet infrastructure. To do so, we aim to identify open DNS resolvers that appear to be authoritative nameservers for a given DNS domain. Iris performs reverse DNS `PTR` lookups for all open resolvers and retains only the resolvers that have a valid `PTR` record beginning with the subdomain `ns[0-9]+` or `nameserver[0-9]*`. This filtering step reduces the number of usable open resolvers—from millions to thousands—yet even the remaining set of open DNS resolvers provides broad country- and network-level coverage (characterized further in §4.1).

Using `PTR` records to identify infrastructure can have

[1] Our extension has been accepted into the open source project and the results of our scans are available as part of the Censys [21] system.

both *false negatives* and *false positives*. Not all infrastructure resolvers will have a valid PTR record, nor will they all be authoritative nameservers. These false negatives limit the scope and scale of our measurement, but are necessary to reduce risk. Similarly, if a user operated their own authoritative nameserver on their home IP or if a PTR record matched our naming criteria but was not authoritative, our method would identify that IP as infrastructure (false positives).

3.4 Performing the Measurements

Given a list of DNS domain names to query and a global set of open DNS resolvers from which we can issue queries, we need a mechanism that issues queries for these domains to the set of resolvers that we have at our disposal. Figure 2 shows an overview of the measurement process. At a high level, Iris resolves each DNS domain using the global vantage points afforded by the open DNS resolvers, annotates the response IP addresses with information from both outside datasets as well as additional active probing, and uses *consistency* and *independent verifiability* metrics to identify manipulated responses. The rest of this section outlines this measurement process in detail, while §3.5 describes how we use the results of these measurements to ultimately identify manipulation.

Step 1: Performing global DNS queries. Iris takes as input a list of suitable open DNS resolvers, as well as the combined CLBL and Alexa domain names. In addition to the DNS domains that we are interested in testing, we include 3 DNS domains that are under our control to help us compute our consistency metrics when identifying manipulation.

Querying tens of thousands of domains across tens of thousands of resolvers required the development of a new DNS query tool, because no existing DNS measurement tool supports this scale. We implemented this tool in Go [27]. The tool takes as input a set of domains and resolvers, and coordinates random querying of each domain across each resolver. The tool supports a variety of query types, multiple of which can be specified per run, including A, AAAA, MX, and ANY. For each (domain, resolver) pair, the tool crafts a recursive DNS request and sends it to the resolver. The recursive query requests that the resolver resolve the domain and return the ultimate answer, logging all responses, including timeouts. The tool follows the set of responses to resolve each domain to an IP address. For example, if a resolver returns a CNAME, the tool then queries the resolver for resolution of that CNAME.

To ensure resolvers are not overloaded, the tool includes a configurable rate-limit. For our experiments, we limited queries to resolvers to an upper bound of 5 per second. In practice, this rate tends to be much lower due to network latency in both reaching the resolver, as well as the time it takes the resolver to perform the recursive response. To cope with specific resolvers that are unstable or timeout frequently, the tool provides a configurable failure threshold that halts a specific resolver's set of measurements should too many queries fail.

To ensure the domains we query are not overloaded, the tool randomizes the order of domains and limits the number of resolvers queried in parallel such that in the worst case no domain experiences more than 1 query per second, in expectation.

Step 2: Annotating DNS responses with auxiliary information. Our analysis ultimately relies on characterizing both the *consistency* and *independent verifiability* of the DNS responses that we receive. To enable this classification we first must gather additional details about the IP addresses that are returned in each of the DNS responses. Iris annotates each IP address returned in the set of DNS responses with additional information about each IP address's geolocation, autonomous system (AS), port 80 HTTP responses, and port 443 HTTPS X.509 certificates. We rely on the Censys [21] dataset for this auxiliary information; Censys provides daily snapshots of this information. This dataset does not contain every IP address; for example, the dataset does not include IP addresses that have no open ports, or adversaries may intentionally return IP addresses that return error pages or are otherwise unresponsive. In these cases, we annotate all IP addresses in our dataset with AS and geolocation information from the Maxmind service [37].

Additional PTR and TLS scanning. For each IP address, we perform a DNS PTR lookup to assist with some of our subsequent consistency characterization (a process we detail in §3.5). Another complication in the annotation exercise relates to the fact that in practice a single IP address might host many websites via HTTP or HTTPS (i.e., virtual hosting). As a result, when Censys retrieves certificates via port 443 (HTTPS) across the entire IPv4 address space, the certificate that Censys retrieves might differ from the certificate that the server would return in response to a query via TLS's Server Name Indication (SNI) extension. Such a discrepancy might lead Iris to mischaracterize virtual hosting as DNS inconsistency. To mitigate this effect, for each resulting IP address we perform an additional active HTTPS connection using SNI, specifying the name originally queried. We annotate all responses with this information, which we use for answer classification (examined further in §5.1).

3.5 Identifying DNS Manipulation

To determine whether a DNS response is manipulated, Iris relies on two types of metrics: *consistency* metrics

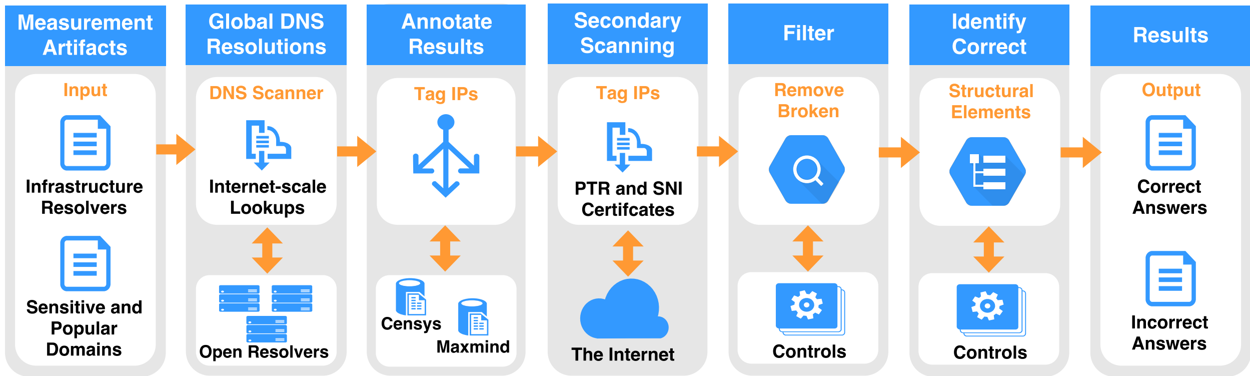

Figure 2: *Overview of DNS resolution, annotation, filtering, and classification. Iris inputs a set of domains and DNS resolvers and outputs results indicating manipulated DNS responses.*

and *independent verifiability* metrics. We say that a response is correct if it satisfies *any* consistency or independent verifiable metric; otherwise, we classify the response as *manipulated*. In this section, we outline each class of metrics as well as the specific features we develop to classify answers. The rest of this section defines these metrics; §5.1 explores the efficacy of each of them.

3.5.1 Consistency

Access to a domain should have some form of *consistency*, even when accessed from various global vantage points. This consistency may take the form of network properties, infrastructure attributes, or even content. We leverage these attributes, both in relation to control data as well as across the dataset itself, to classify DNS responses.

Consistency Baseline: Control Domains and Resolvers. Central to our notion of consistency is having a set of geographically diverse resolvers we control that are (presumably) not subject to manipulation. These controls give us a set of high-confidence correct answers we can use to identify consistency across a range of IP address properties. Geographic diversity helps ensure that area-specific deployments do not cause false-positives. For example, several domains in our dataset use different content distribution network (CDN) hosting infrastructure outside North America. As part of our measurements we insert domain names we control, with known correct answers. We use these domains to ensure a resolver reliably returns unmanipulated results for non-sensitive content (e.g., not a captive portal).

For each domain name, we create a set of consistency metrics by taking the union of each metric across all of our control resolvers. For example, if Control A returns the answer `192.168.0.10` and `192.168.0.11` and Control B returns `192.168.0.12`, we create a set of consistent IP set of (`192.168.0.10, 192.168.0.11, 192.168.0.12`). We say the answer is "correct" (i.e., not manipulated) if, for each metric, the answer is a non-empty subset of the controls. Returning to our IP example, if a global resolver returns the answer (`192.168.0.10, 192.168.0.12`), it is identified as correct. When a request returns multiple records, we check all records and consider the reply good if any response passes the appropriate tests.

Additionally, unmanipulated passive DNS [6] data collected simultaneously with our experiments across a geographically diverse set of countries could enhance (or replace) our consistency metrics. Unfortunately we are not aware of such a dataset being available publicly.

IP Address. The simplest consistency metric is the IP address or IP addresses that a DNS response contains.

Autonomous System / Organization. In the case of geographically distributed sites and services, such as those hosted on CDNs, a single domain name may return different IP addresses as part of normal operation. To attempt to account for these discrepancies, we also check whether different IP addresses for a domain map to the same AS we see when issuing queries for the domain name through our control resolvers. Because a single AS may have multiple AS numbers (ASNs), we consider two IP addresses with either the same ASN or AS *organization name* as being from the same AS. Although many responses will exhibit AS consistency even if individual IP addresses differ, even domains whose queries are not manipulated will sometimes return inconsistent AS-level and organizational information as well. This inconsistency is especially common for large service providers whose infrastructure spans multiple regions and continents and is often the result of acquisitions. To account for these inconsistencies, we need additional consistency metrics at higher layers of the protocol stack (specifically HTTP and HTTPS), described next.

HTTP Content. If an IP address is running a webserver on port 80, we include a hash of the content returned as an additional consistency metric. These content hashes come from a port 80 IP address Censys crawl. This metric effectively identifies sites with limited dynamic content. As discussed in §5.1, this metric is also useful in identifying sites with dynamic content but shared infrastructure. For example, as these hashes are based on `HTTP GET` fetches using an IP address as the `Host` in the header, this fetch uniquely fingerprints and categorizes CDN failures or default host pages. In another example, much of Google's web hosting infrastructure will return the byte-wise identical redirection page to `http://www.google.com/` for `HTTP GET`s without a valid Google host header. These identical pages allow us to identify Google resolutions as correct even for IP addresses acting as a Point-of-Presence.

HTTPS Certificate. We label a response as correct if the hash of the `HTTPS` certificate presented upon connection matches that of an IP returned via our controls. Note this is not an independent verifiability metric, as the certificates may or may not be trusted, and may not even be correct for the domain.

PTRs for CDNs. From our control data, we classify domains as hosted on particular CDNs based on `PTR`, AS, and certificate information. We consider a non-control response as consistent if the `PTR` record for that response points to the same CDN.

3.5.2 Independent Verifiability

In addition to consistency metrics, we also define a set of metrics that we can independently verify using external data sources, such as the HTTPS certificate infrastructure. We describe these methods below.

HTTPS Certificate. We consider a DNS response to be correct, independent of controls, if the IP address presents a valid, browser-trusted certificate for the correct domain name when queried without SNI. We further extend this metric to allow for common configuration errors, such as returning certificates for `*.example.com` when requesting `example.com`.

HTTPS Certificate with SNI. We add an additional metric that checks whether the certificate returned from our follow-up SNI-enabled scans returns a valid, browser-trusted certificate for the correct IP address.

3.6 Limitations

To facilitate global coverage in our measurements, our method has limitations that impact our scope and limit our results.

Localized Manipulation. Since Iris relies entirely on open infrastructure resolvers that we do not control, in regions with few resolvers, we cannot differentiate between localized manipulation by the resolver's operator and ISP or country-wide manipulation. Analysis of incorrect results focusing on consistency across ISP or country, or examination of webpage content, could aid in identifying localized manipulation.

Domain Bias. From our set of infrastructure resolvers, we measure manipulation of the CLBL and a subset of Alexa top sites. Although the CLBL is a community-based effort to identify sensitive content globally, by its very nature it is not *complete*. URLs and domains are missing, and sensitive content may change faster than the list is updated. Similarly, the list may exhibit geographic *bias* based on the language of the project and who contributes to it. This bias could affect the relative volume and scope of manipulation that Iris can detect.

Evasion. Although we focus on manipulation at ISP or country scale, an active adversary can still attempt to evade our measurements. Upstream resolvers could use EDNS Client Subnet [16] to only manipulate results for certain target IP ranges, or ISP resolvers could choose to manipulate only their own customers. Country-wide firewalls that perform injection could identify our scanning IP addresses and either not inject results or block our communication entirely. An adversary could also exploit our consistency metrics and inject incorrect IP addresses within the same AS as the targets.

Geolocation Error. We rely on Censys [21] and Maxmind [37] for geolocation and AS labeling of infrastructure resolvers to perform country or ISP-level aggregation. Incorrect labeling would identify country-wide manipulation as incomplete (false negatives), or identify manipulation in countries where it is not present (false positives).

4 Dataset

In this section, we characterize the data collected and how we processed it to obtain the results used in our analysis.

4.1 Open Resolver Selection

We initially identified a large pool of open DNS resolvers through an Internet-wide ZMap scan using our DNS extension to ZMap in January 2017. In total, 4.2 million open resolvers responded with a correct answer to our scan queries. This number excludes resolvers that replied with valid DNS responses but had either a missing or incorrect IP resolution for our scan's query domain.

Resolver Datasets	Total Resolvers	Number Countries	Median / Country
All Usable	4,197,543	232	659.5
Ethically Usable	6,564	157	6.0
Experiment Set	6,020	151	6.0

Table 1: *DNS resolver datasets. We identify all correctly functioning open resolvers are across the IPv4 address space. The experiment set consists of resolvers that passed additional functional tests beyond our basic scan. Note that the number of countries includes dependent territories.*

Resolver Dataset	AF	AS	EU	NA	OC	SA
All Usable	55	49	52	41	21	14
Ethically Usable	29	42	42	25	8	11
Experiment Set	26	41	41	24	8	11

Table 2: *Number of countries (and dependent territories) containing usable resolvers by continent. AF=Africa, AS=Asia, EU=Europe, NA=North America, OC=Oceana/Australia, SA=South America.*

The degree to which we can investigate DNS manipulation across various countries depends on the geographic distribution of the selected DNS resolvers. By geolocating this initial set of resolvers using Censys [21] and MaxMind [37], we observed that these resolvers reside in 232 countries and dependent territories[2], with a median of 659 resolvers per country. Due to the ethical considerations we outlined in §3.2, we restrict this set of resolvers to 6,564 infrastructure resolvers, in 157 countries, again with a median of 6 resolvers per country. Finally, we remove unstable or otherwise anomalous resolvers; §4.3 describes this process in more detail. This filtering reduces the set of usable resolvers to 6,020 in 151 countries, with a median of 6 resolvers in each. Table 1 summarizes the resulting population of resolvers; Table 2 shows the breakdown across continents. We also use 4 geographically diverse resolvers for controlled experiments; the 2 Google Public DNS servers [28], a German open resolver hosted on Amazon AWS, and a resolver that we manage at the University of California, Berkeley.

4.2 Domain Selection

We investigate DNS manipulation for both domains known to be censored and domains for popular websites. We began with the Citizen Lab Block List (CLBL) [14], consisting of 1,376 sensitive domains. We augment this list with 1,000 domains randomly selected from the Alexa Top 10,000, as well as 3 control domains we manage that should not be manipulated. Due to overlap between the two domain sets, our combined dataset consists of 2,330 domains. We excluded 27 problematic domains that we identified through our data collection process, resulting in our final population of 2,303 domains.

[2]Countries and dependent territories are defined by the ISO 3166-1 alpha-2 codes, the granularity of Maxmind's country geolocation.

Response Datasets	Total Responses	Number Resolvers	Number Domains
All Responses	14,539,198	6,564	2,330
After Filtering	13,594,683	6,020	2,303

Table 3: *DNS response dataset before and after filtering problematic resolvers, domains, and failed queries.*

4.3 Response Filtering

We issued 14.5 million DNS `A` record queries for our 2,330 pre-filtered domains, across 6,564 infrastructure and control open resolvers during a 2 day period in January 2017. We observed various erroneous behavior that required further filtering. Excluding these degenerate cases reduced our dataset collection to 13.5 million responses across 2,303 domains and 6,020 resolvers, as summarized in Table 3. The rest of this section details this filtering process.

Resolvers. We detected that 341 resolvers stopped responding to our queries during our experiment. An additional 202 resolvers incorrectly resolved our control domain names, despite previously answering correctly during our Internet-wide scans. The common cause of this behavior was rate limiting, as our Internet-wide scans queried resolvers only once, whereas our experiments necessitated repeated queries. We identified another problematic resolver that exhibited a query failure rate above 70% due to aggressive rate limiting. We eliminated these resolvers and their associated query responses from our dataset, reducing the number of valid responses by 510K.

Domains. Our control DNS resolvers could not resolve 15 domain names. We excluded these and their associated 90K query responses from our dataset. We removed another 12 domains and their 72K corresponding query responses as their DNS resolutions failed an automated sanity check; resolvers across numerous countries provided the same incorrect DNS resolution for each of these domains, and the IP address returned was unique per domain (i.e., not a block page or filtering appliance). We did not expect censors to exhibit this behavior; a single censor is not likely to operate across multiple countries or geographic regions, and manipulations such as block pages that use a single IP address across countries should also be spread across multiple domains. These domains do not support HTTPS, and exhibit geograph-

ically specific deployments. With increased geographic diversity of control resolvers or deployment of HTTPS by these sites, our consistency or verifiability metrics would account for these domains.

Queries. We filtered another 256K queries that returned failure error codes; 93.7% of all errors were timeouts and server failures. Timeouts denote connections where the resolver did not respond to our query within 15 seconds. Server failures indicate when a resolver could not recursively resolve a domain within its own pre-configured time allotment (10 seconds by default in BIND). Table 4 provides a detailed breakdown of error responses.

Failure Type	Count	% of Responses
Timeout	140,551	0.97%
Server Fail	107,826	0.74%
Conn Refused	7,823	0.05%
Conn Error	3,686	0.03%
Truncated	3,451	0.02%
NXDOMAIN	1,713	0.01%

Table 4: *Breakdown of the 265,050 DNS responses that returned a non-success error code.*

Returning an NXDOMAIN response code [38], which informs a client that a domain does not exist, is an obvious potential DNS censorship mechanism. Unfortunately, some CDNs return this error in normal operations, presumably due to rate limiting or client configuration settings. We found that the most prevalent NX behavior occurred in the countries of Tonga and Pakistan; both countries exhibited censorship of multiple content types, including adult and LGBT. Previous studies have observed NXDOMAIN blocking in Pakistan [38]. These instances comprise a small percentage of overall NXDOMAIN responses. Given the many non-censorship NXDOMAIN responses and the relative infrequency of their use for censorship, we exclude these from our analysis. Another 72K responses had a `SUCCESS` response code, but contained no IP address in the response. This failure mode frequently coincide with `CNAME` responses that could not be resolved further. We excluded these queries. Table 5 provides a geographic breakdown of NXDOMAIN responses.

After removing problematic resolvers, domains, and failed queries, the dataset comprises of 13,594,683 DNS responses. By applying our *consistency* and *independent verifiability* metrics, we identify 41,778 responses (0.31%) as manipulated, spread across 58 countries (and dependent territories) and 1,408 domains.

Country	% NXDOMAIN
Tonga	2.93%
Pakistan	0.37%
Bosnia/Herzegovina	0.12%
Isle of Man	0.04%
Cape Verde	0.04%

Table 5: *The top 5 countries / dependent territories by the percent of queries that responded with NXDOMAIN.*

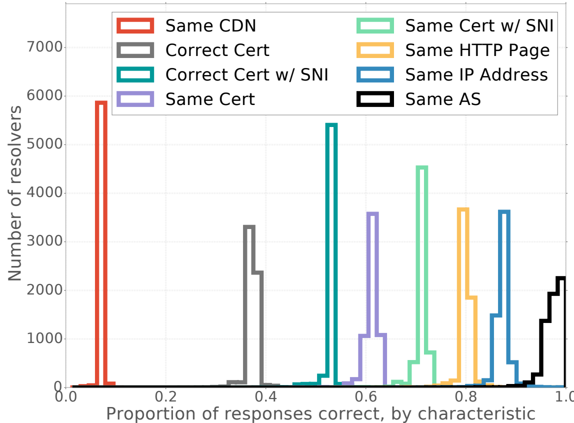

Figure 3: *The ability of each correctness metric to classify responses as correct. Table is ordered (top to bottom, left to right) by the lines on the graph (left to right).*

5 Results

We now evaluate the effectiveness of our DNS manipulation metrics and explore manipulated DNS responses in the context of Internet censorship.

5.1 Evaluating Manipulation Metrics

To assess the effectiveness of the *consistency* and *independent verifiability* metrics, we quantify the ability of each metric to identify unmanipulated responses (to exclude from further investigation). Figure 3 shows each metric's efficacy. The horizontal axis represents the fraction of responses from a particular resolver that are classified as correct by a given metric. The vertical axis indicates the number of resolvers that exhibit that same fraction of correct responses (again under the given metric). For example, almost 6,000 resolvers had roughly 8% of their responses identified as correct under the "Same CDN" metric. A narrow band indicates that many resolvers exhibit similar fractions of correct responses under that metric (i.e., it is more *stable*). The closer the center mass of a histogram lies to 1.0, the more *effective* its corresponding metric, since a larger fraction of responses are classified as correct (i.e., not manipulation) using that metric.

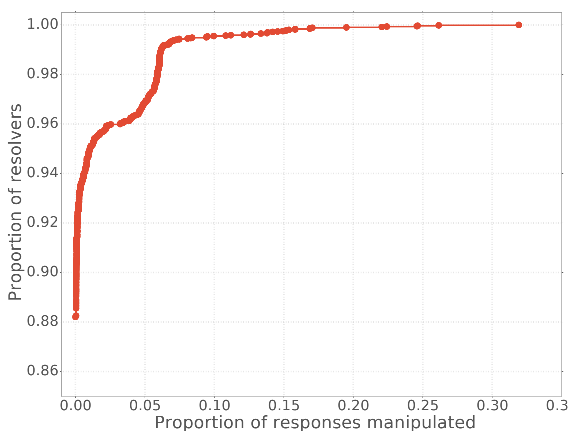

Figure 4: *The fraction of responses manipulated, per resolver. For 89% of resolvers, we observed no manipulation.*

Country (# Res.)	Median	Mean	Max	Min
Iran (122)	6.02%	5.99%	22.41%	0.00%
China (62)	5.22%	4.59%	8.40%	0.00%
Indonesia (80)	0.63%	2.81%	9.95%	0.00%
Greece (26)	0.28%	0.40%	0.83%	0.00%
Mongolia (6)	0.17%	0.18%	0.36%	0.00%
Iraq (7)	0.09%	1.67%	5.79%	0.00%
Bermuda (2)	0.04%	0.04%	0.09%	0.00%
Kazakhstan (14)	0.04%	0.30%	3.90%	0.00%
Belarus (18)	0.04%	0.07%	0.30%	0.00%

Table 6: *Top 10 countries by median percent of manipulated responses per resolver. We additionally provide the mean, maximum, and minimum percent for resolvers in each country. The number of resolvers per country is listed with the country name.*

The AS consistency metric ("Same AS") is the most effective: it classified 90% of the DNS responses as consistent. Similarly, identifying matching IP addresses between responses from our control resolvers and our experiment resolvers flagged about 80% of responses as correct across most resolvers. "Same HTTP Page" is also relatively effective, as many geographically distributed deployments of the same site (such as with Points-of-Presence) have either identical content or infrastructure error characteristics (see §3.5.1). This figure also illustrates the importance of SNI, increasing the effectiveness of correct and valid HTTPS certificates from 38% to 55%. The same HTTPS certificate ("Same Cert") metric turns out to be more effective than simply having a correct certificate ("Correct Cert"), because so many sites incorrectly deploy HTTPS.

5.2 Manipulated DNS Responses

We detect nearly 42,000 manipulated DNS responses; we now investigate the distribution of these responses across resolvers, domains, and countries.

Manipulated responses by resolver. Figure 4 shows the cumulative fraction of results that return at least a certain fraction of manipulated responses: 88% of resolvers exhibited no manipulation; for 96% of resolvers, we observe manipulation for fewer than 5% of responses. The modes in the CDF highlight differences between resolver subpopulations, which upon further investigation we discovered reflected differing manipulation practices across countries. Additionally, 62% of domains are manipulated by at least one resolver, which is expected given that more than half of our selected domains are sensitive sites on the CLBL. We explore these variations in more detail later in this section.

Manipulated responses by country. Previous work has observed that some countries deploy nation-wide DNS censorship technology [5]; therefore, we expected to see groups of resolvers in the same country, each manipulating a similar set of domains. Table 6 lists the percent of manipulated responses per resolver, aggregated across resolvers in each country. Resolvers in Iran exhibited the highest degree of manipulation, with a median of 6.02% manipulated responses per Iranian resolver; China follows with a median value of 5.22%. These rankings depend on the domains in our domain list, and may merely reflect that the CLBL contained more domains that are censored in these countries.

The top 10 countries shown in Table 6 all have at least one resolver that does not manipulate *any* domains; IP address geolocation inaccuracy may partially explain this surprising finding. For example, uncensored resolvers in Hong Kong may be incorrectly labeled as Chinese. Additionally, for countries that do not directly implement the technical manipulation mechanisms but rather rely on individual ISPs to do so, the actual manifestation of manipulation may vary across ISPs within a single country. Localized manipulation by resolver operators in countries with few resolvers could also influence these results. §5.3 investigates these factors further.

Figure 5 shows the representation of responses in our dataset by country. For example, the leftmost pair of bars shows that, while less than 5% of all responses in our dataset came from Iranian resolvers, the responses that we received accounted for nearly 40% of manipulated responses in the dataset. Similarly, Chinese resolvers represented 1% of responses in the data but contributed to 15% of the manipulated responses. In contrast, 30% of our DNS responses came from resolvers in the United States, but accounted for only 5% of censored responses.

Table 7 shows the breakdown of the top manipulated

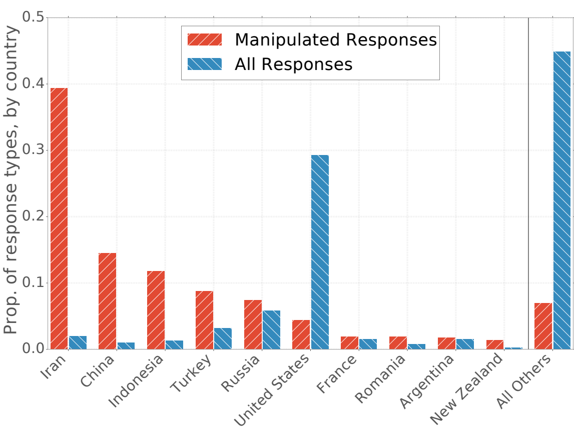

Figure 5: *The fraction of all responses in our dataset from each country (blue), and the fraction of all manipulated responses in our dataset from the corresponding country (red).*

responses, by the IP address that appears in the manipulated answer. The top two special-purpose (i.e., private) IP addresses appear in the majority of responses within Iran. The third most common response is an OpenDNS (a DNS filtering and security product [13]) blockpage indicating adult content. The fourth most frequent response is an IP address hosting an HTTP error page known to be used in Turkey DNS manipulation [11].

Private and special-purpose IPv4 addresses in manipulated DNS responses. Of the roughly 42,000 manipulated DNS responses, 17,806 correspond to special-purpose IPv4 addresses as defined by RFC 6890 [17]; the remaining 23,972 responses corresponded to addresses in the public IP address space. Table 8 shows the extent to which countries return private IP addresses in responses, for the top 10 countries ranked by the relative amount of DNS manipulation compared to the total number of results from that country. For example, we observed more manipulated responses from Turkey than Iraq, but Iris used more open DNS resolvers in Turkey, so observed frequencies require normalization. Here, we notice that countries that manipulate DNS tend to either return only special-purpose IP addresses in manipulated responses (as in the case of Iran, Iraq, and Kuwait) or only public IP addresses (China).

Figure 6 presents the distribution of observed public IP addresses across manipulated responses in our dataset. The most frequently returned public IP address, an OpenDNS blockpage, constituted almost 15% of all manipulated responses containing public IP addresses. The top ten public IP addresses accounted for nearly 60% of responses.

Many IP answers have been observed in previous studies on Chinese DNS censorship [5, 25]. These addresses are seemingly arbitrary; they host no services, not even a fundamental webpage. The 10 most frequent Chinese responses constituted almost 75% of Chinese responses. The remaining 25% are spread over a long tail of nearly 1,000 seemingly arbitrary non-Chinese IP addresses.

Answer	Results	Names	Category
10.10.34.36	12,144	140	Private

Table 7: *Most common manipulated responses by volume, with manual classification for public, non-resolver IP addresses. The category "China*" are IP addresses previously observed by Farnan et al. in 2016 [25].*

5.3 Manipulation Within Countries

Figure 7 shows the DNS manipulation of each domain by the fraction of resolvers *within* a country, for the 10 countries with the most normalized amount of manipulation. Each point represents a domain; the vertical axis represents the fraction of resolvers in that country that manipulate it. Shading shows the density of points for that part of the distribution. The plot reveals several interesting phenomena. One group of domains is manipulated by about 80% of resolvers in Iran, and another group is manipulated by fewer than 10% of resolvers. This second group of domains is manipulated by a smaller fraction of resolvers, also returning non-public IP addresses. These effects are consistent with previously noted blackholing employed by DNS manipulation infrastructure [7]; this phenomenon deserves further investigation.

Similarly, one set of domains in China experiences manipulation by approximately 80% of resolvers, and another set experiences manipulation only half the time. In contrast, manipulation in Greece and Kuwait is more homogeneous across resolvers.

Country (# Res.)	% Incor.	% Pub.
Iran (122)	6.02%	0.01%
China (62)	4.52%	99.46%
Indonesia (80)	2.74%	95.08%
Iraq (7)	1.68%	1.49%
New Zealand (16)	1.59%	100.00%
Turkey (192)	0.84%	99.81%
Romania (45)	0.77%	100.00%
Kuwait (10)	0.61%	0.00%
Greece (26)	0.41%	100.00%
Cyprus (5)	0.40%	100.00%

Table 8: *Percent of public IP addresses in manipulated responses, by country. Countries are sorted by overall frequency of manipulation.*

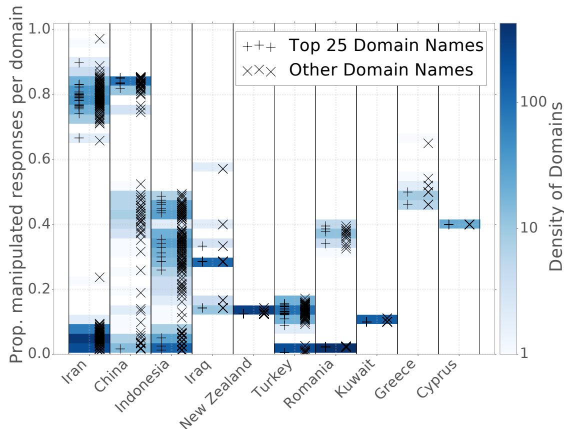

Figure 7: *The fraction of resolvers within a country that manipulate each domain.*

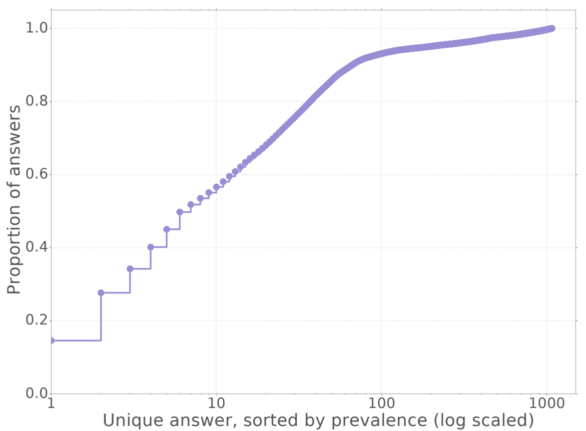

Figure 6: *Manipulated but public IP addresses in our dataset. The horizontal axis is sorted by the most common IP.*

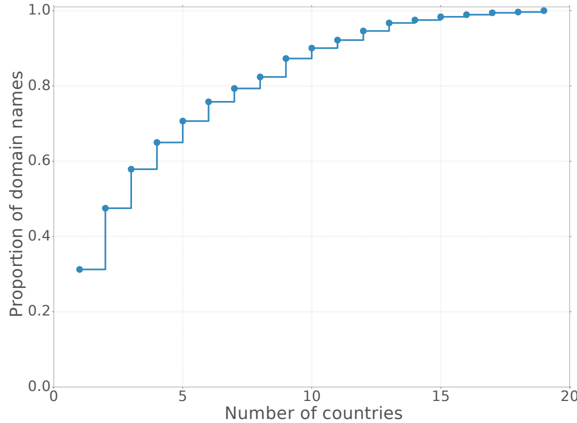

Figure 8: *The number of countries (or dependent territories) that block each domain with observed manipulated responses, sorted by manipulation prevalence.*

Heterogeneity across a country may suggest a situation where different ISPs implement filtering with different block lists; it might also indicate variability across geographic region within a country. The fact that manipulation rates vary even among resolvers in a certain group within a country may indicate either probabilistic manipulation, or the injection of manipulated responses (a phenomenon that has been documented before [5]). Other more benign explanations exist, such as corporate firewalls (which are common in the United States), or localized manipulation by resolver operators.

Ceilings on the percent of resolvers within a country performing manipulation, such as no domain in China experiencing manipulation across more than approximately 85% of resolvers, suggest IP geolocation errors are common.

5.4 Commonly Manipulated Domains

Commonly manipulated domains across countries. Many domains experienced manipulation across a range of countries. Figure 8 shows a CDF of the number of countries (or dependent territories) for which at least one resolver manipulated each domain. 30% of domains were manipulated in only a single country, while 70% were manipulated in 5 or fewer countries. No domain was manipulated in more than 19 countries.

Table 9 highlights domains that experience manipulation in many countries (or dependent territories). The 2 most manipulated domains are both gambling websites, each experiencing censorship across 19 different countries. DNS resolutions for pornographic websites are similarly manipulated, accounting for the next 3 most commonly affected domains. Peer-to-peer file sharing

Table 10: *Top 10 domain categories, ordered by number of countries (or dependent territories) with manipulated answers.*

sites are also commonly targeted, particularly The Pirate Bay. The Tor Project [50] DNS domain is the most widely interfered with domain amongst anonymity and censorship tools, manipulated across 12 countries. Citizen Lab [15] also experienced manipulation across 4 countries. We note that `www.google.com` is impacted across more countries than `google.com`, unsurprising since all HTTP and HTTPS queries to `google.com` immediately redirect to `www.google.com`; for example, China manipulates `www.google.com` queries but disregards those for `google.com`. This result underscores the need for domain datasets that contain complete domains and subdomains, rather than simply second-level domains.

We also note that commonly measured sites such as The Tor Project, Google, and Twitter, experience manipulation across significantly fewer countries than some sites. Such disparity points to the need for a diverse domain dataset.

China focuses its DNS manipulation not just on adult content but also major English news outlets, such as `nytimes.com`, `online.wsj.com`, and `www.reuters.com`. China is the only country observed to manipulate the DNS responses for these domains; it also censored the Chinese language Wikipedia domain.

Commonly manipulated categories. Table 10 shows the prevalence of manipulation by CLBL categories. We consider a category as manipulated within a country if any resolver within that country manipulates a domain of that category. Domains in the Alexa Top 10K experienced the most manipulation; these domains did not appear in the CLBL, which highlights the importance of measuring both curated lists from domain experts as well as broad samples of popular websites. Although no single domain experiences manipulation in more than 19 countries, several categories experience manipulation in more than 30 countries, indicating that while broad categories appear to be commonly targeted, the specific domains may vary country to country.

To study how manipulated categories vary across countries, we analyzed the fraction of resolvers within each country that manipulate a particular category. The top categories vary extensively across countries. Table 11 shows the most frequently manipulated categories for the top 10 countries by normalized amounts of manipulation. The top category of manipulated content in Iran, "provocative attire," is not a category across any of the other top 10 countries. Manipulation of domains randomly selected from Alexa but not in the CLBL ("Alexa Top 10k") is prevalent across numerous countries, again reinforcing the need for diverse domain datasets. Anonymity and censorship tools are manipulated extensively across 85% of resolvers in China, but not across the rest of the top 10. Pornography and gambling sites are manipulated throughout.

6 Summary

Internet censorship is widespread, dynamic, and continually evolving; understanding the nature of censorship thus requires techniques to perform continuous, large-scale measurement. Unfortunately, the state-of-the-art techniques for measuring manipulation—a common censorship technique—rely on human volunteers, limiting the scale and frequency of measurements. This work introduces a method for measuring DNS manipulation on

Country	Domain Category	% of Resolv.
IR	Provocative attire	90.98%
	Alexa Top 10k	90.16%
	Freedom of expr.	90.16%
CN	Alexa Top 10k	85.48%
	Freedom of expr.	85.48%
	Anon. & censor.	85.48%
ID	Pornography	57.50%
	Alexa Top 10k	56.25%
	P2P file sharing	52.50%

	Gambling	40.00%

Table 11: *Breakdown of the top 3 domain categories experiencing manipulation, per country. Countries are ordered by the relative amount of manipulated responses for that country. Both Greece (GR) and Cyprus (CY) only experience manipulated responses across 2 categories.*

a global scale by using as vantage points open DNS resolvers that form part of the Internet's infrastructure.

The major contributions of our work are: (1) Iris: a scalable, ethical system for measuring DNS manipulation; (2) an analysis technique for disambiguating natural variation in DNS responses (e.g., due to CDNs) from more nefarious types of manipulation; and (3) a large-scale measurement study that highlights the heterogeneity of DNS manipulation, across countries, resolvers, and domains. Notably, we find that manipulation is heterogeneous across DNS resolvers even within a single country. Iris supports regular, continuous measurement, which will ultimately facilitate tracking DNS manipulation trends as they evolve over time; our next step is to operationalize such measurements to facilitate longitudinal analysis.

Abstract

Facing abusive traffic from the Tor anonymity network, online service providers discriminate against Tor users. In this study, we characterize not only the extent of such discrimination but also the nature of the undesired traffic originating from the Tor network—a task complicated by Tor's need to maintain user anonymity. We address this challenge by leveraging multiple independent data sources: email complaints sent to exit operators, commercial IP blacklists, webpage crawls via Tor, and privacy-sensitive measurements of our own Tor exit nodes. As part of our study, we also develop methods for classifying email complaints and an interactive crawler to find subtle forms of discrimination, and deploy our own exits in various configurations to understand which are prone to discrimination. We find that conservative exit policies are ineffective in preventing the blacklisting of exit relays. However, a majority of the attacks originating from Tor generate high traffic volume, suggesting the possibility of detection and prevention without violating Tor users' privacy.

1 Introduction

Anonymity systems like Tor provide a useful service to users who wish to access the Internet without revealing their intended destination to any local monitoring, or their network-layer identity to the final destination. However, as Tor has increased in scale and usage, tensions have emerged between Tor users and online service providers. Specifically, service providers claim that the anonymity provided by Tor is often used maliciously for spamming, vulnerability scanning, scraping, and other undesired behavior (e.g., [1]). As a result, Tor users now face differential treatment (e.g., needing to solve CAPTCHAs before receiving services) and even outright blocking [2].

At its core, the problem is that in return for anonymity, each Tor user shares their reputation with other users. As a result, the malicious actions of a single Tor user can lead IP abuse blacklists to include IP addresses used by Tor exit relays. Consequently, websites and content providers treat even benign Tor users as malicious. In this paper, we characterize aspects of the conflict between users desiring anonymity and websites aiming to protect themselves against malicious Tor traffic. We investigate the nature of traffic that exits the Tor network and is undesired by online service providers. We also actively measure various forms of discrimination performed against Tor users.

Challenges. We grapple with two key challenges: First, measuring Tor traffic is antithetical to the goals of the anonymity system and poses ethical challenges. Second, defining and identifying *undesired* or *abusive* network traffic is hard as opinions vary and encryption can render inspection of traffic infeasible. We address both challenges by focusing on the receivers' reactions to Tor traffic rather than the traffic itself. We consider email complaints sent to Tor relay operators (§4) and blacklisting of Tor-related IP addresses (§5), and take measurements of server responses to Tor traffic, both synthetic (§6) and user-driven (§7). These datasets not only allow us to observe the effects of undesired traffic without measuring it, but also provide an operational definition of *undesired traffic*: the traffic that leads to complaints, blacklisting, or rejecting of Tor users. This operationalization allows us to sidestep debates over what constitutes abuse and to focus on the subset of undesired Tor traffic that has affected operators and users.

Additionally, collecting and analyzing each of these four datasets presented technical challenges. Analyzing 3 million email complaints received by Tor relay operators since June 2010 required us to construct automated processing methods (§4). Understanding the inclusion of Tor-related IP addresses in IP blacklists required us to develop methods for teasing apart *reactive blacklisting*—i.e., blacklisting triggered by abuse—from *proactive blacklisting*—i.e., blacklisting due to Tor's pre-existing

reputation (§5). Measuring the prevalence of discrimination faced by users required exercising multiple aspects of websites and inspecting them for subtle forms of discrimination (e.g., CAPTCHAs and interaction-based discrimination) in addition to outright blocking. To address this issue and accurately measure discrimination against users, we go beyond the prior work of Khattak et al. and develop a crawler capable of exercising the search and login features of websites. Taking measurements of real Tor traffic required the creation and deployment of a privacy-sensitive logging approach for our own Tor exit relays. We also consider aspects of Tor exit relays that make them more susceptible to complaints, IP blacklisting, or blocking. We augment this analysis by deploying several Tor exits with varied configurations and monitoring the reactions they produced.

Key Findings. One major takeaway from our analysis is that many of the attacks originating from Tor generate high traffic volume (e.g., DDoS attacks, port scanning), raising the possibility of blocking them using privacy-sensitive techniques (§8). We believe developing, implementing, and deploying such techniques may provide online service operators a more effective means of curbing abuse than IP blacklisting while also preventing lost utility to Tor from blocking.

Our analysis of email complaints shows that, historically, the most vocal complainants about Tor traffic were a small number of copyright enforcement firms. This is no longer be the case, possibly due to Tor blocking BitTorrent's standard ports by default (Table 2 in §4). The most common non-copyright complaints were about network abuse and attempts to gain unauthorized access (Table 3 in §4).

From our analysis of commercial IP blacklists, we find that 7% of the commercial IP blacklists we analyze engage in *proactive* blocking of Tor users—i.e., blacklisting Tor exit relays soon after they are listed in the consensus. This is indicative of blacklists performing discrimination against Tor exit relays as a matter of policy, rather than based on undesired traffic (§5). Currently, 88% of Tor relays are blacklisted on one or more of the blacklists, compared to 9% and 69% of the endpoints of the VPNGate and HMA VPN services, respectively (Figure 4 in §5). We also find that conservative exit policies do not reduce Tor exit relays' susceptibility to getting blacklisted, which appears to reflect that such policies still allow for Web access, the channel most extensively used for abuse.

Finally, we find discrimination to be a pressing concern. Our synthetic experiments show that discrimination occurs on 20% of all Alexa Top 500 website front-page loads through a subset of Tor exits. Focusing on the search and login functionalities of the Alexa Top 500 websites, we see a 3.9% and 7.5% increase in observed discrimination (compared to front-page load discrimination), respectively (Table 6 in §6). We also find that real Tor users experience high fractions of failed HTTP requests (15.8–33.4%) and HTTPS handshakes (35.0–49.6%) while browsing the Alexa Top 1M websites using our deployed relays (Table 8 in §7).

2 Background and Related Work

Tensions between Tor and online services. Tor is a low-latency onion routing network with over 2M daily users and over 7K supporting servers [3]. While proponents of Internet freedom laud the anonymity provided by Tor, it can also provide a cloak for malicious network activities. Indeed, CloudFlare reported that 94% of the requests from the Tor network are "malicious", consisting of comment spam, scanning, and content scraping [1]. According to a report published by Distill networks, 48% of Tor requests are malicious, higher than non-Tor requests (38%) [4]. A study of the Sqreen application protection service found that connections through Tor are responsible for ≈30% of all attacks on their customers, including password brute force attacks, account enumerations, and fraudsters [5]. As per Akamai's State of the Internet report, an HTTP request from a Tor IP address is 30 times more likely to be a malicious attack than one from a non-Tor IP address [6]. Imperva-Incapsula found that in a period of 2.5 weeks, 48.53% of the attack requests came from Tor [7]. However, the majority of these attack sessions were originated from well-known DDoS bots and bad clients, which can be identified using approaches other than IP reputation. Not counting the attacks from well-known attackers, the fraction of attack sessions originating from Tor went down to 6.78%, which is comparable to the attacks coming from the rest of the Internet population in Ireland (5.45%).

Different services have reported similar types of attacks from Tor. The three most common attacks from Tor to Akamai's services were automated scanning (path scanning and vulnerability scanning), SQL injection, and cross-site scripting attacks [6]. IBM reports that SQL injection, automated scanning, and DDoS are the most common attacks from Tor [8]. Sqreen found authentication attacks (brute force attack on a specific user account, or accounts enumeration), path scanning, and SQL/NoSQL injections [9] are likely to originate from Tor [5]. Our analysis of the abuse complaints to a number of Tor exit relays reflects similar proportions of attack traffic (Section 4).

Despite reports claiming a higher likelihood of malicious traffic from Tor, there have been debates about the correctness of their inference methods. For instance, Perry, writing for the Tor Project's blog, ques-

tions whether CloudFlare's methods considered as malicious all traffic from an exit relay that ever sent any malicious traffic [10].

While websites might be tempted to blacklist all Tor IPs in a proactive attempt at security, doing so could cause a loss in revenue. Akamai's report highlights that Tor users are just as likely to make purchases from revenue generating websites as non-Tor users [6].

Blocking and Filtering of Tor. Many government censors around the world block access to Tor [11], the subject of numerous measurement studies [12–16]. However, such government censorship blocks access *to* the Tor entry nodes, which is different from server-side Tor blocking, which blocks access *from* the Tor exit nodes.

Khattak et al. is the only systematic measurement study of server-side Tor blocking [2]. They showed that in 2015 at least 1.3 million IP addresses blocked Tor at the TCP/IP layer, and 3.6% of the Alexa Top 1,000 websites blocked Tor at the HTTP layer. At the TCP/IP layer, the hosting services GoDaddy and Dreamhost are among the top five Tor blockers. CloudFlare blocks access at the HTTP layer. Our work extends the work of Khattak et al. by additionally measuring the blocking of login and search functionality. We find a higher rate of blocking (20.03%) than Khattak et al. (3.6%). We demonstrate that Khattak et al.'s headless crawler underestimates the blocking rate (Figure 12).

To understand the impact of blocking on Tor users, we measure the number of failed requests to Alexa Top 1M web pages at the exit level using privacy-sensitive logging on our exits.

3 Our Deployed Exits

To aid our studies of complaint emails, IP blacklisting, and discrimination, we deployed and used data from ten of our own exits in addition to current and historical records about pre-existing Tor exits.

	Max. BW	Exit Policy	Num.
Large-Default	61 MBps*	Default	2
Medium-Default	10 MBps	Default	2
Medium-RR	10 MBps	RR	2
Small-Default	2 MBps	Default	2
Small-RR	2 MBps	RR	2

Table 1: Configurations of our deployed exit relays. *The large exits' policy allows for unlimited bandwidth usage. We provide the maximum bandwidth achieved during the study period.

We vary the bandwidth and exit policy of our exits in order to understand the impact of relay characteristics on email complaints, blacklisting, and discrimination. We used bandwidth allocations for the relays of 2 MBps (small exits), 10 MBps (medium exits), and unlimited (huge exits). In total, our deployed relays handled over 3% of all Tor exit traffic during their deployment. The exit policies were varied to either be the Tor default policy or the "Reduced-Reduced" policy. The default policy [17] allows all ports except those misused for email and news spam (25, 119), network attacks (135–139, 445, 563), or peer-to-peer file sharing (1214, 4661–4666, 6346–6348, 6699, 6881–6999, plus the adjacent ports 6349–6429). The Reduced-Reduced (RR) exit policy, designed to avoid blacklisting, additionally blocks ports associated with SSH, Telnet, IRC(S), and other protocols [18]. We summarize our relay configurations in Table 1.

Analyzing the usage statistics of ports on our exit relays, we see that web-traffic accounts for 98.88% of all connections made through the RR policy exits. In contrast, traffic though the default policy exits has higher application/port diversity, with only 31.36% of observed traffic being HTTP(S). We measure this using our privacy-sensitive logging described in Section 7.

4 Email Complaints about Abuse

In this section, we look at the abuse complaints received by exit operators. We use these complaints as a proxy for understanding the type and frequency of undesired incidents happening through Tor exit relays.

4.1 The Email Corpus

In addition to our own exits, we obtained access to abuse complaints emailed to four exit relay operators, (Table 2). The largest email corpus, consisting of ≈3M emails, came from a subset of exits operated by Torservers.net (`https://torservers.net/`). Using whois queries on exit IP addresses and counting the number of exits that use Torservers.net as their abuse contact, we estimate that they run 10 to 20 exits, with the uncertainty coming from fuzzy matches.[1] According to the latest Tor consensus, Torservers is one of the largest exit operators in terms of overall bandwidth capacity. The apx exit family includes three exits: apx1 [19], apx2 [20] and apx3 [21]. The other two exits are TorLand1 [22] and jahjah [23]. TorLand1 was one of the oldest Tor exits, running since 2011 until February 2017.

Our complaints dataset lacks any complaints sent by fax or mail, or those sent to only the abuse contact of the associated autonomous system. Also, some email complaints might have been lost or deleted. For example, the

[1] The current operators of Torservers were unable to answer the exact number of exits they ran over time.

Exit Family	# Exits	% Tor Traffic	Email Dates	# Complaints	Top Complaint
Torservers.net	10–20	7.05%	2010/06–2016/04	2,987,017	DMCA Violation (99.74%)
apx	3	1.94%	2014/11–2016/05	293	Automated Scan (38.49%)
TorLand1	1	0.75%	2011/12–2016/10	307	Malicious Traffic (16.99%)
jahjah	1	0.17%	2016/1–2017/1	75	Unauthorized Login Attempts (34.15%)
Our exits	10	3.14%	2016/9–2017/2	650	Network Attack (48.68%)

Table 2: Email complaints sent to the exit operators

jahjah exit was started in 2015 but the operator was only able to provide complaints received from 2016 onwards.

4.2 Analysis

We extract the nature of abuse, the time of complaint, and the associated exit IP addresses. 99.7% of the complaints received by Torservers.net related to Digital Millennium Copyright Act (DMCA) violations, with over 1 million of the complaints sent by one IP address. These emails use a template, enabling parsing of email text with regular expressions. The majority of the non-DMCA emails also follow a template, but the structure varied across a large number of senders. To extract the relevant abuse information from non-DMCA complaint emails, we first applied KMeans clustering to identify similar emails. We manually crafted regular expressions for each cluster. We used these regular expressions to assign high confidence labels to emails. Not all emails matched such a template regular expression—e.g., one-off complaints sent by individuals. We classified these emails by looking for keywords related to types of abuse. We iteratively refined this process until manually labeled random samples showed the approach to be quite accurate, with only 2% cases of misidentification.

99.99% of all DMCA violation complaints were against the Torservers' exits. The other exits collectively received only 12 such complaints. Over 99% of DMCA complaints mentioned the usage of BitTorrent for infringement; the rest highlighted the use of eDonkey.

We categorized the Non-DMCA complaints into five broad categories enumerated in Table 3. Network abuse is the most frequent category of non-DMCA complaints. $\approx$15% of the complaints related to network abuse came from Icecat [24], a publisher of e-commerce statistics and product content. Icecat's emails complain about excessive connection attempts from the jahjah exit and 13 exit IP addresses hosted by Torservers. These emails were received from November 2011 until December 2012. Other exit operators also received similar complaints during the same time frame [25]. We checked a recent Tor consensus in November 2016 and found eight exits that avoided exiting to the Icecat IP address.

The second most common non-DMCA complaints are about automated scans and bruteforce login attacks on Wordpress. Automated scanning, specifically port and vulnerability scanning, accounts for 13.6% of the non-DMCA complaints across the entire time range of our dataset. Instances of Wordpress bruteforce login attacks lasted for a comparatively shorter period, September 2015 until May 2016, but constitute 12.1% of non-DMCA complaints. All of the exits in our dataset received complaints about bruteforce login attempts from Wordpress except our own exits, probably because we started our exits after the attack stopped.

Email, comment, and forum spam constitutes 9.01% of non-DMCA complaints. Note that all of the exits in question have the SMTP port 25 blocked. Our data shows a spike in the number of abuse complaints regarding referrer spam from Semalt's bots [26] towards the end 2016. 1.05% of the non-DMCA emails complain about harassment. Over 11% of the non-DMCA emails do not fall under the mentioned categories. These emails include encrypted emails and emails unrelated to abuse.

4.3 Consequences of Undesired Traffic

Along with the complaints, some emails mention the steps the sender will take to minimize abuse from Tor. 34.3% of the emails mentioned temporary blocking (19.8%), permanent blocking (0.2%), blacklisting (9.8%) or other types of blocking (4.6%). The rest of the emails notify the exit operators about the abuse. For the most frequent form of blocking, temporary blocking, the emails threaten durations ranging from 10 minutes to a week. Some companies (e.g., Webiron) maintain different blacklists depending on the severity of the abuse. The majority of the blacklists mentioned in the emails are either temporary or unspecified. Only 18 emails mentioned permanently blocking the offending IP address. A small fraction (less than 1%) of the emails ask exit operators to change the exit policy to disallow exiting to the corresponding website.

We did not find any complaint emails from known Tor discriminators, such as Cloudflare and Akamai. Among the websites we crawled to quantify discrimination against Tor, we found complaints from Expedia and

Category	Includes	Percent
Network abuse	DDoS, botnet, compromised machines	38.03%
Unauthorized access	Failed login attempts, brute-force attacks, exploits for gaining access	26.45%
Automated scan	Port scans, vulnerability scans, automated crawling	14.15%
Spam	Email, comment, and forum spam	9.01%
Harassment	Threats, obscenity	1.05%
Other	(unreadable encrypted emails, emails not reporting abuse)	11.31%

Table 3: Categories of the Non-DMCA Email Complaints (Total 8,370 emails)

Zillow. Expedia complained about an unauthorized and excessive search of Expedia websites and asked exit operators to disallow exiting to the Expedia website. Zillow's complaint was less specific, about experiencing traffic in violation of their terms and conditions.

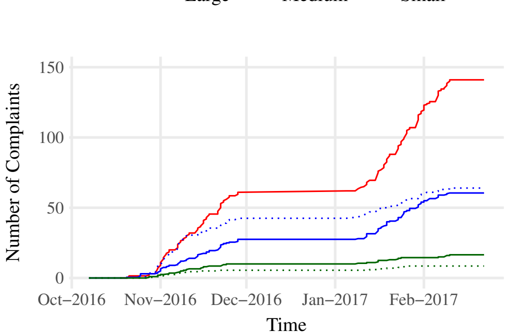

Figure 1: The cumulative number of complaints averaged over our exits sharing the same bandwidth and policy. Solid lines represent default policy exits and dashed lines represent RR policy exits.

4.4 Exit Properties and Complaints

We investigate the effects of two exit properties on the number of corresponding abuse complaints received: policy and bandwidth. For this analysis, we counted the number of email complaints that explicitly mention the IP address of our exits. We find that higher-bandwidth exits received more complaints (Figure 1). This correlation is statistically significant (Pearson's product-moment correlation = 0.98, p-value = 0.0016). However, exit policy did not have any statistically significant correlation with the number of complaints. We also did not notice any significant differences between the types of complaints that exits received.

4.5 Comparison with Average Tor Traffic

We estimate the average number of simultaneous Tor users per day through the exits getting complaints and compare it with the total amount of abuse going through the exits. Our goal is to understand how many Tor users will be affected if we block an exit because of abuse complaints. To do this, we collect the estimation of simultaneous Tor users per day from Tor Metrics [27]. Then we collect the historical Tor consensus to compute how much traffic went through an exit per day. If an exit A handles $e\%$ of the total Tor bandwidth on day d and the number of simultaneous users of Tor on d is u, then approximately $\frac{eu}{100}$ of the users used A on day d.[2] We estimate users for each exit in Table 2 from September 2011 (the beginning of the Tor metrics data). We exclude the Torservers exits because tracing the Torservers exits in the historical consensuses is difficult as those exits changed IP addresses and exit fingerprints more than once.

Exit Family	Avg. users	Avg. complaints
apx	23,082.08	0.53
TorLand1	59,284.54	0.17
jahjah	1,206.30	0.19
Our exits	3,050.81	5.55

Table 4: Avg. simultaneous users and complaints per day

Compared to the average number of Tor users, the amount of abuse is insignificant (Table 4). However, we are considering one abuse email as one instance of abuse, but in practice one email can correspond of many instances of abuse, for example, one brute-force attack can consist of thousands of visits to a website.

5 IP Address Blacklisting

We analyze how popular commercial IP blacklists treat Tor relays. IP blacklisting can be in response to malicious traffic originating from the IP, which we call *reactive blacklisting*. We also observed *proactive black-*

[2] Even though the bandwidth is one of the main factors for selecting an exit, the other factors such as the exit policy might affect which exits will be selected. For our estimation, we do not consider the effect of exit policies.

listing, blacklisting based upon a network's pre-existing reputation or the online service's policy (e.g., the video-on-demand service, Hulu, blocks access to all VPN endpoints). After discussing our data sources, we describe how we classify blacklist entries into *proactive* blacklisting of Tor simply due a policy decision to deny access from Tor, versus *reactive* blacklisting in response to abuse. We then look at the amount of blacklisting of Tor and compare it to VPN IP address spaces and the IP address space of a large university in the USA. We analyze the impact of relay uptime, consensus weight, and exit policy on blacklisting behaviour.

5.1 Data Sources

For our study we were given access to a system that gathers commercial IP threat intelligence, including blacklists, from large Web companies. Facebook's ThreatExchange [28] platform is a major contributor to the system. This system has gathered roughly 2TB of data from 110 sources since July 25, 2015. We have anonymized the names of some IP blacklists in our results.

Along with the hourly Tor consensus data, we use additional methods to gather the set of Tor exit IP addresses seen by servers. While the Tor consensus provides the IP addresses used to reach exit relays (their "onion routing" IP addresses), a significant fraction of all exit relays (6% to 10%) use a different IP address for connecting to servers. To capture these IP addresses, we also associate with each relay its exit IP address provided by Tor DNSEL [29]. Tor DNSEL gathers the IP address used by a relay for exiting traffic based on active testing.

5.2 Classifying Blacklist Entries

Given Tor's reputation of transiting undesired traffic, some blacklists proactively include Tor relay IP addresses. Since we are interested in the rate and impact of undesired traffic Tor is currently producing, we must separate *proactive* blacklisting based upon historical events from *reactive* blacklisting based upon current events.

We use several methods to classify blacklist entries into *proactive* and *reactive* ones. In the simplest case, the blacklist provides the reason behind inclusion, either on an entry or on a list-wide basis. In some cases of *reactive* listing, the blacklist even provides information about the undesired traffic leading to blacklisting.

For those entries on lists that do not provide reasons for inclusion, we look at the behavior of the list overall to infer its reason for blacklisting. We infer that lists including a large percentage of Tor IP addresses soon after they appear in the consensus data likely reflect *proactive* listing of the addresses. If more than 30% of Tor relay addresses have been enlisted on a blacklist within 24 hours of them appearing in the consensus, we consider that blacklist *proactive*. We consider the remaining lists to be *reactive*. We discuss the details of deciding the threshold of 30% in Section A of the Appendix.

Figures 2a and 2b compare the rate of blacklisting by a *proactive* and a *reactive* blacklist. These graphs show the rate of blocking Tor exit IP addresses and of non-exit Tor IP addresses, whose blocking may be superfluous. In a small number of cases, the time until blacklisting is negative since the address was blacklisted before appearing in the consensus data, presumably from the IP address's prior use or the blacklisting of whole blocks of addresses. Under our analysis, the blacklist *Paid Aggregator*, a large paid provider of threat intelligence, is a *proactive* blacklist since 76.6% of Tor IPs enlisted on it were added within 24 hours of them first appearing in the consensus (Fig. 2a). The distributions show that the majority of the listed IP addresses get listed within a few hours of them becoming Tor relays. We classify *Contributed Blacklist 12*, a data source that contributes threat intelligence to a community aggregation project, as *reactive* since only 0.06% of all Tor IP addresses were added within the first 24 hours of their appearance in the consensus or the DNSEL (Fig. 2b).

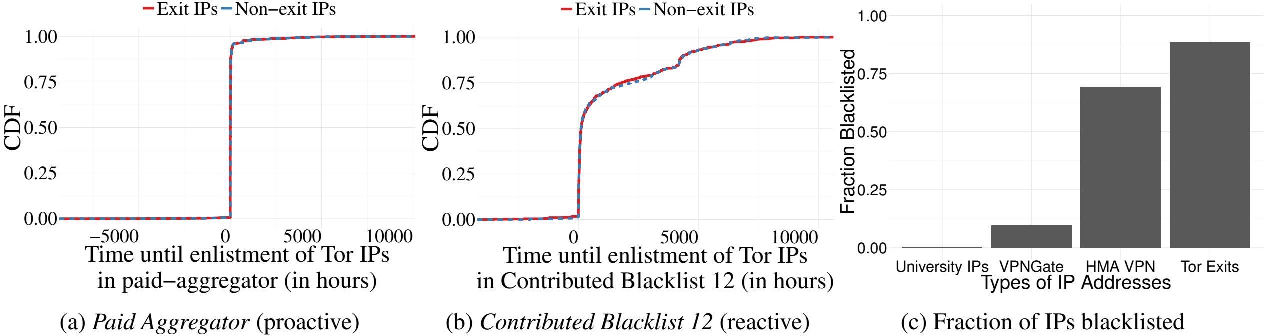
Using both methods of classifying lists, we found 84 lists that either include Tor exits proactively or reactively. Using the lists' labels and names, we classified 4 blacklists as *proactive*. We additionally classify 2 blacklists as *proactive* based on the time taken by them to enlist Tor IP addresses.

Identifying the *proactive* blacklisting of Tor exits also sheds light on the nature of Tor blocking employed by servers today. *Proactive* blacklisting implies that Tor users share fate not only with other users of their exits but also with *all* Tor users, including the ones in the distant past. We find that 6 out of 84 (7%) large commercially deployed blacklists proactively block Tor IP addresses.

5.3 Amount of Blacklisting

Figure 3 depicts the fraction of exit/non-exit relay IP addresses blacklisted by various lists during the observation time frame. From 110 blacklists that the IP reputation system gathers, 84 list Tor IP addresses in the observation time frame. For legibility, Figure 3 shows only the lists that included more than 1% of either Tor non-exit relays, Tor exit relay, or a VPN's IP addresses.

We observe that a few blacklists list a large number of Tor IP addresses, including non-exit relay IP addresses. In particular, *Paid Aggregator* (the *proactive* list shown in Fig. 2a) listed not only 48% of Tor exit addresses, but also 35% of entry and middle relay IP addresses. Blacklisting non-exit relays is surprising, since non-exit relays are not responsible for exiting traffic from the Tor net-



(a) *Paid Aggregator* (proactive)

(b) *Contributed Blacklist 12* (reactive)

(c) Fraction of IPs blacklisted

Figure 2: (a) and (b) provide the time (in hours) between first seeing a relay IP address in the consensus until the given blacklist enlists the IP address. Negative values indicate cases where the IP address was blacklisted before appearing in the consensus. Figure (c) compares the fraction of public IP addresses of different types of networks that are currently in any tracked blacklist.

work. Some relays have historically, at different points in time, been both exit and non-exit relays in the Tor consensus. In our analysis, we consider a relay an exit if it had the *Exit* flag at any point in its lifetime. Doing so provides a conservative estimate for the number of non-exit IP addresses that get blacklisted. In contrast, the *Snort IP* blacklist (another *proactive* list) enlists nearly 37% of exit IP addresses but less than 1% of non-exit relays.

5.4 Blacklisting of Tor vs. VPN nodes

VPN services are similar to Tor since they provide users with the option to obscure their IP addresses. In addition, like Tor exit relays, VPN nodes also egress traffic belonging to many users who could be using the VPN service for different purposes. In this section we compare blacklisting of Tor with that of popular VPN providers.

VPN providers like VPNGate [30] and HideMyAss [31] publish lists of their free-tier endpoints, making them good candidates for our study. Figure 2c shows, that in February 2017, over 88% of Tor exits are blacklisted (excluding the *proactive* blacklists) on one or more of the commercially available blacklists. In comparison, 10% of VPNGate endpoints and 69% of HMA endpoints appear on blacklists. All of these proxy services are considerably more blacklisted as compared to the IP space of a major university (three /16 prefixes used by the university campus network), of which only 0.3% IPs are blacklisted.

To have a fair comparison of the rate of blacklisting with Tor, we need a set of VPN endpoint IP addresses and a notion of when they first began to operate as VPN endpoints (similar to the notion of exit relays and their birth in the consensus). However, it is challenging to gather the IP addresses of VPN nodes over time since most VPN services do not archive such information. This is in contrast with Tor, which archives information about its relays on an hourly basis. However, the VPN provider HideMyAss (HMA) publishes a daily list of its free VPN endpoints [31]. We crawled archived versions of this list using the Wayback Machine [32] for IP addresses published between June 14, 2014 and October 27, 2016. We can then approximate the time when an IP address first served as an HMA VPN endpoint, assuming this occurs at least 60 days after the start of the time frame. In this manner we collected a set of 4,234 HMA endpoints and their *first seen* creation times. Of these, 1,581 IP addresses became HMA endpoints after our IP address reputation system started gathering blacklist data. We analyze the blacklisting of these endpoints using the IP reputation system.

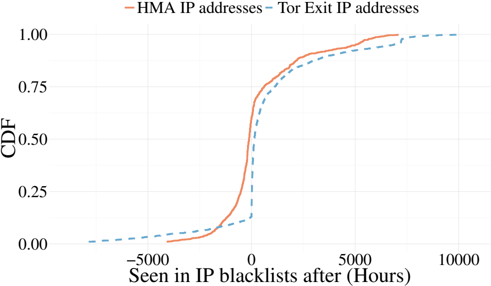


Figure 4: Comparing the time taken for Tor exit IP addresses and HMA endpoints to get blacklisted.

Figure 3 shows the fraction of HMA endpoints blacklisted by various blacklists. Unlike for Tor relays, no particular blacklist dominates in the listing of HMA IPs. Figure 4 shows how quickly HMA endpoints get blacklisted compared to Tor exits; *reactive* blacklisting of both occurs at a similar rate.

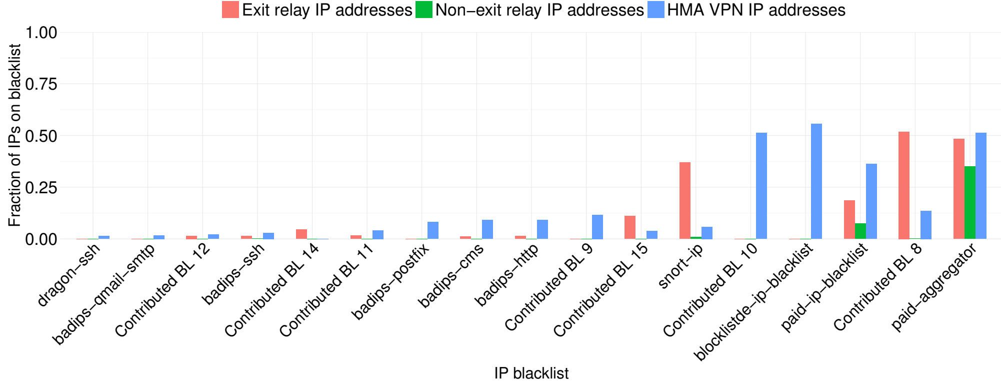

Figure 3: Fraction of Tor relay and HMA VPN IP addresses listed in IP blacklists (including *proactive* and *reactive)*. Some feed names are derived based on the broad categories of undesired traffic they blacklist: e.g., ssh (badips-ssh, dragon-ssh), content management systems/Wordpress (badips-http, badips-cms).

5.5 Exit policies and bandwidth

We looked for but did not find any associations between various factors and blacklisting. In an attempt to counter IP blacklisting and abusive traffic, the Tor community has suggested that exit operators adopt more conservative exit policies [18]. Intuitively, a more open exit policy allows a larger variety of traffic (e.g., BitTorrent, ssh, telnet) that can lead to a larger variety of undesired traffic seen to originate from an exit. We analyze the exit relays that first appeared in the consensus after the IP reputation system started to gather data using the hourly consensuses of year 2015 and 2016. Since exit relays have a variety of exit policies, we find which well-known exit policy (Default, Reduced, Reduced-Reduced, Lightweight, Web) most closely matches the relay's exit policy. To compute this closeness between exit policies, we calculate the Jaccard similarity between the set of open ports on a relay and each well-known exit policy. (See Appendix B). In this way, we associated approximate exit policies to 21,768 exit relays. We found that in the last 18 months, only 1.2% of exit relays have exhibited different well-known exit policies, and excluded these from our analysis. In the resulting set of exits, we assigned 81% to Default, 17% to Reduced, 0.6% to Reduced-Reduced, 0.5% to lightweight and 0.4% to Web policy.

We also compute the uptime (in hours) for each of the exit relays as the number of consensuses in which the relay was listed. In addition, we maintain the series of consensus weights that each relay exhibits in its lifetime. Higher consensus weights imply more traffic travelling through the relay, proportionally increasing the chance of undesired traffic from a relay. A high uptime increases the chance of use of a relay for undesired activities.

We trained a linear regression model on the policies, scaled uptimes, and consensus weights of exit relays, where the observed variable was the ratio of hours the IP address was blacklisted (*reactive* blacklisting only) and its overall uptime. Based on the coefficients learned by the regression model, we conclude that policy, consensus weight, and relay uptime have very little observed association on IP blacklisting of Tor relays. We provide more details about the regression model in Appendix C.

5.6 Our Newly Deployed Exit Relays

As described in Section §3, we operated exit relays of various bandwidth capacities and exit policies to actively monitor the response of the IP reputation system. In this subsection, we analyze the sequence of blacklisting events for each exit relay that we ran. Figure 5 shows the timeline of blacklisting events for each of the exit relays we operated. Each coloured dot represents an event. An event is either the appearance of a relay on a blacklist or its appearance in the consensus (an *up* event).

Prior to launching the exits, none of our prospective relays' IP addresses were on any blacklist. We see that within less than 3 hours of launching, feeds like *Snort IP* listed all our relays, supporting our classification of *Snort IP* as a *proactive* blacklist. Additionally, both *Snort IP* and *Paid Blacklist* (also classified as *proactive*) block our relay IP addresses for long periods of time. *Snort IP* enlists all of relays, and did not remove them for the entire duration of their lifetime. *Paid Blacklist* enlists IP addresses for durations of over a week. Blacklists such as badips-ssh (for protecting SSH) and badips-cms (for protecting content management systems such as Wordpress and Joomla) have short bans spanning a few days. *Contributed Blacklist 12* has the shortest bans, lasting only a few hours. We consider *Contributed Blacklist 12*'s blacklisting strategy in response to undesired traffic to be in the interest of both legitimate Tor users and content providers that do not intend to lose benign Tor traffic. On November 29, 2016, we turned off all of our relays

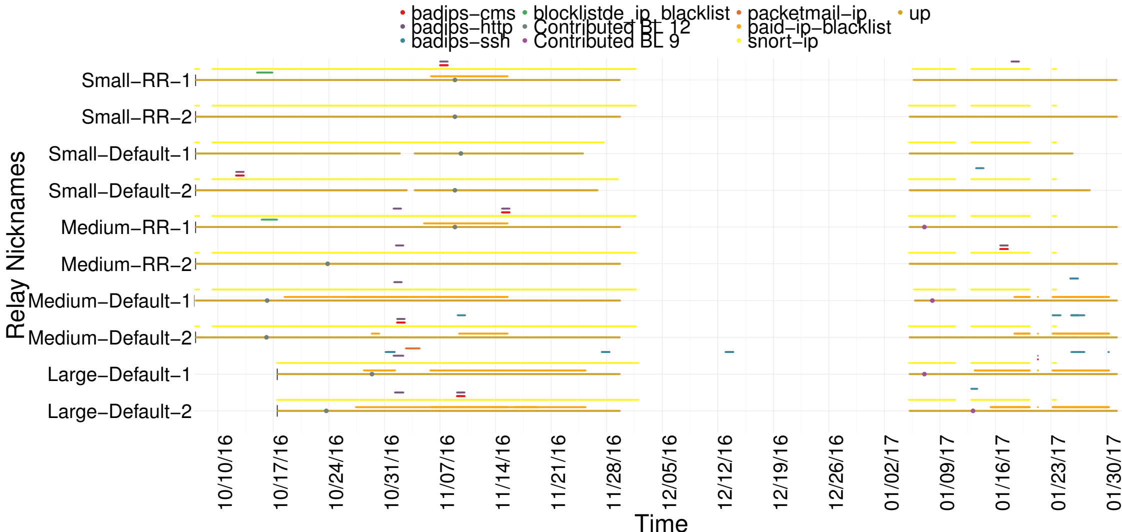

Figure 5: Blacklisting of our exit relays over time. Each coloured dot shows the instant when a relay was on a blacklist. *Snort IP* and *Paid Blacklist* have long term bans while other blacklists enlist IPs for short periods of time ranging from hours to a few days.

to observe how long a *proactive* blacklist like *Snort IP* would take to de-enlist our relays. We observe that such blacklists drop our relays just as fast as they enlist them, suggesting a policy of crawling the Tor consensus.

Note that a synchronised absence of data from any blacklist, while the relays are up, represents an outage of the IP reputation system.

6 Crawling via Tor

To quantify the number of websites discriminating against Tor, we performed crawls looking both at front-page loads, as in prior work [2], and at *search and login functionality*. We crawled the Alexa Top 500 web pages from a control host and a subset of Tor exit relays. These crawls identify two types of discrimination against Tor users: (1) the Tor user is blocked from accessing content or a service accessible to non-Tor users, or (2) the Tor user can access the content or service, but only after additional actions not required of non-Tor users—e.g., solving a CAPTCHA or performing two-factor authentication.

6.1 Crawler Design

We developed and used a Selenium-based interactive crawler to test the functionality of websites. We performed three types of crawls: (1) *Front-page crawls* attempt to load the front page of each website. We repeated the crawl four times over the course of six weeks. (2) *Search functionality crawls* perform front-page loads and then use one of five heuristics (Table 5) to scan for the presence of a "search box". Upon finding the search box, the crawler enters and submits a pre-configured search query. Our crawler found and tested the search functionality of 243 websites from the Alexa Top 500. We performed the search functionality crawl once. (3) *Login functionality crawls* load front pages and scan them for the presence of a "login" feature. Upon finding the feature, and if it has credentials for the webpage available, the crawler authenticates itself to the site (using Facebook/Google OAuth when site-specific credentials were unavailable). We created accounts on OAuth-compatible websites prior to the crawl. Since the created accounts had no prior history associated with them, we speculate that they were unlikely to be blocked as a result of unusual behavior. For example, we found that LinkedIn blocks log ins from Tor for accounts with prior log in history, but not for new accounts. Our crawler found and tested the login functionality of 62 websites from the Alexa Top 500. We performed the login functionality crawl once.

The crawler records screenshots, HTML sources, and HARs (HTTP ARchives) after each interaction. Our interactive crawler improves upon previous work in several ways. First, it uses a full browser (Firefox) and incorporates bot-detection avoidance strategies (i.e., rate-limited clicking, interacting only with visible elements, and action chains which automate cursor movements and clicks). These features allow it to avoid the (bot-)based blocking observed while performing page-loads via utilities such as `curl` and other non-webdriver libraries (`urllib`). Second, its ability to interact with websites and exercise their functionality allows us to

Heuristic	Coverage
1. Visible and clickable textbox elements containing search related keywords (`q`, `query`, `querytext`, `search`) in their element `name`, `id`, `value`, or `label` are assumed to be search boxes.	98
2. The above heuristic is repeated while considering all input DOM elements.	81
3. If the DOM contains exactly one visible and clickable textbox element, it is assumed to be a search box.	22
4. If the DOM contains exactly one visible and clickable input element with a defined `max-length`, it is assumed to be a search box.	12
5. If the DOM contains exactly one visible and clickable input element, it is assumed to be a search box.	30

Table 5: Heuristics used to identify search input boxes. Heuristics are described from most specific to least specific. Coverage indicates the number of sites that were identified using the corresponding heuristic.

identify cases where discrimination occurs beyond the front page — e.g., `www.tumblr.com` serves Tor users CAPTCHAs only after they submit a search query, and `www.imdb.com` blocks Tor users when they attempt to log in.

6.2 Relay selection

We randomly selected 100 exit relays from the set of all exit relays that supported HTTP(S) connections (i.e., the exit policy allows outbound connections to ports 80 and 443). In addition to these randomly sampled relays, we also conducted crawls through our own relays (described in Table 1) and a university-hosted control host.

Since we performed our crawls over a six-week period, several of the selected exit relays intermittently went offline, with a total of 0, 12, 19, and 28 offline during crawls 1–4, respectively. We account for the resulting page-load failures by excluding the failures from our analysis.

6.3 Identifying discrimination

In each of our experiments we simultaneously performed crawls exiting through all online sampled exits and our university-hosted control host. To identify discrimination of a selected exit relay, we first rule out cases of client and network errors through HAR file analysis. We use the HAR files to verify, for each page load, that (1) the requests generated by our browser/client were sent to the destination server (to eliminate cases of client error), and (2) our client received at least one response from the corresponding webpage (to eliminate cases of network errors). If, for a given site, either the control host or the selected exit relay did not satisfy both these conditions, we did not report discrimination due to the possibility of a client or network error.

Next, we compare the crawler-recorded screenshots of the control server and each selected exit relay using *perceptual hashing (pHash)* [33], a technique that allows us to identify the (dis)similarity of a pair of images. We report images with high similarity scores (pHash distance < 0.40) as cases where no discrimination occurred and images with high dissimilarity (pHash distance > 0.75) as cases of discrimination, while flagging others for further inspection. The thresholds were set so that only pages with extreme differences in content and structure would be automatically flagged as cases of discrimination, while similar pages were automatically flagged as cases of non-discrimination. In general, minor changes in ads/content (e.g., due to geo-location changes) do not result in flagging. We set the thresholds using data obtained from a pilot study (Figure 6).

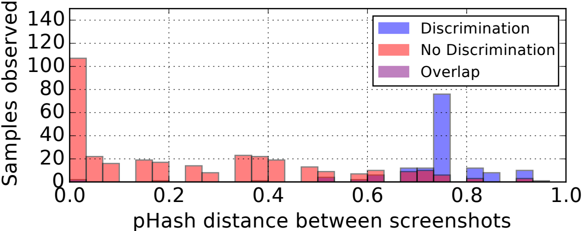

Figure 6: Results of pilot study to identify pHash distance thresholds for automatically identifying cases of (non) discrimination. We manually tagged 500 randomly chosen samples (i.e., pairs of control and exit relay screenshots of the same website) and computed the pHash distances. Based on the above distribution, we classified distances < 0.40 as "non-discrimination" and distances > 0.75 as "discrimination". Instances having pHash distances in the 0.40 to 0.75 range were manually inspected and tagged.

Then, we classified as discrimination cases where exit relays received HTTP error codes for requests that our control host successfully loaded with a 200 status. Finally, we manually tag the screenshots of remaining cases to identify more subtle discrimination—e.g., a block-page served with a 200 status.

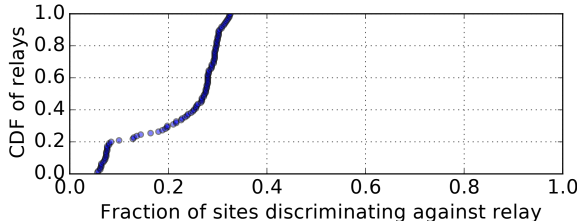
6.4 Results

Table 6 summarizes the main results of our three types of crawls over compatible websites in the Alexa Top 500. Here, we show the fraction of interactions on which discrimination was detected. We find that 20.03% of all Alexa Top-500 (A-500) website front-page loads showed evidence of discrimination against Tor users, compared

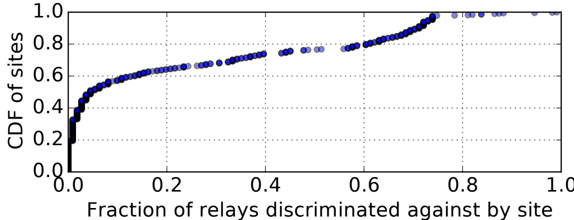
to 17.44% of the search-compatible (S-243) and 17.08% of the login-compatible (L-62) website front-page loads. When exercising the search functionality of the 243 search-compatible websites, we see a 3.89% increase in discrimination compared to the front-page load discrimination observed for the same set of sites. Similarly, when exercising the login functionality of the 62 login-compatible websites, we observe a 7.48% increase in discrimination compared to the front-page discrimination observed for the same set of sites.

Websites	Interaction	Discrimination observed
A-500	Front page	20.03%
S-243	Front page	17.44%
	Front page + Search	21.33% (+3.89%)
L-62	Front page	17.08%
	Front page + Login	24.56% (+7.48%)

Table 6: Fraction of interactions blocked from 110 exits. A-500 denotes the Alexa Top 500 websites, S-243 denotes the 243 search-compatible websites, and L-62 denotes the 62 login-compatible websites.



(a) Distribution of discrimination faced by relays.



(b) Distribution of discrimination performed by websites.

Figure 7: Distribution of discrimination by Alexa Top 500 websites against 110 exit relays.

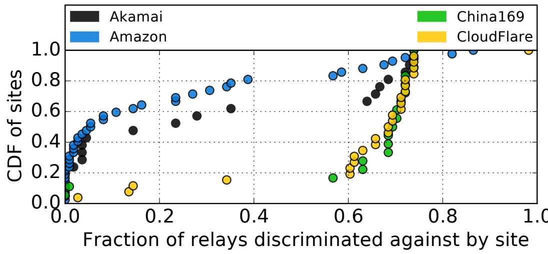


Figure 8: Distribution of discrimination performed by websites hosted on four of the six most popular hosting platforms.

Figure 7a shows the distribution of discrimination (for any interaction) faced by relays from websites in the Alexa Top 500. We find that no relay experiences discrimination by more than 32.6% of the 500 websites, but 50% of the exit relays are discriminated against by more than 27.4% of the 500 websites. Figure 7b shows the distribution of discrimination performed by websites against Tor exit relays. Here, we see that 51% of the websites perform discrimination against fewer than 5% of our studied exits, while 11% of websites perform discrimination against over 70% of our studied exits.

We now examine various factors associated with Tor discrimination. Since we did not (and in many cases cannot) randomly assign these factors to websites or relays, these associations might not be causal.

Hosting Provider. Figure 8 shows the fraction of relays discriminated against by websites hosted on four of the six most-used hosting platforms. We find that Amazon- and Akamai-hosted websites show the most diversity in discrimination policy, which we take as indicative of websites deploying their own individual policies and blacklists. In contrast, CloudFlare has several clusters of websites, each employing a similar blacklisting policy. This pattern is consistent with CloudFlare's move to allow individual website administrators to choose from one of several blocking policies for Tor exit relays [1]. Finally, we see 80% of China169- and CloudFlare-hosted websites perform discrimination against at least 60% of our studied relays.

Relay Characteristics. Our analysis of the association between exit-relay characteristics and the discrimination faced by them found no significant correlations when accounting for relay-openness (fraction of ports for which the exit relay will service requests) or for the age of the relay. We found a small positive correlation (Pearson correlation coefficient: 0.147) between the relay bandwidth and degree of discrimination faced, but the result was not statistically significant (p-value: 0.152). Figure 9 presents these results graphically. We further analyze the impact of relay characteristics on discrimination performed by websites using popular hosting providers . We find that only Amazon has a statistically significant positive correlation between discrimination observed and relay bandwidth (Pearson correlation coefficient: 0.247, p-value: 0.015). These results are illustrated in Figure 10.

Service Category. We now analyze how aggressively

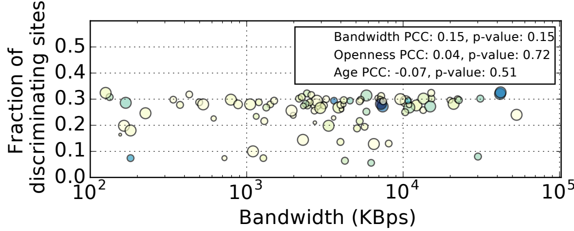

Figure 9: Relationship between relay characteristics and discrimination faced. Each circle represents a single relay. Lighter colors indicate younger relays and larger circles indicate more open exit policies. The legend shows the Pearson correlation co-efficient (PCC) and the p-value for each characteristic.

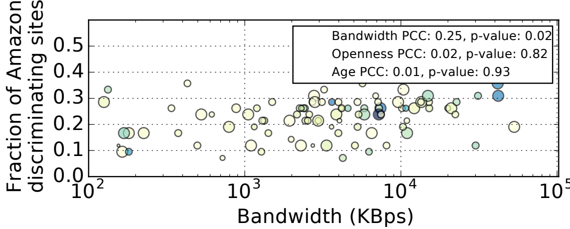

Figure 10: Impact of relay characteristics on discrimination performed by websites hosted by Amazon.

four different categories of sites—search engines, shopping, news, and social networking—discriminate against Tor exit relays. We categorize sites using the McAfee URL categorization service [34]. We find that search engines are the least likely to discriminate against exit relays, with 83% of all search engines discriminating against fewer than 20% of our studied exit relays, compared to 30% of social networking sites, 32% of shopping sites, and 53% of news sites. We also find social networking and online shopping sites share similar blocking behavior. Websites in these categories are also observed to be the most aggressive—with 50% of them blocking over 60% of the chosen relays. Figure 11 illustrates the results.

The Evolution of Tor Discrimination. We now focus on discrimination changes over time. For this experiment, we conducted four crawls via our own ten exit relays to the Alexa Top 500 websites. Let Day 0 denote the day when we set the relay's exit flag. We conducted crawls on Day -1, Day 0, and once a week thereafter. Table 7 shows the fraction of websites found to to discriminate against each exit set during each crawl. We observe increases in discrimination when the exit flag is assigned. We can attribute some of this can to our improved crawling methodology deployed on Day 0 (the

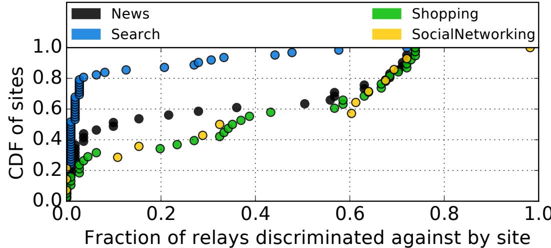

Figure 11: Distribution of discrimination performed by websites in various categories.

Day -1 crawl utilized the crawler from Khattak et al.; see below), although we note that the IP addresses used by our exit relays were never used by other Tor exit relays in the past, and did not appear in any of our studied commercial blacklists before Day 0, while they immediately manifested after setting the exit flags.

Configuration	Day -1	Day 0	Wk. 2	Wk. 3	Wk. 4
Large-Default	NA	17.0	19.0	21.1	25.4
Medium-Default	9.4	20.5	24.4	25.6	24.8
Medium-RR	9.9	18.3	24.1	22.7	24.7
Small-Default	9.3	20.3	20.9	23.9	23.6
Small-RR	9.4	20.5	20.7	25.7	25.3

Table 7: Percentage of discriminating page loads for each set of deployed relays.

The high amount of discrimination observed on our Day-0 crawl for all exit relays is indicative of *proactive* discrimination against Tor exit relays. Our results do not indicate differences due to relay cateogry in the amount of discrimination experienced.

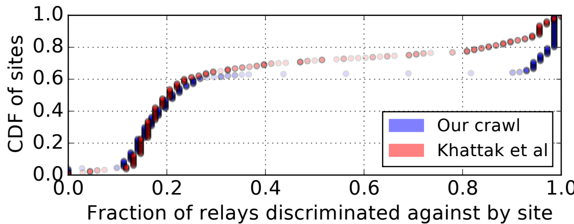

Figure 12: Impact of methodological changes on measured discrimination from data generated by a single front-page crawl.

Measurement Methodology. We now measure the impact of changes in our discrimination identification methodology compared to previous work by Khattak et al. [2]. The key differences between the methodologies are: (1) The measurements conducted by Khattak et al.

are limited to identifying front-page discrimination. Our crawler also tests search and login interactions. Table 6 presents the impact of this feature. (2) Khattak et al. identify discrimination using the difference in HTTP status codes returned by the control and test nodes. This method is prone to underestimating discrimination due to the inability to detect block pages that return a HTTP 200 OK status code. Our method relies on screenshot differences and HTTP status codes as a signal for discrimination. As a result, we are able to detect discrimination performed by sites such as `livejournal.com`, `hdfc.com`, and `glassdoor.com`. (3) Khattak et al. rely on sending HTTP requests for front pages of websites using the python `urllib2` library. Although they modify the user agent of their crawler to match a regular web browser, they are easily identifiable as an irregular user since they do not load third-party objects and JavaScript. Such crawlers are blocked by many websites and bot-mitigation tools [35]. In contrast, we perform complete page loads, including third-party content and execution of JavaScript. As a consequence, our crawls are slower, requiring around 12 hours for 500 page loads (compared to 1–2 minutes required by the `urllib2` crawler).

To understand the impact of (2) and (3), we compare the discrimination results obtained from a single front-page crawl performed by both crawlers. We started both crawls on the same day, on the same set of websites, using the same set of 100 randomly sampled exit relays. The results, illustrated in Figure 12, confirm that previous work underestimates the amount of discrimination.

7 Privacy-sensitive Exit Logging

While our crawls systematically explore popular websites, they might not be typical of actual Tor usage. Thus, we performed privacy-sensitive logging on our deployed exit relays to measure how commonly users interacting with Alexa Top 1M web pages experienced failed TLS handshakes or HTTP requests This observational dataset, based on actual Tor-user web traffic distributions and user interactions, provides us with a picture of the discrimination actually encountered by users.

7.1 Logging Approach

In order to measure the number of failed TLS handshakes and HTTP requests, we developed a custom logger. Although tools such as PrivEx [36], Historε [37], and PrivCount [38] were specifically built for measuring characteristics of Tor exit traffic, they are not suitable for our study for two reasons: First, they currently do not have the capability to inspect HTTP and TLS traffic headers. Adding such functionality to the tools requires modifying the Tor relay source code—possibly introducing users of our relays to new vulnerabilities. Second, they were built with the goal of performing secure data aggregation across multiple relays. Since a single entity owned and operated all of the relays used in our study, this feature was unnecessary for our purposes.

We maintain counters for several events of interest associated with users browsing websites in the Alexa Top 1M. Our approach, designed after consultation with members of the Tor developer community, takes precautions to avoid de-anonymization of users. Since neither the Tor users nor the service operators were the subjects of our study, we were exempt from an IRB review.

First, we use bucketing and split the Alexa Top 1M websites into exponentially growing sets based on their Alexa ranks, as follows: The first set contains the top 100 websites (ranked 1–100) and the nth set for $n > 1$ contains the top $100 \times 2^{n-2} + 1$ to $100 \times 2^{n-1}$ websites. We keep a separate event counter for each set. Second, we maintain our event counters in memory and write to disk only once a day. Doing so allows our event counters to attain higher count values, increasing anonymity-set sizes. Third, to deal with the possibility of encountering cases where 24 hours does not suffice to achieve reasonably high anonymity-set sizes—e.g., if only one person visited a site during a 24 hour period—we round up each event counter to the nearest multiple of eight before writing to disk. A similar approach is used by Tor metrics [3] for reporting counts of bridge users per country.

We maintained per-bucket event counters for the number of: (1) HTTP requests to website front pages, (2) error status codes observed in their corresponding responses, (3) HTTP(S) handshakes initiated, and (4) timed-out handshakes encountered. Additionally, we also maintained a counter for the number of packets sent through each open port.

7.2 Results

Table 8 shows the percentage of failed HTTP requests and incomplete HTTPS handshakes encountered by users of our exit relays. We find that the fraction of incomplete handshakes steadily increases over time. We attribute the steep increase in HTTP error codes received during weeks four and five to our relays being (ab)used in a scraping attempt on a popular website (we received a complaint notice due to this behavior). Besides this sudden increase, we see that the fraction of HTTP errors accords with data observed through our crawls, but the fraction of incomplete HTTPS handshakes runs higher. This is likely because incomplete handshakes provide only very noisy indicators for user discrimination, with many reasons for them to occur naturally.

HTTP requests and error response codes. For exiting packets using the HTTP protocol, *iff* the URI

Week	1	2	3	4	5	6
HTTP	15.8	18.1	19.8	32.8	33.4	17.9
HTTPS	36.3	35.0	41.1	45.2	47.9	49.6

Table 8: The percentage of failed HTTP requests and incomplete HTTPS handshakes observed over time.

on the HTTP request was identical (ignoring case) to a Top 1M website, we incremented a *front-page request* event counter associated with the set containing the site. For every matching request, we maintained state to identify the corresponding response packet. If the corresponding response packet contained an error status code (4XX/5XX), we incremented an *error-status* event counter associated with the corresponding set. We break down the fraction of errors by website ranks and time in Figure 13a. We see that the fraction of error response codes is nearly evenly distributed across each set, indicating that errors are independent of website ranks.

HTTPS handshake initiation and failure. The procedure for HTTPS is similar to that for HTTP. However, we use the SNI value of *client-hello* handshake initiation packets instead of the URI of HTTP requests. Furthermore, we look for handshake failures and timed-outs instead of HTTP errors. The results in Figure 13b show a strong increasing trend in incompletion rates over time.

8 Discussion and Future Work

Limitations. Our studies each come with their own limitations, some resulting from our desire to protect the privacy of Tor users, others from the limited data sets available for study. Neither our set of emails nor our set of blacklists are complete. Given that Tor assigns traffic to exits in a mostly random fashion, we believe the emails from our sample to be representative of the complaints during their time periods for exits with similar exit policies. While there are blacklists that we were not able to observe during the period of our study, the set of blacklists used in our analysis includes numerous types from a wide range of suppliers, leading us believe that they capture all common blacklisting phenomena. Our crawls, while more in-depth than prior efforts [2], were too time-consuming to run often enough to gain statistical guarantees about discrimination by any one website. Nevertheless, taken together, they show that discrimination is common and sometimes subtle.

Implications for Tor. The large amounts of blocking and discrimination identified by our crawling and privacy-sensitive measurements suggest that Tor's utility is threatened by online service providers opting to stifle Tor users' access to their services (§6 & §7).

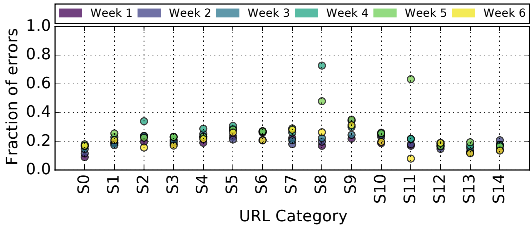
From studying blacklists we learned that some, but not all, proactively add Tor exit IP addresses (§5), presumably in response to prior undesired traffic and an expectation of more. This result highlights that Tor users fate-share with not just the Tor users sharing their current exit relay, but all Tor users—present and past. Other blacklisting appears to be reacting to undesired traffic, suggesting that blocking may decrease if Tor can reduce the amount of abuse it emits. Such a reduction may even, over time, decrease *proactive* blacklisting as Tor's reputation improves. These findings suggest the utility to implement any privacy-sensitive abuse-reduction approaches for Tor.

From the emails, we learned of the types of undesired traffic that server operators find concerning enough to warrant sending a complaint. Of the types of abuse identified in email complaints (§4), the vast majority—the DMCA complaints—appear irrelevant to blocking since DMCA violators largely use peer-to-peer services. Furthermore, at least in our sample they are no longer common (Table 2). Of the remaining complaints, nearly 90% related to large-scale abuse, such as excessive connection attempts, scanning, brute-force login attempts, and spam. While the rate of complaining might not be proportional to the rate of undesired traffic, it may provide some insights into the nature of the most troubling abuse exiting the Tor network. The exit policies have no significant impact on reducing abuse complaints and rate of discrimination against Tor users.

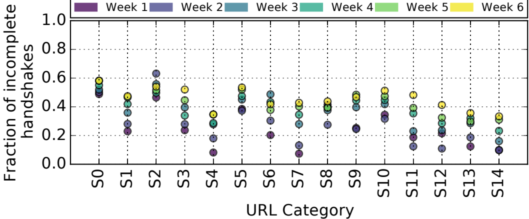
Given the large footprints of the observed abuse, we believe future research should seek to provide tools to curb such abuse while preserving privacy and Tor functionality. We envision Tor nodes using cryptographic protocols, such as secure multi-party computation and zero-knowledge proofs, to detect and deter users producing large amounts of traffic in patterns indicative of abuse. For example, Tor could compute privacy-sensitive global counts of visits to each threatened domain and throttle exiting traffic to ones that appear over-visited.

Implications for online services. Combining our study results, we can put the difficulties facing Tor users and online service operators into perspective: at most 182 email complaints per 100K Tor users, and over 20% of the top-500 websites blocking Tor users. Given that Tor users *do* make purchases at the same rate as non-Tor users [6], this response may be excessive and operators might wish to use less restrictive means of stifling abuse.

Operators can aid Tor in developing approaches to curb abuse or unilaterally adopt local solutions. For example, instead of outright blocking, servers could rate-limit users exiting from Tor for certain webpages (e.g., login pages). Indeed, CloudFlare is developing a cryptographic scheme using blindly signed tokens to rate limit Tor users' access to websites it hosts [39].



(a) Fraction of HTTP error codes



(b) Fraction of incomplete TLS handshakes

Figure 13: Fraction of errors encountered by users visiting the Top 1M websites over time. The URL category S1 consists of the top (1–100) websites and Sn ($n \geq 2$) consists of sites in the top [$100 \times 2^{n-2} + 1$ to $100 \times 2^{n-1}$] ranks.

Ultimately, we do not view IP-based blacklisting as a suitable long-term solution for the abuse problem. In addition to Tor aggregating together users' reputations, IPv4 address exhaustion has resulted in significant IP address sharing. IPv6 may introduce the opposite problem: the abundance of addresses may make it too easy for a single user to rapidly change addresses. Thus, in the long run, we believe that online service operators should shift to more advanced ways of curbing abuse; ideally, ones compatible with Tor.

Acknowledgements

Appendix

A Picking threshold values for *proactive* blacklisting

We classify a blacklist as *proactive* if it enlists a large fraction of Tor exit relays within the first 24 hours of them appearing in the consensus. In order to decide the threshold for the fraction of Tor exit relays that, if blocked within 24 hours, we should consider the blacklist, we analyze the value of the fraction for all blacklists. We find two blacklists: *Snort IP* and *Paid Aggregator* blacklist 37% and 31% of all Tor exits within 24 hours, respectively. All other blacklists listed fewer than 5% of Tor IP addresses within 24 hours. This large difference in the behaviour of blacklists encouraged us to pick the threshold as 30%.

B Classifying exit policies

In this section we describe our method for classifying the exit policies of all exit relays observed in 2015 and 2016. Since each relay could potentially have an arbitrary set of ports open (from the 65,535 possible ports), comparing the *openness* of exit policies is difficult. To simplify the process, we parse the exit policy of each relay to extract the set of open ports and then compute the Jaccard similarity between the relay's open ports and each of the well-known exit policies that Tor supports (Default, Reduced, Reduced-Reduced, Lightweight and Web). We classify a relay into one of the 5 categories based on the Jaccard similarity value. To ensure that the similarity in policy is large enough, we classify the relay to the category of highest similarity, provided that the similarity value is at least 0.7. Only the relays with a high enough similarity value with any of the well known exit policies are considered for further analysis.

C IP blacklisting and relay characteristics

We train a linear regression model to find the impact of relay characteristics like uptime, policy, and consensus weight on the time a relay spends on *reactive* blacklists. The observed variable is the ratio of hours spent on the blacklist to the uptime of the relay. We trained the model on 20,500 exit relays' data (with feature scaling) and found that the coefficients learned for all the factors are extremely small (consensus weight = -0.00007, uptime = 0.009, policy = -0.00001). This shows that these factors have very little impact on blacklisting of relays. It also suggests that changing to more conservative exit policies does not reduce the chances of relays getting blacklisted.

DeTor: Provably Avoiding Geographic Regions in Tor

Zhihao Li, Stephen Herwig, and Dave Levin
University of Maryland

Abstract

Large, routing-capable adversaries such as nation-states have the ability to censor and launch powerful deanonymization attacks against Tor circuits that traverse their borders. Tor allows users to specify a set of countries to exclude from circuit selection, but this provides merely the illusion of control, as it does not preclude those countries from being on the path *between* nodes in a circuit. For instance, we find that circuits excluding US Tor nodes definitively avoid the US 12% of the time.

This paper presents DeTor, a set of techniques for proving when a Tor circuit has avoided user-specified geographic regions. DeTor extends recent work on using speed-of-light constraints to prove that a round-trip of communication physically could not have traversed certain geographic regions. As such, DeTor does not require modifications to the Tor protocol, nor does it require a map of the Internet's topology. We show how DeTor can be used to avoid censors (by never transiting the censor once) and to avoid timing-based deanonymization attacks (by never transiting a geographic region twice). We analyze DeTor's success at finding avoidance circuits through simulation using real latencies from Tor.

1 Introduction

Tor [8] has proven to be an effective tool at providing anonymous communication and combating online censorship. Over time, Tor's threat model has had to adapt to account for powerful nation-states who are capable of influencing routes into and out of their borders—so-called *routing-capable* adversaries [34].

We consider two key threats that the presence of routing-capable adversaries now makes a practical reality. First, routing-capable adversaries can (and regularly do) censor Tor traffic. While it is well-known that some countries block Tor traffic beginning or ending within borders, recent studies have shown that some also block any Tor traffic that happens to transit *through* their borders [4]. Second, routing-capable adversaries can launch deanonymization attacks against Tor. If an adversarial network is on the path of the circuit between source and entry, and between exit and destination, then it can introduce small, detectable jitter between packets to correlate the two connections and therefore uncover the source and destination [19].

In light of increasingly powerful attacks like these, Tor has added the ability for users to specify a set of countries to exclude when selecting circuits. However, as we will demonstrate, this offers users only the illusion of control over where their traffic does not go. Among the circuits that Tor uses to ostensibly ignore the US, we could identify only 12% of them as definitively avoiding the US. Alternative schemes have been proposed that involve using `traceroute` to construct a map of the Internet's topology. However, routing-capable adversaries can easily (and regularly do [35]) provide incomplete responses to `traceroute`, precluding provable security from mapping-based approaches.

In this paper, we present a set of techniques that can *prove* that a circuit has avoided a geographic region. One of the most powerful features of these techniques is how little they require compared to many prior approaches: they do not require modifying the hardware [3] or routing protocols [30] of the Internet, nor do they require a map of the Internet's routing topology [12]. Instead, our work extends recent work on "provable avoidance routing" [24] that uses geographic distances and speed-of-light constraints to prove where packets physically could not have traversed. Users can specify arbitrary geographic regions (our techniques do not rely on any notion of network topology or ownership), and we return per-packet proofs of avoidance, when available.

We construct avoidance in Tor in two applications:

Never-once proves that packets forwarded along a circuit never traversed a given geographic region, even once. With this, users can avoid website fingerprinting attacks [23] and censoring regimes [4].

Never-twice proves that packets forwarded along a circuit do not reveal more information to a geographically constrained adversary than is strictly necessary by ensuring that they do not appear on two non-contiguous legs of the Tor circuit. With this, users can prevent certain deanonymization attacks [2, 17, 29, 10, 15].

In sum, this paper makes the following contributions:

- We introduce the notion of Tor circuits that *provably* avoid regions of the world. Unlike prior approaches, our proofs do not depend on any model of network or

AS-level topologies, and are instead based on round-trip time measurements. Therefore, they are easy to collect, do not require modifications to Tor, and do not depend on Internet measurements that are manipulable by a powerful adversary.

- We present the design, analysis, and evaluation of two novel forms of avoidance: never-once to avoid censors and website fingerprinting attacks, and never-twice to avoid various traffic deanonymization attacks.
- We build these techniques in a system we call *DeTor*, and evaluate it using real Tor latencies collected by the Ting measurement tool [6]. We show that provable, never-once avoidance is possible even when avoiding routing-central countries like the US, and that provable never-twice avoidance works for *98.6%* of source-destination pairs not in the same country.

Collectively, our results show that, with client-side techniques alone, it is possible to achieve greater control over where Tor data does *not* go. We believe this to be a powerful building block in future defenses.

2 Background and Related Work

In this section, we describe some of the attacks that are possible against Tor from a powerful routing-capable adversary. We also discuss prior work that has sought to mitigate these attacks. First, we begin by reviewing the relevant details of the Tor protocol.

2.1 A Brief Review of Tor

Tor [8] is a peer-to-peer overlay routing system that achieves a particular type of anonymity known as unlinkable communication. A source-destination pair is *unlinkable* if no one other than the two endpoints can identify *both* the source and destination. That is, an observer may know the source (or destination) is communicating with *someone*, but cannot identify with whom.

Tor achieves unlinkable communication by routing traffic through a *circuit*: a sequence of overlay hosts. There are typically three hosts in a circuit: an entry node[1] (who communicates with the source), a middle node, and an exit node (who communicates with the destination). The source node is responsible for choosing which Tor routers to include in a circuit, and for constructing the circuit. Tor's default circuit selection algorithm chooses nodes almost uniformly at random to be in a circuit, with three notable exceptions: (1) nodes with greater bandwidth are chosen more frequently, (2) no two nodes from the same subnet are chosen to be in the same circuit, and (3) no nodes are chosen from a user-specified list of countries to ignore.

[1] Alternatively, clients can make use of so-called bridge nodes, which are in essence non-public entry nodes. Because they serve the same purpose as traditional entry nodes, they pose no difference in DeTor, and so we refer to them collectively as "entry nodes."

Circuit construction is done in such a way that the only host who knows all hops on the circuit is the source: each other host knows only the hop immediately preceding and succeeding it. By the end of the circuit construction protocol, the source has established a pairwise secret (symmetric) key with each hop on the circuit.

The salient feature of Tor is the manner in which it performs "onion routing." When sending a packet p to the destination, the source encrypts p with the symmetric key it shares with the exit node; it then encrypts this ciphertext with the key shared with the middle node; and in turn encrypts this doubly-encrypted ciphertext with the key shared with the entry node. Each hop on the circuit "peels off" its layer of encryption, thereby ensuring that anyone overhearing communication between any two consecutive Tor routers learns nothing about the other Tor routers on the circuit.

2.2 Threat Model

We assume a powerful routing-capable adversary [34], e.g., a nation-state. Such an attacker has the ability to make (potentially false) routing advertisements and can therefore attract routes to its administrative domain. Thus, routing-capable adversaries are able to insert themselves onto the path between two communicating endpoints. Once on the path, they can launch various man-in-the-middle attacks by injecting, dropping, delaying, or reordering packets.

Routing-capable adversaries can also mislead or obfuscate attempts to map their networks. For example, one common approach for mapping a network is to use `traceroute`, but even benign networks sometimes refuse to respond to ICMP packets, tunnel their packets through their internal network, or simply do not decrement TTLs. These efforts effectively hide routers from a `traceroute` measurement, and could allow a nation-state adversary to hide its presence on a path. It is because of these kinds of attacks that we choose not to employ `traceroute`-based measurements in our system.

Because we are mainly focused on nation-state adversaries, we assume that the attacker can be geographically localized. For example, to avoid the United States, we assume that a user can download the geographic information (GPS coordinates) that succinctly describe where the US is (including its territories, such as Guam) and that these constitute all of the locations from which the country could launch attacks. This was the same assumption made by Levin et al. [24]. In practice, it may be possible that an adversary could infiltrate other countries' networks, but there are many instances where a nation-

state deploys its censorship mechanisms within its borders [7, 13].

This attack model extends naturally to colluding countries, such as the Five Eyes: one can simply consider them as one large "nation-state" that is constrained to its (potentially noncontiguous) borders. As we will demonstrate, because our techniques apply to noncontiguous geographic regions, they are not restricted to single nation-states, and can be applied to arbitrary sets of countries.

The attacker can also run its own Tor routers or collude with some Tor routers, but, as per the previous assumption, only within its own (or its fellow colluders') borders.

Finally, we make several assumptions about what an attacker *cannot* do. We assume the attacker cannot violate standard cryptographic assumptions, particularly that it cannot invert cryptographically secure hash functions, infer others' private keys, or forge digital signatures or MACs. Also, we note that, while an attacker can lie about having *larger* latencies (by delaying its own packets), it is unable to lie about having *lower* latencies than its links actually permit.

2.3 Attacks

This paper considers three very powerful attacks that are at the disposal of a routing-capable adversary. We review the attacks here, and then describe how prior work has sought to mitigate them.

Censorship A routing-capable adversary can censor traffic that enters its borders. Commonly, with Tor, this involves identifying the set of active Tor routers and simply dropping traffic to or from these hosts. The Tor Metrics project monitors several countries who appear to perform this kind of censorship [37].

Traffic deanonymization Consider an attacker who is able to observe the traffic on a circuit between the source and the entry node and between the exit node and the destination. The attacker can correlate these two seemingly independent flows of traffic in a handful of ways. For instance, a routing-capable adversary operating a router on the path between source and entry could introduce jitter between packets that it could detect in the packets between exit and destination. This works because Tor routers do not delay or shuffle their packets, but rather send them immediately in order to provide low latencies [6].

Website fingerprinting Even an attacker limited to observing only the traffic between the source and entry node can be capable of deanonymizing traffic. In particular, if the destination's traffic patterns (e.g., the number of bytes transferred in response to apparent requests) are well-known and unique, then an attacker may be able to infer the destination by observing the traffic on any leg of the circuit [23]. Such attacks run into challenges when there is sufficient cover traffic, but unfortunately Tor users have little control over how much cover traffic there is.

2.4 Related Work

Sneaking through censors The traditional way of mitigating censoring nation-states is to sneak through them by making would-be-censored traffic look benign. For example, decoy routing [21, 41] uses participating routers that are outside the censoring regime but on a benign path to effectively hijack traffic and redirect it to a destination that would be censored. To the censoring regime, the traffic appears to be going to a destination it permits.

Other approaches employ protocol obfuscation techniques to make one protocol look like another. A slew of systems [26, 40, 27, 38, 39, 18] has explored making Tor traffic appear to be other, innocuous traffic, notably Skype (many censors permit video chat applications, so as to allow their citizens to keep in touch with friends and family abroad). We seek an altogether different approach of *avoiding these nefarious regions altogether*, rather than trying to sneak through them. However, these are somewhat orthogonal approaches, and may be complementary in practice.

AS-aware Tor variants The work perhaps closest to ours in terms of overall goals is a series of systems that try to avoid traversing particular networks once (or twice). To the best of our knowledge, these have focused almost exclusively on using autonomous system (AS)-level maps of the Internet [2, 19, 10]. Like DeTor, the idea is that if we can reason about and enforce where our packets may (or may not) go *between* hops in the circuit, we can address attacks such as censorship and certain forms of traffic deanonymization.

As described in §2.2, however, we assume in this paper an adversary who has the ability to manipulate an observer's map of the Internet, for instance by withholding some routing advertisements, withholding `traceroute` responses, and so on. Instead of relying on these manipulable data sources, we base our proofs on *physical, natural* limitations: the fact that information cannot travel faster than the speed of light. As an additional departure from this line of work, we focus predominately on nation-state adversaries, which are easier to locate and geographically reason about than networks (which may have points of presence throughout the world).

DeTor's proofs of avoidance come at a cost that systems that do not offer provable security do not have to

pay. DeTor discards any circuit for which it cannot obtain proof of avoidance, but it is possible that there are circuits that achieve avoidance that do not meet the requirements of the proof. As a result, DeTor clients have fewer circuits to choose from than more permissive systems that rely only on AS maps, potentially leading to greater load imbalance in DeTor. We believe this to be a fundamental cost of security with provable properties; however, we also believe that future work can reduce DeTor's "false negatives."

Avoidance routing Recent work has proposed not to sneak through attackers' networks, but to avoid them altogether. Edmundson et al. [11] propose to use maps of the Internet's routing topology to infer through which countries packets traverse, and to proxy traffic through those who appear to avoid potential attackers. However, as with AS-aware Tor variants, this approach relies on data that can be significantly manipulated by the kind of powerful routing-capable adversaries that we consider. In this paper, we seek techniques that yield provable security, even in the presence of such adversaries.

Alibi Routing [24] uses round-trip time measurements and speed of light constraints to provably avoid user-specified, "forbidden" geographic regions. The Alibi Routing protocol only uses a single relay; we generalize this approach to apply to Tor's three-hop circuits. Moreover, our never-twice application avoids doubly-traversing any region of the world, and does not require an *a priori* definition of a forbidden region. We review Alibi Routing next.

3 Background: Alibi Routing

We build upon techniques introduced in Alibi Routing [24] to achieve provable avoidance in Tor. In this section, we briefly review how Alibi Routing achieves its proofs of avoidance, and we outline the challenges we address in translating it to Tor.

3.1 Proofs of Avoidance

Alibi Routing [24] is a system that provides proof that packets have avoided a user-specified geographic region. Specifically, a source node s specifies both a destination t and a *forbidden region* F. Node s trusts all nodes that are provably outside F (we return to this point at the end of this subsection). Alibi Routing then seeks to identify a relay a that is not in F and that satisfies the following property. Let $R(x,y)$ denote the round-trip time (RTT) between hosts x and y, and let R_{e2e} denote the end-to-end RTT that s observes; then for a user-configurable $\delta \geq 0$:

$$(1+\delta)\cdot R_{\text{e2e}} < \min \begin{cases} \min_{f\in F}\left[R(s,f)+R(f,a)\right]+R(a,t) \\ R(s,a)+\min_{f\in F}\left[R(a,f)+R(f,t)\right] \end{cases} \quad (1)$$

When this inequality holds, it means that the RTT for s forwarding packets through a to t is significantly less than the smallest round-trip time that would *also* include a host in the forbidden region. In other words, if s can verify that its traffic is going through a and t, then the traffic could not also go through F without inducing a noticeable increase in end-to-end round-trip time. With such a relay, s can prove that his packets avoided F with two pieces of evidence:

1. A MAC (or digital signature) from a attesting to the fact that it did indeed forward the packet, and
2. A measured end-to-end round-trip time that satisfies Eq. (1).

These two pieces of evidence form an "alibi": the packets went through a and could not also have gone through F, therefore it avoided F. As a result, Levin et al. [24] refer to a relay a who provides such a proof an *alibi peer*.

These proofs of avoidance must be obtained for *each* round-trip of communication. The factor of δ acts as an additional buffer against variable latencies. The larger δ is, the fewer potential alibis there will be, but they will be able to provide proofs of avoidance even when packets suffer an uncharacteristically high delay, for instance due to congestion. DeTor makes use of δ in the same manner.

One technical detail in Alibi Routing's proof that we will make use of is the process of computing $\min_{f\in F}[R(s,f)+R(f,a)]$ and $\min_{f\in F}[R(a,f)+R(f,t)]$. After all, how can one compute the shortest RTT through a host in an untrusted region of the world? The insight is that, if we know the geographic locations of the hosts in question, then we can obtain a lower bound on the round-trip time between them. In particular, if $D(x,y)$ denotes the great-circle distance between hosts at locations x and y, then we have the following bound:

$$\min_{f\in F}\left[R(s,f)+R(f,a)\right]+R(a,t) \geq \frac{3}{c}\cdot\left(\min_{f\in F}\left[D(s,f)+D(f,a)\right]+D(a,t)\right) \quad (2)$$

where c denotes the speed of light. In general, information cannot travel faster than the speed of light; in practice, information tends to travel no faster than two-thirds the speed of light. Coupled with a 2× factor to capture the RTT, this gives us the $\frac{3}{c}$ value in Eq. (2) as a way to convert the great-circle distance between two hosts to a

minimum RTT on the Internet. Provided with the set of geographic coordinates defining the border of F, one can compute the geographic coordinate $f \in F$ that provides this minimum distance. Critically, computing this does not require any participation from F (e.g., sending responses to pings)—it only depends on knowing the geographic coordinates of those trusted to forward the packets: s, t, and a.

As mentioned above, Alibi Routing assumes that node s trusts all nodes that are provably outside of its specified forbidden region F. To determine if a node n is definitively outside of F, s directly measures the RTT to n by asking it to echo a random nonce. Recall from §2 that attackers cannot lie about having lower latencies; thus, if this measured RTT is smaller than the theoretical minimum RTT between s and F, then n cannot be in F. Alibi Routing applies these trust inferences transitively. We adopt this assumption in our DeTor, as well.

3.2 Remaining Challenges

Applying Alibi Routing to Tor is not immediately straightforward. First, Alibi Routing is defined only with respect to a single alibi relay, whereas Tor circuits consist of three or more relays. Even if we were to extend the proofs from Eqs. (1) and (2), it is not obvious how well this would work in practice. As we will demonstrate, we are able to extend Alibi Routing's approach to Tor, and that it is surprisingly effective at finding "alibi circuits."

Second, the notion of a fixed forbidden region does not directly apply to the problem of deanonymization attacks like those described in §2.3. Recall that these attacks arise when an adversary is on both (a) the path between source and entry node and (b) the path between exit node and destination. Avoiding a region F altogether (as with Alibi Routing) ensures that F could not have launched such an attack, but it is overly restrictive to do so. Note that it is not necessary to avoid a given region altogether—it suffices to ensure that the region is not on the path *twice*, at both the entry and exit legs of the circuit. This relaxation allows users to protect themselves against deanonymization attacks launched by their home countries, whereas it would be impossible to avoid one's own country altogether.

Moreover, using a static forbidden region would require users to anticipate all of those who could have launched an attack. Ideally, a solution would be more adaptive, by permitting avoidance of the form "wherever packets might have gone between source and entry, avoid those places between exit and destination."

We demonstrate an adaptive "never-twice" technique that provably avoids regions that could launch deanonymization attacks, and we demonstrate that it is highly successful on the Tor network.

4 Provable Avoidance in Tor

In this section, we introduce how to construct proofs that a round-trip of communication (a packet and its response) over a Tor circuit has avoided geographic regions of the world. These proofs have the benefit of being easy to obtain (they largely consist of taking end-to-end round-trip time measurements), easy to deploy (they do not require modifications to Internet routing or buy-in from ISPs), and resilient to manipulation.

4.1 Never-Once Avoidance

The goal of never-once avoidance is to obtain proof that at no point during a round-trip of communication could a packet or its response have traversed a user-specified forbidden region F. Like with Alibi Routing, our proof consists of two parts:

First, we obtain proof that the packets *did* go through selected Tor routers. Whereas Alibi Routing traverses only a single relay, we traverse a circuit of at least three hops. Fortunately, Tor already includes end-to-end integrity checks in all of its relay cells [8], which successfully validate so long as the packets followed the circuit and were unaltered by those outside or inside the circuit. This serves as proof that the packets visited each hop, and, thanks to onion routing, that they visited each hop in order.

Second, we obtain proof that it could not *also* have gone through the forbidden region. To this end, we measure the end-to-end round-trip time R_{e2e} through the entire circuit, and we compute the shortest possible time necessary to go through each circuit *and* the forbidden region:

$$R_{\mathsf{min}} = \frac{3}{c} \cdot \min \begin{cases} D_{\mathsf{min}}(s,F,e,m,x,t) \\ D_{\mathsf{min}}(s,e,F,m,x,t) \\ D_{\mathsf{min}}(s,e,m,F,x,t) \\ D_{\mathsf{min}}(s,e,m,x,F,t) \end{cases} \quad (3)$$

Here, $D_{\mathsf{min}}(x_1,\ldots,x_n)$ denotes the shortest possible great-circle distance to traverse nodes $x_1 \to \cdots \to x_n$ in order. We abuse notation to also account for regions—for example, $D_{\mathsf{min}}(s,F,e) = \min_{f \in F}[D(s,f) + D(f,e)]$. Note that Eq. (3) is in essence a generalization of Alibi Routing's single-relay proof (Eq. (2)), and can be easily extended to support longer circuits.

Equation (3) captures the shortest possible distance to go through each hop in the circuit (in order) as well as through F. It also applies the observation that information tends to travel no faster than two-thirds the speed of light on the Internet. For example, in Figure 1, the top circuit has its shortest detour through F between the middle and exit nodes; the bottom circuit's shortest trajectory

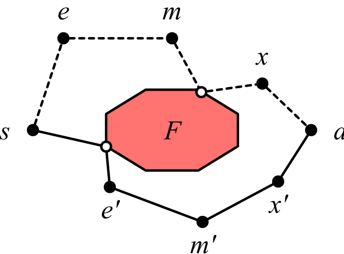

Figure 1: **Never-once:** To prove that a Tor circuit has avoided region F, we compute the shortest possible distance to traverse the circuit as well as a point in F. This figure has two example circuits, showing that the shortest distance might traverse F at different legs of the circuit.

that includes F does so between source and entry.

Last, we compare this theoretical minimum RTT including F (R_{min}) with the end-to-end measured RTT (R_{e2e}), and ensure that

$$(1+\delta)\cdot R_{\mathsf{e2e}} < R_{\mathsf{min}}. \tag{4}$$

For round-trip communications that pass Tor's integrity checks and satisfy Eq. (4), we obtain our proof that the packets could not have possibly traversed the forbidden region. For those that do *not* satisfy the equation, much like Alibi Routing, we are unable to distinguish whether the packets traversed the forbidden region or, e.g., were simply delayed on a congested link. We discuss such application-level considerations in §5.3.

4.2 Never-Twice Avoidance

The goal of never-twice is to ensure that a potential adversary is not able to see and manipulate *both* the traffic between source and entry node *and* the traffic between exit node and destination. Adversaries who are on both the entry and exit legs of a circuit are able to launch deanonymization attacks [28, 14, 17, 15]. However, an adversary on no more than one of those legs cannot.

As with never-once, Tor's onion routing ensures that the packet and its response indeed traveled through the Tor circuit in order, and we measure the end-to-end round-trip time R_{e2e}. However, as described in §3.2, our step for establishing mutual exclusion requires a significantly different approach.

The attacker seeks to be on the path both between s and e (the entry leg) and between x and t (the exit leg). All other parts of the circuit (entry to middle and middle to exit) do not help the adversary in this particular attack.

Never-twice avoidance of a single host We begin by constructing a proof that a circuit could not have traversed any single host on both the entry and exit legs. Ultimately, we seek to show that there is no point p for which $\frac{3}{c}\cdot D_{\mathsf{min}}(s,p,e,m,x,p,t) \le R_{\mathsf{e2e}}$.

Iterating through all points on the Earth would be computationally infeasible; although we do not have a closed-form solution, we present an efficient empirical check.

Note that the best-case scenario for the attacker is that all traffic on the (e,m) and (m,x) legs of the circuit take the least amount of time possible: a total of $R_m = \frac{3}{c}\cdot D(e,m,x)$. This leaves a total remaining end-to-end latency of $R_{\mathsf{e2e}} - R_m$. This is the total time the packets have to traverse (s,e) and (x,t); the larger this value, the greater the chance an attacker can be on the path of both of these legs (in the extreme, were this difference on the order of seconds, there would be enough time to theoretically traverse any point on the planet on both legs).

A useful way to visualize this problem is as two ellipses. Recall that an ellipse with focal points a and b and radius r represents all points p such that $d(a,p)+d(p,b) \le r$. Larger values of r result in ellipses with greater area, while larger values of $d(a,b)/r$ result in more elongated ellipses (in the extreme, an ellipse with $d(a,b)=0$ is a circle).

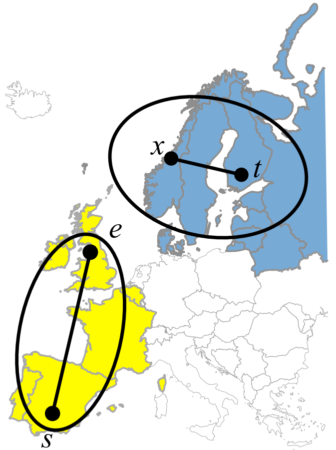
Thus, we can view this problem as two ellipses—one with focal points s and e and radius r_e and the other with focal points x and t and radius r_x, such that $r_e + r_x = \frac{c}{3}\cdot(R_{\mathsf{e2e}} - R_m)$.

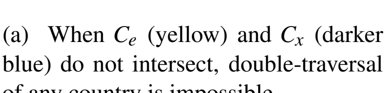
If these two ellipses intersect, then there could exist a host through which the traffic on both the entry and exit leg could have traversed.

Never-twice avoidance of a country The above technique for avoiding double traversal of a single host does not preclude a powerful attacker such as a nation-state from deploying multiple vantage points within their borders. For example, as in Figure 2b, consider an ellipse around the entry leg that traverses southwest Europe, and an exit leg that traverses central and eastern Europe—even though the two ellipses never intersect one another, they share two common nation states: France and Belgium. We next explore how to avoid double traversal of countries.

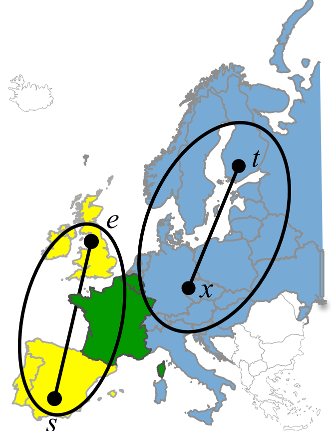
This process begins by identifying the set of countries that either leg could go through were all of the extra latency spent on either leg individually. This corresponds to two ellipses: one with focal points s and e and radius $\frac{c}{3}\cdot(R_{\mathsf{e2e}} - R_m) - D(x,t)$, and the other with focal points x and t and radius $\frac{c}{3}\cdot(R_{\mathsf{e2e}} - R_m) - D(s,e)$. We intersect these ellipses with a database of countries' borders to obtain the sets of countries that could have been traversed on the entry leg (C_e) and on the exit leg (C_x).

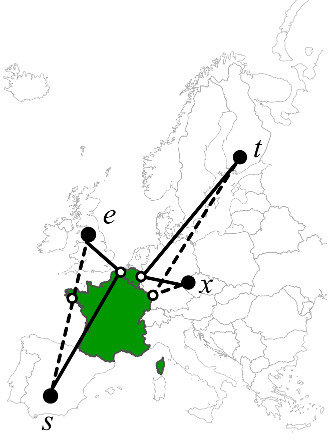
If $C_e \cap C_x = \emptyset$, as in Figure 2a, then it is not possible for the same country to have been traversed twice, and





(a) When C_e (yellow) and C_x (darker blue) do not intersect, double-traversal of any country is impossible.





(b) When C_e and C_x *do* intersect (dark green), we must compute the shortest distances for both legs to go through each country (right). The dashed lines show the shortest distances through France, and the solid lines through Belgium.

Figure 2: **Never-twice**: To prove that a Tor circuit did not traverse any given country at the beginning and end of the circuit, we compute the set of countries C_e that could have been on the path of the entry leg and the countries C_x that could have been on the exit leg. This figure shows two example circuits with different exit nodes.

we have our proof of never-twice avoidance.

However, if the intersection is non-empty, as in Figure 2b, then we need to perform additional checks. For each country $F \in C_e \cap C_x$, we ensure that the minimum RTT to go through the entry leg and F plus the minimum RTT to go through the exit leg and F is larger than the end-to-end RTT would allow:

$$\begin{aligned}\forall F \in C_e \cap C_x : \quad (1+\delta) \cdot R_{\mathsf{e2e}} \quad < \\ \frac{3}{c} \cdot \left(D_{\mathsf{min}}(s,F,e) + D(e,m,x) + D_{\mathsf{min}}(x,F,t)\right)\end{aligned} \tag{5}$$

The subtle yet important difference between Eq. (5) and the previous equations is that the right hand side need not minimize distance with respect to a single $f \in F$. Rather, there could be two distinct points in F: one on the entry leg's path and another on the exit leg's. This puts the attacker at a greater advantage; consider the above example wherein the entry leg was geographically isolated to western France and the exit leg was isolated to eastern France. When a single $f \in F$ required to be present on both legs, the packets would be required to traverse an extra distance of roughly twice the width of France. But with separate points in F, it could impose arbitrarily low additional delay.

What Eq. (5) does share in common with the other equations is that it can be computed purely locally, using only the knowledge of the circuit relays' locations and a database of countries' borders, which are readily available [16].

Never-twice avoidance of colluding countries Finally, we consider how to avoid deanonymization attacks from a group of countries who might coordinate their efforts. For example, the Five Eyes is an alliance of five countries (Australia, Canada, New Zealand, the United Kingdom, and the United States) who have agreed to share intelligence. Were such a group of countries to collude, then traversing one of them on the entry leg and another on the exit leg could result in a successful deanonymization attack.

Our above method for avoiding double-traversal of a country extends naturally to colluding nation-states. One can simply use a modified database of country borders to flag all those in an alliance as a single "country." That this would result in a set of disjoint geographic polygons is of no concern to our algorithm; in fact, many countries are already made up of disjoint regions (for instance islands off of a country's coast).

5 DeTor Design

The previous section demonstrates how to prove, for a given circuit, whether a single round-trip of communication provably avoided a region (once or twice). Unfortunately, not all circuits can provide such proofs, even if they were to minimize latencies between all hosts. Trivially, any circuit with a Tor router in some region F cannot be used to avoid F. Subtler issues can also arise, such as when two consecutive hops on a circuit are in direct line-of-sight of a forbidden region.

In this section, we describe how DeTor identifies

which circuits could *possibly* provide a proof by alibi, and how we choose from among them to maximize both anonymity and likelihood of success.

5.1 Identifying Potential DeTor Circuits

Alibi Routing identifies potential alibi peers through a sophisticated overlay routing protocol in which peers assist one another in finding alibis. This is necessary in Alibi Routing because no one peer knows all other peers. Fortunately, Tor's design includes downloading a list of all Tor routers, so we can search for alibi circuits without requiring any explicit assistance from Tor hosts, and thus without requiring any modifications to Tor clients or the Tor protocol in general.

A DeTor peer first downloads the list of all Tor routers. This includes many pieces of information about each router, including its name, IP address, port, public key, and typically also which country it is in. We make the simplifying assumption that we can also obtain each Tor router's GPS coordinates. We envision two ways this information could be made available: First, we can use publicly available IP geolocation databases that map IP addresses to locations [25, 31]. Second, we could augment the Tor protocol to allow routers to include their locations (perhaps within some privacy-preserving range) in the public list of Tor routers.[2] For never-once, as with Alibi routing, we trust the nodes to be honest so long as they can be proved to be outside the forbidden region (§3); for such nodes, we trust the GPS coordinates they self-report.

If we have the latitude and longitude of each Tor router as well as the source and destination, then we can determine if a circuit has the potential to offer proof of avoidance by replacing R_{e2e} in Eqs. (4) and (5) with the shortest possible RTT (by two-thirds the speed of light) through the circuit. This is in essence testing whether, in the best case scenario, it would be possible to obtain a proof of avoidance. DeTor considers all circuits that meet these criteria as *potential DeTor circuits*.

Alternatively, if precise GPS coordinates are not available, we can assume that we do not have exact GPS locations, but only which country each router is in (as Tor currently reports). In this case, we redefine $D_{\mathsf{min}}(x_1,\ldots,x_n)$ to be the shortest sum distance from any point in x_1's country to any point in x_2's country to any point in x_3's country, and so on.

Armed with a set of potential DeTor circuits, we next address the question: which among them should we choose?

[2] We require that Tor routers not move significant distances between the time that a client obtains their GPS coordinates through the time the client uses those routers.

5.2 Choosing Circuits

There are two key considerations in choosing from among potential DeTor circuits:

First, the circuit should have a high likelihood of actually providing proofs of avoidance. Satisfying the above alibi conditions are necessary but not sufficient to truly offer proof of avoidance. If any host on the circuit has very high latencies (e.g., because their last-mile link is a satellite or cellular link [32]), then we will never be able to definitively prove with RTT measurements alone where their packets could not have gone.

It is difficult to determine whether there are such high-latency links without directly measuring them. However, as multiple prior studies have shown, there is a strong correlation between distance and RTT [6, 1], with very long distances typically resulting in significantly larger departures from the minimum speed-of-light propagation time. Therefore, as a first approximation, we seek to choose very distal legs less often than shorter legs. We must be cautious here: using very short legs, while likely to offer successful proofs of avoidance, runs the risk of choosing Tor routers within the same administrative domain, violating the goal of having three (or more) distinct routers on the circuit. To address this, DeTor can optionally take a parameter Δ representing a desired minimum distance between any two routers on the circuit. Note that this naturally captures Tor's policy of never choosing two hosts on the same subnet.

This brings us to our second consideration: the chosen circuit should be chosen randomly, minimizing the difference in probabilities of choosing one node (or administrative domain) over another. Tor's circuit selection provides greater weight to nodes with greater bandwidth; we incorporate this with our desire for higher likelihood of success (lower latencies). After filtering the circuits that can never provide us with an alibi, as well as filtering the circuits based on minimum distance Δ, we then choose from all remaining circuits with probability weighted in favor of higher bandwidth and lower latency.

5.3 Constructing and Using Circuits

DeTor makes use of Tor's transport plug-ins to guide circuit construction without requiring any modifications to the Tor client. In particular, DeTor uses the Stem [36] Tor controller for constructing circuits and attaching TCP connections to them.

Much like Alibi Routing, DeTor must check for proofs of avoidance for every round-trip of communication. Half of this is provided by Tor's checks that the packets followed the circuit and were not altered; additionally, a DeTor client measures the end-to-end RTT for each round-trip of communication and checks this against

Eq. (4) for never-once avoidance and/or Eq. (5) for never-twice. A natural question is: what should DeTor do when a round-trip of communication does not provide proof, for instance because the end-to-end RTT is too high? For never-once avoidance, we believe that this is an application-specific concern. Some applications may wish not to accept any packet that might have traversed a forbidden region, and so they may drop these packets. Other applications may accept some rounds of communication without proof, particularly if the data in them had end-to-end verification or if it were not sensitive. This is an interesting area of future work.

However, when DeTor is used for never-twice avoidance, it is critical that not too many packets be sent if there is the possibility that they doubly traversed an adversary. After a round-trip of communication fails to obtain proof, it may be useful for the source node to try to trick the adversary by inserting a random number of packets that terminate at the middle node. Such defenses are another interesting area of future work; in the remainder of this paper, we focus primarily on how often we are able to obtain proof of avoidance, and the quality of the circuits that provide such proof.

6 Evaluation

In this section, we present the evaluation of DeTor in terms of both never-once and never-twice avoidance.

Our evaluation is driven by several fundamental questions: who can avoid whom, does provable avoidance harm anonymity, what is the performance of the circuits that DeTor provides, and what are the primary indicators of DeTor's success (or failure)?

6.1 Experimental Setup

We evaluate DeTor in simulation, using a Tor latency dataset collected with the Ting measurement tool [6]. As a brief overview, Ting performs active measurements of the Tor network and, through a novel sequence of circuits, is able to directly measure the RTT between *any* two active Tor relays. This measured RTT between two Tor relays contains the forwarding delays, which includes Tor's crypto operations. As a part of this work, Cangialosi et al. [6] released a dataset comprising RTTs between all pairs of a set of 50 Tor relays spread throughout the world.[3] Also included in this dataset is the GPS location of all 50 nodes obtained from a publicly available IP geolocation database [31] (as measured at the time of their study). Although we used this static database for our evaluation, the DeTor design assumes

[3]For seven pairs of nodes, the RTT was reported as `'Error'`. For these, we assume an RTT of 10 seconds; this is surely greater than their real RTT, and so it strictly puts our results at a disadvantage.

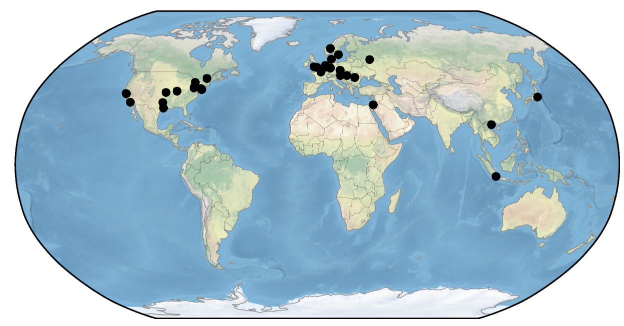


Figure 3: Locations of the 50 nodes used in our evaluation: a subset of real Tor nodes, as provided in the Ting [6] dataset.

that a client can obtain Tor relays' GPS coordinates, through one of several means discussed in §5.1.

Figure 3 shows the position of the Tor routers we use in our study. Note that, like real Tor deployments, it is skewed towards North America and Europe.

We simulate DeTor by using Ting data as a stand-in for both `ping` (when establishing the set of trusted Tor relays; see §3) and for end-to-end RTTs of the circuit. Recall that we only use these RTT measurements when determining if a chosen circuit successfully provides provable avoidance. Conversely, when we compute whether a circuit could *possibly* offer avoidance, we rely only on distances (computed using great-circle distance over the relays' GPS coordinates) and the two-thirds speed of light propagation of data. For the purpose of the simulation, the source and destination are also Tor nodes from the selected Tor nodes set. For never-once, we construct candidate circuits by selecting all possible permutations of three nodes from this set. For never-twice, we construct candidate circuits in the same way, but due to the additional computation needed, we only evaluate a random sample of the candidate circuits (1000 circuits per source-destination pair).

For never-once avoidance, we attempt to avoid several countries identified as having performed censorship [33]: China, India, PR Korea, Russia, Saudi Arabia, and Syria. Also, to see how well DeTor avoids countries with high "routing centrality" [22], we also attempt to avoid some countries that are on many paths: Japan and the US.

6.2 Never-Once

6.2.1 Who can avoid whom?

We begin by evaluating how successfully DeTor can find circuits to provably avoid various regions of the world. Figure 4 shows DeTor's overall success rate for each different forbidden country and δ values ranging from 0 to 1. Each stacked histogram represents the frac-

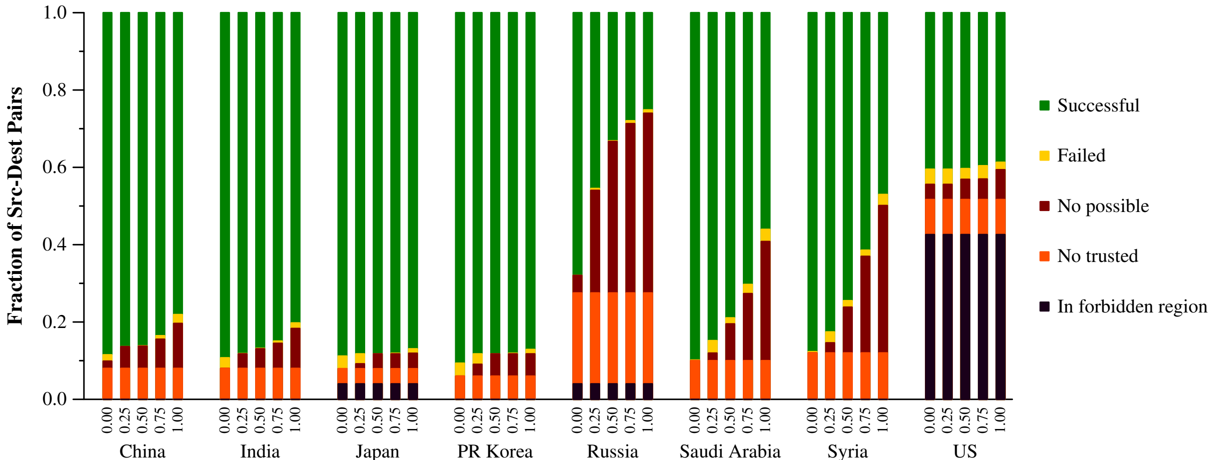

Figure 4: DeTor's success at never-once avoidance, and reasons for failure, across multiple choices of forbidden regions and δ. Overall, DeTor is successful at avoiding all countries, even those prevalent on many paths, like the US.

tion of all source-destination pairs who (from bottom to top): (1) terminate in the forbidden region and therefore cannot possibly achieve avoidance, (2) do not have any trusted nodes, typically because they are too close to the forbidden region to ensure that anyone they are communicating with is not in it, (3) have trusted nodes but no circuits that could possibly provide provable avoidance, (4) have circuits that could theoretically avoid the forbidden region, but none that do with real RTTs, and (5) successfully avoid the forbidden region over at least one DeTor circuit.

The key takeaway from this figure is that DeTor is generally successful at finding at least one DeTor circuit for all countries and all values of δ. We note two exceptions to this: Russia can only be avoided by approximately 35% of all source-destination pairs when $\delta = 0.5$. We believe this is due to the fact that Russia is close to the large cluster of European nodes in our dataset.

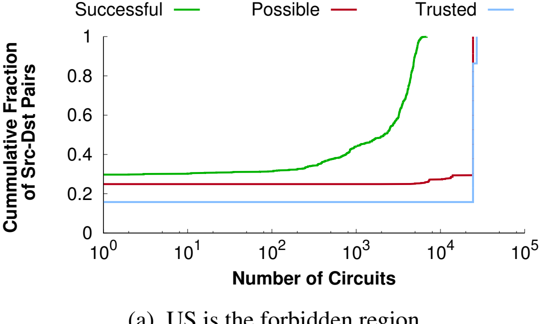
The US is another example of somewhat lower success rate; this is due, again, to our dataset comprising many nodes from the US, and thus 45% of all pairs in our dataset cannot possibly avoid the US. However, of the remaining source-destination pairs who do not already terminate in the US, 75% of them can successfully, provably avoid the US. We find this to be a highly encouraging result, particularly given that the US is on very many global routes on the Internet. We note that this is a higher avoidance rate than Alibi Routing was able to achieve; we posit that this is because DeTor uses longer circuits, thereby allowing it to maneuver around even nearby countries by first "stepping away" from them. Investigating the quality of longer DeTor circuits is an interesting area of future work.

We also observe from Figure 4 that larger values of δ lead to lower likelihoods of avoidance, as expected. This is particularly more pronounced with Russia, Syria, and Saudi Arabia; we believe that this, too, is because these countries are near the cluster of European nodes. Interestingly, this impact is least pronounced with the more routing-central adversaries we tested (Japan and the US). Some have proposed defense mechanisms that introduce packet forwarding delays in Tor [9, 5, 20]; these results lend insight into how these defenses would compose with DeTor. In particular, note that increasing δ in essence simulates greater end-to-end delays, which these defense mechanisms would introduce. Thus, with greater delay (intentional or not), DeTor experiences a lower likelihood of providing proofs of avoidance.

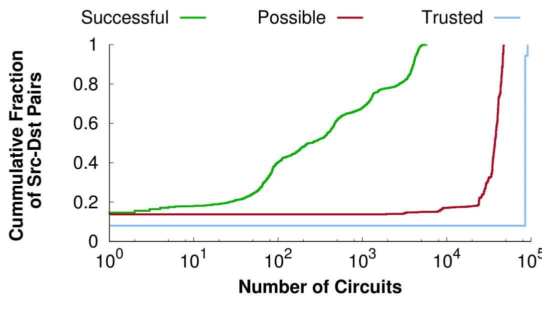
Number of DeTor circuits The above results show that we are successful at identifying *at least one* DeTor circuit for most source-destination pairs. We next look at *how many* DeTor circuits are available to each source-destination pair.

Figure 5 shows the distribution, across all source-destination pairs in our dataset, of the number of circuits that (1) offered successful never-once avoidance, (2) were estimated to be possible (but may not have achieved avoidance with real RTTs), and (3) were trusted, but not necessarily estimated to be possible. We look specifically at the number of circuits while attempting to avoid the US and China, with $\delta = 0.5$.

This result shows that approximately 30% of the source-destination pairs were only able to successfully use a single circuit while avoiding the US; 18% of pairs avoiding China had a single circuit. Fortunately, the majority had much more: avoiding the US, the median source-destination pair has over 1,000 successful circuits

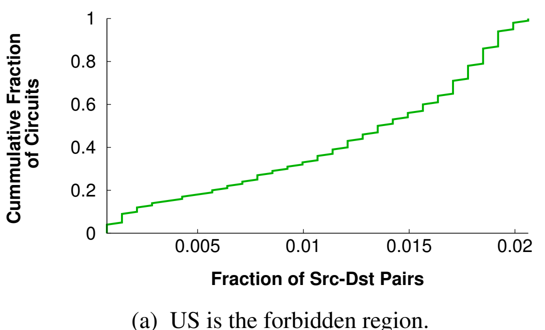


(a) US is the forbidden region.

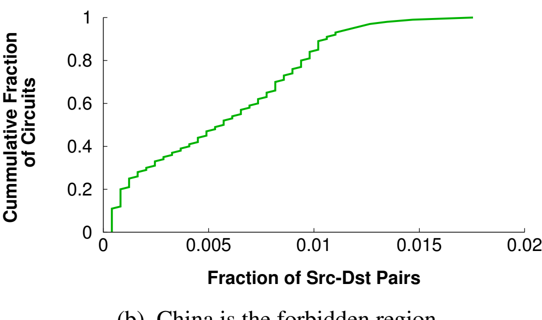


(b) China is the forbidden region

Figure 5: The distribution of the number of circuits that DeTor is able to find while avoiding (a) US and (b) China, with $\delta = 0.5$. Some source-destination pairs get only a single DeTor circuit, but the majority get 500 or more.



(a) US is the forbidden region.



(b) China is the forbidden region

Figure 6: The distribution of the fraction of source-destination pairs for which a given circuit successfully provides provable avoidance. ($\delta = 0.5$)

at its disposal; when avoiding China, this number is 500.

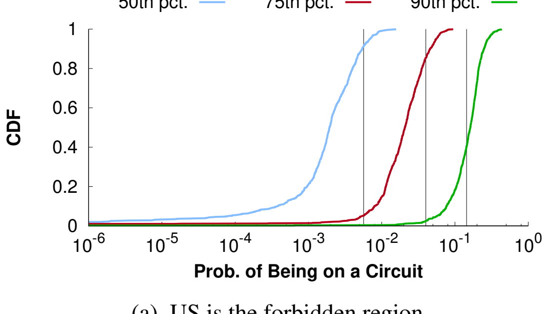
Even the most successful source-destination pairs tend to have far fewer successful circuits than "trusted" Tor circuits. These results allow us to infer how well Tor's current policies work. Recall that, in today's Tor, users can specify a set of countries from which they wish not to choose relays on their circuit. This is similar to the "trusted" line in the plots of Figure 5 (in fact, because we actually test the ping times to verify that it is not in the country, Tor's policy is even more permissive). This means that roughly 88% of the time (comparing the successful median to the trusted median), Tor's approach to avoidance would in fact not be able to deliver a proof of avoidance. It is in this sense that we say that Tor offers its users merely the illusion of control.

All together, these results demonstrate the *power* of DeTor—simply relying on random chance is highly unlikely to result in a circuit with provable avoidance.

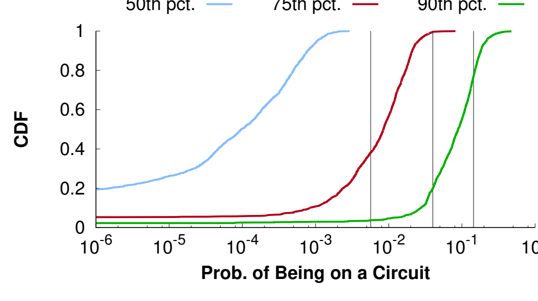
Given that there are source-destination pairs that have only a handful of DeTor circuits, we ask the converse: are there some circuits that offer avoidance for only a small set of source-destination pairs? If so, then this opens up potential attacks wherein knowing the circuit could uniquely identify the source-destination pair using that circuit. To evaluate this, we show in Figure 6 the distribution of the fraction of source-destination pairs for which a given circuit successfully provides proof of avoidance. The median circuit achieves provable avoidance to only 1.4% of source-destination pairs avoiding the US; 0.6% when avoiding China. These numbers are lower than desired (compare them to standard Tor routing for which nearly 100% of circuits are viable), but we believe they would be more reasonable in practice, for two reasons: First, the Ting dataset we use is not representative of the kind of node density that exists in the Tor network; in collecting that dataset, the experimenters explicitly avoided picking many hosts that were very close to one another, yet proximal peers are common in Tor. Second, in our simulations, we choose our source and destinations from the Tor nodes in our dataset; in practice, clients and destinations represent a far larger, more diverse set of hosts, and thus, we believe, would make it much more difficult to deanonymize.

6.2.2 Circuit diversity

Having many circuits is not enough to be useful in Tor; it should also be the case that there is diversity among the set of hosts on the DeTor circuits. Otherwise,

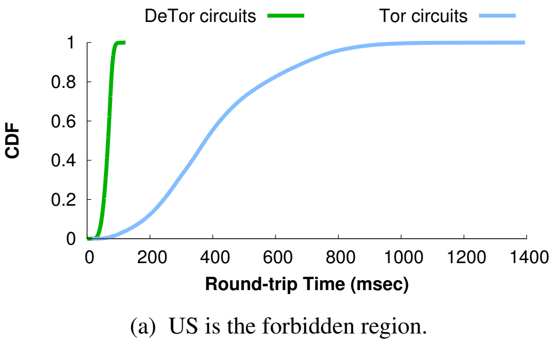


(a) US is the forbidden region.

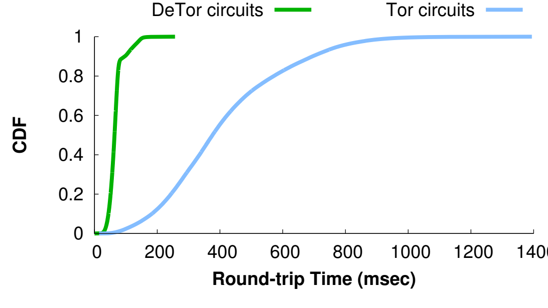


(b) China is the forbidden region

Figure 7: Distribution of the 50th, 75th, and 90th percentile probabilities of a node being selected to be on a circuit, taken across all DeTor circuits across source-destination pairs. Vertical lines denote these same percentiles across all Tor circuits. DeTor introduces only a slight skew, preferring some nodes more frequently than usual. ($\delta = 0.5$)



(a) US is the forbidden region.



(b) China is the forbidden region

Figure 8: The distribution of round-trip times for DeTor circuits ($\delta = 0.5$) and regular Tor circuits. Because avoidance becomes more difficult with higher-RTT circuits, DeTor's successful circuits tend to have lower RTTs.

popular Tor routers may become overloaded, and it becomes easier to predict which Tor routers will be on a circuit, thereby potentially opening up avenues for attack. We next turn to the question of whether the set of circuits that DeTor makes available disproportionately favor some Tor routers over others.

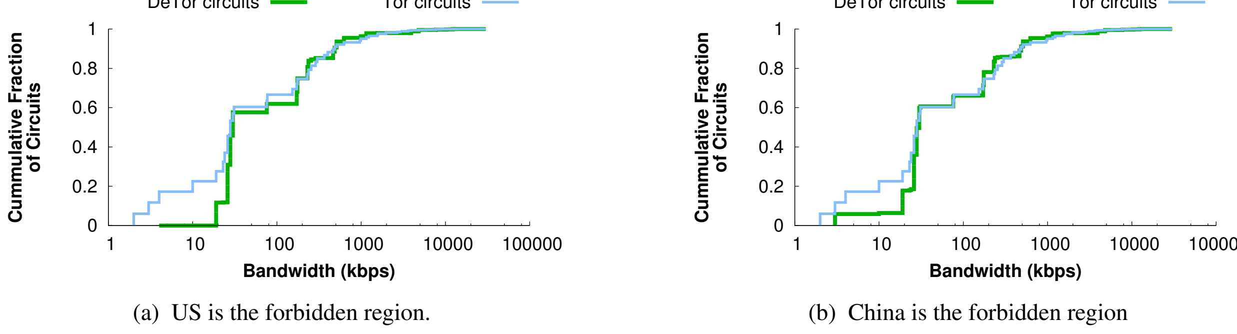
To measure how equitably DeTor chooses available Tor relays to be on its circuits, we first compute, for each source-destination pair, the probability distribution of each Tor relay appearing on a successful DeTor circuit. Figure 7 shows the distribution of the 50th, 75th, and 90th percentiles across all source-destination pairs. As a point of reference, the vertical lines represent these same percentiles for Tor's standard circuit selection (recall that Tor does not choose nodes uniformly at random, but instead weights them by their bandwidth).

We find that DeTor's median probability of being chosen to be in a circuit is less than normal, as evidenced by the 50th percentile curve being almost completely less than the 50th percentile spike. When avoiding the US, there is a slight skew towards more popular nodes, as evidenced by the 75th percentile also being less than normal. When avoiding China, on the other hand, DeTor's 90th percentile is typically less than Tor's, indicating that DeTor more equitably chooses nodes to be on its circuits.

It is true that DeTor may result in load balancing issues, especially if Tor routers are not widely geographically dispersed – this is fundamental to DeTor: after all, if many users are avoiding the US, then all of this load would have to shift from the US to other routers. However, as shown in Figure 7, while DeTor does introduce some node selection bias, it is within the skew that Tor itself introduces.

6.2.3 Circuit performance

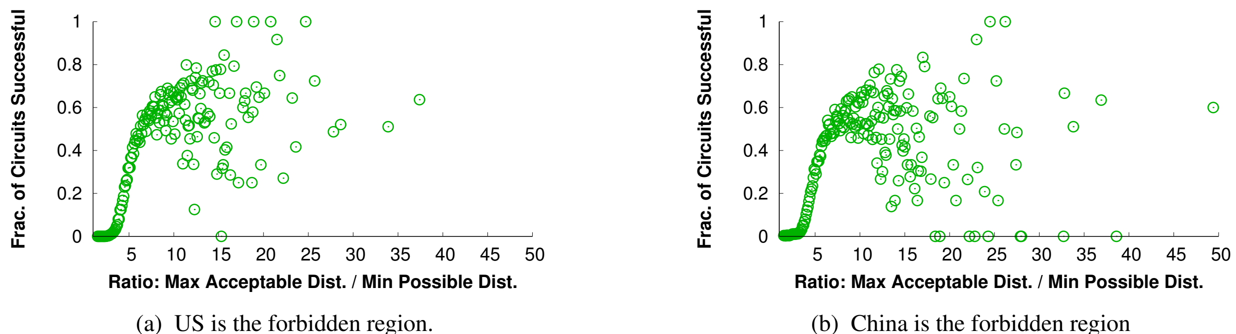
We investigate successful DeTor circuits by their latency and expected bandwidth. Figure 8 compares the distribution of end-to-end RTTs through successful DeTor circuits to the RTT distribution across *all* Tor circuits in our dataset. DeTor circuits have significantly lower RTTs—on the one hand, this is a nice improvement in performance. But another way to view these results is that DeTor precludes selection of many circuits, predominately those with longer RTTs. For some source-destination-forbidden region triples, this is a necessary byproduct of the fact that we are unlikely to be able



(a) US is the forbidden region.

(b) China is the forbidden region

Figure 9: The distribution of minimum bandwidth for DeTor circuits ($\delta = 0.5$) and regular Tor circuits.



(a) US is the forbidden region.

(b) China is the forbidden region

Figure 10: Success rates for never-once circuits as a function of the ratio between the maximum acceptable distance (through the circuit but not through F) and the minimum distance (directly through the circuit). This shows a positive correlation, indicating that it is feasible to predict which circuits will be successful. ($\delta = 0.5$)

to get proofs of avoidance if we must traverse multiple trans-oceanic links. In these examples, China has access to some circuits with longer RTTs, because it is farther away from many of our simulated hosts than is the US.

Figure 9 compares bandwidths of DeTor and Tor circuits. For each circuit, we take the minimum bandwidth, as reported by Tor's consensus bandwidths. Here, we see largely similar distributions between DeTor and Tor, with Tor having more circuits with lower bandwidth. We suspect that those lower-bandwidth hosts that Tor makes use of may also have higher-latency links, therefore making them less likely to appear in DeTor circuits.

6.2.4 Which circuits are more likely to succeed?

As Figure 5 showed, it is not uncommon for there to be one to two orders of magnitude more circuits that meet the *theoretical* requirements for being a DeTor circuit than there are circuits who achieve avoidance in practice. In a deployed setting, a client would ideally be able to identify which circuits are more likely to work before actually going through the trouble of setting up the connection and attaching a transport stream to it.

As a predictor for a circuit's success for never-once avoidance, we take the ratio of the maximum acceptable distance (how far the packet could travel without traversing the circuit *and* the forbidden region) to the minimum possible distance (the direct great-circle distance through the circuit). Our insight is that, the larger this ratio is, the more "room for error" the circuit has, and the more resilient it is to links whose RTTs deviate from the two-thirds speed of light.

Figure 10 shows this ratio corresponds to the fraction of theoretically-possible circuits that achieve successful avoidance. As this ratio increases from 0 to 10, there is a clear positive correlation with success. However, with large ratio values, the relationship becomes less clear; this is largely due to the fact that large ratio values can be a result of very small denominators (the shortest physical distance).

These results lend encouragement that clients can largely determine *a priori* which circuits are likely to provide provable avoidance. Exploring more precise filters is an area of future work.

6.3 Never-Twice

6.3.1 How often does never-twice work?

Recall that, unlike never-once, there are no forbidden regions explicitly stated *a priori* with never-twice. Therefore, to evaluate how well never-twice works, we measure the number of source-destination pairs that yield a successful DeTor circuit.

Ruling out the source-destination pairs who are in the same country (as these can never avoid a double-transit), we find that *98.6% of source-destination pairs can find at least one never-twice DeTor circuit*. This is a very promising result, as it demonstrates that simple client-side RTT measurements may be enough to address a wide range of attacks. In the remainder of this section, we investigate the quality of the circuits that our never-twice avoidance scheme finds.

Turning once again to the number of circuits, Figure 11 compares the number of circuits that DeTor identified as *possibly* resulting in a proof of avoidance (as computed using Eq. (5), and those that were successful given real RTTs. Never-twice circuits tend to succeed with approximately 5× the number of circuits that never-once receives. This demonstrates how fundamentally different these problems are, and that our novel approach of computing "forbidden" countries on the fly (as opposed to some *a priori* selection of countries to avoid with never-once) results in greater success rates.

6.3.2 Circuit diversity

We turn again to the question of how diverse the circuits are; are some Tor relays relied upon more often than others when achieving never-twice avoidance?

Figure 12 shows the percentile distribution across all successful never-twice DeTor circuits. Compared with never-once (Fig. 7), never-twice circuits fall even more squarely within the distribution of normal Tor routers (the vertical spikes in the figures). In particular, the top 10% most commonly picked nodes appear roughly as often as Tor's top 10% (the median 90th percentile is almost exactly equal to Tor's 90th percentile). The median node is slightly less likely to be selected than in Tor, indicating only a small skew to more popular nodes.

6.3.3 Circuit performance

We investigate successful DeTor never-twice circuits, once more turning to latency and expected bandwidth. Figure 13 compares successful never-twice DeTor circuits' RTTs to those of Tor. Compared to never-once (Fig. 8), there are never-twice DeTor circuits with greater RTTs. We conclude from this that never-twice avoidance has the ability to draw from a more diverse set of links—particularly when the entry and exit legs are farther from one another.

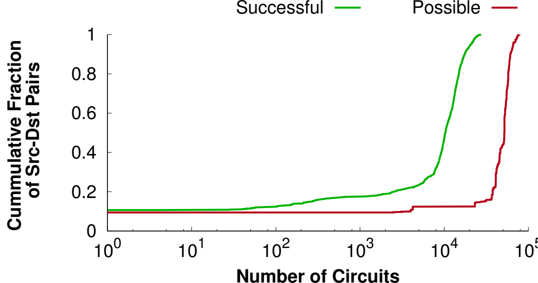


Figure 11: The distribution of the number of circuits that DeTor is able to find with never-twice ($\delta = 0.5$).

Figure 14 reinforces our finding that never-twice has access to a larger set of routers, as the distribution of successful never-twice bandwidths matches those of the full Tor network much more closely.

6.3.4 Which circuits are more likely to succeed?

We close by investigating what influences a never-twice DeTor circuit's success or failure. Figure 15 shows the fraction of possible never-twice circuits that were found to be successful, and plots them as a function of $D(e,m,x)/D(s,e,m,x,t)$. This ratio represents how much of the overall circuit's length is attributable to the middle: that is, everything but the entry and exit legs.

There are several interesting modes in this figure that are worth noting. When this ratio on the x-axis is very low, it means that almost the entire circuit is made up of the entry and exit legs, and therefore they are very likely to intersect—as expected, few circuits succeed at this point. DeTor succeeds more frequently as the middle legs take on a larger fraction of the circuit's distance, but then begins to fail as the length of the middle legs approaches the combined length of the entry and exit legs. This is because, in our dataset, when the middle legs are approximately as long as the entry and exit legs, this tends to correspond to circuits made out of the two clusters of nodes: one in North America and the other in Europe. Because these clusters are tightly packed, the probability of intersecting entry and exit legs increases. This probability of intersection decreases when the circuits no longer come from such tightly packed groups.

When the middle legs dominate the circuit's distance (the ratio in the figure approaches one), we again enter a particular regime in our dataset: These very high ratio values correspond to circuits with source and entry node both in North America (or in Europe), and with middle legs that traverse the Atlantic (and then return).

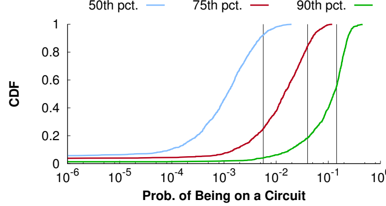

Figure 12: Nodes' probability of being on a successful never-twice DeTor circuit. ($\delta = 0.5$)

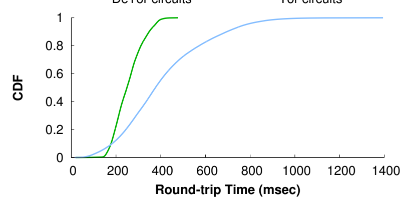

Figure 13: Round-trip times for never-twice DeTor circuits ($\delta = 0.5$) and regular Tor circuits.

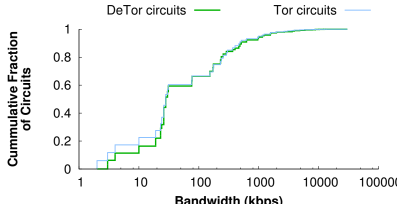

Figure 14: Bandwidth for never-twice DeTor circuits ($\delta = 0.5$) and regular Tor circuits.

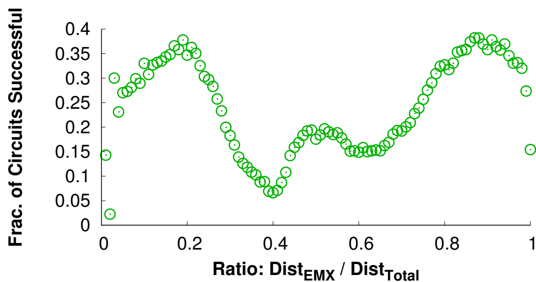

Figure 15: Success rate of never-twice DeTor circuits as a function of how long the (e,m,x) legs of the circuit are.

In other words, to accommodate such long middle legs, the source and entry node (and exit node and destination) are forced into the same cluster (either North America or Europe), which again increases the chances of intersection.

In sum, for never-twice, DeTor interestingly prefers circuits that have middle legs that are disproportionately large or small relative to the entry and exit legs. However, this may be dependent on the node locations from the Ting dataset we use, as the overall success rate of never-twice avoidance depends on the geographical diversity of where Tor routers are located.

7 Conclusion

In this paper, we have presented techniques that allow end-users to *provably* verify when packets over their Tor circuits have avoided traversing a geographic region once or twice. Our system, DeTor, builds upon prior work on provable avoidance routing [24], and extends it (1) to work over Tor's multiple hops, and (2) to achieve "never-twice" avoidance. Through extensive simulations using real Tor latency data [6], we have demonstrated that DeTor achieves provable avoidance for most source-destination pairs, even when avoiding large, routing-central countries like the United States.

Although the dataset we use in evaluating DeTor comes from live Tor measurements [6], the scale and geographic positions do not reflect the Tor network in its entirety; our results indicate that having more Tor routers would lead to more potential DeTor circuits and greater overall success rates. As with any such system, the best evaluation would be a longitudinal study with real users on the Tor network; this would be an interesting area of future work.

This paper is the first step towards bringing provable avoidance to Tor, but we believe that DeTor has the potential to be a powerful building block in future defenses against censorship and deanonymization of Tor.

Abstract

Internet of Things (IoT) platforms often require users to grant permissions to third-party apps, such as the ability to control a lock. Unfortunately, because few users act based upon, or even comprehend, permission screens, malicious or careless apps can become overprivileged by requesting unneeded permissions. To meet the IoT's unique security demands, such as cross-device, context-based, and automatic operations, we present a new design that supports user-centric, semantic-based "smart" authorization. Our technique, called *SmartAuth*, automatically collects security-relevant information from an IoT app's description, code and annotations, and generates an authorization user interface to bridge the gap between the functionalities explained to the user and the operations the app actually performs. Through the interface, security policies can be generated and enforced by enhancing existing platforms. To address the unique challenges in IoT app authorization, where states of multiple devices are used to determine the operations that can happen on other devices, we devise new technologies that link a device's context (e.g., a humidity sensor in a bath room) to an activity's semantics (e.g., taking a bath) using natural language processing and program analysis. We evaluate SmartAuth through user studies, finding participants who use SmartAuth are significantly more likely to avoid overprivileged apps.

1 Introduction

The rapid progress of Internet of Things (IoT) technologies has led to a new era of home automation, with numerous smart-home systems appearing on the market. Prominent examples include Samsung's SmartThings [49], Google's Weave and Brillo [23, 25] and Apple's HomeKit [5]. These systems use cloud frameworks to integrate numerous home IoT devices, ranging from sensors to large digital appliances, and enable complicated operations across devices (e.g., "turn on the air conditioner when the window is closed") to be performed by a set of applications. Such an application, called a *SmartApp* in Samsung SmartThings or generally an *IoT app*, is instantiated in the cloud. A user interface (UI) component on the user's smartphone enables monitoring and management. Like mobile apps, IoT apps are disseminated through app stores (e.g., the SmartThings Marketplace [47]), which accept third-party developers' apps to foster a home-automation ecosystem. Unlike mobile apps, IoT applications control potentially security-critical physical devices in the home, like door locks. Without proper protection, these devices can inflict serious harm.

A recent study on Samsung SmartThings brought to light security risks of such IoT apps, largely caused by inadequate protection under the framework [19]. Most concerning is the *overprivilege* problem in SmartApp authorization. Each SmartApp asks for a set of *capabilities* (the device functionality the app needs), and the user must choose the IoT devices to perform respective functions for the app (for example, see Figure 1). In mapping capabilities to devices, the user allows the IoT app to perform the set of operations defined by those capabilities (e.g., turn on a light, unlock the door) based on event triggers (e.g., the room becomes dark, a valid token is detected near the door). However, this *implicit authorization* suffers from issues related to coarse granularity and context ignorance, namely that an app given *any* capability (e.g., monitoring battery status) of a device (e.g., a smart lock) is automatically granted *unlimited* access to the whole device (e.g., lock, unlock) and allowed to subscribe to *all* its events (e.g., when locked or unlocked).

In addition to the overprivilege that results from conflating all capabilities of a single device, malicious IoT apps can overprivilege themselves by requesting unneeded, and sometimes dangerous, permissions. While asking users to authorize third-party apps' access to IoT devices would, in concept, seem to prevent this sort of overprivileging, prior work on permissions systems for mobile apps has repeatedly documented that users often fail to act based on, or even understand, these permission screens [18, 32, 33].

Even worse, unlike the Android permission model, which asks the user for permission to access specific resources on a *single* device (e.g., location, audio, camera), access control in a smart home system is much more

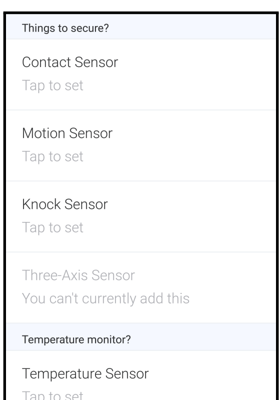

Figure 1: The installation interface of SmartApp SAFETY WATCH lists configuration options without connecting to higher-level app functionality. There is also no guarantee the app's actual behavior is consistent with its description.

complicated. The policy applies across devices, defining the operations of certain devices in certain scenarios based on observations of other devices (e.g., "ring the bell when someone knocks on the door"). Explaining such complicated policies to users is challenging, and effective authorization assistance should certainly go beyond what is provided by SmartThings (illustrated in Figure 1). In particular, it may be difficult for a user to understand what is being requested in the capability authorization UI, due to the gap between the app's high-level mission and the technical details of capabilities across devices. For example, a user may have no idea how reading from an accelerometer relates to detection of someone knocking on a door. Furthermore, in the absence of robust monitoring and enforcement by the platform, the authorization system provides little guarantee that the capabilities requested by an app actually align with the app description.

As a result, despite the existing authorization system for IoT platforms, there can exist a crucial *gap between what a user believe an IoT app will do, and what the app actually does*. The idea that privacy is context-sensitive has been widely studied [41]. For example, providing an individual's sensitive health information to a doctor for the purpose of treating the individual would often not violate the notion of contextual integrity, whereas providing the same information to the individual's financial institution would likely violate his or her privacy. A similar principle holds in the IoT ecosystem. If an IoT app describes its own purpose as unlocking the door when a visitor arrives, it is likely no surprise to a user that the app can unlock the door. If, however, the same app had advertised itself as a temperature-monitoring app, a user would likely find the app's ability to unlock the door to be a security risk.

In this paper, we propose new user-centered authorization and system-level enforcement mechanisms for current and future IoT platforms. We designed our approach, *SmartAuth*, to minimize the gap between a user's expectations of what an IoT app will do and the app's true functionality. To this end, SmartAuth learns about each IoT app's actual functionality by automatically harvesting and analyzing information from sources such as the app's source code, code annotations, and capability requests. Because the natural-language description developers write to advertise an app in the app store is the key source of users' expectations for what the app will do, we use natural language processing (NLP) to automatically extract capabilities from this description.

SmartAuth then compares the app's actual functionality (determined through program analysis) to the functionality developers represent (determined through NLP). This automated process is far from trivial because an in-depth understanding of the app focuses not only on the *semantics* of the app activities, but also their *context* among the app's broader goals. Our approach for achieving this level of contextual understanding relies on program analysis of the SmartApp's source code and applying NLP techniques to code annotations (e.g., the constant string for explaining the position of a sensor). We use further NLP to analyze the app description provided by the developer to extract higher-level information about the stated functionality, including entities (e.g., "a coffee machine"), actions (e.g., "taking a shower"), and their relationships (e.g., "turn on the coffee machine after taking a shower"). SmartAuth then compares such descriptions against insights from program and annotation analysis to verify that the requested capabilities and called APIs match the stated functionality, leveraging semantic relations among different concepts and auxiliary information that correlates them. For example, an annotation indicating a "bathroom" and the activity "take a shower" are used to identify the location of the humidity sensor of interest.

To minimize user burden, SmartAuth automatically allows functionality that is consistent between the app's natural-language description and code, yet points out discrepancies between the description and code since these are potentially unexpected behaviors. SmartAuth employs natural-language-generation techniques to explain, and seek approval for, these unexpected behaviors. The outcome of this verification analysis is presented to the user through an automatically created interface that is built around a typical user's mental model (for example, as in Figure 4). SmartAuth then works within the platform to enforce the user's authorization policy for the IoT app.

We incorporated SmartAuth into Samsung SmartThings as a proof of concept and evaluated our implementation over the 180 apps available in the SmartThings marketplace. SmartAuth successfully recovered authorization-related information (with 3.8% false positive rate and no false negatives) within 10 seconds. We found that 16.7% of apps exhibit the new type of overprivilege in which some functionality is not described to the

user despite passing Samsung's official code review [51]. Examples of cases found stem from vague descriptions (e.g., an app stating it can "control some devices" in your home) or hidden security-sensitive functionality (e.g., accessing and actuating an alarm without consent).

We also performed user studies to evaluate SmartAuth's impact on users' decision-making process for installing IoT apps[1]. In a 100-participant laboratory study, we found that SmartAuth helped users better understand the implicit policies within apps, effectively identify security risks, and make well-informed decisions regarding overprivilege. For instance, given two similar apps, one of which was overprivileged, using the current Samsung SmartThings interface, 48% of participants chose to install the overprivileged app in each of five tasks. With SmartAuth, however, this rate reduces to 16%, demonstrating the value of SmartAuth in avoiding overprivileged apps.

We also generated automated patches to the 180 SmartApps to validate compatibility of our policy enforcement mechanism, and we found no apparent conflicts with SmartAuth. Given our observations of the effectiveness of the technique, the low performance cost, and the high compatibility with existing apps and platforms, we believe that SmartAuth can be utilized by IoT app marketplaces to vet submitted apps and enhance authorization mechanisms, thereby providing better user protection.

Our key contributions in this paper are as follows:

- We propose the SmartAuth authorization mechanism for protecting users under current and future smart home platforms, using insights from code analysis and NLP of app descriptions. We provide a new solution to the overprivilege problem and contribute to the process of human-centered secure computing.
- We design a new policy enforcement mechanism, compatible with current home automation frameworks, that enforces complicated, context-sensitive security policies with low overhead.
- We evaluate SmartAuth over real-world applications and human subjects, demonstrating the efficacy and usability of our approach to mitigate the security risks of overprivileged IoT apps.

The remainder of this paper is organized as follows. In Section 2, we present the models and assumptions for our work. In Section 4, we describe the high-level design of SmartAuth. We present the details of our design and implementation in Section 5, and our evaluation of SmartAuth follows in Section 6. We highlight relevant related work in Section 7 and conclusions in Section 9.

[1]Our user studies were conducted with IRB approval.

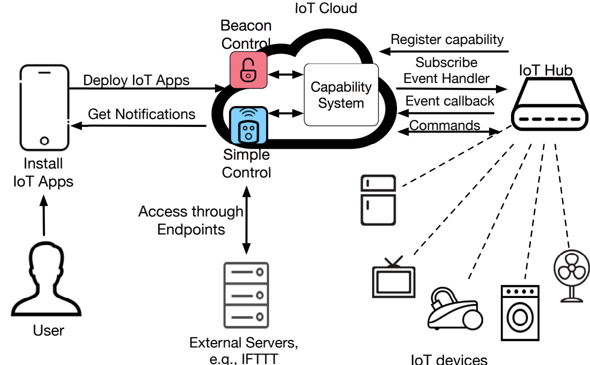

Figure 2: Users install IoT apps through mobile devices, allowing the vendor's IoT cloud to interact with the user's locally deployed devices. IoT apps pair event handlers to devices, issue direct commands, and enable external interaction via the web.

2 Background

2.1 Home Automation Systems

Home automation is growing with consumers, and many homeowners deploy cloud-connected devices such as thermostats, surveillance systems, and smart door locks. Recent studies predict home automation revenue of over $100 billion by 2020 [31], drawing even more vendors into the area. As representative examples, Samsung SmartThings and Vera MiOS [54] connect smart devices with a cloud-connected smart hub. Such vendors typically host third-party IoT apps in the cloud, allowing remote monitoring and control in a user's home environment.

Figure 2 illustrates a typical home automation system architecture. We use Samsung SmartThings to exemplify key concepts and components of such a system.

IoT apps written by third-party developers can get access to the status of sensors and control devices within a user's home environment. Such access provides the basic building blocks of functionality to help users manage their home, for example turning on a heater only when the temperature falls below the set point. Figure 2 depicts cloud-based IoT apps Beacon Control and Simple Control installed by a user from their mobile device and with access to the user's relevant IoT devices.

Current IoT platforms use *capabilities* [36] to describe app functionality and request access control and authorization decisions from users. Unlike permissions, capability schemes are not designed for security, but rather for device functionality. A smart lighting application, for example, would have capabilities to read or control the light switch, light level, and battery level. Due to complexity, capabilities in home automation platforms are often coarse grained. One capability might allow an app to check several device attributes (status variables) or issue a variety of commands. This functionality-oriented design creates potential privacy risks, as granting an app

a capability for a device allows it to access all aspects of the device's status and fully control the device.

An IoT app can also act as a *web service* (an *endpoint* in Samsung Smartthings) to interact with the outside world. Such an app handles remote commands from servers and reacts accordingly. Many home automation platforms support standard authentication and authorization mechanisms such as OAuth [4, 50] to grant permission to third parties for commanding or accessing devices.

2.2 NLP Technologies

Since our approach analyzes app descriptions and gaps in users' mental models, we rely on several existing tools and techniques for natural language processing (NLP). The following tools are employed in our work.

Word2Vec [22] is a state-of-the-art tool used to produce word embedding that maps words to vectors of real numbers. Specifically, Word2Vec models are neural networks trained to represent linguistic contexts of words. We use Word2Vec to determine the relation between two words by calculating the distance between the words in the embedding space. Word2Vec has many advantages over previous approaches, including catching syntactic and semantic information better than WordNet [39] and achieving lower false positive rates than ESA [21].

Part-of-speech (POS) tagging is used to identify a word's part of speech (e.g., noun or verb) based on definition and context. A word's relations with adjacent and related words in a phrase, sentence, or paragraph impact the POS tag assigned to a word of interest. In our work, we rely on the highly accurate Stanford POS Tagger [38].

We also rely on the typed dependencies analysis [27] to understand the grammatical structures of sentences, grouping words together to recognize phrases and pair subjects or objects with verbs. The Stanford parser applies language models constructed from hand-parsed sentences to accurately analyze sentences of interest.

3 IoT App Security Challenges

Beyond basic overprivilege where an app requests an unnecessary capability, previous IoT research has studied two additional types of overprivilege [19]: coarse capability and device-app binding. In the former, a capability needed to support app functionality also allows unneeded activities. In the latter, a device is implicitly granted additional capabilities that are not needed or intended.

We have identified an additional type of overprivilege that relates not only to the functionality of the IoT app, but also to the user's perception of the app functionality, as seen through the app description. We observe that several IoT apps exhibit capability-enabled functional behaviors that are not disclosed to the user, causing a discrepancy between the user's mental model and the actual privilege of the app. We refer to this problem as *undisclosed overprivilege*. This kind of overprivilege has been discussed in mobile apps, but was never studied in the IoT space. An example of this type is an IoT app that describes the ability to control lights while requesting capabilities to read and control a door lock. Previous approaches may not flag this app as overprivileged, as long as the capabilities are used. In fact, even after a majority of Samsung SmartThings apps were removed from the market due to the previously reported overprivilege issues [19], we found that 16.7% of the remaining apps still exhibit overprivilege risks.

Remote access is also an important security risk, as it enables apps to send sensitive data to and receive commands from third-party servers. In our study, we found 27 cases of such behavior, including cases where data was shared without user consent, a clear privacy concern. A SmartApp's ability to act as a web service expands the attack surface and potentially allows a malicious server to send dangerous commands to an app running on a user's smart devices, even though users may not expect such remote control. We observed 17 apps with this behavior. Similar to the undisclosed overprivilege, remote access does not match the user's mental model, which illustrates a gap in the current configuration and approval process.

Based on these observations, a general threat in the IoT app landscape is the ability for a malicious or compromised IoT app to steal information from sensors or home appliances or to gain unauthorized access to IoT device functionality. Even if the IoT platform itself is secure and trustworthy and previous issues of authentication and unprotected communication are patched [7, 19, 40], such issues with malicious apps may remain.

4 SmartAuth Design Overview

We next present the high-level design of SmartAuth, including design goals, architecture, and security model.

Given the unique security challenges of smart home systems, we believe that an authorization system for IoT apps should be designed to achieve the following goals.

- *Least-privilege*: The system should grant only the minimum privileges to an IoT app, just enough to support the desired functionality.
- *IoT-specific*: Compared with authorization models for mobile devices, which are designed to manage a single device, the authorization system for a smart home framework should meet the needs for multi-device, context-based, automatic operations. Permission models based on manifest permissions or runtime prompts, such as those employed in Android or iOS, either do not allow users to make context-based decisions or cannot satisfy real-time demands (e.g., approval to actuate an alarm when fire is detected).
- *Usable*: The authorization system should be human-centric, minimizing the burden on users while supporting effective authorization decisions.

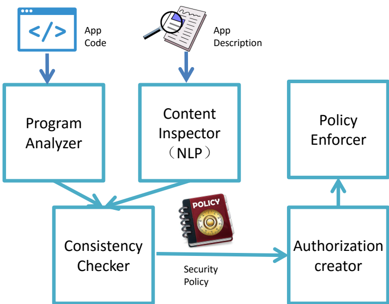

Figure 3: We provide a high-level block diagram to illustrate the design overview of our SmartAuth system.

- *Lightweight*: The authorization approach should not inhibit performance with significant overhead.
- *Compatible*: The authorization approach should be compatible with existing smart home platforms and applications without breaking app functionality.

Since authorization decisions are made by humans, providing a human-centric design to help users to make well-informed decisions is critical. Toward this goal, we design an intelligent authorization system that recovers adequate semantic information from IoT apps and presents it to users in an understandable way. We leverage semantic analysis techniques to automatically interpret the description, code, parameters, and annotations of an IoT app. We analyze the semantic meaning of these components to discovery inconsistency, then automatically generate an authorization interface explaining the findings to the user.

Based on these design principles, our SmartAuth system includes five components: a program analyzer, a content inspector, a consistency checker, an authorization creator and a policy enforcer, as illustrated in Figure 3. The code analyzer extracts the semantics of an IoT app through program analysis and NLP of app code and annotations, creating a set of *privileges* that support the app functionality. In parallel, the content inspector performs NLP on the app description to identify the required privileges explained to the user. The consistency checker compares the results of code analysis and content inspection to generate security policies and identify discrepancies between what is claimed in the description and what the app actually does. These policies and information needed to support user decisions are then presented through an authorization interface produced automatically by the authorization creator. The resulting policies are then implemented by the policy enforcer.

Our security policy model for the smart home architecture is described in the form of a triple (E, A, T). Item E represents the events, inputs, or measurements involving IoT devices and describes the *context* of the policy. Item A represents the actions triggered by elements of E, including commands such as "turn on". Item T represents the group of *targets* of the actions in A, such as a light

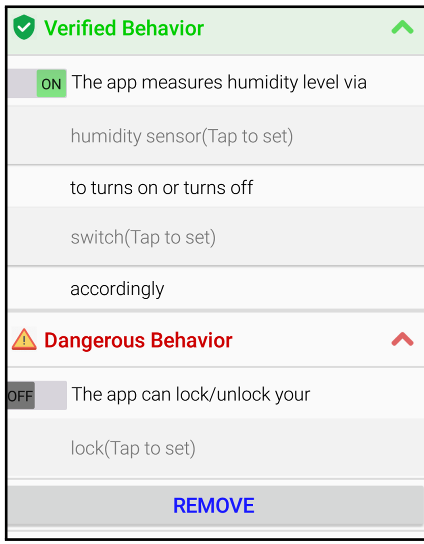

Figure 4: We illustrate the security policy generated for the HUMIDITY ALERT app, which is communicated to the user to request authorization. The indication of behavior type is discussed in more detail in Section 5.3

receiving a command, noting that an empty target implies broadcast of a message or command. This model captures typical IoT app functionality, as apps are designed to issue commands to respond to observed state changes.

This model describes not only the policy produced by the authorization process, but also the privileges both claimed in an app's description and recovered from its code. Analysis of the policy actions thus allows identification of overprivilege and presentation of conflicts or situations that require the user to make a policy decision. Figure 4 illustrates an example of such policies.

5 Design and Implementation

In this section, we detail our design and implementation of SmartAuth.

5.1 Automatically Discovering App Behaviors

To extract an app's security-critical behaviors, we perform static analysis on the app's source code and use NLP techniques on code annotations and API documents.

We collected the source code for 180 Samsung SmartThings apps from an source-level market in May 2016 [48]. This represents 100% of open-source SmartApps and 80.2% of all SmartApps at that time.

For each app collected, we parse its code and create an Abstract Syntax Tree (AST) from the code, resolving classes, static imports, and variable scope. We choose to do AST transformation for the app analysis for two reasons. First, we have access to the source code which is suitable for AST transformation. To enable further analysis, we extract the key components of method names, variable names and scope, a variety of statements. Second,

SmartThings apps are written in Groovy, which transfers method calls into reflective ones and creates challenges for existing binary analysis tools to deal with reflections. Therefore, binary analysis is not suitable.

We first extract capabilities, which are directly associated with security behaviors, by searching for the term "capability" in the preference block. We incorporate any search results into the list of requested capabilities collected from the IoT app documentation.

To further understand how the IoT app is intended to make use of the requested capabilities, we analyze the commands and attributes associated with each requested capability. To enable this analysis, we maintain a global mapping of capabilities to commands and attributes, noting that one capability may involve multiple commands and attributes. Since a SmartApp gets status updates by subscribing to events, namely as `subscribe(dev,attr,hndl)` for relevant IoT device `dev`, device attribute `attr`, and invoked method `hndl`, we use this global mapping to search the AST for relevant commands called and attributes subscribed.

We then generate the security policy, starting from the method invoked on event subscription and perform forward tracing. We first analyze the invoked function's code blocks to determine whether it contains conditional statements, which we analyze immediately. Otherwise, we trace into the called function. Within condition blocks, we look for (1) the event and (2) the object and action. The invoked function of the event subscription takes a subscription parameter that carries information about the event. Combining this information with the variables in the AST, we identify both the event and associated capability. We further identify the action triggered by the event. For example, for an app that controls a heater based on a threshold temperature setting, it is critical to distinguish whether the app turns the heater on or off. We thus search the result statement for commands that control a device. If found, we continue our analysis to match the capability through variable analysis. Otherwise, we record the event and trace into the called function.

The previous analysis covers an app's direct access to IoT devices, which we use to identify overprivilege. We also analyze whether the app has remote access to servers other than the SmartThings cloud. We consider two types of remote access: whether the app sends data to the remote server and whether the app works as a web service to take commands from the remote server. Both cases are privacy-invasive and may violate user expectations. We search the AST to match patterns including OAuth, `createAccessToken`, and `groovyx.net.http`.

We also examine clues from code annotations (e.g., comments and text strings) to gain further information about context and device state. We apply Stanford POS Tagging and analyze the nouns to determine whether they represent location or time contexts. We find that most context clues in smart homes relate to a place in the home, such as a bedroom. For example, we can extract that the humidity sensor is associated with bathroom from understanding the annotation in the following code snippet.

Listing 1: Code Snippet about Device Selection

```
section("Bathroom humidity sensor") {
  input "bathroom", "capability.
      relativeHumidityMeasurement", title:
      "Which humidity sensor?"
}
```

5.2 Analyzing App Descriptions

A key goal of our project is revealing any discrepancy between what the app claims to do and what it actually does. To find such discrepancies, we use NLP techniques to extract the security policy from the app's free-text description and program analysis to compare it with the security policy extracted from the code. We extract and correlate the behaviors in three layers: (1) entity, (2) context and action, and (3) condition.

We infer the security policy based on human-written, free-text app descriptions. To do this, we first identify the parts of speech of the words used, then analyze the typed dependencies in the description. Nouns and verbs are often related to entities; for example, movement might be related to a motion sensor. From the structure of the descriptions, we can then infer relationships between entities by identifying the typed dependencies. For instance, in the phrase "lock the door", the noun *door* is the accusative object of the verb $lock$ (written as $dobj(lock, door)$). In the corresponding security policy, $lock$ is the $action$ and $door$ is the $target$. Most cases are more complex than this example, and our more comprehensive analysis follows.

Specifically, we use the Stanford POS Tagger to identify parts of speech and the Stanford Parser to analyze sentence structure, including typed dependencies, as illustrated in Figure 5. We follow standard NLP practices, such as removing stop words (e.g., "a," "this") [11].

We analyze noun and verb phrases to pinpoint the relevant entities, as these phrases usually describe core app functionality. However, as discussed later, analyzing a developer's description comes with non-trivial challenges. In addition, the device's context can significantly impact the implications of the entities. To overcome these difficulties, we design and implement the following process.

The most straightforward case is when the description explicitly includes the name of the entity (e.g., humidity sensors). If so, we match words directly.

Because of language diversity, the first step may not produce meaningful results. However, even when the description does not contain the device name, the description might contain contextual clues related to specific

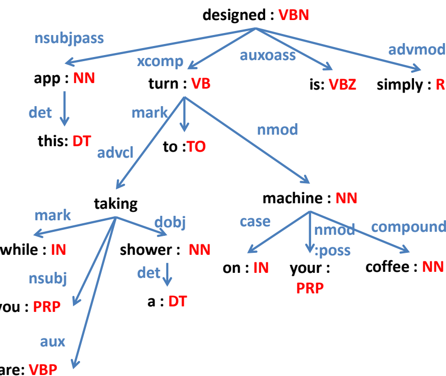

Figure 5: We illustrate example NLP analysis for the COFFEE AFTER SHOWER description: "This app is designed simply to turn on your coffee machine while you are taking a shower." Red and blue characters respectively indicate parts of speech (e.g., "VB" for verb) and typed dependencies (e.g., "advcl" for adverbial clause modifier).

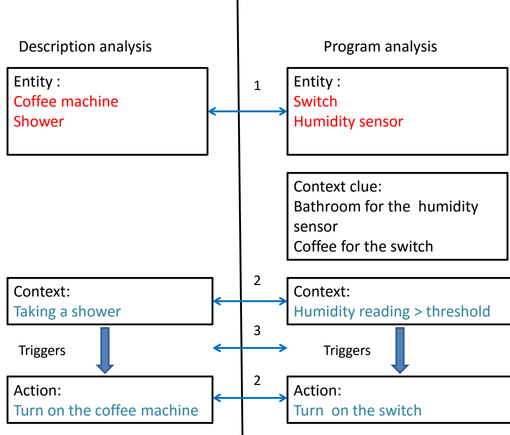

Figure 6: We illustrate the three-step policy correlation for the COFFEE AFTER SHOWER app. 1) We apply the context clues "bathroom" and "coffee" for entity correlation. 2) We use the attribute model and command model to extract and correlate the context and action. 3) We use typed-dependency analysis and causal relationship model to correlate the policies generated from the description and program analysis.

devices. For example, mention of flood detection hints to a humidity or moisture sensor. We evaluate relationships between words in the descriptions to the relevant devices through a word distance model that combines Word2Vec with a language model. Our language model includes a vocabulary of three million words and phrases, trained on roughly 100 billion words from Google News [24].

The most challenging case is when the words in the description are not directly related to the entity in the generated security policy. In this case, we compare the description to the context clues from code annotations. In the example in Figure 6, we first extract the entity "bathroom" (the context clue) from the annotation for the *humidity sensor* (`capability.relativeHumidityMeasurement`) identified through code analysis (Section 5.1). We link this entity to the entity "shower" using the semantic relation revealed using Word2Vec. In this way, we link "taking a shower" to the humidity sensor. Similarly, our technique relates "coffee machine" in the description to the *switch* device (`capability.switch`) recovered from the code.

However, simply connecting an entity in the description to a device in the code is insufficient to determine whether only expected behaviors (as specified in the description) happen. For example, "lock the door when nobody is at home" and "unlock the door when nobody is at home" have starkly different security implications. To compare the semantics of an activity in description to the operation of a device, we utilize a knowledge-based model. Specifically, we parse the API documentation of SmartThings to generate the attribute and command models, namely the keyword sets for attributes and commands that represent their semantics. We thus parse words and phrases in the description connected to the entity-related word. This can be done by going through the typed-dependency graph. For example, in Figure 6, we have identified that "coffee machine" is an entity related to the phrase "turn on". Such phrases will be compared with the keywords in the attribute and command models to find matches.

After comparing the devices used in the code to those mentioned in the description, we also need to know whether the actual control flow matches that of the policy model. The causal relationship is critical for multi-device management where devices have impacts on each other. For example, two IoT apps may both ask for access to a door lock, motion sensor on the door, and presence sensor. A benign app might unlock the door when a family member is at the door and locks it when someone other than a family member is there. A malicious app might unlock the door anytime anyone is there. These two apps use the same devices, but with different control flow.

To perform causal analysis, we analyze the typed dependencies and build knowledge-based models of causal relationships. The causal relationships model is built with sentence structures and conjunctions related to conditional relationships. We apply the initial models to the descriptions to identify which devices caused other devices to change status. For example, the sentence "turn on the light *when* motion is sensed" represents that motion status is the cause, and turn on the light is the result. At the end of this process, we obtain *verified behaviors* that match in code and descriptions and *unexpected behaviors* that exhibit a mismatch.

5.3 Authorization Interface Generation

Towards making usability a first-order concern in designing our authorization scheme, we first conduct an online

survey to understand users' mental models related to IoT app installation and the overprivilege problem. Using Amazon Mechanical Turk, we recruit adult participants who have experience using smartphones. To avoid biasing participants towards fraudulently claiming experience with SmartThings to participate in the survey, we do not require that participants have used any smart home platforms to take the survey. However, we only analyze data from the 31.6% of the survey participants who have previous experience with SmartThings. Please refer to the appendix refquestion1 for the sample survey questions.

Our survey asked about: (1) experience using IoT platforms and demographics, (2) the factors considered when installing third-party IoT apps, and (3) perspective on smart home capabilities. We received responses from 300 participants who had used SmartThings, identified by an average age of 30.8 years old (age range is 18-60) with a gender breakdown of 32% female, 67% male.

We asked participants to respond using a five-point scale (strongly care, care, neither care or not care, not care, strongly not care) about factors they consider when deciding whether or not to install a SmartThings app. App functionality (66% strongly care and 24% care) and privacy (57% strongly care and 28% care) were the factors participants stated they cared about most in their decision.

To understand participants' perspectives on smart home capabilities, we asked them to rate the sensitivity of different IoT device functions and to compare the sensitivity of SmartThings capabilities and Android/iOS permissions. To ensure that participants understood what we meant by *smart home capabilities*, we both formally defined the concept and demonstrated it using an example screen shot from a SmartThings device permission screen.

We asked participants to rate the sensitivity of eight IoT device behaviors on a four-point scale (from "not sensitive" to "very sensitive"). We find that participants have very different risk perceptions for different behaviors of the same IoT device. For example, we find the average sensitivity rating for app's ability to *unlock* their door is 3.28, whereas reading the battery level of their door is only 1.87 (Mann–Whitney $U = 21350, n1 = n2 = 300, P < 0.001$ two-tailed) [8]. These sharp distinctions highlight the importance of increasing the transparency to users about what precise behaviors an app will perform in the home, rather than considering all behaviors for a particular device monolithically. Our approach of automatically identifying discrepancies between the actual behavior of an app determined through program analysis and the free-text app descriptions that users generally rely on when considering whether to install apps [32] better supports these distinctions.

To this point, most work on app permissions focuses on smartphones. We thus asked participants to specify whether they considered Android/iOS permissions and smart home capabilities equally sensitive, Android/iOS permissions to be more sensitive, smart home capabilities to be more sensitive, or whether they were unsure. In support of our continued study, 69% of participants indicated that they considered smart home capabilities to be more sensitive than Android/iOS permissions. Participants provided a free-text explanation of why, and we performed qualitative coding on these responses by two researchers (with an agreement rate of 90.3%). The leading reason participants found IoT apps more sensitive is that they perceived the home environment to inherently present greater risks. One participant wrote:

> "Smart home compromises can inflict serious damage or injury. Imagine being locked in your house, with the heat cranked up. Or an invader monitoring your location in the house, or studying your patterns. The risk involved in a smartphone knowing your location or accessing the devices hardware, like reading contents, contacts or accessing the camera are far more limited in potential effects by an attacker."

In generating the user interface, we aim to minimize the burden on the user and provide information that matches the user's mental model of the system. We rely on a policy model that links app functionality with authorization. We first automatically summarize the security policy, removing redundant logic, and then create language models to translate the security policy into a human-understandable description. We achieve this task using state-of-the-art natural language generation tool SimpleNLG [1], a realization engine that generates and linearizes syntactic structures. The automatically generated description details what device attributes and commands are being used, and why. For example, the app monitors the temperature from the temperature sensor and whether someone is at home by the presence sensor to turn on a heater when it is cold and someone is home.

We designed our authorization approach to better align users' mental models with the actual behaviors of smart home apps, as well as to reduce user burden during the authorization process. Because many users rely on app descriptions, rather than permissions screens, to evaluate smartphone apps [32], one way of reducing user burden is to assume that a user would implicitly grant an app the permission to perform actions stated in the app description. While any assumption that a user's actions with an app perfectly follow the user's intent is necessarily flawed, prior work on smartphone permissions [32] suggests that assuming a user would permit an app to perform the behaviors described in its app description is practical. The assumption of a user would permit an app to perform the behaviors in its description is likely at least as robust as assuming that a user intended to grant the permissions

specified on a permissions screen. We therefore minimize users' burden by automatically granting the attributes inferred from the app description. For the attributes absent from the app description, we present the user with our automatically generated description of the policy model rather than potentially confusing settings.

To help users understand the potential risky behaviors, we use risk level indicators with corresponding colors and icons in the user interface, as illustrated in Figure 4. We define three indicator categories: verified behaviors that match the claimed functionality, unexpected behaviors that are not sensitive, and dangerous behaviors that are unexpected and risky. We determine these risk levels by asking security experts and average users to rate their perceived risk based on status changes and device operations. Specific parameters are further described in the Appendix.

5.4 Policy Enforcement

Once a user sets his or her policy settings through the user interface, we enforce the policy end-to-end by blocking unauthorized command and attribute access.

Our proof-of-concept implementation of the policy enforcement mechanism operates locally on the device through the use of REST APIs, mimicking the ideal integration directly into the SmartThings Cloud. We patched existing SmartApps by substituting each command or attribute function call with an equivalent REST API call to the module that includes the device handler, command or attribute name, and any additional parameters. After the module processes the request, a return value is sent back to the patched app and handed to the code that invokes this command or attribute, which is transparent to the original app. Similarly, the patched app also subscribes to events by connecting to the enforcement module. Appendix A further details how we patch existing Groovy apps to interact with our policy enforcement module.

The policy enforcement mechanism starts when the user begins to install a SmartApp. The user is directed to our enhanced interface to set up the relevant devices and policies for the app. This information is transmitted to the policy enforcement module to ensure that the app can only access what the user allows. Based on the policies, the module will make two type of decisions.

First, whenever the module receives a command or attribute request from a patched app, it will extract the device ID and actions and check the associated policies from the database for proper authorization. If allowed, the module will forward the request to the cloud service to execute and respond, after which the module will forward the response to the patched app. If denied, the request will be dropped and an error message will be returned to the patched app. We expect that SmartApps will already be designed to handle error messages, so the denial of requests should not impede normal operation. We further analyze compatibility in Section 6.3. Second, whenever there is an event reported by the SmartThings Cloud, the module will retrieve the associated app IDs and policies from the database and forward the event only to the apps that are allowed to access the event according to the app policy. The module thus blocks all unauthorized subscribe, command, and attribute requests.

6 Evaluation

We evaluate SmartAuth in several dimensions, finding SmartAuth is effective at automatically extracting security policies, significantly helps users avoid overprivileged apps, and adds minimal performance overhead when enforcing users' desired policies.

6.1 Effectiveness in Extracting Policies

We first evaluate SmartAuth's ability to accurately identify unexpected behaviors. To this end, we manually analyze the description and the code of the 180 available SmartApps and compare the results to those of the automatic analysis. In this process, we do not observe any false negatives, though we identify seven false positives (3.9%) in which SmartAuth flagged a behavior as unexpected though manual analysis of these cases suggests otherwise.

In two of these cases, the app uses a product name to represent a device, but the product name is not relevant to its functionality; for example, the Mini Hue Controller app uses the Aeon Minimote[2] device. In two other cases, the app references another app by name to explain its functionality; for example, the Keep Me Cozy Two app claims that it "works the same as Keep Me Cozy, but enables you to pick an alternative temperature sensor in a separate space from the thermostat." These cases could be eliminated using named entity analysis to identify the referred app and merge the behaviors and descriptions accordingly. In another case, the description has complicated logic spread through several sentences, causing the description to be ambiguous. In the two remaining cases, the correlation of the context is not intuitive, even for a human reader; for example, a relationship between vibration of the floor with someone waking up at night is not immediately clear.

6.2 Impact on Users

We first describe our user study to evaluate how SmartAuth impacted users' app-installation decisions, followed by additional data on the usability of SmartAuth itself.

We performed a between-subjects user study with 100 participants recruited from across our institutions. Participants completed app installation tasks in our lab using phones we provided and answered several relevant questions. We required participants to be adults who regularly use a mobile device and are knowledgeable about home automation systems. We verify participants understand

[2] http://aeotec.com/homeautomation

key concepts of smartphones and home automation using screening questions. For example, we ask them how IoT apps are installed and what purposes IoT apps serve. We also ask questions about demographics, as well as questions about their experiences installing IoT apps. The protocol takes around 20 minutes. For the 100 participants in our study, their ages ranged from 19 to 41 years with a mean age of 25.7 years, and 59% of participants reported as male and 41% as female. The participants have education backgrounds ranging from high school to graduate school. 68% of participants have a technical background (engineers or students in computer science or related field).We carefully avoid the IoT developers when we recruit in the company because they are very familiar with the system and their results might be biased.

The study's primary task is a series of selection tasks for IoT apps using the phone we provide. For five different types of IoT apps, the participant chooses between one of two similar apps. Each of the two apps in a pair has identical functionality, yet only one of the two apps in a pair is overprivileged. To prevent this difference in permissions from being the obvious variable of interest, we used apps whose titles and descriptions were roughly comparable. For example, participants choose between "Lights Off with No Motion and Presence (by Bruce Adelsman)" that will "Turn lights off when no motion and presence is detected for a set period of time" and "Darken Behind Me (by Michael Struck)" that will "Turn your lights off after a period of no motion being observed."

Each participant is randomly assigned into one of two groups, specifying whether they will see Samsung SmartThings' authorization interface or SmartAuth while completing all tasks. For each of the five app-selection tasks, participants saw the app installation page with two choices. We asked the participant to choose only one of the two apps to install, and to explain why.

For each of the five tasks, between 48% and 60% of participants who saw the current SmartThings interface chose the overprivileged app, as shown in Figure 7. Even though the current Samsung SmartThings authorization interfaces shows users a list of the devices the app can access, including potentially unexpected devices, this current interface did not help users avoid overprivileged apps.

In contrast, 84% of participants who saw the SmartAuth interface successfully avoided the overprivileged app, differing significantly from the current SmartThings interface (Holm–Bonferroni corrected χ^2, $p \leq .022$ for all five tasks). Note that for two of the tasks (A and B in Figure 7), the overprivilege was a potentially dangerous behavior (e.g., unlock a door), whereas the overprivilege for tasks C–E was potentially less risky (e.g., learn the temperature). For tasks A and B with dangerous overprivilege, only 10% and 6% of SmartAuth participants, respectively, chose the overprivileged app, compared to

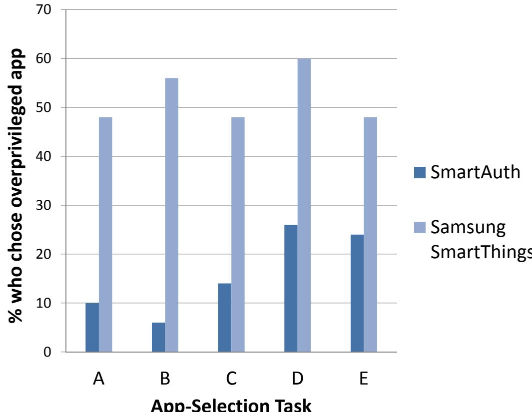

Figure 7: For 5 tasks, participants chose between two similar IoT apps, one of which was overprivileged. This graph shows the proportion of participants who chose the overprivileged app. Similar to what one would expect from random selection, around half of participants who saw the Samsung SmartThings interface chose the overprivileged app. In contrast, only between 6% and 26% of SmartAuth participants chose the overprivileged app.

48% and 56% for the current SmartThings interface. Even when they still chose the overprivileged app, we found that many SmartAuth participants were aware of the overprivilege, yet said they either did not care about the unexpected behaviors or thought the app might benefit from these behaviors in the future.

In addition to evaluating SmartAuth's impact on user behavior, we also measure the usability of SmartAuth itself. In the laboratory study, after users choose among pairs of apps and answer questions about privacy, we ask questions to elicit their perceptions of what the interface communicated to them. For some of these questions, participants respond to statements on a five-point Likert scale (from "1: strongly disagree" to "5: strongly agree").

The first statement gauges the apparent completeness of explanations ("I feel that the app interface explains thoroughly why the app can access and control these sensors/-doors"); SmartAuth participants were more likely than those who used Samsung SmartThings to agree (SmartAuth mean 4.06, SmartThings mean 2.40, Mann–Whitney $U = 337.5, n1 = n2 = 50, P < 0.001$ two-tailed). The second statement measures user comfort in making decisions ("I feel confident to make a decision whether or not to install the app after reading the interface"); SmartAuth participants were significantly more confident in their decisions (SmartAuth mean 4.12, SmartThings mean 2.46, Mann–Whitney $U = 320.5, n1 = n2 = 50, P < 0.001$ two-tailed). The third statement evaluates perceived difficulty of finding information ("It is difficult to find the information from the interface"); SmartAuth participants were more likely to *disagree* with this difficulty, meaning they found it easier (SmartAuth mean 2.72, SmartThings mean 3.56, Mann–Whitney $U = 713, n1 = n2 =$

$50, P < 0.001$ two-tailed).

We also asked open-ended questions about what factors participants consider when deciding to install an app. Both SmartAuth and Samsung SmartThings participants focused on two factors in common: functionality and ease of configuration. However, SmartAuth participants also discussed privacy and unexpected or dangerous behaviors as a major factor. In comparison, *only one of the 50 Samsung SmartThings participants pointed out a mismatch between the description and the authorization screen*.

6.3 Performance and Compatibility

To evaluate the performance impact and ease of deployability for SmartAuth, we collected all 180 open-source SmartApps in the Samsung SmartThings marketplace at the time of research. In order to demonstrate that SmartAuth is both lightweight and backward compatible, we performed two performance tests: (1) pre-processing performance comprising program analysis, description analysis, behavior correlations, and policy description generation and (2) run-time performance comprising authorization interface generation and policy enforcement.

For testing the pre-processing performance, we timed the generation of the policy description for each of the 180 apps, averaging over 10 trial runs. On a 3.1 Ghz Intel Core i7 CPU with 16 GB memory, the pre-processing overhead for an app is 10.42 seconds on average. Since pre-processing is a one-time cost and can be done offline, we believe that the performance is reasonable even for vetting a large number of applications.

For the run-time performance test and compatibility test, we instrumented the SmartApp to interact with our policy server running on the Amazon EC2 cloud, which enforces the rules defined by the user. Given our purpose of evaluating the compatibility of our technique with existing SmartApps, we set the authorization policies (granting permissions to certain commands, attributes and event handlers) ourselves, instead of letting the user do that, as would happen in practice. We designed our experiments to test the technique in the worst-case scenarios. That is, we assume users would reject all unexpected and dangerous behaviors, requiring the maximum amount of policy enforcement. To enable large-scale testing without requiring the purchase of every physical SmartThings device, we used Samsung's online SmartApp simulator platform[3]. Instrumented apps are then installed on the simulator, and their functionalities are tested with simulated IoT devices.

As shown in Figure 8, we recorded the delay incurred by different command, attribute, and event handler actions. We performed 1800 experiments among the 180 SmartApps on a cloud server with 3.1 Ghz Intel Core i7 CPU and 1 GB memory. SmartAuth incurs an average delay of 35.4 msec, which is small relative to the dominant network latency in cloud-based IoT platforms.

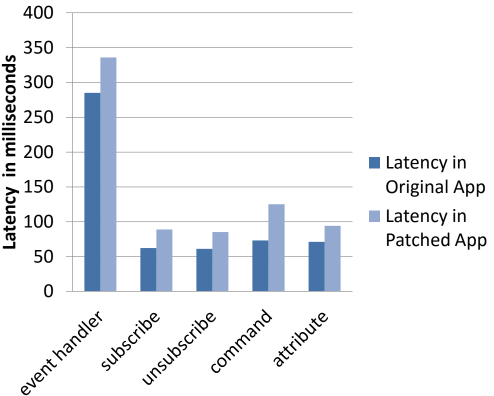

Figure 8: We plot the average delay of various functions in the SmartThings platform. The darker bar in each pair represents the delay in the unmodified platform with virtual devices, while the lighter represents the delay in our customized platform with the additional overhead introduced by SmartAuth. Event handlers incur the highest incremental overhead, while commands incur the highest proportional overhead (almost double the base case).

Next, we test the degree to which SmartAuth policies to mitigate overprivilege and block third-party remote access impact backward compatibility with existing SmartApps. As with our performance analysis, we test the worst case of users blocking all unexpected and dangerous behaviors and all remote access. We again test patched apps on Samsung's online simulator environment. We trigger events at least five times and insert debug messages into the modified apps' source code to observe apps' behaviors while they gather data from the cloud or when events have been triggered. To evaluate backward compatibility, we both observe app behaviors and analyze the debugging messages. For tests related to overprivilege policy, we focused on the 30 apps that exhibit undisclosed overprivilege. For the interested reader, these 30 apps are listed in the Appendix as Table 2. These apps either request capabilities not mentioned in their descriptions (unexpected capability), or even worse, request capabilities that could do harm (e.g., unlocking the door). For example, the SMART SECURITY app presents a description: "alerts you when there are intruders but not when you just got up for a glass of water in the middle of the night." After scanning the source file, this app requests access to `motionSensor`, `contactSensor`, and `alarm` capabilities, satisfying the description, but also requests sensitive commands including turning on/off a switch, which is not mentioned in its description. Therefore, we mark this access as an unexpected behavior. For the remaining 150 apps, we further patch them to comply with our policy enforcement mechanism. Specifically, apps with coarse capability overprivilege and device-app binding overprivilege are also

[3] https://graph.api.smartthings.com/

constrained to ensure least privilege.

In our compatibility tests, **none** of the 180 apps crash after patching, even with overprivilege security rules enforced. Even after they are patched to remove overprivilege, the 180 apps behave the same as their original versions. In other words, patching does not break the functionalities claimed in the app's description.

We further test how apps function if we block all third-party remote access, an extreme case where the user denies all such requests. Of the 180 apps, only six apps suffer from a loss of valid functionality. For example, VINLI HOME CONNECT allows remote services to control IoT devices, and this functionality breaks entirely when we block remote access. We believe such examples will continue to be rather rare, especially when users are given clear information and useful options to configure the app's security policy. In addition, we envision the possibility of a cloud-based reference monitor that could check run-time remote access and filter out dangerous access, but such a design is beyond the scope of this work.

6.4 Limitations

Although SmartAuth advances user-centered IoT app authorization, our design has limitations. A malicious developer could use custom-defined methods and property names mirroring SmartThings commands and attributes to fool the program analysis. A future version of SmartAuth could better recognize this technique. Our static analysis tool is based on Groovy AST transformation. If handled correctly, the tool can detect obfuscated logic (which cannot evade AST transformation), and obfuscated dynamic variable/function names can be handled with define-use analysis citenielson2015principles. Furthermore, a malicious developer could craft app descriptions for which SmartAuth mistakenly extracts a malicious behavior from the description, even when humans would not perceive such a behavior. Future work could focus on recognizing such adversarial descriptions. External services like IFTTT could be the future work for our project. Our approach can be applied if we know the control flow information from IFTTT. External devices, if they are approved by Samsung, will be included in the capability system and covered by our project.

In addition, dynamic method invocation from remote servers is a threat that requires future investigation. However, this is less of a concern because Samsung bans dynamic method execution through code review [51].

Our user studies also have important limitations. While we did not draw attention to this fact, particularly attentive participants might have recognized that SmartAuth was a novel interface. This recognition might have biased participants to be complimentary of an interface they assumed was being tested, as well as to pay particular attention to the interface in the absence of habituation effects. Furthermore, users will not always have a choice between an overprivileged app and a less privileged variant, and it is an open question whether users might still install an overprivileged app if it is the only option. We have one assumption that users will read the app description when they decide to install apps. However, we did not run a formal user study to verify the assumption. We did observe in the lab study that most users payed attention to the app description, but it would be better to verify the assumption formally. Currently, the smart home market is still at an early stage, and most of the users are with a technical background. Many participants in our lab study have good technical background, which is representative for the current users. However, when the smart home systems get much more popular, our participants might not be representative for future users.

7 RELATED WORK

We next compare our work with previous research.

7.1 Mobile Permission Studies

Many researchers have studied permission systems for mobile devices. While some insights apply in both domains, the unique features of IoT platforms introduce new security and privacy challenges. Most similarly to SmartAuth, the Whyper system identifies Android permissions that might be used from the app's description [42]. The researchers do an extensive analysis of app descriptions and match them with permissions, but they do not evaluate the real security behaviors from the code of the applications. Even for analyzing descriptions, SmartAuth is fundamentally different because Android permissions and APIs have very specific privacy implications. In contrast, reasoning about implications in the IoT is much more context-sensitive, necessitating our further use of NLP. Zhang et al. instead analyze Android apps using static analysis, generating descriptions for the security behaviors in the applications [57]. These descriptions are helpful for users to understand the app's behavior. However, users are burdened with reading the long logs and still need to use the original Android interface to authorize. In contrast, we remove many overprivilege cases automatically and both design and test a new scheme that minimizes user burden.

Many approaches build on this prior work. AutoCog compares descriptions with permissions requested [43]. AsDroid analyzes the text in the user interface and the current behavior to see whether it is a stealthy behavior [29]. Appcontext analyzes context that triggers security behaviors and compares the context among apps to differentiate benign and malicious apps [56]. Other researchers compare app behaviors to app descriptions by clustering applications with similar functionality and finding apps that use uncommon APIs [26]. Besides mobile permissions, researchers also look into the privacy policies to

identify privacy inconsistency of the code and the privacy policy [58].

Another line of work studies users' mental model about permissions, focusing on users' perceived risks [17, 18]. For example, Egelman et al. investigate user's perceptions of sensitive data stored on their phones, including banking information and home address [13]. However, our study about users' mental model about IoT permission makes new contribution because the perceptions and requirements in IoT platfroms are different from mobile platforms. Many researchers have sought to improve mobile permissions. For example, Liu et al. propose privacy profiles to ease user burden [37]. Almuhimedi et al. propose information visualization to improve user awareness of risks [3], Harbach et al. suggest using personal examples to better explain permission requests [28], and Tan et al. suggest using developer-specified explanations for understanding [52]. Researchers have also provided general guidelines for designing permission systems [16, 44]. Users' perceptions of mobile permissions and IoT permissions share some characteristics. For instance, Wijesekera et al. observe through a field study that mobile apps sometimes violate contextual integrity by accessing unexpected resources [55]. However, due to the differing privacy and security implications for IoT platforms, SmartAuth further rethinks the design of authorization systems.

7.2 IoT Security and Privacy

IoT security and privacy is an emerging area. Previous research has largely focused on identifying security and privacy vulnerabilities. Naveed et al. discuss the security binding problems of smart devices that are external to the mobile phone [40]. Fernandes et al. run a black-box analysis of Samsung SmartThings, pinpointing the overprivilege problem [19]. We instead reconceptualize overprivilege to be more practical and user-centered. To enhance security and privacy goals in IoT and home automation systems, FlowFence [20] uses information flow control and explicitly isolates sensitive data inside sandboxes. This approach requires intensive modification to SmartApps, and the enforcement is done on Android instead of a real smart home hub. Jia et al. [30] gather information before a sensitive action is executed, and ask for user approval through frequent run-time prompts. However, in-context prompts cannot satisfy the real-time automation of IoT apps (e.g., users need to be awake to approve a permission when an emergency happens). Users will likely become habituated to approving these prompts, mistakenly approving unexpected behaviors. Furthermore, the information they provide to users is directly dumped from code, whereas we generate natural language to improve communication with users. BLE-Guardian [15] controls who can discover, scan, and connect to an IoT interface. CIDS [10] designs an anomaly-based intrusion detection system to detect in-vehicle attacks by measuring fingerprints from deployed ECUs based on clock behaviors. Sivaraman et al. [45] propose managing IoT devices through software-defined networking (SDN) based on day-to-day activities.

Beyond framework or architecture solutions, enhancing the security of smart devices is also a common countermeasure against attacks from remote or near field communication surfaces. For example, SEDA [6] proposed their attestation protocol for embedded devices. Through software attestation and showing states gathered from booting sequences, SEDA can construct a security model for swarm attestation. Similar approaches to ensure IoT or smart device integrity [2, 7, 9, 10] complement our system.

Some researchers have also examined IoT privacy from a usability perspective. For example, Egelman et al. suggest using crowdsourcing to improve IoT devices' privacy indicators [14]. Further, Ur et al. investigate parents' and teens' perspectives on smart home privacy [53] and Demiris et al. study seniors' privacy perspectives for smart homes [12]. Kim et al. study the challenges in access control management in smarthome and present usable access control policies [34, 35]. In contrast, beside understanding user's mental model about smarthome privacy. we design a new usable IoT authorization scheme.

8 Acknowledgement

We would like to thank Tadayoshi Kohno, Soteris Demetriou, and the anonymous reviewers for their invaluable feedback. The project is supported in part by NSF CNS-1223477, 1223495, 1527141 and 1618493, and ARO W911NF1610127.

9 Conclusion

In this paper, we have identified the fundamental gap between how users expect an IoT app to perform and what really takes place. We rethink the notion of authorization in IoT platforms and propose an automated and usable solution called SmartAuth to bridge the gap. SmartAuth automatically collects security-relevant information from an IoT app's code and description, and generates a user-friendly authorization interface. Through manual verification and in-lab human subject studies, we demonstrate that SmartAuth can enable users to make more well-informed authorization decisions for IoT apps compared to the current approach.

A SMARTAPP PATCHING

Our patching script is written in roughly 600 lines of python code to modify the original Groovy source file by the following steps. A toy example for a patched app TURN IT ON FOR 5 MINUTES is given in Listing 2.

Listing 2: We provide a code snippet for patched IoT app TURN IT ON FOR 5 MINUTES. Text in blue indicates statements that need to be patched, and text in red indicates either new code instrumented by the script or replaced with our wrapped functions. The `appSetting` section added after the definition block is used for OAuth configuration.

```
definition(
  name: "Turn It On For 5 Minutes",
  namespace: "smartthings",
  author: "SmartThings",
  description: "When a SmartSense Multi is
      opened, a switch will be
    turned on, and then turned off after 5
        minutes.",
  category: "Safety Security",
   ... \\
) {
  appSetting "client_idFPS" // used to config
      app identifier for OAuth.
  appSetting "client_secretFPS" // used to
      config app secret for OAuth.
  appSetting "http_serverFPS" // we configure
      cloud server url here.
}
...
mappings { // act as end-points for policy
    enforcement module to deliver event data
  path("/post_event") {
    action: [
      POST: "handleEventFromProxyServer"
    ]
  }
}
preferences {
  section("When it opens...") {
    input "contact1",
        "capability.contactSensor"
  }
  section("Turn on a switch for 5
      minutes..."){
    input "switch1", "capability.switch"
  }
}
def installed() {
  log.debug "Installed with settings:
      \${settings}"
```

```
  subscribe(contact1, "contact.open",
      contactOpenHandler)
  subscribeToServer(contact1, "contact",
      "open", contactOpenHandler)
}
def updated(settings) {
  log.debug "Updated with settings:
      \${settings}"
  unsubscribe()
  unsubscribeToServer()
  subscribe(contact1, "contact.open",
      contactOpenHandler)
  subscribeToServer(contact1, "contact",
      "open", contactOpenHandler)
}
def contactOpenHandler(evt) {
  switch1.on()
  sendCommandToProxyServer(switch1, "on", NULL,
      NULL, NULL, NULL)
  def fiveMinuteDelay = 60 * 5
  runIn(fiveMinuteDelay, turnOffSwitch)
}
def turnOffSwitch() {
  switch1.off()
  sendCommandToProxyServer(switch1, "off",
      NULL, NULL, NULL, NULL)
}
...
```

To enable authorization in the for policy enforcement module, the script automatically inserts dynamic pages and prepares a URL for the patched app to enable an OAuth authentication flow at install time. The SmartThings platform provides a trigger for an OAuth authorization flow via the URL containing an app identifier and its cloud-generated app secret. When the user navigates to the URL, they will be redirected to the SmartThings login page to enter credentials and receive an authorization token for later use.

The script next scans all devices on the SmartThings capability list[4] by parsing all input labels from the `preferences` section and its corresponding child pages, e.g., `mainPage` page section. The script builds an internal structure called DL, maintaining a pair of information (input label, device capability), for later code substitution for command or attribute statements.

The script then parses event handler subscription and unsubscription statements by scanning the keywords. A subscription statement consists of its input label, associated attributes, and the corresponding event handler function. For instance, `subscribe(motionSensors, "motion.active", motionActive)` means the app subscribes an event handler for status activity of input `motionSensors` which has motion capability, and assign function `motionActive` as callback handler. Therefore, our patching engine replaces this statement with an internal function `subscribeToServer()` to send all corresponding parameters to the policy enforcement module along with its app identifier. The module will determine whether this subscription is allowed depending on user's rules. If successful, the module will forward the event data to the registered SmartApp. Unsubscription is much easier to implement, namely by removing all subscriptions registered on the policy enforcement module.

The last step is to search all statements for possible command issuing or attribute retrieving associated with those device labels collected above. For example, the structure DL may contain an input device called **switch1** which has a `switch` capability. When the script parses a statement containing the label switch1, e.g., `switch1.on()`, the script catches the function call `on()` and checks against a capability structure defined based on the list of capabilities and their associated functions and attributes[5]. Once the script confirms the call or attribute, it replaces the original statement with the internal API call `sendCommandToProxyServer()` by sending the request to the policy enforcement module with its app identifier, device label (switch1), command label (`on()`) and any corresponding parameters.

After patching, each Groovy source file will contain around 128 new lines to provide endpoint interfaces for the policy enforcement module.

B SmartAuth Working Example

Here we use one example to show how SmartAuth works. The Flasher is an app that claimed to flash a set of lights to notify user when motion, open/close event, or switch event is detected. However, besides subscribing to motion sensor, contact sensor, and switch, the app also subscribes to the presence sensor and the acceleration sensor. To bridge the gap between what the users think the app do and the app's real behaviors, we generate the security policy from the code and from the description. We display the verified capabilities according to their functionality, and notify users about the unexpected behaviors, similar to Figure 4. On the interface, we further classify the unexpected actions into "unexpected" and "dangerous", according to the user perception measured through our crowd-sourcing result. We present the security policy and unexpected/dangerous behaviors in a usable authorization interface. After getting the response from the users, we enforce the policy so that the app only gets what it needed for the functionality and what the user understand and would like the app to access.

C Apps Used in the Lab Study

We show the participants five group of apps in the SmartAuth and SmartThing interface, as shown in Table 1.Interfaces used in the experiments can be found at [46].

Table 1: Apps in the lab study

App ID	App Name	Description	Overprivileged? If so, Behavior Type
1A	SMART HUMIDIFIER	Turn on/off humidifier based on relative humidity from a sensor.	NO
1B	HUMIDITY ALERT	Notify me when the humidity rises above or falls below the given threshold. It will turn on a switch when it rises above the first threshold and off when it falls below the second threshold.	YES, Lock (Dangerous)
2A	VIRTUAL THERMOSTAT	Control a space heater or window air conditioner in conjunction with any temperature sensor, like a SmartSense Multi.	YES, Motion Sensor (Dangerous)
2B	SMART HEATER	Turn on/off the heater based on the temperature.	NO
3A	LIGHTS OFF	Turn lights off when no motion and presence is detected for a set period of time.	NO
3B	DARKEN BEHIND ME	Turn your lights off after a period of no motion being observed.	YES, Temperature Sensor (Unexpected)
4A	FLASH A NOTICE	When something happens (open/close, switch on/off, motion detected), flash lights to indicate.	NO
4B	THE FLASHER	Flashes a set of lights in response to motion, an open/close event, or a switch.	YES, Presence Sensor (Unexpected)
5A	LEFT IT OPEN	Turn lights off when no motion and presence is detected for a set period of time.	YES, Power Meter (Unexpected)
5B	SMART WINDOW	Compares two temperatures - indoor vs outdoor, - then sends an alert if windows are open (or closed). If you don't use an external temperature device, your zipcode will be used instead.	NO

D Example Survey questions

We list a few representative survey questions.

D.1 Example questions in the Mturk study

1. What factors will you consider when making decision of whether to install a third party app or not? And please indicate how much you care on each factor that you will consider. {Strongly care, care, neither care or not care, not care, Strongly not care}
   () The source / author of the app
   () The popularity of the app
   () The functionality of the app
   () The privacy aspect of the app
   () The smarthome capabilities that the app request
   () The relation of capability requests to the app's functionality
   () Others:
2. Third-party apps can access devices in the smart home after they are installed. Please rate the risk levels of the different behaviors to access devices. {Very sensitive, sensitive, a bit sensitive, not sensitive}
   () Unlock your door
   () Lock your door
   () Read the input of your door lock
   () Read the battery level
   () Read your motion sensor
   () Control your water pump
   () Turn on/off your light
   () Adjust the level of your light
3. Similar to smarthome capabilities, Android or iOS also provide permissions to third-party apps to control the access to resources in the mobile phone such as your location and contact book. Which one do you think is more sensitive?
   A) Smarthome capabilties are more sensitive
   B) Android or iOS permissions are more sensitive
   C) I think they are the same
   D) I don't know
4. Please explain your reasons for the last question:

D.2 Example questions in the in-lab study

Please choose how much you agree with the following statements. {Strongly disagree, disagree, neither agree or disagree, agree, strongly agree}.

1. I feel that the app description explains thoroughly why the app can access and control these sensors and devices.
2. I feel confident to make a decision whether or not to install the app after reading the description.
3. It is difficult to find information from the description.

E Crowdsourcing for Unexpected Behavior Sensitivity

We evaluate how sensitive the unexpected behaviors are by combining expert reviews and crowdsourcing together. In particular, we have two security experts and 100 Mturkers to look into the apps' unexpected behaviors and evaluate how sensitive the unexpected behavior is given the context of the app. We asked the participants to classify whether these unexpected behaviors are dangerous or not(dangerous is counted as 1, and not dangerous is counted as 0). From the expert and Mturk responses, we assign each security expert a weight of 0.25, and each Mturker a weight of 0.005. If the weighted sum is over 0.5, we consider the behavior as dangerous.

Table 2: Compatibility test results among 30 SmartApps exhibiting undisclosed overprivilege, meaning they contain capabilities for functionality not disclosed in the app description. Of these undisclosed overprivilege cases, we refer to the low-risk cases as unexpected capabilities and the high-risk cases as dangerous capabilities. Note that the risk levels are crowd-sourced via online surveys. We remove the access to all the unexpected and dangerous capability to test whether the apps can still perform correctly.

App	Unexpected Capability	Dangerous Capability	Compatible
ALFRED WORKFLOW	switch	lock	Not if block remote access
BRIGHT WHEN DARK AND/OR BRIGHT AFTER SUNSET	switchLevel		Yes
CAMERA POWER SCHEDULER	switch		Yes
CURLING IRON		motionSensor	Yes
FORGIVING SECURITY	contactSensor, switch	alarm, motionSensor	Yes
GOOD NIGHT		switch	Yes
JENKINS NOTIFIER	colorControl	switch	Yes
NOTIFY ME WHEN	button, contactSensor, accelerationSensor, presenceSensor, smokeDetector, waterSensor	motionSensor, switch	Yes
PHOTO BURST WHEN	accelerationSensor, contactSensor	imageCapture, motionSensor, switch, presenceSensor	Yes
PREMPOINT		imageCapture, switch, lock, garageDoorControl	Yes
RISE AND SHINE		motionSensor	Yes
SAFE WATCH	contactSensor, accelerationSensor, threeAxis, temperatureMeasurement	motionSensor, presenceSensor	Yes
SEND HAM BRIDGE COMMAND WHEN	contactSensor, accelerationSensor, switch, waterSensor, smokeDetector	motionSensor, presenceSensor	Yes
SIMPLE CONTROL	switch, lock, thermostat, doorControl, colorControl, musicPlayer, switchLevel	lock, doorControl	Not if block remote access
SMART LIGHT TIMER	contactSensor	motionSensor	Yes
SMART SECURITY		switch	Yes
SMART WINDOWS	contactSensor		Yes
SMARTBLOCK NOTIFIER		switch	Yes
SPEAKER CONTROL	contactSensor, accelerationSensor, switch, waterSensor, button	motionSensor, presenceSensor	Yes
SPEAKER MOOD MUSIC	contactSensor, accelerationSensor, button, waterSensor,musicPlayer	motionSensor, presenceSensor, switch	Yes
SPRAYER CONTROLLER 2		switch	Yes
SPRUCE SCHEDULER	contactSensor		Yes
TALKING ALARM CLOCK	switchLevel, temperatureMeasurement, thermostat, relativeHumidityMeasurement		Yes
THE FLASHER		presenceSensor	Yes
TURN IT ON FOR 5 MINUTES	contactSensor		Yes
UNDEAD EARLY WARNING	contactSensor	switch	Yes
VINLI HOME CONNECT		switch,lock	Not if block remote access
VIRTUAL THERMOSTAT		motionSensor	Yes
WEATHER WINDOWS	contactSensor		Yes
WHOLE HOUSE FAN	contactSensor		Yes

F APPS WITH UNDISCLOSED OVERPRIVILEGE

Table 2 tabulates the 30 apps that exhibit undisclosed overprivilege. These apps either request unexpected capabilities not mentioned in their descriptions or dangerous capabilities that could cause harm.

AWare: Preventing Abuse of Privacy-Sensitive Sensors via Operation Bindings

Abstract

System designers have long struggled with the challenge of determining how to control when untrusted applications may perform operations using privacy-sensitive sensors securely and effectively. Current systems request that users authorize such operations once (i.e., on install or first use), but malicious applications may abuse such authorizations to collect data stealthily using such sensors. Proposed research methods enable systems to infer the operations associated with user input events, but malicious applications may still trick users into allowing unexpected, stealthy operations. To prevent users from being tricked, we propose to bind applications' operation requests to the associated user input events and how they were obtained explicitly, enabling users to authorize operations on privacy-sensitive sensors unambiguously and reuse such authorizations. To demonstrate this approach, we implement the AWare authorization framework for Android, extending the Android Middleware to control access to privacy-sensitive sensors. We evaluate the effectiveness of AWare in: (1) a laboratory-based user study, finding that at most 7% of the users were tricked by examples of four types of attacks when using AWare, instead of 85% on average for prior approaches; (2) a field study, showing that the user authorization effort increases by only 2.28 decisions on average per application; (3) a compatibility study with 1,000 of the most-downloaded Android applications, demonstrating that such applications can operate effectively under AWare.

1 Introduction

Contemporary desktop, web, and mobile operating systems are continually increasing support for applications to allow access to privacy-sensitive sensors, such as cameras, microphones, and touch-screens to provide new useful features. For example, insurance and banking applications now utilize mobile platforms' cameras to collect sensitive information to expedite claim processing[1] and check depositing[2], respectively. Several desktop and mobile applications provide screen sharing[3] and screen capturing features for remote collaboration or remote control of desktop and mobile platforms. Also, web search engines now embed buttons to call the businesses linked to the results directly.

Unfortunately, once an application is granted access to perform such sensitive operations (e.g., on installation or first use), the application may use the operation at will, opening opportunities for abuse. Indeed, cybercriminals have built malware applications available online for purchase, called *Remote Access Trojans* (RATs), that *abuse authorized access* to such sensors to exfiltrate audio, video, screen content, and more, from desktop and mobile platforms. Since 75% of operations requiring permissions are performed when the screen is off, or applications are running in the background as services [54], these attacks often go unnoticed by users. Two popular RAT applications, widely discussed in security blogs and by anti-virus companies, are *Dendroid* [1] and *Krysanec* [19]. In the "Dendroid case", the Federal Bureau of Investigations and the Department of Homeland Security performed an investigation spanning several years in collaboration with law enforcement agencies in over 20 countries. The cybercriminal who pleaded guilty for spreading the malware to over 70,000 platforms worldwide was convicted of 10 years in prison and a $250,000 fine [16, 18]. Several other cases of abuse have been reported ever since. Some cases leading to legal actions, including the case of the NBA Golden State Warriors' free application that covertly turns on smartphones' microphones to listen to and record conversations [17], school laptops that were found to use their cameras to spy on students to whom they were given [13], and others [14, 15].

Researchers have also designed mobile RAT applications to demonstrate limitations of access control models adopted by contemporary operating systems when mediating access to privacy-sensitive sensors. For instance, *PlaceRaider* [51] uses the camera and built-in sensors to construct three-dimensional models of indoor environments. *Soundcomber* [46] exfiltrates sensitive data, such as credit card and PIN numbers, from both tones and speech-based interaction with phone menu systems. Even the Meterpreter Metasploit exploit, enables microphone recording remotely on computers running Ubuntu[4].

To address these threats, researchers have proposed methods that enable the system to infer which operation requests are associated with which user input events. Input-Driven [33] access control authorizes the operation request that immediately follows a user input event, but a malicious application may steal a user input event targeted at another application by submitting its request first. User-Driven [39, 41] access control requires that applications use system-defined gadgets associated with particular operations to enable the system to infer operations for user input events unambiguously, but does not enable a user to verify the operation that she has requested by providing input. We describe four types of attacks that are still possible when using these proposed defenses.

In this work, we propose the AWare authorization framework to prevent abuse of privacy-sensitive sensors by malicious applications. Our goal is to enable users to verify that applications' operation requests correspond to the users' expectations explicitly, which is a desired objective of access control research [24, 28]. To achieve our objective, AWare binds each operation request to a user input event and obtains explicit authorization for the combination of operation request, user input event, and the user interface configuration used to elicit the event, which we call an *operation binding*. The user's authorization decision for an operation binding is recorded and may be reused as long as the application always uses the same operation binding to request the same operation. In this paper, we study how to leverage various features of the user interface to monitor how user input events are elicited, and reduce the attack options available to adversaries significantly. Examples of features include the widget selected, the window configuration containing the widget, and the transitions among windows owned by the application presenting the widget. In addition, AWare is designed to be completely transparent to applications, so applications require no modification run under AWare control, encouraging adoption for contemporary operating systems.

We implement a prototype of the AWare authorization framework by modifying a recent version of the Android operating system and found, through a study of 1,000 of the most-downloaded Android applications, that such applications can operate effectively under AWare while incurring less than 4% performance overhead on microbenchmarks. We conducted a laboratory-based user study involving 90 human subjects to evaluate the effectiveness of AWare against attacks from RAT applications. We found that at most 7% of the user study participants were tricked by examples of four types of attacks when using AWare, while 85% of the participants were tricked when using alternative approaches on average. We also conducted a field-based user study involving 24 human subjects to measure the decision overhead imposed on users when using AWare in real-world scenarios. We found that the study participants only had to make 2.28 additional decisions on average per application for the entire study period.

In summary, the contributions of our research are:

- We identify four types of attacks that malicious applications may still use to obtain access to privacy-sensitive sensors despite proposed research defenses.
- We propose AWare, an authorization framework to prevent abuse of privacy-sensitive sensors by malicious applications. AWare binds application requests to the user interface configurations used to elicit user inputs for the requests in *operation bindings*. Users then authorize operation bindings, which may be reused as long as the operation is requested using the same operation binding.
- We implement AWare as an Android prototype and test its compatibility and performance for 1,000 of the most-downloaded Android applications. We also evaluate its effectiveness with a laboratory-based user study, and measure the decision overhead imposed on users with a field-based user study.

2 Background

Mobile platforms require user authorization for untrusted applications to perform sensitive operations. Mobile platforms only request such user authorizations once, either at application installation time or at first use of the operation [2, 3] to avoid annoying users.

The problem is that malicious applications may abuse such blanket user authorizations to perform authorized, sensitive operations stealthily, without users' knowledge and at times that the users may not approve. Operations that utilize sensors that enable recording of private user actions, such as the microphone, camera, screen, etc., are particularly vulnerable to such abuse. Research studies have shown that such attacks are feasible in real systems, such as in commodity web browsers and mobile apps [21, 29, 37]. These studies report that more than 78%

[4] null-byte.wonderhowto.com

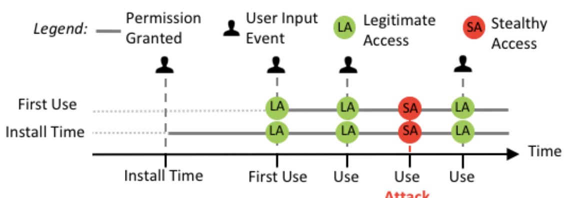

Figure 1: In mobile platforms, once the system authorizes an application to perform a operation, the application may perform that operation at any time, enabling adversaries to stealthily access privacy-sensitive sensors, e.g., record speech using the microphone, at any time.

of users could be potentially subject to such attacks. Furthermore, security companies, such as Check Point, have reported several malware apps that performs stealthy and fraudulent auto-clicking [4], such as `Judy`, `FalseGuide`, and `Skinner` that reached between 4.5 million and 18.5 million devices worldwide. Figure 1 shows that once an application is granted permission to perform an operation using a privacy-sensitive sensor, such as recording via the microphone, that application may perform that operation at any time, even without user consent. This shortcoming enables adversaries to compromise user privacy, e.g., record the user's voice and the surrounding environment, without the user being aware. Research studies have already shown that users have a limited understanding of security and privacy risks deriving from installing applications and granting them permissions [10].

Research [45, 51, 52] and real-world [1, 19] developers have produced exploits, called *Remote Access Trojans* (RATs), that abuse authorized operations to extract audio, video, screen content, etc., from personal devices while running in the background to evade detection by users. Instances of permission abuse have been reported in several popular mobile applications such as `Shazam`, `TuneIn Radio`, and `WhatsApp` [48].

Researchers have proposed defenses to prevent stealthy misuse of operations that use privacy-sensitive sensors [33, 39, 41]. Figure 1 also provides the insight behind these defenses: legitimate use of these sensors must be accompanied by a user input event to grant approval for all operations targeting privacy-sensitive sensors. First, Input-Driven Access Control [33] (IDAC) requires every application request for a sensor operation to follow a user input event within a restricted time window. Thus, IDAC would deny the stealthy accesses shown in Figure 1 because there is no accompanying user input event. Second, User-Driven Access Control [39, 41] (UDAC) further restricts applications to use trusted access control gadgets provided by the operating system, where each access control gadget is associated with a specific operation for such sensors. Thus, UDAC requires a user input event and limits the requesting application only to perform the operation associated with the gadget (i.e., widget) by the system.

3 Problem Definition

Although researchers have raised the bar for stealthy misuse of sensors, malicious applications may still leverage the user as the weak link to circumvent these protection mechanisms. Previous research [6, 12, 30] and our user study (see Section 8.1.1) show that users frequently fail to identify the application requesting sensor access, the user input widget eliciting the request, and/or the actual operation being requested by an application. Such errors may be caused by several factors, such as users failing to detect phishing [12], failing to recognize subtle changes in the interface [20], and/or failing to understand the operations granted by a particular interface [38]. In this section, we examine attacks that are still possible given proposed research solutions, and what aspects of proposed solutions remain as limitations.

3.1 User Interface Attacks

In this research, we identify four types of attacks that malicious applications may use to circumvent the protection mechanisms proposed in prior work [33, 39, 41].

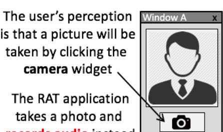

Figure 2: The user's perception of the operation that is going to be performed differs from the actual operation requested by the application, which abuses a previous granted permission.

Operation Switching: A malicious application may try to trick a user into authorizing an unintended operation by changing the mapping between a widget and the associated operation, as shown in Figure 2. This type of attack is possible in IDAC because the relationship between a user input event and the operation that will be authorized as a result of that event is implicit. Indeed, any application can request any operation for which they have been authorized previously (e.g., by first use) and will be approved if it is the first request received after the event. UDAC [39, 41] avoids this type of attack by design by having the system define a mapping between widgets (gadgets) and operations, so the operation is determined precisely by the widget. Any solution we devise must prevent this kind of attack as well.

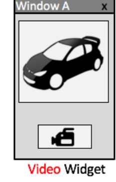

Figure 3: A photo capturing application presents a video camera widget, instead of a camera widget, to trick the user into also granting access to the microphone. The windowing display context surrounding the widget shows a camera preview for photo capturing.

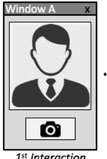
Bait-and-Context-Switch: A malicious application may try to trick the user to authorize an unintended operation by presenting a widget in a misleading display context, as shown in Figure 3. In this case, the win-

dowing context surrounding the widget indicates one action (e.g., taking a picture) when the widget presented requests access to a different operation (e.g., taking a video). This type of attack is possible because users engaged in interface-intensive tasks may focus on the context rather than the widget and infer the wrong widget is present, authorizing the wrong operation. Neither IDAC [33] nor UDAC [39, 41] detect the attack shown. Although UDAC [39] checks some properties of the display context[5], plenty of flexibility remains for an adversary to craft attacks since applications may choose the layout around which the widget is displayed.



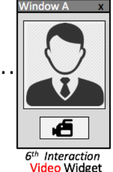


Figure 4: A malicious application keeps the windowing display context but switches the widget to trick users who have made several similar selections to grant the malicious application also access to the microphone mistakenly.

Bait-and-Widget-Switch: A malicious application may present the same widget for the same operation to the user several times in succession, but then substitute another widget for another operation, hoping that the user will not notice the widget change. An example of this attack is shown in Figure 4. Again, this type of attack is possible because users engaged in interface-intensive tasks may be distracted, thus, not notice changes in the widget. Again, UDAC methods to detect deceptive interfaces [39] are not restrictive enough to prevent this attack in general. For example, one UDAC check restricts the gadget's location for the user input event, but this does not preclude using different gadgets at the same location.

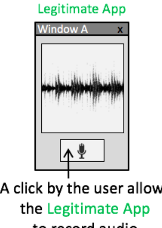

Figure 5: The user may mistakenly authorize access to the microphone to a RAT application spoofing the graphical aspect of a well-known legitimate application.

Application Spoofing: A malicious application replicates the look-and-feel of another application's interface and replaces the foreground activity of that application with one of its own to gain access to a sensor as shown in Figure 5, similar to a phishing attack. For example, when the benign application running in the foreground elicits a user input event, the malicious application may also try to elicit a user input event using its own activity window by replacing the benign application currently in the foreground. If the user supplies an input to the masquerading application's widget, then the masquerading application can perform any operation for which it is authorized (e.g., from first use or its manifest). While researchers have explored methods to increase the user's ability to detect the foreground application [6], mistakes are still possible. Indeed, prior studies have reported that few users notice the presence of security indicators, such as the browser lock icon [9, 53], and that even participants whose assets are at risk fail to react as recommended when security indicators are absent [44]. Since IDAC and UDAC [33, 39, 41] both treat user input as authorization, both will be prone to this attack[6].

3.2 Limitations of Current Defenses

The main challenge is determining when users allow applications to use particular privacy-sensitive sensors without creating too much burden on users. As a result, current mobile platforms only request user authorization once (e.g., on first use or installation), and proposed research solutions aim to infer whether users authorize access to particular sensors from user actions implicitly. However, inferring user intentions implicitly creates a semantic gap between what the system thinks the user intended and what the user actually intended.

Traditionally, access control determines whether subjects (e.g., users and applications) can perform operations (e.g., read and write) on resources (e.g., sensors). Proposed approaches extend traditional access control with additional requirements, such as the presence of a user input event [33, 41] or properties of the user interface [39]. However, some requirements may be difficult to verify, particularly for users, as described above, so these proposed approaches still grant adversaries significant flexibility to launch attacks. Proposed approaches still demand users to keep track of which application is in control, the operations associated with widgets, which widget is being displayed, and whether the widget or application changes.

Finally, application compatibility is a critical factor in adopting the proposed approaches. The UDAC solutions [39, 41] require developers to modify their applications to employ system-defined gadgets. It is hard to motivate an entire development community to make even small modifications to their applications, so solutions that do not require application modifications would be preferred, if secure enough.

4 Security Model

Trust Model - We assume that applications are isolated from each other either using separate processes, the same-origin policy [42], or sandboxing [7, 36], and have no direct access to privacy-sensitive sensors by default due to the use of Mandatory Access Control [49, 50].

[5] UDAC Audacious [39] checks that the user interface presented does not have misleading text, that the background and text preserve the contrast, and that the gadget is not covered by other user interface elements.

[6] UDAC authors [41] did acknowledge this attack, and indicated that solutions to such problems are orthogonal.

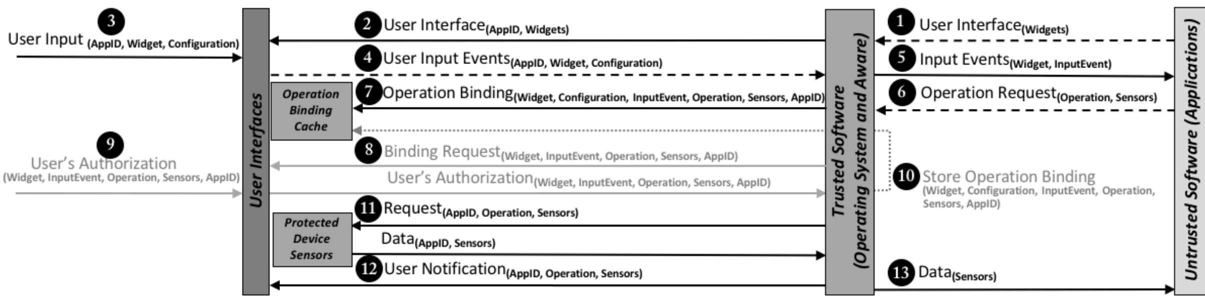

Figure 6: Overview of the AWare authorization framework. The three dashed lines highlight the parts of information used by AWare to generate an *operation binding*. The gray arrows represent *one-time* steps required to obtain an explicit authorization from the user for the creation of a new *operation binding*, which are not required when the *operation binding* has been explicitly authorized by the user in previous interactions.

We assume the presence of a *trusted path* for users to receive unforgeable communications from the system and provide unforgeable user input events to the system. We assume that trusted paths are protected by mandatory access control [49, 50] as well, which ensures that only trusted software can receive input events from trusted system input devices to guarantee the authenticity (i.e., prevent forgery) of user input events.

Trusted path communication from the system to the user uses a *trusted display area* of the user interface, which we assume is available to display messages for users and applications do not have any control of the content displayed in this area; thus they cannot interfere with system communications to or overlay content over the trusted display area.

These assumptions are in line with existing research that addresses the problem of designing and building trusted paths and trusted user interfaces for browsers [55], X window systems [47, 56], and mobile operating systems [26, 27]. The design of our prototype leverages mechanisms provided by the Android operating system satisfying the above assumptions, as better described in Section 7.

Threat Model - We assume that applications may choose to present any user interface to users to obtain user input events, and applications may choose any operation requests upon any sensors. Applications may deploy user interfaces that are purposely designed to be similar to that of another application, and replay its user interface when another application is running to trick the user into interacting with such interface to "steal" such user input event. Applications may also submit any operation request at any time when that application is running, even without a corresponding user input event. Applications may change the operation requests they make in response to user input events.

5 Research Overview

Our objective is to develop an authorization mechanism that eliminates ambiguity between user input events and the operations granted to untrusted applications via those events, while satisfying the following security, usability, and compatibility properties:

User Initiation Every operation on privacy-sensitive sensors must be initiated by an authentic user input event.

User Authorization Each operation on privacy-sensitive sensors requested by each application must be authorized by the user explicitly prior to that operation being performed.

Limited User Effort Ideally, only one explicit user authorization request should be necessary for any benign application to perform an operation targeting privacy-sensitive sensors while satisfying the properties above.

Application Compatibility No application code should require modification to satisfy the properties above.

We aim to control access to privacy-sensitive sensors that operate in discrete time intervals initiated by the user, such as the cameras, microphone, and screen buffers. We believe the control of access to continuous sensors, such as GPS, gyroscope, and accelerometer, requires a different approach [34], but we leave this investigation as future work.

To achieve these objectives, we design the AWare authorization framework. The main insight of the AWare design is to extend the notion of an authorization tuple (i.e., subject, resource, operation) used to determine whether to authorize an application's operation request to include the user interface configuration used to elicit the user input event. We call these extended authorization tuples *operation bindings*, and users explicitly authorize operation bindings before applications are allowed to access sensors. An operation binding may reused to authorize subsequent operations as long as the application uses the same user interface configuration to elicit input events to request the same operation.

Approach Overview. Figure 6 summarizes the steps taken by the AWare to authorize applications' operation requests targeting privacy-sensitive sensors.

In a typical workflow, an application starts by specifying a set of user interface configuration, such as widgets and window features, to the trusted software (step 1) in charge of rendering such widgets with windows to elicit user input (step 2). An authentic user interaction with the application's widgets in a user interface configuration generates user input events (step 3), which are captured

by the trusted software (step 4) together with the current user interface configuration (e.g., enclosing window, window features, ancestors windows, etc.) and forwarded to the application (step 5). Based on the user input events, the application may generate a request for a particular operation targeting one or more privacy-sensitive sensors, which is captured by the trusted software (step 6).

At this stage, the AWare authorization framework (part of the trusted software layer) has full visibility of: (1) the application's identity; (2) the application's user interface widget; (3) the authentic user input event associated with that widget; (4) the user interface configuration within which the widget is presented to the user; (5) the application's operation request; and (6) the target set of privacy-sensitive sensors for such an operation. Thus, the AWare authorization framework can *bind* these pieces of information together, creating an *operation binding*.

Next, the AWare authorization framework checks whether such an operation binding has already been authorized by the user (step 7). If not, AWare presents a request for authorization of the operation binding to the user (Section 7), called the *binding request* (step 8). Upon receiving a binding request, the user can *explicitly* authorize the use of the set of privacy-sensitive sensors by the requesting application for the identified operation binding (step 9). Upon the user's authorization, the operation binding is then cached (Section 6.5) for reuse in authorizing future requests using the same operation binding automatically (step 10).

After the operation authorization, the trusted software controlling the set of privacy-sensitive sensors starts the data collection (step 11), while the user is *explicitly* notified about the ongoing operation via an on-screen notifications in a trusted display area (step 12). Finally, the collected data is delivered to the requesting application for data processing (step 13).

The sequence of events in Figure 6 shows that AWare relies on a one-time, explicit user authorization that binds the user input event, the application identity, the widget, the widget's user interface configuration, the operation, and the set of target sensors; then, it reuses this authorization for future operation requests.

6 AWare Design

6.1 Operation Bindings

As described above, AWare performs authorization using a concept called the operation binding.

Definition 1: An *operation binding* is a tuple $b = (app, S, op, e, w, c)$, where: (1) *app* is the application associated with both the user interface widget and the operation request; (2) S is the set of sensors (i.e., resources) targeted by the request; (3) *op* is the operation being requested on the sensors; (4) e is the user input event; (5) w is a user interface widget associated with the user input event; (6) c is the user interface configuration containing the widget.

The user interface configuration describes the structure of the user interface when a user input event is produced, which includdes both features of the window in which the widget is displayed and application's activity window call graph, which relates the windows used by the application. We define these two aspects of the configuration precisely and describe their use to prevent attacks in Sections 6.3 and 6.4.

The first part of an operation binding corresponds to the traditional authorization tuple of (subject, object, operation). An operating binding links a traditional operation tuple with a user input event and how it was obtained in terms of the rest of the operation binding tuple (event e, widget w, configuration c). AWare's authorization process enables users to authorize operation requests for the authorization tuple part of the operation binding (*app*, S, *op*) associated with a particular way the user approved the operation from the rest of the operation binding (e, w, c). AWare reuses that authorization to permit subsequent operation requests by the same application when user input events are obtained in the same manner.

A user's authorization of an operation binding implies that *the application will be allowed to perform the requested operation on the set of sensors whenever the user produces the same input event using the same widget within the same user interface configuration*.

We explain the reasoning behind the operation binding design by describing how AWare prevents the attacks described in Section 3.1 in the following subsections.

6.2 Preventing Operation Switching

AWare prevents operation switching attacks by producing an operation binding that associates a user input event and widget with an application's operation request.

Upon a user input event e, AWare collects the widget w, the user interface configuration c in which it is presented, and the application associated with the user interface *app*. With this partial operation binding, AWare awaits an operation request. Should the application make an operation request within a limited time window [33], AWare collects the application *app*, operation sensors S, and operation requested *op*, the traditional authorization tuple, to complete the operation binding for this operation request.

The constructed operation binding must be explicitly authorized by the user. To do so, AWare constructs a *binding request* that it presents to the user on the platform's screen. The binding request clearly specifies: (1) the identity of the requesting application; (2) the set of sensors targeted by the operation request; (3) the type of operation requested by the application; and (4) the widget receiving the user input event action.

This approach ensures that the user authorizes the combination of these four components enabling the user to verify the association between the operation being authorized and the widget used to initiate that operation. Also, each operation binding is associated with the specific user interface configuration for the widget used to activate the operation. Although, this information is not presented to the user, it is stored for AWARE to compare to future operation requests to prevent more complex attacks, as described below.

This prevents the operation switching attack on IDAC [33], where another operation may be authorized by a user input event. AWARE creates a binding between a widget and operation as UDAC [39, 41] does, but unlike UDAC AWARE creates these bindings dynamically. Applications are allowed to choose the widgets to associate with particular operations. In addition, AWARE informs the user explicitly of the operation to be authorized for that widget, whereas UDAC demands that the user learn the bindings between widgets and operations correctly. The cost is that AWARE requires an explicit user authorization on the first use of the widget for an operation request, whereas UDAC does not. However, as long as this application makes the same operation requests for user input events associated with the same widget, AWARE will authorize those requests without further user effort.

6.3 Preventing Bait-and-Switch

Applications control their user interfaces, so they may exploit this freedom to perform bait-and-switch attacks by either presenting the widget in a misleading window (Bait-And-Context-Switch) or by replacing the widget associated with a particular window (Bait-And-Widget-Switch). Research studies have shown that such attacks are feasible in real systems and that the damage may be significant in practice [21, 29, 37]. To prevent such attacks, AWARE binds the operation request with the user interface configuration used to display the widget, in addition to the widget and user input event.

One aspect of the user interface configuration of the operation binding describes features of the window enclosing the widget.

Definition 2: A *display context* is a set of structural features of the most enclosing activity window a_w containing the widget w.

Structural features describe how the window is presented, excepting the content (e.g., text and figures inside web pages), which includes the position, background, borders, title information, and widgets' position within the window. The set of structural features used by AWARE are listed in Table 5. AWARE identifies a_w as a new activity window should any of these structural features change.

The hypothesis is that the look-and-feel of an application window defined by its structural features should be

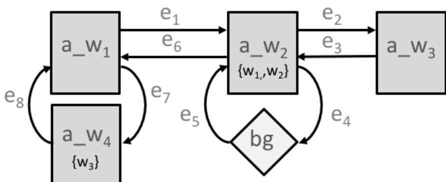

Figure 7: Activity window call graphs are created at runtime for the activity windows that produce authorized operations. (bg) is the background activity.

constant, while the content may change. Our examination of Android applications shows that the same windows retain the same look-and-feel consistently, but not perfectly. For example, the exact location of the window may vary slightly, so we consider allowing modest ranges for some feature values. We further discuss the authentication of display context in Section 7.

This approach prevents Bait-and-Widget-Switch attacks because clearly an instance of the same window (i.e., display context) with a different widget will not match the previous operation binding. Similarly, for Bait-and-Context-Switch attacks, the same widget presented in a different window (i.e., display context) will not match the previous operation binding, therefore a new operation binding request will be prompted to the user.

Once the widget and the display context are bound together and kept fixed, the adversary is left only with the content (e.g., text and figures inside a web page) as possible misleading tool. However, since the display context also measures the window's UI elements and their positions, little space is left to the adversary for attacks.

Therefore, such an approach prevents bait-and-switch attacks possible in both IDAC [33] and UDAC [39, 41], where users must continuously check for subtle changes to the widgets or their display contexts rendered on the platform's screen.

6.4 Preventing Application Spoofing

To launch such an attack an application must succeed in replacing the foreground activity window of one application with its own activity window and adopt the same look-and-feel of the replaced application.

We can prevent applications from presenting their activity windows arbitrarily by enforcing the application's authorized activity window call sequences.

Definition 3: An *activity window call graph* $G := (N, E)$ is a graph, where each node in N represents an activity window and each edge in E represents an inter-activity window transition enabled either via user input events (i.e., click of a button) or system events (i.e., incoming phone call).

An activity window call graph records the relationships among the windows used by an application. An example of an activity window call graph is shown in Figure 7, where events may cause transitions between windows

a_w_1 and a_w_4 and the application may enter the background only from the activity window a_w_2. Note that an application's activity window call graph can be built while the application runs, as the user authorizes operation bindings.

If the malicious application has not used this spoofing window previously, then a *binding request* will be created for the user, which then shows the identity of the application. Thus, the user could prevent the malicious application from ever performing this operation in any user interface configuration. IDAC [33] and UDAC [39, 41] do not explicitly force the user to check the application that will be authorized, although UDAC identified the need for such a mechanism [41].

On the other hand, a malicious application may try to hijack a foreground activity window of another application for a window that has been authorized by the user previously. However, if the malicious application's window is not authorized to transition from the background (e.g., only the activity window a_w_2 is authorized in Figure 7), then the transition will not match the activity call graph. In this case, a new *binding request* will be made to the user, which will clearly identify the (malicious) application. We discuss the authentication of the app identity in Section 7. Both IDAC and UDAC allow such hijacking and rely on the user to detect these subtle attacks.

A malicious application may try to circumvent the activity call graph checking by creating a more fully connected graph that allows more attack paths. However, such an activity window call graph will require more user authorizations, which may dissuade the user from that application. Furthermore, intrusion analysis may leverage such activity window call graphs to detect possible attacks.

6.5 Reusing Operation Bindings

Authorized *operation bindings* are cached to minimize the user's effort in making explicit authorizations of *binding requests* to improve usability. Thus, AWARE uses a caching mechanism to require an explicit user's authorization only the first time an *operation binding* is identified, similarly to the first-use permission mechanism. We hypothesize that in most benign scenarios an authentic user interaction with a specific application's widget is going to generate a request for the same operation for the same set of privacy-sensitive sensors each time. Hence, the previous explicit authorization can be reused securely as *implicit* authorization, as long as the integrity of the *operation binding* is guaranteed. In Section 8.1.2, we show that such an approach does not prohibitively increase the number of access control decisions that users need to make thus avoiding *decision fatigue* [11].

However, we must ensure that *operation bindings* do not become stale. For example, if the application changes the way it elicits an operation, we should not allow the application to reuse old methods to elicit that same operation. Thus, we require that an *operation binding* must be removed from the cache whenever a new operation binding is created for the same application that partially matches the existing binding, except for the application field. For example, this prevents an operation from being authorized in multiple ways, a widget from being used for multiple operations or in multiple configurations, etc.

6.6 Supporting Existing Applications

As an alternative to previously proposed approaches [39, 41], AWARE is completely transparent to, and backward compatible with, existing applications. In fact, AWARE does not require any new external libraries, application code annotation or rewriting, which would require significant development effort/burden and impede backward compatibility for existing applications.

AWARE can be integrated with existing off-the-shelf operating systems, as we show with our AWARE prototype discussed in Section 7. AWARE only requires the integration of three software components at the middleware layer. AWARE's components dynamically monitor the creation of operation bindings and provide visual output to the user to enable authorization of operations on privacy-sensitive sensors. The integration with existing off-the-shelf operating systems facilitates adoption and deployability.

We discuss how AWARE addresses special cases of applications accessing privacy-sensitive sensors via alternative methods, such as via background processes and remote commands, in Appendix A .

7 AWARE Implementation

We implemented an AWARE prototype by modifying a recent release of the Android operating system (version 6.0.1_r5) available via the Android Open Source Project (AOSP)[7]. The AWARE prototype is open-sourced on github.com[8]. Its footprint is about 500 SLOC in C, 800 SLOC in C++ and 600 SLOC in Java. We tested the AWARE prototype on Nexus 5 and Nexus 5X smartphones.

In the following paragraphs, we describe how we implemented the components required for AWARE authorization mechanism[9].

Application Identity: To prove an app's identity in *binding requests*, AWARE applies two methods. First, AWARE uses the checksum of the app's binary signed with the developer's private key and verifiable with the developer's public key [40], similarly to proposals in related work [6]. In addition, AWARE detects spoofing of apps' names or identity marks by using the Comparison Algo-

[7] https://source.android.com

[8] https://github.com/gxp18/AWare

[9] For brevity, in this and the following sections, we use the abbreviation *app* to refer to an application.

rithm for Navigating Digital Image Databases (CANDID) [25]. This comparison ensures that malicious apps do not use the same name or identity mark of other official apps. AWare collects the developers' signatures and the apps identity marks (names and logos) from the Google Play store.

Widget and Display Context Authentication: AWare identifies application-defined widgets and display contexts at runtime before rendering the app's user interface to the user on the platform's screen. AWare uses the widget and window objects created in memory by the Window Manager, before rendering them on the platform's screen, to collect their graphical features reliably. A secure operating systems must prevent apps from being able to directly write into the frame buffers read by the hardware composer, which composes and renders graphic user interfaces on the platform screen. Modern operating systems, such as the Android OS, leverage mandatory access control mechanisms (i.e., SELinux rules) to guarantee that security sensitive device files are only accessible by trusted software, such as the Window Manager. Therefore, as shown in Figure 6, although apps can specify the graphic components that should compose their user interfaces, only the Window Manager, a trusted Android service, can directly write into the screen buffers subsequently processed by the hardware composer. Thus, the Window Manager is the man-in-the-middle and controls what apps are rendering on screen via their user interfaces. In the Appendix, Tables 4 and Table 5 show comprehensive sets of widgets and windows' features used by AWare to authenticate the widgets and their display contexts.

Activity Window Call Graph Construction: At runtime, AWare detects inter-activity transitions necessary to construct the per-application activity window call graph by instrumenting the Android Activity Manager and Window Manager components. Also, AWare captures user input events and system events by instrumenting the Android Input Manager and the Event Manager components. We discuss nested activity windows in Appendix C.

User Input Event Authentication: AWare leverages SEAndroid [49] to ensure that processes running apps or as background services cannot directly read or write input events from input device files (i.e., /dev/input/*) corresponding to hardware interfaces attached to the mobile platform. Thus, only the Android Input Manager, a trusted system service, can read such files and forward input events to apps. Also, AWare leverages the Android screen overlay mechanism to detect when apps or background services draw over the app currently in the foreground to prevent input hijacking and avoid processing of any user input event on overlaid GUI widgets. Thus, AWare considers user input events for the identification of an operation binding only if the widget and the corresponding window

Figure 8: AWare *Binding Request* prompted to the user on the mobile platform's screen at *Operation Binding* creation. The app's identity is proved by the name and the graphical mark. For better security, in mobile platforms equipped with a fingerprint scanner, AWare recognizes the device owner's fingerprint as the only authorized input for creating a new *Operation Binding*.

are fully visible on the platform's screen foreground. To intercept user input events, we placed twelve hooks inside the stock Android Input Manager.

Operation Request Mediation: The Hardware Abstraction Layer (HAL) implements an interface that allows system services and privileged processes to access privacy-sensitive sensors indirectly via well-defined APIs exposed by the kernel. Further, SEAndroid [49] ensures that only system services can communicate with the HAL at runtime. Thus, apps must interact with such system services to request execution of specific operations targeting privacy-sensitive sensors. Thus, AWare leverages the complete mediation guaranteed at the system services layer to identify operation requests generated by apps at runtime, using ten hooks inside the stock Android Audio System, Media Server, and Media Projection.

Operation Binding Management: The AWare prototype implements the AWare Monitor to handle callbacks from the AWare hooks inside the Input Manager and other system services. The AWare Monitor is notified of user input events and apps' requests to access privacy-sensitive sensors via a callback mechanism. Also, the AWare Monitor implements the logic for the *operation binding* creation and caching as well as the display of *binding requests* and alerts to the user. User approvals for *binding requests* are obtained by the AWare Monitor via authorization messages prompted to the user on the mobile platform's screen, as shown in Figure 8. To protect the integrity of the trusted path for binding requests, we prevent apps from creating windows that overlap the AWare windows or modifying AWare windows. To prevent overlapping, AWare leverages the Android screen overlay protection mechanism. To prevent unauthorized modification, AWare implements the Compartmented Mode Workstation model [8] by using isolated per-window processes forked from the Window Manager.

7.1 Control Points Available to the User

AWare provides the users with control points during authorized use of privacy-sensitive sensors by apps. These control points allow the users to control the apps' use of sensors and correct possible mistakes made during the authorization process.

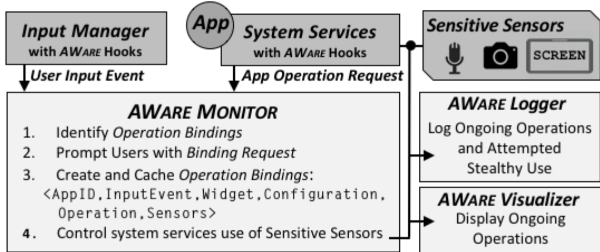

Figure 9: Architecture of the AWARE authorization framework.

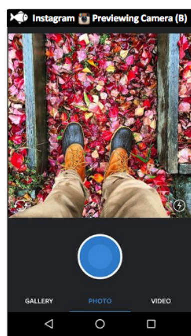

Figure 10: AWARE *security message* displayed on the mobile platform's status bar notifying the user that the `Instagram` application is previewing the back camera (B) for pictures. The security companion (e.g., a white fish) aids the user in verifying the authenticity of the authorization request. Each *security message* includes the app identifier (e.g., application name and identity mark) and a text message specifying the ongoing operation and the set of privacy-sensitive sensors being accessed.

Figure 9 shows an overview of the AWARE prototype components and how the control points are activated. The AWARE MONITOR is designed to activate the AWARE VISUALIZER and the AWARE LOGGER, upon the user authorization of an *operation binding*.

7.1.1 Visualizing Ongoing Operations

AWARE displays *security messages* on a reserved portion of the screen, drawable only by the Window Manager and not accessible by untrusted applications, to make ongoing use of privacy-sensitive sensors visible to users until they terminate. An example of *security message* is shown in Figure 10. A *security message* includes the app identifier (e.g., application name and identity mark) and a text message specifying the ongoing operation and the set of privacy-sensitive sensors being accessed. The use of *security messages* follows the principle of *what the user sees is what is happening* [23], in fact, *security messages* convey *ongoing operations* targeting privacy-sensitive sensors when authorized by the user.

AWARE leverages the Compartmented Mode Workstation principle [8] to ensure integrity and authenticity of *security messages*. Also, AWARE uses a security companion, a secret image chosen by the user, to aid users in verifying the authenticity of *security messages*. We modified the stock Android system user interface (SystemUI), by adding an image view and a text view on the Android status bar to display the AWARE *security messages* specifying the application IDs and the ongoing operations, whenever the AWARE MONITOR authorizes system services to operate on privacy-sensitive sensors on behalf of applications. Also, the AWARE prototype leverages the Android screen overlay mechanism to detect when applications or background services draw over the application currently in the foreground, to prevent GUI overlay.

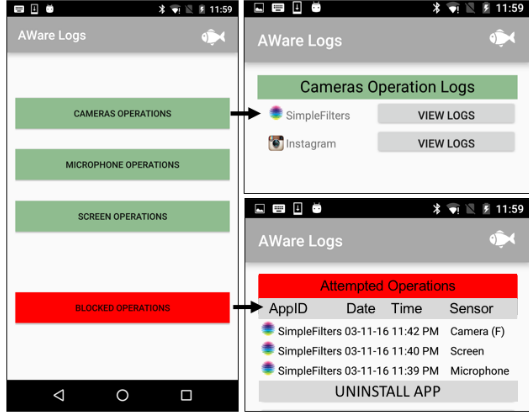

Figure 11: AWARE Users may leverage AWARE *logs* to take retrospective security actions. The figure at the top right shows the list of operations targeting the camera in authorized sessions. The figure at the bottom right summarizes attempted accesses to privacy-sensitive sensors by the `SimpleFilters` app, as examples of stealthy operations. The security companion chosen by the user (e.g., a white fish) aids the user in authenticating the logs.

Further, *security messages* are made visible to the user even if the application runs in full-screen mode. Reserving a small portion of the screen (5%) to convey a security message is a reasonable trade-off for preventing unwanted user distraction while delivering critical content in a timely and appropriate manner [32]. Our evaluation with existing full-screen applications (Section 8.1.2) reports that *security messages* do not impair the correct functioning of full-screen apps. A transparent background can also be used to reduce overlap with the foreground application's window. Lastly, the user can be given the option to explicitly replace the on-screen notification with a periodic distinctive sound or a hardware sensor-use indicator LED.

7.1.2 Logging Authorized Operations

AWARE produces real-time logs of any operation explicitly authorized by the user and of any attempted use of privacy-sensitive sensors from applications without a user-initiated input. AWARE makes attempted stealthy accesses, by installed applications, visible to users via full-screen alert messages and by producing a distinctive sound, or by enabling a hardware sensor-use indicator LED. AWARE then allows the user to either uninstall suspicious applications or to terminate ongoing suspicious operations. Logs are visible to users via a system application called AWARE LOGGER, which is accessible via the applications menu or by tapping on the AWARE security messages/alerts dis-

played on the mobile platform's screen. Each log entry reports information regarding the app ID, date, time, and the privacy-sensitive sensors target of the operation, as shown in Figure 11. Logs are not accessible to applications to preserve their integrity and avoid the creation of side channels.

8 AWare Evaluation

We investigated the following research questions.

To what degree is the AWare *operation binding concept assisting the users in avoiding attacks?* We performed a laboratory-based user study and found that the operation binding enforced by AWare significantly raised the bar for malicious apps trying to trick the users in authorizing unintended operations, going from an average attack success rate of 85% down to 7%, on average, with AWare.

What is the decision overhead imposed to users due to per-configuration access control? We performed a *field-based* user study and found that the number of decisions imposed to users by AWare remains confined to less than four decisions per app, on average, for the study period.

How many existing apps malfunction due to the integration of AWare*? How many operations from legitimate apps are incorrectly blocked by* AWare *(i.e., false positives)?* We used a well-known compatibility test suite to evaluate the compatibility of AWare with existing apps and found that, out of 1,000 apps analyzed, only five of them malfunctioned due to attempted operations that AWare blocked as potentially malicious. However, these malfunctioning instances have been resolved by features developed in subsequent versions of the AWare prototype.

What is the performance overhead imposed by AWare *for the operation binding construction and enforcement?* We used a well-known software exerciser to measure the performance overhead imposed by AWare. We found that AWare introduced a negligible overhead on the order of microseconds that is likely to be not noticeable by users.

8.1 Preliminaries for the User Studies

We designed our user studies following suggested practices for human subject studies in security to avoid common pitfalls in conducting and writing about security and privacy human subject research [43]. Participants were informed that the study was about mobile systems security, with a focus on audio and video, and that the involved researchers study operating systems security. An Institutional Review Board (IRB) approval was obtained from our institution. We recruited user study participants via local mailing lists, Craigslist, and local groups on Facebook, and compensated them with a $10 gift card. We excluded friends and acquaintances from participating in the studies to avoid acquiescence bias. Participants were given the option to withdraw their consent to participate at any time after the purpose of the study was revealed. For all the experiments, we configured the test environment on Nexus 5X smartphones and used a background service, automatically relaunched at boot time, to log participants' responses to system messages/alerts and all user input actions taken by participants while interacting with the testing apps.

8.1.1 Laboratory-Based User Study

We performed a *laboratory-based* user study to evaluate the *effectiveness* of AWare in supporting users in avoiding attacks by malicious apps and compared it with alternative approaches.

We divided the participants into six groups. Participants in `Group1` interacted with a *stock* Android OS using install-time permissions. Participants in `Group2` interacted with a *stock* Android OS using first-use permissions. Participants in `Group3` interacted with a *modified* version of the Android OS implementing input-driven access control, which binds user input events to the operation requested by an app but does not prove the app's identity to the user. Participants in `Group4` interacted with a *modified* version of the Android OS implementing the first-use permissions and a security indicator that informs the users about the origin of the app (i.e., developer ID [6]). Participants in `Group5` interacted with a *modified* version of the Android OS implementing the use of access control gadgets [41] including basic user interface configuration checks (i.e., no misleading text, UI background and the text must preserve the contrast, no overlay of UI elements, and user events occur in the correct location at the correct time [39]) and timing checks for implicit authorizations. Lastly, participants in `Group6` interacted with a *modified* version of the Android OS integrating the AWare authorization framework.

Experimental Procedures: Before starting the experiment, *all participants were informed that attacks targeting sensitive audio and video data were possible during the interaction with apps involved in the experimental tasks*, but none of the participants were aware of the attack source. Further, the order of the experimental tasks was randomized to avoid ordering bias. All the instructions to perform the experimental tasks were provided to participants via a handout at the beginning of the user study. Participants were given the freedom to *ignore task steps if they were suspicious* about the resulting app activities.

We used two apps, a well-known voice note recording app called Google `Keep`, and a testing app (developed in our research laboratory) called `SimpleFilters`, which provides useful photo/video filtering functionality. However, `SimpleFilters` also attempts adversarial use of privacy-sensitive sensors, such as the microphone and the

Task Description (Randomized)	Attack Scenario	Authorization Requests (△ AWARE)	Attack Success Rate
TASK 1 : Take a picture with the smartphone's front camera by using the `SimpleFilters` app.	Operation Switching: The `SimpleFilters` app also starts recording audio via the smartphone's microphone instead of only taking a picture.	• Allow `SimpleFilters` to use the Front Camera and Microphone to Record Video when pressing ?	`Group1` (Install-Time): 100% `Group2` (First-Use): 93% `Group3` (Input-Driven): 100% `Group4` (Developer ID): 100% `Group5` (AC Gadgets): 0% `Group6` (`AWARE`): 0%
TASK 2 : Take a picture with the front camera by using the `SimpleFilters` app.	Bait-and-Context-Switch: We make the video camera widget appear in the photo capture window, with a camera preview, to trick the user into allowing `SimpleFilters` to record audio instead of just take a picture. □	• Allow `SimpleFilters` to use the Front Camera and Microphone to Record Video when pressing ?	`Group1` (Install-Time): 87% `Group2` (First-Use): 87% `Group3` (Input-Driven): 93% `Group4` (Developer ID): 87% `Group5` (AC Gadgets): 87% `Group6` (`AWARE`): 7%
TASK 3 : Take six consecutive pictures with the smartphone's front camera by using the `SimpleFilters` app.	Bait-and-Widget-Switch: Before the participants took the fifth picture, the `SimpleFilters` app replaced the camera widget with the video camera widget to enable video recording instead. The camera button was restored before the users took the sixth picture. □	• Allow `SimpleFilters` to use the Front Camera and Microphone to record Video when pressing ?	`Group1` (Install-Time): 87% `Group2` (First-Use): 87% `Group3` (Input-Driven): 93% `Group4` (Developer ID): 87% `Group5` (AC Gadgets): 87% `Group6` (`AWARE`): 7%
TASK 4 : Record a voice note using the `Keep` app.	Identity Spoofing: We let the participants select the `Keep` app from the app menu, however, we programmatically triggered the `SimpleFilters` app to hijack the on-screen activity and spoof the `Keep` app.	• Allow `SimpleFilters` to use the Microphone to Record Audio when pressing ?	`Group1` (Install-Time): 93% `Group2` (First-Use): 93% `Group3` (Input-Driven): 93% `Group4` (Developer ID): 47% `Group5` (AC Gadgets): 93% `Group6` (`AWARE`): 0%

Table 1: Experimental tasks for the laboratory-based user study to evaluate the effectiveness of AWARE in preventing four types of user interface attacks. The authorization requests reported in the third column are due to the fact that AWARE requests a new explicit authorization whenever a widget is presented within a new configuration. △ Participants from Groups6 received additional authorization requests because the widgets were presented within new configurations automatically identified by AWARE. □ The camera preview showed a static picture to simulate a photo capture during video recording.

camera. We explicitly asked the participants to install such apps on the testing platforms[10].

Before starting the experiment tasks, we asked the participants to familiarize themselves with Google `Keep`, by recording a voice note, and with `SimpleFilters`, by taking a picture and recording a video with the smartphone's front camera. *During this phase, participants were presented with authorization requests at first use of any of the privacy-sensitive sensors.*

All the user study participants in `Groups1-6` were asked to perform the four experimental tasks reported in Table 1. We designed such tasks to test the four types of attacks discussed in Section 3.1. During the experiment, the researchers recorded whether the participants commented noticing any suspicious activity in the apps' user interface, while a background service logged whether the designed attacks took place.

Experimental Results: 90 subjects participated and completed our experimental tasks. We randomly assigned 15 participants to each group. The last column of Table 1 summarizes the results for the four experimental tasks used in the laboratory-based user study. The third column of Table 1 reports additional authorization requests prompted only to subjects in `Group6` using the AWARE system. Indeed, only AWARE is able to identify the change in configuration (e.g., widget in a different activity window, widget linked to a different operation or different privacy-sensitive sensor) under which the experimental applications are attempting access to the privacy-sensitive sensors (i.e, microphone and cameras).

[10] `SimpleFilters` is providing interesting features to convince the users to install it and grant the required permissions.

Overall, we found that all the operation binding components used by AWARE were useful in helping the users in avoiding the four types of attacks. Moreover, AWARE outperformed alternative approaches conspicuously, while each experimental task revealed interesting facts.

In particular, the analysis of the subjects' responses to **TASK 1** revealed that the operation performed by the app was not visible to users in the alternative approaches, thus, leading them into making mistakes. The only exceptions were the subjects from `Group5` (AC Gadgets) because the `SimpleFilters` app was not in control of the requested operation due to the use of a system-defined access control gadget. Furthermore, all subjects from `Group6` (AWARE) did not authorize `SimpleFilters` to access the microphone. Thus, the *binding request* clearly identifying the operation requested by the app aided them in avoiding to be tricked into granting an unintended operation.

The analysis of the subjects' responses to **TASK2** and **TASK3** revealed that the users were successfully tricked by either switching the user interface configuration within which a widget is presented, or by changing the widget presented within the same configuration, thus, leading them into making mistakes. Interestingly, there was no noticeable improvement for subjects in `Group5` (AC Gadgets) where the system put in place some basic user interface configuration checks [39] for the presentation of the access control gadgets. The reason was that such basic checks were insufficient to identify the user interface modifications made by the malicious app when performing the attacks described in Table 1. Furthermore, one subject from `Group6` (AWARE) had mistakenly authorized `SimpleFilters` to carry out an unintended operation

App Category	App Name	Explicit User Authorizations		Total Operation Authorizations
		First-Use	AWARE	Avg. (s.d.)
Audio Recording	WhatsApp	3	6 (±1)	1,217 (±187)
	Viber	1	1 (±1)	88 (±9)
	Messenger	3	7 (±2)	2,134 (±176)
Photo and Video Recording	Facebook	2	4 (±1)	3,864 (±223)
	SilentEye	2	5 (±1)	234 (±20)
	Fideo	2	4 (±1)	213 (±23)
Screenshot Capture	Ok Screenshot	1	2 (±1)	49 (±8)
	Screenshot Easy	1	2 (±1)	76 (±7)
	Screenshot Capture	1	2 (±1)	64 (±4)
Screen Recording	REC Screen Recorder	2	3 (±1)	41 (±8)
	AZ Screen Recorder	2	4 (±2)	49 (±7)

	HappyShutter	1	1 (±0)	3 (±1)
	SnapClap	1	1 (±0)	4 (±2)

Table 2: Applications tested during the field-based user study, selected among the most popular apps from the Google Play store. The last column reports the average and standard deviation for the total number of operation authorizations automatically granted by AWARE after the user's explicit authorizations. The values are rounded to ease the presentation.

even after receiving a *binding request* clearly identifying the operation. This event hints to the fact that users may still make mistakes even after they are given an explicit authorization request specifying the actual app-requested operation. However, users who make mistakes have still control points provided by AWARE via the *security messages* and *logs*, which allow addressing such mistakes by means of retrospective actions (Section 7.1).

Lastly, the analysis of the subjects' responses to **TASK 4** revealed that the real identity of the app performing the operation was not visible to users in the alternative approaches, thus, leading them into making mistakes. However, no subjects from `Group6` (AWARE) authorized `SimpleFilters` to access the microphone. Therefore, the security message including the app's identity aided the user in identifying the attack.

8.1.2 Field-Based User Study

We performed a *field-based* user study to address the concern that AWARE may increase the decision overhead imposed on users as a result of finer-grained access control. We measured the number of explicit authorizations users had to make when interacting with AWARE under realistic and practical conditions. We also measured the total number of authorizations handled by AWARE via the operation binding cache mechanism that, transparently to users, granted previously authorized operations.

Experimental Procedures: Participants were asked to use, for a period of one week, a Nexus 5X smartphone running a *modified* version of the Android OS integrating the AWARE authorization framework. During this period, participants interacted with 21 popular apps (i.e., average number of apps users have installed on personal smartphones[11]) selected among the most popular apps with up to millions of downloads from the Google Play store. A description of the functionality provided by each app was given to participants. We then asked participants to explore each app and interact as they would normally do. Table 2 summarizes all the apps that were pre-installed on the smartphones for the field-based user study. The smartphones provided to participants were running a background service with a run-time log enabled, automatically restarted at boot time, to monitor the number of app activations, the number of widgets per app, and the number of decisions per app made by the users.

Experimental Results: 24 subjects participated and completed the field-based user study. Table 2 reports the average number of explicit authorizations performed by the participants when using AWARE, for each of the 21 apps used in the field-based user study. We compare them with the number of explicit authorizations that would be necessary if the first-use permission mechanism was used instead. The results show that 4 apps required the same number of explicit authorizations as for the first-use permission approach. For the remaining 17 apps, the number of decisions imposed to the users remains very modest. Over the 21 apps, an average of 2.28 additional explicit user authorizations are required per app.

Also, as expected, the number of explicit authorizations made by the users remained a constant factor compared to the number of operation authorization requests, automatically granted by AWARE (last column of Table 2), which instead grew linearly during the experiment period. Indeed, all the successive authorizations were automatically granted by AWARE.

8.2 Compatibility Analysis

We used the Compatibility Test Suite (CTS)[12], an automated testing tool, to evaluate the compatibility of AWARE with 1,000 existing apps selected from the Google Play store among the most downloaded apps[13].

The experiment took 13 hours and 28 minutes to complete, and AWARE passed 126,681 of the 126,686 executed tests. Two of the failed tests were minor compatibility issues due to attempted programmatic accesses to the platform's camera and microphone, respectively. The first failure was due to `HappyShutter`, an app that automatically takes pictures when the user smiles. The second failure was due to `SnapClap`, an app that automatically takes snapshots when the user claps. By default, AWARE blocks apps from programmatically accessing privacy-

[12] `https://source.android.com/compatibility/cts/`
[13] The Absolute 1,000 Top Apps for Android. `http://bestapps`

sensitive sensors by intercepting API calls from running apps and verifying if the user has indeed initiated the operation. These checks provide a high level of protection. Thankfully, as described in Appendix A, less than 1% of the 1,000 analyzed apps require programmatic access to privacy-sensitive sensors. However, we enhanced the original AWare prototype to notify the user the first time that a programmatic access is attempted by an app. Such notification asks the user for an explicit authorization to grant the app *persistent* access to the privacy-sensitive sensor. The user is notified of the inherent high risk and is discouraged from granting such type of permission. We evaluated such feature in our field-based study as reported in Table 2. From our experiments, we found that only 1 of the 24 users granted persistent access to the front camera for the HappyShutter app, whereas, only 2 other users granted persistent access to the microphone for the SnapClap app.

The other two failures were due to remote access to the smartphone's camera attempted by two apps, namely Lockwatch and Prey Anti-Theft, which can capture pictures with the front camera when someone tries to unlock the smartphone's screen with a wrong passcode. However, as described in Appendix A, we anticipated this issue and suggested the extension of the mechanisms provided by AWare also to the remote app components that enable remote access. To validate the proposed extension, we have developed a proof-of-concept app that receives remote commands for the initiation of video recording via the mobile platform's back camera. We successfully tested it on a Nexus 5X smartphone running the Android OS integrating AWare.

Lastly, AWare caused another spurious false positive with the Viber app, which attempted access to the cameras and microphone at each system reboot. AWare, identified the access without a user input action and blocked the operation after displaying an onscreen alert and logging the attempted operation. After analyzing the Viber app, we noticed that the app was testing the sensors (e.g., cameras and microphone) at each reboot. However, preventing the Viber app from using the sensors for testing purposes did not cause subsequent video or voice calls to fail. Thus, we believe that blocking such attempts is the desired behavior to prevent stealthy operations targeting privacy-sensitive sensors.

8.3 Performance Measurements

We measured the overall system performance overhead introduced by AWare by using a macrobenchmark that exercises the same 1,000 apps selected from the Google Play store via the Android UI/Application Exerciser Monkey[14]. Although software exercisers only achieve a low code coverage, they can create events that target specific high-level operations and generate the same sequence of events for comparison among several testing platforms. Indeed, the Monkey was configured to exercise apps by generating the exact same sequence of events and target all operations on privacy-sensitive sensors on both the Nexus 5X and Nexus 5 smartphones when running both the stock Android OS and the modified version of Android with AWare enabled. We open-sourced the exerciser script for the macrobanchmark on github.com[15].

The experimental results reported in the first row of Table 3 show that the average recorded system-wide performance overhead is 0.33% when measuring the additional time required by AWare to handle the operation binding construction, authorization and caching.

We also performed a microbenchmark to measure the overhead introduced by AWare while specifically handling access requests for operations targeting privacy-sensitive sensors, such as the camera to take photos and videos, the microphone to record audio, and the screen to capture screenshots; and to measured the overhead introduced for the authentication of app-specific widgets and their display contexts. The overhead for operations targeting privacy-sensitive sensors was calculated by measuring the time interval from the time a user input action was detected to the time the corresponding app request was granted/denied by AWare. Instead, the overhead for the widgets' and display contexts' authentication was calculated by measuring the time interval from the time the app provided the user interface to the Window Manager to the time such interface was rendered on the platform's screen by AWare. Table 3 reports the average time and stadard deviation over 10,000 operation/rendering requests, and the recorded overhead introduced by AWare.

Our measurements show that AWare performs efficiently, with the highest overhead observed being below 4%, as shown in Table 3. Notice, the experiment artificially stressed each operation with unusual workloads, and the overhead for a single operation/rendering is on the order of microseconds. Thus, the overhead is likely not to be noticeable by users.

Lastly, we recorded the average cache size used by AWare to store authorized operation bindings and the activity window call graphs, which was around 3 megabytes. Overall, we did not observe a discernible performance drop compared to the stock Android OS.

9 Related Work

Security-Enhanced Android [49] and *Android Security Framework* [5] deploy restrictive security models based on the *Android Permission* mechanism. However, such models mainly operate at the kernel level, therefore, do

not have the necessary information regarding higher level events required to associate app requests to user input actions for operations targeting privacy-sensitive sensors.

Input-Driven Access Control (IDAC) [33] mediates access to privacy-sensitive sensors based on the temporal proximity of user interactions and applications' access requests. However, if another application's request occurs first after a user input event and within the given temporal threshold, then the user input is directly used to authorize the other applications request, no matter what operation the application is requesting.

In *What You See is What They Get* [23] the authors propose the concept of a *sensor-access widget*. This widget is integrated into the user interface within an applications display and provides a real-time representation of the personal data being collected by a particular sensor to allow the user to pay attention to the application's attempt to collect the data. Also, a widget is a control point through which the user can configure the sensor to grant or deny the application access. Such widgets implement a so-called *Show Widget and Allow After Input and Delay* (SWAAID) policy. According to such policy, any active user input, upon notification, is implicitly considered as an indication that the user is paying attention to the widget. Thus, after a waiting period, the application is directly authorized to access the sensor. However, the delay introduced for the waiting time (necessary to allow explicit denial) may cause issues for time-constrained applications and may frustrate users.

User-Driven Access Control (UDAC) [39, 41] proposes the use of *access control gadgets* to prevent malicious operations from applications trying to access privacy-sensitive sensors without a user-initiated input. However, access control gadgets define the start points for when permissions are granted but do no provide an end limit for the sensor's use or control points (Section 7.1) to the users. Moreover, each sensor's usage should be limited to the particular configuration within which it has been authorized by the user and should be terminated when the application tries to continue using the sensor in a different configuration.

Researchers have also explored a *trusted output* solution to provide the user with an on-screen security indicator to convey the application developer's identity for the application with which the user is interacting [6]. Such a solution aids the user in identifying applications developed by trusted sources (i.e., Google Inc.), but it does not provide the user with the actual application identity or information about *when* and *how* such an application uses privacy-sensitive sensors.

Lastly, researchers have proposed a new operating system abstraction called *object recognizer* for Augmented Reality (AR) applications [22]. A trusted object recognizer takes raw sensor data as input and only exposes higher-level objects, such as a skeleton of a face, to applications. Then, a fine-grained permission system, based on the visualization of sensitive data provided to AR applications, is used to request permission at the granularity of recognizer objects. However, the proposed approach applies only to AR applications which are a very small fraction of the applications available on the app market. Indeed, among the 1,000 applications used for our evaluation, fewer than 1% of them provide AR features. All the other applications require full access to the raw data in order to function properly.

10 Conclusion

To prevent abuse of privacy-sensitive sensors by untrusted applications, we propose that user authorizations for operations on such sensors must be explicitly bound to user input events and how those events are obtained from the user (e.g., widgets and user interface configuration), called *operation bindings*. We design an access control mechanism that constructs operation bindings authentically and gains user approval for the application to perform operations only under their authorized operation bindings. By reusing such authorizations, as long as the application always requests that operation using the same user input event obtained in the same way, the number of explicit user authorizations can be reduced substantially. To demonstrate the approach, we implemented the AWARE framework for Android, an extension of the Android Middleware that controls access to privacy-sensitive sensors. We evaluated the effectiveness of AWARE for eliminating ambiguity in a laboratory-based user study, finding that users avoided mistakenly authorizing unwanted operations 93% of the time on average, compared to 19% on average when using proposed research methods and only 9% on average when using first-use or install-time authorizations. We further studied the compatibility of AWARE with 1,000 of the most-downloaded Android applications and demonstrated that such applications can operate effectively under AWARE while incurring less than 4% performance overhead on microbenchmarks. Thus, AWARE offers users an effective additional layer of defense against untrusted applications with potentially malicious

purposes, while keeping the explicit authorization overhead very modest in ordinary cases.

Appendices

A Compatibility Discussion

Here, we discuss how AWARE addresses special cases of applications' accesses to privacy-sensitive sensors.

Background Access: To enable background access, AWARE still uses the explicit authorization mechanism via the creation of a *binding request*. However, as soon as the application goes in the background, any on-screen security message used to notify ongoing operations over privacy-sensitive sensors is replaced with a periodic distinctive sound or a small icon on the system status bar (Section 7.1), if the platform's screen is on, or a hardware sensor-use indicator LED when the platform's screen goes off. These periodic notifications will be active until the user terminates the background activity explicitly. Our

notification mechanism leverages the concept introduced in previous work [23] and extends the mechanism used in modern operating systems for location.

Remote Access: Remote commands are instantiated by the user via an application's user interface displayed on the remote terminal, thus, the AWARE mechanisms are also applicable to the widgets displayed by such remote user interfaces. Therefore, as long as remote commands are coming from AWARE-enabled remote platforms, AWARE may pair the AWARE modules running on the two platforms by creating a Secure Socket Layer (SSL) connection to allow secure and remote control of the privacy-sensitive sensors by the user.

Programmatic Access: There are very rare cases of legitimate applications requiring programmatic access to privacy-sensitive sensors, as shown by our large-scale compatibility analysis reported in Section 8.2. Examples are anti-theft applications that capture pictures with the front camera in the attempt to identify the thief when trying to unlock the screen by guessing the passcode. Or even, an application that uses the camera to take a picture when the user smiles. However, only trusted software (as part of the operating system) should be allowed to perform such operations to be inline with our research objective of ensuring a secure use of privacy-sensitive sensors.

Hardware Peripheral Access: An application may use hardware peripherals (e.g., Bluetooth® remotes, selfie sticks, headphone jacks or built-in hardware buttons) as user interface. However, hardware peripherals are typically managed by a trusted software component, i.e., the Input Manager, and mandatory access control mechanisms (i.e., SELinux [31]) are adopted to ensure that peripheral driver files are not accessible by untrusted applications. By monitoring input events received by the Input Manger, AWARE can identify user input events coming from such hardware peripherals and bind them with the corresponding operation requests from applications.

Access through Voice Commands: AWARE enables personal assistant services that recognize voice commands, such as Apple's Siri, Google Now, and Windows' Cortana, by leveraging recent work that prevents untrusted application from exploiting voice commands by controlling access over audio channels created by applications and system services through the platform's microphone and speaker [35].

B UI Elements' Features Analysis

We performed a large-scale analysis by using the 10,000 most popular application from the Google Play store, Ubuntu Software Center and Chrome Extensions to evaluate how frequently the widgets' and activity windows' features used by AWARE change among subsequent rendering events on the platform screen. We rendered a widget and its activity window 50 times under different system settings and configurations to cause the a widget or its activity window to be rendered in different ways (i.e., screen orientation, concurrent activity windows, etc.).

N/A	**100%**	**100%**	**100%**	**99%**	**99%**	**99%**

Table 5: Study of fixed features for GUI activity window objects in X Window Manager, Aura (Chrome Browser) Window Manager (in *italic*), and Android Window Manager (in **bold**). The percentage values indicate the times the features did not change when the same window was rendered by the Window Manager.

C Discussion on Activity Windows

For the ease of presentation we used the general case where a widget appears within an activity window. However, desktop and web operating system may allow more sophisticated user interfaces, or GUI scaling for different screen sizes. Thus, we recognize that an activity window could be embedded inside another activity window and such innermost activity window could be reused across several activity windows even in a hierarchy. Therefore, AWARE does not limit the use of nested activity windows or prohibit activity window reuse but rather ensures that the context is defined by the entire hierarchy of nested activity windows. As a consequence, an application may be authorized by the user to use a widget in a nested activity window X in the outer activity window Y, but this authorization does not extend for another outer activity window Z.

6thSense: A Context-aware Sensor-based Attack Detector for Smart Devices

Abstract

Sensors (e.g., light, gyroscope, accelerometer) and sensing enabled applications on a smart device make the applications more user-friendly and efficient. However, the current permission-based sensor management systems of smart devices only focus on certain sensors and any App can get access to other sensors by just accessing the generic sensor API. In this way, attackers can exploit these sensors in numerous ways: they can extract or leak users' sensitive information, transfer malware, or record or steal sensitive information from other nearby devices. In this paper, we propose 6thSense, a context-aware intrusion detection system which enhances the security of smart devices by observing changes in sensor data for different tasks of users and creating a contextual model to distinguish benign and malicious behavior of sensors. 6thSense utilizes three different Machine Learning-based detection mechanisms (i.e., Markov Chain, Naive Bayes, and LMT) to detect malicious behavior associated with sensors. We implemented 6thSense on a sensor-rich Android smart device (i.e., smartphone) and collected data from typical daily activities of 50 real users. Furthermore, we evaluated the performance of 6thSense against three sensor-based threats: (1) a malicious App that can be triggered via a sensor (e.g., light), (2) a malicious App that can leak information via a sensor, and (3) a malicious App that can steal data using sensors. Our extensive evaluations show that the 6thSense framework is an effective and practical approach to defeat growing sensor-based threats with an accuracy above 96% without compromising the normal functionality of the device. Moreover, our framework costs minimal overhead.

1 Introduction

Smart devices such as smartphones and smartwatches have become omnipresent in every aspect of human life. Nowadays, the role of smart devices is not limited to making phone calls and messaging only. They are integrated into various applications from home security to health care to military [18, 60]. Since smart devices seamlessly integrate the physical world with the cyber world via their sensors (e.g., light, accelerometer, gyroscope, etc.), they provide more efficient and user-friendly applications [37, 41, 85, 55, 48].

While the number of applications using different sensors [38] is increasing and new devices offer more sensors, the presence of sensors have opened novel ways to exploit the smart devices [76]. Attackers can exploit the sensors in many different ways [76]: they can trigger an existing malware on a device with a simple flashlight [28]; they can use a sensor (e.g., light sensor) to leak sensitive information; using motion sensors such as accelerometer, and gyroscope, attackers can record or steal sensitive information from other nearby devices (e.g., computers, keyboards) or people [10, 87, 26, 42]. They can even transfer a specific malware using sensors as a communication channel [76]. Such *sensor-based* threats become more serious with the rapid growth of Apps utilizing many sensors [6, 2].

In fact, these sensor-based threats highlight the flaws of existing sensor management systems used by smart devices. Specifically, Android sensor management system relies on permission-based access control, which considers only a few sensors (i.e., microphone, camera, and GPS)[1]. Android asks for access permission (i.e., with a list of permissions) only while an App is being installed for the first time. Once this permission is granted, the user has no control over how the listed sensors and other sensors (not listed) will be used by the specific App. Moreover, using some sensors is not considered as a violation of security and privacy in Android. For instance, any App is permitted to access to motion sensors by just accessing the *sensor* API. Access to motion sensors is not controlled in Android.

[1] IOS, Windows, and Blackberry also have permission-based sensor management systems. In this work, we focus on Android.

Existing studies have proposed enhanced access control mechanisms for some of the sensors, but these enhancements do not cover all the sensors of a smart device [69]. Some proposed solutions introduced trusted paths on top of the existing security mechanism for controlling information flow between sensors and Apps, but these are also App-specific solutions and depend upon explicit user consent [32, 61]. Thus, introducing additional permission controls for sensors of a smart device will not mitigate the risk of all sensor-based threats as they are App specific and address only data leakage risks. Some attacks may not abuse sensors directly, instead, they may use sensors as side channels to activate another malware [34]. Albeit useful, existing security schemes overlook these critical threats which directly impact the security and privacy of the smart device ecosystem. Moreover, although sensors on smart devices seem to work independently from each other, a task or activity on a smart device may activate more than one sensor to accomplish the task. Hence, it is necessary to secure all the different sensors [5] on a smart device and consider the context of the sensors in building any solution against sensor-based threats.

In order to address the sensor-based threats, in this paper, we present a novel intrusion detection (IDS) framework called *6thSense*, a comprehensive security solution for sensor-based threats for smart devices. The proposed framework is a *context-aware IDS* and is built upon the observation that for any user activity or task (e.g., texting, making calls, browsing, driving, etc.), a different, but a specific set of sensors becomes active. In a context-aware setting, the 6thSense framework is aware of the sensors activated by each activity or task. 6thSense observes sensors data in real time and determines the current use context of the device according to which it concludes whether the current sensor use is malicious or not. 6thSense is context-aware and correlates the sensor data for different user activities (e.g., texting, making calls, browsing, driving, etc.) on the smart device and learns how sensors' data correlates with different activities. As a detection mechanism, 6thSense observes sensors' data and checks against the learned behavior of the sensors. In 6thSense, the framework utilizes several different Machine Learning-based detection mechanisms to catch sensor-based threats including Markov Chain, Naive Bayes, and LMT. In this paper, we present the design of 6thSense on an Android smartphone because of its large market share [7] and its rich set of sensors. To evaluate the efficiency of the framework, we tested it with data collected from real users (50 different users, nine different typical daily activities [3]). We also evaluated the performance of 6thSense against three different sensor-based threats and finally analyzed its overhead. Our evaluation shows that 6thSense can detect sensor-based attacks with an accuracy and F-Score over 96%. Also, our evaluation shows a minimal overhead on the utilization of the system resources.

Contributions: In summary, the main contributions of this paper are threefold—

- *First*, the design of 6thSense, a context-aware IDS to detect sensor-based threats utilizing different machine learning based models from Markov Chain to Naive Bayes to LMT.
- *Second*, the extensive performance evaluation of 6thSense with real user experiments over 50 users.
- *Third*, testing 6thSense against three different sensor-based threats.

Organization: The rest of the paper is organized as follows: we give an overview of sensor-based threats and existing solutions in Section 2. In section 3, we briefly discuss the *Android's* sensor management system. Adversary model and design facts and assumptions for 6thSense are briefly discussed in Section 4. Different detection techniques used in our framework are described in Section 5. In Sections 6 and 7, we provide a detailed overview of 6thSense including its different components and discuss its effectiveness by analyzing different performance metrics. Finally, we discuss features and limitations and conclude this paper in Sections 8 and 9, respectively.

2 Related Work

Sensor-based threats [76] on mobile devices have become more prevalent than before with the use of different sensors in smartphones such as user's location, keystroke information, etc. Different works [73] have investigated the possibility of these threats and presented different potential threats in recent years. One of the most common threats is keystroke inference in smartphones. Smartphones use on-screen QWERTY keyboard which has specific position for each button. When a user types in this keyboard, values in smartphone's motion sensor (i.e., accelerometer and gyroscope) change accordingly [16]. As different keystrokes yield different, but specific values in motion sensors, typing information on smartphones can be inferred from an unauthorized sensor such as motion sensor data or motion sensor data patterns collected either in the device or from a nearby device can be used to extract users' input in smartphones [9, 66, 52]. The motion sensor data can be analyzed using different techniques (e.g., machine learning, frequency domain analysis, shared-memory access, etc.) to improve the accuracy of inference techniques such as [12, 53, 81, 46, 58, 47]. Another form of

keystroke inference threat can be performed by observing only gyroscope data. Smartphones have a feature of creating vibrations while a user types on the touchpad. The gyroscope is sensitive to this vibrational force and it can be used to distinguish different inputs given by the users on the touchpad [51, 15, 44]. Recently, ICS-CERT also issued an alert for accelerometer-based attacks that can deactivate any device by matching vibration frequency of the accelerometer [2, 1, 70]. Light sensor readings also change while a user types on the smartphone; hence, the user input in a smartphone can be inferred by differentiating the light sensor data in normal and typing modes [71]. The light sensor can also be used as a medium to transfer malicious code and trigger message to activate malware [28, 76]. The audio sensor of a smartphone can be exploited to launch different malicious attacks (e.g., information leakage, eavesdropping, etc.) on the device. Attackers can infer keystrokes by recording tap noises on touchpad [24], record conversation of users [63], transfer malicious code to the device [73, 76], or even replicate voice commands used in voice-enabled different Apps like *Siri*, *Google Voice Search*, etc. [21, 39]. Modern smartphone cameras can be used to covertly capture screenshot or video and to infer information about surroundings or user activities [68, 43, 67]. GPS of a smartphone can be exploited to perform a false data injection attack on smartphones and infer the location of a specific device [75, 19].

Solutions for sensor-based threats: Although researchers identified different sensor-based threats in recent years, no complete security mechanism has been proposed that can secure sensors of a smart device. Most of the proposed security mechanisms for smart devices are related to anomaly detection at the application level [78, 74, 80, 22] which are not built with any protection against sensor-based threats. On the other hand, different methods of intrusion detection have been proposed for wireless sensor networks (WSN) [72, 30, 86, 23, 59], but they are not compatible with smart devices. Xu et al. proposed a privacy-aware sensor management framework for smartphones named *Semadroid* [82], an extension to the existing sensor management system where users could monitor sensor usage of different Apps and invoke different policies to control sensor access by active Apps on a smartphone. Petracca et al. introduced *AuDroid*, a SELinux-based policy framework for smartphones by performing behavior analysis of microphones and speakers [57]. AuDroid controls the flow of information in the audio channel and notifies users whenever an audio channel is requested for access. Jana et al. proposed *DARKLY*, a trust management framework for smartphones which audits applications of different trust levels with different sensor access permissions [31]. Darkly scans for vulnerability in the source code of an application and try to modify the run-time environment of the device to ensure the privacy of sensor data.

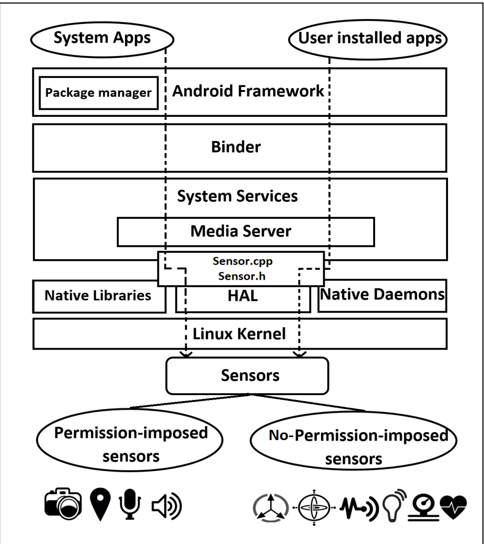

Figure 1: Android Sensor Management Architecture

Differences from the existing solutions: Though there is no direct comparable work to compare 6thSense with, differences between existing solutions and our framework can be noted as follows. The main limitation of Semadroid [82] is that the proposed solution is only tested against a similar type of attack scenario (information leakage by a background application). Semadroid also does not provide any extensive performance evaluation for the proposed scheme. Finally, this work depends on user permissions to fully enforce an updated policy on the sensor usage which is vulnerable as users might unknowingly approve the sensor permissions for malicious Apps. In another prior work Darkly [31], the proposed framework is not tested against any sensor-based threats. More recent work Audroid presented a policy enforced framework to secure only the audio channels of a smart device. Albeit useful, similar to the others, this work does not consider other sensor-based threats, either. *Compared to these prior works, 6thSense provides a comprehensive coverage to all the sensors in a smart device and ensures security against three different types of sensor-based threats with high accuracy.*

3 Background: Sensor Management in Smart Devices

Present versions of Android, iOS, or Blackberry do not comprise of any security mechanism to manage the information flow from sensors or among them. For example, any App can get access to motion sensors by just accessing *sensor* API. One task may need more than one sensor,

but protecting only one sensor is not a viable design. The lack of ability to secure the information flow between the sensors and Apps and a holistic view into the utilization of sensors can lead to different malicious scenarios like information leakage, eavesdropping, etc.

In our work, we focus on Android because of its open-source nature. In Figure 1, we present how Android handles access to different sensors by Apps (installed by the user) and system Apps (installed automatically by Android). Apps access to sensors by sending requests via Software Development Kit (SDK) API platform which then registers the App to a corresponding sensor [45]. If more than one App tries to access the same sensor, the SDK API runs a multiplexing process which enables different Apps to be registered in the same sensor. Hardware Abstraction Layer (HAL) works as an interface to bind the sensor hardware with the device drivers in Android. HAL has two parts: *Sensors.h* works as HAL interface and *Sensors.cpp* works as the HAL implementation. Through the HAL library, different applications can communicate with the underlying Linux kernel to read and write files associated with sensors. For most of the sensors, no permission is needed to access these files. For *permission-imposed sensors* (i.e., camera, microphone, and GPS), a permission is explicitly needed from the user to ensure file access to a specific App. This user permission is declared inside the *AndroidManifest.xml* file of an App and once the user accepts the permission, that App can have access to the corresponding sensor and other *no-permission imposed sensors* even without any explicit approval from the users. This lack of security in sensor access can lead to different malicious attacks on a device.

4 Adversary Model and Assumptions

In this section, we discuss different threats that may use sensors to execute malicious activities on a smart device. Different design assumptions are also explained in this section.

4.1 Adversary Model

For this work, we consider the following sensor-based threats similar to [76]:

- ***Threat 1*-Triggering a malicious App via a sensor.** A malicious App can exist in the smart device which can be triggered by sending a specific sensory pattern or message via sensors.

- ***Threat 2*-Information leakage via a sensor.** A malicious App can exist in the device which can leak information to any third party using sensors.

- ***Threat 3*-Stealing information via a sensor.** A malicious App can exist in the device which can exploit the sensors of a smart device and start stealing information after inferring a specific device mode (e.g., sleeping).

In this paper, we cover these three types of malicious sensor-based threats. We also note that to build our adversary model, we consider any component on a smart device that interacts with the physical world as a sensor [57]. In section 7, we show how 6thSense defends against these threats.

4.2 Design Assumptions and Features

In designing a comprehensive security scheme like 6thSense for sensor-based threats, we note the following design assumptions and features:

- ***Sensor co-dependence:*** A sensor in a smart device is normally considered as an independent entity on the device. Thus, one sensor does not know what is happening in another sensor. However, in this work, we consider sensors as co-dependent entities on a device instead of independent entities. The reason for this stems from the fact that for each user activity or task on a smart device, a specific set of sensors remains active. For example, if a user is walking with a phone in hand, motion sensors (i.e., gyroscope, accelerometer), the light sensor, GPS will be active. On the contrary, if the user is walking with the phone in the pocket or bag, instead of the light sensor, the proximity sensor will remain active. Thus, a co-dependent relationship exists between sensors while performing a specific task. Each activity uses different, but specific set of sensors to perform the task efficiently. Hence, one can distinguish the user activity by observing the *context of the sensors* for a specific task. 6thSense uses the context of all the sensors to distinguish between normal user activities and malicious activities. In summary, *sensors in a smart device are individually independent, but per activity-wise dependent* and 6thSense considers the context of the activities in its design.

- ***Adaptive sensor sampling:*** Different sensors have different sampling frequencies. To monitor all the sensor data for a specific time, a developed solution must consider and sample the sensor data correctly. Our proposed framework considers sampling the sensor data over a certain time period instead of individual sensor frequencies which mitigates any possible error in processing of data from different sensors.

- ***Faster computation:*** Modern high precision sensors on smart devices have high resolution and sampling rate. As a result, sensors provide large volume of data even for a small time interval. A solution for sensor-based threats should quickly process any large data from different sensors in real time while ensuring a high detection rate. To address this, we use different machine learning algorithms which are proven simple and fast techniques [11, 62].

- ***Real-time monitoring:*** 6thSense provides real-time monitoring to all the sensors which mitigates the possibility of data tempering or false data injection on the device.

5 Detection Techniques: Theoretical Foundation

In this section, we describe the details of the detection techniques used in 6thSense from a theoretical perspective.

For the context-aware IDS in 6thSense, we utilize several different machine learning-based techniques including Markov Chain [13], Naive Bayes [50] and alternative set of ML algorithms (e.g., PART, Logistic Function, J48, LMT, Hoeffding Tree, and Multilayer Perception) to differentiate between normal behavior from malicious behavior on a smart device. The main advantage of using Markov Chain model is that it is easy to build the model from a large dataset and computational requirements are modest which can be met by resource-limited devices. As smart devices have less processing speed, a Markov Chain-based approach can work smoothly in the context of sensor data analysis. On the other hand, Naive Bayes technique is chosen for its fast computation rate, small training dataset requirement, and ability to modify it with new training data without rebuilding the model from scratch. Other ML techniques are also common in malware detection because of higher accuracy rate. A brief discussion of these approaches in the context of 6thSense is given below. The efficacy of these different approaches utilized in 6thSense is analyzed in Section 7.

5.1 Markov Chain-Based Detection

A Markov Chain-based detection model can be described as a discrete-time stochastic process which denotes a set of random variables and defines how these variables change over time. Markov Chain can be applied to illustrate a series of events where and what state will occur next depends only on the previous state. In 6thSense, a series of events represents user activity and state represents sensor conditions (i.e., sensor values, on/off status) of the sensors in a smart device. We can represent the probabilistic condition of Markov Chain as in Equation 1 where X_t denotes the state at time t [35]:

$$\begin{aligned} P(X_{t+1} = x | X_1 = x_1, X_2 = x_2 ..., X_t = x_t) = \\ P(X_{t+1} = x | X_t = X_t), \\ when,\ P(X_1 = x_1, X_2 = x_2 ..., X_t = x_t) > 0 \end{aligned} \quad (1)$$

In 6thSense, we observe the changes of the conditions of a set of sensors as a variable which changes over time. The condition of a sensor indicates whether the sensor value is changing or not from a previous sensor value in time. As such, S denotes a set which represents current conditions of n number of sensors. So, S can be represented as follows.

$$\begin{aligned} S = \{S_1, S_2, S_3, ..., S_n\}, \\ S_1, S_2, S_3, ..., S_n = 0\ or\ 1 \end{aligned} \quad (2)$$

For 6thSense, we use a modified version of the general Markov Chain. Here, instead of predicting the next state, 6thSense determines the probability of a transition occurring between two states at a given time. In 6thSense, the Markov Chain model is trained with a training dataset collected from real users and the transition matrix is built accordingly. Then, 6thSense determines conditions of sensors for time *t* and *t+1*. Let us assume, *a* and *b* are a sensor's state in time *t* and *t+1*. 6thSense looks up for the probability of transition from state *a* to *b* which can be found by looking up in the transition matrix, *P* and calculating *P(a,b)*. As the training dataset consists sensor data from benign activities, we can assume that, if transition from state *a* to *b* is malicious, the calculated probability from transition matrix will be zero. Details of this Markov Chain-based detection model in 6thSense are given in Appendix A1.

5.2 Naive Bayes Based Detection

Naive Bayes model is a simple probability estimation method which is based on Bayes' method. The main assumption of the Naive Bayes detection is that the presence of a particular sensor condition in a task/activity has no influence over the presence of any other feature on that particular event. The probability of each event can be calculated by observing the presence of a set of specific features.

6thSense considers users' activity as a combination of n number of sensors. Assume X is a set which represents current conditions of n number of sensors. We consider that conditions of sensors are conditionally independent (See Section 4.2), which means a change in one sensor's working condition (i.e., on/off states) has no effect over a change in another sensor's working condition.

As explained earlier, the probability of executing a task depends on the conditions of a specific set of sensors. So, in summary, although one sensors' condition does not control another sensor's condition, overall the probability of executing a specific task depends on all the sensors' conditions. As an example, if a person is walking with his smartphone in his hand, the motion sensors (accelerometer and gyroscope) will change. However, this change will not force the light sensor or the proximity sensor to change its condition. Thus, sensors in a smartphone change their conditions independently, but execute a task together. We can have a generalized model for this context-aware detection [49] as follows:

$$p(X|c) = \prod_{i=1}^{n} p(X_i|c) \tag{3}$$

Detailed description of this Naive Bayes model in 6thSense is given in Appendix A2.

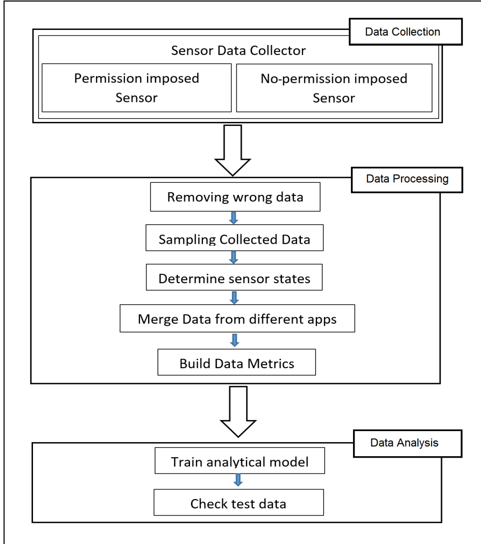

Figure 2: Overview of 6thSense.

5.3 Alternative Detection Techniques

In addition to Markov Chain and Naive Bayes models above, there are other machine learning algorithms (such as PART, Logistic Function, J48, LMT, Hoeffding Tree, and Multilayer Perception) that are very popular for anomaly detection frameworks because of their faster computation ability and easy implementation feature. In the alternative detection techniques, we used four types of ML-based classifier to build an analytical model for 6thSense. The following briefly discusses these classifiers and our rationale to include them.

Rule-based Learning. Rule-based ML works by identifying a set of relational rules between attributes of a given dataset and represents the model observed by the system [25]. The main advantage of the rule-based learning is that it identifies a single model which can be applied commonly to any instances of the dataset to make a prediction of outcome. As we train 6thSense with different user activities, the rule-based learning provides one model to predict data for all the user activities which simplifies the framework. For 6thSense, we chose, *PART* algorithm for the rule-based learning.

Regression Model. Regression model is widely used in data mining for its faster computation ability. This type of classifier observes the relations between dependent and independent variables to build a prediction model [20, 79]. For 6thSense, we have a total 11 attributes where we have one dependent variable (device state: malicious/benign) and ten independent variables (sensor conditions). Regression model observes the change in the dependent variable by changing the values of the independent variables and build the prediction model. We use the logistic regression model in 6thSense, which performs with high accuracy against conventional Android malware [65].

Neural Network. Neural network is another common technique that is being adapted by researchers for malware detection. In neural network techniques, the relation between attributes of dataset is compared with the biological neurons and a relation map is created to observe the changes for each attribute [40]. We chose *Multilayer Perceptron* algorithm for training the 6thSense framework as it can distinguish relationships among non-linear dataset.

Decision Tree. Decision tree algorithms are predictive models where decision maps are created by observing the changes in one attribute in different instances [84]. These types of algorithms are mostly used in a prediction model where output can have a finite set of values. For 6thSense, we utilized and tested three different decision tree algorithms (*J48*, *LMT (Logistic Model Tree)*, and *Hoeffding tree*) to compare the outcome of our framework.

6 6thSense Framework

In this section, we provide a detailed overview of our proposed contextual behavior IDS framework, 6thSense, for detecting sensor-based threats on smart devices. As illustrated in Figure 2, 6thSense has three main phases: (1) data collection, (2) data processing, and (3) data analysis. In the data collection phase, we use a custom Android application to collect the sensor data for different user activities and the collected sensor data are then processed in the data processing phase. Note that in 6thSense some sensors provide discrete values as data (e.g., accelerometer, gyroscope, light sensor, etc.) while

other sensors provide their on-off state as sensor data (e.g., microphone, speaker, etc.). In phase 3, the collected data is fed into detection models and the end result indicates whether the current state of the device is malicious or not. The following sub-sections briefly describe these three phases.

6.1 Data Collection Phase

In this phase, 6thSense collects data from different sensors of a smart device. There can be multiple sensors in a smart device. We chose nine sensors in total to identify different user activities using a sensor-rich Android device. The sensors selected are accelerometer, gyroscope, light sensor, proximity sensor, GPS, audio sensor (microphone and speaker), camera, and headphone. 6thSense does not consider all the other sensors available in the device because all typical user activities do not affect all the sensor values. For example, the gravity sensor value does not change effectively while talking or walking with the phone. The chosen sensors are then categorized into two following categories.

- *No-permission-imposed sensors:* No-permission-imposed sensors can be defined as sensors that do not need any user permission explicitly to be accessed by an App. For 6thSense, we chose four no-permission imposed sensors (i.e., accelerometer, gyroscope, light, proximity sensors). We can also refer these sensors as data-oriented sensors in the context of 6thSense because values provided by these sensors need to be observed to infer user activities. For example, accelerometer's and gyroscope's values change with motion and they give values on *X, Y,* and *Z* axes. These values change along with the motion in different axes. To detect whether a sensor is activated or not for a specific activity, one needs to observe values of these sensors.

- *Permission-imposed sensors:* Permission-imposed sensors are those which need user permission to be accessed by an App. For 6thSense, we chose five permission-imposed sensors to build the context-aware model (camera, microphone, GPS, speaker, and headset). The conditions of these sensors can be represented by their logical states (on/off status) for different user activities. Hence, we also referred to these sensors as logic-oriented sensors in the context of 6thSense. For example, camera has only two values to identify users' activity: on and off. So, it can be represented with 0 or 1 to detect if the camera is on or off correspondingly.

To collect the data and logical values from sensors, we built a custom Android App and 6thSense used this in the data collection phase. In Android, this App uses *sensoreventlistener* API to log numerical values of the data-oriented sensors. On the other hand, the App determines the state of the sensor and logs 0 or 1 if the sensor is on or off, respectively. This App uses the user permission access to use the microphone, GPS, and camera to record the working condition of these sensors. For GPS, we consider two datasets - either GPS is turned on or not and either location is changing or not. In total, six different logic state information for five aforementioned permission-imposed sensors are collected by this App.

Note that we chose different typical daily human activities [4] that involve the smart device to build our contextual model. These activities include walking (with phone in hand and pocket), talking, interacting (playing games, browsing, listening to music), video calling, driving (as driver and passenger). Furthermore, the number of activities is configurable in 6thSense and is not limited to aforementioned examples. In the evaluation of 6thSense, we chose a total of nine typical daily activities as they are considered as common user activities for a smart device [4]. We collect these data using the App for different users to train the 6thSense framework which is then used to distinguish the normal sensor behavior from the malicious behavior. In summary, the aforementioned App collects data from nine different sensors for nine typical user activities. We observe sensor state (combination of working conditions (i.e., values, on/off status) of nine different sensors) in a per second manner for each user activity. Each second of data for user activity corresponds to 1024 state information from nine different sensors.

6.2 Data Processing Phase

After the data collection, in the second phase of the framework, we organize the data to use in the proposed IDS framework. As different sensors have different frequencies on the smart device, the total number of readings of sensors for a specific time period is different. For example, the accelerometer and gyroscope of *Samsung Galaxy S5* have a sampling frequency of approximately 202 Hz while the light sensor has a sampling frequency of 5.62 Hz. Thus, the data collected in Phase 1 needs to be sampled and reorganized. 6thSense observes the change in the sensor condition in each second to determine the overall state of our device and from this per second change, 6thSense determines the activity of users. For this reason, 6thSense takes all the data given by a single sensor in a second and calculates the average value of the sensor reading. This process is only applicable for the data oriented sensors as mentioned earlier. Again, the data collected from the App is numerical value given by the sensor. However, for the detection model, we only

Sensor type	Name	Model	Specification
No-permission imposed sensors	Accelerometer	MPU6500 Acceleration Sensor	19.6133 m/s^2, 203.60 Hz, 0.25 mA
	Gyroscope	MPU6500 Gyroscope Sensor	8.726646 rad/s, 203.60 Hz, 6.1 mA
	Light Sensor	TMG399X RGB Sensor	600000 lux, 5.62 Hz, 0.75 mA
	Proximity Sensor	TMG399X proximity sensor	8V, 0.75 mA
Permission-imposed sensors	Camera	Samsung S5K2P2XX	12 megapixels, 30 fps, 4.7 mA
	Microphone	Qualcomm Snapdragon 801 Processor built in microphone	86 dB, .75 mA
	Speaker	Qualcomm Snapdragon 801 Processor built in speaker	110 dB, 1 mA

Table 1: Sensor list of Samsung Galaxy S5 Duo used in experiment.

consider the condition of the sensors. 6thSense observes the data collected by the aforementioned App and determines whether the condition of sensors is changing or not. If the sensor value is changing from the previous value in time, 6thSense represents the sensor condition as 1 and 0 otherwise. The logic state information collected from the sensors need to be reorganized, too as these data are merged with the data collected from the collected values from the other sensors to create an input matrix. The sampling frequency of the logical state detection is 0.2 Hz which means in every five seconds the App generates one session of dataset. We consider the condition of the sensors to be the same over this time period and organize the data accordingly. The reorganized data generated from the aforementioned App are then merged to create the training matrices.

6.3 Data Analysis Phase

In the third and final phase, 6thSense uses different machine learning-based detection techniques introduced in the previous section to analyze the data matrices generated in the previous phase.

For the Markov Chain-based detection, we use 75% of the collected data to train 6thSense and generate the transition matrix. This transition matrix is used to determine whether the transition from one state to another is appropriate or not. Here, state refers to generic representation of all the sensors' conditions on a device. For testing purposes we have two different data set — basic activities or trusted model and malicious activities or threat model. The trusted model consists of 25% of the collected data for different user activities. We test the trusted model to ensure the accuracy of the 6thSense framework in detecting benign activities. The threat model is built from performing the attack scenarios mentioned in Section 4. We calculate the probability of a transition occurring between two states at a given time and accumulate the total probability to distinguish between normal and malicious activities.

To implement the Naive Bayes-based detection technique, we use the training sessions to define different user activities. In 6thSense, we have nine typical user activities in total as listed in Table 2. We use groundtruth user data to define these activities. Using the theoretical foundation explained in Section 5, we calculate the probability of a test session to belong to any of these defined activities. As we consider one second of data in each computational cycle, we calculate the total probability up to a predefined configurable time interval (in this case five minutes). This calculated probability is used to detect malicious activities from normal activities. If the computed probability for all the known benign activities is not over a predefined threshold, then it is detected as a malicious activity.

For the other alternative machine-learning-based detection techniques, we used WEKA, a data mining tool which offers data analysis using different machine learning approaches [64, 27]. Basically, WEKA is a collection of machine learning algorithms developed at the University of Waikato, New Zealand, which can be directly applied to a dataset or can be integrated with a framework using JAVA platform [56]. WEKA offers different types of classifier to analyze and build predictive model from given dataset. We use 10 fold cross-validation method to train and test 6thSense with different ML techniques in Section 7.

7 Performance Evaluation of 6thSense

In this section, we evaluate the efficiency of the proposed context-aware IDS framework, 6thSense, in detecting the sensor-based threats on a smart device. We test 6thSense with the data collected from different users for benign activities and adversary model described in Section 4. As discussed earlier, 6thSense considers three sensor-based threats: (1) a malicious App that can be triggered via a light or motion sensors, (2) a malicious App that can leak information via audio sensor, and (3) a malicious App that steals data via camera. Furthermore, we measured the performance impact of 6thSense on the device and present a detailed results for the efficiency of

the 6thSense framework. Finally, we discuss the performance overhead of the framework in this section.

7.1 Training Environment

In order to test the effectiveness of 6thSense, we implemented it on a sensor-rich Android-based smartphone. However, our framework would also efficiently work in another smart device such as smartwatch. In the evaluations, we used *Samsung Galaxy S5 Duos* as a reference Android device to collect sensor data for different typical user activities. We chose this Android device as *Samsung* currently holds approximately 20.7% of total marketshare of smartphone [8] and provides a rich set of sensors. A list of sensors of *Samsung Galaxy S5 Duos* is given in Table 1. As discussed earlier, we selected 9 different typical user activities or tasks to collect user data. These are typical basic activities with smartphones that people usually do in their daily lives [3]. The user activities/tasks are categorized in two categories as generic activities and user related activities.

Generic activities are the activities in which the sensor readings are not affected by the smartphone users. Sleeping, driving with the phone using GPS as a navigator, and driving with phone in pocket are three generic activities that we considered in this work. Basically, in the generic activities, sensors' data are not affected by different users since the smart phone is not in contact with the user or user is not directly interacting with the phone. For *user-related activities*, in which the sensor readings may be affected by the device user, we identified six different activities including walking with the phone in hand, playing games, browsing, and making voice calls and video calls.

6thSense was tested by 50 different individuals aged from 18 to 45 while the sensor data was collected. We note that our study with human subjects was approved by the appropriate Institutional Review Board (IRB) and we followed all the procedures strictly in our study. Each participant received some monetary compensation for participating in our experiments. To ensure privacy and anonymity, we used fake user IDs rather than any personal information. We collected 300 sets of data for six user-related activities where each dataset comprised of 5 minutes long data from the selected nine sensors mentioned in Section 6. We also collected three sets of data for each general activity. We asked the different users to perform the same activity to ensure the integrity for different tasks. Note that each five minute of data collected for user related and generic activities corresponds to 300 events with 1024 different states. Here, states represent a combination of conditions (i.e., values, on/off status) of nine different sensors and events represent user activities per second. So, a total of 307,200 different event-state information were analyzed by 6thSense.

For the malicious dataset, we created three different attack scenarios considering the adversary model mentioned in Section 4. For Threat 1, we developed two different Android Apps which could be triggered using the light sensor and motion sensors on the smartphone. To perform the attack described in Threat 2, we developed a malware that could record conversations as audio clips and playback after a specific time to leak the information. This attack scenario included both the microphone and speaker on the smartphone. For Threat 3, we developed a malicious App that could scan all the sensors and if none of the sensors were changing their working conditions, the malicious App could open up the camera and record videos surreptitiously. We collected 15 different datasets from these three attack scenarios to test the efficacy of 6thSense against these adversaries.

Task Category	Task Name
Generic Activities	1. Sleeping
	2. Driving as driver
	3. Driving as passenger
User-related Activities	1. Walking with phone in hand
	2. Walking with phone in pocket/bag
	3. Playing games
	4. Browsing
	5. Making phone calls
	6. Making video calls

Table 2: Typical Activities of Users on Smart Device [3].

7.2 Dataset

In order to test 6thSense, we divided the collected real user data into two sections as it is a common practice [77]. 75% of the collected benign dataset was used to train the 6thSense framework and 25% of the collected data along with malicious dataset were used for testing purposes. For the Markov Chain-based detection technique, the training dataset was used to compute the state transitions and to build the transition matrix. On the other hand, in the Naive Bayes-based detection technique, the training dataset was used to determine the frequency of sensor condition changes for a particular activity or task. As noted earlier, there were nine activities for the Naive Bayes technique. We split the data according to their activity for this approach. For the analysis of the other ML-based approaches, we define all the data in benign and malicious classes. The data were then used to train and test 6thSense using 10-fold cross validation for different ML algorithms.

Threshold (Number of consecutive malicious states)	Recall rate	False negative rate	Precision rate (specificity)	False positive rate	Accuracy	F-score
0	0.62	0.38	1	0	0.6833	0.7654
1	0.86	0.14	1	0	0.8833	0.9247
2	0.96	0.04	1	0	0.9667	0.9796
3	0.98	0.02	1	0	0.9833	0.9899
5	1	0	0.9	0.1	0.9833	0.9474
6	1	0	0.8	0.2	0.9667	0.8889
8	1	0	0.6	0.4	0.9333	0.75
10	1	0	0.5	0.5	0.9167	0.6667
12	1	0	0.5	0.5	0.9167	0.6667
15	1	0	0.3	0.7	0.8833	0.4615

Table 3: Performance evaluation of Markov Chain based model.

7.3 Performance Metrics

In the evaluation of 6thSense, we utilized the following six different performance metrics: Recall rate (sensitivity or True Positive rate), False Negative rate, Specificity (True Negative rate), False Positive rate, Accuracy, and F-score. True Positive (TP) indicates number of benign activities that are detected correctly while true negative (TN) refers to the number of correctly detected malicious activities. On the other hand, False Positive (FP) states malicious activities that are detected as benign activities and False Negative (FN) defines number of benign activities that are categorized as malicious activity. F-score is the performance metric of a framework that reflects the accuracy of the framework by considering the recall rate and specificity. These performance metrics are defined as follows:

$$Recall\ rate = \frac{TP}{TP+FN}, \quad (4)$$

$$False\ negative\ rate = \frac{FN}{TP+FN}, \quad (5)$$

$$Specificity = \frac{TN}{TN+FP}, \quad (6)$$

$$False\ positive\ rate = \frac{FP}{TN+FP}, \quad (7)$$

$$Recall\ rate = \frac{TP}{TP+FN}, \quad (8)$$

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN}, \quad (9)$$

$$F-score = \frac{2*Recall\ rate*Precision\ rate}{Recall\ rate+Precision\ rate} \quad (10)$$

In addition to the aforementioned performance metrics, we considered Receiver Operating Characterstic (ROC) curve as another performance metric for 6thSense.

7.4 Evaluation of Markov Chain-Based Detection

In the Markov Chain-based detection technique, we question whether the transition between two states (sensors' on/off condition in each second) is expected or not. In the evaluations, we used 65 testing sessions in total, among which 50 sessions were for the benign activities and the rest of the sessions were for the malicious activities. A session is composed of a series of sensory context conditions where a sensory context condition is the set of all available sensor conditions (on/off state) for different sensors. As discussed earlier in Section 6, a sensor condition is a value indicating whether the sensor data is changing or not. In this evaluation, the sensory context conditions were computed every one second. We observed that in real devices sometimes some sensor readings would be missed or real data would not be reflected probably due to hardware or software imperfections. And, real malicious Apps would cause consecutive malicious states on the device. Therefore, to overcome this, we also keep track of number of consecutive malicious states and use it as a threshold after which the session is considered as malicious. Table 3 displays the evaluation results associated wit the Markov Chain-based detection technique. When the threshold for consecutive malicious states is 0, i.e., when no threshold is applied, the accuracy is just 68% and FNR is as high as 38%. With increasing the threshold value, the accuracy first increases up to 98% then start decreasing.

The possible cut-off threshold can be three consecutive malicious occurrences which has both accuracy and F-score over 98%. In Table 3, different performance indicators for Markov Chain based detection are presented. We can observe that FN and TN rates of Markov Chain-based detection decrease as the threshold of consecutive malicious states increases. Again, both accuracy and F-

Threshold Probability	Recall rate	False negative rate	Precision rate (specificity)	False positive rate	Accuracy	F-score
55%	1	0	0.6	0.4	0.9333	0.75
57%	1	0	0.7	0.3	0.95	0.8235
60%	1	0	0.7	0.3	0.95	0.8235
62%	1	0	0.7	0.3	0.95	0.8235
65%	0.94	0.06	0.7	0.3	0.9	0.8024
67%	0.88	0.12	0.7	0.3	0.85	0.7797
70%	0.7	0.3	0.8	0.2	0.7167	0.7467
72%	0.7	0.3	0.9	0.1	0.7333	0.7875
75%	0.66	0.34	0.9	0.1	0.7	0.7616
80%	0.66	0.34	0.9	0.1	0.7	0.7615

Table 4: Performance evaluation of Naive Bayes model.

score reach to a peak value with the threshold of three consecutive malicious states on the device. From Figure 3, we can see that FP rate remains zero while TP rate increases at the beginning. The highest TP rate without introducing any FP case is over 98%. After 98%, it introduces some FP cases in the system which is considered as a risk to the system. In summary, Markov Chain-base detection in 6thSense can acquire accuracy over 98% without introducing any FP cases.

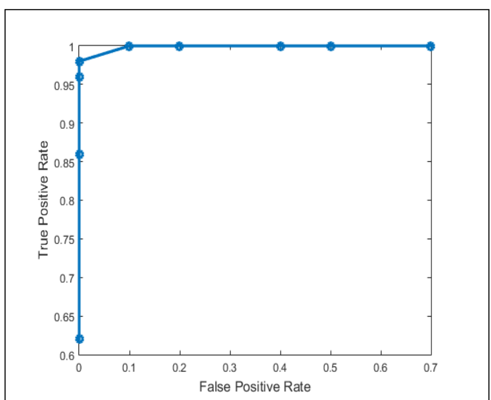

Figure 3: ROC curve of Markov Chain-based detection.

7.5 Evaluation of Naive Bayes-based Detection

In the Naive Bayes-based detection technique, 6thSense calculates the probability of a session to match it with each activity defined in Section7.1. Since all the activities are benign and there is no malicious activity (i.e., ground-truth data), 6thSense checks calculated probability of an activity from dataset against a threshold to determine the correct activity. If there is no match for a certain sensor condition with any of the activities, 6thSense detects the session as malicious. Table 4 shows the evaluation results.

For a threshold value of 55%, FN rate
is zero. However, FPR is too high, which lowers F-score of the framework. For a threshold of 60%, FPR decreases while FNR is still zero. In this case, accuracy is 95% and F-score is 82%. If the threshold is increased over 65%, it reduces the recall rate which affects accuracy and F-score. The evaluation indicates that the threshold value of 60% provides an accuracy of 95% and F-score of 82%.

From Figure 4, one can observe the relation between FPR and TPR of Naive Bayes-based detection. For FPR larger than 0.3, TPR becomes 1.

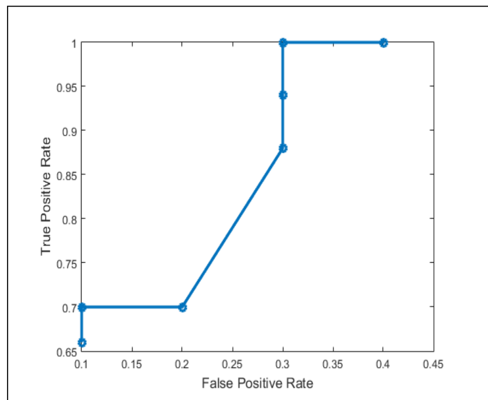

Figure 4: ROC curve of Naive Bayes-based detection.

7.6 Evaluation of Alternative Detection Techniques

In alternative detection techniques, we used other supervised machine learning techniques to train the 6thSense framework. For this, we utilized WEKA and it provides three types of analysis - split percentage analysis, cross-validation analysis, and supplied test set analysis. We chose 10 fold cross-validation analysis to ensure that all the data was used for both training and test. Thus, the

Algorithms	Recall rate	False negative rate	Precision rate	False positive rate	Accuracy	F-score
PART	0.9998	0.0002	0.6528	0.3472	0.99	0.7899
Logistic Function	0.9997	0.0003	0.2778	0.7222	0.998	0.4348
J48	0.9998	0.0002	0.6528	0.3472	0.99	0.7899
LMT	0.9998	0.0002	0.9306	0.0694	0.9997	0.964
Hoeffding Tree	1	0	0.0556	0.9444	0.9978	0.1053
Multilayer Perceptron	0.9998	0.0002	0.6944	0.3056	0.9991	0.8196

Table 5: Performance of other different machine learning based-detection techniques tested in 6thSense.

error rate of the predictive model would be minimized in the cross validation. In Table 5, a detailed evaluation of different machine learning algorithms is given for 6thSense. For *Rule Based Learning*, 6thSense has the best result for *PART* algorithm, which has an accuracy of 0.99 and F-score of 0.7899. On the other hand, for *Regression Analysis*, we use the logistic function which has high FPR (0.7222) and lower F-score (0.4348). *Multilayer Perceptron* algorithm gives an accuracy of 0.9991 and F-score of 0.8196, which is higher than previously mentioned algorithms. However, FPR is much higher (0.3056), which is actually a limitation for intrusion detection frameworks in general. Compared to these algorithms, *Linear Model Tree (LMT)* gives better results in detecting sensor-based attacks. This evaluation indicates that *LMT* provides an accuracy of 0.9997 and F-score of 0.964.

7.7 Comparison

In this subsection, we give a comparison among the different machine-learning-based detection approaches tested in 6thSense for defending against sensor-based threats. For all the approaches, we select the best possible case and report their performance metrics in Table 6. For Markov Chain-based detection, we choose three consecutive malicious states as valid device conditions. On the other hand, in Naive Bayes approach, the best performance is observed for the threshold of 60%. For other machine learning algorithms tested via WEKA, we choose LMT as it gives highest accuracy among other machine learning algorithms. These results indicate that LMT provides highest accuracy and F-score compared to the other two approaches.

On the contrary, Naive Bayes model displays higher recall rate and less FNR than other approaches. However, the presence of FPR in IDS is a serious security threat to the system since FPR refers to a malicious attack that is identified as a valid state, which is a threat to user privacy and security of the device. Both Markov Chain and LMT has lower FPR. In summary, considering F-score and accuracy of all these approaches, we conclude that LMT performs better than the others.

Performance Metrics	Markov Chain	Naive Bayes	LMT
Recall rate	0.98	1	0.9998
False Negative Rate	0.02	0	0.0002
Precision rate	1	0.7	0.9306
False positive rate	0	0.3	0.0694
Accuracy	0.9833	0.9492	0.9997
F-Score	0.9899	0.8235	0.964
auPRC	0.947	0.686	0.91

Table 6: Comparison of different machine-learning-based approaches proposed for 6thSense (i.e., Markov Chain, Naive Bayes, and LMT).

7.8 Performance Overhead

As previously mentioned, 6thSense collects data in an Android device from different sensors (permission and no-permission imposed sensors). In this sub-section, we measure the performance overhead introduced by 6thSense on the tested Android device in terms of CPU usage, RAM usage, file size, and power consumption and Table 7 gives the details of the performance overhead.

For no-permission-imposed sensors, the data collection phase logs all the values within a time interval which causes an increased usage of RAM, CPU and Disc compared to permission- imposed or logic-oriented sensors. For the power consumption, we observe that no-permission-imposed sensors use higher power than permission-imposed sensors. This is mainly because logic-oriented sensors have lower sampling rate, which reduces its resource needs.

The overall performance overhead is as low as 4% of CPU, less then 40*MB* RAM space, and less than 15*MB* disc space. Thus, its overhead is minimal and acceptable for an IDS system on current smartphones. One of the main concerns of implementing 6thSense on Android device is the power consumption.

Table 7 also shows the power consumption of the Android app used in 6thsense. For one minute, 6thsense consumes 16.62 mW power which increases

upto 178.33mW for ten seconds. The main reason of this high power consumption is that all the sensors are kept on for the data collection and all the data are saved on device for later analysis. However, in practical settings, the data would not be saved on device rather a real time analysis would be done, which indeed will decrease the power consumption. Without saving the data, the power consumption significantly becomes smaller. From Table 7, we can observe that the power consumption of 6thSense becomes 72.35 mW which is almost 2.5 times lower than otherwise. Also, all the sensors do not have to remain on for the analysis part. Data can be observed if the smart device is in unlocked status. Also, a suitable interval can be chosen for the data analysis by estimating average time of an attack. This is one of the possible future research directions for 6thSense.

Parameters	**Time**	**No-permission imposed sensors**	**Permission imposed sensors**
CPU Usage	N/A	3.90%	0.3%
RAM Usage	N/A	23 MB	14 MB
Disc Usage	For 1 min	6.5 MB	1 KB
	For 5 min	9 MB	2 KB
	For 10 min	12 MB	3 KB
Power Consumption	1 min	13.5 mW	3.12 mW
	5 min	96.67 mW	27.4 mW
	10 min	133.33 mW	45 mW
Power Consumption (without datafile)	1 min	2.68 mW	0.23 mW
	5 min	23.4 mW	9.63 mW
	10 min	55.35 mW	17 mW

Table 7: Performance Overhead of Android Apps.

8 Discussion and Limitations

- **Features and Benefits-** Compared to the existing solutions, 6thSense differentiates itself by considering a context-aware model to detect sensor-based threats. As sensors provide continuous data to the apps, security schemes must handle real-time data rather than stored data in the system. While most of the existing solutions work with the stored data or the data used by Apps [14, 29], 6thSense offers real-time sensor monitoring. On the other hand, modern high precision sensors on-board have higher frequency and sensitivity. These sensors can detect slight changes in the smart device's ambiance which reflects on sensor values. To overcome frequent changes in sensor values, 6thSense considers average values over one second, which mitigates the effect of changes in sensor values caused by the device ambiance. For example, if a person walks by a smartphone, the light sensor and motion sensors values will be changed for that instance. However, if one considers the average value over one second, it will be compensated by other readings recorded over one second. Another unique feature of 6thSense is that instead of considering the individual sensor data accessed by the Apps, user activities are monitored, which forms the basis of the contextual model for the 6thSense framework. 6thSense observes changes in sensors for different user activities. As more than one sensor remain active to perform a task, attackers need to learn the pattern of all the sensors for user activities to outperform 6thSense. If an attacker targets one specific sensor, an attack scenario will differ from normal user activity which can be easily detected by 6thSense. Thus, the context of user activities is very important to detect malicious activities in 6thSense. Moreover, 6thSense considers all the sensors' conditions as one device state, which provides easy monitoring of the sensors by one framework. Finally, 6thSense can work with all the sensors on a smart device extending the security beyond the traditional permission-imposed sensors (i.e., GPS, microphone, and camera).

- **Application Level Detection-** One of the promising practical applications of 6thSense is to combine the sensor level detection with an application level intrusion detection. 6thSense focuses on detecting malicious activities by observing working conditions of sensors rather than individual App behaviors. However, some prior works [82, 57, 78] also show that it is possible to achieve good accuracy when detecting malicious activities by observing sensor usage in the application level. The combination of application and sensor level detection might be one promising way to further improve the performance of 6thSense. Another interesting application of 6thSense would be to combine it with an online training method to eliminate the necessity of offline training.

- **Sensor-based threats in real-life settings -** One limitation of 6thSense is the adversaries (sensor-based attacks) used in the evaluation were constructed in a lab environment. Note that as of this writing, there are no real sensor-based malware in the wild. However, recently, many independent researchers have confirmed the feasibility of sensor-based threats for smart devices [57, 17, 1, 70]. Indeed, more recently, ICS-CERT also warned the vendors and the wider communities about the possibility of exploiting the sensors of a device to alter sensors' output in a controlled way to perform malicious behavior in the device [2]. Although there

are different limited security schemes to mitigate these attacks, there is no comprehensive contextual solution to secure smart devices from the sensor-based threats. Furthermore, we note that even locking down the sensor API with explicit permissions at the OS level would not surpass the sensor-based threats as users are not aware of these threats yet and can allow malicious Apps to use sensors unknowingly. For all these points, we built the prof-of-concept versions of the sensor-based threats discussed in Section 4. We also note that to ensure the reliability of the lab-made malware (i.e., a specific malicious App) for three threats described in the Adversary Model Section, we checked how they perform with respect to the real malicious software scanners. For this, we uploaded our lab-made malware on *VirusTotal* and tabulated the results of the performance of 60 different malware scanners available at the VirusTotal website in Table 8. As seen in this table, the sensor-based threats are not recognized by the different scanners. Only 2 out of 60 reported that they could detect, but these two only reported risks without clearly identifying any explicit malicious behaviour. Hence, it is difficult to detect the sensor-based threats mentioned in this paper by existing security schemes. Moreover, some security schemes only provide security to the specific sensors [57]. 6thSense covers several sensors as opposed to other existing existing security schemes without alerting the device. Also, existing sensor management systems of Android depends on explicit user-permission only for specific sensors (e.g., microphone, camera, speaker). As users are not aware of sensor-based threats yet, they can allow malicious Apps to use sensors unknowingly. Additionally, 6thSense also covers no-permission-imposed sensors (e.g., motion sensors, light sensor, etc.) in its design.

Adversary Model	Detection Ratio
Threat-1	2/60
Threat-2	2/60
Threat-3	3/62

Table 8: *VirusTotal* scan result for the adversary models.

- **Context-aware Malicious App-** One compelling case is that how 6thSense can defend against a malicious App which can learn and imitate a user's behavior. As described earlier, Threat 3, described in Section 4.1, can observe the working conditions of all the sensors and detect, for instance, a sleeping activity that records videos stealthily. 6thSense can even detect this powerful context-aware malware successfully. In summary, to outperform 6thSense, a malicious App must behave like a benign App all the time in a device, which limits its malicious purposes. Any incompatible behavior in the sensors of a smart device can be easily detected by 6thSense.

9 Conclusion

Wide utilization of sensor-rich smart devices created a new attack surface namely sensor-based attacks. Accelerometer, gyroscope, light, etc. sensors can be abused to steal and leak sensitive information or malicious Apps can be triggered via sensors. Security in current smart devices lacks appropriate defense mechanisms for such sensor-based threats. In this paper, we presented 6thSense, a novel context-aware task-oriented sensor-based attack detector for smart devices. We articulated problems in existing sensor management systems and different sensor-based threats for smart devices. Then, we presented the design of 6thSense to detect sensor-based attacks on a sensor-rich smart device with low-performance overhead. 6thSense utilized different machine learning (ML) techniques to distinguish malicious activities from benign activities on a device. To the best of our knowledge, 6thSense is the first comprehensive context-aware security solution against sensor-based threats. We evaluated 6thSense on real devices with 50 different individuals. 6thSense achieved over 95% of accuracy with different ML algorithms including Markov Chain, Naive Bayes, and LMT . We also evaluated 6thSense against three different sensor-based threats, i.e., information leakage, eavesdropping, and triggering a malware via sensors. The empirical evaluation revealed that 6thSense is highly effective and efficient at detecting sensor-based attacks while yielding minimal overhead.

Future Work: While 6thSense detects different sensor-based threats with high accuracy, we will expand 6thSense in our future work as follows: We will study other performance metrics such as Precision Recall Curve (PRC). We will evaluate the efficacy of 6thSense in other smart devices such as smartwatches and analyze all of its phases in its operations. Moreover, due to limited resources of the smart devices, trade-off between power consumption and effectiveness is a prime concern of any intrusion detection framework. Hence, we will study frequency-accuracy trade-off, battery-accuracy trade-off, and battery-frequency trade-off of 6thSense in different smart devices.

A Theoretical Foundation

A.1 Markov Chain-Based Detection

For the Markov Chain detection model, 6thSense observes the changes of condition of a set of sensors as a variable which changes over time. The condition of a sensor indicates whether the sensor value is changing or not from a previous value in time. For a specific time, t, 6thSense considers the combination of all the sensors' condition in the smart device as the state of our model. As 6thSense considers change in a sensor's condition as binary output (1 or 0, where 1 denotes that sensor value is changing from previous instance and 0 denotes that sensor value is not changing), the number of total states of in the detection model will be exponents of 2. For example, if we consider the total number of sensors in set S is 10, the number of states in our Markov Chain will be 2^{10} or 1024 and the states can be represented as a 10 bit binary number where each bit will represent the state of a corresponding sensor. Assume that p_{ij} denotes the probability that the system in a state j at time $t+1$ given that system is in state i at time t. If we have n number of sensors and $m = 2^n$ states in our model, the transition probability matrix of this Markov Chain can be constructed by observing the transitions from one state to another state for a certain time. Assume that 6thSense's states are $X_0, X_1, \ldots, X_T$ at a given time $t = 0, 1, \ldots, T$. We can represent the transition probability matrix [83]

with $P_{ij} = \frac{N_{ij}}{N_i}$ with N_{ij} = the number of transitions from X_t to X_{t+1}, where X_t in state i and X_{t+1} in state j; N_i = the number of transitions from X_t to X_{t+1}, where X_t in state i and X_{t+1} in any other state. The initial probability distribution of this Markov Chain can be as follows [33]:

$$Q = \begin{bmatrix} q_1 & q_2 & q_3 & \dots & \dots & q_m \end{bmatrix} \quad (11)$$

where, q_m is the probability that the model is in state m at time 0. The probability of observing a sequence of states $X_1, X_2, \dots, X_T$ at a given time $1, \dots, T$ can be computed using the following equation:

$$P(X_1, X_2, \dots, X_T) = q_{x1} \prod_{2}^{T} P_{X_{t-1}Xt} \quad (12)$$

As described earlier in Section 5, for 6thSense, we use a modified version of the general Markov Chain model. Instead of predicting the next state, 6thSense determines the probability of a transition occurring between two states at a given time.

A.2 Naive Bayes Based Detection

Naive Bayes model is a simple probability estimation method which is based on Bayes' method. The main assumption of the Naive Bayes detection is the presence of a particular particular sensor condition in a task/activity has no influence over the presence of any other feature on that particular event.

Assume $p(x_1, x_2)$ is the general probability distribution of two events x_1, x_2. Using the Bayes rule, we can have $p(x_1, x_2) = p(x_1|x_2)p(x_2)$ where, $p(x_1|x_2)$ = Probability of event x_1 given that event x_2 will happen. Now, with c, we can rewrite this formula as $p(x_1, x_2|c) = p(x_1|x_2, c)p(x_2|c)$. If c is sufficient enough to determine the probability of event x_1, we can state that there is conditional independence between x_1 and x_2 [54]. So, we can rewrite the first part as $p(x_1|x_2, c) = p(x_1|c)$, which then modifies the formula as follows:

$$p(x_1, x_2|c) = p(x_1|c)p(x_2|c) \quad (13)$$

6thSense considers users' activity as a combination of n number of sensors. Assume X is a set which represents current conditions of n number of sensors. We consider that conditions of sensors are conditionally independent (See Section 4.2), which means a change in one sensor's working condition (i.e., on/off states) has no effect over a change in another sensor's working condition. As explained earlier, the probability of executing a task depends on the conditions of a specific set of sensors. So, in summary, although one sensors' condition does not control another sensor's condition, overall the probability of executing a specific task depends on all the sensors' conditions. As an example, if a person is walking with his smartphone in his hand, the motion sensors (accelerometer and gyroscope) will change. However, this change will not force the light sensor or the proximity sensor to change its condition. Thus, sensors in a smartphone change their conditions independently, but execute a task together. We can have a generalized model for this context-aware detection [49] as follows:

$$p(X|c) = \prod_{i=1}^{n} p(X_i|c) \quad (14)$$

In 6thSense's context-aware activity-oriented detection model, we have a set of training data for users' activities. Assume that B represents a set which denotes m numbers of user activities. We can determine the probability of a dataset X to be classified as a user activity using the following equation:

$$P(B_i|X) = \frac{P(X|B_i)P(B_i)}{P(X)}, \quad (15)$$

where $i = 1, 2, \dots, m$. As the sum of all the conditional probabilities for X will be 1, we can have the following equation, which then will lead to Equation 17 [36]:

$$\sum_{i=1}^{m} P(B_i|X) = 1. \quad (16)$$

$$P(B_i|X) = \frac{P(X|B_i)P(B_i)}{\sum_{i=1}^{m} P(X|B_i)P(B_i)}. \quad (17)$$

This calculated conditional probability then is used to determine the benign user activity or malicious attacks in 6thSense. In this way, 6thSense computes the probability of occurring an activity over a certain period of time.

6thSense divides the sensor data into smaller time values (1 second) and calculates the probability of each instance to infer the user activity. The calculated probability of each second data is then used in the expected value to calculate the total probability. As such, the probability of the first instance is p_1 with a value of a_1, the probability of the second instance is p_2 with a value of a_2 and so on up to the value a_n. Then, the expected value can be calculated by the following formula:

$$E[N] = \frac{a_1 p_1 + a_2 p_2 + a_3 p_3 + \dots\dots + a_n p_n}{a_1 + a_2 + \dots \dots + a_n}. \quad (18)$$

As all the values of a_1, a_2, ..., a_n are equally likely, this expected value becomes a simple average of the cumulative probability of each instance. In this way, 6thSense infers the user activity by setting up a configurable threshold value and checking whether the calculated value is higher than the threshold or not. If it is lower than the threshold value, 6thSense concludes that the malicious activity is occurring in the smart device.

Identifier Binding Attacks and Defenses in Software-Defined Networks *

Abstract

In this work, we demonstrate a novel attack in SDN networks, Persona Hijacking, that breaks the bindings of all layers of the networking stack and fools the network infrastructure into believing that the attacker is the legitimate owner of the victim's identifiers, which significantly increases persistence. We then present a defense, SECUREBINDER, that prevents identifier binding attacks at all layers of the network by leveraging SDN's data and control plane separation, global network view, and programmatic control of the network, while building upon IEEE 802.1x as a root of trust. To evaluate its effectiveness we both implement it in a testbed and use model checking to verify the guarantees it provides.

1 Introduction

Modern networks use various identifiers to specify entities at network stack layers. These identifiers include addresses, like IP addresses or MAC addresses, and domain names, as well as less explicitly known values such as the switch identifier and the physical switch port to which a machine is connected. Identifiers are used in modern networks not only to establish traffic flow and deliver packets, but also to enforce security policies such as in firewalls or network access control systems [3]. In order to achieve proper operation and security guarantees, network infrastructure devices (*e.g.,* switches, network servers, and SDN controllers) implicitly or explicitly associate various identifiers of the same entity with each other in a process we call *identifier binding*. For example, when a host acquires an IP address from a DHCP server, the server *binds* that IP address to the host's MAC address; when an ARP reply is sent in response to an ARP request, the source host binds the IP address in the ARP request to the MAC address in the ARP reply.

Given the importance of these identifier bindings, it is not surprising that numerous attacks against them have been developed, including DNS spoofing [48], ARP poisoning [29], DHCP forgery, and host location hijacking [24]. These attacks are facilitated by several network design characteristics: (1) reliance on insecure protocols that use techniques such as broadcast for requests and responses without any authentication mechanisms, (2) allowing binding changes without considering the network-wide impact of services relying on them, (3) allowing independent bindings across different layers without any attempt to check consistency, and (4) allowing high-level changes to identifiers that are designed and assumed to be unique. Numerous defenses have also been proposed to prevent identifier binding attacks of various types in traditional networks [18, 48, 2].

Software-Defined Networking (SDN) is a new networking paradigm that facilitates network management and administration by providing an interface to control network infrastructure devices (*e.g.,* switches). In this paradigm, the system responsible for making traffic path decisions (the control plane) is separated from the switches responsible for delivering the traffic to the destination (the data plane). The SDN controller is the centralized system that manages the switches, installs forwarding rules, and presents an abstract view of the network to SDN applications. SDN provides flexibility, manageability, and programmability for network administrators. Although previous work has focused on various aspects of the intersection of security and SDNs [46, 27, 28, 45, 26, 36, 44, 5, 14, 52], there has been little work on studying identifier binding attacks and their implications in SDN systems.

In this paper, we first study identifier binding attacks in SDN systems. We show that the centralized control exacerbates the implications and consequences of weak identifier binding. This allows malicious hosts to poi-

son identifier bindings not only in their own broadcast domain, as is the case with many identifier binding attacks in traditional networks, but also in the entire SDN network. Moreover, we show that, unlike traditional networks where identifier binding attacks are limited to a small subset of identifiers, in SDN, identifier binding attacks can be so severe that they allow complete takeover of *all* network identifiers of the victim host at once, in an attack we dub *Persona Hijacking*. More damagingly, in a Persona Hijacking attack the malicious host fools the network infrastructure devices into believing that it is the legitimate owner of the victim's identifiers, allowing it to persistently hold the compromised identifiers. Our attack succeeds even in the presence of the latest secure SDN solutions such as TopoGuard [24], SPHINX [14], and SE-Floodlight [45].

We then show how the SDN design philosophies of programmable infrastructure, separation of control and data planes, and centralized control can be used to prevent identifier binding attacks. We design and implement a defense, SECUREBINDER, to establish strong bindings between various network identifiers. First, we extend the 802.1x protocol to establish a root-of-trust for strong authentication of a machine. Building on this root-of-trust, we then implement additional components of the defense to strongly bind higher-level identifiers to the MAC address. As part of SECUREBINDER, we force all identifier binding broadcast traffic to go through the control plane and program switches to drop all data plane broadcasts, preventing the hijacking of higher-level identifiers (IP or domain name) bound to a given MAC address. Our solution does not require any changes on the end-hosts.

We extensively evaluate the effectiveness of our defense experimentally, using testbed implementations of various identifier binding attacks, as well as formally, using model checking. Our experimental and formal evaluations indicate that SECUREBINDER can successfully stop identifier binding attacks while incurring a small overhead, mainly in the form of additional network join latency due to the initial authentication step.

Roadmap. In section 2, we discuss the key bindings in a modern network stack. In section 3 we describe the Persona Hijacking attack. We present our defense in section 4, then evaluate it formally and experimentally in section 5. We discuss limitations of our attack and defense in section 6 and then consider related work in section 7 before concluding in section 8.

2 Identifier Binding

In this section we provide an overview of the main identifiers used at different network layers and discuss identifier binding attacks in traditional networks and what makes these attacks more dangerous in SDN networks.

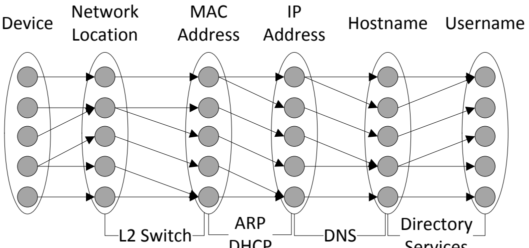

Figure 1: Network Identifier Bindings. Protocols mediating the binding for IPv4 are shown at bottom.

2.1 Overview of Identifier Bindings

Network protocols rely on identifier binding in order to operate correctly and efficiently. Because of the stack model where layers can access services only from adjacent layers, identifier binding takes place in two forms, *explicit* – achieved through network protocols or manual configuration, and *implicit* – achieved through already existing mappings. Below we describe the identifier bindings that are critical to correct functioning of a network (see Fig. 1). For additional background on the identifiers discussed here, please see Appendix A.

Network location to device: In traditional networks, a device's network location is represented implicitly by the switch and port that packet forwarding rules are bound to and the location of ACL rules or other configuration specific to that device.

MAC address to network location: Binding MAC addresses to network locations is done implicitly based on observed network traffic by Layer-2 switches; the source MAC address of traffic is used to learn which network port on a switch corresponds to that MAC address.

IP address to MAC address: Mapping a unicast IP address to a MAC address is usually done via ARP for IPv4 and NDP for IPv6. These mechanisms broadcast a query asking who has a given IP address and the device with that IP address unicasts a response including its MAC address. An interface with a single MAC address may have more than one IP address associated with it.

Host names to IP addresses and IP addresses to hostnames: Hostnames are mapped to IP addresses in several ways. The most common is unicast, centrally configured DNS. However, multicast DNS (mDNS) without a central server also exists, as does a legacy naming service for Microsoft Windows known as NETBIOS. Note that DNS and mDNS can also be used for reverse resolution: finding a hostname given an IP address. A single IP address may be associated with multiple hostnames and a single hostname may be associated with multiple IP addresses.

In unicast DNS, the hostname to IP bindings are either manually configured by an administrator or automatically updated using the DNS update command. The protocol for automatically updating hostnames is Dynamic

DNS [51] and lacks authentication. A secure version [53] exists, but is rarely used. Microsoft Active Directory has its own scheme to authenticate DNS updates to AD-integrated DNS servers while other directory services have the DHCP server update the DNS records for clients when they acquire IP addresses [19]. To map a hostname to an IP address, unicast DNS uses UDP (although TCP can also be used) to send a request to the DNS server. Responses are returned in the same way and contain no authentication. DNSSEC [2] cryptographically authenticates DNS responses, preventing modification or forgery, but is rarely deployed. Both Multicast DNS (mDNS) and NETBIOS rely on unauthenticated broadcast requests. Hosts listen for these requests and respond if they have the queried hostname. NETBIOS can use a registration server to speed up this process.

Username to hostname: This binding occurs either as per-system user accounts or via a directory service, of which Active Directory is the most prominent.

Active Directory (and its open-source counterpart Samba) is a directory service that maintains information on users, groups, access rights, and configuration information for an organization and uses this information for centralized authentication and management. It leverages LDAP for directory access and Kerberos for authentication. It authenticates both users and machines to the network and provides configuration management to Windows clients. Unfortunately, Active Directory machine authentication does not provide authentication of lower level network identifiers like MAC or IP addresses. Authentication is based on Kerberos, but Active Directory-issued tickets are bound only to the hostname and not to the IP address by default [17].

Directory services like Active Directory do *not* know precisely who is logged in at any given point in time. Further, a connection to the network might *not* trigger authentication. For example, if a user is already logged in when they connect to the network, the connection does not trigger authentication. For per-system user accounts, the authentication and management is local to each system and not visible to the network. Higher level protocols, like NFS, may still rely on this information.

2.2 Binding Attacks in non-SDN Networks

The ultimate goal of layer-to-layer bindings is to allow a mapping across the entire stack where higher level identifiers are mapped by transitivity to lower layers and, ultimately, to device identifiers.

Definition 1 (Identifier binding attack): We define an identifier binding attack as 1) replacing or creating a binding such that the identifiers bound together are associated with different devices, or 2) utilizing identifiers associated with a known, offline device in a binding.

There are several design factors and architectural characteristics that facilitate identifier binding attacks:

(1) Reliance on insecure protocols: Many of these bindings are constructed based on broadcast requests that query the entire broadcast domain while others are formed implicitly based on spoof-able identifiers in observed traffic. Thus, an attacker can easily impact these bindings simply by sending spoofed packets or listening for broadcast queries and responding.

(2) Treating binding creation and changes as the same operation: Once a binding is created, there are services that rely on it. Changing a binding, for example, because of a host migration or IP address reassignment, has implications on all services that rely on it network-wide. Not distinguishing between creation and changes to a binding allows an attacker to reset existing bindings simply by claiming to have an identifier.
