(3) Independent changes: Many bindings are treated independently from each other with no attempts to use information recorded in one binding, for example the MAC to network location binding, to validate updates being made to others, like the IP address to MAC address binding. This enables attackers to use packets that violate one binding to successfully attack a different binding.

(4) Ability to change identifiers: Identifiers that are assumed to be unique, like MAC addresses, are actually mutable and easily changed in software. Hence, attackers can readily impersonate other devices to the network.

These characteristics enable a wide variety of attacks on identifier binding protocols, including ARP spoofing, DNS spoofing, and Rogue DHCP servers. ARP spoofing is enabled by the broadcast mechanism employed by ARP to bind IP addresses to MAC addresses as well as by bindings at different layers not being used to validate each other. In a similar manner, Rogue DHCP servers are enabled by the broadcast nature of DHCP that allows any host to listen for and respond to requests. DNS spoofing is possible because bindings are treated independently, allowing a host to use spoofed packets to send DNS responses as if they came from the legitimate DNS server.

Limitations of identifier binding attacks in traditional networks: Identifier management in IPv4 Ethernets must contend with several architectural aspects of the network stack that impact the scope, consistency, and security of identifier bindings between different network identifiers.

(1) Distributed Control State: Traditional networks maintain distributed control state in both network infrastructure (*e.g.,* switches and routers) as well as dedicated identifier management servers such as DHCP and DNS. This ensures that network layer boundaries define the scope of the relevant identifier bindings. Layer-2 switches form broadcast domains over which packets are forwarded based on MAC–Port bindings maintained by

each device. Outside of these layer boundaries, Layer-2 identifiers are overwritten by routers and forwarding is based on Layer-3 IP addresses. This effectively limits the scope of Layer-2 attacks like ARP or MAC spoofing only to that broadcast domain, as all other regions of the network are only reachable via Layer-3 routing.

(2) Intelligent Routers: Modern switches and routers have defenses to mitigate attacks on identifier bindings. These include techniques such as Cisco's Dynamic ARP Inspection and DHCP Snooping systems, which maintain local databases of identifier bindings and can drop packets based on coarse-grained heuristics and manually configured trust relationships [10]. Network interfaces which are not registered as DHCP servers, can be set to drop server-side DHCP messages such as lease offers.

(3) Rapid Rule Consistency: Modern IPv4 Ethernets rely on interior gateway protocols (*e.g.,* OSPF) to build a network information base (NIB) at every router. The NIB is used to install routing rules, which are updated whenever the NIB state changes. Since this update is local to the router, there is very little delay between a NIB update and a routing rule change to make forwarding behavior consistent with the NIB. This limits the ability of an attacker to cause blackhole or redirection attacks based on stale routing rules (though attacks on the routing protocol itself remain possible).

2.3 Binding Attacks in SDN Networks

While identifier management in SDNs uses largely the same protocols as those used by IPv4 Ethernets, the architecture of an SDN imposes different challenges to maintaining the security of identifier bindings. SDNs differ from traditional networks in three key aspects that can be used to amplify the impact of existing identifier binding attacks: a unified control plane, bare-metal switches, and delayed rule consistency.

Unified Control Plane: OpenFlow networks are divided into a separate data plane (the switches) and control plane (the controller). This unifies the entire network under a single SDN controller (or communicating set of controllers) and removes most traditional divisions of a network into broadcast domains and subnets. Protocol data structures which would normally be maintained per-switch or per-router are maintained only at the controller, and messages which would normally not leave the local switch/router are instead sent to the controller. Many controllers implement Proxy ARP, for example, in which a single master ARP table is maintained for the entire network. ARP Requests are sent to the controller, which generates an ARP Reply via a `packet_out`. Attackers can use this to their advantage. Any ARP Spoofing attack can now target any victim on the entire SDN, whereas a traditional network requires the attacker and victim to share a broadcast domain.

Bare-Metal Switches: OpenFlow switches have no internal packet-processing logic beyond the flow rules installed by a controller. Thus, defenses that have traditionally been implemented by network infrastructure (such as Dynamic ARP inspection and DHCP Snooping [10]) are not present in SDNs. Additionally, no open source SDN controller currently provides any Layer-2 or Layer-3 security systems beyond user-configurable firewall rules. As a result, attacks which are easily detected in traditional networks (such as Rogue DHCP servers) go unnoticed in vanilla OpenFlow networks.

Delayed Rule Consistency: SDN controllers implement a global NIB in order to determine what flow rules to install in response to a `packet_in` event. Approaches to populating it have a common component. During `packet_in` processing, the source IP and MAC addresses are used to update the NIB with the switch and port on which an end-host is located. Destination IP and MAC addresses are looked up in the NIB to determine the switch port on which the packet should be forwarded. A flow rule is then synchronously installed in the relevant switch(es) with match fields determined by the current NIB state before the packet is sent back to the switch for forwarding. Unfortunately, when the NIB state is updated, old flow rules are not removed from switches (probably because attempting to differentially update all flow rules on NIB updates would dramatically increase flow latency). A common work-around (used by Ryu and POX) is to set a hard or soft timeout on flow rules. Soft timeouts count down from the last time the rule was triggered, while hard timeouts count down from rule installation. When a timeout is reached, the rule is deleted. This bounds the duration that inconsistent rules can persist, but does not solve the problem on shorter timescales. Attackers can take advantage of temporarily inconsistent flow rules to intercept messages meant for another host or blackhole traffic.

We have observed the lack of traditional ARP poisoning/DHCP snooping defenses and the presence of delayed rule consistency experimentally in ONOS and Ryu and confirmed both in the Floodlight and POX source code. We leave a complete exploration of additional controllers to future work.

3 Persona Hijacking

We present an attack against identifier bindings in SDNs that allows complete takeover of *all* network identifiers of the victim host at once, an attack we dub *Persona Hijacking*. We first describe the attacker capabilities required by the attack, then describe the Persona Hijacking attack in detail.

Table 1: Impact of Identifier Binding Attacks

Attack	Spoofed ID			Persistence	Area Affected	Legitimized	Defenses	
	MAC	IP	Hostname				Non-SDN	SDN
ARP Spoofing	X	X	–	Minutes	Broadcast Domain	–	X	–
Rogue DHCP	–	X	X	Days	Subnet	–	X	–
DNS Spoofing	–	X	X	Minutes	DNS Domain	X	X	X
Persona Hijacking	X	X	X	Days	Entire Network	X	–	–

3.1 Attacker Model

We consider an enterprise IPv4 Ethernet network using the Openflow SDN architecture and a standard OpenFlow controller such as Ryu, POX, NOX, Floodlight, OpenDaylight, ONOS, or Beacon. End-hosts use ARP to look up the MAC address associated with an IP and use DHCP to obtain IP addresses from a single DHCP server. Additionally, the network has an internal DNS server for managing intranet hostnames and a directory services package such as Microsoft Active Directory.

We assume the attacker has compromised one or more end-hosts on this network and is attempting to use those hosts to impersonate a target server to clients in order to subvert additional end-hosts and move laterally in the network. OpenFlow switches and the controller are outside of adversarial control and act as trusted infrastructure. Thus, the attacker cannot perform a man-in-the-middle attack without corrupting network routing state or stealing the identifiers (*e.g.,* IP address) of the victim end-host.

We assume that the attacker has not compromised any of the critical servers (such as directory services, DNS, or DHCP). This is because the attacker would have more powerful options than the attack presented here, if such servers have been compromised.

3.2 Persona Hijacking Attacks

While several attacks against identifier bindings exist, their impact is limited in traditional networks. They impact only a single binding, persist briefly, have a limited area of effect, and many defensive solutions exist. We summarize the characteristics of the most common attacks on identifier bindings in Table 1. ARP Spoofing, for example, corrupts a MAC–IP binding within a Layer 2 broadcast domain until the ARP cache entry times out, at which point the attack must be re-launched.

These limitations do not hold for SDNs, which permit powerful new attacks on identifier bindings. We introduce one such attack, Persona Hijacking, which allows complete takeover of *all* network identifiers of the victim host at once, can persist for days, affects the entire network, and has no existing defenses. Specifically, our Persona Hijacking attack allows an attacker in an SDN-based network to take over an IP address and DNS domain name from a victim end-host by progressively breaking the MAC Address to Network Location, IP Address to MAC address, and (in some network configurations) Hostname to IP Address bindings.

A key feature of our attack, which is unachievable using traditional identifier binding attacks (*e.g.,* ARP spoofing), is that it affects the network infrastructure such that the attacker becomes the *owner of record* for the IP address. That is, the DHCP server believes that the victim's IP is bound to the *attacker's* MAC address. This allows Persona Hijacking attacks to effectively co-opt the DHCP server and propagate the deception further into the network.

Persona Hijacking consists of two main phases. The first phase, which we refer to as *IP takeover*, relies on a client-side attack against DHCP to break the IP address to MAC address and hostname to IP address bindings in order to hijack the IP address and hostname of the victim by binding both of them to the attacker's MAC address. The second phase, which we refer to as *Flow Poisoning*, exploits the delayed flow rule consistency present in SDNs to break (from the perspective of the victim) the MAC address to network location binding of the DHCP server in order to (from the perspective of the DHCP server) legitimize the first phase and make the victim appear to have willingly given up its IP address. A timeline of the complete attack is shown in Figure 2.

IP takeover Details. IP takeover operates in two steps. First, the attacker breaks the binding between the victim's IP address and MAC address by forging a DHCP_RELEASE message to make the DHCP server release the victim's IP address into the pool of available addresses. This does *not* break the hostname to IP address binding, as the recommended practice in an enterprise setting is for the *client* to manage DNS A record updates [33]. The next step is to bind the released IP address to the *attacker's* MAC address. However, the DHCP specification [15] recommends that the DHCP server should offer addresses from their unused pool before offering addresses that were recently released. Hence, the attacker mounts a partial (and temporary) DHCP starvation attack. The DHCP server is flooded with DHCP_DISCOVER messages using random MAC addresses, until the target's IP address is offered. Once the DHCP server offers the victim's IP, the attacker confirms the lease, and the starvation attack is halted. The

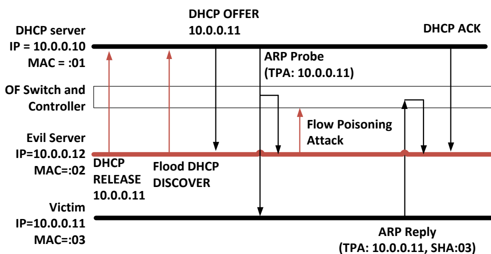

Figure 2: Timeline of the Persona Hijacking attack.

victim's IP address and hostname are now bound to the attacker's MAC address *by the DHCP server*.

Note that the DHCP_DISCOVER is the first half of the DHCP handshake. An additional confirmation from the client is required to finalize the lease, and most DHCP servers will avoid offering such addresses to other clients for a few minutes. This limits the exposure of the exhaustion attack and its impact on legitimate clients to a short time window. Furthermore in networks with high DHCP churn, an attacker can perform strategically timed and limited DHCP starvation to avoid detection by allowing new clients to consume the IP addresses in the unused pool.

IP takeover Impact: SDN controllers that use DHCP to manage forwarding rules will redirect traffic bound for the victim's IP address to the attacker's network location. This blackholes the victim, preventing them from receiving further traffic, and allows the attacker to impersonate the victim. Any client request made to the hostname associated with the stolen IP address will be sent to the attacker. Any existing connections made by the victim will continue uninterrupted. New connection requests made by the victim will reach their destination but the response packets will be sent to the attacker. Since the victim is unaware that its IP address has been re-bound, the attack lasts until the victim obtains a new DHCP lease, which would typically be hours or days later. This ensures the hijacked binding will persist over large timescales.

Flow Poisoning Details. In some cases the IP takeover phase is sufficient, and the victim's persona is successfully hijacked. However, in order to be compliant with the DHCP RFC [15], many DHCP servers probe a reused address before re-allocating it to a new client. Typically, the DHCP server sends a broadcast ARP request to see if any host claims the reused address, validating that this IP address is not in use. If this probing

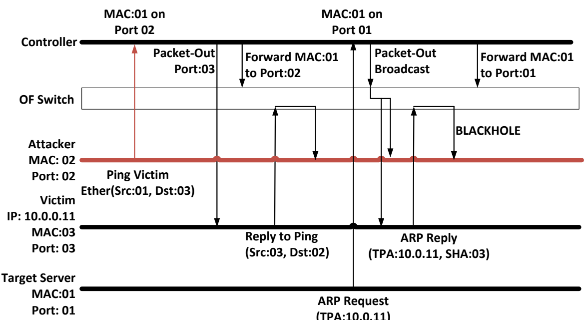

Figure 3: Timeline of the Flow Poisoning Attack

before re-allocating an IP address is used, the IP takeover phase will fail, because the victim is not aware that their IP address has been released by the DHCP server and will respond to the ARP request, causing the DHCP server to refuse to lease the target IP address. In order to ensure that IP takeover succeeds even in the presence of probing, we developed a Flow Poisoning attack that breaks the MAC address to network location binding of the DHCP server in order to blackhole this response.

Our Flow Poisoning attack takes advantage of a race condition unique to SDNs in order to break the MAC address to network location binding of a targeted end-host. The attack relies on the fact that SDN flow rules may be temporarily inconsistent with the NIB maintained by the controller. Since flow rules reflect the NIB state at the time of their installation and (due to scalability challenges and network latency) are not updated instantly when the NIB state changes, they may reflect previous network states that no longer hold. Two approaches are used to bound the duration of this inconsistency. The first, used by Ryu and other learning-switch-based controllers, relies on installing hard or soft timeouts on all rules. The second, used by ONOS and other controllers that implement a Host-Discovery Protocol, uses a separate monitoring thread to detect host movement and remove inconsistent rules. This monitor runs concurrently with the NIB updater responsible for generating `packet_out` events, which introduces an exploitable race condition where the message is sent prior to new flow rules being installed.

The attacker can take advantage of this temporary inconsistency to blackhole traffic from a target source s to a target destination d. Figure 3 depicts a timeline of this attack. First, the attacker sends traffic (we chose ICMP pings, but the attack is agnostic to the packet payload) to s with the source MAC address of d. This breaks the MAC address to network location binding of d.

Upon entering the switch, the forged packets cause a flow table miss (since the MAC address of d is not bound to the network location of the attacker) and are sent to the controller. The controller updates its MAC to location

binding such that the destination MAC d is bound to the attacker's switch port. It then installs a new flow rule in the switch enforcing this binding and forwards the ping to the victim s. The victim s replies to the forged ICMP ping, which causes another flow rule to be inserted into the switch that sends all traffic from s to d to the switch port on which the attacker resides.

Once d originates traffic, the controller will update its internal mappings to correctly track d's location (*i.e.,* re-binding the MAC address of d to the network location of d). This begins the race condition on which Flow Poisoning relies. The now-inconsistent flow rule which binds the attacker's location to d's MAC address will *not* be removed from the switch upon NIB update. Instead, it will either timeout several seconds later or be deleted by the separate host mobility tracking thread. Until this occurs, traffic from s to d will be sent to the attacker.

In the context of IP takeover, this technique can be used to blackhole the reachability probe conducted by a DHCP server prior to assigning the victim's IP to the attacker. Since the initial ARP request from the DHCP server is broadcast to all ports, it is not possible to blackhole. We, therefore, blackhole the unicast response from the victim to the DHCP server by breaking the DHCP server's MAC address to network location binding. Note that while the Flow Poisoning phase of the attack only lasts until the flow rules are updated, the larger Persona Hijacking attack utilizes this to create an attack that will persist until the victim's DHCP lease expires.

3.3 Attack Implementation

We have implemented both the IP takeover and Flow Poisoning phases as fully automated Python scripts running on an attacking end-host. We use Scapy[1] to forge a DHCP_RELEASE message for the IP takeover phase and to request new IP addresses until the victim's address is offered. The Flow Poisoning phase simply consists of sending an ICMP ping with the DHCP server's MAC address to the victim as soon as the DHCP Offer is received by the attacker. The entire attack was tested in an emulated SDN environment using Mininet 2.2.1 [30], against both the ONOS and Ryu controllers. An analysis of the Floodlight and POX source code suggests that they are also vulnerable.

Because Flow Poisoning relies on a race condition, we measured the Persona Hijacking success rate over 10 trials, each of which took an average of 90.39 seconds to acquire the target IP address. For Ryu, which uses hard flow rule timeouts, the success rate was 90%. Failures corresponded to an ARP Reply that was sent by the victim to the DHCP server after the inconsistent flow rule expired. For ONOS, the Flow Poisoning phase was not

[1] http://www.secdev.org/projects/scapy/

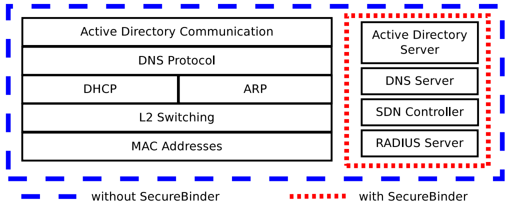

Figure 4: Components of the network that must be trusted with and without SECUREBINDER

necessary because ONOS provides a DHCP server in the controller which does not probe reused addresses before allocating them to new clients. Persona Hijacking was always successful.

Our testbed was a machine running Ubuntu 14.04 with an Intel Core i7-3740QM CPU and 16GB memory. The experimental topology consisted of three hosts directly connected to an OpenFlow 1.3 switch. One of these hosts was a DHCP server running `udhcpd` from BusyBox v1.21.1. The other two were the attacker and the victim. The DHCP server was configured to lease a total of 5 IP addresses.

4 SECUREBINDER

This section presents SECUREBINDER, our system for securing network identifier bindings. We first present our design and then describe our implementation.

4.1 Design

The Persona Hijacking attack and other identifier attacks are possible because of several network design characteristics of identifier binding in traditional networks: (1) reliance on insecure protocols using techniques like broadcast for requests and responses without any authentication mechanisms, (2) allowing the changing of bindings without considering the network-wide impact to services relying on them, (3) allowing for independent bindings across different layers without any attempt to check consistency, and (4) allowing high-level changes to identifiers that are designed and assumed to be unique. We design SECUREBINDER as a comprehensive solution to identifier binding attacks and the above attack facilitating factors, not merely as another defense against a specific attack. In doing so we dramatically reduce the number of network components that must be trusted, as shown in Figure 4.

SECUREBINDER leverages SDN and IEEE 802.1x to target the facilitating factors as follows:

• It leverages SDN functionality to separate the identifier binding control traffic from the regular data plane, isolating it from an attacker, and creating a binding mediator which can perform additional security checks on

identifier bindings. While this approach does not eliminate the use of insecure protocols for identifier binding (which would require changes to every end host), it does remove the requirement to trust these protocols.

- It validates identifier binding changes, by leveraging the global view of the network and its identifiers that SDN provides. It distinguishes between creating new bindings and changing existing ones, requiring validation that the old binding is no longer active before allowing changes.
- It prevents independent binding across layers by using lower layer bindings to validate messages that attempt to change bindings at higher layers.
- It protects against readily changed, but supposedly unique, identifiers by leveraging IEEE 802.1x to provide a root-of-trust for network identifiers, binding the MAC address to a cryptographic authentication and eliminating disconnected host race conditions.

Assumptions. SECUREBINDER assumes that the switches and the controller are not compromised and that OpenFlow messages are cryptographically protected (*e.g.,* with TLS). It also assumes that the controller implements secure topology detection, to be able to correctly differentiate network edge ports from internal ports. This is in line with protection already provided by solutions such as TopoGuard [24].

At a high-level, SECUREBINDER consists of a binding protocol mediator module, a binding store database, a port control module, and a device authenticator module. The binding store maintains authenticated bindings at all layers that the protocol mediator uses to validate binding protocol messages. It is updated by the binding protocol mediator as bindings are updated. The binding protocol mediator itself is responsible for verifying the bindings in these protocol messages, performing additional validation for binding updates, and ensuring that bindings are consistent with lower layers. The port control module is responsible for configuring flow rules on individual network ports to separate binding protocol traffic and enable egress filtering based on identifier binding updates, 802.1x authentication, and changes in port or switch status. The device authenticator is responsible for authenticating the MAC addresses of hosts using 802.1x.

Mediator. The mediator separates identifier binding control traffic, like DHCP, ARP, and 802.1x, from normal data plane traffic and sends it to the control plane. This means broadcast traffic no longer goes to all hosts on the network, enabling all hosts to influence identifier bindings, but only to the controller and a few select applications processing those broadcast requests. Once this identifier binding control traffic reaches the controller, the binding mediator validates it by using the global view of the network enabled by SDN to check incoming binding control traffic against existing bindings. If an attempt is made to rebind an identifier that is already bound, for example, binding an IP address to a different MAC address, the mediator performs additional verification, by checking that the old identifier is no longer reachable, before allowing this rebinding. Similarly, the mediator enforces cross-layer consistency in identifier bindings, requiring binding requests to originate at the same location as the known identifier.

Port control. This module addresses bindings (*i.e.,* MAC address to network location) that are implicitly inferred from network traffic without an explicit signaling protocol. It performs dynamic egress (*i.e.,* source-address) filtering on a per-port basis based on the binding information, thus preventing spoofed packets at the first SDN-controlled port and changing this implicit binding to an explicit one controlled by the configuration of the egress filters. While egress filtering has been used in the past [29], SDN's ability to automatically identify network edge ports and dynamically configure flow rules allows egress filtering to be done automatically.

Device authenticator. While the mediator and port controller securely bind all higher identifiers to a MAC address, they cannot guarantee that a MAC address corresponds to a particular physical device. This is because MAC addresses can be easily changed on all modern NICs and operating systems. This fundamental weakness affects many traditional and SDN-based security and access control systems, including Ethane [6] and techniques that tie a MAC address to a single physical port. The device authenticator addresses this issue by extending IEEE 802.1x, a network access technology supported by all major operating systems and platforms that is designed to enable a network port if-and-only-if an authorized client is connected. Traditionally, the RADIUS authentication server used with 802.1x only verifies that the device is authorized to connect to the network without checking its MAC address or any other network identifier. If the device is authorized, 802.1x enables the port and the device to send arbitrary traffic into the network. We extend the authentication to validate each device's MAC address as well, providing a cryptographic root-of-trust for our network identifier bindings.

802.1x operates using an authenticator on the switch which tunnels EAP [1] messages between a supplicant on the client and a RADIUS [42] authentication server on the backend. The use of EAP and RADIUS enable many authentication mechanisms, including both password based mechanisms (*e.g.,* EAP-MSCHAPv2) and certificate based mechanisms (*e.g.,* EAP-TLS). We choose to deploy EAP-TLS [47], which uses client certificates signed by a CA in the RADIUS server. A client that is able to present a certificate signed by the CA is considered authorized to access the network.

We augment 802.1x to validate the client's MAC ad-

dress by having the (trusted) 802.1x authenticator, implemented in the SDN controller, pass the client's MAC address to the RADIUS server. We then maintain a database in our RADIUS server that associates each certificate's common name with its MAC address.[2] When a new device is added to the network, the admin generates a certificate for it and adds its common name and the device's MAC address to this database. When the client presents its certificate, it is first verified, and then, if it is valid, its common name and the client's MAC are checked against this database. Only if they match is the client authenticated. Note that this database is not accessible outside of the system running the RADIUS server and is only modified manually by the admin.

While we seek to provide a secure network that completely prevents identifier binding attacks, we also take into account the currently-existing network devices. In particular, while 802.1x is supported by the majority of devices and operating systems, it is not yet universally supported. For those devices, like printers or IP phones, that do not support it, SECUREBINDER provides a weak authentication based on the device's MAC address. It is important to understand that this drastically weakens the authentication guarantees provided for that device, allowing an attacker to impersonate that device to the network.

Due to space constraints, for further details we refer the reader to Appendix B.

4.2 Implementation

The introduction of multiple flow tables in OpenFlow 1.3 [38] eases the implementation of SECUREBINDER. In particular, we reserve the first table, table 0, for separating identifier binding traffic from regular data-plane traffic and doing egress filtering, while tables 1+ are used for routing and other applications as normal. High priority flow rules are inserted into table 0 such that all 802.1x, ARP, and DHCP traffic is sent to the controller while DNS and Active Directory traffic are routed directly to their respective servers. Egress filtering is accomplished by inserting flow rules into table 0 such that flows with expected source identifiers (both MAC and IP addresses) are sent directly to table 1 to be routed as normal, while all other traffic is rate limited and sent to the controller.

SECUREBINDER takes the form of a privileged SDN controller application which has configured itself to handle all `packet_in` events before any other application. It then looks for packets sent to it as a result of rules in table 0. Any identifier binding traffic is validated, used to update binding information, and sent to the relevant application. Any other packets sent to the controller from rules in table 0 will be logged and dropped.

We implemented SECUREBINDER as an SDN application in ONOS 1.5.1.[3] We had to make a few modifications, totaling 548 lines of code, to the core of ONOS. The major change, totaling 438 lines, was to secure the implementation of topology detection provided by ONOS. SECUREBINDER leverages secure topology detection as a major performance optimization to dramatically reduce the overhead by only validating packets and installing egress filters at the edge of the network. While existing work like TopoGuard [24] has demonstrated the importance of secure topology detection and provided an implementation, ONOS has not yet incorporated this feature. Secure topology detection protects against a wide range of attacks so we believe it should be a service provided by all SDN controllers. Hence, we use it as an optimization in SECUREBINDER. The remaining modifications reserve table 0 for SECUREBINDER, moving all other applications to table 1.

Our SECUREBINDER application itself is 2,350 lines of Java. Since it processes packets prior to any other application in the controller, it protects other applications in use from incorrect binding information. This enables us to use the existing ONOS ProxyARP and DHCP applications without modification.

5 Evaluation

In this section we provide a formal evaluation of the security provided by SECUREBINDER against identifier binding attacks and evaluate its effectiveness against our new Persona Hijacking attack and its performance impact in a testbed environment.

5.1 Formal Evaluation

In order to assess the security properties of SECUREBINDER, we conducted a formal, model checking-based analysis of hosts interacting via ARP and DHCP over an SDN, both with and without SECUREBINDER in place at the controller. We defined a set of security invariants which, if violated, correspond to the successful malicious use of ARP, DHCP, or IP/MAC spoofing. Using the SPIN model checker [22], we first ran an analysis without SECUREBINDER. This returned a large set of automatically discovered counter-examples (invariant violations) that correspond to known ARP spoofing, Host-Location Hijacking (also independently and manually discovered by Hong, *et al.* [24]), and rogue DHCP attacks, as well as our own IP takeover and Flow Poisoning attacks. Next, we enabled SECUREBINDER in the model and re-ran the analysis against the same set of security invariants. In

[2]This indirection enables a single certificate to be used on a multi-homed host that has multiple MAC addresses.

[3]`http://onosproject.org/`

this case, SPIN was unable to find any security violations, indicating that our defense prevented all of the previously discovered attacks.

Model Checking. Our formal models were written in the Promela process modeling language, and the security properties were checked using the SPIN model checker. Models written in Promela define properties written in Linear Temporal Logic (LTL). LTL has been used to check safety and liveness properties, but also security invariants. For a full explanation of LTL syntax and semantics, the interested reader can refer to the book by Reeves and Clarke [41]. Once a Promela model is written and the logical properties of its state variables defined, SPIN can then be used to verify that those properties hold over all reachable system states, or to find a counter-example (*i.e.,* an attack violating a security property). SPIN models all possible inter-leavings of non-atomic actions in a concurrent system of communicating processes.

Model Architecture. Our analysis considers end-hosts communicating via packets passed to an SDN switch managed by a controller that uses the source address fields of `packet_in` events to populate a NIB used to make routing decisions. A packet consists of an Ethernet frame (containing source and destination MAC addresses) encapsulating either an ARP message or an IP header and DHCP payload.

ARP is implemented as defined in RFC 826 [40], but does not include the message fields or associated checks for hardware and protocol types, since our analysis is focused on IPv4 Ethernet networks. ARP clients may also send gratuitous ARP requests or replies.

A fragment of DHCP is implemented as defined in RFC 2131 [15]. The full client and server state machines are implemented (using symbolic addresses), but we do not include any generic representation of DHCP options or other configuration parameters not essential to the assignment of IP addresses. This is because we define *any* DHCP payload from an unauthorized DHCP server to be malicious, regardless of its content.

Communication occurs through uni-directional channels, in which senders place packets on a finite-length FIFO queue and receivers remove messages from the head of that queue. All communication between end-hosts is mediated by the switch: that is, end-hosts place packets in a switch queue, and the switch determines the end-host queue to which it should forward the packet.

End-hosts are processes which non-deterministically[4] send and receive ARP and DHCP client messages. The target of unicast traffic is chosen non-deterministically. One end-host is also designated as a DHCP server and implements a DHCP server that uses ARP probes to determine if a previously-used address is still in use. All end-hosts faithfully follow protocol specifications (*e.g.,* using correct source addresses).

An adversarial end-host does not follow protocol specifications. Any data field in an Ethernet, ARP, IP, or DHCP message may be non-deterministically assigned any symbolic value (*e.g.,* another end-host's source address). Adversarial end-hosts may also act simultaneously as both DHCP servers and clients.

Security Properties. Our analysis is based on checking the same set of invariants in two different cases: a basic SDN, and one in which SECUREBINDER is deployed. These invariants are designed to completely capture correct network identifier binding behavior in the case of an IPv4 Ethernet network with at most one IP address assigned to each network interface, one end-host connected to each switch port, and no multi-homed end-hosts, as described in Section 2.1. They utilize several ground-truth tracking tables maintained in the model to check the actual values of client and controller data structures against their intended values in the absence of adversarial behavior. The ground-truth invariants are intended to represent 'idealized' network security enforcement, which, while not implementable in the real world, will be violated in the presence of any kind of attack against network identifier bindings. Note that a number of sub-invariants (such as a one-to-one binding of IP-to-MAC and Mac-to-Port mappings) are implicitly captured, as a violation of these would result in a violation of one or more of the explicitly checked invariants.

We define two kinds of security properties: invariants, which must hold in all model states, and assertions, which must hold in a subset of model states. The former are encoded as LTL formulas over model state variables (*e.g.,* the entries in each end-host's ARP cache). SPIN uses an automata-theoretic construction (see [22]) to ensure that no LTL violations occur in any reachable model state, and to return an execution trace in the case that a violation was found. Assertions are encoded as Boolean predicates inserted inline in the model code, which are checked whenever the model executes that line. LTL invariants were used when security requirements constrained the value of a persistent data structure, such as ARP or DHCP tables. The `G` operator in LTL states that the formula must hold Globally over all reachable states. Assertions were used for constraints on the value of non-persistent messages passed over the network.

The security requirements that we checked are presented in Table 2 and discussed in detail in Appendix C.

Results. Because model checking is limited to a finite state space search, it is necessary to bound the size of the network for each analysis. We checked our invariants for networks with a single attacker, DHCP server, and SDN switch. Analyses were conducted for networks with end-host populations ranging from 1 to 20.

[4]Promela's control structures are non-deterministic, because SPIN considers all possible orderings of events in a system.

Table 2: Identifier Correctness Requirements

Requirement Name	Requirement Formula (LTL Invariants and Message Assertions)
Port–MAC Binding	`G(port_to_mac[p] == g_mac_at[p])` for each port p
MAC–IP Binding (ARP)	`G(arp_tbls[c][i] == NO_ENTRY || g_mac_to_ip[arp_tbls[c][i]] == i || g_mac_to_ip[arp_tbls[c][i]] == NO_ENTRY)` for each ARP table c and each entry i
Authorized DHCP	`(msg.cid == DHCP_SERVER && (msg.dhcp.type==DHCP_OFFER || msg.dhcp.type==DHCP_ACK || msg.dhcp.type==DHCP_NAK)) || (msg.cid != DHCP_SERVER && (msg.dhcp.type==DHCP_DISCOVER || msg.dhcp.type==DHCP_REQUEST || msg.dhcp.type==DHCP_DECLINE || msg.dhcp.type == DHCP_RELEASE))`
Genuine chaddr	`msg.dhcp.chaddr == g_mac[msg.cid]`
Genuine ciaddr	`msg.dhcp.ciaddr == g_ip[msg.cid]`
Genuine MAC	`msg.frame.eth_src == g_mac[msg.cid]`
Genuine IP	`msg.ip.nw_src == g_ip[msg.cid]`

Table 3: Attacks Found Through Invariant Checking

Attack Class	Description	Invariant Violated
ARP Spoof	Gratuitous Request with Victim's SPA and TPA and own SHA	MAC–IP Binding (ARP)
ARP Spoof	Gratuitous Reply with Victim's SPA and own TPA	MAC–IP Binding (ARP)
ARP Spoof	Reply to Request with Victim's SPA and own TPA	MAC–IP Binding (ARP)
Host-Location Hijacking [24]	Ethernet packet with victim's MAC	Port–MAC Binding, Genuine MAC
IP takeover	DHCP_Release with victim's IP	Genuine ciaddr
Flow Poisoning	Ethernet packet to victim with target's MAC	Port–MAC Binding, Genuine MAC
Rogue DHCP	DHCP_OFFER from attacker	Authorized DHCP

When SECUREBINDER was not deployed, many invariant violations were found corresponding to existing attacks. Manual inspection of the execution traces revealed that all of these are either known attacks or correspond to our IP takeover or Flow Poisoning attacks. These are summarized in Table 3.

When SECUREBINDER was enabled, no invariant violations were found. This indicates that the set of SDN-based checks implemented by SECUREBINDER is equivalent to the ideal invariants that can be checked with access to ground truth. Note that formal verification via model checking is sound but incomplete, because it is based on a finite state space search of a larger, potentially infinite, space. Model checking can be made complete, however, if it can be shown that the larger region reduces (*e.g.,* via equivalence classes) to the explored region.

We argue (but do not formally prove) that this is the case for our analysis. Above an end-host population of 3, all invariant violations were variants of those already found in networks of 3 or fewer end-hosts. That is, while the specific details of the violation (*e.g.,* the protocol address, hardware address, or ARP table) varied, the actual violating condition (*e.g.,* an IP address bound to a MAC address not assigned by the DHCP server) was one already seen in the smaller analyses. Given this empirical evidence, we suspect that no new attacks will be found by adding more end-hosts to the analysis, nor will any attacks be found in the case that SECUREBINDER is deployed. Clearly, making the analysis more complex in other ways (*e.g.,* allowing multi-homing or multiple end-hosts to share a switch port) may introduce new vulnerabilities. Exploring these more complex scenarios is a component of our future work.

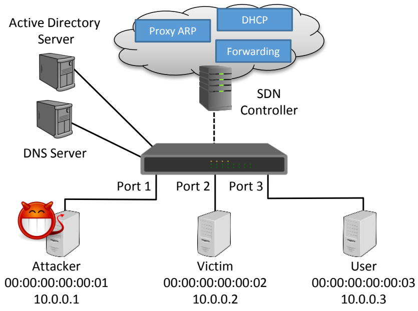

Figure 5: Testbed Evaluation Network Topology

5.2 Experimental Evaluation

We construct an emulated SDN testbed network and launch three separate identifier binding attacks, including our Persona Hijacking attack, at ONOS 1.5.1 with and without SECUREBINDER. To guarantee representative results, we repeat each of the attacks ten times.

For our emulated SDN testbed we used Mininet 2.2.1 [30] with Open vSwitch 2.4.0[5] software switches. We chose a minimal topology with a single switch and

[5] `http://openvswitch.org/`

Table 4: Performance Results

Controller	Host Join	New Flow	pkt_in's
ONOS 1.5.1	505±578ms	8±4ms	131±2
SECUREBINDER	3,505±678ms	6±5ms	193±8
Overhead	+3000ms	-2ms	+62

three hosts—an attacker, a victim, and a user that wishes to contact the victim—for our network, as shown in Figure 5. The attacks we test are also relevant for more complex topologies; we demonstrate them on a minimal topology for simplicity. The experiments were performed in an Ubuntu 14.04.4 VM with 2 cores of an 2.70GHz Intel i7 CPU available and 15GB of RAM. Our test network uses ONOS 1.5.1 as the controller, providing shortest path routing, proxyARP, and DHCP.

Persona Hijacking attack. Since we test against ONOS, we need only the IP takeover phase of the attack. The attack was successful, allowing the attacker to steal the victim's IP address. On average, an attack took 49.8 seconds to execute, with effects lasting indefinitely.

ARP poisoning. The attack was successful, allowing the attacker to receive traffic destined for the victim. This attack lasts until the victim sends traffic that traverses the controller, 41 seconds in our experiments, but depends highly on the workload of the victim machine.

Host location hijacking. In this attack, previously reported by Hong, *et al.* [24], the attacker sends spoofed packets that contain the victim's MAC address as their Ethernet source address with the goal of confusing the SDN controller into thinking that the victim has moved to the attacker's location. If this can be accomplished, traffic for the victim will be sent to the attacker's location. We observed this attack to be completely successful as well, allowing the attacker to receive traffic destined for the victim. Like the ARP poisoning attack, this attack has a limited lifetime. Once the victim sends traffic that traverses the controller, the controller is able to correct the victim's location, ending the attack. In our experiments, this was an average of 51 seconds, but highly depends on the workload of the victim.

In all of the above scenarios, SECUREBINDER threw an alert and blocked the attack immediately.

5.3 Performance Evaluation

We evaluate the additional overhead our defense imposes in terms of extra latency for devices joining the network and on each new flow, as well as the additional controller load and flow rules it generates. We run each experiment 10 times and present averages and standard deviations.

Latency. We measure Host Join Latency and New Flow Latency. Host Join latency measures the latency for a host to join the network and includes network link detection, DHCP negotiation, 802.1x authentication–for SECUREBINDER–, host detection, and flow rule setup and installation of the first flow. New Flow Latency measures the latency to start a new flow—sending a packet_in to the controller, forwarding, and rule installation. We measure Host Join Latency from the first packet a host sends until the insertion of the first flow rule. For New Flow Latency, we measure it from the moment the first packet of the flow arrives at the switch until the first flow rule is inserted. No packets after the first in each flow will be diverted to the controller, so any additional latency only impacts the first packet of a flow.

We compared unmodified ONOS 1.5.1, providing shortest path routing, proxyARP, and DHCP, with SECUREBINDER in a network topology with a single switch. Table 4 shows the results. Host Join Latency is higher for SECUREBINDER, at about 3.5 seconds. This is compared to about 0.5 seconds for ONOS 1.5.1. Most of this difference is due to the 802.1x authentication and additional flow rule insertions required by SECUREBINDER. However, 3.5 seconds is actually fairly reasonable considering that Host Join Latency represents the latency for a host to join a new network.

New Flow Latency, by contrast, is essentially the same between unmodified ONOS 1.5.1 and SECUREBINDER. Our results even appear to indicate a slight decrease when using SECUREBINDER, although that difference is within the noise and not actually meaningful.

Controller load. We approximate controller load as the number of packets handled by the controller. While different packets may take noticeably different amounts of processing to handle, this is a common proxy for controller load and does accurately account for the additional load placed on the network via packet_in messages, TLS message encryption load, message parsing, and event loop processing.

We measured the number of packet_in messages sent to the controller using a Mininet network with 3 switches and 4 hosts in a tree toplogy and compare unmodified ONOS 1.5.1, providing shortest path routing, proxyARP, and DHCP, with SECUREBINDER. Our experiment consists of starting the network, waiting 30 seconds for the network to stablize, performing a pairwise ping between all hosts, and shutting the network down. Our results appear in the third column of Table 4. We observe a 47% increase in the number of packet_in's processed by SECUREBINDER, which is fairly significant. However, of the 62 additional packet_in's, 32 are a result of 802.1x authentication. This means that this additional load occurs only when a new host joins the network.

Number of additional flow rules needed by SECUREBINDER. Flow rules are a limited resource in OpenFlow switches. We can calculate the number of additional flow

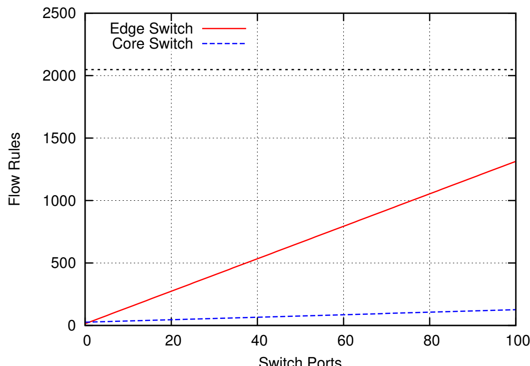

Figure 6: Number of flow rules needed in each switch for SECUREBINDER, as a function of the number of switch ports. Dashed black line marks minimum TCAM rule slots in a modern SDN switch.

rules required per switch by SECUREBINDER as:

$$26 + 13 * edge_ports + internal_ports$$

The first term relates to static flow rules installed globally in each switch to send 802.1x, ARP, and DHCP traffic to the controller and block DNS, mDNS, and Active Directory by default. The second term describes flow rules installed for each edge switch port to enable egress filtering and allow non-spoofed Active Directory and DNS traffic destined for the legitimate servers. The final term includes the flow rules that are inserted in table 0 for internal network ports to send traffic directly to the normal forwarding rules in table 1.

We plot this equation for both edge and core switches with between 1 and 100 ports in Figure 6. We assume edge switches have one port connected to the core network with all other ports connected to edge devices while core switches are connected only to other switches. Keep in mind that most edge switches are usually in the 24-48 port range with the very high degree switches in the core of the network. For a 48 port edge switch, SECUREBINDER would require 638 flow rules.

Determining the number of flow rules supported by modern SDN switches is surprisingly challenging. The number of TCAM slots in current SDN switches of about 48-ports varies from around 512 to 8,192 [12, 43, 7, 21] and many vendors claim to be able to support 65,536 flow rules or more [7, 21]. We use 2,048 TCAM entries (available on many switches) as a lowerbound and denote it with a black dashed lined in Figure 6. For this lowerbound, SECUREBINDER would require 31% of the rules in a 48 port edge switch, 16% in a 24 port edge switch, and only 4% in a 48 port core switch. For edge switches, this is a significant, but still practical, overhead; assuming the devices connected to such a switch communicate evenly, each can talk to 29 other devices simultaneously before exceeding the flow table limits. For core switches, the overhead of SECUREBINDER is insignificant. Further, if we consider the use of higher-end switches with 8,192 rules per switch, these overhead figures become 8%, 4%, and 0.9%, respectively.

6 Limitations and Discussion

Although the Persona Hijacking attack is extremely powerful, it does have some limitations as well as several possible partial mitigations that may not prevent the attack but can alert an attentive defender.

DHCP. Principle among these is that the target must be using DHCP for Persona Hijacking to be applicable. Another limitation is that DHCP starvation, despite being extremely transient, is easily detectable and likely to be monitored because it can also indicate network malfunction. In a similar way, the large number of DHCP_DISCOVERs needed to launch the attack would be readily noticed by a network anomaly detector. If such monitoring systems are deployed, Persona Hijacking would quickly be brought to the attention of the network administrators. However, even if detected, mitigation would require the involvement of a human operator, probably on a time scale of tens of minutes to hours.

Another factor that can complicate a Persona Hijacking attack is the use of static DHCP leases fixing IP addresses to specific MAC addresses. If the network protects against MAC spoofing, this will completely prevent Persona Hijacking. However, we are unaware of any SDN controller implementing any form of MAC spoofing protection. As a result, the attacker is free to launch the Persona Hijacking attack by spoofing DHCP_DISCOVERs with the target's MAC address at a different network location. Interestingly, in this case DHCP starvation is not required.

A number of security features commonly found in traditional switches (*e.g.,* port security [9] and DHCP snooping [8]) make it more difficult to launch a DHCP starvation attack by limiting the number of source MAC addresses originating from a single port; however, a recent starvation technique has been developed to bypass these defensive mechanisms [50]. This technique exploits the DHCP server's IP address conflict detection by answering all the probes used to check if an address is in use, *without* spoofed MAC addresses.

Despite these limitations Persona Hijacking remains a powerful attack that co-opts the network infrastructure to propagate a malicious identifier binding that will reliably last for a significant time even in the presence of a vigilant system administrator running many monitoring tools. This level of persistence is unmatched among existing network identifier attacks and gives the attacker a reasonable window in which to achieve their goals. Fur-

ther, while various security features can make this attack more challenging to launch, they do not prevent it.

Our new defense, SECUREBINDER, is designed to prevent not only Persona Hijacking attacks, but also any other identifier binding attack. Much of the existing work on defenses has focused on preventing single attacks. Once such a defense is deployed, the attacker modifies their attack slightly or transitions to a new binding and continues. SECUREBINDER's goal is to end this game of whack-a-mole by providing a defense against all identifier binding attacks. This influenced our design choices.

Use of 802.11 IEEE 802.1x is not required to defend against Persona Hijacking or ARP poisoning. However, it is still an essential component of a unified defense against identifier binding attacks, despite potentially complicated configuration and deployment. In particular, 802.1x prevents MAC spoofing from being used to bypass network access controls, like firewalls. Without 802.1x, an attacker can present a fake MAC address belonging to a more privileged device. This presents network access control systems with a confused deputy problem; a device is identified by its MAC address and any identifiers bound to that address, while the attacker presents a MAC address corresponding to an authorized device. Restricting MAC addresses to specific network ports or ensuring that a MAC address is only present at a single network port at a time can only partially mitigate this attack. There will still be some important system that must be widely mobile and occasionally powered off. Attackers can simply attack this system.

Universal IEEE 802.1x deployment is not needed on networks implementing a Bring Your Own Device (BYOD) or public access policy. The purpose of 802.1x is to prevent the attacker from impersonating a more privileged device. In these networks, all BYOD or public devices are unknown to the network and therefore equally (un)privileged. Hence, no confused deputy problem arises that would require strong device identities. Note, however, that any known and trusted devices sharing the same network *should* use 802.1x to protect themselves from being impersonated.

Applicability to wireless networks. Wireless devices, like cell phones and laptops, are particularly vulnerable to impersonation in this manner. We have focused in this work on wired networks; however, SECUREBINDER is equally applicable to wireless networks. Unfortunately, OpenFlow support for wireless networks is still nascent. While a few efforts have looked at the changes to OpenFlow needed to support wireless networks [34, 54, 13], no code, devices, or emulators exist yet. Note that deploying SECUREBINDER at the first wired switch after a wireless access point would still provide significantly improved security and would prevent attacks that have to traverse the wired network.

7 Related Work

The closest work to ours is Ethane [6], which leveraged the SDN-provided global view of the network to enable access control based on identifiers like hostnames and users. However, it does not provide a root-of-trust for network identifiers, instead authenticating based on MAC addresses, and does not appear to distinguish between creating new bindings and updating existing bindings. Additionally, Ethane does not manage or protect the hostname-to-IP or user-to-hostname bindings.

A number of efforts [23, 20, 25] have investigated access control in SDN networks. This is an important, but orthogonal line of research. Access control allows or denies network flows based on particular network identifiers or characteristics. In this work, we attack and secure the bindings between these identifiers. By breaking these bindings an attacker can gain access to a false identity and all the network access rights of that false identity. Access control is also being applied in the controller to protect against malicious SDN applications [39].

TopoGuard [24] and SPHINX [14] studied attacks on the MAC address to network location binding, which they refer to as Host Location Hijacking. TopoGuard proposes a defense based on differentiating between creating new bindings and updating existing bindings, requiring a host to not be reachable at its old location before updating the binding. SPHINX defends against these attacks by ensuring that new flows conform to existing identifier bindings, preventing spoofed packets. Both defenses are vulnerable to MAC address spoofing.

In traditional networks, several network identifier attacks and defenses have been developed over the years; they tend to only address a single layer of the network stack at a time, and the defenses may only be heuristic in nature. Port Security [9] is a heuristic defense against MAC spoofing, which limits the number of MAC addresses that can be present on a single network port.

To prevent ARP spoofing [11], a wide range of defenses based on replacing ARP with secure variants have been proposed [4, 32, 35]; however, vendor-supported technologies such as Cisco Dynamic ARP Inspection (DAI) [29], which compares ARP replies with DHCP server records, or monitoring tools like `arpwatch` [31] are used more often in practice. These technologies have a number of limitations, including not protecting static IP addresses and requiring manual configuration.

To prevent rogue DHCP servers [49], DHCP Snooping [8] can be used to separate the switch ports into trusted and untrusted zones. This defense requires manual configuration of the trusted and untrusted zones and is limited to protecting against attacks on DHCP only.

Defenses against DNS spoofing [48] include increasing the randomness in the DNS query, using random

source ports and transaction IDs, to protect against blind attackers [48], as well as cryptographic techniques like DNSSEC [2] that protect the authoritative response from tampering. DNSSEC has yet to be widely deployed.

The username to hostname binding can be protected using Kerberos [37] for authentication, as is the case in Microsoft Active Directory, but architectural and implementation issues enable various attacks, such as pass-the-hash [16, 17], in practice.

8 Conclusion

We have built a proof-of-concept attack in SDNs to hijack MAC and IP addresses, steal hostnames, and poison flows to remove victim bindings and accessibility. We have thereafter shown how to use SDN capabilities to prevent such attacks by implementing a new defense that exploits SDN's data and control plane separation, programmability, and centralized control to protect network identifier bindings, and builds upon the IEEE 802.1x standard to establish a cryptographic root-of-trust. Evaluation shows that our defense formally and experimentally prevents identifier binding attacks with little additional burden or overhead.

A Network Identifiers

Network protocols rely on identifiers of the communicating entities in order to achieve their goals. Such goals, are not only to ensure delivery of packets from a source to a destination, but also to enforce access control and authorization policies (*e.g.,* authority to update a DNS record or to access a service using Kerberos). The key identifiers used at different layers of the networking stack are: network location, MAC address, IP address, hostname, and username.

We consider the *device* as the basic entity with an identifier, be it an end-host, a server, a printer, or an embedded system, *etc.* Devices are distinct from *users* of those devices. Devices may have multiple network interfaces (*e.g.,* virtualized interfaces or multiple Network Interface Cards (NICs)), which may have different identifiers.

Network Location: The lowest level network identifier is the physical switch and port to which a device is connected. We refer to this identifier as the Network Location of a device and define it as a tuple $(switch, port)$, where *switch* is a unique identifier for a switch, a serial number or management IP address in traditional networks and a Data Path Identifier (DPID) in OpenFlow SDNs, and *port* is an integer representing the port number on that switch. As a device's network location is at the edge of the network, a device could potentially have multiple network locations if it is multi-homed. Additionally, multiple devices may be associated to the same network location due to, *e.g.,* virtualization of end-hosts. Thus the mapping between devices and network location is a many-to-many mapping.

MAC Address: A MAC address identifies a NIC or group of NICs on an Ethernet network. There are three

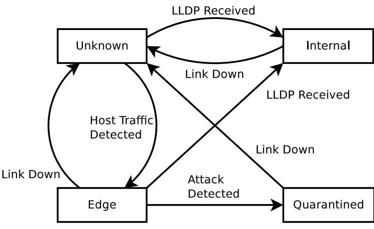

Figure 7: State Machine for each Network Port in SECUREBINDER

types of these addresses: Unicast, Multicast, and Broadcast. Multicast and broadcast addresses allow sending traffic to a particular subset of devices simultaneously while unicast addresses are intended to unambiguously identify a device on the network. Unicast MAC addresses need to be unique in any given Ethernet network or traffic mis-delivery will occur; a unicast MAC address is assigned to each NIC during manufacture.

IP Address: An IP address is used to route traffic across and between networks to a particular device. There are four types of these addresses: Unicast, Multicast, Anycast, and Broadcast. The last three categories are special addresses used to send traffic to a particular subset of devices simultaneously. A Unicast IP address is a unique identifier for a device interface which is constrained to a particular subnetwork (to enable route aggregation). They are either statically configured or assigned using DHCP for IPv4 or DHCPv6 for IPv6. IPv6 also adds a stateless autoconfiguration assignment mechanism known as SLAAC. Only one device in a network can have a particular unicast IP address.

Hostname: A hostname is a human readable name for a system that can be used instead of an IP address. Since one hostname could be associated with multiple IP addresses and one IP address could be associated with multiple hostnames, this is a many-to-many mapping.

Username: A user account identifies a particular user logged onto a system (denoted with a hostname). Many users may be logged into the same system and a single user may be logged into multiple systems, making this a many-to-many mapping.

B SECUREBINDER Design Details

In SECUREBINDER, each network port in the system is in one of four states: `Unknown`, `Internal`, `Edge`, or `Quarantined`. Each port initially comes up in the `Unknown` state, where all traffic is sent to the controller. A port connected to another switch, as identified by the controller's topology detection using LLDP, is put into the `Internal` state, where it sends all traffic directly to table 1 for forwarding. Once at least one host is detected on a port, it is put into the `Edge` state, where it is part of the network edge. In this state, rules are inserted to send packets from known and validated source addresses directly to table 1 while all other traffic is sent to the controller. Finally, a port is placed into the `Quarantined` state when it has been determined that a device on that port is misbehaving. All traffic from `Quarantined` ports is dropped. See Figure 7 for the state machine.

To protect the MAC address to network location binding, we use egress filtering along with 802.1x such that all packets except 802.1x frames that are not associated with an existing binding on a port are dropped. 802.1x frames are passed to our system's 802.1x authenticator in the SDN controller, where the encapsulated EAP messages are sent to the RADIUS server.

We use EAP-TLS authentication, which requires the client to present a valid certificate signed by our internal CA. Additionally, we maintain a database mapping certificate common names to MAC addresses and require the MAC address of the client (as recorded by the trusted 802.1x authenticator in the SDN controller) to match the MAC address associated with the the common name of its certificate in the database. This database is updated manually by the administrator as part of the initial device configuration. If the authentication succeeds, we bind this MAC address to this port and insert flow rules sending packets with this MAC address and port to table 1, for forwarding.

To identify hosts that have disconnected, we listen for port down events and 802.1x log-off messages and remove the corresponding MAC to location bindings. To account for cases where a host may leave the network without sending a log-off message and without the port going down (*e.g.,* a device behind a hub), we periodically query all idle hosts with an ARP ping; devices that do not respond are removed.

We provide support for non-802.1x devices by monitoring the MAC addresses seen on each port and checking whether each one attempts 802.1x authentication within 60 seconds of connecting. If it does not, we assume the device does not support 802.1x and send a RADIUS access request where the username and password attributes simply contain the device's MAC address. The RADIUS server uses a separate database to look up this username and password pair (*i.e.,* MAC address) to see if this device has been granted access. If it has, we then setup the MAC address to network location binding and egress filters to allow it access to the network. Note that since there is no guarantee that this MAC address represents the expected physical device, we recommend statically configuring the network port that each of these devices may connect to and placing stringent ACL rules in the network for such devices to limit network access to only expected locations.

To secure the binding from IP addresses to MAC ad-

dresses, we insert high priority flow rules sending all DHCP and ARP traffic to the controller. Our controller application then checks these packets to ensure that they are self-consistent (*i.e.,* source identifiers in the Ethernet header match those in the ARP/DHCP headers) and that they are consistent with our existing IP to MAC and MAC to location bindings. Inconsistent packets are dropped while validated packets are passed off to an external DHCP server or the controller's ProxyARP application to handle. Note that since our application is the first application to handle these packets, any packets with invalid mappings will be dropped by our application before they can poison other controller applications.

For DHCP, we drop all server messages except those originating from the legitimate server's network location, thereby preventing rogue DHCP servers. We also track the IP address assigned by the server to update our IP to MAC binding information.

We support manually configured static IP addresses by requiring the IP to MAC mapping to be entered in a configuration file. This static IP can be additionally constrained to a single network location. Note that traditional networks with multiple subnets would require similar configuration.

Once we have an IP to MAC address binding, whether from DHCP or static configuration, and know the location of this MAC address in the network, we update the egress filters. In particular, we add one flow rule matching on the port, MAC, and IP address that belongs to this device which sends legitimate traffic to table 1 for forwarding, and we add a second rule that sends all other IP traffic from this port and MAC address to the controller (after a rate limit), preventing IP spoofing.

Interestingly, with 802.1x, DHCP, and manual static IP configuration, we can automatically populate the MAC to location and IP to MAC bindings for all possible reachable hosts. This means we never need to depend on ARP replies from end hosts to populate our bindings. This completely eliminates all ARP poisoning attacks, which operate by either changing the IP to MAC binding or the MAC to location binding.

To secure the hostname to IP address binding, we insert high priority flow rules to drop spoofed DNS packets and send all valid DNS requests to the DNS server while dropping all DNS replies that do not originate at the legitimate DNS server. This prevents the operation of rogue DNS servers and the use of alternate DNS servers. We also drop all multicast DNS and NETBIOS traffic because the broadcast nature of these protocols makes them inherently insecure.

Finally, to secure the username to hostname binding we separate directory service traffic from the dataplane by inserting high priority flow rules to send this traffic directly to the directory server while dropping all spoofed packets. This prevents rogue directory servers and many replay attacks.

C SecureBinder Security Requirements

We used SPIN to check our formal model of identifier bindings and SecureBinder against the following security requirements listed in Table 2 in Section 5. These formal security requirements attempt to capture the following natural goals:

- **Port–MAC Binding** checks that the SDN's mapping of MAC addresses to switch ports is consistent with the ground-truth mapping.
- **MAC–IP Binding (ARP)** checks that for every entry in the client's ARP Table, one of the following properties holds:
  - There is no MAC address for the associated IP.
  - The MAC address for that IP address is the ground-truth owner of that IP address.
  - There is no ground-truth owner of that IP address. This condition arises due to stale ARP cache entries for a released IP address.
- **Authorized DHCP** checks that DHCP messages which should only be sent by the DHCP server are sent by the DHCP server. It also checks that messages which should only be sent by a DHCP client were not sent by the server. This assertion is checked whenever a DHCP message is received by a client or server, prior to any other packet processing.
- **Genuine chaddr** checks that the client hardware address in a DHCP message matches the ground-truth MAC address of the sender. This assertion is checked whenever the DHCP server receives a DHCP message.
- **Genuine ciaddr** checks that the client network address in a DHCP message matches the ground-truth IP address of the sender. This condition is checked whenever the DHCP Server receives a DHCP_REQUEST or DHCP_RELEASE.
- **Genuine MAC** checks that the source MAC in an Ethernet frame matches the ground-truth MAC address of the originator. This condition is checked whenever a packet is received on a switch port.
- **Genuine IP** checks that the source address in an IP header matches the ground-truth IP address of the originator. This condition is checked whenever a packet is received on a switch port.

HELP: Helper-Enabled In-Band Device Pairing Resistant Against Signal Cancellation

*Department of Electrical and Computer Engineering,
University of Arizona, Tucson*

Abstract

Bootstrapping trust between wireless devices without entering or preloading secrets is a fundamental security problem in many applications, including home networking, mobile device tethering, and the Internet-of-Things. This is because many new wireless devices lack the necessary interfaces (keyboard, screen, etc.) to manually enter passwords, or are often preloaded with default keys that are easily leaked. Alternatively, two devices can establish a common secret by executing key agreement protocols. However, the latter are vulnerable to Man-in-the-Middle (MitM) attacks. In the wireless domain, MitM attacks can be launched by manipulating the over-the-air transmissions. The strongest form of manipulation is signal cancellation, which completely annihilates the signal at a targeted receiver. Recently, cancellation attacks were shown to be practical under predictable channel conditions, without an effective defense mechanism.

In this paper, we propose HELP, a helper-assisted message integrity verification primitive that detects message manipulation and signal cancellation over the wireless channel (rather than prevent it). By leveraging transmissions from a helper device which has already established trust with one of the devices (e.g., the hub), we enable signal tampering detection with high probability. We then use HELP to build a device pairing protocol, which securely introduces new devices to the network without requiring them to share any secret keys with the existing devices beforehand. We carry out extensive analysis and real-world experiments to validate the security and performance of our proposed protocol.

1 Introduction

In recent years, we have experienced a proliferation of advanced personal wireless devices (APDs) such as smartwatches, wearable sensors, RFID devices, home monitoring sensors for Internet-of-Things applications, etc. [38]. These devices often connect to a gateway/hub (e.g., a Wi-Fi access point) for data collection or for remote actuation. Securing the communication between APDs and the hub is of paramount importance when the former collect sensitive data, or can control critical functions within their environment. The process of establishing trust between the APD and the hub is known as *secure bootstrapping* and is achieved via a two-party mutual authentication and key-agreement mechanism.

The prevailing methods for secure device bootstrapping are either by manually loading the hub's secret to the device or to preload the APDs with some unique secret. The preloaded secret of APDs can be made known to the hub using an out-of-band (OOB) channel, e.g., the user enters the secret manually. However, many APDs such as smart bulbs, motion sensors, smart key locks, etc., lack advanced interfaces for entering or changing passwords. Moreover, it is a common occurrence that manufacturers opt to preload devices with default keys that are easily leaked. In fact, the largest DDoS attack launched to date exploited default passwords preloaded to APDs–IP cameras, digital video recorders, smart TVs–to recruit hundreds of thousands of nodes into the Mirai botnet and attack the DNS infrastructure [57].

On the other hand, a public key infrastructure (PKI) is also impractical for wide deployments. This is because a PKI typically requires a connection to a centralized certification authority. For devices deployed on-the-fly in areas with intermittent Internet connectivity, reachback to central certificate repositories may not be a robust option. Moreover, PKIs face significant scalability, heterogeneity, and interoperability challenges. As an average person or household owns an increasing number of devices, the device association process must happen within a short time and require very little or no human effort. Also, a trust initialization protocol must be lightweight, as APDs typically have low processing capability and are energy constrained.

Several device pairing protocols have been proposed for device pairing without pre-shared secrets [1, 8, 11, 18, 26, 29, 32, 37, 40–42, 44, 54]. Most such protocols require an auxiliary secure out-of-band (OOB) channel, an audio or visual channel for example, that is observable by a user to aid the authentication of messages transmitted over the public wireless channel. However, such OOB channels introduce practical interoperability issues due to the heterogeneity of the devices and are not user-friendly. Recently, in-band pairing protocols [10, 17, 23] have been proposed as an alternative to OOB pairing. The former protocols only require that devices possess a common wireless interface to communicate. Since the wireless channel is known to be insecure in general, the security of these protocols relies on the assumption that wireless signal cancellation is infeasible, so that message integrity and authentication properties can be derived by encoding the messages in a special way. However, as demonstrated by Popper *et al.* [47], this assumption may not hold in many cases. Thus, it remains an open problem as to whether secure in-band device pairing protocols can still be designed under a strong Dolev-Yao attacker which can annihilate wireless signals.

In this paper, for the first time, we seek an answer to the above question. Instead of trying to *prevent* signal cancellation attacks, we propose an approach to *detect* the presence of an attacker who attempts to nullify the signal at a receiver. Our core idea for verifying the integrity of a message m is to superimpose another signal from a *helper* device (e.g., a smartphone) while m is being transmitted. Any cancellation attack on m is bound to also cancel the superimposed signal from the helper. The helper is assumed to have an existing trust association with one of the devices in the network (e.g., the hub), and is co-present with the primary device that is authenticated by the hub. The superimposed signal is later revealed by the helper via the authenticated channel, to allow for the recovery of m. Our protocol achieves a strong "tamper-evidence" property where there are no restrictions on what kind of signal manipulation the attacker is allowed to do.

Specifically, the device's message m is encoded with ON-OFF keying and Manchester-coding. During the transmission of m, the helper synchronously injects some random signal at randomly selected slots. Any signal nullification attempt will cancel both the legitimate transmitter's and the helper's signal, presuming that the activity periods for the helper are not easily discernible. The helper later reveals its activity periods via an authenticated channel to enable the hub in the detection of signal nullification attempts. Trust between the hub and the helper is established using traditional means (e.g., input a shared random password on the smartphone when it is first paired with the hub), which is a one-time cost. With only one helper in a network, we can securely introduce many new devices at no extra hardware cost, thus ensuring scalability and usability. Essentially, by exploiting the co-presence of the helper with the new device(s), our protocol transfers the trust from the helper to the new device(s).

The main contributions of this paper are four-fold:

- We construct a novel physical layer message integrity verification primitive to detect signal cancellation attacks over the wireless channel. We show that our primitive achieves message integrity protection with only in-band communications.

- We utilize the proposed message integrity verification primitive to construct a secure in-band device pairing protocol named HELP based on the Diffie-Hellman (DH) key agreement [14]. Whereas the primitive provides one-way integrity verification (device-to-hub), we show that HELP achieves two-way authenticated key agreement (counter-intuitively). This is done via a novel way that exploits the helper's superposed random signals to simultaneously protect both the integrity and confidentiality of the DH public parameters, such that an adversary impersonating the hub cannot successfully establish a key with a legitimate device.

- We theoretically analyze the security of the proposed integrity verification primitive and the HELP protocol, and we establish bounds for the adversary's success probability under active attacks (especially Man-in-the-Middle attacks). We show that the adversary's success probability is a negligible function of the protocol parameters and thus can be driven to an arbitrary small value.

- We carry out extensive experiments to evaluate the effectiveness of the signal cancellation detection mechanism and the pairing protocol. Our experiments verify that device co-presence significantly hardens the adversary's ability to distinguish between the helper's and the legitimate device's transmissions. We also implement the proposed protocol in our Universal Software Radio Peripheral (USRP) testbed and evaluate the adversary's successful pairing probability with and without the protection of our integrity verification primitive. The experimental results are in line with our analytical findings.

The paper is organized as follows: we discuss related work in Section 2. We state the system and threat models in Section 3. We present the integrity verification primitive and the HELP pairing protocol in Section 4. The security of the pairing primitive and of HELP are analyzed in Section 5. In Section 6, we study the adversary's

capability in inferring the helper's transmissions and injecting modified messages by performing experiments on the USRP platform. We further experimentally evaluate the HELP assisted key-agreement protocol. We conclude the paper in Section 7.

2 Related Work

In this section, we review previous works in trust establishment without prior associations, which involves both message authentication and key-agreement. It is well known that key agreement can be achieved using traditional cryptographic protocols such as a DH key exchange [14]; however, public message exchange over the wireless medium is vulnerable to Man-in-the-Middle (MitM) attacks, which are notoriously difficult to thwart without any prior security associations. To thwart MitM attacks, additional message authentication and integrity protection mechanisms are required. Therefore, next we mainly review works in authentication/integrity protection without pre-shared secrets.

2.1 Out-of-Band Channel based Approaches

Many existing secure device pairing methods rely on some out-of-band (OOB) channel to defend against MitM attacks [1, 8, 11, 18, 26, 29, 32, 37, 40–42, 44, 54]. The OOB channel is assumed to possess certain security properties (e.g., it is only accessible by the user), which helps verify the integrity of messages transmitted over the wireless channel. However, OOB channels usually require non-trivial human support and advanced user interfaces. For example, when a visual channel is used, a user needs to read a string from one device's screen and input it into another [1, 11, 37], or visually compare multiple strings or LED flashing patterns [31, 32, 44]. Other works require specialized hardware such as a Faraday cage to isolate the legitimate communication channel [27, 30]. On the other hand, biometric signals [3,12,21,46,53,61,62,64] have been proposed to create a secure channel through which nodes on the same body can derive a shared secret. However, their applications are restricted to wearable devices, require uniform sensing hardware, and are susceptible to remote biometrics sensing attacks [20]. In addition, others have proposed to exploit the shared physical context for authentication and key agreement. Examples of common modalities include the accelerometer measurements when two devices are shaken together [35, 36], or light and sound for two devices located in the same room [38,52]. Again, these require additional hardware and are not interoperable, whereas in many cases the contextual source has low entropy.

2.2 Non-cryptographic Device Authentication

As an alternative, non-cryptographic authentication techniques usually derive trust from *hard-to-forge* physical-layer characteristics unique to each device/link. They usually transmit information "in-band" without requiring an OOB channel. Existing approaches on non-cryptographic device authentication [9,25,33,45,60,65] can be classified into three categories: (a) *device proximity*, (b) *location distinction*, and (c) *device identification*. In device proximity methods, the common idea is to exploit the channel reciprocity and its rapid decorrelation (within a few wavelengths) with distance. However, such techniques typically require advanced hardware which is not suitable for constrained wireless devices. For example, [9, 45, 65] require multiple-antennas, and [33] needs a wide-band receiver. Moreover, these techniques only address the common key extraction problem, leaving them vulnerable to MitM attacks. Distance bounding techniques [5, 49, 50] were also proposed to ensure proximity, but they are not so practical yet (either resort to OOB channels or specially designed hardware). Location distinction methods such as temporal link signatures that detect location differences [25, 43, 60] require high bandwidth ($>$ 40MHz), which is not always available to low-cost, resource-constrained devices. Finally, device identification techniques [6,13,16] distinguish devices based on their unique physical-layer or hardware features. Unfortunately, both location distinction and device identification techniques require prior training or frequent retraining, which is not applicable to APDs first introduced to an environment.

2.3 In-Band Approaches for Message Integrity Protection

Whereas the above approaches authenticate a device's presence, they do not necessarily protect the integrity of the messages transmitted by a device, due to the possibility of signal manipulation attacks over the wireless channel [10]. There have been few past attempts to design in-band message integrity protection mechanisms, which assume that signal cancellation over the wireless channel is not possible [10, 23], or occurs with bounded success [22]. For example, Tamper-Evident Pairing (TEP) proposed by Gollakota *et al.* in 2011 [17], and integrity codes (I-codes) proposed by Čapkun *et al.* in 2008 [10] both assumed the infeasibility of signal cancellation. Based on message integrity, message authentication can be achieved by assuming the presence of the legitimate device is known (a.k.a. authentication through presence). However, the infeasibility of signal cancellation assumption does not always hold. Pöpper *et al.*

demonstrated an effective relay signal cancellation attack using a pair of directional antennas, which works regardless of the packet content and modulation [47]. Recently, Hou *et. al.* [22] showed that it is possible to prevent signal cancellation only if the channel itself has enough randomness. A typical indoor environment may not be sufficient because the devices are static and the channel is usually stable.

To remedy the significant shortcomings of existing device pairing schemes, we (for the first time) introduce the core idea of detecting signal manipulation attacks even if signal cancellation is 100% effective. This is achieved through the introduction of a *helper* device which is already securely paired with the hub in an offline fashion (e.g., using conventional pairing methods). With the aid of the helper, trust can be established securely for newly introduced devices without significant human effort or any advanced hardware. Our protocol only uses in-band wireless communication, and thus, it is interoperable.

3 Problem Statement

3.1 System Model

We consider a star network topology, where a wireless base station (*BS*) services multiple personal devices, which is similar to an Internet-of-things (IoTs) scenario. For example, the network can reside inside a home or an office space. Our goal is to securely pair an unauthenticated device with the base station in the presence of an adversary and establish a common key between the device and the *BS*. The adversary can either try to hijack the uplink communication to pair with the *BS*, or spoof a rogue *BS* to pair with a legitimate device. The device and the *BS* do not pre-share any common secrets (*e.g.* secret cryptographic keys). We assume that a user initiates the pairing process by powering the device and setting it to pairing mode. Figure 1 describes the system model. Formally, the following entities are part of the system model.

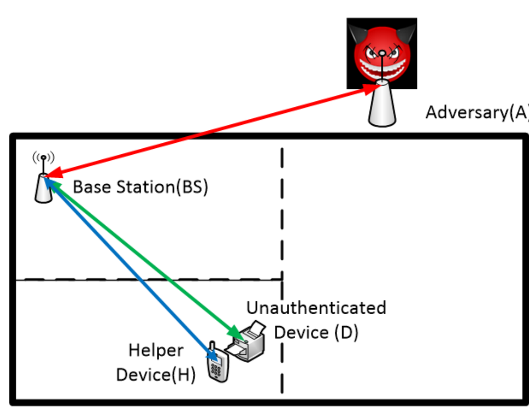

Figure 1: Entities of the system model and basic setup.

Base Station (*BS*): The *BS* serves all the legitimate devices and needs to establish a secure communication link with each of them. The *BS* connects with the legitimate devices through a wireless channel. The *BS* verifies and pairs with any legitimate device requesting to join the network.

Helper Device (*H*): The helper is an auxiliary device such as a smartphone, that assists the *BS* in the pairing process. The helper has already established a secure authenticated channel with the *BS*, either by establishing a common key, using a public/private key pair, or through some OOB channel [1, 37]. Using this secure channel, H can apply an authenticated encryption function $\mathrm{AE}(\cdot)$ on a message m_H to guarantee the confidentiality and integrity of m_H, and the authenticity of the source. Any such $\mathrm{AE}(\cdot)$ can be utilized with the proposed protocol. For example, if H and the *BS* share a public/private key pair, H can encrypt/sign/encrypt (or sign/encrypt/sign) its message to guarantee the necessary security properties. If H and *BS* share a common master symmetric key, an encrypt-then-MAC operation can be followed to implement $\mathrm{AE}(\cdot)$, after separate symmetric keys are generated from the master key for the encryption and MAC operations. One of the examples is to use encryption then message authentication code hashing with the shared key. We refer the reader to [2] for more details on authenticated encryption. We leave the exact specification of $\mathrm{AE}(\cdot)$ open to allow for both symmetric and/or asymmetric methods.

Note that pairing H to the *BS* is a one-time effort and need not be repeated with every device join. Moreover, only the helper is required to have an advanced interface to pair with the *BS*.

Legitimate Device (D): A legitimate device is a typical APD which does not share any secrets with the *BS* or H. The device is usually small and has simple user interfaces (such as a power button) and hardware capabilities. The legitimate device, H, and the *BS* are assumed to be copresent during the pairing process. H and D are placed in close proximity such that they have a highly correlated wireless channel.

3.2 Threat Model

Adversary: We consider the typical *Dolev-Yao model* [15]. The adversary (A), can fully control the wireless channels of the network. For example, it can eavesdrop, modify, remove, replay or inject messages (frames) transmitted on the wireless channel. The adversary is also powerful enough to annihilate signals transmitted

from D and H over the wireless channel, such that they do not reach the BS (and vice versa). This can be accomplished by techniques proposed by Pöpper *et al.* [47]. The pairing protocol itself is known to A, but the adversary does not have physical access to any of the devices. The helper device is assumed to be trusted and its secret key with the BS is kept away from adversaries.

Note that we do not impose any location restriction for the attacker. Although the devices are typically located in a physically bounded area such as a home, we do not assume that this is a secure region. Instead, the attacker can be located inside the physical space, as long as the attacker cannot physically control the device and the BS to be paired. That is, the attacker does not control the helper so that it cannot initiate the pairing with the BS when no legitimate device is present. The user is aware of the presence of both the BS and of the legitimate device (which are powered on) when the pairing is initiated. This is the minimal assumption adopted by the majority of the previous works in device pairing.

The goal of an attacker is to pair successfully with the BS and/or D. Therefore, we mainly consider a MitM attacker in our security analysis. However, in this paper, we do not focus on preventing denial-of-service (DoS) attacks such as jamming, which is orthogonal to our studies. Similarly with all relevant literature, we assume that the adversary is incapable of physically blocking signals (e.g., by adding a Faraday cage) to the device, the helper, or the base station.

In addition, at any point in time, the attacker may try to find out who is transmitting on the wireless channel. There could be several cases: device only, helper only, BS only, or device plus helper together. For example, the attacker can do so via energy detection or use physical layer identification/fingerprinting techniques [7,19,28,39,55,59]. Since we assume that D and H have a highly correlated channel due to their proximity, it is generally difficult for the attacker to differentiate between the cases of device only and helper only. Thus, the attacker can differentiate between the number of transmitters (i.e., $D+H$ or D/H alone), but the attacker cannot perfectly distinguish D and H (i.e., the probability of successful detection is less than 100%). We propose specific power and slot synchronization randomization methods to ensure that D and H are not easily distinguishable. Note that any device distinction method has to operate only to correspond to the online nature of a MitM attack.

4 HELP: Helper-Enabled Pairing

In this section, we present HELP, an in-band Helper-enabled pairing protocol that does not require secret preloading. HELP makes use of a new PHY-layer message integrity protection primitive to detect signal cancellation attacks that are launched to perform a MitM attack against a key agreement protocol. We first describe the PHY-layer protection primitive and then use this primitive to construct HELP.

4.1 Message Integrity Protection Against Signal Cancellation

Consider the simple scenario depicted in Figure 1. A new legitimate device D wants to pair with the BS by transmitting a message m_D over a wireless channel. Message m_D is not protected by any cryptographic message integrity mechanism such as a MAC because D and the BS do not share any prior security association. Let $\mathbf{x}_D$ denote the corresponding signal transmitted from D carrying m_D. Let also an adversary A perform a signal cancellation attack on the received signal $\mathbf{y}_D = \mathbf{h}_{D,BS}\mathbf{x}_D$ at the BS, where $\mathbf{h}_{D,BS}$ denotes the channel between D and the BS. Simultaneously, A injects his own signal $\mathbf{x}_A$ carrying message m_A. The main challenge in providing message integrity is to detect that a cancellation/injection has taken place.

To combat signal cancellations, we employ Manchester-coded (MC) ON-OFF keying modulation to transmit m_D from D to the BS similar to [10,17]. In ON-OFF keying, a zero bit is mapped to (OFF, ON) slots pair, whereas a one bit is mapped to (ON, OFF) slots pair. The receiver demodulates the ON-OFF keying sequence by applying energy detection on every slot. The advantage of ON-OFF keying is that it hardens signal cancellations, as the adversarial device, A has to "erase" the received signal $\mathbf{y}_D$ at the BS by synchronizing its own signal transmission $\mathbf{x}_A$ and taking into account the channels $\mathbf{h}_{D,BS}$ and $\mathbf{h}_{A,BS}$. Different from previous approaches [10, 17, 24], we consider the worst case scenario where signal cancellation is possible due to the stability and predictability of the respective channels, as it was demonstrated in [47].

The MC facilitates several functions. First, the alteration between ON and OFF slots prevents the zero wandering problem, allowing the receiver to keep a power reference for differentiating between ON and OFF slots, irrespective of the data sequence. More importantly, an MC message contains an equal number of zeros and ones. Our integrity protection mechanism relies on the detection of canceled ON slots and therefore, the guarantee of ON slots irrespective of the data sequence is critical to the protocol security. Finally, the use of MC allows for the recovery of the device's message when the latter has been corrupted from the intentional transmissions of the helper. Revealing the "time locations" of the helper's ON slots enables the message recovery.

In the proposed integrity primitive, the helper is placed in close proximity to the unauthenticated device D and

synchronously transmits a message m_H while m_D is being transmitted. A signal cancellation targeted at the *BS* is bound to also cancel the signal from H. With the completion of the m_D transmission, the helper reveals m_H to the *BS*, who verifies if any part of m_H has been canceled.

If the message integrity verification test is passed, the *BS* exploits the knowledge of m_H to recover m_D. A key requirement for the successful detection of signal cancellations is that the adversary A cannot *swiftly* identify the ON slots of the helper. We achieve this requirement by placing the helper in close proximity to D and by randomizing the transmit power and the starting time of each ON-OFF slot at D and H. Placing H close to D makes it difficult to differentiate the two devices using transmission directionality or the uniqueness of the wireless channel. Note that the ON-OFF transmissions contain no preambles, so channel estimation becomes difficult. The randomization of the power and ON slot firing times aim at preventing the device distinction using RSS measurements or the possible time misalignment between the two devices due to inaccurate synchronization or different paths to the adversary. We emphasize that any device distinction mechanism must operate online—the adversary has to decide to cancel an ON slot within the first few samples—which renders existing sophisticated radio fingerprinting techniques inadequate [7,19,28,39,55,59]. We now describe the PHY-layer message integrity verification primitive in detail.

4.2 HELP Integrity Verification

We propose a message integrity verification method called HELP that operates with the assistance of a helper device H. The integrity of a message m_D transmitted from D to the *BS* is verified via the following steps.

1. **Device Placement:** The helper H is placed in close proximity to the unauthenticated device D.
2. **Initialization:** The user presses a button on D or simply switches D on to set it to pairing mode. The user then presses a button on H to initiate the protocol. The helper sends an authenticated *request-to-communicate* message to the *BS* using the $\text{AE}(\cdot)$ function. This message attests that the legitimate device D is present and H is placed near D.
3. **Device Synchronization:** The *BS* sends a publicly known synchronization frame SYNC to synchronize the clocks of D, H and itself[1]. The SYNC frame is similar in function to the known preamble that is attached to wireless transmissions for synchronizing the receiver to the transmitter. In our protocol, all three entities synchronize to the same time reference, using the known SYNC message.
4. **Transmission of m_D:** D transmits m_D in the form $[h(m_D)], m_D$, where $[\cdot]$ denotes an MC ON-OFF keyed message and h is a cryptographically-secure hash function. Note that no key input is used with h, as D and the *BS* do not share a common key.
5. **Helper Signal Superposition:** Synchronously with the transmission of $[h(m_D)]$, the helper transmits a signal m_H with ON slots in a random number of slot locations determined by vector $\mathbf{s}$. The ON slots in $\mathbf{s}$ are time-aligned with the slots (ON or OFF) of $[h(m_D)]$. Only one slot of m_H can be ON per MC ON-OFF bit of $[h(m_D)]$. Sequence m_H is not necessarily a proper MC sequence (and hence, is not marked by $[\cdot]$).
6. **Reception at the *BS*:** The *BS* receives $([h(m_D)] + m_H)'$ and m_D'.
7. **Revealing m_H:** The helper reveals $\text{AE}(\mathbf{s}, K)$ to the *BS*.
8. **Integrity Verification of s:** The *BS* decrypts $\mathbf{s}$ and verifies its integrity using function $\text{VD}(\cdot)$, which is the corresponding decryption/verification function to $\text{AE}(\cdot)$. If verification fails, the *BS* aborts m_D'.
9. **Integrity Verification of m_D:** The *BS* verifies that all slot locations indicated by $\mathbf{s}$ are ON on the received $([h(m_D)] + m_H)'$. If not, a signal cancellation attack is detected and m_D' is rejected. Otherwise, the *BS* recovers $h(m_D)'$, by removing m_H from $([h(m_D)] + m_H)'$ using the knowledge of $\mathbf{s}$. For bits where $\mathbf{s}$ was OFF in both corresponding slots, the MC sequence is decoded using typical decoding. For an ON slot in $\mathbf{s}$, a bit b_D is decoded using the truth table in Figure 2(a). Upon recovery of $h(m_D)'$, the *BS* checks if $h(m_D') \stackrel{?}{=} h(m_D)'$. If the integrity verification fails at the *BS*, either the *BS* or H display a FAILURE message, and all entities abort the protocol. The user has to restart the pairing process from the initialization step. If the integrity verification passes, then *BS* or H display a SUCCESS message.

The steps for extracting $[h(m_D)']$ from $([h(m_D)] + m_H)'$ at the *BS* are shown in Figure 2(b). After synchronization, D transmits $h(m_D) = 0110110101$ in the form of $[h(m_D)]$ (for illustration purposes, we have restricted the length of the hash function to 10 bits). The helper synchronously transmits during slots $\mathbf{s} =$

[1]The SYNC message doesn't need to be secured since if it is canceled at both device and helper, it becomes a DoS attack. If the device and helper are forced to be out of sync by an attacker, BS will fail to decode which is again a DoS.

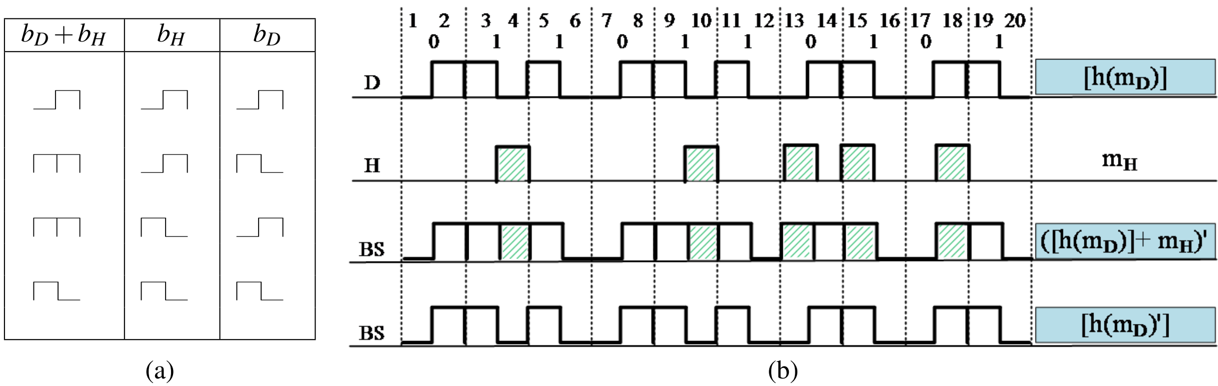

Figure 2: (a) Truth table for recovering $[h(m_D)']$ from $([h(m_D)]+m_H)'$, using **s**, and (b) an example of recovering $[h(m_D)']$ from $([h(m_D)]+m_H)'$.

$\{4,10,13,15,18\}$. The *BS* receives the superimposed signal $([h(m_D)]+m_H)'$. Using the truth table in Figure 2(a), the original MC sequence corresponding to $h(m_D)$ is recovered.

4.3 Device Pairing with HELP

In this section, we describe how the *BS* and *D* can establish a secret key in the presence of a MitM adversary. We complement the DH key agreement protocol with the HELP integrity verification primitive. The latter is used to detect the cancellation portion of a MitM attack. Moreover, the helper provides the necessary authentication for the DH message exchange. The HELP-enabled DH message exchange is shown in Figure 3.

To fix the ideas, the *BS* (or *D*) publishes parameters $(\mathbb{G},q,g)$ of the DH scheme, where ($\mathbb{G}$ is a cyclic group of order q and g is a generator of G). If $(\mathbb{G},q,g)$ are already publicly known, they need not be sent by either party. Device *D* computes $z_D = g^{X_D}$, where X_D is chosen from $\mathbb{Z}_q$ uniformly at random. After the initialization and synchronization steps (omitted from Figure 3), *D* transmits the integrity-protected form of $m_D : ID_D, z_D$ to the *BS*, while the helper is injecting m_H on slot positions denoted by **s**. Here, we opt to protect both $h(m_D)$ and m_D with the PHY-layer primitive to conceal the value of m_D from an adversary *A*, who cannot learn the helper's sequence m_H. This prevents a rogue *BS* from recovering m_D, so that it cannot pair with the device successfully. The helper then reveals **s** to the *BS* through the secret channel implemented by AE$(\cdot)$. The *BS* uses **s** to verify the integrity of m_D and recover z_D. *BS* replies with $z_{BS} = g^{X_{BS}}$, where X_{BS} is chosen in $\mathbb{Z}_q$ uniformly at random. Each party independently calculates $k_{D,BS} = g^{X_D \cdot X_{BS}}$. Immediately following the key-agreement, *D* and *BS* engage in a key confirmation phase, initiated by *D*. This can be done by executing a two-way challenge-response protocol [4], as shown in Figure 4. If any of the verification steps fail, the corresponding party aborts the pairing protocol.

D		*BS*
Given ID_D, $(\mathbb{G},q,g)$		Given ID_{BS}, $(\mathbb{G},q,g)$
Pick $X_D \in_U \mathbb{Z}_q$		$X_{BS} \in_U \mathbb{Z}_q$
$z_D \leftarrow g^{X_D}$		$z_{BS} \leftarrow g^{X_{BS}}$
$m_D \leftarrow ID_D, z_D$		$m_{BS} \leftarrow ID_{BS}, z_{BS}$
(*H* active)	$\xrightarrow{[h(m_D)],m_D] + m_H}$

5 Security Analysis

In this section, we analyze the security of the HELP integrity verification primitive and evaluate the security of the DH-based pairing protocol presented in Section 4.3.

5.1 Security of the HELP primitive

Consider the transmission of $[h(m_D)], m_D$ from *D* to the *BS*, superimposed with the transmission of m_H. The goal of the adversary *A* is to replace m_D with some desired m'_D and pass the verification at the *BS*. In the absence of the helper, a straightforward strategy for *A* is to annihilate $[h(m_D)], m_D$ and inject $[h(m'_D)], m'_D$. However, when m_H is superimposed on $[h(m_D)]$, a cancellation of $[h(m_D)] + m_H$ leads to the likely detection of the cancellation attack due to the "erasure" of the helper's ON slots.

Rather than blindly canceling the composite signal $[h(m_D)] + m_H$ transmitted by *D* and *H*, the adversary can attempt to detect the ON slots of the helper and leave those intact. He can then target only the OFF symbols of m_H and modify those to desired values so that the *BS* decodes m'_D. To pass the integrity verification performed by

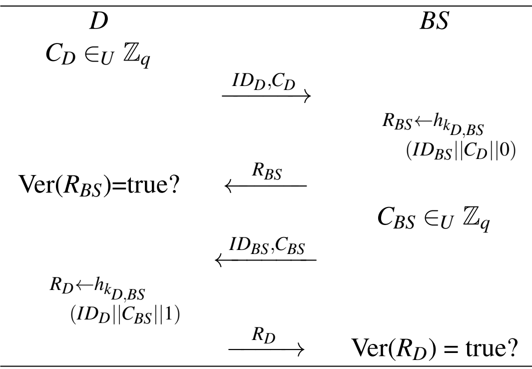

Figure 4: Key confirmation of $k_{D,BS}$ using a challenge-response protocol.

the *BS*, it must hold that (a) all the ON slots indicated in $\mathbf{s}$ are also ON slots in $[h(m'_D)] + m_H$, and (b) the removal of m_H during step 8 of HELP (see Section 4.2), leads to the decoding of $[h(m'_D)]$. As m_D follows in plaintext, the adversary can then replace m_D with m'_D.

We first show that if the adversary can identify the ON slots of the helper (this is equivalent to knowing m_H), then it can modify the transmitted signal such that the desired value m'_D is decoded at the *BS*. Consider the transmission of one MC ON-OFF bit b_D and the superposition of an ON slot by H either during the ON or the OFF slot of the coded b_D. The possible outcomes of this superposition are shown in the third column of Table 1. Moreover, we show the signal b_A that must be injected by A to cause the decoding of the desired value b'_D at the *BS*. For illustration purposes, we show the signal cancellation as a negation of the ON value.

From Table 1, we observe that if b_H is known, the adversary can always make the *BS* decode the desired bit b'_D, irrespective of the value of b_D. Moreover, since the ON bits of m_H stay intact, the modified signal will pass the PHY-layer integrity verification at the *BS*. However, identifying the ON slots of the helper is difficult due to the location proximity between D and H and also the strict reaction time necessary to perform the cancellation attack in an online fashion. In the next proposition, we prove the security of the integrity verification mechanism under the realistic assumption that an ON slot for the helper is timely identified by A with some probability. We experimentally evaluate this probability in Section 6. The security of the integrity verification of HELP is given by Proposition 1.

Proposition 1. *The HELP integrity verification primitive is δ–secure with*

$$\delta = \left(1 - \frac{1-p_I}{4}\right)^{|\mathbf{s}|}. \qquad (1)$$

Here δ is the probability that the BS accepts a message forgery by A, $|\mathbf{s}|$ is the length of the vector indicating the number of the helper's ON slots, and p_I is the probability of inferring the helper's activity during one MC ON-OFF bit when D and H do not co-transmit. Here, δ is a negligible function of $|\mathbf{s}|$. In eq. (1), it is assumed that a strongly universal hash function is used as part of the HELP primitive.

Table 1: Injection of desired bit b'_D, when the ON slots of the helper can be detected.

	b_D	b_H	$b_D + b_H$	b_A	$b_D + b_H + b_A$	b'_D
1	OFF-ON	OFF-ON	OFF-ON	OFF-ON	OFF-ON	OFF-ON
2	OFF-ON	OFF-ON	OFF-ON	ON-OFF	ON-ON	ON-OFF
3	OFF-ON	ON-OFF	ON-ON	OFF-ON	ON-ON	OFF-ON
4	OFF-ON	ON-OFF	ON-ON	ON-(−ON)	ON-OFF	ON-OFF
5	ON-OFF	OFF-ON	ON-ON	(−ON)-ON	OFF-ON	OFF-ON
6	ON-OFF	OFF-ON	ON-ON	ON-OFF	ON-ON	ON-OFF
7	ON-OFF	ON-OFF	ON-OFF	OFF-ON	ON-ON	OFF-ON
8	ON-OFF	ON-OFF	ON-OFF	ON-OFF	ON-OFF	ON-OFF

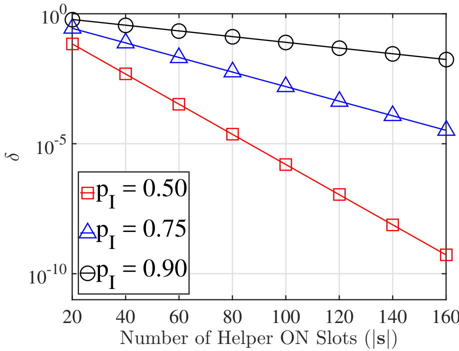

Figure 5: Probability of accepting a forged message m'_D at the *BS* as a function of $|\mathbf{s}|$, for varying inference capabilities of helper activity.

Proof. The proof is provided in Appendix A. □

In our analysis, we set the inference probability of H's activity to one when either D and H co-transmit or none transmits. In the former case, the presence of high power can be used to detect the superposition of D and H ON slots, and hence infer H's ON slot. In the latter case, the absence of power can be used to detect a helper's OFF slot. When either D or H are active, the inference prob-

ability is set to $p_I < 1$ due to the ambiguity in deciding which of the two devices is active. Summarizing,

$$\Pr[\text{Inference}] = \begin{cases} 1, & D \;\&\; H \text{ transmit} \\ 1, & D \;\&\; H \text{ do not transmit} \\ p_I, & \text{D or } H \text{ transmits.} \end{cases} \quad (2)$$

In Proposition 1, δ depends on two variables; the cardinality of $\mathbf{s}$ and p_I. From (1), it is evident that δ is a negligible function of $|\mathbf{s}|$, and a monotonically increasing function of p_I. In Figure 5, we show δ as a function of $|\mathbf{s}|$ for various values of p_I. As expected, a higher p_I yields a higher δ value for the adversary. For instance, when $p_I = 0.9$, $\delta = 0.0174$, when $|\mathbf{s}| = 160$, which may not be acceptable. However, doubling the size of $\mathbf{s}$ lowers δ to 0.0003. Note that in a single use of the HELP primitive, the attacker has only one chance to guess $\mathbf{s}$ and modify the value of m_D in an online fashion. Hence, a higher probability of forgery is acceptable here relative to standard cryptographic security (similar security values are sought in previous pairing protocols, which use short authentication strings [40]).

5.2 Security of the Device Pairing Protocol

We now analyze the security of the device pairing protocol proposed in Section 4.3. Since the security of the DH key-agreement protocol under a passive adversary is standard [56], we focus on the security under active attacks. We divide our analysis into two parts. In the first part, we examine if the adversary can pair a rogue device to a legitimate *BS*. In the second part, we examine if a legitimate device can be deceived to pair with a rogue base station. These two steps are part of a MitM attack.

5.2.1 Pairing a Rogue Device with a legitimate *BS*

The pairing of a rogue device D' with the *BS* can occur under two different scenarios: (a) D' pairs in the absence of a legitimate device D, and (b) D' pairs while D and the *BS* execute a pairing session.

Pairing in the absence of a legitimate device: The pairing protocol described in Section 4.3 is initiated with the placement of H in close proximity to the legitimate device and the press of a button on H and D, respectively. The button pressing sends a pairing initialization message to the *BS* which is authenticated using the secure $\mathrm{AE}(\cdot)$ function. Without access to the helper device, the adversary cannot initiate the pairing process from a remote location.

Hijacking a legitimate pairing session: Since A cannot initiate the pairing process with the *BS*, he can only attempt to pair a rogue device with the *BS* by hijacking a pairing session involving a legitimate device D. To establish a secret key with the *BS*, the adversary must modify the DH public number z_D of D into its own DH public number z'_D, where z_D is contained in the first message m_D sent from D to the *BS* (similar to a typical MitM attack against a DH key exchange).

However, m_D is protected by our integrity verification primitive. Note that in the HELP primitive, only $h(m_D)$ is encoded using MC ON-OFF keying while m_H is being superimposed. The actual value of m_D follows in plaintext. In our proposed modified DH protocol, both $h(m_D)$ and m_D are encoded using HELP. According to Proposition 1, the adversary's success probability in forging m_D in the HELP primitive is δ. When both $h(m_D)$ and m_D are encoded using HELP, we claim that the adversary's success probability in replacing m_D is upper bounded by δ. This is because in the primitive, the adversary can change m_D into any m'_D with probability 1, but his advantage is limited by the probability of changing $h(m_D)$ into $h(m'_D)$, which is δ. In the pairing protocol, the adversary's success probability of changing m_D into m'_D is less or equal to 1. Thus overall, its success probability is less or equal to δ, which is a negligible function of $|\mathbf{s}|$ (number of ON slots injected by helper during $[h(m'_D)]$). Therefore, the adversary will be unable to pair D' with the legitimate *BS*.

5.2.2 Pairing D with a Rogue Base Station

We now examine whether the adversary acting as a rogue *BS* can pair with a legitimate device D. To do so, the adversary can perform a similar MitM attack as in the uplink direction, by replacing the *BS*'s DH public parameter z_{BS} with its own number $z_{BS'}$. This step of the MitM attack corresponding to the message sent by A to D after the reception of m_D is shown in Figure 6.

For this attack to be successful, the adversary must extract the DH public value z_D so that it can compute $k_{D,BS'} = (z_D)^{X_{BS'}}$. The value of z_D is carried in $[h(m_D), m_D] + m_H$, using the HELP primitive. To recover m_D, the adversary must be able to determine the location vector $\mathbf{s}$ that is used to generate m_H for the portion that corresponds to the transmission of m_D. However, $\mathbf{s}$ is transmitted from H to *BS* using the authenticated encryption function $\mathrm{AE}(\cdot)$, so A cannot obtain $\mathbf{s}$ directly from the encrypted version of it.

Alternatively, A can collect and analyze the transmitted signal of $[h(m_D), m_D] + m_H$ after receiving it and attempt to identify all the ON slots in m_H using radio fingerprinting methods [7,19,28,39,55,59]. However, none of the fingerprinting methods can achieve 100% accuracy. As long as A infers H's ON slots with some probability smaller than one, we can drive the probability of successfully extracting m_D arbitrarily low by increasing

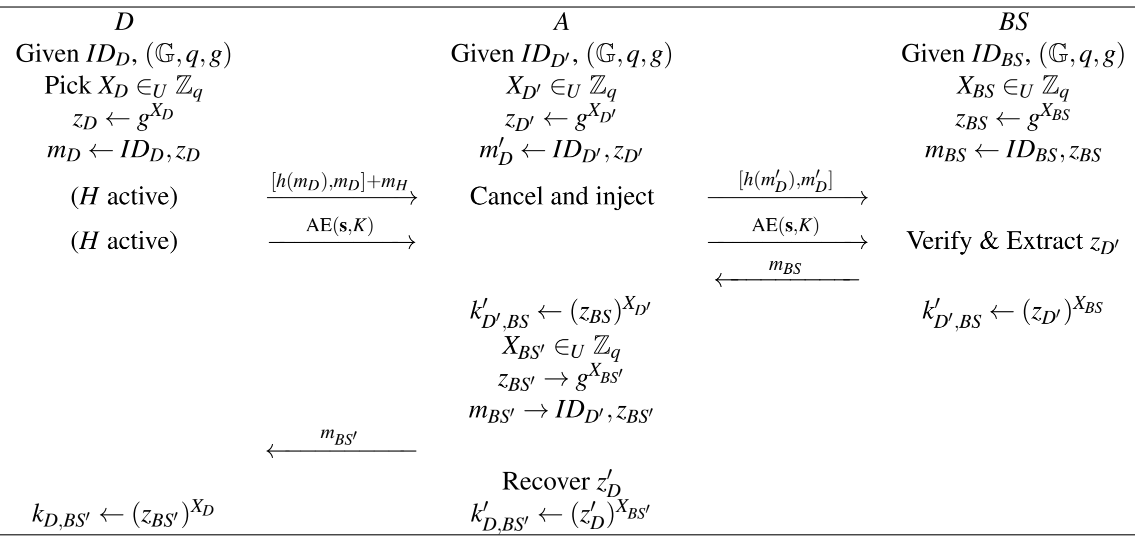

Figure 6: MitM attack against the key-agreement phase of HELP-enabled pairing protocol.

the number of slots carrying m_D.

In the following proposition, we derive the probability of D successfully pairing with a rogue BS, when the ON slots of the helper are inferred with probability p'_I. Note that in general p'_I is different than the p_I of Proposition 1. The inference of the helper's ON slots in Proposition 1 must occur based on very few samples because the adversary must quickly decide whether to perform signal cancellation. In the rogue BS case, the adversary can analyze $[h(m_D), m_D] + m_H$ based on all the samples, so it is expected that $p'_I > p_I$.

Proposition 2. *A legitimate device D pairs with a rogue BS with probability $\delta + \varepsilon$, where*

$$\delta = (p'_I)^{|\mathbf{s}'|}, \quad (3)$$

and ε is a negligible function of the hash length. Here $|\mathbf{s}'| < |\mathbf{s}|$ corresponds to the number of helper's ON slots only during the transmission of m_D in the $[h(m_D), m_D]$, p'_I is the probability of inferring the helper's activity during one MC ON-OFF bit when D and H do not co-transmit, and δ is a negligible function of $|\mathbf{s}'|$ when $p'_I < 1$.

Proof. The proof is provided in Appendix B. □

In Proposition 2, δ depends on two variables; the cardinality of set $\mathbf{s}'$ which is a subset of $\mathbf{s}$ corresponding to H's ON signal only during the transmission of m_D in $[h(m_D), m_D]$, and the inference probability of the helper's activity during the transmission of $[h(m_D), m_D] + m_H$, which is p'_I. From eq. (3), it is evident that δ is a negligible function of $|m_D|$, and a monotonically increasing function of p'_I. In Figure 7, we show δ as a function of $|\mathbf{s}'|$ for various values of p'_I and fixed hash length of $\ell = 160$. As expected, a higher p'_I yields a higher δ value for

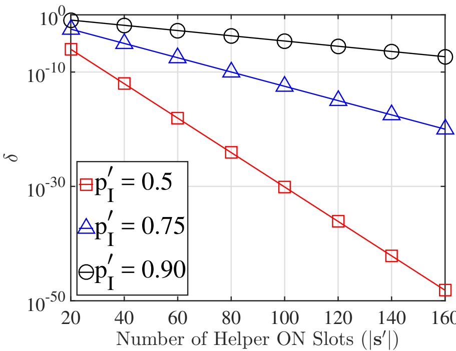

Figure 7: Probability of pairing with a rogue BS as a function of $|\mathbf{s}|$, for varying inference capabilities of helper activity.

the adversary. For instance, when $p'_I = 0.9$, $\delta = 0.0018$, when $|\mathbf{s}'| = 80$, which may not be acceptable. However, doubling the size of $\mathbf{s}'$ lowers δ to 5×10^{-8}. Note that, such an attack has to happen in an online manner. This is because the rogue BS must pass the challenge-response phase from the device in the key confirmation phase, so the attacker only has one chance to guess $\mathbf{s}$ and derive a probable DH key from the guessed z_D, which is only successful with small probability δ (similar to limited-guess online password attacks).

6 Evaluation

6.1 Helper Activity Inference

In this section, we first analyze A's capability in timely identifying the helper's ON slot when the helper is transmitting the ON-OFF message m_H. For this purpose, the adversary could employ several PHY-layer characteris-

tics of the helper's transmission to pinpoint when H is active. These include (a) the received signal strength [55], (b) the frequency offset [59], (c) the channel impulse response $\mathbf{h}_{H,A}$ [39], (d) the I/Q origin offset [7], (e) the transient radio state [19], and (f) the angle of arrival for the incoming signal [28].

We first examine A's attempt to perform the signal cancellation and injection required by the MitM attack of Figure 6. To avoid rejection of m'_D by the BS, the adversary has to *swiftly detect* a helper's ON slot and decide whether to perform signal cancellation. Most existing radio fingerprinting methods are not suitable for such quick online detection. The frequency offset and channel impulse response are estimated using known preambles that are typically included in headers. Such preambles do not precede the helper's ON slots. The I/Q origin offset is not a suitable method because we employ ON-OFF modulation for message transmission. The methods that detect the transient state of a radio when it turns on can only be used to identify the start of a transmission (although an ON-OFF modulation implies a transition from an OFF to an ON state, the radio transmitter is powered through the entire transmission of an ON-OFF signal and a transient state is not observed with every slot). Differentiating between D and H using an AOA requires a very narrow directional beam due to the proximity between H and D. Such narrow beamwidths can be achieved by using an antenna array [48] or a parabolic antenna [63]. However, the hardware cost is prohibitive and the antenna would be quite visible. For example, an adversary at 50ft from D and H requires two 50-element antenna arrays pointed to D and H respectively via the LoS path, to differentiate between D and H when their distance is set to 4ft. This calculation assumes a 2.4GHz operating frequency.

6.1.1 Fast Helper Detection based on RSS

The simplest and most timely method for detecting the presence of the helper is to measure the received signal strength over some small number of samples at the beginning of every slot. Let b_D and b_H represent the bit simultaneously transmitted by D and H respectively over two slots t_i and t_{i+1}. There are four possible bit combinations that yield two candidate power profiles for $b_D + b_H$, as measured by the adversary. When $b_D = b_H$, the helper and D overlap in one of the two slots (either t_i or t_{i+1}), depending on the value of b_D, b_H. In this case, one of the slots is OFF whereas the other slot is ON with a significantly higher power because the two ON slots of H and D are superimposed (here, we have considered the worst-case scenario and ignored the possibility of destructive interference). We expect that A will be able to infer the ON slot of the helper with probability $p_I = 1$, due to the higher RSS value of the first few samples of the ON slot.

When $b_D \neq b_H$, both t_i and t_{i+1} are ON and have similar power profiles if H and D transmit with the same power and are placed in close proximity. In this case, the adversary is expected to be unable to differentiate a helper's ON slot from a device's ON slot with the probability much higher than a random guess. The four possible cases for one slot observed by the adversary are: (a) P_1 : both H and D are ON, (b) P_2 : H is ON and D is OFF, (c) P_3 : D is ON and H is OFF, and (d) P_4 : both H and D are OFF. For each case, the adversary determines four threshold values $E[P_1], E[P_2], E[P_3]$, and $E[P_4]$, that represent the average expected power, as measured by the first few samples of a slot.

Without loss of generality, let $E[P_1] > E[P_2] > E[P_3] > E[P_4]$.[2] Let also $E[P(t_i)]$ denote the average power measured over slot t_i using the first few samples. The adversary classifies t_i to one of four cases by mapping $E[P(t_i)]$ to the closest threshold. That is, case P_1 is inferred if $E[P(t_i)] > \frac{E[P_1]+E[P_2]}{2}$, case P_2 is inferred if $\frac{E[P_1]+E[P_2]}{2} \leq E[P(t_i)] < \frac{E[P_2]+E[P_3]}{2}$, etc. A wrong inference is made when $E[P(t_i)]$ that belongs to case P_i is mapped to a case P_j with $P_i \neq P_j$. In Proposition 1, we have assumed that the probability p_I for correctly inferring cases P_1 and P_4 is equal to one. In P_1, the RSS is expected to be relatively high due to the co-transmission from D and H. In P_4, the RSS is expected to be low because neither D nor H are transmitting. However, the thresholds for cases P_2 and P_3 are expected to be very close, thus leading to frequent wrong inferences. We experimentally verify this claim.

Experimental Evaluation of p_I: *Experimental setup:* To evaluate p_I, we setup three NI-USRP 2921 devices in an indoor laboratory environment. Two USRP devices represented D and H, whereas a third USRP device is placed at 24 feet away acting as an adversary. The transmit power for an ON slot was set to 20dBm for both D and H with a symbol duration of 1ms. The devices were set to work at 2.4GHz and were synchronized. The sampling frequency was set to 2MHz. We tested two scenarios: (1) H is stacked on top of D, and (2) H is moved away from the legitimate device. The experiment setup is shown in Figure 8(a).

We implemented amplitude shift keying (ASK) to transmit MC ON-OFF coded messages and repeatedly transmitted message $\{1,0,1,0\}$ from D and message $\{1,1,0,0\}$ from H simultaneously. The signals from H are MC-coded only when the bit value is one. The superposition of the two signals implemented all four cases P_1-P_4.

Results: Let P_{DH} denote the probability of detecting that D and H transmit simultaneously, P_{NDH} denote the prob-

[2] $E[P_2]$ and $E[P_3]$ can be similar but not exactly the same, so we can assume some ordering to make a classification rule.

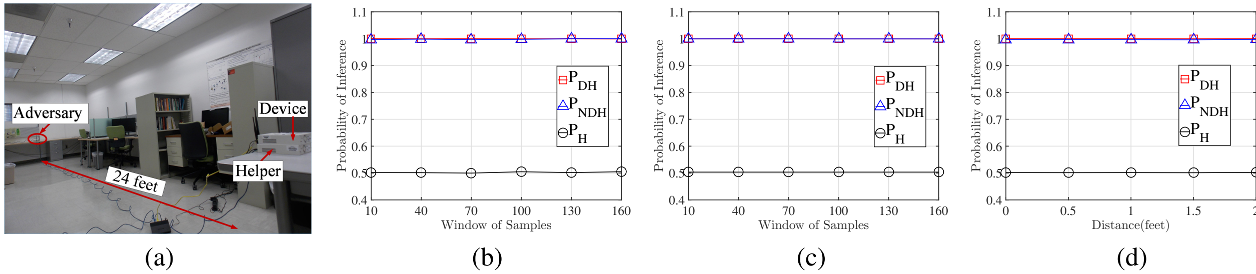

Figure 8: (a) Experimental setup, (b) detection probability as a function of the window of samples when the power at H and D is fixed, (c) detection probability as a function of the window of samples when the power at H and D varies, and (d) detection probability as a function of the distance between D and H, when H and D remain equidistant from A.

ability of detecting that neither D nor H transmit, and P_H denote the probability of detecting that H is transmitting alone. These correspond to p_I for any of the candidate scenarios. In the first experiment, we measured the detection probability as a function of the sampling window size used for computing the average RSS value for a given slot. Intuitively, a longer sampling window would lead to better inference but will delay the cancellation operation. Figure 8(b) shows the resulting detection probabilities as a function of the sample window. We observe that the detection probabilities P_{DH} and P_{NDH} are relatively low and are further reduced with the increase of the sample window. However, the detection probability P_H is close to 0.5 irrespective of the sample window size. This indicates that differentiating between the ON slots of the helper and of the legitimate device, when only one of the two transmits, is practically equivalent to a random guess. Our results justify the selection of $p_I = 1$ when the H and D are simultaneously absent or present, and $p_I = 0.5$ otherwise.

In the second experiment, we repeated the first experiments but configured H and D to vary their transmission power on a per-slot basis. The power was varied to reduce the inference capability of A. Specifically, H and D oscillated their power at random between 10dBm and 20dBm. Figure 8(c) shows the detection probabilities as a function of the window of samples used for inference.

Effect of proximity on p_I: We further performed experiments to evaluate the effect of the proximity between D and H on their distinguishability. We repeated the first experiment and varied the distance between H and D. In the first part of the experiment, H was moved away from D while keeping the D-A and H-A distances similar (the helper's motion was perpendicular to the D-A line. Figure 8(d) shows that the detection probability for each case is similar to the case where H is stacked on top of D. In the second part of the experiment, H was moved towards A, and therefore, the distance between H and A was gradually reduced. Figure 9(a) shows the respective detection probabilities. As expected, decreasing the distance between A and H improves the adversary's inference capability, but the inference remains imperfect

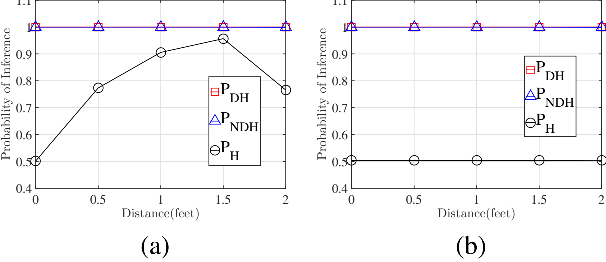

Figure 9: (a) Detection probability as a function of the distance between D and H when H is moved towards A, and (b) detection probability as a function of the distance between D and H when H is moved towards A, when D and H are transmitting random powers.

when D and H remain relatively close.

In the fourth experiment, we repeated the second part of the third experiment but configured H and D to vary their transmission power on a per-slot basis. The power was varied to reduce the inference capability of A. Specifically, H and D oscillated their power at random between 10dBm and 20dBm. Figure 9(b) shows the same results when the distance between D and H was also varied, with H moving towards A. We observe that P_H remains a random guess even when H is moved away from D (comparison of P_H in Figures 9(a) and 9(b)), indicating that a power variation approach can account for situations where H is not placed exactly on top of D. Distinguishing signals from D and H using RSS remains a random guess even when H is 2ft away from D.

6.1.2 Fast Helper Detection Based on Time

In this section, we discuss an inference technique that exploits the possible time misalignment between the transmissions of H and D due to clock drift and different path delays to the receiver. There have been extensive studies on synchronization of independent wireless nodes, but practically it is impossible to reach perfect synchronization [51]. The adversary can exploit the synchronization offset between H and D to infer the presence of helper's ON signals. If H is faster (slower) than D, the ON slots of H will appear slightly earlier (later) than the ON slots of D. An example of a fast H is shown in Figure 10,

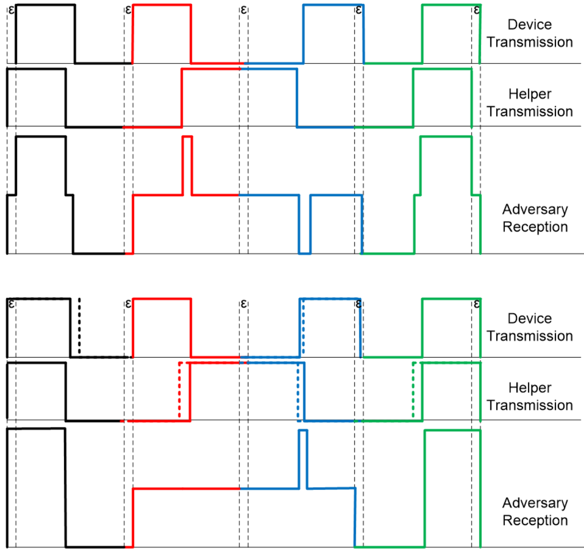

Figure 10: Synchronization offset without and with randomized start time of each bit.

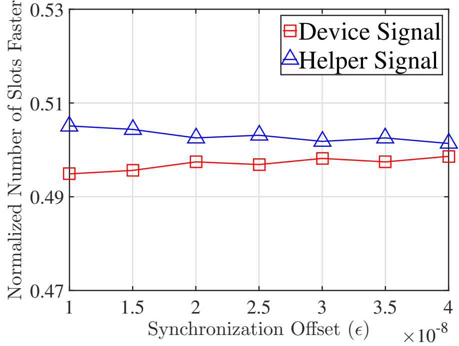

Figure 11: Fraction of slots that one device is faster than the other as a function of the delay offset ε.

where there is a synchronization offset ε between D and H. If A fixes his clock to H, it can infer the presence of helper's ON slots without having to resort to RSS estimation. It should be noted here, the BS performs detection of ON slots by taking an average value of the power of all the samples. Therefore, a perfect synchronization between D and H is not required for the correctness of the proposed protocol.

To prevent the inference of the helper's ON slots based on time misalignment, we randomize the start times of each bit (first slot of the MC ON-OFF bit) both at H and D. Specifically, a random time offset ε, positive or negative, is selected from a uniform distribution $\mathscr{U}(\varepsilon_l, \varepsilon_h)$. The lower bound ε_l is selected to be the maximum synchronization error between D and H. This can be calculated as the expected clock drift over the transmission time of H plus a maximum time difference between path delays. The upper bound τ_h can be some reasonable value (e.g., $2\varepsilon_l$). Moreover $\tau << t$, where t is the slot duration. This will ensure the correct sequence decoding at the BS. The lower part of Figure 10 shows an example of applying the randomized start time for each bit. We observe that no device is always faster (slower), thus preventing A from fixing its clock to H.

Experimental Evaluation of p_I: To verify the validity of our time randomization approach and its impact on the inference probability p_I, we setup three NI-USRP 2921 devices in an indoor laboratory environment as D, H, and A, respectively. As in previous experiments, H was stacked on top of D, whereas A was placed 24 feet away from D,H. The transmit power for an ON slot was set to 20dBm with a symbol duration of 1ms. An artificial clock misalignment $\tau = 0.1$msec was set between H and D to emulate the maximum synchronization error. We then varied the random time offset ε selected by H and D. The experiment lasted for the transmission of 10^6 sequences of 40 bits each.

Figure 11 shows the fraction of slots for which each device was detected to be faster as a function of the maximum synchronization error ε. We observe that for sufficiently high values of ε, H is almost 50% of the time faster than D. Practically, using time misalignment to distinguish the helper becomes a random guess.

6.2 Protocol Evaluation

In the final set of experiments, we evaluated the integrity protection offered by HELP against an adversary capable of canceling and injecting signals. We setup two USRP devices stacked over each other as D and H, one device (Rx_1) at 24ft from D,H acting as the BS and a second device RX_2 set by RX_1 that performed cancellation on RX_1. The transmitters and the receivers are shown in Figure 12(a) and Figure 12(b), respectively. The distance between the two receivers was set to approximately one wavelength λ to cause signal inversion at RX_1. After receiving the transmissions of D and H at Rx_1 and Rx_2, cancellation was performed via signal processing in MATLAB [34]. The signal of RX_2 was added to RX_1 to cancel the transmission of D and H, whereas a random signal was added to emulate A's signal injection.

In the first scenario, we transmitted MC ON-OFF sequences of length $\ell = \{4, 8, 12, 20\}$, while the helper was inactive. We measured the probability δ of accepting A's random sequence at the BS (RX_1). We also varied the probability of successful cancellation p_C by suppressing cancellation for a corresponding fraction of bits. Figure 12(c), shows δ as a function of ℓ for various p_C. We observe that for high cancellation probability values p_C, a message cancellation/injection has a high success probability (close to one).

We repeated the experiment of the first scenario in the presence of H who transmitted at random slot locations simultaneously with D. In the experiment, the adversary

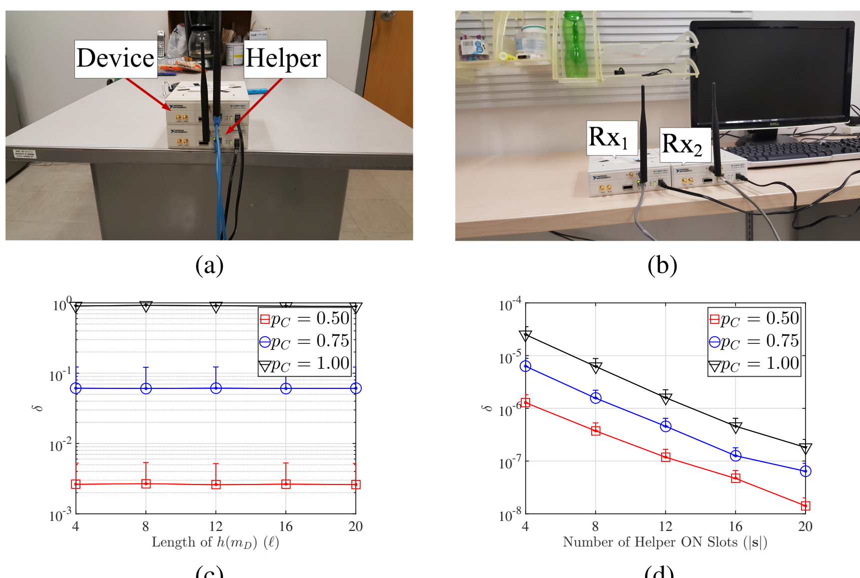

Figure 12: (a) Placement of D and H, (b) placement of the BS (RX_1) and RX_2. (c) probability of acceptance of a modified message at the BS in the absence of H, and (d) probability of acceptance of a modified message at the BS in the presence of H.

attempted to distinguish between D and H using the RSS sampling method discussed in Section 6.1.1. Also, the adversary canceled slots on which D or H's signals were indistinguishable. Figure 12(d) shows the probability δ of accepting the adversary's modified message as a function of the number of active helper slots $|\mathbf{s}|$ when the message length is $\ell = 20$. We observe that δ decreases drastically compared to Figure 12(c). Moreover, imperfect cancellation ($p_C < 1$) leads to further deterioration of the adversary's performance. The results obtained support the analytical results provided in Section 5, which are computed assuming $p_C = 1$.

Timing performance: The upper bound on the execution time of the DH protocol with HELP primarily depends on the communication time of the ON-OFF keyed message, since the rest of the messages are exchanged in the normal communication mode. Public key parameters for an EC-DH key-agreement [58] can have values from 160–512 bits, depending on the security requirement. Assuming a hash length of 160 bits and a slot duration of 1ms, the time required to transmit the HELP protected DH public primitive varies between 0.6–1.4s, which is acceptable.

7 Conclusion

We considered the problem of pairing two devices using in-band communications in the absence of prior shared secrets. We proposed a new PHY-layer integrity protection scheme called HELP that is resistant to signal cancellation attacks. Our scheme operates with the assistance of a helper device that has an authenticated channel to the BS. The helper is placed in close proximity to the legitimate device and simultaneously transmits at random times to allow the detection of cancellation attacks at the BS. We showed that a pairing protocol such as the DH key agreement protocol using HELP as an integrity protection primitive can resist MitM attacks without requiring an authenticated channel between D and the BS. This was not previously feasible by any of the pairing methods if signal cancellation is possible. We studied various implementation details of HELP and analyzed its security. Our protocol is aimed at alleviating the device pairing problem for IoT devices that may not have the appropriate interfaces for entering or pre-loading cryptographic primitives.

Appendix A

Proposition. *The PHY-layer integrity verification of D by mechanism in Section 4.2 is δ–secure, where*

$$\delta \quad = \quad \left(1 - \frac{1-p_I}{4}\right)^{|\mathbf{s}|}. \qquad (4)$$

Here δ is the probability that the BS accepts a message forgery by A, $|\mathbf{s}|$ is the length of the vector indicating the number of the helper's ON slots, and p_I is the probability of inferring the helper's activity during one MC ON-OFF bit when D and H do not co-transmit. Here, δ is a negligible function of $|\mathbf{s}|$. In eq. (4)*, it is assumed that a strongly universal hash function is used as part of the HELP primitive.*

Proof. Assume that the adversary A wants to modify the message m_D sent from D to the BS to a message $m'_D \neq m_D$. To accept m'_D, the BS must correctly receive $[h(m'_D)], m'_D$ and all the slots indicated in $\mathbf{s}$ must be ON

slots. The modification of m_D to m'_D can be made by canceling m_D and injecting m'_D. However, to pass verification, A has to modify $[h(m_D)]$ to $[h(m'_D)]$. Since, m_D is unknown to the adversary while $[h(m_D)]$ is being transmitted due to the one-wayness of $h(\cdot)$, A cannot predict the signal transmitted from D.

To modify $[h(m_D)]$, the adversary must launch a signal cancellation on $[h(m_D)]+m_H$ and inject $[h(m'_D)]$ at the same time. Moreover, all the ON slots denoted in the helper's location vector **s** must remain as ON slots in $[h(m'_D)]$. Also, the *BS* must decode $[h(m'_D)]$ after m_H is removed. This can be achieved if A does not apply any cancellation on the ON slots indicated in **s** and modifies the rest of the slots (OFF slots in m_H) to decode to the desired message. The signal injections of A are made according to Table 1.

The derivation of the probability δ that the adversary's modification is accepted at the *BS* is performed in two parts. In the first part, we derive the probability that A's cancellation/injection is detected, when A modifies the transmission one bit. We then compute the probability of detecting signal modifications by A over all bits. Consider the ith bit of $h(m'_D)$ which corresponds to Manchester-coded slots t_{2i-1} and t_{2i}.

Here, we assume a probability p_I, which is the probability of inference of detecting the presence of H's signal. This is discussed in details in the Section 6. Here we state an assumption, that if H's signal is detected the adversary does not cancel the signal. The probability of cancel is $(1-p_I)$.

The adversary is detected for i^{th} bit on which H is active, for two conditions with wrong inference $(1-p_I)$. (a) First, the helper bit is zero *i.e.* H injects energy on t_{2i} slot, device bit is one slot and adversary bit is one. (b) Second, the helper bit is one *i.e.* H injects energy on the t_{2i-1} slot, device bit is zero and the adversary bit is zero.

Let P_r denote the probability that the *BS* rejects the corresponding bit of $[h(m'_D)]$ at bit b_i due to cases (a) and (b). This probability can be calculated as:

$$\begin{aligned} p_r &= (\Pr[b_i^H=0, b_i^D=1, b_i^A=1] \\ &\quad + \Pr[b_i^H=1, b_i^D=0, b_i^A=0]) \\ &\quad\quad \Pr[\text{wrong inference}] \\ &= \left(\frac{1}{2}\cdot\frac{1}{2}\cdot\frac{1}{2}+\frac{1}{2}\cdot\frac{1}{2}\cdot\frac{1}{2}\right)(1-p_I) \\ &= \frac{1-p_I}{4}, \end{aligned} \tag{5}$$

In (5), b_i^X denotes the transmitted value of device X at bit b_i, and p_I is the probability of inference of helper's activity by the A on a given bit. For (5), we have used the fact that a strictly universal hash function is the part of HELP. For a strictly universal hash function, output hashes for two different inputs differ on each bit with probability 1/2.

The probability δ of accepting the modified message of A at the *BS* is computed by taking into account all $|\mathbf{s}|$ cardinality of the set of bits on which the helper was active. The adversary's modified message is accepted by the *BS* if *none of the bits* in $|\mathbf{s}|$ is rejected. Each bit b_i is rejected with probability p_r given by (5). As rejection on each slot occurs independently, the overall probability of accepting $[h(m'_D)]$ is computed via the Binomial distribution with parameter p_r. That is,

$$\begin{aligned} \delta &= 1-\sum_{x=1}^{|\mathbf{s}|} B(x,|\mathbf{s}|,p_r) \\ &= 1-\sum_{x=0}^{|\mathbf{s}|} B(x,|\mathbf{s}|,p_r)+B(0,|\mathbf{s}|,p_r) \\ &= (1-p_r)^{|\mathbf{s}|} \\ &= (1-\frac{1-p_I}{4})^{|\mathbf{s}|}. \end{aligned} \tag{6}$$

where $B(\alpha,\beta,\gamma)$ is the Binomial probability density function.

We now show that δ is a negligible function of $|\mathbf{s}|$.

In (6), δ is a negligible function if $(1-p_r)^{|\mathbf{s}|}$ is shown to be a negligible function. To prove the latter, let $\mu(|\mathbf{s}|)=a^{-|\mathbf{s}|}$ where $a=\frac{1}{1-p_r}$. For $\mu(|\mathbf{s}|)$ to be a negligible function, $\forall\, c\in\mathbb{N}$ there exists a $n_0\in\mathbb{N}$ such that $|\mathbf{s}|>n_0$ and $\mu(|\mathbf{s}|)<n^{-c}$. Let $n_0=c^{\frac{a}{a-1}}$. Then

$$\begin{aligned} a^{|\mathbf{s}|} &= (a^{\log_a|\mathbf{s}|})^{-\frac{|\mathbf{s}|}{\log_a|\mathbf{s}|}} \\ &= (|\mathbf{s}|)^{-\frac{|\mathbf{s}|}{\log_a|\mathbf{s}|}}, \end{aligned}$$

Since $|\mathbf{s}|>n_0$, it follows that

$$\frac{|\mathbf{s}|}{\log_a|\mathbf{s}|} > \frac{n_0}{\log_a n_0} > \frac{n_0}{n_0^{\frac{1}{a}}} > c.$$

Therefore,

$$\begin{aligned} \mu(|\mathbf{s}|) &= a^{-|\mathbf{s}|} \\ &= (|\mathbf{s}|)^{-\frac{|\mathbf{s}|}{\log_a|\mathbf{s}|}} \\ &< n^{-c}. \end{aligned}$$

This proves that $(1-p_r)^{|\mathbf{s}|}$ is a negligible function for $a\neq 1$ or equivalently $p_r\neq 0$, thus concluding the proof on the negligibility of δ for $p_r\neq 0$. □

Appendix B

Proposition. *A legitimate device D pairs with a rogue BS with probability* $\delta+\varepsilon$, *where*

$$\delta = (p'_I)^{|\mathbf{s}'|}, \tag{7}$$

and ε is a negligible function of the hash length. Here $|\mathbf{s}'| < |\mathbf{s}|$ corresponds to the number of helper's ON slots only during the transmission of m_D in the $[h(m_D), m_D]$, p_I' is the probability of inferring the helper's activity during one MC ON-OFF bit when D and H do not co-transmit, and δ is a negligible function of $|\mathbf{s}'|$ when $p_I' < 1$.

Proof. Assume that the adversary A wants to decode the m_D which contains the key public parameter z_D from $[h(m_D), m_D] + m_H$ without the knowledge of set **s**.

For $[h(m_D), m_D]$ a bit zero corresponds to (OFF, ON) whereas a bit one corresponds to (ON, OFF). With superimposing H's signal, the BS will also receive slots combinations of (ON, ON). The adversary can extract some information of m_D from the (OFF, ON) and (ON, OFF) slots in the $[h(m_D), m_D] + m_H$. But to extract the information from (ON, ON) slots without the knowledge of **s**. The adversary has to make intelligent guesses for received (ON, ON) slots, which is parameterized as the probability of inferring the helper's activity by A.

Let p_I' be the inference probability for detecting the presence of H's signal. This is discussed in details in Section 6. Note that, if H's signal is wrongly inferred (with probability $(1 - p_I')$), A maps the received bit on which H was active to a wrong outcome.

The adversary makes wrong mapping when it receives (ON, ON) slots on received $[h(m_D), m_D] + m_H$. It happens when A cannot detect the presence of the helper's signal on the slot where D has injected no energy.

$$p_r = \Pr[\text{wrong inference}] = (1 - p_I'). \tag{8}$$

In (8), p_I' is the probability that A detects the H's signal correctly on a particular bit.

The probability δ of extracting correct m_D from received signal $[h(m_D), m_D] + m_H$ by A. The adversary can decode correct m_D if *none of the bits* are decoded wrong. Each bit is wrongly mapped with probability p_r, given by (8). As rejection on each slot occurs independently, the overall probability of correctly decoding m_D from $[h(m_D), m_D] + m_H$ is computed via the Binomial distribution with parameter p_r. That is,

$$\begin{aligned} \delta &= 1 - \sum_{x=1}^{|\mathbf{s}'|} B\left(x, |\mathbf{s}'|, p_r\right) \\ &= 1 - \sum_{x=0}^{|\mathbf{s}'|} B\left(x, |\mathbf{s}'|, p_r\right) + B\left(0, |\mathbf{s}'| p_r\right) \\ &= (1 - p_r)^{|\mathbf{s}'|} \\ &= \left(1 - (1 - p_I')\right)^{|\mathbf{s}'|} \\ &= \left(p_I'\right)^{|\mathbf{s}'|}. \end{aligned} \tag{9}$$

where $B(\alpha, \beta, \gamma)$ is the Binomial probability density function and $|\mathbf{s}'| \subset |\mathbf{s}|$, which corresponds to the number of helper's ON signals only during the transmission of m_D in the $[h(m_D), m_D]$.

We now show that δ is a negligible function of $|\mathbf{s}'|$.

In (9), δ is a negligible function if $(1 - p_r)^{|\mathbf{s}'|}$ is shown to be a negligible function. To prove the latter, let $\mu(|\mathbf{s}'|) = a^{-|\mathbf{s}'|}$ where $a = \frac{1}{1-p_r}$. For $\mu(|\mathbf{s}'|)$ to be a negligible function, $\forall\, c \in \mathbb{N}$ there exists a $n_0 \in \mathbb{N}$ such that $|\mathbf{s}'| > n_0$ and $\mu(|\mathbf{s}'|) < n^{-c}$. Let $n_0 = c^{\frac{a}{a-1}}$. Then

$$\begin{aligned} a^{|\mathbf{s}'|} &= \left(a^{\log_a |\mathbf{s}'|}\right)^{-\frac{|\mathbf{s}'|}{\log_a |\mathbf{s}'|}} \\ &= \left(|\mathbf{s}'|\right)^{-\frac{|\mathbf{s}'|}{\log_a |\mathbf{s}'|}}, \end{aligned}$$

Since $|\mathbf{s}'| > n_0$, it follows that

$$\begin{aligned} \frac{|\mathbf{s}'|}{\log_a |\mathbf{s}'|} &> \frac{n_0}{\log_a n_0} \\ &> \frac{n_0}{n_0^{\frac{1}{a}}} \\ &> c. \end{aligned}$$

Therefore,

$$\begin{aligned} \mu(|\mathbf{s}'|) &= a^{-|\mathbf{s}'|} \\ &= \left(|\mathbf{s}'|\right)^{-\frac{|\mathbf{s}'|}{\log_a |\mathbf{s}'|}} \\ &< n^{-c}. \end{aligned}$$

This proves that $(1 - p_r)^{|\mathbf{s}'|}$ is a negligible function for $a \neq 1$ or equivalently $p_r \neq 0$.

After the attacker extracts m_D, the rogue BS needs to pass the challenge-response authentication in the key confirmation phase. Assuming the use of a strongly universal hash function to compute the response $h_{k_{D,BS'}}(ID_{BS}||C_D||0)$, he can only pass this authentication if he has the correct key $k_{D,BS'}$. Otherwise, his successful probability ε is negligible. But he can only obtain the correct key by extracting the correct m_D value. Therefore, the success probability of the rogue BS to pair with the device is upper bounded by $\delta + \varepsilon$, where ε is a negligible function (of the length of the hash function). Since δ is a negligible function of $|\mathbf{s}'|$ which can be the same as the message length (and here the m_D is a DH public number, whose bit length is typically larger or equal to the hash length), the overall probability is a negligible function. This concludes the proof. □

Attacking the Brain: Races in the SDN Control Plane

Abstract

Software-Defined Networking (SDN) has significantly enriched network functionalities by decoupling programmable network controllers from the network hardware. Because SDN controllers are serving as the brain of the entire network, their security and reliability are of extreme importance. For the first time in the literature, we introduce a novel attack against SDN networks that can cause serious security and reliability risks by exploiting harmful race conditions in the SDN controllers, similar in spirit to classic TOCTTOU (Time of Check to Time of Use) attacks against file systems. In this attack, even a weak adversary without controlling/compromising any SDN controller/switch/app/protocol but only having malware-infected regular hosts can generate external network events to crash the SDN controllers, disrupt core services, or steal privacy information. We develop a novel dynamic framework, CONGUARD, that can effectively detect and exploit harmful race conditions. We have evaluated CONGUARD on three mainstream SDN controllers (Floodlight, ONOS, and OpenDaylight) with 34 applications. CONGUARD detected totally 15 previously unknown vulnerabilities, all of which have been confirmed by developers and 12 of them are patched with our assistance.

1 Introduction

Software-Defined Networking (SDN) is rapidly changing the networking industry through a new paradigm of network programming, in which a logically centralized, programmable control plane, i.e., the *brain*, manages a collection of physical devices (i.e., the data plane). By separating data and control planes, SDN enables a wide range of new innovative applications from traffic engineering to data center virtualization, fine-grained access control, and so on [16].

Despite the popularity, unfortunately, SDN has also changed the attack surface of traditional networks. An SDN controller and its applications maintain a list of network states such as host profile, switch liveness, link status, etc. By referencing proper network states, SDN controllers can enforce various network policies, such as end-to-end routing, network monitoring, and flow balancing. However, referencing network states is under the risk of introducing concurrency vulnerabilities because external network events can concurrently update the internal network states.

In this paper, we present a new attack, namely *state manipulation attack*, in the SDN control plane that is rooted in the asynchronism of SDN. The asynchronism leads to many harmful race conditions on the shared network states, which can be exploited by the attackers to cause denial of services (e.g., controller crash, core service disruption) and privacy leakage, etc. On the surface, this is similar to the well-known TOCTTOU (Time of Check to Time of Use) attacks [46, 14, 12] against file systems. However, this attack is closely tied to the unique SDN semantics, which makes all popular SDN controllers (e.g., Floodlight [1], ONOS [3], and OpenDaylight [4]) vulnerable. Consider a real example we discovered in the Floodlight controller in Figure 1. When the controller receives a `SWITCH_JOIN` event, it updates a network state variable (i.e., *switches*) to store the profile of the joining switch. Shortly, the LinkDiscoveryManager application fetches the activated switch information from *switches* to discover links between switches. However, a `SWITCH_LEAVE` event can concurrently remove the profile of the activated switch in *switches*. If the operation at line 4 is executed before that at line 8, it will trigger a Null-Pointer Exception (NPE) when the null switch object is dereferenced at line 9, which leads to the crash of the thread and eventually causes Denial-of-Service (DoS) attacks on the controller.

The root cause of this vulnerability is a logic flaw in the implementation of Floodlight that permits a harmful race condition. In the SDN control plane, race condi-

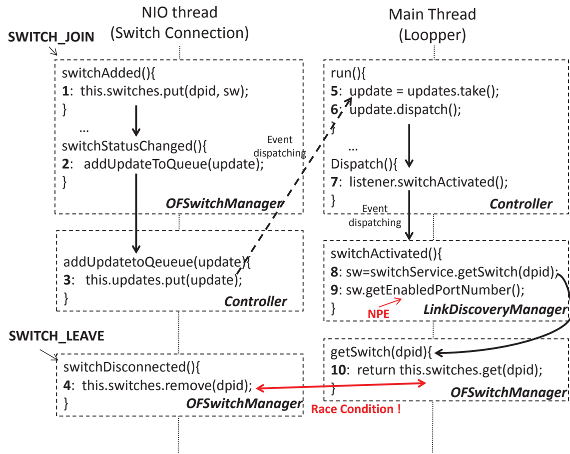

Figure 1: A harmful race condition in Floodlight v1.1.

tions are common due to a massive number of network events on the shared network states. To meet the performance requirement, the event handlers in the SDN controller may run in parallel, which allows race conditions on the shared network states. By design, all such race conditions should be benign since they are protected by mutual exclusion synchronizations and do not break the consistency of the network states. However, in practice, many of these race conditions become harmful races because it is difficult for the SDN developers to avoid logic flaws such as the one in Figure 1.

The key insight of State Manipulation Attack is that we can leverage the existence of such harmful race conditions in SDN controllers to trigger inconsistent network states. Nevertheless, a successful attack requires tackling two challenging problems:

- First, how to locate such harmful race conditions in the SDN controller source code?
- Second, how to trigger the harmful race conditions by an external attacker who has no control of the controller schedule?

For the first problem, the key challenges are that it is generally unknown if a race condition is harmful or not, and that detecting race conditions in a program is generally undecidable. Although many data race detectors have been developed for different domains [18, 32, 22, 19, 31, 36], there is no existing tool to detect race conditions in the SDN controllers. We note that race conditions are different from data races but are a more general phenomenon; while data races concern whether accesses to shared variables are properly synchronized or not, race conditions concern about the memory effect of high-level races, regardless of synchronizations. For example, a data race detector cannot find the race condition in Figure 1 because the accesses to the *switches* variable are all protected by synchronization. Moreover, in SDN controllers there are many domain-specific happens-before rules. These rules must be properly modeled in a race detector; otherwise, a large number of false alarms will be reported. Therefore, conventional data race detectors are inadequate to find race conditions in SDN controllers.

To address this problem, we develop a technique called *adversarial state racing* to detect harmful race conditions in the SDN control plane. Our key observation is that harmful race conditions are commonly rooted by two conflicting operations upon shared network states that are not commutative, i.e., mutating the scheduling order of them leads to a different state though the two operations can be well-synchronized (e.g., by using locks). Because there is no pre-defined order between the two conflicting operations, we can hence actively control the scheduler (e.g., by inserting delays) to run an adversarial schedule, which forces one operation to execute after another. If we observe an erroneous state (e.g., an exception or a crash) in the adversarial schedule, we have found a harmful race condition.

For the second problem, the key challenge is that a harmful race condition occurs very rarely in normal operations, but relies on a combination of a certain input and an unexpected thread schedule to manifest. As the adversary typically has no control of the machine or operating system running the SDN controllers, even if a harmful race condition is known, it is difficult for an adversary to create the input and schedule combination to trigger the harmful race condition.

Nevertheless, we show that an adversary can remotely exploit many harmful race conditions with a high success ratio by injecting the "right" external events into the SDN network. Because SDN controllers define an event handler to process each network event, a correlation between external network events and their corresponding event handlers can be established by analyzing the controller source code. By further mapping the event handlers to their operations, we can correlate the conflicting operations in a harmful race condition to their corresponding network events. An adversary can then generate many sequences of these network events repeatedly to increase the chance of hitting a right schedule to trigger the harmful race condition.

We have designed and implemented a framework called CONGUARD for exploiting concurrency vulnerabilities in the SDN control plane, and we have evaluated it on three mainstream open-source SDN controllers – Floodlight, ONOS, and OpenDaylight, with 34 applications in total. CONGUARD found 15 previously unknown harmful race conditions in these SDN controllers. We show that these harmful race conditions can incur serious

reliability issues and remote attacks to the whole SDN network. Some attacks can be mounted by compromised hosts/virtual machines within the network, and some of them are possible if the SDN network uses in-band control messages[1] even when those messages are protected by SSL/TLS.

We highlight our key contributions as follows:

- We present a new attack on SDN networks by exploiting the harmful race conditions in the SDN control plane, which can be triggered by asynchronous network events in unexpected schedules.
- We design CONGUARD, a novel framework to pinpoint and exploit harmful race conditions in SDN controllers. We present a causality model that captures the domain-specific happens-before rules of SDN, which significantly increases the precision of race detection in the SDN control plane.
- We present an extensive evaluation of CONGUARD on three mainstream SDN controllers. CONGUARD has uncovered 15 previously unknown vulnerabilities that can result in both security and reliability issues. All these vulnerabilities were confirmed by the developers. By the time of writing, we have already assisted the developers to patch 12 of them.

The rest of the paper is organized as follows: Section 2 introduces background. Section 3 discusses the state manipulation attack. Section 4 and Section 5 describe the design and implementation of our CONGUARD framework. Section 6 evaluates CONGUARD. Section 7 discusses defense mechanisms to mitigate this kind of attacks. Section 8 discusses limitations of our approach and future work. Section 9 reviews related work and Section 10 concludes this paper.

2 Background

In this section, we introduce the necessary background of SDN in order to understand the harmful race conditions in this domain.

The heart of SDN is a logically centralized control plane (i.e., SDN controllers) that is separated from the data plane (i.e., SDN switches). The programmable SDN controllers allow the network administrators to perform holistic management tasks, e.g., load-balancing, network visualization, and access control. OpenFlow [6] is the dominant communication protocol between the

[1]There are two deployment options for SDN/OpenFlow networks, i.e., out-of-band option and in-band option. The out-of-band option requires a separated physical network for control traffic. In contrast, the in-band option allows OpenFlow switches also forward the SDN control traffic, which is a more convenient and cost-efficient way for large area networks [6, 13].

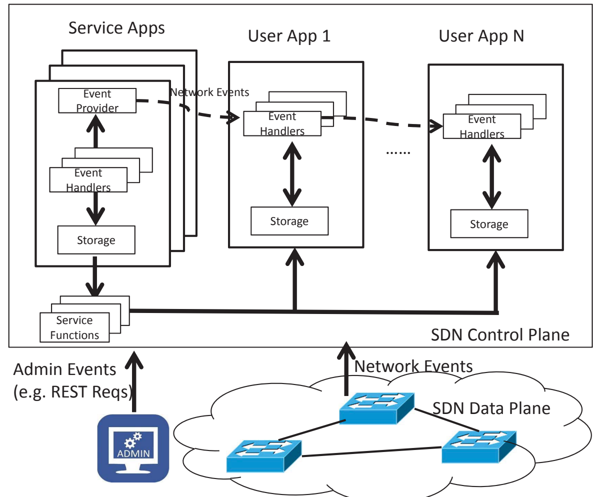

Figure 2: The abstraction model of the SDN control plane .

SDN control plane and the data plane. In this paper, we may use SDN and OpenFlow interchangeably.

The SDN control plane embraces a concurrent modular model. As shown in Figure 2, the SDN control plane embeds various modules (also known as applications) to enforce various network management policies, e.g., traffic engineering, virtualization, and access control. An SDN application manages a set of network states and provides *service functions* for other applications to reference the managed network states. For example, an access control application can install access control rules to all activated switches by querying the switch state from a switch manager application in the SDN controller. Also, each application operates in an event-driven fashion that implements handlers to process its corresponding events. It will update its managed network states when it receives corresponding network events.

Also, some applications, namely *service applications*, in the SDN control plane paraphrase external network events (i.e., OpenFlow messages) to its own internal network events and dispatch them to other applications' event handlers. For example, when a switch manager application recognizes that a new OpenFlow-enabled switch[2] has joined the network, it issues a `SWITCH_JOIN` event to all corresponding handlers for policy enforcement. In addition, a network administrator can configure the SDN controller via REST APIs, which we call *administrative events* in the paper.

Table 1 shows several network-related events and administrative events in the SDN control plane. In this paper, we focus on these network events because they are

[2]Without specific description, all term "switch" in this paper refer to OpenFlow-enabled switch.

Table 1: Common network events in SDN controllers.

	Entity	Events
Network	HOST	`JOIN`, `LEAVE`
	SWITCH	`JOIN`, `LEAVE`
	PORT	`UP`, `DOWN`
	LINK	`UP`, `DOWN`
	OFP	`PACKET_IN`, `OFP_PORT_STATUS`, etc
Admin	REST	`HOST_CONFIG`, `CREATE_VIP`, etc

commonly supported in all SDN controllers and they can be purposely generated by remote adversaries to exploit the race condition vulnerabilities.

We also note that certain events form implicit causal relationships. For example, a `SWITCH_LEAVE` event can implicitly trigger corresponding `LINK_DOWN` and `HOST_LEAVE` events. These implicit causal relationships must be captured to reason about race conditions in the SDN control plane. We present a comprehensive model of such causal relationships in Section 4.1.1.

3 State Manipulation Attacks

In this section, we present state manipulation attacks in SDN networks by exploiting harmful race conditions. We first present the threat model and explain how an external adversary can generate various network events in an SDN network. We then discuss two vulnerabilities related to harmful race conditions that we discovered in existing SDN controllers, and we show how an attacker can exploit them to steal privacy information and disrupt important services of SDN networks. We will discuss more vulnerabilities found in our experiments in Section 6.

3.1 Threat Model

We consider two scenarios: non-adversarial and adversarial. In a non-adversarial case, a harmful race condition in the SDN control plane can happen rarely under normal network operation by asynchronous events as listed in Table 1.

In contrast, in an adversarial case, the adversary could identify the harmful race conditions in the SDN controller source code and externally trigger them by controlling compromised hosts or virtual machines (e.g., via malware infection) with the system privilege to control network interfaces.

We do *not* assume that the adversary can compromise SDN controllers or switches, and we do *not* assume the adversary can compromise SDN applications or protocols. That is, we consider operating systems of SDN controllers and switches are well protected from the adversary, and the control channels between SDN controllers and SDN switches, as well as administrative management channels between administrators and SDN controllers, e.g., REST APIs, can be properly protected by SSL/TLS, which is particularly important when the SDN network is configured to use in-band control messages. As we discuss in Section 6.5, some of our attacks are possible even when the network is configured to use out-of-band control messages. For those attacks that assume in-band control messages, we assume control messages are properly protected by SSL/TLS.

3.2 Adversarial Event Generation

Host-related events (`HOST_JOIN`, `HOST_LEAVE`, and `OFP_PACKET_IN`) can be easily generated by an attacker from a compromised host or virtual machine without any knowledge about the switch. More specifically, to generate `HOST_JOIN` and `HOST_LEAVE` events, the attacker can simply enable/disable the network interface linked to a switch. The attacker can also send out crafted packets with randomized IP and MAC addresses to force a table miss in the switch's flow table[3], which can trigger `OFP_PACKET_IN` events. Switch port events (i.e., `PORT_UP` and `PORT_DOWN`) can also be indirectly generated by network interface manipulation (up and down) from a connected compromised host by using interface configuration tools, e.g., *ifconfig*.

In addition, an attacker can generate switch-dedicated events (i.e., `SWITCH_JOIN` and `SWITCH_LEAVE`) atop an in-band deployment of SDN networks. Even control messages are well protected by SSL/TLS, the attacker could still find important communication information (e.g., TCP header fields and types of control messages) between an SDN controller and switches by utilizing legacy techniques such as TCP/IP header analysis, size-based classification (given fixed size of control messages), etc. Then, the attacker may launch TCP session reset attacks [49] or drop control messages to disrupt the connection to generate `SWITCH_LEAVE`, thereby incurring `SWITCH_JOIN` subsequently. For example, as shown in Figure 3, we can use TCP reset to generate a `SWITCH_LEAVE` event in the Floodlight controller.

[3] An OpenFlow switch reports all packets to the SDN control plane if those packets do not hit its existing flow rule table.

3.3 Attack Cases

Here, we discuss two attack cases exploiting harmful race conditions we detected in the LoadBalancer application of the Floodlight controller and DHCPRelay application of the ONOS controller.

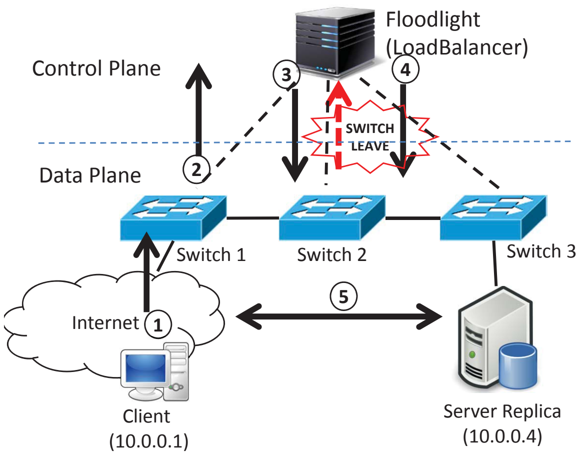

Figure 4: Attacking the Floodlight LoadBalancer.

3.3.1 Stealing Privacy Information

Figure 4 shows the workflow of the Floodlight LoadBalancer application. (1) A client sends out a service request packet with the virtual IP address (10.10.10.10) of server. (2) Switch 1 issues an OFP_PACKET_IN event to Floodlight controller to report a table-miss packet. (3) The OFP_PACKET_IN handler selects a service replica (10.0.0.4) to process the request and installs inbound flow rules in each switch along the route from the client to the replica. In addition, for routing and privacy purposes, an extra flow rule is installed into switch 1 to convert the destination IP address of packets from virtual IP address (10.10.10.10) to physical IP address of the replica (10.0.0.4). (4) The OFP_PACKET_IN handler also installs outbound flow rules from the service replica to the client and restores the virtual IP address on Switch 1 (i.e., from 10.0.0.4 to 10.10.10.10). (5) As a result, the client can successfully communicate with the server replica.

We found a harmful race condition in this application, i.e., a concurrent SWITCH_LEAVE event from any switch along the routing path can trigger an internal exception of the Floodlight controller and further violate the policy enforcement from step (3) to step (4). If that happens, no source IP address conversion rule (from 10.10.10.10 to 10.0.0.4) will be installed in switch 1. As a result, the sensitive physical IP address information is disclosed to the client which sent requests to the public service. We detail more about the exploitation of such vulnerability in Section 6.6.

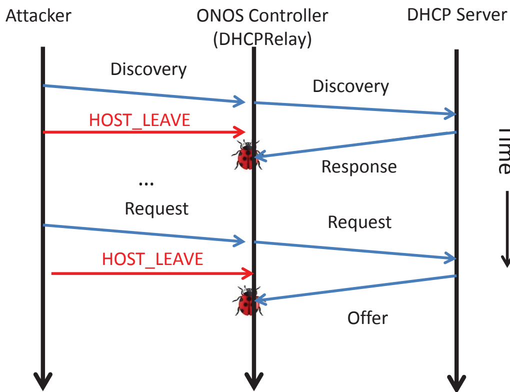

Figure 5: Attacking the ONOS DHCPRelay application.

3.3.2 Disrupting Packet Processing Service

In order to provide a DHCP service in different subnets, the DHCPRelay application in the ONOS controller relays DHCP messages between DHCP clients and the DHCP server. However, due to a harmful race condition, a conflicting HOST_LEAVE event can manipulate the internal state of the host, which may result in an unexpected exception and further disrupt the packet processing service when the DHCPRelay application relays DHCP response/offer messages to the sender, as illustrated in Figure 5. The root cause of this vulnerability lies in that the host state variable referenced by DHCPRelay application can be nullified by a HOST_LEAVE event. We detail more about such attack in Section 6.6.

4 ConGuard Overview

In this section, we present our framework, ConGuard, for detecting and exploiting the race condition vulnerabilities in SDN controllers. ConGuard contains two main phases: (i) locating harmful race conditions in the controller source code by utilizing dynamic analysis and adversarial state racing, (ii) triggering harmful race conditions in the running SDN controller by remotely injecting right external network events with the proper timing.

4.1 Pinpointing Harmful Race Conditions

To locate harmful race conditions, our basic idea is to use dynamic analysis to first detect a superset of potentially harmful race conditions, and then use adversarial

state racing to manifest those real harmful ones. More specifically, given a target SDN controller, we first analyze its dynamic behavior (by generating network events as inputs to it and then tracing the execution) to detect race conditions consisting of two race operations on a shared network state. These two operations may or may not have a common lock protecting them, but there should not be any predefined order causality between them. Then, for each pair of such operations, we re-run the SDN controller but force it to follow an erroneous schedule to check if a race condition is harmful or not.

In this step, there are two major challenges:

- *First, how to avoid reporting a myriad of race warnings that are in fact false alarms?* Lack of accurate modeling of the SDN semantics can significantly impede the precision of race detection. For example, in Figure 1, without reasoning the causality order between line 3 and line 5 for the internal event dispatching, the state update operation at line 1 and state reference at line 10 will be reported as a false positive.

- *Second, how to manifest and verify harmful race conditions?* Witnessing/reproducing concurrency errors is infamously difficult since they may be non-deterministic that only occur in rare scenarios with the special input and schedule. For example, the vulnerability in Figure 1 is triggered when the write operation on the state variable *switches* (e.g., triggered by the `SWITCH_JOIN` event) occurs before the read operation of the state variable (e.g., caused by the `SWITCH_JOIN` event). In addition, the runtime context of the two state operations must be consistent, e.g., the value of *dpid* at lines 4 and 10 must be equal.

To address the first challenge, we develop an execution model of the SDN control plane that formulates happens-before semantics in the SDN domain, which can help us greatly reduce false positives. For the second challenge, we develop an adversarial testing approach with a context-aware and deterministic scheduling technique, called *Active Scheduling*, to verify and manifest harmful race conditions.

4.1.1 Modeling the SDN Control Plane

Generally, an execution of an SDN controller corresponds to a sequence of operations performed by threads on a collection of state objects. For detecting races, we would like to develop a model such that it captures all the critical operations inside the SDN control plane (as an execution trace) and their causality relationships in any execution of the SDN controller (as happens-before relations). Different from general multi-thread programs, there are a number of distinct types of operations and domain-specific causality rules in the SDN control plane.

Execution Trace: First, we model an execution of the SDN control plane as a sequence of operations as listed following:

- ***read(T,V)***: reads variable *V* in thread *T*.
- ***write(T,V)***: writes variable *V* in thread *T*.
- ***init(A)***: initializes the functions of application *A* in the SDN control plane.
- ***terminate(A)***: terminates the functions of application *A* in the SDN control plane.
- ***dispatch(E)***: issues event *E*.
- ***receive(H,E)***: receives event *E* by event handler *H*.
- ***schedule(TA)***: instantiates a singleton task *TA*.
- ***end(TA)***: terminates a singleton task *TA*.

Happens-Before Causality: In this paper, we utilize happens-before relations [28] to model the concurrency semantics of the SDN controller. A happens-before relation is a transitively closed binary relation to represent *order causality* between two operations, as denoted by $\prec$ in this paper. That is, $\alpha \prec \beta$ means operation α happens before operation β. Moreover, we utilize $\alpha <_\tau \beta$ to denote that operation α occurs before operation β in an execution trace τ. As illustrated in Figure 6, we list happens-before relations we derive in the SDN context by studying implementations of SDN controllers and OpenFlow switch specification [5]. For simplicity, we do not list those happens-before rules widely used in traditional thread-based programs, e.g., program order rules and fork/join rules. Instead, we elaborate some happens-before rules mostly unique to the SDN control plane as listed in Figure 6, which we intend to expand over time.

Application Life Cycle. We define two happens-before rules to model the life cycle of an SDN application. First, an application must be initialized before it can handle any network event; second, all event handling operations in an application must happen before the deactivation of the application.

Event Dispatching. For each network event (as shown in Table 1), we consider dispatching of the event must happen before the receipt of the event in various event handlers.

Sequential Event Handling. Moreover, most SDN controllers (e.g., OpenDaylight, ONOS, Floodlight, Pox, Ryu, etc.) handle network events sequentially, i.e., at any time an event can only be processed in a single event handler. Hence, we deduce that the receipt of a specific event for different handler functions should follow their orders in the observed execution trace.

Switch Event Dispatching. Before issuing `SWITCH_JOIN` event, the SDN control plane must

Explicit Link Down and Host Leave

$$\frac{\begin{array}{c}\alpha = (H,E_1) \quad \beta = dispatch(E_2) \quad E_1.port_id = E_2.port_id \\ E_1.type = \texttt{PORT_DOWN} \quad E_1.type = \{\texttt{LINK_DOWN}, \texttt{HOST_LEAVE}\} \\ E_1.port_id = E_2.port_id\end{array}}{\alpha \prec \beta}$$

$$\frac{\begin{array}{c}\alpha = (H,E_1) \quad \beta = dispatch(E_2) \quad E_1.switch_id = E_2.switch_id \\ E_1.type = \texttt{SWITCH_LEAVE} \quad E_1.type = \{\texttt{LINK_DOWN}, \texttt{HOST_LEAVE}\}\end{array}}{\alpha \prec \beta}$$

Singleton Task

$$\frac{\alpha = end(TA) \quad \beta = schedule(TA) \quad \alpha <_\tau \beta}{\alpha \prec \beta}$$

Figure 6: Happens-before rules in the SDN control plane.

receive an `OFP_FEATURES_REPLY` event that includes important information of the joining switch, e.g., *Datapath ID*.

Port Event Dispatching. The SDN control plane monitors `OFP_PORT_STATUS` OpenFlow messages to detect the addition and deletion of switch ports in the data plane. Consequently, the corresponding *PortManager* application dispatches `PORT_UP` or `PORT_DOWN` events to inform other applications.

Implicit Host Leave or Link Down. In the SDN control plane, we also monitor implicit causalities between events, i.e., a `PORT_DOWN` or `SWITCH_LEAVE` event may implicitly indicate a `HOST_LEAVE` or `LINK_DOWN` event.

Singleton Task. We note that a specific singleton task can only be instantiated once at a time. In order to avoid non-determinism of thread scheduling (especially in a thread pool), we define one happens-before relation to model the causality order that the last completion of a specific singleton task happens before the next schedule of the task.

4.1.2 Detecting Race State Operations

Our algorithm for detecting race state operations upon shared network state variables is based on the happens-before rules constructed in the previous section. Given an observed execution trace τ of an SDN controller, we construct happens-before relations $\prec$ between each pair of operations listed in the execution model in Section 4.1.1. For each pair of memory access operations, i.e., (α, β), on the same state variable, we report (α, β) as a race state operation, if it meets two conditions: 1) either α or β updates the state variable; 2) $\alpha \not\prec \beta$ and $\beta \not\prec \alpha$.

Taking the raw execution trace as input, we first conduct an effective preprocessing step to filter out redundant operations in the trace. Specifically, we remove those operations on thread-local or immutable data, since we only need to reason about conflicting operations on shared state variables. We also perform a duplication checking to prune duplicated *write* and *read* operations. In SDN, an event handler can repeatedly process identical network events, which produces a large number of duplicated events in the trace. Removing such redundant events significantly improves the efficiency of race condition detection.

We note that standard vector-clock based techniques [19] for computing happens-before relation is difficult to scale to the SDN domain, which typically contains a large number of network events and threads. Instead, we develop a graph-based algorithm [24, 31] that constructs a directed acyclic graph (DAG) from the preprocessed trace to detect commutative races. In the DAG, nodes denote operations, and edges denote happens-before relations between them. The rationale is that the problem of checking happens-before can be converted to a graph reachability problem. To facilitate race detection, we group operations by their accessed state variable. We can then pinpoint race operations by checking if there is a path between each pair of conflicting nodes in the DAG. Specifically, if a *write* node and a *read* node are from the same group, and there is no path between them, we report they are race operations.

4.1.3 Adversarial State Racing

Verifying a potentially harmful race condition is a challenging problem because it can only be triggered in a specific execution branch of the SDN controller under a certain schedule of operations. An intuitive approach is to instrument control logic to force an erroneous execution order, e.g., the state update executes before the state reference. However, we find such strawman approach introduces non-determinism due to two reasons. First, SDN applications may reference the same network state variable in different program branches. Second, inconsistent input parameters of the library methods upon a

state variable may impede the verification, e.g., scheduling *switches.remove(sw1)* before *switches.get(sw2)* will not lead to a harmful race condition. To address the first problem, we propose to explore all possible program branches to the reference operation upon the state variable and verify all of them at runtime deterministically. To address the second problem, we check the consistency of parameters for library methods upon the same state variable.

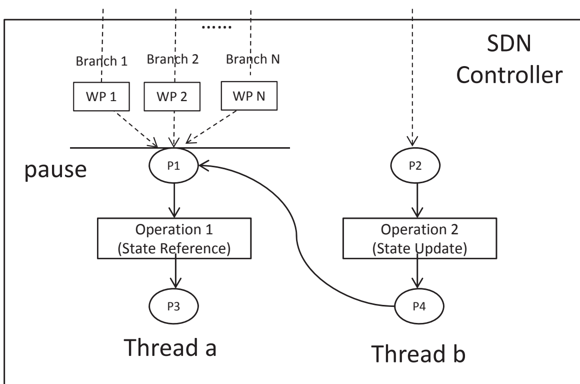

Figure 7: *Active Scheduling* to force a state update to execute before a state reference (WP denotes waypoint).

Active Scheduling. Taking a potentially harmful race condition as input, our active scheduling technique re-executes the program to force two operations (like operations in line 4 and line 10 in Figure 1) to follow a specific erroneous order, as shown in Figure 7. To force the deterministic schedule in a certain control branch (and external triggers), we put an exclusive waypoint (a check point in the code) to differentiate it with other branches. In addition to utilizing the waypoint to ensure execution context, we also add four atomic control points (P1, P2, P3, and P4) and one flag (F1) to enforce the deterministic scheduling between the state reference operation and the state update operation with consistent runtime information.

More specifically, we place P1 ahead of Operation 1, P2 ahead of Operation 2, P3 after Operation 1 and P4 after Operation 2. The active scheduling works as follows: In P1, if the corresponding waypoint is marked (which means the branch under test is covered), we pause Thread *a* by using a blocking method and save the runtime parameter value if necessary (e.g., the *dpid* of *switches.getSwitch(dpid)* in Figure 1). When Thread *b* enters P2, we set flag F1 if two conditions are satisfied: (1) Thread *a* is blocked; (2) the runtime value for Operation 2 is equal to runtime value of Operation 1. In P4, we unblock Thread *a* if flag F1 is set.

4.2 Remotely Triggering Harmful Race Conditions

To launch the attack, an adversary, who has no control of the SDN controller except sending external network events, first needs to figure out what external events to trigger a harmful race condition. For example, in Figure 1, a `SWITCH_JOIN` event can trigger a reference on the switch state and `SWITCH_LEAVE` event can trigger an update on the switch state. In addition, the attacker needs to trigger a "bad" schedule that can expose the harmful race condition. For example, a schedule in which the update on the switch state happens before the dereference.

4.2.1 Trigger Correlation

Since SDN controllers define different handler functions to process various network events, we first statically analyze the program to extract a map from external events to their corresponding handler functions. Then, for each operation in a potentially harmful race condition, we backtrack the control flow graph from the operation to correlate the operation with the external event. In particular, we consider that a *trigger event* is correlated to a state reference operation and an *update event* is correlated to a state update operation. Moreover, we resolve potential contextual relations between *trigger event* and *state update event* by inspecting input parameters of state operations. For example, to exploit the vulnerability in Figure 1, the dpid of the *update event* `SWITCH_LEAVE` should be consistent with that of the *trigger event* `SWITCH_JOIN`.

4.2.2 Exploitation

In general, hitting a specific schedule that manifests harmful races is difficult because the space of all possible schedules is huge. Nevertheless, in SDN networks, an attacker can explore several effective ways to increase the chance of hitting an erroneous schedule.

First, we come up with a basic attack strategy, i.e., an attacker can repeat a proper sequence of crafted events (including ordered <*trigger event*, *update event*>). The trigger events will push the SDN controller to reference the state while the *update events* will modify the state. Hence, there are two resulting scenarios: 1) if the *update event* can update the network state before the reference happens, the exploitation succeeds; 2) if the *update event* falls behind the reference operation, a harmful race condition will not be triggered. In addition to injecting ordered attack event sequences, an attacker can probe the signals from SDN controllers to infer the attack results which can also benefit next-round exploitations. For example, in Figure 1, if the *update event* is late, we can observe the SDN controller send out LLDP packets to all

enabled ports of the activated switch. The attacker can hence tune the timing interval between *trigger event* and *update event* to enhance the exploitability. Several other kinds of feedback information such as responses from service IP address and DHCP response/offer messages can also be utilized by the attacker to increase the success rate of the exploitations. We present more examples later in Table 5.

Moreover, an attacker can tactically increase the probability of success by selecting a larger vulnerable window [51] for a specific exploitation. The vulnerable window is the timing window that a concurrency vulnerability may occur. For some vulnerabilities, we found that their vulnerable windows are subject to network conditions, e.g., the size of network topology or network round-trip latency. For example, as the harmful race condition in Figure 5, the attacker can launch the attack when the network delay is high. In such a case, an attacker can first utilize a probe testing to pick up an advantageous condition to launch the attack.

5 Implementation

We have implemented CONGUARD and tested it on three mainstream SDN controllers, including Floodlight [1], ONOS [3] and OpenDaylight [4].

Input Generation: To inject network events, we introduce an SDN control plane specific input generator in our framework. We utilize Mininet 2.2 [7], an SDN network simulator, to mock an SDN testbed. Mininet can generate all the network events as shown in Table 1. In addition, we create test scripts to send REST requests as another source of inputs to the SDN controller.

Instrumentation: We use the ASM [9] bytecode rewriting framework to instrument and analyze SDN controllers at the Java bytecode level. For each event in the execution trace, we assign a global incremental number as its identifier, a location ID to store its source code context (i.e., class name and line number), and a thread ID. At runtime, the execution traces and contextual metadata are stored in a database (H2 [2]). Since we focus on locating harmful race conditions in the SDN controller source code, we exclude external packages in third-party libraries from the instrumentation. In addition, to improve performance, we only instrument those network state variables with reference data types and exclude primitive types (e.g., int, bool) because typically only reference types are involved in harmful race conditions.

We log memory accesses (e.g., *putfield* and *getfield*) upon objects and class fields as well as their values as metadata. We note that the SDN control plane embraces heterogeneous storages for network state including third party libraries such as java.util.HashMap. Failing to resolve those storage methods (e.g., *remove()* and *get()*) would lead to missing of potential vulnerabilities. Hence, we map those library method invocation operations as *write* or *read* operations upon the state object. For example, we consider *switches.remove(dpid)* is a *write* operation on *switches*.

We locate two kinds of event dispatching manners in SDN controllers, i.e., queue-based and observer-based. For queue-based rules, we record write and read operations upon global event queues as *dispatch* and *receive* operations. In contrast, for observer-based scheme, we log the invocations of event handler functions with the context of application name as *receive* operations upon the event.

We track *schedule* and *end* task operations by monitoring the life-cycle of *run()* method for singleton tasks. We log application life-cycle operations (i.e., *init* and *terminate*) by monitoring application-related callback methods (as listed in Table 2) with the identifier of the name of the class.

Table 2: Initialization and destroy methods of SDN controllers.

Controller	Init Methods	Destroy Methods
Floodlight	init(), startup()	–
ONOS	activate()	deactivate()
OpenDaylight	init()	destroy()

Active Scheduling: We implement active scheduling as a service module in the SDN controller that provides functions such as atomic control points (i.e., P1-P4) and waypoints. In order to cover all potential branches to trigger the bug, we statically generate the call graph of the tested controller. For each race state operations, we backtrack all paths (i.e., sequences of calling methods) to reach the state reference operation. For each path, we choose the method as the waypoint if it is: (1) nearest to the use operation in the call graph and (2) not listed in any other path. Taking the location of race state operations and all its corresponding waypoints as input, we instrument the SDN controller to invoke methods of the active scheduling service module.

6 Evaluation

In this section, we present our evaluation results of CONGUARD on the three mainstream open-source SDN controllers with 34 applications as listed in Table 7 in Appendix A. We hosted all the tested SDN controllers on a machine running GNU/Linux Ubuntu 14.04 LTS with dual-core 3.00 GHz CPU and 8 GB memory.

Table 3: Overall race detection results. (#RT: the size of raw traces before preprocessing; #OT: the size of optimized traces; RE: reduction ratio by preprocessing; OTATime: the total time for offline trace analysis; #Races: the number of detected race conditions; #RSVs: the number of Race State Variables)

1	2	3	4	5	6	7	8
SDN Controller		Trace Processing			Race Detection Results		
Name	Version	#RT	#OT	RE	OTATime	#Races	#RSVs
Floodlight	1.1	234,517	8,063	96.6%	43s	153	22
	1.2	410,128	52,271	87.2%	101s	184	35
OpenDaylight	0.1.7	47,855	3,752	92.1%	5s	221	26
ONOS	1.2	69,214	1,292	98.1%	5s	13	5

6.1 Detection Results

Table 3 summarizes our race detection results in Floodlight 1.1 and 1.2, ONOS 1.2 and OpenDaylight 0.1.7. In total, our tool found 153 race conditions on 22 network state variables in Floodlight 1.1, 184 race conditions on 35 variables in Floodlight 1.2, 221 race conditions on 26 variables in OpenDaylight, and 13 race conditions on 5 variables in ONOS. The numbers of detected race operations and network state variables in ONOS are much smaller than those of the other two controllers, because ONOS uses a centralized data storage to manage the network states. In addition, our results show that our offline trace analysis is highly effective and efficient. The preprocessing step reduces the size of traces (by removing redundant events) by more than 87%. For all the three controllers, the offline analysis was able to finish in less than two minutes.

To evaluate the effectiveness of the SDN domain-specific happens-before rules, we compared the following two configurations on running race detection of CONGUARD with Floodlight version 1.1: (1) enforces only thread-based happens-before rules; (2) enforces both thread-based and SDN-specific rules. Our results show that adopting SDN-specific happens-before rules reduces 105 reported race conditions in total (153 vs 258). We manually inspected all those race condition warnings filtered by SDN-specific rules and found that all of them are false positives. We expect that the happens-before rules formulated in this work greatly complement existing thread-based rules for conducting more precise concurrency defect detection in SDN controllers.

6.2 Comparing With Existing Techniques

To evaluate the effectiveness of our approach for identifying harmful race conditions, we also compared CONGUARD with an SDN-specific race detector, SDNRacer [18], and a state-of-the-art general dynamic race detector, RV-Predict (version 1.7) [22].

Comparing with SDNRacer. SDNRacer is a dynamic race detector that also locates concurrency violations in SDN networks. Because SDNRacer can also work on the Floodlight controller, we directly compared their results with ours. In a single-switch topology, SDNRacer reported 2, 281 data races. However, we find that none of those data races are relevant to our detected harmful race conditions. The reason lies in that SDNRacer only models memory operations in SDN *switches* but ignores internal state operations in SDN controllers. In this sense, we consider our new detection solution is orthogonal and complementary to SDNRacer.

Comparing with RV-Predict. RV-Predict is the state-of-the-art general-purpose data race detector that achieves maximal detection capability based on a program trace but does not consider harmful race conditions, and does not have SDN-specific causality rules. We evaluated RV-Predict as a Java agent for Floodlight v1.1 with our implemented network event generator and REST test scripts. We found that RV-Predict reported a total of 29 data races. However, none of them was harmful and none of them was related to harmful race conditions[4]. The reason is that all those harmful race conditions are caused by well-synchronized operations in Java concurrent libraries, which are not data races.

6.3 CONGUARD Runtime Performance

We evaluated the runtime performance of CONGUARD for trace collection using Cbench [8], an SDN controller performance benchmark. We use Cbench to generate a sequence of `OFP_PACKET_IN` events and test the delay. To remove network latency, we locate Cbench in the same physical machine with SDN controllers and range testbed from 2 switches to 16 switches. Our results show that CONGUARD incurs about 30X, 10X and 8X latency overhead for Floodlight, ONOS and OpenDaylight, respectively. The network functionalities can work properly and the instrumentation does not affect the collection of execution traces. The performance overhead mainly comes from instrumentation sites that frequently write event traces into the database. Although apparently

[4] We manually backtracked the call graph information for every data race reported by RV-Predict and checked if it could lead to harmful race conditions.

8X-30X latency is not small, we note that our tool is for *offline* bug/vulnerability finding purpose in the development and testing phase instead of online use in the actual operation phase. Thus, the overhead is acceptable as long as the tool can effectively find true bugs/vulnerabilities.

6.4 Impact Analysis of the Detected Vulnerabilities

By utilizing adversarial testing, we identified 15 concurrency bugs/vulnerabilities caused by harmful race conditions including 10, 2, 3 in Floodlight, ONOS and OpenDaylight, respectively. Furthermore, we conduct an impact analysis for those vulnerabilities, as shown in Table 4. We note that a single harmful race condition can have multiple impacts depending on different program branches/schedules and contexts.

Impact #1: System Crash. In Floodlight, we found 4 serious crash bugs, in which three of them (**Bug-1**, **Bug-2** and **Bug-3**) are in the LinkDiscoveryManager application and one of them (**Bug-4**) is in DHCPSwitchServer application. We manifested such vulnerabilities by active scheduling (as shown in Figure 8) and found that the main thread of Floodlight controller was unexpectedly terminated.

Impact #2: Switch Connection Disruption. We found 7 bugs (**Bug-5**, **Bug-6**, **Bug-7**, **Bug-8**, **Bug-9**, **Bug-11** and **Bug-12**) that could cause the SDN controller to actively close the connection to an online switch. Figure 9 and Figure 10 show stack traces reproducing this issue in Floodlight and ONOS controllers. The connection disruption is a serious issue in SDN domain since: (1) by default, the victim switch may downgrade to traditional Non-OpenFlow enabled switch and then traffic can go through it without controller's inspection; (2) an SDN controller may send instructions to clear the flow table of the victim switch when the controller recognizes a connection attempt from the switch[5]. As a result, security-related rules may also be purged.

Impact #3: Service Disruption. We also found several bugs that could interrupt the enforcement of services inside the SDN control plane, which may lead to serious logic bugs that hazard the whole SDN network.

In Floodlight, we found 3 bugs (**Bug-1**, **Bug-2**, and **Bug-3**) in the LinkDiscoveryManager application that can violate the operation of link discovery procedure. Moreover, we found 1 bug (**Bug-10**) in the Statistics application that disrupts the processing of REST requests. In addition, we located 5 such bugs in the `OFP_PACKET_IN` handler of LoadBalancer application. **Bug-5** and **Bug-6** could cause a logic flaw that leaks the physical IP address of the public server's replica. **Bug-7**, **Bug-8** and **Bug-9** could disrupt the handling of `OFP_PACKET_IN` events.

In ONOS, we found two such bugs (**Bug-11** and **Bug-12**). The bug **Bug-11** is in the SegmentRouting application that can disable the proxy ARP service and lead to the temporary block of end-to-end communication on a specific host. Similarly, the bug **Bug-12** is in the DHCPRelay application that will disable the DHCP relay service to send out DHCP reply to its clients.

In OpenDaylight, we found two such bugs. One (**Bug-13**) is in the HostTracker application, which could deny the REST API requests for creating a static host for a known host. The other (**Bug-15**) could affect the functionality of a Web UI application.

Impact #4: Service Chain Interference. We found several bugs that could violate the network visibility among various applications and could block applications from receiving their subscribed network events. In Floodlight, we found 5 such bugs (**Bug-5**, **Bug-6**, **Bug-7**, **Bug-8** and **Bug-9**) in the LoadBalancer application that

[5] This is an optional feature specified in OpenFlow protocol to prevent residual flow rule problem. However, we find that this feature could be enabled in most of SDN controllers.

Table 4: Summary of harmful race conditions uncovered by CONGUARD. Impact #1: System Crash; Impact #2: Connection Disruption; Impact #3: Service Disruption; Impact #4: Service Chain Interference.

* exploitable if the network is configured with in-band control, or if the adversary has access to the out-of-band network

† exploitable if the adversary can send authenticated administrative events (REST APIs) to the controller

could break the service chain for `OFP_PACKET_IN` event handlers. Similarly, we found 1 bug (**Bug-14**) in OpenDaylight, i.e., a concurrent `HOST_LEAVE` event can break the host event handling chain.

6.5 Remote Exploitation Analysis

We consider all of the detected harmful race conditions can be triggered non-deterministically in normal operations of an SDN/OpenFlow network. In addition, we study the adversarial exploitations of those harmful race conditions by a remote attacker as discussed in Section 3.1. We first investigate their external triggers, i.e., the *trigger event* and *update event* pair, as shown in Table 4. For 15 harmful race conditions we detected, we found 9 of them can be exploited by external network events. An attacker with the control of compromised hosts/virtual machines in SDN networks can easily trigger three harmful race conditions (i.e., **Bug-11**, **Bug-12** and **Bug-14**) by generating `OFP_PACKET_IN`, `HOST_JOIN`, `HOST_LEAVE`, `PORT_UP`, and `PORT_DOWN`. Moreover, the attacker can remotely exploit 6 more harmful race conditions (i.e., **Bug-1**, **Bug-2**, **Bug-3**, **Bug-4**, **Bug-5** and **Bug-6**) by utilizing `SWITCH_JOIN` and `SWITCH_LEAVE` events when the SDN network utilizes in-band control messages. For the rest 6 harmful race conditions (i.e., **Bug-7**, **Bug-8**, **Bug-9**, **Bug-10**, **Bug-13**, and **Bug-15**), we found that they correlate with REST API requests which are administrative events and might be protected by TLS/SSL. We consider the exploitation of those 6 harmful race conditions is out of scope of the paper since we do not assume an attacker can generate authenticated administrative events in the paper. Also, we found that there might have multiple triggers for a specific harmful race condition since SDN applications may reference the same network state variable in order to react upon various network events.

Moreover, based on results from Table 4, we evaluate the feasibility of an external attacker to exploit harmful race conditions. In particular, we utilize Mininet to inject ordered attack event sequences with a proper timing and test how many trials an external attacker needs to trigger a harmful race condition. Table 6 shows the average number of injected event sequences from 5 successful exploitations for an attacker to exploit a harmful race condition in an SDN controller[6]. Consequently, we found an attacker can exploit 7 out of 9 harmful race conditions within only hundreds of attempts.

Furthermore, Table 5 lists some feedback information that an attacker can use to infer the result of exploitations. For **Bug-1**, **Bug-2**, **Bug-3**, and **Bug-4**, the attacker can infer the failure of exploitation by monitoring LLDP packets from the SDN controller to the active ports of the activated switch. For **Bug-5** and **Bug-6**, the attacker can notice the unsuccessful exploitations by receiving re-

[6]Note that since some attack event sequence may trigger multiple harmful race condition (e.g., <`SWITCH_LEAVE`, `SWITCH_JOIN`> can trigger **Bug-1**, **Bug-2**, **Bug-3**, and **Bug-4**), we only record the first bug exploitation because an exploitation of harmful race condition may disrupt the operation of the SDN controller.

sponses from the virtual IP address of the public service. For **Bug-12**, as long as the attacker receives a DHCP response/offer message, he/she can infer that the exploitation fails. More importantly, the indicative information is useful for the attacker to tune their exploitations such as to minimize the timing interval between *trigger event* and *update event*.

In addition to injecting ordered attack events and tuning the timing between attack events, we also found that, the vulnerable windows of 7 harmful race conditions (i.e., **Bug-1**, **Bug-2**, **Bug-3**, **Bug-4**, **Bug-5**, **Bug-6**, and **Bug-12**) can be enlarged in some conditions. In particular, the vulnerable windows of **Bug-1** and **Bug-4** include the dispatch of all previous updates of Floodlight controller as shown in Figure 1, where the more unprocessed network events (e.g., `SWITCH_JOIN`, `PORT_UP`, and `PORT_DOWN`) and the more event handler functions of SDN applications can enlarge the window. The vulnerable windows of **Bug-2** and **Bug-3** are linearly correlated with the numbers of active ports of the switch. The vulnerable windows of **Bug-5** and **Bug-6** are relevant to the number of switches in the route between the compromised host and the target server in Figure 4. Lastly, as discussed in Section 3.3.2, the vulnerable window of **Bug-12** is subject to round-trip delay between ONOS controller and the DHCP server. An attacker could utilize them to increase the success rate of exploitation.

Table 5: Feedback information for the exploitations of harmful race conditions.

Bug #	Indications of Failed Exploitation
1,2,3,4	receipt of LLDP packets
5,6	receipt of responses from the service IP address
12	receipt of DHCP response/offer messages

6.6 Case Studies

Here we detail two state manipulation attack examples as briefly introduced in Section 3.3.

Sniffing Physical IP Address of Service Replica. In order to exploit the harmful race condition remotely, we set up an experiment as shown in Figure 4 in Mininet [7]. To launch the attack, we periodically injected `OFP_PACKET_IN` and `SWITCH_LEAVE` events. In particular, we updated the source IP address of a host and sent out ICMP echo requests (with the destination IP address of the public service 10.10.10.10) into the network to trigger the `OFP_PACKET_IN` messages. We also reset the TCP session between switch 2 and the Floodlight controller to generate `SWITCH_LEAVE`. As long as observing an ICMP echo reply whose source IP address is the physical replica (10.0.0.4), we consider the exploitation succeeds. Consequently, we successfully sniffed the physical IP address of the service replica after injecting tens of `SWITCH_LEAVE` events, as shown in Figure 11 below.

```

Figure 11: Privacy leakage in Floodlight LoadBalancer.

Disrupting Packet Processing Service. We set up an attack experiment in Mininet (with 500ms delay link between the DHCP server and its connected switch), where we injected ordered attack event sequences, i.e., <`OFP_PACKET_IN`, `HOST_LEAVE`>. In detail, we controlled a host to send out a DHCP request (to generate `OFP_PACKET_IN`) and turn off the network interface (to inject a `HOST_LEAVE` event) immediately after the transmission of the DHCP request. As a result, the harmful race condition is triggered by injecting an attack event sequence, which actually disrupts the packet processing service (as shown in Figure 12) to dispatch the incoming packets to `OFP_PACKET_IN` event handlers of SDN controller/applications. The exploitation possibility of such harmful race condition is comparatively high for a remote attacker since its vulnerable window is subject to round-trip delay between the ONOS controller and the DHCP server. In this case, a tactical attacker can even pick up a network congestion timing to increase the success ratio of the exploitation.

7 Defense Schemes

In this section, we discuss some possible defense techniques that developers or network administrators can use to mitigate this type of attacks.

Safety Check. To defend against the attack, one way is to remove those harmful race conditions once detected. The root cause of harmful race conditions is the concurrency violations inside the SDN controller/applications that may render inconsistency during state transition. For example, a concurrent `SWITCH_LEAVE` event modifying the state of a switch may incur some logic flaw in the handler of `SWITCH_JOIN` event for the switch. In this paper, we mitigate the exploitation of harmful race conditions by adding extra state checks in the SDN controller/applications to ensure the state is unchanged at the referenced location. By adding such safety checks, we have assisted the developers of SDN controllers to patch 12 harmful race conditions. Our future work will investigate how to automate this procedure.

Deterministic Execution Runtime. Another defense solution is to guarantee the deterministic execution of state operations in the SDN control plane at runtime. However, such a solution is difficult to correctly implement due to the undecidable order of two race operations. Even though we successfully resolve the orders between race operations, it inevitably undermines the parallelism of event processing, which further affects the overall performance of SDN controllers for a large-scale network environment. Designing a deterministic execution runtime system to mitigate concurrency errors in the SDN control plane with minor performance overhead is a meaningful future research direction.

Sanitizing External Events. One important factor of successful exploitation of harmful race conditions lies in that an attacker can intentionally inject various control plane messages (e.g., `HOST_LEAVE`, `SWITCH_LEAVE`) to modify the internal state inside the SDN control plane. In this sense, adopting an anomaly detection system to sanitize suspicious state update events could impede the exploitation of harmful race conditions. For example, an anomaly detection system may block some host to join SDN networks if its connection status is flipping frequently in a short time. Designing such anomaly detection with low false positives/negatives is worth future investigation.

8 Limitations and Discussion

Testing Coverage. As a common drawback of dynamic analysis techniques [10], the race detection part of CONGUARD cannot cover all execution paths. Thus, CONGUARD may not cover all harmful race conditions due to its dynamic nature. Instead, it focuses on locating the vulnerabilities more accurately given an execution trace. Also, our SDN-specific input generator is designed to cover essential and remote-attacker-accessible SDN events as much as possible to pinpoint concurrency vulnerabilities in the SDN control plane. To increase the code coverage, in our future work, we plan to complement CONGUARD with other coverage-based techniques such as symbolic execution [47, 42].

Supporting More Controllers and Other Event-driven Systems. The current implementations of CONGUARD are targeting Java-based mainstream SDN controllers such as Floodlight, ONOS and Opendaylight, which are widely adopted in both academia and industry. In fact, our technical principles and approaches are generic because the design of CONGUARD is based on the abstracted semantics of the SDN control plane. In that sense, we can easily port CONGUARD to other SDN controllers. We consider this work as a starting point for the security research on the concurrency issues inside the SDN control plane. In the future, we plan to extend our platform to other SDN controllers.

In addition to the SDN control plane and its applications, we note that harmful race conditions may occur in other multi-threaded event-driven systems, such as Web and Android applications. At high level, our approach is generic to those systems because our basic principle is to locate harmful race conditions from commutative races. In order to adapt our approach to other systems, one needs to feed CONGUARD with precise domain-specific models (like happens-before rules discussed in Section 4.1.1) and proper design of *Active Scheduling*.

Misuses of SDN Control Plane Northbound Interfaces (NBIs). An application may provide service functions to other applications for referencing its managed state (e.g., Switch Manager application provides switch state by the service function *getSwitch()*). If the state variable is subject to race state operations, an SDN application may misuse service functions (which are also known as NBIs) to reference network state variables from other applications. In this work, we have studied the concurrency violations introduced by specific misuses of those NBIs. However, verification and sanitization of more generalized uses of SDN control plane NBIs are still challenging issues. We plan to study these problems in future work.

9 Related Work

TOCTTOU vulnerabilities and attacks. One infamous category of concurrency vulnerabilities is TOCTTOU (Time of Check to Time of Use) vulnerabilities widely identified in file systems, which allow attackers to violate access control checks due to non-atomicity between the check and the use on the system resources [46, 14, 12]. In this paper, we study harmful race conditions in SDN networks, i.e., harmful race conditions upon shared network state variables triggered by external network events. In contrast to TOCTTOU vulnerabilities, a harmful race condition detected in this paper is a more general type of concurrency errors which does not necessarily include a check operation upon race state variables.

Race Detectors. To date, researchers have developed numerous race detectors for general thread-based programs [39, 19, 22] and domain-specific programs in web and Android [21, 31, 36, 33]. However, these existing detectors do not work well for harmful race conditions discussed in this paper because (1) harmful race condition vulnerabilities are not necessary data races as discussed earlier (in many cases they are not), (2) these detectors lack SDN concurrency semantics.

In the SDN domain, SDNRacer [32, 18] proposes to detect concurrency violations in the *data plane* of SDN networks while treating the SDN control plane as a blackbox. SDNRacer utilizes happens-before relations to model SDN data plane and commutative specification to locate data plane commutative violations. Attendre [45] extends OpenFlow protocol to mitigate three kinds of data plane race conditions to facilitate packet forwarding and model checking. However, SDNRacer and Attendre are exclusively effective in the SDN data plane and fail to solve concurrency flaws in the SDN control plane, which has different semantics. In this sense, our work is complementary to those work in effectively locating unknown concurrency flaws in the SDN control plane.

Active Testing Techniques. Our active scheduling technique is inspired by the schools of active testing techniques for software testing [41, 23], which actively control thread schedules to expose certain concurrency bugs such as data races and deadlocks. Differently, our technique is specialized for the SDN controllers.

Verification and Debugging Research in SDN. Anteater [30] presents a static analysis approach to debug SDN data plane by translating network invariant verification to the boolean satisfiability problem. NICE [15] complements model checking with symbolic execution to locate operation bugs inside SDN controller applications. Vericon [11] develops a system to verify if an SDN program is correct to user-specified admissible network topologies and desired network-wide invariants. OFRewind [40] proposes to reproduce SDN operation errors by utilizing record-and-replay technique. SOFT [27] complements symbolic execution with cross checking to test interoperability of SDN switches. STS [50] leverages delta debugging algorithm to derive minimal causal sequence for SDN controller operation bugs, which can facilitate network troubleshooting and root-cause analysis. Veriflow [26] proposes a shim layer between the SDN controller and switches to check network invariants. NetPlumber [25] introduces Header Space Analysis to verify network-wide invariant at real-time. None of the above verification tools are designed to precisely pinpoint concurrency flaws inside SDN control plane, which is the focus of this work.

Security Research in SDN. Recently, there are many studies investigating security issues in SDNs. Ropke and Holz propose that attackers can utilize rootkit techniques to subvert SDN controllers [38]. DELTA [29] presents a fuzzing-based penetration testing framework to find unknown attacks in SDN controllers. TopoGuard [20] pinpoints two new attack vectors against SDN control plane that can poison network visibility and mislead further network operation, as well as proposes mitigation approaches to fortify SDN control plane. In contrast to existing threats, in this paper we study a new threat to the SDN, i.e., harmful race conditions in the SDN control plane.

To fortify SDN networks, AvantGuard [44] and FloodGuard [48] propose schemes to defend against unique Denial-of-Service attacks inside SDN networks. FortNOX [35] and SE-FloodLight [34] propose several security extensions to prevent malicious applications from violating security policies enforced in the data plane. SPHINX [17] presents a novel model representation, called flow-graph, to detect several network attacks against SDN networks. Rosemary [43] and [37] propose sandbox strategies to protect SDN control plane from malicious applications. Although some of those work could isolate some impacts introduced by the harmful race conditions, such as system crash, they are not designed to detect those concurrency flaws as we have illustrated in this paper.

10 Conclusion

In this work, we present a new attack on SDN networks that leverages harmful race conditions in the SDN control plane to crash SDN controllers, disrupt core services, steal privacy information, etc. We develop a dynamic framework including a set of novel techniques for detecting and exploiting harmful race conditions. Our tool CONGUARD has found 15 previously unknown vulnerabilities in three mainstream SDN controllers. We hope this work will pave a foundation for detecting concurrency vulnerabilities in the SDN control plane, and in

general will stimulate more future research to improve SDN security.

Detecting Credential Spearphishing Attacks in Enterprise Settings

Grant Ho[†] Aashish Sharma[◇] Mobin Javed[†] Vern Paxson[†*] David Wagner[†]

[†]UC Berkeley [◇]Lawrence Berkeley National Laboratory [*]International Computer Science Institute

Abstract

We present a new approach for detecting credential spearphishing attacks in enterprise settings. Our method uses features derived from an analysis of fundamental characteristics of spearphishing attacks, combined with a new non-parametric anomaly scoring technique for ranking alerts. We evaluate our technique on a multi-year dataset of over 370 million emails from a large enterprise with thousands of employees. Our system successfully detects 6 known spearphishing campaigns that succeeded (missing one instance); an additional 9 that failed; plus 2 successful spearphishing attacks that were previously unknown, thus demonstrating the value of our approach. We also establish that our detector's false positive rate is low enough to be practical: on average, a single analyst can investigate an entire month's worth of alerts in under 15 minutes. Comparing our anomaly scoring method against standard anomaly detection techniques, we find that standard techniques using the same features would need to generate at least 9 times as many alerts as our method to detect the same number of attacks.

1 Introduction

Over the past several years, a litany of high-profile breaches has highlighted the growing prevalence and potency of spearphishing attacks. Leveraging these attacks, adversaries have successfully compromised a wide range of government systems (e.g., the US State Department and the White House [1]), prominent companies (e.g., Google and RSA [3]), and recently, political figures and organizations (e.g., John Podesta and the DNC [21]).

Unlike exploits that target technical vulnerabilities in software and protocols, spearphishing is a type of social engineering attack where the attacker sends a targeted, deceptive email that tricks the recipient into performing some kind of dangerous action for the adversary. From an attacker's perspective, spearphishing requires little technical sophistication, does not rely upon any specific vulnerability, eludes technical defenses, and often succeeds. From a defender's perspective, spearphishing is difficult to counter due to email's susceptibility to spoofing and because attackers thoughtfully handcraft their attack emails to appear legitimate. For these reasons, there are currently no generally effective tools for detecting or preventing spearphishing, making it the predominant attack for breaching valuable targets [17].

Spearphishing attacks take several forms. One of the most well-known involves an email that tries to fool the recipient into opening a malicious attachment. However, in our work, which draws upon several years worth of data from the Lawrence Berkeley National Lab (LBNL), a large national lab supported by the US Department of Energy, none of the successful spearphishing attacks involved a malicious attachment. Instead, the predominant form of spearphishing that LBNL encounters is *credential spearphishing*, where a malicious email convinces the recipient to click on a link and then enter their credentials on the resulting webpage. For an attachment-driven spearphish to succeed against a site like LBNL, which aggressively scans emails for malware, maintains frequently updated machines, and has a team of several full-time security staff members, an attacker will often need to resort to an expensive zero-day exploit. In contrast, credential spearphishing has an incredibly low barrier to entry: an attacker only needs to host a website and craft a deceptive email for the attack to succeed. Moreover, with widespread usage of remote desktops, VPN applications, and cloud-based email providers, stolen credentials often provide attackers with rich information and capabilities. Thus, although other forms of spearphishing constitute an important threat, credential spearphishing poses a major and unsolved threat in-and-of itself.

Our work presents a new approach for detecting credential spearphishing attacks in enterprise settings. This domain proves highly challenging due to base-rate issues. For example, our enterprise dataset contains 370 million emails, but fewer than 10 known instances of spearphishing. Consequently, many natural methods fail, because their false positive rates are too high: even a false positive rate as low as 0.1% would lead to 370,000 false alarms. Additionally, with such a small number of known spearphishing instances, standard machine learning approaches seem unlikely to succeed: the training set is too small and the class imbalance too extreme.

To overcome these challenges, we introduce two key contributions. First, we present an analysis of character-

istics that we argue are fundamental to spearphishing attacks; from this analysis, we derive a set of features that target the different stages of a successful spearphishing attack. Second, we introduce a simple, new anomaly detection technique (called *DAS*) that requires no labeled training data and operates in a non-parametric fashion. Our technique allows its user to easily incorporate domain knowledge about their problem space into the anomaly scores DAS assigns to events. As such, in our setting, DAS can achieve an order-of-magnitude better performance than standard anomaly detection techniques that use the same features. Combining these two ideas together, we present the design of a real-time detector for credential spearphishing attacks.

Working with the security team at LBNL, we evaluated our detector on nearly 4 years worth of email data (about 370 million emails), as well as associated HTTP logs. On this large-scale, real-world dataset, our detector generates an average of under 10 alerts per day; and on average, an analyst can process a month's worth of these alerts in 15 minutes. Assessing our detector's true positive accuracy, we find that it not only detects all but one spearphishing attack known to LBNL, but also uncovers 2 *previously undiscovered* spearphishing attacks. Ultimately, our detector's ability to identify both known and novel attacks, and the low volume and burden of alerts it imposes, suggests that our approach provides a practical path towards detecting credential spearphishing attacks.

2 Attack Taxonomy and Security Model

In a spearphishing attack, the adversary sends a targeted email designed to trick the recipient into performing a dangerous action. Whereas regular phishing emails primarily aim to make money by deceiving any arbitrary user [18, 22], spearphishing attacks are *specifically targeted* at users who possess some kind of *privileged access or capability* that the adversary seeks. This selective targeting and motivation delineates spearphishing (our work's focus) from regular phishing attacks.

2.1 Taxonomy for Spearphishing Attacks

Spearphishing spans a wide range of social-engineering attacks. To better understand this complex problem space, we present a taxonomy that characterizes spearphishing attacks across two dimensions. These correspond to the two key stages of a successful attack. Throughout this paper, we refer to the attacker as Mallory and the victim as Alice.

2.1.1 Lure

Spearphishing attacks require Mallory to convince Alice to perform some action described in the email. To accomplish this, Mallory needs to imbue her email with a sense of trust or authority that convinces Alice to execute the action. Attackers typically achieve this by sending the email under the identity of a trusted or authoritative entity and then including some compelling content in the email.

Real User
"Alice Good"
<alice@enterpriseX.com>

Address Spoofer
"Alice"
<alice@enterpriseX.com>

Name Spoofer
"Alice Good"
<alice@evil.com>

Previously Unseen Attacker
"Enterprise X IT Staff"
<director@enterpriseY.com>

Lateral Attacker
"Alice Good"
<alice@enterpriseX.com>

Figure 1: Examples of four different impersonation models for a real user "Alice Good". In the *address spoofer* impersonation model, an attacker might also spoof the username to exactly match the true user's (e.g., by using `Alice Good` instead of just `Alice`). Our work focuses on detecting the latter three threat models, as discussed in Section 2.2: *name spoofer*, *previously unseen attacker*, and *lateral attacker*.

Impersonation Model: Spearphishing involves impersonating the identity of someone else, both to create trust in the recipient and also to to minimize the risk of attribution and punishment. There are several types of impersonation:

1. An *address spoofer* uses the email address of a trusted individual in the `From` field of the attack email. The attacker may spoof the name in the `From` header as well, so that the attacker's `From` header exactly matches the true user's typical `From` header.
   DKIM and DMARC [2] block this impersonation model by allowing domains to sign their sent emails' headers with a cryptographic signature, which receiving servers can verify with a DNS-based verification key. In recent years, these protocols have seen increasingly widespread adoption, with many large email providers, such as Gmail, deploying them in response to the rise of phishing attacks [4].

2. A *name spoofer* spoofs the name in their email's `From` header to exactly match the name of an existing, trusted individual (e.g.,`Alice Good` in `Alice Good <alice@evil.com>`). However, in this impersonation model, the attacker does not forge the email address of their `From` header, relying instead on the recipient to only view the name of the sender, or on the recipient's mail client to show only the name of the sender. By not spoofing the `From` email address, this impersonation model circumvents DKIM/DMARC.
3. A *previously unseen attacker* selects a name and email address to put in the `From` field of the spearphishing email, where neither the name nor the email address actually match a true user's name or email address (though they might be perceived as trustworthy or similar to a real user's identity). For instance, Mallory might choose to spoof the name `LBNL IT Staff` and the email address `<helpdesk@enterpriseY.com>`.
4. A *lateral attacker* sends the spearphishing email from a compromised user's email account.

2.1.2 Exploit Payload

Once Mallory has gained Alice's trust, she then needs to exploit this trust by inducing Alice to perform some dangerous action. Three types of exploitation are commonly seen: (i) attachments or URLs that contain malware, (ii) URLs leading to websites that attempt to trick Alice into revealing her credentials, and (iii) out-of-band actions (e.g., tricking a company's CFO into wiring money to a fake, malicious "corporate partner").

2.2 Security Model

Threat Model: In this work, we specifically focus on an enterprise *credential spearphishing* threat model, where Mallory tries to fool a targeted enterprise's user (Alice) into revealing her credentials. We assume that the adversary can send arbitrary emails to the victim and can convince the recipient to click on URLs embedded in the adversary's email (leading the victim to a credential phishing website). To impersonate a trusted entity, the attacker may set any of the email header fields to arbitrary values.

In other words, we focus on attacks where Mallory's lure includes masquerading as a trusted entity, her payload is a link to a credential phishing page, and she chooses from any of the last three impersonation models. Because organizations can deploy DKIM/DMARC to mitigate address spoofing (and many large email providers have done so), we exclude address spoofing from our work.

Security Goals: First, a detector must produce an extremely low false positive burden, ideally only 10 or so false alarms per day that take at most minutes for an incident response team to process. Second, a detector must detect real spearphishing attacks (true positives). Given that current methods for detecting credential spearphishing often rely on users to report an attack, if our approach can detect even a moderate number of true positives or identify undiscovered attacks, while achieving a low false positive rate, then it already serves as a major improvement to the current state of detection and mitigation.

Data Source	Fields/Information per Entry
SMTP logs	Timestamp `From` (sender, as displayed to recipient) `RCPT TO` (all recipients; from the SMTP dialog)
NIDS logs	URL visited SMTP log id for the earliest email with this URL Earliest time this URL was visited in HTTP traffic # prior HTTP visits to this URL # prior HTTP visits to any URL with this hostname Clicked hostname (fully qualified domain of this URL) Earliest time any URL with this hostname was visited
LDAP logs	Employee's email address Time of current login Time of subsequent login, if any # total logins by this employee # employees who have logged in from current login's city # prior logins by this employee from current login's city

Table 1: Schema for each entry in our data sources. All sensitive information is anonymized before we receive the logs. The NIDS logs contain one entry for each visit to a URL seen in any email. The LDAP logs contain one entry for each login where an employee authenticated from an IP address that he/she has never used in prior (successful) logins.

3 Datasets

Our work draws on the SMTP logs, NIDS logs, and LDAP logs from LBNL; several full-time security staff members maintain these extensive, multi-year logs, as well as a well-documented incident database of successful attacks that we draw upon for our evaluation in Section 6. For privacy reasons, before giving us access to the data, staff members at LBNL anonymized all data using the procedure described in each subsection below. Additionally, our anonymized datasets do not contain the contents of email bodies or webpages. Table 1 shows the relevant information in these datasets and Table 2 summarizes the size and timeframe of our data.

3.1 SMTP Logs

The SMTP logs contain anonymized SMTP headers for all inbound and outbound emails during the Mar 1, 2013 – Jan 14, 2017 time period. These logs contain information about all emails sent to and from the organization's employees (including emails between two employees), a total of 372,530,595 emails. The second row of Table 1 shows the relevant header information we receive for each email in these logs.

The data was anonymized by applying a keyed hash to each sensitive field. Consider a header such as `Alice Good <ali@company.com>`. The 'name' of a header is the human name (`Alice Good` in our example); when no human name is present, we treat the email address as the header's 'name'. The 'address' of a header is the email address: `<ali@company.com>`. Each name and each email address is separately hashed.

3.2 NIDS Logs

LBNL has a distributed network monitor (Bro) that logs all HTTP GET and POST requests that traverse its borders. Each log entry records information about the request, including the full URL.

Additionally, the NIDS remembers all URLs seen in the bodies of inbound and outbound emails at LBNL.[1] Each time any URL embedded in an email gets visited as the destination of an HTTP request, the NIDS will record information about the request, including the URL that was visited and the entry in the SMTP logs for the email that contained the fetched URL. The NIDS remembers URLs for at least one month after an email's arrival; all HTTP visits to a URL are matched to the earliest email that contained the URL.

We received anonymized logs of all HTTP requests, with a keyed hash applied to each separate field. Also, we received anonymized logs that identify each email whose URL was clicked, and anonymized information about the email and the URL, as shown in Table 1.

3.3 LDAP Logs

LBNL uses corporate Gmail to manage its employees' emails.[2] Each time an employee successfully logs in, Gmail logs the user's corporate email address, the time when the login occurred, and the IP address from which the user authenticated. From these LDAP logs, we received anonymized information about login sessions where (1) the login IP address had never been used by the user during any previous successful login, (2) the user had more than 25 prior logins, and (3) the login IP address did not belong to LBNL's network. The last row of Table 1 shows the anonymized data in each entry of the LDAP logs.

4 Challenge: Diversity of Benign Behavior

Prior work has used machine learning to identify spearphishing attacks, based on suspicious content in email headers and bodies [8,19]. While that work detects several spearphishing attacks, their optimal false positive rates (FPR) are 1% or higher, which is far too high for our setting: a FPR of 1% would lead to 3.7 million false alarms on our dataset of nearly 370 million.

Time span	Mar 1, 2013– Jan 14, 2017
Total emails	372,530,595
Unique sender names (names in `From`)	3,415,471
Unique sender addresses (email addresses in `From`)	4,791,624
Emails with clicked URLs	2,032,921
Unique sender names (names in `From`)	246,505
Unique sender addresses (email addresses in `From`)	227,869
# total clicks on embedded URLs	30,011,810
Unique URLs	4,014,412
Unique hostnames	220,932
Logins from new IP address	219,027
# geolocated cities among all new IP addresses	7,937
# of emails sent during sessions where employee logged in from new IP address	2,225,050

Table 2: Summary of data in the three logs. Note that some emails contain multiple URLs, some or all of which may be visited multiple times by multiple recipients (thus, there are more clicked-URLs than emails that contain clicked-URLs).

In this section, we identify several issues that make spearphishing detection a particularly difficult challenge. Specifically, when operating on a real-world volume of millions of emails per week, the diversity of benign behavior produces an untenable number of false positives for detectors that merely look for anomalous header values.

4.1 Challenge 1: Senders with Limited Prior History

A natural detection strategy is to compare the headers of the current email under analysis against all historical email headers from the current email's purported sender. For example, consider a *name spoofer* who attempts to spearphish one of Alice's team members by sending an email with a `From` header of `Alice Good <alice@evil.com>`. An anomaly-based detector could identify this attack by comparing the email's `From` address (`<alice@evil.com>`) against all `From` addresses in prior email with a `From` name of `Alice Good`.

However, this approach will not detect a different spearphishing attack where neither the name nor the address of the `From` header have ever been seen before: `Alice <alice@evil.com>` or `HR Team <hr.enterpriseX@gmail.com>`. In this *previously unseen attacker* setting, there is no prior history to determine whether the `From` address is anomalous.

[1] Shortened URLs are expanded to their final destination URLs.

[2] Email between two employees also flows through corporate Gmail, which allows our detector to scan "internal" emails for lateral spearphishing attacks.

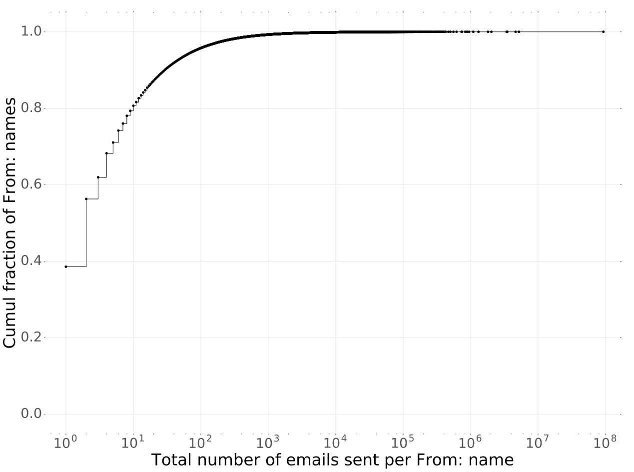

Figure 2: Distribution of the number of emails sent per `From` name. Nearly 40% of all `From` names appear in only one email and over 60% of all `From` names appear in three or fewer emails.

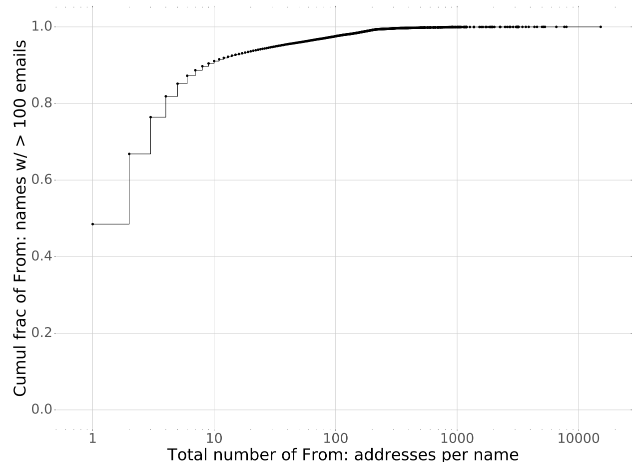

Figure 3: Distribution of the total number of `From` addresses per `From` name (who send over 100 emails) across all emails sent by the `From` name. Over half (52%) of these `From` names sent email from two or more `From` addresses (i.e., have at least one new `From` address).

To address this gap, one might flag all emails with a new or previously unknown `From` name (e.g., any email where the `From` name has been seen in two or fewer emails leads to an alert). Unfortunately, this approach generates an overwhelming number of alerts in practice because millions of `From` names are only ever seen in a few emails. Figure 2 shows the distribution of the number of emails per `From` name in our dataset. In particular, we find that over 60% of `From` names sent three or fewer emails and over 40% of `From` names sent exactly one email. Thus, even if one ran a detector retrospectively to alert on every email with a `From` name that had never been seen before and did not eventually become an active and engaged sender, it would produce over 1.1 million alerts: a false positive rate of less than 1% on our dataset of nearly 370 million emails, but still orders of magnitude more than our target. Even though spam might account for a proportion of these emails with new `From` names, LBNL's security staff investigated a random sample of these emails and found a spectrum of benign behavior: event/conference invitations, mailing list management notices, trial software advertisements, and help support emails. Thus, a detector that only leverages the traditional approach of searching for anomalies in header values faces a stifling range of anomalous but benign behavior.

4.2 Challenge 2: Churn in Header Values

Even if we were to give up on detecting attacks that come from previously unseen `From` names or addresses, a detector based on header anomalies still runs into yet another spectrum of diverse, benign behavior. Namely, header values for a sender often change for a variety of benign reasons. To illustrate this, we consider all `From` names that appear in at least 100 emails (our dataset contains 125,172 of them) and assess the frequency at which these names use a new `From` email address when sending email.

Figure 3 shows the cumulative distribution of the total number of `From` email addresses per `From` name. From this graph, we see that even among `From` names with substantial history (sent over 100 emails), there is considerable variability in header values: 52% of these `From` names send email from more than one `From` email address. We find that 1,347,744 emails contain a new `From` email address which has never been used in any of the `From` name's prior emails. Generating an alert for each of these emails would far exceed our target of 10 alerts per day.

This large number of new email addresses per `From` name stems from a variety of different sources: work vs. personal email addresses for a user, popular human names where each email address represents a different person in real life (e.g., multiple people named `John Smith`), professional society surveys, and functionality-specific email addresses (e.g. `Foo <noreply@foo.com>`, `Foo <help@foo.com>`, `Foo <donate@foo.com>`). While it might be tempting to leverage domain reputation or domain similarity between a new `From` address and the `From` name's prior addresses to filter out false positives, this fails in a number of different cases. For example, consider the case where `Alice` suddenly sends email from a new email address, whose domain is a large email hosting provider; this could either correspond to Alice sending email from her personal email account, or it might rep-

resent a *name spoofer* using a Gmail account with a spoofed `From` name.

Given the prevalence of emails with anomalous, yet benign, header values, a practical detector clearly needs to leverage additional signals beyond an email's header values. Some prior academic work has attempted to incorporate stylometry features from an email's body to identify spearphishing attacks [19]; however, as discussed earlier, these systems have false positive rates of 1% or higher, which would lead to millions of false alarms, a prohibitively high number for practical usage. In the following section, we present a novel approach that leverages a different set of signals based on the underlying nature of spearphishing attacks.

5 Detector Design

At a high level, our detector consists of three stages illustrated in Figure 4 and described below: a feature extraction stage (§ 5.1 and § 5.2), a nightly scoring stage (§ 5.4), and a real-time alert generation stage (§ 5.5). Conceptually, our work introduces two key ideas that enable our detector to detect a wide range of attacks, while achieving a practical volume of false positives that is over 200 times lower than prior work. First, our detector extracts two sets of reputation-based features that independently target the two key stages of a spearphishing attack identified in our attack taxonomy. Second, we introduce a novel, unsupervised anomaly detection technique that enables our detector to automatically rank a set of unlabeled events and select the most suspicious events for the security team to review. We first discuss each of these elements and then show how to combine them for our real-time detector.

5.1 Features per Attack Stage

Fundamentally, spearphishing attacks aim to trick their recipients into performing a dangerous action described in the email. If the attacker fails to persuade the victim into taking the action, the attack fails. For credential spearphishing, the dangerous action is clicking on a link in an email that leads the victim to a credential phishing website.[3] Thus, we analyze every email that contains a link that a user clicked on; we call this clicked link a *click-in-email* event.

As discussed in our taxonomy (§ 2.1), spearphishing attacks consist of two necessary stages: the lure stage, where the attacker persuades the victim to trust him, and the exploit stage, where the victim performs a dangerous action for the attacker. This insight leads to the first core idea in our approach: we craft two sets of features to target both of these stages of a spearphishing attack. Prior work has often used features that capture only the lure or the exploit; our insight is that we can do significantly better by using both types of features.

Accordingly, we have two classes of features: *domain reputation* features, and *sender reputation* features. In order to steal the victim's credentials, the attacker must link to a site under her control. Because spearphishing attacks are so tightly targeted, visits to this malicious website will presumably be rare among the historical network traffic from the organization's employees. Therefore, for each click-in-email event, the domain reputation features characterize the likelihood that an employee would visit that URL, based on its (fully qualified) domain. The sender reputation features characterize whether the sender of that email falls under one of the impersonation models outlined in our taxonomy. Effectively, the sender reputation features capture elements of the lure (by recognizing different types of spoofing that the attacker might use to gain the victim's trust), and the domain reputation features capture characteristics of the exploit.

Because the sender reputation features differ for each impersonation model (§ 5.2.2), our detector actually consists of three sub-detectors, one for each impersonation model. As discussed below (§ 5.5), if any of the sub-detectors flags an email as spearphishing, the detector treats it as an attack and generates an alert for the security team.

5.2 Features

Each sub-detector uses a feature vector containing four scalar values, two for domain reputation and two for sender reputation; Appendix A contains a summary table of these features, which we discuss below. As we show later (§ 6), these compact feature vectors suffice to detect a wide-range of attacks while achieving a practical volume of false positives.

5.2.1 Domain Reputation Features

All sub-detectors use the same two features to characterize the reputation of a link that the user clicked on. Intuitively, if few employees from the enterprise have visited URLs from the link's domain, then we would like to treat a visit to the email's link as suspicious. Additionally, if employees have never visited URLs from a domain until very recently, then we would also like to treat visits to the domain's URLs as risky. Based on these two ideas, the first feature counts the number of prior visits to any URL with the same fully qualified domain name (FQDN) as the clicked URL; this is a global count across all employees' visits, from the NIDS logs. The second fea-

[3] While an adversary could attempt to spearphish an employee's credentials by fooling them into including the credentials in an email response, this attack variant is likely more difficult to successfully execute given employee awareness from security training and education. Based on their multi-year incident database, LBNL has not observed such attacks succeed in practice.

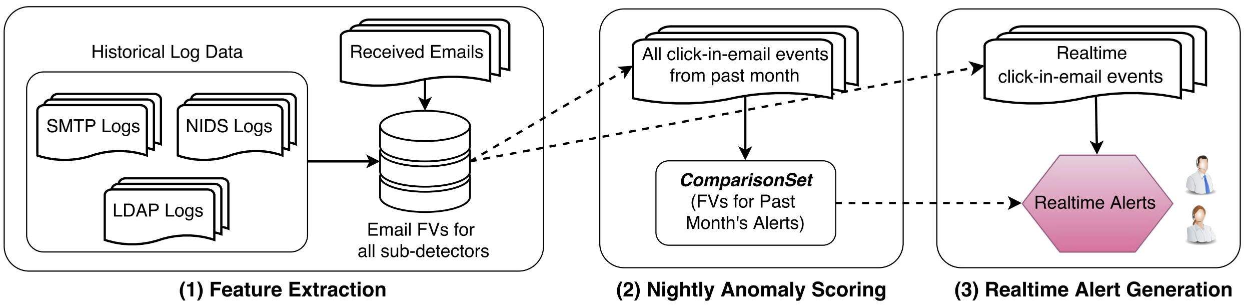

Figure 4: Overview of our real-time detector, which leverages output from a nightly batch job during its real-time analysis, as described in § 5.4 and § 5.5. As emails arrive, our detector leverages historical logs to extract and save three feature vectors (one FV per impersonation model) for each URL in the email (§ 5.1). Using the network traffic logs, our detector logs all clicks on URLs embedded in emails. Each night, our detector runs our anomaly scoring algorithm on the FVs from a sliding window over the past month's clicked URLs and stores a *ComparisonSet* of the month's most suspicious FVs for each impersonation model (§ 5.4). Observing real-time network traffic, our detector sees clicked email URLs, compares the real-time click's feature vector for each impersonation model against the *ComparisonSet*, and generates an alert for the security team if needed (§ 5.5).

ture counts the number of days between the first visit by any employee to a URL on the clicked link's FQDN and the time when the clicked link's email initially arrived at LBNL.

We chose to characterize a clicked link's reputation in terms of its FQDN, rather than the full URL, because over half of the clicked URLs in our dataset had never been visited prior to a click-in-email event. Consequently, operating at the granularity of the full URL would render the URL reputation features ineffective because the majority of URLs would have the lowest possible feature values (i.e., never been visited prior to the email recipient). Additionally, using a coarser granularity such as the URL's registered domain name or its effective second-level domain could allow attackers to acquire high reputation attack URLs by hosting their phishing webpages on popular hosting sites (e.g., attacker.blogspot.com). By defining a URL's reputation in terms of its FQDN, we mitigate this risk.

5.2.2 Sender Reputation Features

Name Spoofer: As discussed earlier (§ 2.1.1), in this attacker model Mallory masquerades as a trusted entity by spoofing the name in the `From` header, but she does not spoof the name's true email address. Because the trusted user that Mallory impersonates does not send email from Mallory's spoofed address, the spearphishing email will have a `From` email address that does not match any of the historical email addresses for its `From` name. Therefore, the first sender reputation feature counts the number of previous days where we saw an email whose `From` header contains the same name and address as the email being scored.

Also, in this attacker model, the adversary spoofs the `From` name because the name corresponds to someone known and trusted. If that name did not correspond to someone trustworthy or authoritative, there would be no point in spoofing it, or it would manifest itself under our *previously unseen attacker* threat model. Thus, the second sender reputation feature for a clicked email reflects the trustworthiness of the name in its `From` header. We measure the trustworthiness of a name by counting the total number of weeks where this name sent at least one email for every weekday of the week. Intuitively, the idea is that `From` names that frequently and consistently send emails will be perceived as familiar and trustworthy.

Previously Unseen Attacker: In this threat model (§ 2.1.1), Mallory chooses a name and email address that resembles a known or authoritative entity, but where the name and email address do not exactly match any existing entity's values (e.g.,`IT Support Team <helpdesk@company.`*net*`>`); if the name or address did exactly match an existing entity, the attack would instead fall under the *name spoofer* or *address spoofer* threat model. Compared to name-spoofing attacks, these attacks are more difficult to detect because we have no prior history to compare against; indeed, prior work does not attempt to detect attacks from this threat model. To deal with this obstacle, we rely on an assumption that the attacker will seek to avoid detection, and thus the spoofed identity will be infrequently used; each time Mallory uses the spoofed identity, she runs the risk that the employee she's interacting with might recognize that Mallory has forged the name or email address and report it. Accordingly, we use two features: the number of prior days that the `From` name has sent email, and the number of prior days that the `From` address has sent emails.

Lateral Attacker: This sub-detector aims to catch spearphishing emails sent from a compromised user's accounts (without using any spoofing). To detect this pow-

erful class of attackers, we leverage the LDAP logs provided by Gmail's corporate email services (§ 3). When a recipient clicks on a link in an email, if the email was sent by an employee, we check the LDAP logs to see if the email was sent during a login session where the sender-employee logged in using an IP address that the sender-employee has never used before. If so, this sub-detector computes the geolocated city of the session's IP address, say city C. It then extracts two features: the number of distinct employees that have logged in from city C, and the number of previous logins where this sender-employee logged in from an IP address that geolocated to city C.

Content-Based Features: As discussed in Section 3, for privacy reasons we do not have access to either the bodies of emails or the contents of a clicked URL's webpage. If desired, enterprises could augment our sender reputation features with additional features from the raw content in the email message or website (e.g., NLP features that characterize whether the email message relates to accounts/credentials/passwords or reflects particular sentiments such as urgency).

5.3 Limitations of Standard Detection Techniques

Once our detector has extracted features for each click-in-email event, it needs to decide which ones should trigger an alert for the security team. We first discuss three natural, but ultimately ineffective, approaches for determining which events to alert on. Then, in the following subsection, we present a new technique that our detector uses to overcome the limitations of these canonical approaches.

Manual Thresholds: The simplest approach would be to manually select a threshold for each feature, and generate an alert if all feature values are below the threshold. One might use domain knowledge of each feature to guess a threshold for each feature dimension: e.g., spearphishing attacks will use URLs whose domain has fewer than five visits or was first visited less than five days ago. Unfortunately, this approach is inherently arbitrary since we do not know the true distribution of feature values for spearphishing attacks. Thus, this ad hoc approach can easily miss attacks, and does not provide a selection criteria that generalizes across different enterprises.

Supervised Learning: A large body of literature on attack detection, from spam classification to prior spearphishing work, draws heavily on supervised machine learning algorithms. However, those methods are not suitable for our setting.

To accurately classify new events, supervised learning techniques require a labeled training dataset that reflects the range of possible malicious and benign feature values. Unfortunately, in our context, it is difficult to assemble a large enough training set. Because spearphishing attacks are extremely difficult to detect and occur at a low rate, we have few malicious samples to train on.

Additionally, our setting exhibits extreme class imbalance: because of the scarcity of data on known spearphishing attacks, the training set will have vastly more benign instances than malicious instances. Supervised techniques often need a relatively balanced dataset; classifiers trained on highly imbalanced data often learn to always predict the majority class (missing real attacks), pathologically overfit to accidental characteristics of the minority class, or generate too lax of a decision boundary and generate prohibitively high numbers of false positives [10]. While the machine learning community has explored a number of techniques for addressing imbalanced training data [6, 10], such as undersampling the over-represented class or synthetically generating samples for the under-represented class, these techniques do not scale to imbalances on the order of millions to one.

Standard Anomaly Detection: Alternatively, one might consider unsupervised or semi-supervised anomaly detection techniques. While a number of such techniques exist, including density estimation techniques such as Gaussian Mixture Models (GMMs) [5] and clustering and distance-based techniques such as k-nearest-neighbor (kNN) [13], these classical techniques suffer from three limitations.

First, in a number of security settings, scalar features often have a directionality to their values; and indeed, all of our features have this property. For example, the fewer visits a domain has, the more suspicious it is; an unusually small number of visits is grounds for suspicion, but an unusually large number is not. Standard anomaly detection techniques do not incorporate notions of asymmetry or directionality into their computations. For example, density-based anomaly detection techniques such as kernel density estimation (KDE) and GMMs fit a probability distribution to the data and alert on the lowest-probability events. Events that have statistically extreme—but benign—feature values will have a very low probability of occurring, triggering a large number of useless alerts.

Second, standard anomaly detection techniques often treat an event as anomalous even if only one or a few of the event's features are statistically anomalous. However, in our setting, we expect that attacks will be anomalous and suspicious in *all* feature dimensions. Consequently, in our setting, classical techniques will generate

Algorithm 1 Scoring and Alert Selection in DAS

```
Score(E, L):
1: for each event X in L do:
2:     if E is more suspicious than X in every dimension:
3:         Increment E's score by one

AlertGen(L (a list of events), N):
1: for each event E in L do:
2:     Score(E, L)
3: Sort L by each event's score
4: return the N events from L with the highest scores
```

many spurious alerts for events that are only anomalous in a few dimensions. As we show in Section 6.3, this causes classical techniques to miss the vast majority of spearphishing attacks in our dataset because they exhaust their alert budget with emails that have benign feature values in all but one dimension.

Third, classical techniques are parametric: they either assume the data comes from a particular underlying distribution, or they contain a number of parameters that must be correctly set by their deployer in order for the technique to obtain acceptable performance. GMMs assume the data comes from a mixture of Gaussian distributions, KDE has a bandwidth parameter that requires tuning by the deployer, and kNN needs the deployer to select a value of k (the number of nearest neighbors/most similar events, which the algorithm will use to compute an event's anomaly score). These requirements are problematic for spearphishing detection since we do not know the true distribution of attack and benign emails, the underlying distribution might not be Gaussian, and we do not have a sound way to select the parameters.

5.4 Directed Anomaly Scoring (DAS)

Given the limitations of traditional detection techniques, we introduce a simple and general technique for automatically selecting the most suspicious events from an unlabeled dataset. We call our technique Directed Anomaly Scoring (DAS). At a high level, DAS ranks all events by comparing how suspicious each event is relative to all other events. Once all events have been ranked, DAS simply selects the N most suspicious (highest-ranked) events, where N is the security team's alert budget.

Algorithm 1 shows the procedure for scoring and generating alerts with DAS. Concretely, DAS first assigns an anomaly score for each event, E, by computing the total number of other events where E's feature vector is at least as *suspicious* as the other event in *every* feature dimension. Thus, E's score counts how many events it is at least as suspicious as; events with higher scores are more suspicious than ones with lower scores. Figure 5 presents a few visual examples of computing DAS scores. After scoring every event, our algorithm simply sorts all events by their scores and outputs the N highest-scoring events.

Formally, we identify each event with its feature vector $E \in \mathbb{R}^d$. We consider event E to be at least as suspicious as event E', written $E \succcurlyeq E'$, if $E_i \leq E'_i$ for all $i = 1, 2, \ldots, d$. (For simplicity, we assume that smaller feature values are more suspicious, in every dimension; for dimensions where the reverse is true, we replace the comparator $\leq$ with $\geq$. Appendix A summarizes the comparators we use for each feature.) Then, the score of event E is the cardinality of the set $\{E' : E \succcurlyeq E'\}$.

DAS is well-suited for a range of security detection problems where attacks can be characterized by a combination of numerical and boolean features, such as our spearphishing use case. As we show in Section 6, DAS achieves orders-of-magnitude better results than classical anomaly detection techniques because it leverages domain knowledge about which regions of the feature space are most suspicious; in particular, it overcomes all three limitations of classical techniques discussed in Section 5.3.

5.5 Real-time Detection Architecture

We now synthesize the ideas discussed in previous subsections to provide an end-to-end overview of how we leverage DAS to generate alerts (illustrated in Figure 4). Our detector has access to the enterprise's log data, real-time network traffic (e.g., via a NIDS like Bro), and an alert budget β for each sub-detector, which specifies the daily volume of alerts that the security team deems acceptable. As each email arrives, for each URL in the email, our detector extracts the feature vector for that URL and saves it in a table indexed by the URL. Each HTTP request seen by the enterprise's NIDS is looked up in the table. Each time the detector sees a visit to a URL that was earlier seen in some email (a "click-in-email event"), it adds that feature vector to a list of events. Finally, our detector uses the DAS algorithm to rank the events and determine which ones to alert on.

This approach would work fine for a batch algorithm that runs the DAS algorithm once a month on the past thirty day's events. However, a spearphishing attack might not be detected by this batch approach until as much as a month after it occurs. Therefore, we now turn to extending our approach to work *in real-time*.

Naively, at the end of each day we could gather the day's events, rank them using DAS, and alert on the β most suspicious. However, this might miss attacks that would have been detected by the batch algorithm, as some days might have many benign but seemingly-suspicious events that mask a true attack.

Instead, we use a more sophisticated algorithm that comes closer to the batch algorithm, yet operates in real time. Each night, our detector collects all the click-in-

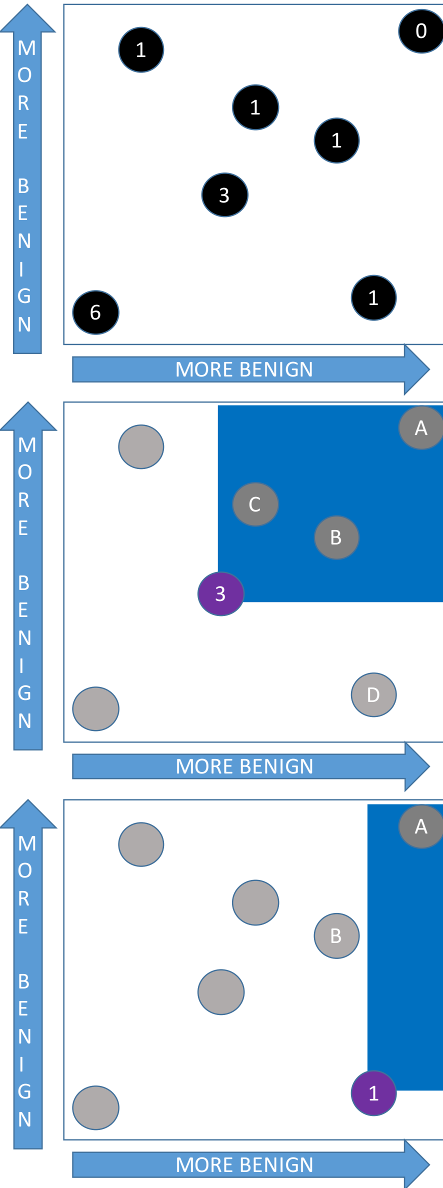

Figure 5: Example diagrams of DAS scores for events in a 2 dimensional feature space. X-values to the right and Y-values toward the top are more benign (thus, values toward the bottom and left are more suspicious). Each circle represents an example event. The number in each circle is the DAS score for the event. For example, looking at the third diagram, the purple event only receives a score of 1. Although the purple event has a more suspicious feature value in the Y dimension than event B, it is more benign in the X dimension. Thus, event B does **not** cause the purple event's score to increment.

email events for the past month and computes their associated feature vectors. For each sub-detector, we rank these events using DAS, select the $30 \times \beta$ most suspicious events, and save them in a set that we call the *ComparisonSet*.

In real time, when our detector observes a click-in-email event from the NIDS, it fetches the event's feature vectors for each impersonation model. Our detector then computes if any of the current click's feature vectors are at least as suspicious as any of the feature vectors in the *ComparisonSet* for its respective impersonation model.[4] If so, our detector generates an alert for the security team. Intuitively, this approach alerts if the event would have been selected by DAS on any day in the past month; or, more precisely, if it is among the 30β most suspicious events in the past month. Our evaluation (§ 6) shows that this real-time approach can safely detect the same attacks as the batch scoring procedure. On some days our real-time approach might generate more alerts than the target budget if a day has a burst of particularly suspicious click-in-email events; however, we show in the next section that this occurs infrequently in practice.

6 Evaluation and Analysis

We evaluated our real-time detector on our dataset of 370 million emails from LBNL, measuring its detection performance (true positives), the time burden (false positives) it imposes on an enterprise's security staff, and how it performs relative to standard anomaly detection techniques that use the same set of features.

For each click-in-email event, we computed its reputation features using log data from a sliding window over the six months prior to the click event. To bootstrap this process, we use the first six months of our dataset as a burn-in period and do not generate alerts for any emails in that period. Later (§ 7), we explore the impact of using a smaller window of historical data to compute feature values.

We configured our detector with a daily budget of 10 alerts per day. LBNL's security team specified 10 alerts per day as a very tolerable number since their team consists of several analysts who routinely process a few hundred alerts each day. To divide this budget among each of our three sub-detectors, we allocated 4 alerts per day for each of the *name spoofer* and *previously unseen attacker* sub-detectors and 2 alerts per day for our *lateral attacker* sub-detector; since lateral spearphishing requires the use of a compromised account, we expect it to occur less often than spoofing-based spearphishing.

6.1 Detection Results: True Positives

Because spearphishing attacks occur infrequently and often go undetected, developing ground truth and measuring true positives is a hard problem. For our evaluation, we draw upon LBNL's incident database, which contains

[4] This is equivalent to running DAS to score the current feature vector against the *ComparisonSet* and checking whether it gives the current feature vector a score of at least 1.

Alert Classification	*Name spoofer*	*Previously unseen attacker*	*Lateral attacker*	Total Count
Spearphish: *known* + successful attack	2	2	2	6 / 7
Spearphish: **unknown** + successful attack	1	1	0	2 / 2
Spearphish: failed attack	3	6	0	9 / 10
Total Spearphish Detected	6	9	2	17 / 19

Table 3: Summary of our real-time detection results for emails in our test window from Sep 1, 2013 - Jan 14, 2017 (1,232 days). Rows represent the type/classification of an alert following analysis by security staff members at LBNL. Columns 2–4 show alerts broken down per attacker model (§ 5.2.2). Column 5 shows the total number of spearphishing campaigns identified by our real-time detector in the numerator and the total number of spearphishing campaigns in the denominator. Out of 19 spearphishing attacks, our detector failed to detect 2 attacks (one that successfully stole an employee's credentials and one that did not); both of these missed attacks fall under the *previously unseen attacker* threat model, where neither the username nor the email address matched an existing entity.

7 known successful spearphishing attacks; this includes 1 spearphishing exercise, designed by an external security firm and conducted independently of our work, that successfully stole employee credentials. Additionally, members of LBNL's security team manually investigated and labeled 15,521 alerts. We generated these alerts from a combination of running (1) an older version of our detector that used manually chosen thresholds instead of the DAS algorithm; and (2) a batched version of our anomaly scoring detector, which ran the full DAS scoring procedure over the click-in-email events in our evaluation window (Sep. 2013 onward) and selected the highest scoring alerts within the cumulative budget for that timeframe.

From this procedure, we identified a total of 19 spearphishing campaigns: 9 which succeeded in stealing an employee's credentials and 10 where the employee clicked on the spearphishing link, but upon arriving at the phishing landing page, did not enter their credentials.[5] We did not augment this dataset with simulated or injected attacks (e.g., from public blogposts) because the true distribution of feature values for spearphishing attacks is unknown. Even for specific public examples, without actual historical log data one can only speculate on what the values of our reputation features should be.

To evaluate our true positive rates, we ran our real-time detector (§ 5.5) on each attack date, with a budget of 10 alerts per day. We then computed whether or not the attack campaign was flagged in a real-time alert generated on those days. Table 3 summarizes our evaluation results. Overall, our real-time detector successfully identifies 17 out of 19 spearphishing campaigns, a 89% true positive rate.

Of these, LBNL's incident database contained 7 known, successful spearphishing campaigns (their incident database catalogues successful attacks, but not ones that fail). Although our detector missed one of these successful attacks, it identified 2 previously undiscovered attacks that successfully stole an employee's credentials. The missed attack used a now-deprecated feature from

[5] A campaign is identified by a unique triplet of ⟨the attack URL, email subject, and email's `From` header⟩.

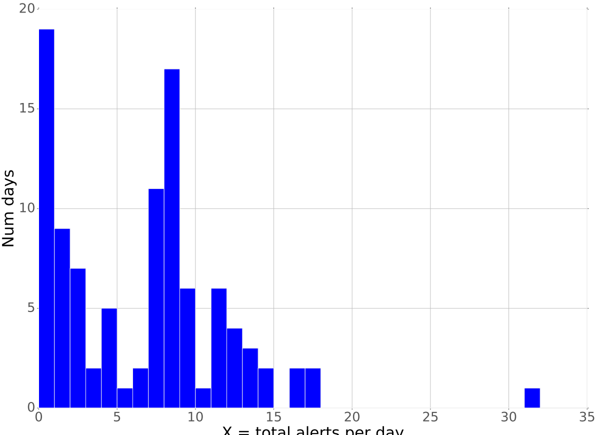

Figure 6: Histogram of the total number of daily alerts generated by our real-time detector (cumulative across all three sub-detectors) on 100 randomly sampled days. The median is 7 alerts/day.

Dropbox [7] that allowed users to host static HTML pages under one of Dropbox's primary hostnames, which is both outside of LBNL's NIDS visibility because of HTTPS and inherits Dropbox's high reputation. This represents a limitation of our detector: if an attacker can successfully host the malicious phishing page on a high-reputation site or outside of the network monitor's visibility, then we will likely fail to detect it. However, Dropbox and many other major file sharing sites (e.g., Google Drive) have dropped these website-hosting features due to a number of security concerns, such as facilitating phishing. Ironically, in the specific case of Dropbox, industry reports mention a large increase in phishing attacks targeted against Dropbox users, where the phishing attack would itself be hosted via Dropbox's website hosting feature, and thus appear to victims under Dropbox's real hostname [11]. Among the attacks that our detector correctly identified, manual analysis by staff members at LBNL indicated that our sub-detectors aptly detected spearphish that fell under each of their respective threat models (outlined in Section 2.1).

6.2 False Positives and Burden of Alerts

At a daily budget of 10 alerts per day, our detector achieved an average false positive rate of 0.004% (the median number of emails per day is 263,086). However, as discussed earlier (§ 5.5), our real-time detector is not guaranteed to produce exactly 10 alerts per day; some days might have a burst of particularly suspicious emails while other days might not have any unusual activity at all. To evaluate the actual daily alert load, we ran our real-time detector on one hundred randomly selected days in our dataset and computed the total number of alerts it generated on each day, shown in Figure 6. From this histogram, we see that while our detector occasionally generates bursts over our target budget, on the vast majority of days (80%) it generates 10 or fewer alerts per day; on nearly 20% of days, it generates no alerts.

During their manual investigation of the 15,521 alerts created during our ground truth generation process, LBNL's security staff tracked how long it took them to investigate these alerts. Surprisingly, LBNL's security staff reported that a single analyst could process an entire month's worth of alerts in under 15 minutes (and thus, on average, under one minute to analyze one day's worth of alerts).

This rapid processing time arises because the analysts were able to develop a two-pass workflow that enabled them to quickly discard over 98% of the alerts, at a rate of 2 seconds per alert; and then follow up with a more in-depth analysis pass (e.g., analyzing detailed HTTP logs and examining the full email headers) over the remaining 2% of alerts, at a rate of 30 seconds per alert. The first pass is so fast because, for the vast majority of our detector's alerts, an analyst could quickly tell if an email constituted a plausible spearphishing threat by inspecting the Subject line, `From` line, and clicked URL of the email. For over 98% of our alerts, this trio of information indicated that the email was highly unlikely to contain a credential spearphishing attack. For example, emails with subjects such as "Never Lose Your Keys, Wallet, or Purse Again!" and "ATTN: Your Stomach Issues FINALLY Explained. See Video Here" are surely not spearphishing attacks.

While the more time-intensive 2% of alerts contained mostly false positives (i.e., not spearphishing), the analysts found two interesting classes of alerts. First, in addition to detecting spearphishing attacks, our detector identified 41 emails from regular phishing campaigns. The analysts distinguished between regular phishing and spearphishing by checking whether the email and HTTP response from the clicked URL contained content that was specifically targeted at LBNL. Second, ironically, our detector generated 40 alerts where the person who clicked on the link in the email was not one of the email's recipients, but rather a member of LBNL's security staff. These clicks were part of routine investigations conducted by LBNL's security staff; for example, in response to a user reporting a suspicious email.

6.3 Anomaly Detection Comparisons

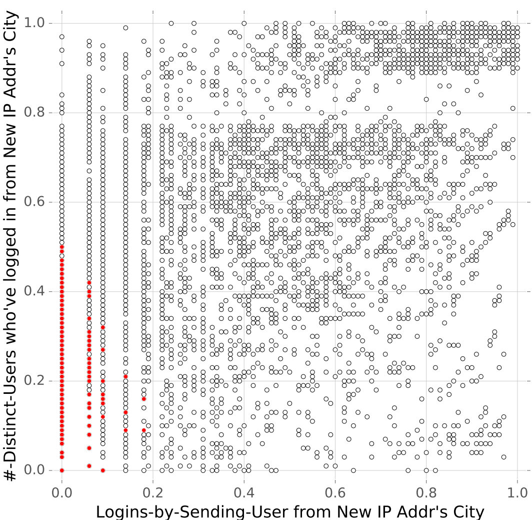
In Section 5.4 we introduced DAS, a simple new technique for anomaly detection on unlabeled data. Now, we evaluate the effectiveness of DAS compared to traditional unsupervised anomaly detection techniques.

We tested three common anomaly detection techniques from the machine learning literature: Kernel Density Estimation (KDE), Gaussian Mixture Models (GMM), and k-Nearest Neighbors (kNN) [5]. To compare the real-time detection performance of each of these classical techniques against DAS's real-time performance, we ran each of these classical techniques using the same training and evaluation procedures we used for our real-time detector's evaluation. Specifically, given the date of each of the 19 attacks and its impersonation model, we extracted the same exact feature values for all click-in-email events that occurred within a thirty day window ending on the attack date; the thirty day window reflected the size of our *ComparisonSet*. We then normalized these feature values and ran each of the three classical anomaly detection techniques on this set of click-in-email events for each attack date. For quantitative comparisons, we computed (1) the number of attacks that would have been detected by each classical technique if it used the same budget that our real-time detector used and (2) the daily budget the classical technique would need to detect all of the attacks that our DAS-driven detector identified.

Like other machine learning methods, these classical algorithms require the user to set various hyperparameters that affect the algorithm's performance. For our evaluation, we tested each classical technique under a range of different hyperparameter values and report the results for whichever values gave the best results (i.e., comparing DAS against the best-case version of these classical techniques).

Table 4 summarizes the results of this comparative experiment. All three traditional techniques detected fewer than 25% of the attacks found by DAS. Moreover, in order for KDE (the best performing classical technique) to detect as many attacks as DAS, it would need a daily budget nearly an order of magnitude larger than ours.

To illustrate why standard unsupervised techniques perform so poorly, the two plots in Figure 7 show the sender reputation features for a random sample of 10,000 *lateral attacker* click-in-email events. The left plot shows the feature values for the actual alerts our DAS detector generated (in red), while the right plot shows the feature values for the alerts selected by KDE using the same budget as our detector. KDE selects a mass



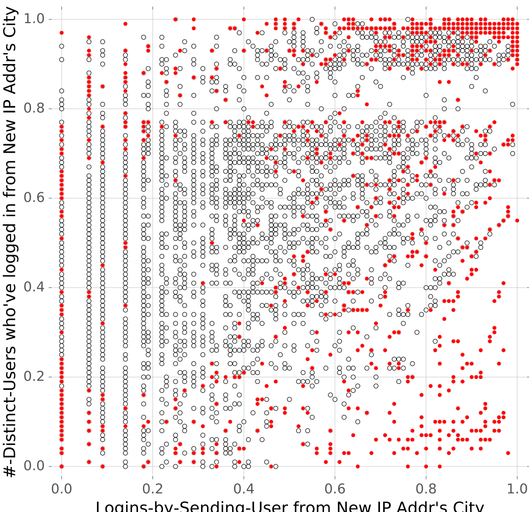


Figure 7: Both plots show the sender reputation feature values (scaled between [0, 1]) of a random sample of 10,000 *lateral attacker* click-in-email events. Filled red points denote events that generated alerts within the daily budget by DAS (left-hand figure) and KDE (right-hand figure).

Algorithm	Detected	Daily Budget
kNN	3/19	10
	17/19	2,455
GMM	4/19	10
	17/19	147
KDE	4/19	10
	17/19	91
DAS (§ 5.4)	17/19	10

Table 4: Comparing classical anomaly detection techniques to our real-time detector, on the same dataset and features. For each of the standard anomaly detection algorithms, the first row shows the number of attacks detected under the same daily budget as ours; the second row shows what the classical technique's budget would need to be to detect all 17 attacks that our real-time detector identified on a daily budget of 10 alerts per day.

of points in the upper-right corner, which illustrates one of limitations of standard techniques discussed in Section 5.4: they do not take into account the directionality of feature values. Because extremely large feature values occur infrequently, KDE ranks those events as highly anomalous, even though they correspond to benign login sessions where the user happened to login from a new IP address in a residential city nearby LBNL. Second, KDE selects a group of events in the bottom-right corner, which correspond to login sessions where an employee logged in from a city that they have frequently authenticated from in the past, but where few other employees have logged in from. KDE's selection of these benign logins illustrates another limitation of standard techniques: they often select events that are anomalous in just one dimension, without taking into account our domain knowledge that an attack will be anomalous in *all* dimensions. Even though the bottom-right corner represents employee logins where few other employees have logged in from the same city, they are not suspicious, because that employee has previously logged in many times from that location: they correspond to benign logins by remote employees who live and work from cities far from LBNL's main campus. Thus, DAS can significantly outperform standard unsupervised anomaly detection techniques because it allows us to incorporate domain knowledge of the features into DAS's decision making.

7 Discussion and Limitations

Detection systems operate in adversarial environments. While we have shown our approach can detect both known and previously undiscovered spearphishing attacks, there are limitations and evasion strategies that adversaries might pursue.

Limited Visibility: Our detection strategy hinges on identifying if an email's recipient engaged in a potentially dangerous action. In the case of credential spearphishing, LBNL's network traffic logs allowed us to infer this behavior. However, our approach has two limitations: first, email and network activity conducted outside of LBNL's network borders will not get recorded in the NIDS logs. Second, LBNL made a conscious decision not to man-in-the-middle traffic served over HTTPS; thus, we will miss attacks where the email links to an HTTPS website. Both of these are typical challenges that network-level monitoring faces in practice. One strategy for alleviating this problem would be to use endpoint monitoring agents on employee machines. Alternatively, a detector could leverage SNI [23] to develop

its domain reputation for HTTPS and identify when users visit potentially dangerous HTTPS domains.

In addition to limited network visibility, our detector might miss attacks if a spearphishing email came from a compromised personal email account. Since our detector relies on access to a user's prior login information to detect lateral spearphishing attacks, it will not have the necessary data to compute the features for this sub-detector. To defend against this genre of lateral spearphishing, one could leverage alternative sender reputation features, such as ones based on stylometry [8, 19].

False Negatives and Evasion Strategies: Our detector attempts to meet an upper-bound on the number of alerts it generates. As a result, it might miss some attacks if a number of successful spearphishing campaigns occur on a given day; in effect, the clicks on URLs from the campaigns earlier in the day will mask campaigns that occur later on. To overcome this problem, the security staff could increase the detector's alert budget on days with many attack alerts.

Aside from trying to mask one attack campaign with another, an adversary could attempt to escape detection by crafting an email whose domain or sender reputation features are high. An attacker could boost her link's domain reputation by compromising a frequently visited website and using it to host the credential spearphishing website. This strategy incurs greater costs to execute than modern-day attacks (where an adversary can simply setup her own cheap phishing webpage), and it is unclear whether such an attack would succeed if the site does not normally ask for the employee's corporate credentials. For example, if an adversary compromises a popular video website (e.g., netflix.com), many users might find it unusual for that popular domain to suddenly start asking for the user's enterprise credentials.

Alternatively, an attacker could attempt to inflate the sender reputation features of their adversarial email before using it in an attack. For instance, to prepare a malicious email address for a name spoofing attack, an adversary could start sending emails with the malicious email address and spoofed `From` name for several days before sending a spearphishing email to the targeted recipient. However, the more frequently this address is used, the more the adversary risks someone detecting the adversary's use of a spoofed name; thus this evasion strategy does incur a cost and risk to the attacker.

Future work could explore methods to make DAS more robust. In particular, rather than treating an event E as more suspicious than another event X only if E is more suspicious than X in every dimension, the scoring algorithm could be changed to treat E as more suspicious if it is more suspicious than X in at least *k* dimensions.

Prior History for Feature Extraction: For each click-in-email event, our detector leveraged 6 months of prior log data in order to compute meaningful reputation features. LBNL stores several years worth of logs, so this amount of prior history was easily available for our detector. However, with less historical data, the quality of our detector might degrade (e.g., in the degenerate case with no prior history, all `From` names and addresses will appear as suspicious new entities). To assess how much history our detector needs, we re-ran our evaluation experiments (§ 6.1 and § 6.2) with 3 months of history and with 1 month of history. A 3-month historical window sufficed to detect the same attacks as our 6-month real-time detector, and the median number of alerts per day remained the same (7 per day). However, a detector with only 1 month of history failed to detect one of the attacks and generated a median of 18 alerts per day. With just one month of prior data, too many click-in-email events have the smallest possible feature values; this causes our detector to select entire batches of them because they share the same DAS score.

Extending to Preventative Protection: One could extend our real-time detector to operate in a preventative fashion. As emails arrived, our detector could compute each email's feature values and then check each URL in the email to see whether or not it would generate an alert if the URL were clicked at that moment. If so, we could rewrite the email's URL (before delivering the email to its recipient) to point to an interstitial warning page set up by the enterprise's security team. Our computations show that if we used our real-time detector with a budget of 10 alerts/day, an employee would encounter a median of 2 interstitial pages over the nearly 4-year time span of our evaluation data (Appendix B). Given this low burden, future work could explore how to design effective warning mechanisms as part of a preventative defense.

8 Related Work

Recently, a number of papers have highlighted the threat of spearphishing and explored potential defenses [8, 12, 19, 24]. Closest to our work, the systems proposed by Stringhini et al. [19], Duman et al. [8], and Khonji et al. [12] build behavioral models for senders based on metadata, stylometry, and timing features. They then classify an email as spearphishing or not by using the behavioral model to see whether a new email's features differ from the sender's historical behavioral profile. This prior work cannot detect spearphish sent by a *previously unseen attacker* since the sender has no prior history (and thus no behavioral model to compare the attack email against). More importantly, when they evaluate their systems on smaller datasets with simulated attacks, the best performing detectors obtain false positive rates (FPRs)

in the range of 1–10%. Although quite low, an FPR of even 1% is too high for a practical enterprise settings; our dataset contains over 250,000 emails per day, so an FPR of 1% would lead to 2,500 alerts each day. In contrast, our detector can detect real-world attacks, including those from a *previously unseen attacker*, with a budget of 10 alerts per day.

Other work has characterized the landscape of spearphishing attacks against individual activists and dissidents [9, 15, 16, 20]. This body of work shows that targeted attacks on individuals span a wide spectrum of sophistication, from simple third-party tracking software and common exploits to purchasing specialized spyware and exploits from commercial firms. Most recently, LeBlond et al. conducted a large-scale analysis of exploit documents used in targeted attacks [14]. Their analysis found that none of these malicious attachments used a zero-day exploit, and over 95% of these documents relied on a vulnerability that was at least one year old. While these attacks can succeed against vulnerable activists and individuals, such dated exploits will likely fail against an enterprise with good security hygiene. Indeed, over the past few years, all of the spearphishing attacks on LBNL have been credential spearphishing.

9 Conclusion

In this work, we developed a real-time detector for identifying credential spearphishing attacks in enterprise settings. Two key contributions enabled our detector to achieve practical performance: (1) a new set of features that targets the two fundamental stages of successful spearphishing attacks, and (2) a new anomaly detection technique that leverages these features to detect attacks, without the need for any labeled training data.

We evaluated our approach on an anonymized dataset of over 370 million emails collected from a large national lab. At a false positive rate of less than 0.005%, our system detected all but two attacks in our dataset and uncovered two previously unknown successful attacks. Compared against our anomaly scoring technique, standard anomaly detection techniques would need to generate orders of magnitude more false positives to detect the same attacks as our algorithm. Because of our approach's ability to detect a wide range of attacks, including previously undiscovered attacks, and its low false positive cost, LBNL has implemented and deployed a version of our detector.

A Feature Vectors and Comparators per Sub-Detector

Name spoofer Features	Comparator for DAS
Host age of clicked URL (email ts − domain's 1st visit ts)	≤
# visits to clicked URL's host prior to email ts	≤
# weeks that `From` name has sent email on ≥ 5 days	≥
# days that `From` name and `From` addr have appeared together in emails	≤

Table 5: Summary of the feature vector for our *name spoofer* sub-detector and the "suspiciousness" comparator we provide to DAS for each feature.

Previously unseen attacker Features	Comparator for DAS
Host age of clicked URL (email ts − domain's 1st visit ts)	≤
# visits to clicked URL's host prior to email ts	≤
# days that `From` name has sent email	≤
# days that `From` addr has sent email	≤

Table 6: Summary of the feature vector for our *previously unseen attacker* sub-detector and the "suspiciousness" comparator we provide to DAS for each feature.

Lateral attacker Features	Comparator for DAS
Host age of clicked URL (email ts − domain's 1st visit ts)	≤
# visits to clicked URL's host prior to email ts	≤
# distinct employees who have previously logged in from the same city as the session's new IP addr	≤
# previous logins by the current employee from the same city as the session's new IP addr	≤

Table 7: Summary of the feature vector for our *lateral attacker* sub-detector and the "suspiciousness" comparator we provide to DAS for each feature.

B Preventative Interstitials

In Section 7 we discussed how to extend our detector from a realtime alert system to a preventative defense by rewriting suspicious URLs in emails to redirect to an interstitial page. This defense can only be practical if it does not cause employees to frequently land on interstial'ed pages. To assess this concern, we ran our detector on our entire evaluation dataset (Sep 1, 2013 – Jan 14, 2017) with an average daily budget of 10 alerts, and selected the alerts that fell within our cumulative budget for that window (i.e., selecting the top $B = 10 * N_{daysInEvalWindow} = 12,310$ most suspicious click-in-email events). For each recipient (`RCPT TO` email address) that received the emails of those 12,310 alerts, we computed the number alerts that recipient received over the entire evaluation time window. Figures 8 and 9 show these results in histogram and CDF form.

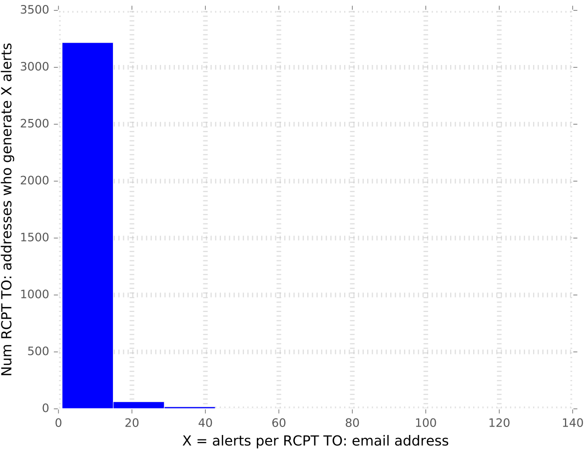

Figure 8: Histogram of alerts per `RCPT TO` address for our detector using an average budget of 10 alerts per day across the Sep 1, 2013 – Jan 14, 2017 timeframe.

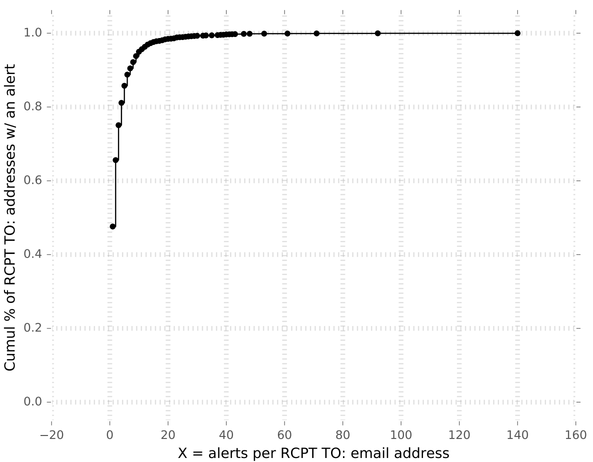

Figure 9: CDF of alerts per `RCPT TO` address for our detector using an average budget of 10 alerts per day across the Sep 1, 2013 – Jan 14, 2017 timeframe.

From these figures, we see that over 95% of employees would see fewer than 10 interstitials across the entire time span of nearly 3.5 years.

SLEUTH: Real-time Attack Scenario Reconstruction from COTS Audit Data*

Abstract

We present an approach and system for real-time reconstruction of attack scenarios on an enterprise host. To meet the scalability and real-time needs of the problem, we develop a platform-neutral, main-memory based, dependency graph abstraction of audit-log data. We then present efficient, tag-based techniques for attack detection and reconstruction, including source identification and impact analysis. We also develop methods to reveal the big picture of attacks by construction of compact, visual graphs of attack steps. Our system participated in a red team evaluation organized by DARPA and was able to successfully detect and reconstruct the details of the red team's attacks on hosts running Windows, FreeBSD and Linux.

1 Introduction

We are witnessing a rapid escalation in targeted cyber-attacks ("Enterprise Advanced and Persistent Threats (APTs)") [1] conducted by skilled adversaries. By combining social engineering techniques (e.g., spear-phishing) with advanced exploit techniques, these adversaries routinely bypass widely-deployed software protections such as ASLR, DEP and sandboxes. As a result, enterprises have come to rely increasingly on second-line defenses, e.g., intrusion detection systems (IDS), security information and event management (SIEM) tools, identity and access management tools, and application firewalls. While these tools are generally useful, they typically generate a vast amount of information, making it difficult for a security analyst to distinguish truly significant attacks — the proverbial "needle-in-a-haystack" — from background noise. Moreover, analysts lack the tools to "connect the dots," i.e., piece together fragments of an attack campaign that span multiple applications or hosts and extend over a long time period. Instead, significant manual effort and expertise are needed to piece together numerous alarms emitted by multiple security tools. Consequently, many attack campaigns are missed for weeks or even months [7, 40].

In order to effectively contain advanced attack campaigns, analysts need a new generation of tools that not only assist with detection but also produce a compact summary of the causal chains that summarize an attack. Such a summary would enable an analyst to quickly ascertain whether there is a significant intrusion, understand how the attacker initially breached security, and determine the impact of the attack.

The problem of piecing together the causal chain of events leading to an attack was first explored in Backtracker [25, 26]. Subsequent research [31, 37] improved on the precision of the dependency chains constructed by Backtracker. However, these works operate in a purely forensic setting and therefore do not deal with the challenge of performing the analysis in real-time. In contrast, this paper presents SLEUTH,[1] a system that can alert analysts in real-time about an ongoing campaign, and provide them with a compact, visual summary of the activity in seconds or minutes after the attack. This would enable a timely response before enormous damage is inflicted on the victim enterprise.

Real-time attack detection and scenario reconstruction poses the following additional challenges over a purely forensic analysis:

1. *Event storage and analysis:* How can we store the millions of records from event streams efficiently and have algorithms sift through this data in a matter of seconds?

*This work was primarily supported by DARPA (contract FA8650-15-C-7561) and in part by NSF (CNS-1319137, CNS-1421893, CNS-1514472 and DGE-1069311) and ONR (N00014-15-1-2208 and N00014-15-1-2378). The views, opinions, and/or findings expressed are those of the author(s) and should not be interpreted as representing the official views or policies of the Department of Defense or the U.S. Government.

[1]SLEUTH stands for (attack) Scenario LinkagE Using provenance Tracking of Host audit data.

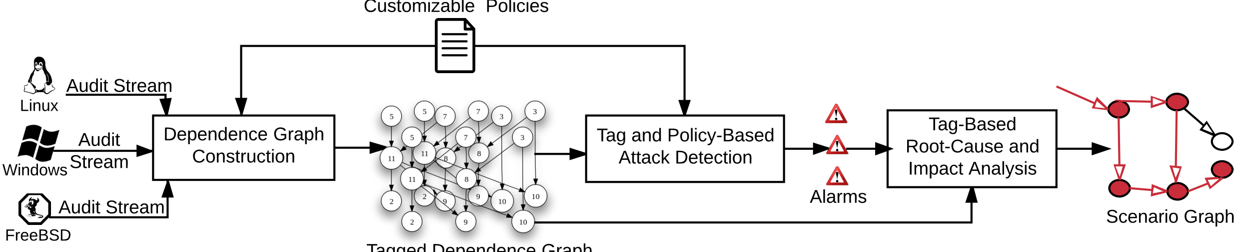

Fig. 1: SLEUTH System Overview

2. *Prioritizing entities for analysis:* How can we assist the analyst, who is overwhelmed with the volume of data, prioritize and quickly "zoom in" on the most likely attack scenario?

3. *Scenario reconstruction:* How do we succinctly summarize the attack scenario, starting from the attacker's entry point and identifying the impact of the entire campaign on the system?

4. *Dealing with common usage scenarios:* How does one cope with normal, benign activities that may resemble activities commonly observed during attacks, e.g., software downloads?

5. *Fast, interactive reasoning:* How can we provide the analyst with the ability to efficiently reason through the data, say, with an alternate hypothesis?

Below, we provide a brief overview of SLEUTH, and summarize our contributions. SLEUTH assumes that attacks initially come from outside the enterprise. For example, an adversary could start the attack by hijacking a web browser through externally supplied malicious input, by plugging in an infected USB memory stick, or by supplying a zero-day exploit to a network server running within the enterprise. We assume that the adversary *has not* implanted persistent malware on the host *before* SLEUTH started monitoring the system. We also assume that the OS kernel and audit systems are trustworthy.

1.1 Approach Overview and Contributions

Figure 1 provides an overview of our approach. SLEUTH is OS-neutral, and currently supports Microsoft Windows, Linux and FreeBSD. Audit data from these OSes is processed into a platform-neutral graph representation, where vertices represent subjects (processes) and objects (files, sockets), and edges denote audit events (e.g., operations such as read, write, execute, and connect). This graph serves as the basis for attack detection as well as causality analysis and scenario reconstruction.

The first contribution of this paper, which addresses the challenge of efficient event storage and analysis, is the development of a compact main-memory dependence graph representation (Section 2). Graph algorithms on main memory representation can be orders of magnitude faster than on-disk representations, an important factor in achieving real-time analysis capabilities. In our experiments, we were able to process 79 hours worth of audit data from a FreeBSD system in 14 seconds, with a main memory usage of 84MB. This performance represents an analysis rate that is 20K times faster than the rate at which the data was generated.

The second major contribution of this paper is the development of a tag-based approach for identifying subjects, objects and events that are most likely involved in attacks. Tags enable us to prioritize and focus our analysis, thereby addressing the second challenge mentioned above. Tags encode an assessment of *trustworthiness* and *sensitivity* of data (i.e., objects) as well as processes (subjects). This assessment is based on data provenance derived from audit logs. In this sense, tags derived from audit data are similar to coarse-grain information flow labels. Our analysis can naturally support finer-granularity tags as well, e.g., fine-grained taint tags [42, 58], if they are available. Tags are described in more detail in Section 3, together with their application to attack detection.

A third contribution of this paper is the development of novel algorithms that leverage tags for root-cause identification and impact analysis (Section 5). Starting from alerts produced by the attack detection component shown in Fig. 1, our backward analysis algorithm follows the dependencies in the graph to identify the sources of the attack. Starting from the sources, we perform a full impact analysis of the actions of the adversary using a forward search. We present several criteria for pruning these searches in order to produce a compact graph. We also present a number of transformations that further simplify this graph and produce a graph that visually captures the attack in a succinct and semantically meaningful way, e.g., the graph in Fig. 4. Experiments show that our tag-based approach is very effective: for instance, SLEUTH can analyze 38.5M events and produce an attack scenario graph with just 130 events, representing five orders of magnitude reduction in event volume.

The fourth contribution of this paper, aimed at tackling the last two challenges mentioned above, is a customizable policy framework (Section 4) for tag initialization and propagation. Our framework comes with sensible

defaults, but they can be overridden to accommodate behaviors specific to an OS or application. This enables tuning of our detection and analysis techniques to avoid false positives in cases where benign applications exhibit behaviors that resemble attacks. (See Section 6.6 for details.) Policies also enable an analyst to test out "alternate hypotheses" of attacks, by reclassifying what is considered trustworthy or sensitive and re-running the analysis. If an analyst suspects that some behavior is the result of an attack, they can also use policies to capture these behaviors, and rerun the analysis to discover its cause and impact. Since we can process and analyze audit data tens of thousands of times faster than the rate at which it is generated, efficient, parallel, real-time testing of alternate hypotheses is possible.

The final contribution of this paper is an experimental evaluation (Section 6), based mainly on a red team evaluation organized by DARPA as part of its Transparent Computing program. In this evaluation, attack campaigns resembling modern APTs were carried out on Windows, FreeBSD and Linux hosts over a two week period. In this evaluation, SLEUTH was able to:

- process, in a matter of seconds, audit logs containing tens of millions of events generated during the engagement;
- successfully detect and reconstruct the details of these attacks, including their entry points, activities in the system, and exfiltration points;
- filter away extraneous events, achieving very high reductions rates in the data (up to 100K times), thus providing a clear semantic representation of these attacks containing almost no noise from other activities in the system; and
- achieve low false positive and false negative rates.

Our evaluation is not intended to show that we detected the most sophisticated adversary; instead, our point is that, given several unknown possibilities, the prioritized results from our system can be right on spot in real-time, without any human assistance. Thus, it really fills a gap that exists today, where forensic analysis seems to be primarily initiated manually.

2 Main Memory Dependency Graph

To support fast detection and real-time analysis, we store dependencies in a graph data structure. One possible option for storing this graph is a graph database. However, the performance [39] of popular databases such as Neo4J [4] or Titan [6] is limited for many graph algorithms unless main memory is large enough to hold most of data. Moreover, the memory use of general graph databases is too high for our problem. Even STINGER [16] and NetworkX [5], two graph databases optimized for main-memory performance, use about 250 bytes and 3KB, respectively, per graph edge [39]. The number of audit events reported on enterprise networks can easily range in billions to tens of billions per day, which will require main memory in the range of several terabytes. In contrast, we present a much more space-efficient dependence graph design that uses only about 10 bytes per edge. In one experiment, we were able to store 38M events in just 329MB of main memory.

The dependency graph is a per-host data structure. It can reference entities on other hosts but is optimized for the common case of intra-host reference. The graph represents two types of entities: *subjects*, which represent processes, and *objects*, which represent entities such as files, pipes, and network connections. Subject attributes include process id (pid), command line, owner, and tags for code and data. Objects attributes include name, type (file, pipe, socket, etc.), owner, and tags.

Events reported in the audit log are captured using labeled edges between subjects and objects or between two subjects. For brevity, we use UNIX names such as `read`, `connect`, and `execve` for events.

We have developed a number of techniques to reduce storage requirements for the dependence graph. Wherever possible, we use 32-bit identifiers instead of 64-bit pointers. This allows a single host's dependence graph to contain 4 billion objects and subjects. The number of objects/subjects in our largest data set was a few orders of magnitude smaller than this number.

While our design emphasizes compact data structures for objects and subjects, compactness of events is far more important: events outnumber objects and subjects by about two orders of magnitude in our largest data set. Moreover, the ratio of events to objects+subjects increases with time. For this reason, we have developed an ultra-compact representation for events that can use as little as 6 bytes of storage for many events.

Events are stored inside subjects, thereby eliminating a need for subject-to-event pointers, or the need for event identifiers. Their representation uses variable-length encoding, so that in the typical case, they can use just 4 bytes of storage, but when needed, they can use 8, 12, or 16 bytes. Most events operate on an object and have a timestamp. Since a per-subject order of events is maintained, we dispense with microsecond granularity for timestamps, instead opting for millisecond resolution. In addition, we store only relative time since the last event on the same subject, which allows us to do with 16-bits for the timestamp in the typical case[2]. Objects are referenced within events using an index into a per-subject table of object identifiers. These indices can be thought of like file descriptors — they tend to have small val-

[2]Longer intervals are supported by recording a special "timegap" event that can represent millions of years.

ues, since most subjects use a relatively small number of objects. This enables object references to be represented using 8 bits or less. We encode event names for frequently occurring events (e.g., open, close, read and write) using 3 bits or less. This leaves us with several bits for storing a summary of event argument information, while still being within 32 bits.

We can navigate from subjects to objects using the event data stored within subjects. However, forensic analysis also requires us to navigate from objects to subjects. For this purpose, we need to maintain event information within objects using object-event records. Object event records are maintained only for a subset of events: specifically, events such as `read` and `write` that result in a dataflow. Other events (e.g., `open`) are not stored within objects. Object-event records are further shrunk by storing a reference to the corresponding subject-event record, instead of duplicating information.

As with subject-event records, we use a variable-length encoding for object-event records that enables them to be stored in just 16 bits in the most common case. To see how this is possible, note that objects tend to be operated on by a single subject at a time. Typically, this subject performs a sequence of operations on the object, e.g., an open followed by a few reads or writes, and then a close. By allowing object-event records to reuse the subject from their predecessor, we can avoid the need for storing subject identifiers in most records. Next, we allow object-event records to store a relative index for event records within subjects. Two successive event records within a subject that operate on the same object are likely to be relatively close to each other, say, with tens or hundreds of events in-between. This means that the relative index stored with object-event record can be 12 bits or less in most cases, thus allowing these records to be 16 bits or less in the typical case.

This design thus allows us to store bidirectional timestamped edges in as little as 6 bytes (4 bytes for a subject-event record and 2 bytes for an object-event record). In experiments with larger data sets, the total memory use of our system is within 10 bytes per event on average.

Our variable length encoding allows us to represent full information about important (but rare) events, such as rename, chmod, execve, and so on. So, compactness is achieved without losing any important information. Although such encoding slows down access, access times are still typically less than 100ns, which is many orders of magnitude faster than disk latencies that dominate random access on disk-resident data structures.

3 Tags and Attack Detection

We use tags to summarize our assessment of the trustworthiness and sensitivity of objects and subjects. This assessment can be based on three main factors:

- *Provenance:* the tags on the immediate predecessors of an object or subject in the dependence graph,
- *Prior system knowledge:* our knowledge about the behavior of important applications, such as remote access servers and software installers, and important files such as `/etc/passwd` and `/dev/audio`, and
- *Behavior:* observed behavior of subjects, and how they compare to their expected behavior.

We have developed a policy framework, described in Section 4, for initializing and propagating tags based on these factors. In the absence of specific policies, a default policy is used that propagates tags from inputs to outputs. The default policy assigns to an output the lowest among the trustworthiness tags of the inputs, and the highest among the confidentiality tags. This policy is conservative: it can err on the side of over-tainting, but will not cause attacks to go undetected, or cause a forward (or backward) analysis to miss objects, subjects or events.

Tags play a central role in SLEUTH. They provide important context for attack detection. Each audited event is interpreted in the context of these tags to determine its likelihood of contributing to an attack. In addition, tags are instrumental for the speed of our forward and backward analysis. Finally, tags play a central role in scenario reconstruction by eliminating vast amounts of audit data that satisfy the technical definition of dependence but do not meaningfully contribute to our understanding of an attack.

3.1 Tag Design

We define the following *trustworthiness tags* (*t-tags*):

- *Benign authentic* tag is assigned to data/code received from sources trusted to be benign, and whose authenticity can be verified.
- *Benign* tag reflects a reduced level of trust than benign authentic: while the data/code is still believed to be benign, adequate authentication hasn't been performed to verify the source.
- *Unknown* tag is given to data/code from sources about which we have no information on trustworthiness. Such data *can sometimes be* malicious.

Policies define what sources are benign and what forms of authentication are sufficient. In the simplest case, these policies take the form of whitelists, but we support more complex policies as well. If no policy is applicable to a source, then its t-tag is set to *unknown.*

We define the following *confidentiality tags* (*c-tags*), to reason about information stealing attacks:

- *Secret:* Highly sensitive information, such as login credentials and private keys.

- *Sensitive:* Data whose disclosure can have a significant security impact, e.g., reveal vulnerabilities in the system, but does not provide a direct way for an attacker to gain access to the system.
- *Private:* Data whose disclosure is a privacy concern, but does not necessarily pose a security threat.
- *Public:* Data that can be widely available, e.g., on public web sites.

An important aspect of our design is the separation between t-tags for code and data. Specifically, a subject (i.e., a process) is given two t-tags: one that captures its *code trustworthiness* (code t-tag) and another for its *data trustworthiness* (data t-tag). This separation significantly improves attack detection. More importantly, it can significantly speed up forensic analysis by focusing it on fewer suspicious events, while substantially reducing the size of the reconstructed scenario. Note that confidentiality tags are associated only with data (and not code).

Pre-existing objects and subjects are assigned initial tags using *tag initialization policies.* Objects representing external entities, such as a remote network connection, also need to be assigned initial tags. The rest of the objects and subjects are created during system execution, and their tags are determined using *tag propagation policies.* Finally, attacks are detected using behavior-based policies called *detection policies.*

As mentioned before, if no specific policy is provided, then sources are tagged with *unknown* trustworthiness. Similarly, in the absence of specific propagation policies, the default conservative propagation policy is used.

3.2 Tag-based Attack Detection

An important constraint in SLEUTH is that we are limited to information available in audit data. This suggests the use of provenance reflected in audit data as a possible basis for detection. Since tags are a function of provenance, we use them for attack detection. Note that in our threat model, audit data is trustworthy, so tags provide a sound basis for detection.

A second constraint in SLEUTH is that detection methods should not require detailed application-specific knowledge. In contrast, most existing intrusion detection and sandboxing techniques interpret each security-sensitive operation in the context of a specific application to determine whether it could be malicious. This requires expert knowledge about the application, or in-the-field training in a dynamic environment, where applications may be frequently updated.

Instead of focusing on application behaviors that tend to be variable, we focus our detection techniques on the high-level objectives of most attackers, such as backdoor insertion and data exfiltration. Specifically, we combine reasoning about an attacker's *motive* and *means.* If an event in the audit data can help the attacker achieve his/her key high-level objectives, that would provide the motivation and justification for using that event in an attack. But this is not enough: the attacker also needs the means to cause this event, or more broadly, influence it. Note that our tags are designed to capture means: if a piece of data or code bears the *unknown* t-tag, then it was derived from (and hence influenced by) untrusted sources.

As for the high-level objectives of an attacker, several reports and white papers have identified that the following steps are typical in most advanced attack campaigns [1, 2, 3]:

1. Deploy and run attacker's code on victim system.
2. Replace or modify important files, e.g., `/etc/passwd` or ssh keys.
3. Exfiltrate sensitive data.

Attacks with a transient effect may be able to avoid the first two steps, but most sophisticated attacks, such as those used in APT campaigns, require the establishment of a more permanent footprint on the victim system. In those cases, there does not seem to be a way to avoid one or both of the first two steps. Even in those cases where the attacker's goal could be achieved without establishing a permanent base, the third step usually represents an essential attacker goal.

Based on the above reasoning, we define the following policies for attack detection that incorporate the attacker's objectives and means:

- *Untrusted code execution:* This policy triggers an alarm when a subject with a higher code t-tag executes (or loads) an object with a lower t-tag[3].
- *Modification by subjects with lower code t-tag:* This policy raises an alarm when a subject with a lower code t-tag modifies an object with a higher t-tag. Modification may pertain to the file content or other attributes such as name, permissions, etc.
- *Confidential data leak:* An alarm is raised when untrusted subjects exfiltrate sensitive data. Specifically, this policy is triggered on network writes by subjects with a *sensitive* c-tag and a code t-tag of *unknown.*
- *Preparation of untrusted data for execution:* This policy is triggered by an operation by a subject with a code t-tag of *unknown,* provided this operation makes an object executable. Such operations include `chmod` and `mprotect`[4,5].

[3]Customized policies can be defined for interpreters such as `bash` so that reads are treated the same as loads.

[4]Binary code injection attacks on today's OSes ultimately involve a call to change the permission of a writable memory page so that it becomes executable. To the extent that such memory permission change operations are included in the audit data, this policy can spot them.

[5]Our implementation can identify `mprotect` operations that occur

It is important to note that "means" is not diluted just because data or code passes through multiple intermediaries. For instance, the untrusted code policy does not require a direct load of data from an unknown web site; instead, the data could be downloaded, extracted, uncompressed, and possibly compiled, and then loaded. Regardless of the number of intermediate steps, this policy will be triggered when the resulting file is loaded or executed. This is one of the most important reasons for the effectiveness of our attack detection.

Today's vulnerability exploits typically do not involve untrusted code in their first step, and hence won't be detected by the untrusted code execution policy. However, the eventual goal of an attacker is to execute his/her code, either by downloading and executing a file, or by adding execute permissions to a memory page containing untrusted data. In either case, one of the above policies can detect the attack. A subsequent backward analysis can help identify the first step of the exploit.

Additional detector inputs can be easily integrated into SLEUTH. For instance, if an external detector flags a subject as a suspect, this can be incorporated by setting the code t-tag of the subject to *unknown*. As a result, the remaining detection policies mentioned above can all benefit from the information provided by the external detector. Moreover, setting of *unknown* t-tag at suspect nodes preserves the dependency structure between the graph vertices that cause alarms, a fact that we exploit in our forensic analysis.

The fact that many of our policies are triggered by untrusted code execution should not be interpreted to mean that they work in a static environment, where no new code is permitted in the system. Indeed, we expect software updates and upgrades to be happening constantly, but in an enterprise setting, we don't expect end users to be downloading unknown code from random sites. Accordingly, we subsequently describe how to support standardized software updating mechanisms such as those used on contemporary OSes.

4 Policy Framework

We have developed a flexible policy framework for tag assignment, propagation, and attack detection. We express policies using a simple rule-based notation, e.g.,

$$exec(s,o):\ o.ttag < benign \rightarrow alert(\texttt{"UntrustedExec"})$$

This rule is triggered when the subject s executes a (file) object o with a t-tag less than *benign*. Its effect is to raise an alert named `UntrustedExec`. As illustrated by this example, rules are generally associated with events, and include conditions on the attributes of objects and/or subjects involved in the event. Attributes of interest include:

in conjunction with library loading operations. This policy is not triggered on those `mprotect`'s.

Event	Direction	Alarm trigger	Tag trigger
`define`			*init*
`read`	O→S	*read*	*propRd*
`load`, `execve`	O→S	*exec*	*propEx*
`write`	S→O	*write*	*propWr*
`rm`, `rename`	S→O	*write*	
`chmod`, `chown`	S→O	*write*, *modify*	
`setuid`	S→S		*propSu*

Table 2: Edges with policy trigger points. In the direction column, S indicates subject, and O indicates object. The next two columns indicate trigger points for detection policies and tag setting policies.

- *name:* regular expressions can be used to match object names and subject command lines. We use Perl syntax for regular expressions.
- *tags:* conditions can be placed on t-tags and c-tags of objects and/or subjects. For subjects, code and data t-tags can be independently accessed.
- *ownership and permission:* conditions can be placed on the ownership of objects and subjects, or permissions associated with the object or the event.

The effect of a policy depends on its type. The effect of a detection policy is to raise an alarm. For tag initialization and propagation policies, the effect is to modify tag(s) associated with the object or subject involved in the event. While we use a rule-based notation to specify policies in this paper, in our implementation, each rule is encoded as a (C++) function.

To provide a finer degree of control over the order in which different types of policies are checked, we associate policies with *trigger points* instead of events. In addition, trigger points provide a level of indirection that enables sharing of policies across distinct events that have a similar purpose. Table 2 shows the trigger points currently defined in our policy framework. The first column identifies events, the second column specifies the direction of information flow, and the last two columns define the trigger points associated with these events.

Note that we use a special event called `define` to denote audit records that define a new object. This pseudo-event is assumed to have occurred when a new object is encountered for the first time, e.g., establishment of a new network connection, the first mention of a pre-existing file, creation of a new file, etc. The remaining events in the table are self-explanatory.

When an event occurs, all detection policies associated with its alarm trigger are executed. Unless specifically configured, detection policies are checked only when the tag of the target subject or object is about to change. ("Target" here refers to the destination of data flow in an operation.) Following this, policies associated with the event's tag triggers are tried in the order in which they are specified. As soon as a matching rule is found, the

tags specified by this rule are assigned to the target of the event, and the remaining tag policies are not evaluated.

Our current detection policies are informally described in the previous section. We therefore focus in this section on our current tag initialization and propagation policies.

4.1 Tag Initialization Policies

These policies are invoked at the *init* trigger, and are used to initialize tags for new objects, or preexisting objects when they are first mentioned in the audit data. Recall that when a subject creates a new object, the object inherits the subject's tags by default; however, this can be overridden using tag initialization policies.

Our current tag initialization policy is as follows. Note the use of regular expressions to conveniently define initial tags for groups of objects.

$init(o)$: $match(o.name,$ `"^IP:(10\.0|127)"`$) \rightarrow$
$o.ttag = \texttt{BENIGN_AUTH}, o.ctag = \texttt{PRIVATE}$
$init(o)$: $match(o.name,$ `"^IP:"`$) \rightarrow$
$o.ttag = \texttt{UNKNOWN}, o.ctag = \texttt{PRIVATE}$
$init(o)$: $o.type == \texttt{FILE} \rightarrow$
$o.ttag = \texttt{BENIGN_AUTH}, o.ctag = \texttt{PUBLIC}$

The first rule specifies tags for intranet connections, identified by address prefixes 10.0 and 127 for the remote host. It is useful in a context where SLEUTH isn't deployed on the remote host[6]. The second rule states that all other hosts are untrusted. All preexisting files are assigned the same tags by the third rule. Our implementation uses two additional policies that specify c-tags.

4.2 Tag Propagation Policies

These policies can be used to override default tag propagation semantics. Different tag propagation policies can be defined for different groups of related event types, as indicated in the "Tag trigger" column in Table 2.

Tag propagation policies can be used to prevent "over-tainting" that can result from files such as `.bash_history` that are repeatedly read and written by an application each time it is invoked. The following policy skips taint propagation for this specific file:

$propRd(s,o)$: $match(o.name,$ `"\.bash_history$"`$) \rightarrow skip$[7]

Here is a policy that treats files read by `bash`, which is an interpreter, as a load, and hence updates the code t-tag.

$propRd(s,o)$: $match(s.cmdline,$ `"^/bin/bash$"`$) \rightarrow$
$s.code_ttag = s.data_ttag = o.ttag, s.ctag = o.ctag$

Although trusted servers such as `sshd` interact with untrusted sites, they can be expected to protect themselves, and let only authorized users access the system. Such servers should not have their data trustworthiness downgraded. A similar comment applies to programs such as software updaters and installers that download code from untrusted sites, but verify the signature of a trusted software provider before the install.

$propRd(o,s)$: $match(s.cmdline,$ `"^/sbin/sshd$"`$) \rightarrow skip$

Moreover, when the login phase is complete, typically identified by execution of a `setuid` operation, the process should be assigned appropriate tags.

$propSu(s)$: $match(s.cmdline,$ `"^/usr/sbin/sshd$"`$) \rightarrow$
$s.code_ttag = s.data_ttag = \texttt{BENIGN}, s.ctag = \texttt{PRIVATE}$

5 Tag-Based Bi-Directional Analysis

5.1 Backward Analysis

The goal of backward analysis is to identify the entry points of an attack campaign. Entry points are the nodes in the graph with an in-degree of zero and are marked untrusted. Typically they represent network connections, but they can also be of other types, e.g., a file on a USB stick that was plugged into the victim host.

The starting points for the backward analysis are the alarms generated by the detection policies. In particular, each alarm is related to one or more entities, which are marked as suspect nodes in the graph. Backward search involves a backward traversal of the graph to identify paths that connect the suspect nodes to entry nodes. We note that the direction of the dependency edges is reversed in such a traversal and in the following discussions. Backward search poses several significant challenges:

- *Performance:* The dependence graph can easily contain hundreds of millions of edges. Alarms can easily number in thousands. Running backward searches on such a large graph is computationally expensive.
- *Multiple paths:* Typically numerous entry points are backward reachable from a suspect node. However, in APT-style attacks, there is often just one real entry point. Thus, a naive backward search can lead to a large number of false positives.

The key insight behind our approach is that tags can be used to address both challenges. In fact, tag computation and propagation is already an implicit path computation, which can be reused. Furthermore, a tag value of *unknown* on a node provides an important clue about the likelihood of that node being a potential part of an attack. In particular, if an *unknown* tag exists for some node A, that means that there exists at least a path from an untrusted entry node to node A, therefore node A is more likely to be part of an attack than other neighbors with *benign* tags. Utilizing tags for the backward search greatly reduces the search space by eliminating many ir-

[6] If SLEUTH is deployed on the remote host, there will be no `define` event associated with the establishment of a network connection, and hence this policy won't be triggered. Instead, we will already have computed a tag for the remote network endpoint, which will now propagate to any local subject that reads from the connection.

[7] Here, "skip" means do nothing, i.e., leave tags unchanged.

relevant nodes and sets SLEUTH apart from other scenario reconstruction approaches such as [25, 31].

Based on this insight, we formulate backward analyis as an instance of shortest path problem, where tags are used to define edge costs. In effect, tags are able to "guide" the search along relevant paths, and away from unlikely paths. This factor enables the search to be completed without necessarily traversing the entire graph, thus addressing the performance challenge. In addition, our shortest path formulation addresses the multiple paths chalenge by by preferring the entry point closest (as measured by path cost) to a suspect node.

For shortest path, we use Dijkstra's algorithm, as it discovers paths in increasing order of cost. In particular, each step of this algorithm adds a node to the shortest path tree, which consists of the shortest paths computed so far. This enables the search to stop as soon as an entry point node is added to this tree.

Cost function design. Our design assigns low costs to edges representing dependencies on nodes with *unknown* tags, and higher costs to other edges. Specifically, the costs are as follows:

- Edges that introduce a dependency from a node with *unknown* code or data t-tag to a node with *benign* code or data t-tag are assigned a cost of 0.
- Edges introducing a dependency from a node with *benign* code and data t-tags are assigned a high cost.
- Edges introducing dependencies between nodes already having an *unknown* tag are assigned a cost of 1.

The intuition behind this design is as follows. A benign subject or object immediately related to an `unknown` subject/object represents the boundary between the malicious and benign portions of the graph. Therefore, they must be included in the search, thus the cost of these edges is 0. Information flows among benign entities are not part of the attack, therefore we set their cost to very high so that they are excluded from the search. Information flows among untrusted nodes are likely part of an attack, so we set their cost to a low value. They will be included in the search result unless alternative paths consisting of fewer edges are available.

5.2 Forward Analysis

The purpose of forward analysis is to assess the impact of a campaign, by starting from an entry point and discovering all the possible effects dependent on the entry point. Similar to backward analysis, the main challenge is the size of the graph. A naive approach would identify and flag all subjects and objects reachable from the entry point(s) identified by backward analysis. Unfortunately, such an approach will result in an impact graph that is too large to be useful to an analyst. For instance, in our experiments, a naive analysis produced impact graphs with millions of edges, whereas our refined algorithm reduces this number by 100x to 500x.

A natural approach for reducing the size is to use a distance threshold d_{th} to exclude nodes that are "too far" from the suspect nodes. Threshold d_{th} can be interactively tuned by an analyst. We use the same cost metric that was used for backward analysis, but modified to consider confidentiality[8]. In particular, edges between nodes with high confidentiality tags (e.g., *secret*) and nodes with low code integrity tags (e.g., *unknown* process) or low data integrity tags (e.g., *unknown* socket) are assigned a cost of 0, while edges to nodes with *benign* tags are assigned a high cost.

5.3 Reconstruction and Presentation

We apply the following simplifications to the output of forward analysis, in order to provide a more succinct view of the attack:

- *Pruning uninteresting nodes.* The result of forward analysis may include many dependencies that are not relevant for the attack, e.g., subjects writing to cache and log files, or writing to a temporary file and then removing it. These nodes may appear in the results of the forward analysis but no suspect nodes depend on them, so they can be pruned.
- *Merging entities with the same name.* This simplification merges subjects that have the same name, disregarding their process ids and command-line arguments.
- *Repeated event filtering.* This simplification merges into one those events that happen multiple times (e.g., multiple writes, multiple reads) between the same entities. If there are interleaving events, then we show two events representing the first and the last occurrence of an event between the two entities.

6 Experimental Evaluation

6.1 Implementation

Most components of SLEUTH, including the graph model, policy engine, attack detection and some parts of the forensic analysis are implemented in C++, and consist of about 9.5KLoC. The remaining components, including that for reconstruction and presentation, are implemented in Python, and consist of 1.6KLoC.

6.2 Data Sets

Table 3 summarizes the dataset used in our evaluation. The first eight rows of the table correspond to attack cam-

[8]Recall that some alarms are related to exfiltration of confidential data, so we need to decide which edges representing the flow of confidential information should be included in the scenario.

Dataset	Duration (hh-mm-ss)	Open	Connect + Accept	Read	Write	Clone + Exec	Close + Exit	Mmap / Loadlib	Others	Total # of Events	Scenario Graph
W-1	06:22:42	N/A	22.14%	44.70%	5.12%	3.73%	3.88%	17.40%	3.02%	100K	Fig. 15

Table 3: Dataset for each campaign with duration, distribution of different system calls and total number of events.

paigns carried out by a red team as part of the DARPA Transparent Computing (TC) program. This set spans a period of 358 hours, and contains about 73 million events. The last row corresponds to benign data collected over a period of 3 to 5 days across four Linux servers in our research laboratory.

Attack data sets were collected on Windows (W-1 and W-2), Linux (L-1 through L-3) and FreeBSD (F-1 through F-3) by three research teams that are also part of the DARPA TC program. The goal of these research teams is to provide fine-grained provenance information that goes far beyond what is found in typical audit data. However, at the time of the evaluation, these advanced features had not been implemented in the Windows and FreeBSD data sets. Linux data set did incorporate finer-granularity provenance (using the unit abstraction developed in [31]), but the implementation was not mature enough to provide consistent results in our tests. For this reason, we omitted any fine-grained provenance included in their dataset, falling back to the data they collected from the built-in auditing system of Linux. The FreeBSD team built their capabilities over DTrace. Their data also corresponded to roughly the same level as Linux audit logs. The Windows team's data was roughly at the level of Windows event logs. All of the teams converted their data into a common representation to facilitate analysis.

The "duration" column in Table 3 refers to the length of time for which audit data was emitted from a host. Note that this period covers both benign activities and attack related activities on a host. The next several columns provide a break down of audit log events into different types of operations. File open and close operations were not included in W-1 and W-2 data sets. Note that "read" and "write" columns include not only file reads/writes, but also network reads and writes on Linux. However, on Windows, only file reads and writes were reported. Operations to load libraries were reported on Windows, but memory mapping operations weren't. On Linux and FreeBSD, there are no load operations, but most of the mmap calls are related to loading. So, the mmap count is a loose approximation of the number of loads on these two OSes. The "Others" column includes all the remaining audit operations, including `rename`, `link`, `rm`, `unlink`, `chmod`, `setuid`, and so on. The last column in the table identifies the scenario graph constructed by SLEUTH for each campaign. Due to space limitations, we have omitted scenario graphs for campaign L-2.

6.3 Engagement Setup

The attack scenarios in our evaluation are setup as follows. Five of the campaigns (i.e., W-2, L-2, L3, F-2, and F3) ran in parallel for 4 days, while the remaining three (W-1, L-1, and F-1) were run in parallel for 2 days. During each campaign, the red team carried out a series of attacks on the target hosts. The campaigns are aimed at achieving varying adversarial objectives, which include dropping and execution of an executable, gathering intelligence about a target host, backdoor injection, privilege escalation, and data exfiltration.

Being an adversarial engagement, we had no prior knowledge of the attacks planned by the red team. We were only told the broad range of attacker objectives described in the previous paragraph. It is worth noting that, while the red team was carrying out attacks on the target hosts, benign background activities were also being carried out on the hosts. These include activities such as browsing and downloading files, reading and writing emails, document processing, and so on. On average, *more than 99.9% of the events corresponded to benign activity.* Hence, SLEUTH had to automatically detect and reconstruct the attacks from a set of events including both benign and malicious activities.

We present our results in comparison with the ground truth data released by the red team. Before the release of ground truth data, we had to provide a report of our findings to the red team. The findings we report in this paper match the findings we submitted to the red team. A summary of our detection and reconstruction results is provided in a tabular form in Table 7. Below, we first present reconstructed scenarios for selected datasets before proceeding to a discussion of these summary results.

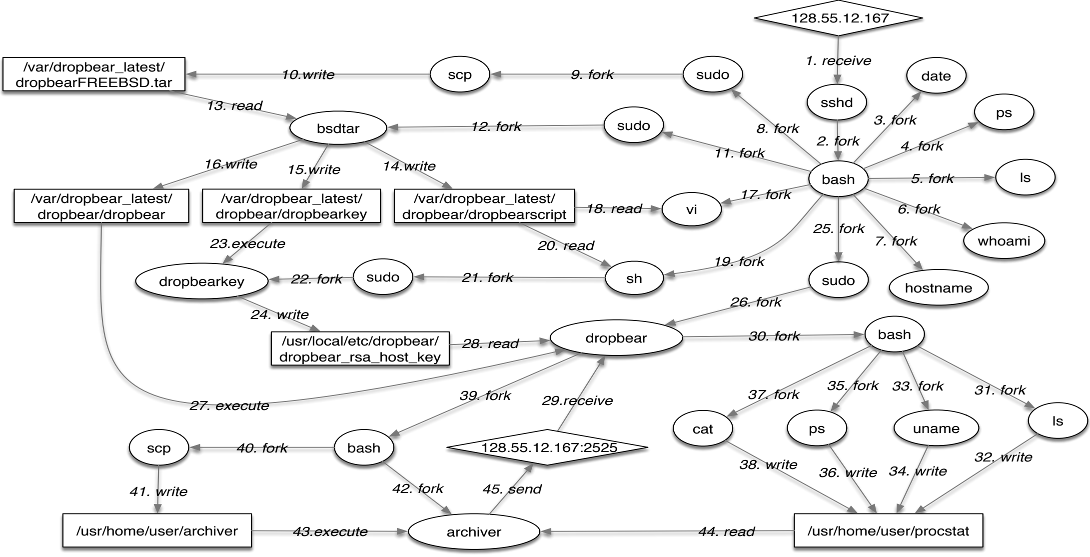

Fig. 4: Scenario graph reconstructed from campaign F-3.

6.4 Selected Reconstruction Results

Of the 8 attack scenarios successfully reconstructed by SLEUTH, we discuss campaigns W-2 (Windows) and F-3 (FreeBSD) in this section, while deferring the rest to Section 6.10. To make it easier to follow the scenario graph, we provide a narrative that explains how the attack unfolded. This narrative requires manual interpretation of the graph, but the graph generation itself is automated. In these graphs, edge labels include the event name and a sequence number that indicates the global order in which that event was performed. Ovals, diamonds and rectangles represent processes, sockets and files, respectively.

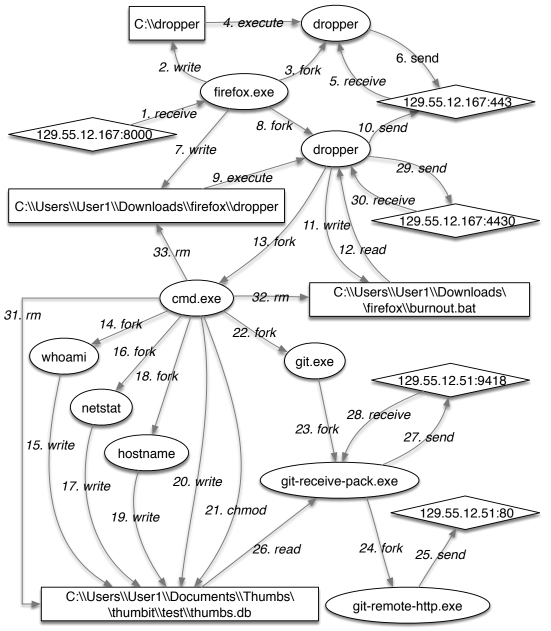

Fig. 5: Scenario graph reconstructed from campaign W-2.

Campaign W-2. Figure 5 shows the graph reconstructed by SLEUTH from Windows audit data. Although the actual attack campaign lasted half an hour, the host was running benign background activities for 20 hours. These background activities corresponded to more than 99.8% of the events in the corresponding audit log.

Entry: The initial entry point for the attack is `Firefox`, which is compromised on visiting the web server `129.55.12.167`.

Backdoor insertion: Once Firefox is compromised, a malicious program called `dropper` is downloaded and executed. Dropper seems to provide a remote interactive shell, connecting to ports 443 and then 4430 on the attack host, and executing received commands using `cmd.exe`.

Intelligence gathering: Dropper then invokes `cmd.exe` multiple times, using it to perform various data gathering tasks. The programs `whoami`, `hostname` and `netstat` are being used as stand-ins for these data gathering applications. The collected data is written to `C:\Users\User1\Documents\Thumbs\thumbit\test\thumbs.db`.

Data exfiltration: Then the collected intelligence is exfiltrated to 129.55.12.51:9418 using `git`.

Clean-up: Dropper downloads a batch file called `burnout.bat`. This file contains commands to clean up the attack footprint, which are executed by `cmd.exe` (see edges 11,12, 31-33).

Campaign F-3. (Figure 4). Under the command of an attacker who uses stolen ssh credentials, `sshd` forks a `bash` process. Note that though there is no direct evidence from the audit data about the stolen ssh credentials, because of the subsequent events (`scp`) from this shell, we conclude this as a sign of an attacker that uses stolen ssh credentials.

Next the attacker, invokes scp, which downloads a file into location /var/dropbear_latest/dropbearFREEBSD.tar, which is then uncompressed. The file dropbearscript is next read and interpreted by sh. This action creates the process dropbearkey, which writes to /usr/local/etc/dropbear/dropbear_ecdsa_host_key and /usr/local/etc/dropbear/dropbear_rsa_host_key. Next, another sudo process created by bash starts another dropbear process which reads these two keys for future use (presumably to assist in connecting to a remote host).

Dropbear next starts a shell process, which executes a series of commands ls, bash, uname, ps, all of which write to a file /usr/home/user/procstats.

Finally, dropbear starts a bash process, which uses scp to download a file called /usr/home/user/archiver, and executes that file. The resulting process, called archiver, reads the file /usr/home/user/procstats, which contains the data output earlier, and exfiltrates this information to 128.55.12.167:2525.

Summary. The above two graphs were constructed automatically by SLEUTH from audit data. They demonstrate how SLEUTH enables an analyst to obtain compact yet complete attack scenarios from hours of audit data. SLEUTH is able to hone in on the attack activity, even when it is hidden among benign data that is at least three orders of magnitude larger.

6.5 Overall Effectiveness

To assess the effectiveness of SLEUTH in capturing essential stages of an APT, in Table 6, we correlate pieces of attack scenarios constructed by SLEUTH with APT stages documented in postmortem reports of notable APT campaigns (e.g., the MANDIANT [3] report). In 7 of the 8 attack scenarios, SLEUTH uncovered the drop&load activity. In all the scenarios, SLEUTH captured concrete evidence of data exfiltration, a key stage in an APT campaign. In 7 of the scenarios, commands used by the attacker to gather information about the target host were captured by SLEUTH.

Another distinctive aspect of an APT is the injection of backdoors to targets and their use for C&C and data exfiltration. In this regard, 6 of the 8 scenarios reconstructed by SLEUTH involve backdoor injection. Cleaning the attack footprint is a common element of an APT campaign. In our experiments, in 5 of the 8 scenarios, SLEUTH uncovered attack cleanup activities, e.g., removing dropped executables and data files created during the attack.

Dataset	Drop & Load	Intelligence Gathering	Backdoor Insertion	Privilege Escalation	Data Exfiltration	Cleanup
W-1	✓	✓			✓	✓
W-2	✓	✓	✓		✓	✓
L-1	✓	✓	✓		✓	✓
L-2	✓	✓	✓	✓	✓	✓
L-3	✓	✓	✓	✓	✓	✓
F-1			✓		✓	
F-2	✓	✓	✓		✓	
F-3	✓	✓			✓	

Table 6: SLEUTH results with respect to a typical APT campaign.

Dataset	Entry Entities	Programs Executed	Key Files	Exit Points	Correctly Identified Entities	Incorrectly Identified Entities	Missed Entities
W-1	2	8	7	3	20	0	0
W-2	2	8	4	4	18	0	0
L-1	2	10	7	2	20	0	1
L-2	2	20	11	4	37	0	0
L-3	1	6	6	5	18	0	0
F-1	4	13	9	2	13	0	1

F-3	4	14	7	1	26	0	0
Total	**19**	**89**	**58**	**24**	**174**	**0**	**2**

Table 7: Attack scenario reconstruction summary.

Table 7 shows another way of breaking down the attack scenario reconstruction results, counting the number of key files, network connections, and programs involved in the attack. Specifically, we count the number of attack entry entities (including the entry points and the processes that communicate with those entry points), attack-related program executions, key files that were generated and used during the campaign, and the number of exit points used for exfiltration (e.g., network sockets). This data was compared with the ground truth, which was made available to us after we obtained the results. The last two columns show the incorrectly reported and missed entities, respectively.

The two missed entities were the result of the fact that we had not spent any effort in cataloging sensitive data files and device files. As a result, these entities were filtered out during the forward analysis and simplification steps. Once we marked the two files correctly, they were no longer filtered out, and we were able to identify all of the key entities.

In addition to the missed entities shown in Table 7, the red team reported that we missed a few other attacks and entities. Some of these were in data sets we did not examine. In particular, campaign W-2 was run multiple times, and we examined the data set from only one instance of it. Also, there was a third attack campaign W-3 on Windows, but the team producing Windows data sets had difficulties during W-3 that caused the attack activities not to be recorded, so that data set is omitted from the results in Table 7. Similarly, the team responsible for producing Linux data sets had some issues during campaign L-3 that caused some attack activities not to be recorded. To account for this, Table 7 counts only the subset of key entities whose names are present in the L-3 data set given to us.

According to the ground truth provided by the red

Dataset	Log Size on Disk	# of Events	Duration hh:mm:ss	Packages Updated	Binary Files Written
Server 1	1.1G	2.17M	00:13:06	110	1.8K
Server 2	2.7G	4.67M	105:08:22	4	4.2K
Server 3	12G	20.9M	104:36:43	4	4.3K
Server 4	3.2G	5.09M	119:13:29	4	4.3K

Table 8: False alarms in a benign environment with software upgrades and updates. No alerts were triggered during this period.

team, we incorrectly identified 21 entities in F-1 that were not part of an attack. Subsequent investigation showed that the auditing system had not been shutdown at the end of the F-1 campaign, and all of these false positives correspond to testing/administration steps carried out after the end of the engagement, when the auditing system should not have been running.

6.6 False Alarms in a Benign Environment

In order to study SLEUTH's performance in a benign environment, we collected audit data from four Ubuntu Linux servers over a period of 3 to 5 days. One of these is a mail server, another is a web server, and a third is an NFS/SSH/SVN server. Our focus was on software updates and upgrades during this period, since these updates can download code from the network, thereby raising the possibility of untrusted code execution alarms. There were four security updates (including kernel updates) performed over this period. In addition, on a fourth server, we collected data when a software upgrade was performed, resulting in changes to 110 packages. Several thousand binary and script files were updated during this period, and the audit logs contained over 30M events. All of this information is summarized in Table 8.

As noted before, policies should be configured to permit software updates and upgrades using standard means approved in an enterprise. For Ubuntu Linux, we had one policy rule for this: when `dpkg` was executed by `apt`-commands, or by `unattended-upgrades`, the process is not downgraded even when reading from files with untrusted labels. This is because both `apt` and `unattended-upgrades` verify and authenticate the hash on the downloaded packages, and only after these verifications do they invoke `dpkg` to extract the contents and write to various directories containing binaries and libraries. Because of this policy, all of the 10K+ files downloaded were marked benign. As a result of this, no alarms were generated from their execution by SLEUTH.

6.7 Runtime and Memory Use

Table 9 shows the runtime and memory used by SLEUTH for analyzing various scenarios. The measurements were made on a Ubuntu 16.04 server with 2.8GHz AMD Opteron 62xx processor and 48GB main memory. Only a single core of a single processor was used. The first column shows the campaign name, while the second shows the total duration of the data set.

Dataset	Duration (hh:mm:ss)	Memory Usage	Runtime	
			Time	Speed-up
W-1	06:22:42	3 MB	1.19 s	19.3 K
W-2	19:43:46	10 MB	2.13 s	33.3 K
W-Mean		6.5 MB		**26.3 K**
L-1	07:59:26	26 MB	8.71 s	3.3 K
L-2	79:06:39	329 MB	114.14s	2.5 K
L-3	79:05:13	175 MB	74.14 s	3.9 K
L-Mean		177 MB		**3.2 K**
F-1	08:17:30	8 MB	1.86 s	16 K
F-2	78:56:48	84 MB	14.02 s	20.2 K
F-3	79:04:54	95 MB	15.75 s	18.1 K
F-Mean		62.3 MB		**18.1 K**

Table 9: Memory use and runtime for scenario reconstruction.

The third column shows the memory used for the dependence graph. As described in Section 2, we have designed a main memory representation that is very compact. This compact representation enables SLEUTH to store data spanning very long periods of time. As an example, consider campaign L-2, whose data were the most dense. SLEUTH used approximately 329MB to store 38.5M events spanning about 3.5 days. Across all data sets, SLEUTH needed about 8 bytes of memory per event on the larger data sets, and about 20 bytes per event on the smaller data sets.

The fourth column shows the total run time, including the times for consuming the dataset, constructing the dependence graph, detecting attacks, and reconstructing the scenario. We note that this time was measured after the engagement when all the data sets were available. During the engagement, SLEUTH was consuming these data as they were being produced. Although the data typically covers a duration of several hours to a few days, the analysis itself is very fast, taking just seconds to a couple of minutes. Because of our use of tags, most information needed for the analysis is locally available. This is the principal reason for the performance we achieve.

The "speed-up" column illustrates the performance benefits of SLEUTH. It can be thought of as the number of simultaneous data streams that can be handled by SLEUTH, if CPU use was the only constraint.

In summary, SLEUTH is able to consume and analyze audit COTS data from several OSes in real time while having a small memory footprint.

6.8 Benefit of split tags for code and data

As described earlier, we maintain two trustworthiness tags for each subject, one corresponding to its code, and another corresponding to its data. By prioritizing detection and forward analysis on code trustworthiness, we cut down vast numbers of alarms, while greatly decreasing

Dataset	Untrusted execution		Modification by low code t-tag subject		Preparation of untrusted data for execution		Confidential data leak	
	Single t-tag	Split t-tags	Single t-tag	Split t-tags	Single t-tags	Split t-tags	Single t-tag	Split t-tags
W-1	21	3	1.2 K	3	0	0	6.1 K	11
W-2	44	2	3.7 K	108	0	0	20.2 K	18
L-1	60	2	53	5	1	1	19	6
L-2	1.5 K	5	19.5 K	1	280	8	122 K	159
L-3	695	5	26.1 K	2	270	0	62.1 K	5.3 K
Average Reduction	**45.39x**		**517x**		**6.24x**		**112x**	

Table 10: Reduction in (false) alarms by maintaining separate code and data trustworthiness tags. The average reduction shows the average factor of reduction we get for alarms generation when using split trustworthiness tag over single trustworthiness tag.

the size of forward analysis output.

Table 10 shows the difference between the number of alarms generated by our four detection policies with single trustworthiness tag and with the split trustworthiness (code and integrity) tags. Note that the split reduces the alarms by a factor of 100 to over 1000 in some cases.

Table 11 shows the improvement achieved in forward analysis as a result of this split. In particular, the increased selectivity reported in column 5 of this table comes from splitting the tag. Note that often, there is a 100x to 1000x reduction in the size of the graph.

6.9 Analysis Selectivity

Table 11 shows the data reduction pipeline of the analyses in SLEUTH. The second column shows the number of original events in each campaign. These events include all the events in the system (benign and malicious) over several days with an overwhelming majority having a benign nature, unrelated to the attack.

The third column shows the final number of events that go into the attack scenario graph.

The fourth column shows the reduction factor when a naive forward analysis with single trustworthiness tag (single t-tag) is used from the entry points identified by our backward analysis. Note that the graph size is very large in most cases. The fifth column shows the reduction factor using the forward analysis of SLEUTH— which is based on split (code and data) trustworthiness tags. As can be seen from the table, SLEUTH achieved two to three orders of magnitude reduction with respect to single t-tag based analysis.

Dataset	Initial # of Events	Final # of Events	Reduction Factor			
			Single t-tag	Split t-tag	SLEUTH Simplif.	Total
W-1	100 K	51	4.4x	1394x	1.4x	1951x
W-2	401 K	28	3.6x	552x	26x	14352x
L-1	2.68 M	36	8.9x	15931x	4.7x	74875x
L-2	38.5 M	130	7.3x	2971x	100x	297100x
L-3	19.3 M	45	7.6x	1208x	356x	430048x
F-1	701 K	45	2.3x	376x	41x	15416x
F-2	5.86 M	39	1.9x	689x	218x	150202x
F-3	5.68 M	45	6.7x	740x	170x	125800x
Average Reduction			**4.68x**	**1305x**	**41.8x**	**54517x**

Table 11: Comparison of selectivity achieved using forward analysis with single trustworthiness tags, forward analysis with split code and data trustworthiness tags, and finally simplifications.

The output of forward analysis is then fed into the simplification engine. The sixth column shows the reduction factor achieved by the simplifications over the output of our forward analysis. The last column shows the overall reduction we get over original events using split (code and data) trustworthiness tags and performing the simplification.

Overall, the combined effect of all of these steps is very substantial: data sets consisting of tens of millions of edges are reduced into graphs with perhaps a hundred edges, representing five orders of magnitude reduction in the case of L-2 and L-3 data sets, and four orders of magnitude reduction on other data.

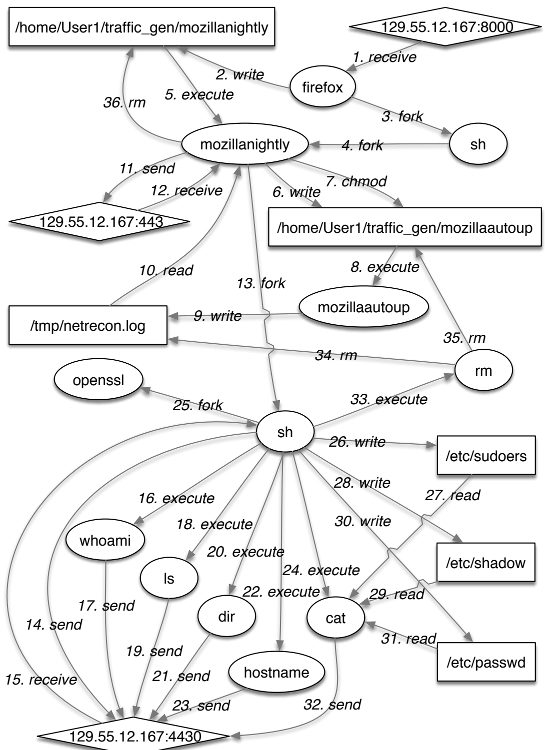

Fig. 12: Scenario graph reconstructed from campaign L-1.

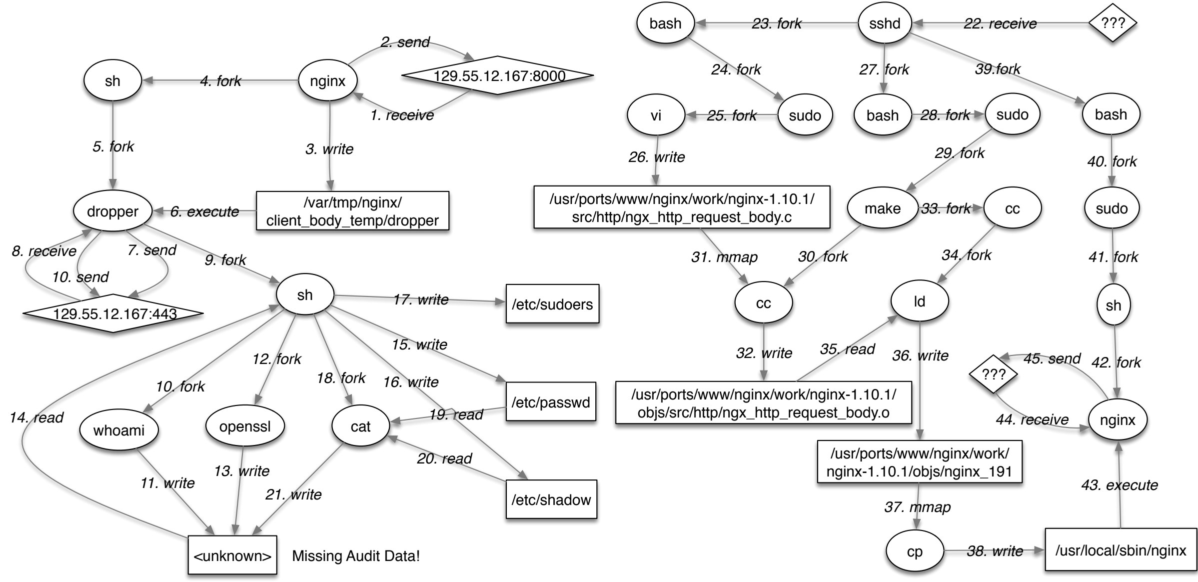

Fig. 13: Scenario graph reconstructed from campaign F-1.

6.10 Discussion of Additional Attacks

In this section, we provide graphs that reconstruct attack campaigns that weren't discussed in Section 6.4. Specifically, we discuss attacks L-1, F-1, F-2, W-1, and L-3. **Attack L-1.** In this attack (Figure 12), `firefox` is exploited to drop and execute via a shell the file `mozillanightly`. The process `mozillanightly` first downloads and executes `mozillaautoup`, then starts a shell, which spawns several other processes. Next, the information gathered in file `netrecon.log` is exfiltrated and the file removed.

Attack F-1. In this attack (Figure 13), the `nginx` server is exploited to drop and execute via shell the file `dropper`. Upon execution, the `dropper` process forks a shell that spawns several processes, which write to a file and reads and writes to sensitive files. In addition, `dropper` communicates with the IP of the attacker. We report in the figure the graph related to the restoration and administration carried out after the engagement, as discussed in Section 6.5.

Attack F-2. The start of this attack (Figure 14) is similar to F-1. However, upon execution, the `dropper` process downloads three files named `recon, sysman`, and `mailman`. Later, these files are executed and used which are used to exfiltrate data gathered from the system.

Attack W-1. In this attack (Figure 15), `firefox` is exploited twice to drop and execute a file `mozillanightly`. The first `mozillanightly` process downloads and executes the file `photosnap.exe`, which takes a screenshot of the victim's screen and saves it to a png file. Subsequently, the jpeg file is exfiltrated by `mozillanightly`. The second `mozillanightly` process downloads and executes two files: 1) `burnout.bat`, which is read, and later used to issue commands to `cmd.exe` to gather data about the system; 2) `mnsend.exe`, which is executed by `cmd.exe` to exfiltrate the data gathered previously.

Attack L-3. In this attack (Figure 16), the file `dropbearLINUX.tar` is downloaded and extracted. Next, the program `dropbearkey` is executed to create three keys, which are read by a program `dropbear`, which subsequently performs exfiltration.

7 Related Work

In this section, we compare SLEUTH with efforts from academia and open source industry tools. We omit comparison to proprietary products from the industry as there is scarce technical documentation available for an in-depth comparison.

Provenance tracking and Forensics Several logging and provenance tracking systems have been built to monitor the activities of a system [21, 41, 23, 22, 13, 45, 9] and build *provenance graphs*. Among these, *Backtracker* [25, 26] is one of the first works that used dependence graphs to trace back to the root causes of intrusions. These graphs are built by correlating events collected by a logging system and by determining the causality among system entities, to help in forensic analysis after an attack is detected.

SLEUTH improves on the techniques of Backtracker in two important ways. First, Backtracker was meant to operate in a forensic setting, whereas our analysis and data representation techniques are designed towards real-time detection. Setting aside hardware comparisons, we note that Bactracker took 3 hours for analyzing au-

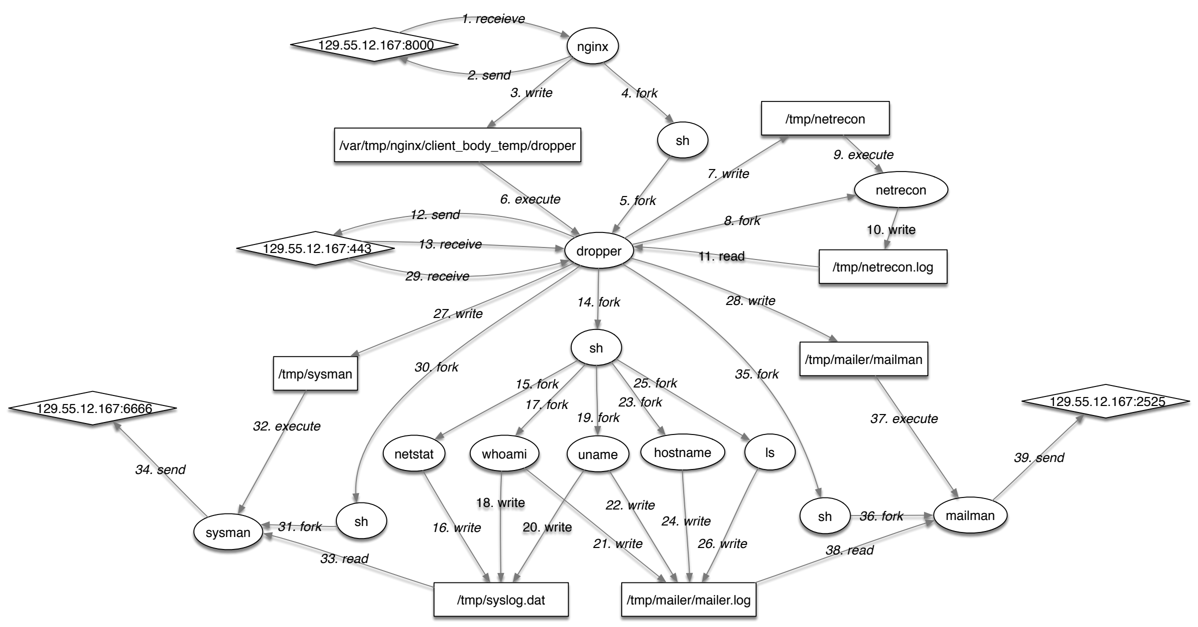

Fig. 14: Scenario graph reconstructed from campaign F-2.

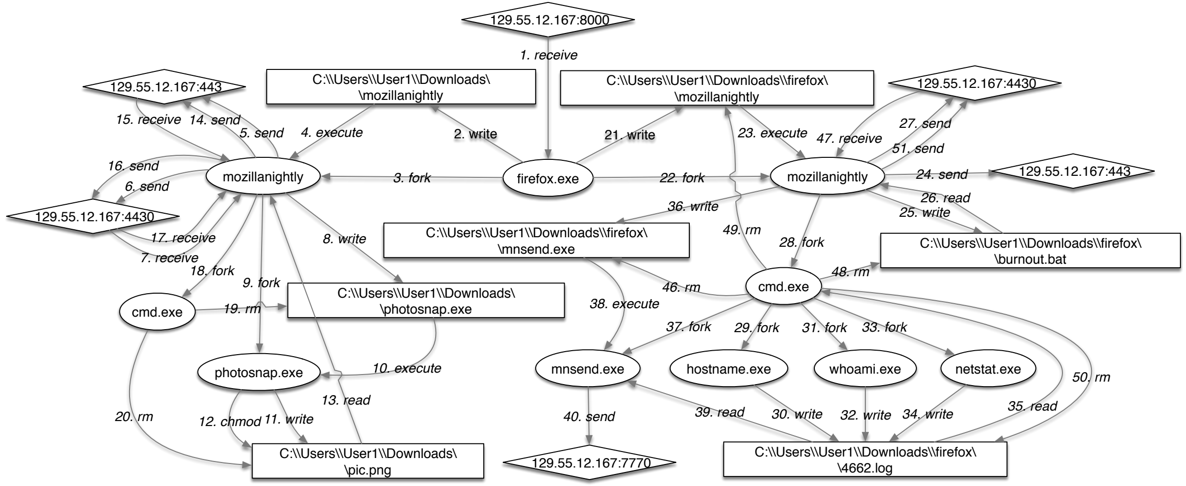

Fig. 15: Scenario graph reconstructed from campaign W-1.

dit data from a 24-hour period, whereas SLEUTH was able to process 358 hours of logs in a little less than 3 minutes. Secondly, Backtracker relies on alarms generated by external tools, therefore its forensic search and pruning cannot leverage the reasons that generated those alarms. In contrast, our analysis procedures leverage the results from our principled tag-based detection methods and therefore are inherently more precise. For example, if an attack deliberately writes into a well-known log file, Backtracker's search heuristics may remove the log file from the final graph, whereas our tag-based analysis will prevent that node from being pruned away.

In a similar spirit, *BEEP* [31] and its evolution *ProTracer* [37] build dependence graphs that are used for forensic analysis. In contrast, SLEUTH builds dependence graphs for real-time detection from which scenario subgraphs are extracted during a forensic analysis. The forensic analysis of [31, 37] ensures more precision than Backtracker [25] by heuristically dividing the execution of the program into execution units, where each unit represents one iteration of the main loop in the program. The instrumentation required to produce units is not always automated, making the scalability of their approach a challenge. SLEUTH can make use of the additional precision afforded by [31] in real-time detection, when such information is available.

While the majority of the aforementioned systems operate at the system call level, several other systems track information flows at finer granularities [24, 8, 31]. They typically instrument applications (e.g., using Pin [35]) to

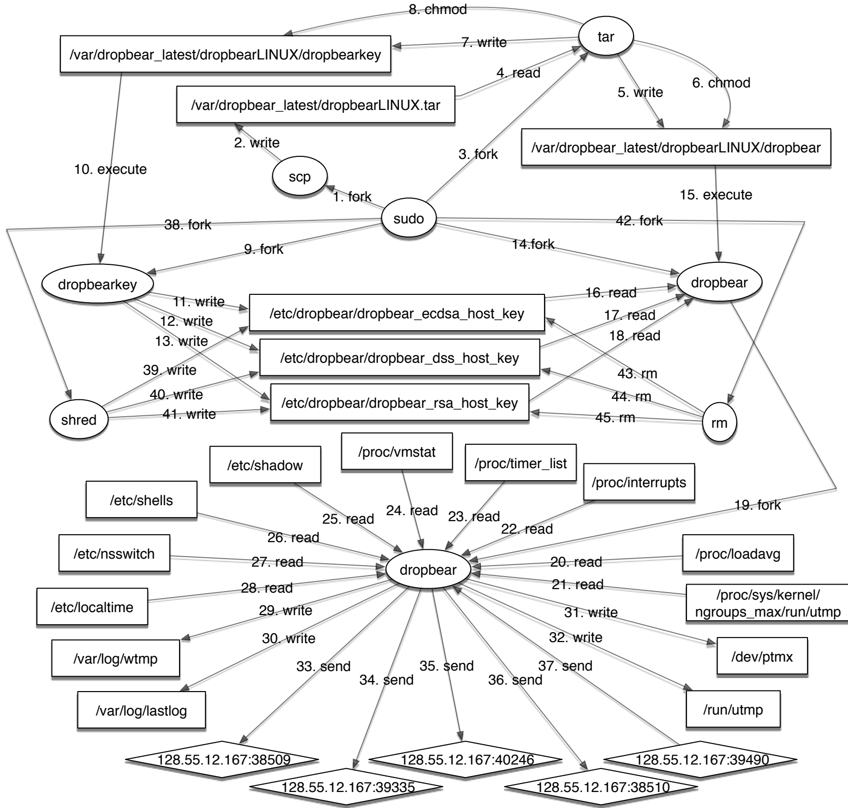

Fig. 16: Scenario graph reconstructed from campaign L-3.

track information flows through a program. Such fine-grained tainting can provide much more precise provenance information, at the cost of higher overhead. Our approach can take advantage of finer granularity provenance, when available, to further improve accuracy.

Attack Detection A number of recent research efforts on attack detection/prevention focus on "inline" techniques that are incorporated into the protected system, e.g., address space randomization, control-flow integrity, taint-based defenses and so on. Offline *intrusion detection* using logs has been studied for a much longer period [15, 36, 19]. In particular, *host-based IDS* using system-call monitoring and/or audit logs has been investigated by numerous research efforts [57, 32, 47, 55, 18, 29].

Host-based intrusion detection techniques mainly fall into three categories: (1) *misuse-based*, which rely on specifications of bad behaviors associated with known attacks; (2) *anomaly-based* [19, 32, 47, 20, 30, 11, 48], which rely on learning a model of benign behavior and detecting deviations from this behavior; and (3) *specification-based* [27, 54], which rely on specifications (or policies) specified by an expert. The main drawback of misuse-based techniques is that their signature-based approach is not amenable to detection of previously unseen attacks. Anomaly detection techniques avoid this drawback, but their false positives rates deter widespread deployment. Specification/policy-based techniques can reduce these false positives, but they require application-specific policies that are time-consuming to develop and/or rely on expert knowledge. Unlike these approaches, SLEUTH relies on *application-independent policies.* We develop such policies by exploiting provenance information computed from audit data. In particular, an audit event

Information Flow Control (IFC) IFC techniques assign security labels and propagate them in a manner similar to our tags. Early works, such as Bell-LaPadula [10] and Biba [12], relied on strict policies. These strict policies impact usability and hence have not found favor among contemporary OSes. Although IFC is available in SELinux [34], it is not often used, as users prefer its access control framework based on domain-and-type enforcement. While most above works centralize IFC, *decentralized IFC* (DIFC) techniques [59, 17, 28] emphasize the ability of principals to define and create new labels. This flexibility comes with the cost of nontrivial changes to application and/or OS code.

Although our tags are conceptually similar to those in IFC systems, the central research challenges faced in these systems are very different from SLEUTH. In par-

ticular, the focus of IFC systems is enforcement and prevention. A challenge for IFC enforcement is that their policies tend to break applications. Thus, most recent efforts [50, 38, 33, 53, 51, 52, 49] in this regard focus on refinement and relaxation of policies so that compatibility can be preserved without weakening security. In contrast, neither enforcement nor compatibility pose challenges in our setting. On the other hand, IFC systems do not need to address the question of what happens when policies are violated. Yet, this is the central challenge we face: how to distinguish attacks from the vast number of normal activities on the system; and more importantly, once attacks do take place, how to tease apart attack actions from the vast amounts of audit data.

Alert Correlation Network IDSs often produce myriad alerts. *Alert correlation* analyzes relationships among alerts, to help users deal with the deluge. The main approaches, often used together, are to *cluster* similar alerts, prioritize alerts, and identify causal relationships between alerts [14, 43, 46, 44, 56]. Furthermore, they require manually supplied expert knowledge about dependencies between alert types (e.g., consequences for each network IDS alert type) to identify causal relationships. In contrast, we are not interested in clustering/statistical techniques to aggregate alerts. Instead, our goals are to use provenance tracking to determine causal relationships between different alarms to reconstruct the attack scenario, and to do so without relying on (application-dependent) expert knowledge.

8 Conclusion

We presented an approach and a system called SLEUTH for real-time detection of attacks and attack reconstruction from COTS audit logs. SLEUTH uses a main memory graph data model and a rich tag-based policy framework that make its analysis both efficient and precise. We evaluated SLEUTH on large datasets from 3 major OSes under attack by an independent red team, efficiently reconstructing all the attacks with very few errors.

Abstract

Success stories in usable security are rare. In this paper, however, we examine one notable security success: the year-long collaborative investigation of more than two terabytes of leaked documents during the "Panama Papers" project. During this effort, a large, diverse group of globally-distributed journalists met and maintained critical security goals–including protecting the source of the leaked documents and preserving the secrecy of the project until the desired launch date–all while hundreds of journalists collaborated remotely on a near-daily basis.

Through survey data from 118 participating journalists, as well as in-depth, semi-structured interviews with the designers and implementers of the systems underpinning the collaboration, we investigate the factors that supported this effort. We find that the tools developed for the project were both highly useful and highly usable, motivating journalists to use the secure communication platforms provided instead of seeking workarounds. We also found that, despite having little prior computer security experience, journalists adopted—and even appreciated—the strict security requirements imposed by the project leads. We also find that a shared sense of community and responsibility contributed to participants' motivation to meet and maintain security requirements. From these and other findings, we distill lessons for socio-technical systems with strong security requirements and identify opportunities for future work.

1 Introduction

On April 3, 2016, a coordinated network of dozens of news organizations around the world [32] began publishing stories based on a set of year-long investigations into the uses of offshore funds by clients of the Panamanian law firm Mossack Fonseca. The revelations contained in these "Panama Papers" led to the ouster of Icelandic Prime Minister Sigmundur David Gunnlaugsson [17], and helped instigate investigations from Argentina and Australia to Canada, Denmark, France, India, Indonesia, Mexico, Pakistan, and others [42].

Facilitated by the International Consortium of Investigative Journalists (ICIJ), the Panama Papers project [31] represents a uniquely positive security case study, wherein systems designed, implemented, and managed by a handful of ICIJ staffers helped meet and maintain the organization's security goals for the project. While it is impossible to state definitively that this (or any) system could *not* have been compromised, ICIJ's efforts appear to have been successful in maintaining their primary security goals, including: (1) protecting the identity of the source of the Panama Papers' documents (2) maintaining control of the documents within their network of collaborators and preventing their early public disclosure, (3) protecting the documents themselves from attackers (e.g., the companies, criminals and political figures they implicated), and, finally (4) keeping the investigation itself a secret for over a year. Remarkably, all of this was achieved while supporting the collaborative analysis of the documents by nearly 400 journalist-contributors worldwide, who communicated regularly across time zones and language barriers.

In the computer security literature and beyond, users are often referred to as "the weakest link" in security systems (e.g., [26, 48, 50]). Recent case studies on activist organizations and NGOs [21, 39, 43], for example, highlight such security failures in context. Through examination of the Panama Papers project, then, we seek to learn (1) what technical and human factors facilitated the successful preservation of the project's security goals and, (2) what lessons can be drawn from this case study to support the development of similarly effective processes for both journalistic collaborations and secure, usable systems in general. For while the technical systems used in the Panama Papers project did not necessarily incorporate all technical security best practices, our investigation helps illuminate how the systems' hundreds of users were nevertheless able to collaborate securely over a long period of time.

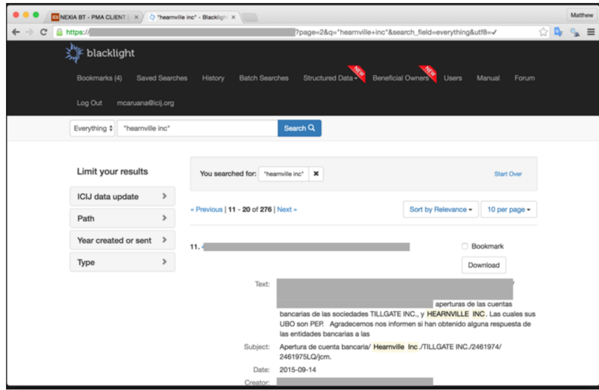

Figure 1: **Blacklight.** Screenshot of the document search platform. *Courtesy: ICIJ.*

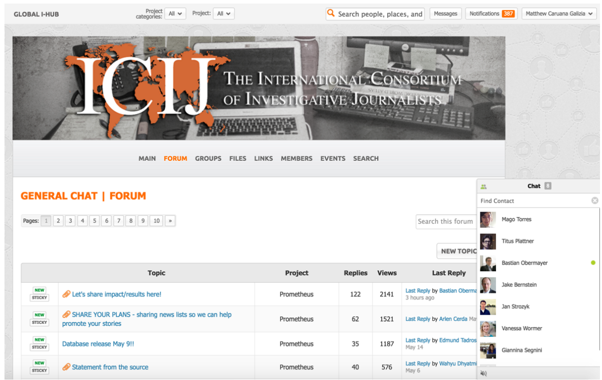

Figure 2: **I-Hub.** Screenshot of the collaboration and communication platform. *Courtesy: ICIJ.*

To uncover the factors that contributed to the Panama Papers' security success, we (1) analyze survey data collected from 118 journalists involved in the project, and (2) conduct in-depth, semi-structured interviews with the designers and implementers of the technical systems and collaborative processes underpinning the Panama Papers collaboration. These systems[1] included:

- **Blacklight** (Figure 1), a document-search platform where contributing journalists could access the leaked documents.
- **I-Hub** (Figure 2), a collaboration and communication platform where contributors formed interest groups, shared discoveries, and exchanged ideas.
- **Linkurious** (Figure 3), a visualization system that provided visual graphs of the relationships between entities mentioned in the leaked documents.

From this survey and interview data, we identify several key design decisions and deployment strategies that appear to have contributed to the security successes of the project.

[1] All screenshots were approved for publication by ICIJ.

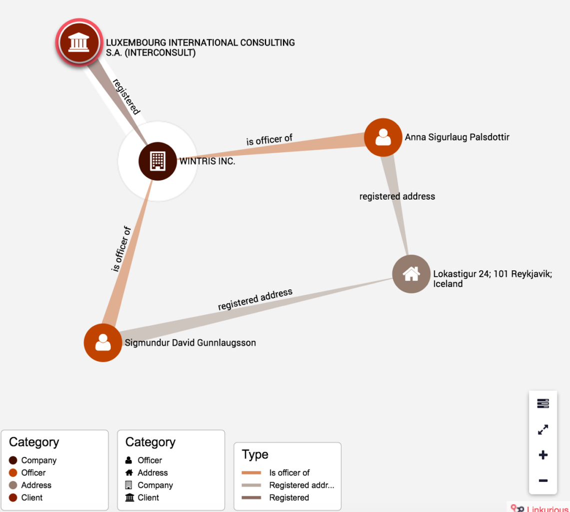

Figure 3: **Linkurious.** Screenshot of the system that visualizes links between entities mentioned in the Panama Papers documents. *Courtesy: ICIJ.*

For example, we were surprised to learn that project leaders were able to consistently enforce strict security requirements–such as two-factor authentication and the use of PGP–despite the fact that few of the participants had previously used these technologies. Our findings suggest that journalists found the collaboration systems provided so *useful* that they relied on them in spite of sometimes onerous security requirements. We observe that project leaders also frequently and consistently articulated the importance of security measures, explicitly cultivating a sense of collaboration, mutual trust and shared security responsibility among system users. Moreover, this organizational buy-in for security measures went beyond rhetoric: in one instance, the organization bought and set up phones as second factors for journalists who did not have them.

From these and other findings, we distill lessons and recommendations for integrating computer security measures into future socio-technical systems. For example, we recommend normalizing secure communication requirements to reduce the decision-making burden they may otherwise impose. In the Panama Papers project, for example, making PGP a default tool and ensuring everyone had a PGP key meant that participants did not need to expend additional energy evaluating secure communication options. We also identify opportunities for future research, such as comparing this to other security successes to determine which factors are necessary and/or sufficient to achieve similarly effective secure socio-technical systems. Instrumenting technical systems to achieve a more complete picture of activity and possible compromises would also contribute to this understanding.

In summary, we make the following contributions:

- We analyze *quantitative survey data* from 118 journalists involved in the Panama Papers project.
- We conduct *semi-structured, in-depth interviews* with key stakeholders–including editorial and technical staff– involved in designing and implementing the technical systems used in the collaboration.
- From these two datasets, we investigate the *socio-technical systems* that supported the realization of the security goals of the Panama Papers' project.
- We identify an actively maintained and explicitly articulated culture of security that leveraged peer-oriented trust and accountability. We also identify several technical security issues that may have been present, but do not appear to have led to compromise in this case.
- Based on this case study, we make *recommendations* for future socio-technical systems with strong computer security requirements and identify opportunities for future work.

Overall, the Panama Papers project—which required international collaboration among hundreds of journalists over an entire year—is a unique case study that provides insight into the design and deployment of secure communication and collaboration systems for diverse, distributed organizations. To the best of our knowledge, this is one of the first in-depth case studies of such a security success. Though this paper is neither a comprehensive description of the technical features of the Panama Papers' systems, nor a prescription for technical security best practices, we believe the insights presented here–taken in conjunction with existing technical security best practices–provide a valuable foundation for secure collaborative system design.

2 Background

In this section, we provide specific background on the Panama Papers project (unless otherwise noted, details here are sourced from [12], published by ICIJ). Additional related work is discussion in Section 7.

The International Consortium of Investigative Journalists (ICIJ) is a non-profit, selective-membership organization founded in 1997. Comprised of just under 200 investigative journalists in more than 65 countries, since 2012 ICIJ has obtained several caches of leaked documents that have led to collaborative investigations across news organizations around the world (e.g., [28–30]). Yet, in the words of one ICIJ staffer interviewed for this paper, the Panama Papers project [31] — which lasted from approximately May 2015 to April 2016 — was where the organization's work collaborative and analytical systems "all came together."

Consisting of over 11.5 million documents in dozens of formats occupying 2.6 TB of disk space, the Panama Papers dataset was by far the largest and most complex that ICIJ had handled (the "Offshore Leaks" project, by contrast, comprised only 260 GB [13]). While just one staffer was devoted to research during ICIJ's first major leak project in 2011, by 2016, data and research positions comprised half of ICIJ's 12-person staff.

To deal with the enormous scale and complexity of the data, as well as facilitate the large, globally distributed team required to investigate it, ICIJ's Data and Research Unit built and/or refined several systems whose development had begun during prior document-based projects. Favoring open-source technologies, they chose Tesseract [7] to OCR the documents, Apache Tika [2] for document processing, and Apache Solr [1] for indexing. The UI for this last platform also became its namesake, Project Blacklight [6] (see Figure 1).

ICIJ also developed a secure communication hub–called Global I-Hub–by customizing OxWall [5], an existing open-source messaging platform (Figure 2). Finally, ICIJ licensed the Linkurious software [4] to visually graph relationships among entities that appeared in the data (Figure 3).

3 Methods

To better understand the decisions that shaped the Panama Papers' suite of collaboration systems–as well as identify factors that may have contributed to the successful maintenance of the group's security goals–we conducted two studies: an analysis of survey data collected from Panama Papers project contributors by the ICIJ, and a semi-structured, in-depth interview with each member of the ICIJ staff who had significant influence over the security features and policies related to the Blacklight, I-Hub and Linkurious systems.

3.1 Participants

All survey participants are investigative journalists who actively participated in the Panama Papers project. All interview participants currently work full-time for the ICIJ and/or had a significant role in determining the security features and requirements of the collaboration systems used throughout the project by the journalists surveyed. In the results presented here, participants completed either a survey *or* an interview.

Survey. Survey participants were 118 journalists working in 58 different countries representing every continent except Antarctica. No other demographic data was collected. This sample represents approximately 33% (118 of 354) of all non-ICIJ staff who worked on the project.

Interview. ICIJ consists of only twelve full-time employees. For this study we interviewed all five of the ICIJ personnel with significant editorial or technical input on the systems used during the Panama Papers project. In-

Security Practice	Unaware	Never	Few	Occasionally	Frequently
Passphrase	9%	21%	13%	15%	52%
Two-factor	16%	29%	14%	13%	42%
PGP	14%	34%	10%	17%	25%

Table 1: **Familiarity with and Usage of Security Practices Prior to Project (N=118).** Scale items were "Never heard of it before" (Unaware); "Knew about it, hadn't used" (Never); "Had used a few times" (Few); "Used occasionally" (Occasionally) and; "Used frequently" (Frequently).

terview participants were two technical and two editorial management staff of ICIJ, as well as the journalist who received the original Panama Papers materials and worked closely with ICIJ on the system requirements. Of these five participants, two participants were women and three were men. To maximize the insight gained from these interviews, we designed the interview script using information from a careful review of public information available about the systems (e.g., [10, 36]), as well as insight from an IRB-approved background (pilot) interview with an individual member of the Panama Papers project who had intimate knowledge of the systems involved. The team then collected and iteratively refined the major themes for the interviews, customizing their content based on the individual's primary (self-identified) role in the project as either an editorial (E) or technical (IT) leader.

3.2 Materials

Materials consisted of a survey and two interview scripts, described here and reproduced in Appendices A and B.

Survey Instrument. The survey was created by ICIJ to investigate collaborating journalists' use of the Blacklight, I-Hub, and Linkurious systems used during the Panama Papers project, as well as their experiences with the security of these systems. In this paper, we focus on the 10 survey questions related to the use and security of the systems provided to journalists by ICIJ (see Appendix A). In addition to these security-related questions, the survey also captured information about the value to journalists of other services provided by ICIJ.

Interview Scripts. We created two distinct, but mostly overlapping interview scripts for the editorial and technical interview participants. Topics for both groups included questions about the participants' background, their experience with the overall system, system functionality, any training they offered as part of the project, any breaches or failures they were aware of, and the potential scalability of the system. Additionally, we asked editors about how they selected and recruited journalists for project participation. Please see Appendix B for the complete interview scripts.

3.3 Procedure

Survey. The survey was conducted between July 28th and August 15th, 2016 by the ICIJ. Participants completed the survey via a Google form and took around 10 minutes to complete. Participants could choose to answer the survey anonymously or provide their name if they wished. ICIJ provided us with the survey responses as a de-identified dataset. Participants were not provided an incentive to take the survey.

Interview. We interviewed participants between December 2016 and January 2017. Interviews typically lasted about one hour and were conducted via telephone/online video/voice conference (four), with one taking place in person. All participants spoke fluent English and were interviewed in English. Participants were not provided an incentive to participate in the interview.

3.4 Data Preparation and Analysis

Once all interviews were complete, we transcribed the audio recordings, producing 96 pages of text. Using an inductive process we completed an initial round of qualitative coding to identify key themes, as substantive categories emerged from the data via grounded theory analysis [19]. These themes were then evaluated and refined through group discussion among all researchers, with a goal of capturing the core variables constituting our participants' experiences.

3.5 Ethical Considerations

Our entire protocol was IRB approved. Furthermore, because of the sensitive nature of our interview topic, we took extra precautions to maintain the privacy and anonymity of research participants. We explicitly did not request information about or publish details about security protocols that could compromise source identities, sensitive information, or future work.

All interview participants agreed to be audio recorded during the interview and answered all of the questions in the interview script. We stored and transmitted audio recordings only in encrypted form and used de-identified transcripts for the majority of the data analysis.

4 Results

In this section, we present results from the survey and semi-structured interviews.

4.1 Survey Results

Apart from de-identification, the survey data analyzed below is a summary of the un-redacted responses (n=118) and comments (n=57) from the 118 journalist contributors who completed the ICIJ survey. Where relevant, we have included representative comments alongside the survey results. We identify quotes using only a letter (J for journalist) and participant number.

4.1.1 Prior Familiarity with Security Practices

The challenge of meeting security goals when working with non-expert users has been widely documented (e.g. [8]). To evaluate the significance of the Panama Papers project as a "security success story," we analyzed survey results to determine whether prior security expertise of the journalist contributors may have been a factor.

In fact, in response to a question about prior familiarity with digital security practices (see Table 1), almost half of participants indicated that they were "Unaware" of or had "Never" used PGP or two-factor authentication prior to this project (47% and 45% respectively).

Familiarity with passphrases (i.e., passwords created by concatenating multiple dictionary words, along the lines of [52]) was somewhat greater, with only about a third (31%) reporting that they were "Unaware" of or had "Never" used a passphrase. More than half (52%) of participants reported that they frequently used a passphrase prior to participation in this project, while 42% reported they frequently used two-factor authentication. Only one-quarter (25%) reported that they frequently used PGP prior to participation in the Panama Papers project.

Given journalists' limited familiarity with strong security practices prior to the Panama Papers project, we note that ICIJ's decision to mandate PGP for all collaborators is especially striking. We discuss the implications of this further in Section 5.

4.1.2 Perceived Difficulty of Security Compliance

Each of the three primary systems journalists used for this project —Blacklight, I-Hub, and Linkurious—had a distinct login that required two-factor authentication for every sign-on. Moreover, every journalist on the project was required to use PGP for password-reset and some system notifications. Despite relatively limited prior exposure to some of these security practices, however, participants reported that they perceived it to be relatively easy to comply with these requirements.

On a seven-point scale from 1 ("Super easy") to 7 ("Extremely Hard"), participants' overall mean rating was 3.13 (see Table 2), with the majority (63%) rating compliance with the security requirements on the "easy" side of the scale. As one participant put it:

> I am kind of technologically challenged, so the fact that I was able to navigate these security features means it was probably as simple as it could be while still being effective. (J11)

Super Easy	1	15%
	2	31%
	3	17%
	4	14%
	5	13%
	6	7%
Extremely Hard	7	3%

Table 2: **Perceived Difficulty of Security Compliance (N=118).** On a scale from 1 - 7, where 1 is "Super easy" and 7 is "Extremely hard", how challenging was it to comply with the digital security requirements?

Meanwhile, only 10% of participants (12/118) rated the difficulty of complying with security practices as extremely hard ("7": 3% or "6": 7%).

Participants' low difficulty ratings of complying with these security requirements is especially surprising given that they include use of PGP, which prior work indicates is notoriously difficult to use (e.g., [40, 60]). We discuss possible explanations for these results—including the participants' trust in the team leading the project—in subsequent sections.

4.1.3 Perceived Utility of ICIJ Technology Services

Research indicates that motivation can play a significant role in the adoption of security practices in organizations (e.g., [23, 54]), and is increased if users find a system useful—or even necessary—to achieving their primary work objectives [57].

When rating the utility/necessity of the technology services provided by ICIJ (summarized in Table 3), the vast majority of participants reported that the technology was essential (83% for data and tools and 78% for coordination). Though less than half of participants (43%) reported that the training was essential, almost all participants (95%) rated the training as at least "useful." None of the 5% of journalist-contributors who did not find the training useful commented on the training, though others did comment specifically on their interest in additional training. For example:

> I would like to receive more training at digital security tools. It was really useful. I learned for myself how to encrypt my computer and find out how vulnerable was my information, due to my lack of expertise using digital security tools. (J81)

Service	Unnecessary	Not Useful	Useful	Very Useful	Essential
Data	0%	0%	4%	13%	83%
Coordination	0%	0%	8%	14%	78%
Tools	0%	0%	4%	13%	83%
Training	2%	3%	23%	29%	43%

Table 3: **Necessity and Usefulness of Technology Services Provided by ICIJ (N=118).**

Service	Never	Daily	Weekly	Monthly
Blacklight	0%	64%	33%	3%
I-Hub	3%	41%	48%	8%
Linkcurious	19%	4%	45%	31%

Table 4: **Frequency of Use of ICIJ Technologies (N=118).** Frequency of use during the three months preceding publication; "monthly" includes responses "every now and then."

4.1.4 Frequency of Use of ICIJ Technologies

In order to assess how well contributors' reported usefulness of the ICIJ systems matched their actual behaviors, we analyzed survey data on how frequently journalists used Blacklight, I-Hub, and Linkurious (see Figures 1-3). These results are summarized in Table 4.

The majority of respondents (64%) indicated that they used Blacklight—the document-search platform where contributing journalists could access the leaked documents—at least daily during the three months prior to the project launch date in April 2016. One third (33%) used Blacklight at least weekly, and only 3% used it monthly.

The vast majority of respondents (89%) used I-Hub—the collaboration and communication platform with forum and chat features—daily or weekly. Only 8% used I-Hub only monthly, while just 3% reported never having used it.

By contrast, a significant portion (19%) of respondents indicated they had never used Linkurious—the system that provided visual graphs of the relationships between entities mentioned in the leaked documents. About a third (31%) said they used it monthly and nearly a half said they used it weekly. Only 4% used it daily.

4.1.5 Collaboration Outside Home Organization

A key objective for ICIJ in facilitating the Panama Papers project was to encourage inter-organizational collaboration among participating journalists, to maximize the quality and impact of the resulting publications. The degree of collaboration therefore offers insight into both the *utility* and *usability* of these systems. Given the global distribution of the journalist-contributors, collaborative data management strategies like using local-only servers or in-person meetings, were not feasible. These circumstances therefore also gave rise to specific *technical* security requirements for inter-organizational collaboration.

Survey participants were asked to rate how much they collaborated outside of their own organization on a scale of 1 - 7 (where 1 indicated "I worked independently" and 7 indicated "I've collaborated more than ever"). Nearly one third (32%) of participants indicated they had collaborated with journalists outside their organization "more than ever" during the Panama Papers project, and the vast majority of participants (74%) responded on the positive side of the scale (5, 6, or 7), with a mean rating of 5.33. Only 13% indicating lower levels of inter-organizational collaboration by responding on the negative side of the scale (1, 2, or 3). This data is summarized in Table 5.

4.1.6 Contributor Suggestions about Security

The survey data we analyzed also included one open-ended question: "Do you have any suggestions or comments about the digital security tools and requirements for this project?" Fifty-seven contributors offered open-ended feedback. While the themes of these comments varied, the most frequent theme was a feature request (14% total, of which more than half were requests for additional security features). The second most common themes were compliments (13%), statements affirming the need for security (5%), and requests for additional training (4%). Notably, only 3% of comments described the project's security requirements as a barrier to work.

For example, several participants (5) specifically mentioned issues around phone-based authentication.

> The Google Authentificator [sic] tool... when I changed my phone (twice during the investigation) I had to communicate with the support team to reboot the passwords. (J118)

> At certain times security turned into a barrier into getting more done... Every time a cellphone died or went missing (frequently) I needed to reconfigure authentication. (J68)

However, another participant noted that while security was a barrier, it was worth the slow-down:

> It's always a pain and even slowed us down. But this work is important and anything to keep it secure is fine. (J78)

Finally, others explicitly called-out the need for security and even praised ICIJ's focus on it:

> I like the fact that ICIJ considers security as a priority. Maybe ICIJ can explore other ways to

Independent	1	3%
	2	4%
	3	6%
	4	14%
	5	25%
	6	17%
Collaborative	7	32%

Table 5: **Collaboration Outside Own Organization (N=118).** Scale items were "I worked independently" (1) and "I've collaborated more than ever" (7).

> find log in ways that will not discourage potential users while at the same time putting security of our work a priority. (J109)

> Not been an expert, I believe the ICIJ team has done a fantastic work on security. (J111)

As we will discuss further in Section 5, this trust placed by contributors in the ICIJ team likely contributed to that team's ability to mandate security requirements.

4.2 Results from Interviews

We now turn to a discussion of our interview results, according to the topics from the interview script. Where relevant, we include verbatim quotes from participants to illustrate our findings. We identify quotes using only a letter (IT for technical staff, E for editorial staff, including the journalist who originally received the Panama Papers documents) and participant number.

4.2.1 Security Goals and Threat Model

Because the documents at the center of the Panama Papers project related largely to tax evasion, government actors—who could expect to recoup lost revenue through their exposure—were explicitly *not* considered to be part of the threat model for the project. That said, the companies, criminals (such as tax evaders, money-launderers and drug-traffickers), and politicians who were implicated in the documents were all identified as actors who could potentially confiscate locally-held data as well as threaten, imprison ,or even kill the journalists involved and/or block publication or access to the work. Given the size and resources of ICIJ, the primary security goals prior to publication therefore centered on protecting the source of the documents, maintaining the secrecy of the project, and maintaining the availability of the Blacklight, I-Hub, and Linkurious systems.

While our research participants only explicitly mentioned DDoS attacks and inadvertent project exposure as risks, training documents provided by participants indicate a range of security concerns, such as: spyware/malware, network monitoring, weak passwords/password reuse, physical interception of data (via locally-stored, unencrypted data or printouts) and legal attacks via third-parties. For example, a training document explicitly warned contributors against using third-party applications to translate, OCR or visualize the Panama Papers data, and encouraged storing local data from the project only in encrypted, hidden volumes.

These concerns informed the system design in myriad ways. First, both the sheer volume of the data–and the goal of protecting its source–led in part to the decision to use a centralized, remotely-accessible method of sharing the documents, rather than providing contributors with individual hard drives, as ICIJ had done in previous projects. As one ICIJ staffer put it:

> This is sensitive data that has been leaked to ICIJ for a reason, and that those sources are trusting us with being... guardians of that information and protectors. So it's not for us to give away to anybody, not even a trusted colleague. (E2)

Instead, the centralized system allowed ICIJ to grant all journalist contributors *access* to the documents, while still allowing ICIJ to monitor–and restrict–the volume of data that they could download from the system.

Second, the lack of a nation-state adversary–in conjunction with the specifics of Amazon Cloud's contractual agreements–made cloud-hosting an option. It was also a technical requirement, due to the volume of data involved and the need for substantial pre-processing.

4.3 System Design

Informing and interacting with ICIJ's security goals for the project were the organization's driving journalistic objectives: supporting high-quality, high-impact reporting and publications. Due to the enormous volume of data and documents involved (2.6 TB consisting of about 11.5 million documents), as well as their global nature, remote search and collaboration were essential—priorities that were clearly shared by both the editorial and technical staff:

> The needs are... communicate, and search documents, and to do it collaboratively. (E3)

> One of the more important impacts was that journalists discovered how convenient, powerful and good it is to collaborate... I think that the I-Hub contributed to this: to teach them how to interact, and it is a really good thing to share knowledge, share documents, share data, and build these networks. (IT2)

One reason the multi-national collaboration was essential was the variety of formats and languages within the source material, especially since participants were warned–through training, tip-sheets, and regular messaging from project leaders–against using third-party tools like Google Translate due to security concerns. ICIJ's

tools were therefore crucial to effective collaboration across timezone and language barriers:

> With cultural barriers, with language barriers and with time zones and all that... I think it was just the speed and the friendliness... it made 11 million documents look easy, look doable, and look—because it was easy and friendly to use, it became addictive to the reporters doing searches... and I like that. (E2)

Indeed, explicitly cultivating collaboration was a key design goal of I-Hub in particular, and it seemed to work:

> You cannot collaborate on email, or encrypted email, or Signal. You need a real space that feels comfortable and friendly and it's colorful, and [I-Hub] was. (E2)

> The forum was never as used and crowded as this time... It felt like everybody was sharing [and] working very collaboratively. (E1)

One reason that I-Hub may have been so easily adopted was its explicit similarity to familiar technologies (see also Figure 2):

> You can upload files, you can "like" a topic. You know, which is something that we're all so used to in the Facebook world. But that simple kind of "liking" thing also helped reporters bond together and encourage one another. And they were not going crazy with the likes, you know, most of the time people were not "liking" things, they were actually contributing useful information. But sometimes, you know, when somebody has made an important discovery...it just helped tremendously with providing a sense of team. (E2)

As we discuss further in Section 5, the fact that the ICIJ explicitly cultivated and supported such a collaborative culture—and that this collaboration was core to the success of the project itself—helped lay the groundwork for users' acceptance of strong security requirements.

4.3.1 Selecting Journalist Collaborators

In line with prior research on investigative journalists (e.g., [46]), our survey results indicate that the majority of the journalist contributors to the Panama Papers project were not security experts. Since any member of the collaboration is a potential "weakest link", we examine how these collaborators were chosen.

While ICIJ explicitly sought project contributors based in as wide a range of countries as possible, the core group of journalists (which numbered approximately 100 as of September 2015 and grew to nearly 400 by project launch in April 2016) were all existing ICIJ members. Interestingly, members who brought in non-member colleagues were considered responsible for disseminating and enforcing security protocols set by ICIJ:

> We would reach out to our member and trusted person... then the trusted journalist talks to a very small group of people in his own media organization... And then, if they get assigned to do the story, then we would train them, we would give them access to platforms... It's up to the trusted member and reporter to enforce all the rules and regulations with any person that that reporter bring on board. (E2)

Our interviews suggest that explicitly leveraging trust relationships within an established social network helped maintain the project's security requirements even as new members joined. While in practice this resembles a "web of trust" model, we note that unlike some traditional web-based implementations, each human "link" in this chain had a strong-tie connection to their closest link.

4.3.2 System Security

We now turn to a discussion of the security decisions made in the design and maintenance of ICIJ's systems, based on our interviews.

Technical Security. Key security aspects of all systems includes careful vetting of the source documents (including scanning them for known malware), deploying well-tested HTTPS, and requiring two-factor authentication for each of the three core systems.

The team experimented with multiple versions of two-factor authentication, including virtual machines (discarded as too complex) and browser extensions (discarded as insufficiently secure). Eventually, they settled on a smartphone-based app solution, which proved scalable despite initial concerns:

> You have to have a smartphone. And, we had a little discussion about, "Is this going to work?" Because Africa is big on cell phones, but mostly they're not smartphones... And then, when we started adding partners to the Panama Papers, everybody pretty much ended up having a smartphone. (E3)

Secure Defaults. One striking security decision was making PGP-encrypted email the default communication method for essential system functions. By summer 2016, participants were required provide a PGP key in order to obtain system credentials (including reset/recovery). Today, all notification emails from those systems are also encrypted by default.

Initially, however, contributors could receive password rest information via HushMail HushMail, and unencrypted system notifications still included details like

the summary of an updated thread. As security concerns increased post-launch, however, all details were eliminated from notifications until default PGP encryption could be implemented. Yet we note that the security culture among these journalists was strong enough by this point that they were willing to tolerate several months of *reduced functionality* for security purposes.

Achieving these secure defaults, however, was not the result of voluntary collective action: at some point, ICIJ mandated that all contributors create and use a PGP key:

> It was not a choice... If somebody did not get themselves a PGP, he did not get access to the forum and to the I-Hub. (E1)

A helpful side-effect of this requirement, however, was that it became possible for PGP-encrypted email to become a default for communication even *beyond* the I-Hub—and it was, even for seemingly non-sensitive material. As one core editorial affiliate put it:

> We had a rule in our team that whatever is about the Panama Papers—and if it's only about, I don't know, "Let's meet at nine, okay?" then we encrypt it because we encrypt everything that has to do with the Panama Papers. So that was our rule... the automatic step was to encrypt. (E1)

By creating secure defaults—especially ones that were useful outside of the project's infrastructure—the security achieved *within* the Panama Papers project systems also enhanced journalists' level of security *beyond* them.

Human Support and Communication with Users. Both technical and editorial staff emphasized the incremental was in which security features were rolled out. Moreover, they highlighted that security mandates from ICIJ were counterbalanced by increasing user investment in the systems, supported in part by open feedback channels and the addition of user-requested features:

> I said, "If you have any suggestions or any questions regarding the platforms, email me." (E3)

> We also encouraged the community to tell us through the Global I-Hub. There was a group called "data geeks" or something like that, and we encouraged them to tell us where we could improve. (E3)

ICIJ also provided accessible (human) technical support:

> We also have a support channel... So we're always assisting them all the time with their technological needs... Some of them forgot to change their phones... [and] didn't know how to re-install or how to reconnect with a new authenticator. (E2)

The result was a pace of security upgrades that matched users' investment in and need for the systems:

> So we have people to teach them how to [set up their PGP key], we have a support team that can help them. . . It went well because they were interested in keeping the access to the [platform]. (IT2)

In addition, these open lines of communication led to broad-based improvements in the platforms' functionality. For example, the user-suggested functionality of "batch search" was mentioned by four out five interview participants as one of the most valuable features of the Blacklight system:

> I was very glad that we could do batch searches in the end, which is a huge help. (E1)

Security Disagreements. Of course, security-related disagreements did arise. As security concerns increased post-launch, for example, reliance on the more usable Hushmail was scrapped in favor of PGP:

> It's much easier to create a Hushmail account. It's like creating a Google account. You know, like it takes that long [snaps finger]. Like nothing. I think that they say it's an encrypted system end-to-end and other things, but the reality is also that you don't know. (E2)

> At one point, I approached my managers and I said, look, everyone has serious doubts about HushMail... we just need to change our policy. (IT1)

ICIJ technologists also considered using CryptDB [3, 49], to encrypt the source documents while keeping them searchable. Yet while both primary technologists agreed that CryptDB was not a good fit, their reasoning around this decision was different. While one participant cited a mismatch in threat model, another had concerns about CryptDB's maturity:

> I don't think that there is any benefit in encrypting data at rest. We had this discussion early on in the project. One of the proposals was to use an encrypted version of MySQL [CryptDB]... the passwords have to be stored on the servers themselves... So what's the point? (IT1)

> We tried to use CryptDB, which is an encrypted database, but it was a new project and it didn't work... because the project was not stable enough. (IT2)

4.3.3 Security Weaknesses

Incidents. Our interviewees knew of no system breaches that took place during the course of the Panama Papers

project. Prior to launch, there was only one occasion when system monitoring suggested a possible attack:

> We had to ask one of our partners to bring his computer because we were detecting some weird requests to our systems. (IT2)

Once the partner in question changed machines, the requests stopped, though the underlying cause was never determined (the device was reviewed by the partner's organization, but no report was made to ICIJ).

Two security incidents occurred post-launch, both centering on the exposure of the systems' URLs, which had been intentionally kept secret. Due in part to the cost of more robust DDoS protection, project leads opted to maintain endpoint secrecy:

> If someone gets the location of the servers, they can do several attacks... We are prepared for this, for brute force [authentication] attacks... But yeah they also can send a DDoS attack, for example... So we have to protect the location, the server location. (IT2)

However, this "security by obscurity" approach suffered from an accidental leak:

> For example, we have requested that no URLs were ever shared or showed on television, like URLs of our platforms. And [partner organization] forgot about it and shared URLs on television... When this thing happened with the URL, we had to basically disconnect everyone from the platform and change the URL. (E2)

Though exposure of the URL only enabled attacks on system availability/uptime—knowledge of the URLs alone did not provide access to sensitive data—ICIJ was concerned enough about these exposures that they chose to take the systems temporarily offline in order to change their locations.

Technical Limitations. Though ICIJ and its collaborators were able to maintain the project's security goals, our study suggests several potential technical security limitations in their approaches.

For example, while ICIJ focused heavily on preventative security measures (e.g., ensuring encrypted communications), systematic approaches to dealing with potential security incidents seemed limited. While some networking monitoring and logging was available for network activity and document downloads, no systematic approaches to detecting or responding to potential data exfiltration events or other system breaches were described by our interview participants. For example, the discovery of an accidentally broadcast system URL was handled in an apparently ad-hoc way.

We also observe a strong focus on communications security (e.g., PGP) but less focus on endpoint security. While ICIJ was in a position to mandate security measures around communications, their influence on endpoint and operational security was limited to occasional training opportunities and "best practices" documents shared with contributors that addressed password management, third-party tool use, use of new/unfamiliar networks and basic threat modeling. They also recommended (and provided instructions for) creating encrypted hidden volumes for project documents stored locally. However, we do not know of any measures taken to verify adherence to these guidelines by participants.

ICIJ may have deployed additional security measures that we did not learn about in our interviews, but we highlight these potential weaknesses to provide context for the overall success of the project. We encourage future system designers to take the lessons from this paper in conjunction with existing security best practices.

4.4 Results Summary

In summary, we found that a large group of geographically and culturally diverse journalistswere able to collaborate securely over roughly a one-year period. To achieve their security goals, they relied on established security mechanisms such as PGP and two-factor authentication, as well as less systematized security practices like a social-network approach to adding members.

Overall, our survey results suggest that participants felt that complying with the security requirements of these systems was relatively easy, in spite of the fact that a large proportion of them had never used security technologies including two-factor authentication and PGP prior to the project. This is even more striking given that the vast majority of participants reported using the Blacklight and I-Hub systems daily in the 3 months prior to the project launch, each of which required a separate, two-factor login for every sign-on.

Our interviews, meanwhile, offer insight into both the core system requirements of the Panama Papers project, as well as the specific ways—such as strong HTTPS, two-factor authentication, a PGP/encrypted email default, and centralized control of the documents—the project's security goals were met. Through secure defaults and strong trust relationships reinforced through these collaborative systems, the limited security incidents were well-tolerated and compromised none of ICIJ's major security goals for the project.

5 Discussion

We now step back and reflect on the contributing factors to the Panama Papers project's security success, and reflect on how these factors may usefully inform the design of secure journalistic collaborations, as well as usably secure socio-technical systems more generally.

5.1 Factors for Success

Useful and necessary system functionality allowed for security mandates. A key factor in the success of ICIJ's approach was that journalists found their systems both *useful and necessary*, independent of their security properties. Journalists needed these systems for their core functionality (i.e., access to the source documents and collaboration with their peers), making strong security requirements (such as two-factor authentication and PGP) acceptable trade-offs to gain and maintain access. ICIJ staff were aware of this dynamic:

> You have to keep a balance between functionality and security. Because if you start with all the good practices in security at once, journalists will react to that and they will resist it, because it will be less functional. (IT2)

Our findings here align with research from management science, such as the Technology Acceptance Model [15, 56, 57], which argues that successful technology adoption in organizations depends not on mandated compliance, but rather on (1) usefulness and (2) ease of use. These factors a blend of both "social influence processes" (e.g., working norm, voluntariness, and image) and "cognitive instrumental processes" (e.g., job relevance, output quality, perceived ease of use) [57]. Among these, however, "usefulness" (defined as the user's perception that the new technology will enhance their job performance and output) was found to be the most powerful determinant of user acceptance.

Normalized security practices and secure defaults. The Panama Papers project leads actively cultivated a security-conscious culture in which secure communications were the norm. This norm helped project participants avoid the need to make granular decisions about which interactions warranted secure treatment. Several of our interview participants clearly identified the value of this approach. For example:

> In this project we just routinely encrypted everything we wrote... Because we were just used to doing it and that helped us a lot as a team, that we understood that it's not such a big thing, it's not such a pain in the ass—but you're always on the safe side of it. (E1)

By contrast, prior work [18] on email encryption adoption in an activist organization identified issues around encryption of non-sensitive messages. By universally encrypting *all* project-related communication, the Panama Papers team avoided such social complexities.

Usable alternatives for secure communication minimized workarounds. The ICIJ's systems supported multiple forms of secure communication, giving users flexibility depending on their needs and task. For example, I-Hub enabled secure group communication:

> For colleagues who are not that experienced with PGP or Signal or whatever...[the I-Hub is] a good way to write secure emails or messages to each other. (E1)

Where ICIJ systems didn't meet a particular need, however, contributors often reached for tools mandated by ICIJ (e.g., PGP) or other secure alternatives, thanks to the overarching security culture of the project, and the familiarity with and trust in these tools that the project provided:

> I don't like using PGP on the cell phone particularly. So then I would mostly switch to other channels, like Signal. (E1)

System designers, meanwhile, were conscious of users' primary task objectives and strove to minimize the friction of security security processes:

> It had to be as secure as possible, and still allow working with it without doing a three-day procedure to get into the I-Hub. (E1)

Cultivating mutual respect and reciprocity. The Panama Papers project systems were the product of an iterative design process within a particular community (journalists) and use case (i.e., facilitating global collaboration around a large trove of documents). This gave the ICIJ team confidence that the systems honored both their needs and values as an organization, and those of the journalist-contributors:

> It's great, it's just software that is designed for journalists. . . and that's all we care about. (E2)

> Panama Papers is *the* project where we tried to apply all the lessons learned from the previous projects. (E3)

ICIJ also maintained a careful balance between mandating security protocols and adding user-requested features (e.g. batch search), creating a sense of balance and equal partnership between the organization and journalist-collaborators:

> Once you have users, users will ask for things. They're helpful, you know? So, batch searching feature, I did not plan that. But people started asking "Would it be possible?" And it's like, "Ah, sure. This is a great idea." (E3)

This culture of mutual interest and respect helped users accept–and even support–ICIJ's strong security requirements.

Consultation with security experts. The ICIJ team chose third-party services carefully, based on advice from outside security experts:

> In the beginning we talked a lot to security experts. We did not really tell them what we had, of course not. But we needed to know more about the whole issue and the [organization] explained a lot about it worked... and why it's secure... So I know this seemed to make sense, and we spoke to other experts and they said "Yeah, you're on the safe side with that." (E1)

For example, while there were initial questions about using cloud hosting, Amazon Cloud Services' contract promises to inform customers of government access requests, allaying some fears:

> Amazon has quite a good reputation when it comes to ensuring the confidentiality of the customers...Their policy is to inform organizations if a state agency has requested a form or information from them. (IT2)

Hushmail, on the other hand, was eventually abandoned due to uncertainty around its security properties:

> I dont even know whether [Hushmail] has end-to-end encryption. It's just completely...non-transparent. It's much better to use PGP. (IT1)

Although the technical security measures deployed by the ICIJ were not necessarily complete, we note that they were thoughtfully constructed. We encourage future system designers to similarly engage security experts and/or rely on current security best practices as much as possible during the design process.

Leveraging social relationships to build trust and shared responsibility. Strong trust and social relationships were integral to the Panama Papers' collaboration from the start: the initial group of contributers were all ICIJ members, and becoming a member requires the explicit support of multiple existing members.

In addition to leveraging their strong ties with existing members, actively cultivating a collaborative, trust-based ecosystem among the non-ICIJ journalists helped security practices permeate the otherwise disparate and physically disconnected group. In addition, frequent project updates and security reminders from the ICIJ team–as well as specific design elements of I-Hub–helped further develop this sense of team and trust:

> [On the I-Hub,] the small things, like the fact that there's an avatar and you can see the face of the journalist, and you can have direct communications and all that... it helps with trust. It helps with bonding. (E2)

This observation echoes prior work [37] which found that users make security decisions motivated in part by a desire to maintain social work relationships. Indeed, social pressure can nudge users towards security compliance even if that compliance is burdensome or time intensive [48]. Prior work [33] has also found that a high rate of in-group communication fosters greater trust. Our findings suggest that these factors all played in a role in the security success of the Panama Papers project.

Sustained emphasis on security. Project leads at ICIJ also clearly and frequently communicated the importance of security and what was at stake:

> In every editorial note I would write, I would remind [contributors] about some security measure, how it takes one of us to make a mistake for the whole thing to basically fall to hell, and you would lose an entire year of work, and we would be—a joke basically. Nobody would ever come to us again with any confidential information. So, I would remind them so they didn't feel comfortable and too confident. (E2)

Organizational resource commitment. A key success factor was the ICIJ's willingness to commit resources to developing useful and secure systems:

> [Collaborating] requires a team, and it requires systematic work... If there's no compelling need, journalists are not going to use it... It has to be enforced also by the managers and embraced by everyone. (E2)

Though stakeholders sometimes disagreed, developers actively sought management buy-in for creating long-term security solutions. For example:

> There is a tendency... to have this kind of quick solution and where it puts the load of the problem onto staff. The solution my managers proposed [for password reset issues].. created a huge support burden... Selling [long-term technical solutions] is a little difficult to directors... But when you do implement it, it works beautifully I think, and becomes an example to other organizations. (IT2)

5.2 Lessons and Opportunities for Future Research

For the computer security research community, this case study represent a rare example of security success, achieved despite many complicating factors. Examples include: mandating important but notoriously inconvenient and/or hard to use protocols, like PGP [60]; contributors' lack of prior experience with the mandated security practices; participants' wide geographic distribution and diverse native languages. Yet ICIJ was able to mandate their security requirements, and hundreds of contributing journalists adhered to—and even applauded—those requirements, allowing the project's security goals to be met. While the systems used in the Panama Papers project are not appropriate for every project, organization, or security scenario, we believe

this example offers important insights for those wishing to design similarly effective systems, especially from a human-centered perspective.

Lessons for Journalistic Collaborations. A key factor in the Panama Papers' security success was the reputation ICIJ had built for exclusive, high-impact investigations. Journalists approached for the Panama Papers' project were thus strongly incentivized to meet ICIJ's security requirements, which were required to gain access to the systems and the documents they held. The risk of being left out of future projects or ostracized by colleagues and partner organizations made the cost of security non-compliance particularly high. Similarly, the importance of clear communication around security suggests that tying security requirements to demonstrable professional advantage, along with clear expectation-setting (including negative consequences) are key factors in motivating journalists to adopt and maintain even potentially onerous security practices.

Recommendations for Socio-Technical Systems. Prior work shows that employees will often sidestep security requirements to focus on their primary tasks [24]. As the Panama Papers project demonstrates, however, when security measures are *integral* to those tasks, they may be better honored by users. This suggests that security measures perceived as a "bolt-on" to existing systems—especially if organizational leaders are not vocal about their importance—may engender avoidance behaviors from users. Similarly, insufficient attention by system and security experts to the specific work needs and task priorities of users may lead to brittle systems: tools and protocols that do not offer multiple methods for meeting a particular security requirement (e.g. text-based communication), may lead users to rely on insecure workarounds to meet their needs. This affirms prior work (e.g., [48, 55]) suggesting that ongoing attention to both security and primary work objectives by organizational leaders *and* security experts is key to creating and maintaining secure collaborative systems.

Opportunities for Future Work. Though our work has identified multiple factors that may have contributed to the effective security of the Panama Papers collaboration, we do not know which of these factors were *necessary*, nor which combination of them would have been *sufficient*. We also cannot tease out the importance of other potentially relevant factors, such as whether the small size of ICIJ itself helped facilitate organizational consensus on security issues.

Two key directions for future work, then, include (1) conducting additional case studies of socio-technical security successes and (2) comparing these case studies to clarify which factors are necessary and/or sufficient. While our findings support prior work on the value of social relationships for motivating security behaviors, exploring other motivations (such as professional norms or organizational identity) may highlight additional paths towards similar types of security success.

6 Limitations

The Panama Papers project provides a remarkable example of a diverse, highly-distributed group of journalists meeting the security goals of the coordinating organization. However, we know that no system is perfectly secure, and that even systems that appear to meet their security goals may have been breached. In this case, a highly-motivated and/or -resourced attacker could—without the organization's awareness—have potentially or actually compromised the systems we described here. We do not claim causality, ultimate system security, or lack of vulnerabilities, but rather identify factors that may have contributed to the ICIJ's success in achieving their security goals (protecting the source and preserving the secrecy of the project until the desired launch date) in a complex socio-technical system.

Thus, the measures describes above should not be interpreted as a guarantee of security or recipe for success, nor a complete technical description of the systems used. Indeed, we highlighted several technical limitations of the system and encourage readers to treat this case study as a potential starting point from which to incorporate other technical security best practices (e.g., mechanisms for detecting compromise or strengthening endpoint security). We leave a technical analysis of these still-evolving systems to future research.

Finally, because the survey instrument was designed by ICIJ, we could not control what questions were asked and how. We include the survey instrument in Appendix A for transparency.

7 Related Work

To the best of our knowledge, this paper represents one of the first in-depth studies of a security success story. Due to the novelty of such a case study in the security literature, below we examine related work in adjacent fields.

7.1 Security for Journalists and Activists

Recent work has studied computer security for journalists specifically, both individually [40, 44] and organizationally [45]. These works identified computer security challenges due to, e.g., the fragility of journalists' relationships with their sources, as well as the limited resources available within journalistic organizations.

Like NGOs and activist groups, journalists' work makes them high-value targets for cyberattack and surveillance (e.g., [20]). Certain nation-states have been known to monitor these groups and scan for evidence

of political dissent, by "eavesdropping, stealing information, and/or unmasking anonymous users" [43]. In addition to surveillance, such groups have also been the target of malware attacks and tailored phishing attacks, on which several case studies have been published [21, 39].

7.2 Security in Organizations

More generally, when considering computer security within organizations or other networks, users are often considered the "weakest link" [8]—a theme that has become common in a range of fields (e.g., [26, 48, 50]).

Usability studies have begun to amend this assumption, looking at how to strike the balance between security and usability (e.g., [35]). Work in this field shows that users make decisions informed by a rational concern for efficiency, so much so that many deliberately ignore security advice and training [24, 25].

Scholars have found that organizational culture is a critical component for the successful implementation of security policy [58]. For example, Kirlappos and Sasse [37] show that social relationships between employees impact compliance with security mandates. Blythe et al. [10] identified factors contributing to employees' security behaviors, including security knowledge and perceptions of responsibility. Thomson et al. [55] highlight the importance of integrating security awareness into an organization's daily culture. Pfleeger et al. [48] discuss the rollout of security mandates in the context of employees' mental workload and interaction with their primary task flow, All of these factors from prior work—peer trust relationships, organizational security culture and norms, and integration with primary tasks—are echoed in our findings.

Other fields, including managerial and behavioral studies as well as social psychology and sensemaking, also consider the role of employee-culture in general managerial compliance. Organizational culture, in particular, has been found to exert outsized influence on employee behavior [16, 22, 26, 34, 41, 48, 51, 53].

7.3 Security on Distributed Teams

As technology has enabled geographically distributed teamwork, top-down management has given way to decentralization and flat hierarchies [14] This change has security implications: top-down enforcement has been shown to be less effective than socially embedded, trust-based cultural compliance [37]. Moreover, top-down mandates can actually lead to employees' distrust of the organization [59] or harm productivity [27]. Our findings here—where security mandates were accepted and even supported by journalist-contributors—suggest that this distrust effect may be overcome by sufficiently strong social relationships and/or respect for the organization.

For digital rather than physical collaborations, computer security becomes critically important, and knowledge management in such teams is a topic of interest for researchers [9, 11, 38, 47]. However, with some notable exceptions [14, 33], the specific requirements of such teams for security compliance are understudied. Our research helps address this gap in the literature.

8 Conclusion

In this paper, we have explored a security success story: the case of the year-long Panama Papers project collaboration among hundreds of journalists around the world. We presented and analyzed survey data from 118 journalists involved with the project, as well as interviews with the editorial and technical staff behind the design and implementation of the collaboration tools used during the project. From these datasets, we distilled success factors and recommendations for designing and implementing secure socio-technical systems.

We found that users will accept strict security requirements in order to use tools critical to their core (non-security) efforts; that a strategy of reducing security decisions by making secure behavior the default and providing secure alternatives for functionality not directly supported may discourage insecure "workaround" behaviors; that leveraging peer relationships can help foster a collaborative culture with a shared sense of security responsibility; and that inviting—and engaging—input from users helps establish a sense of reciprocity that facilitates their adoption of security mandates. This case study demonstrates not only *that* meeting significant security goals is possible in a complex socio-technical system, but provides valuable insights into how similarly successful future systems can be designed.

Acknowledgements

We are especially grateful to our interview participants and the ICIJ Data Team for providing us access to the survey data and images of their systems. We thank undergraduate research assistants Brian Justice and Duyen Nguyen at Clemson for help transcribing the interviews. Finally, we thank our anonymous reviewers and our shepherd, Adrienne Porter Felt, for valuable feedback on an earlier version. This work is supported in part by the National Science Foundation under Awards CNS-1513575, CNS-1513875, and CNS-1513663.

Author Contributions

SM recruited participants, collected all data, and coordinated the writing and editing process. KC originated the study idea and EW and KC conducted data analysis. MA and EW contributed the literature review. MA helped prepare study materials and processed raw data. FR, SM and KC drafted sections of the paper and FR guided its framing for the USENIX Security audience. All au-

thors identified relevant themes and illustrative quotes, contributed to the discussion section, and reviewed and edited the final manuscript.

A Appendix: Survey Instrument

This appendix contains the questions from ICIJ's survey of contributing journalists for which we received data.

A.1 ICIJ Journalist Survey

We want to know your opinion about the project platforms and your experience working on the project. It should take you 10 minutes. Your honest feedback will be important to make adjustments to future investigations and we will use your answers only for ICIJ internal purposes. You can answer the survey anonymously, although we appreciate if you tell us who you are. Thanks for helping us to improve global collaboration in journalism!

1. Name [short answer]
2. Country [short answer]
3. Media Outlet [short answer]
4. Email [short answer]

5. How much did you collaborate with others outside your organization for this project?
(I worked independently) 1 2 3 4 5 6 7 (I've collaborated more than ever)

6. How would you rate the services provided by ICIJ throughout this project?
For 6.A-C, the scale was: Unnecessary, Not useful, Useful, Very useful, Essential.
A. Project coordination
B. Digital tools (I-Hub, Blacklight, etc.)
C. Training (tools, data and digital security)

7. How did you find the coordination of the project?
(Poor) 1 2 3 4 5 6 7 (Excellent)

8. How often did you use ______ during the last three months before publication?
For 8.A-C, the scale was: Every day, Two or three times a week, Once a week, Once a month, Every now and then, I never used the service, Other: [short answer].
A. Blacklight
B. I-Hub
C. Linkcurious

9. Which digital security practices were you familiar with prior to working on this project?

For 9.A-C, the scale was: Never heard of it before, Knew about it but hadn't used, Had used a few times, Used occasionally, Used frequently.
A. Passphrases (instead of passwords)
B. Two-factor authentication (Google authenticator)
C. PGP encryption (for email)

10. Which improvements (if any) would you like to see in Blacklight? [short answer]

B Appendix: Interview Instruments

This appendix contains our interview script for ICIJ editorial personnel and for ICIJ technical staff. We note inline where the interview script differed between editorial and technical staff.

Background

1. What was your [editorial/technical] background and/or main area of responsibility for ICIJ prior to the start of the Panama Papers project?
2. Prior to the Panama Papers, had you worked on any other collaborative investigative projects at ICIJ, or any other organization? If so, can you tell us a little bit about how the Panama Papers differed from these earlier efforts?

Overall System Design

1. Were you directly involved in the [technical] design [and/or deployment] of the collaborative systems used during the Panama Papers to store and/or share the source documents? If so:
    (a) What did you feel were the most important features of the system in terms of functionality? What were the most significant challenges to including these features?
    (b) What did you feel were the most important features of the system in terms of security? What were the most significant challenges to including these features?
    (c) We understand that PGP was required to distribute at least some system credentials. Can you tell me a little bit about why PGP was selected, and how that requirement was communicated to users?
2. Were any of the technologists who worked on the projects not ICIJ employees? If so, how were they selected for involvement? Was their access to the design and/or implementation details of the project limited in any way?
3. To the extent that you are aware, how did the systems evolve over the course of its use during the Panama Papers project? Have they continued to change since the launch? In what ways?
4. From your perspective, what were the most successful aspects of the system design and deployment? What were the least successful? What surprised you the most about how the system was used?
5. *For technical staff only:* Were regular backups performed on the system? If so, how were backups initiated and carried out?
6. *For technical staff only:* Was content stored on the system generally encrypted at rest? If so, was there a mechanism for searching this content?

Recruitment and Participation
For editorial staff only:

1. How did journalists generally get involved in the Panama Papers project? Were they recruited, or did they reach out to ICIJ?
2. What was the general process for vetting individuals or organizations for participation? Was anyone ever rejected? Why?
3. Was there a group of people who were responsible for verifying the authenticity of received documents and information? If so, what type of process did they use?
4. As more information was received, how was it integrated into the system? Who was responsible for this, and how was the process determined?

General System Functionality: BlackLight and I-Hub

1. We understand that there were two primary systems used to manage the Panama Papers project: BlackLight and I-Hub. In your own words, you could describe each of these systems, both in terms of their functionality and how they were implemented?
2. Did journalists have separate logins to the two systems? To the best of your knowledge:
    (a) Were there specific password requirements (e.g., length, various characters, etc.)?
    (b) Was two-factor authentication required?
    (c) How could users change/reset passwords? Were regular password changes required?
3. *For editorial staff only:* Were users allowed to upload files to either system? If so, were there any system features included to scan or clean these files?
4. *For technical staff only:* Were users authorized to upload files to either system? If so, was there any service/feature embedded with the file server, to detect and clean malware when a file is uploaded?
5. *For editorial staff only:* If users had a difficulty with one of the systems, what resources were available to them? Was providing user support a significant consideration in the design of the system?

6. *For technical staff only:* If users had a difficulty with one of the systems, could they contact the IT team directly? If so, what was the mechanism? If not, what types of resources or protocol was made available for these users?

I-Hub

1. Did all journalist users have the same level of permissions on the system?
2. What type of user could create new "chat rooms" or threads? Could administrators see all of these, and/or remove content, if needed?
3. *For editorial staff only:* Were there any features that you would have liked to see included in the system, but that could not be integrated for technical reasons? What were they?
4. *For technical staff only:* What type of encryption was implemented on this system? Was it end-to-end (in the style of PGP or OTR) or client-to-server (e.g. HTTPS connection to platform)?

BlackLight

1. *For editorial staff only:* How did the BlackLight system work? Why was BlackLight selected as the base project from which to create the Panama Papers system? What features do you wish it had that it didn't?
2. *For technical staff only:* Why was BlackLight selected as the base project from which to create the Panama Papers system? Was it difficult to adapt or secure for use on this project? In what ways?

Listserv

1. How did communications on the listserv differ from those on I-Hub?
2. *For technical staff only:* What were the functional/security differences between I-Hub and the listserv?
3. Are you aware of any instances where the listserv was used inappropriately? If so, how was this addressed, and by whom?

Information Security Training

1. Who generally provided security training for journalists? Who designed the content of the trainings?
2. Did you provide or design any of these trainings? If so, please tell me a little bit about how they were delivered and what content they contained:
   (a) Were they "live" (e.g. streamed) or recorded? Why or why not?
   (b) Did they involve hands-on exercises? Why or why not?
   (c) Was there any type of evaluation/grading of participants? Could a "failing" grade limit access or require the training be taken again? Why or why not?
   (d) How many different trainings/topics did each user have to engage before being granted access to the systems?
3. What was the goal of providing these trainings? Do you feel they were successful? What would you change or do differently around training for a similar project in the future?

Security Breaches and System Failures

1. To what extent was keeping the online location (i.e. URL) of the project an important security concern?
2. Was there a specific protocol for taking the system offline due to errors, updates or security incidents? How were these communicated to the users of the system (if at all)?
3. *For editorial staff only:* Were there specific plans in place for detecting and/or handling system exposures or security incidents? How were the users and/or publications involved monitored, if at all? By whom?
4. *For technical staff only:* Were there specific plans in place for detecting and/or handling security incidents? For example, were there automated intrusion detection systems, or checks on the locations of system access?
5. Without revealing specifics that could compromise continued use of the system, can you share a general sense of what kind of security incidents happened during the project, and how they were handled?

Scaling and Future Development

1. Do you feel that you would use – or encourage others to use – this type of system for collaborative investigative projects in the future? Why or why not?
2. From both a functionality and support perspective, do you think the systems used for the Panama Papers are scalable to a larger number of projects and/or users?
3. Are there any [design or deployment / technical or system design] lessons you learned from this project that you intend to apply to the design of future systems, whether for similar projects or not? If so, what features or aspects would you keep or change for other projects, and why?
4. Would you change the content or mechanism of training or support for future systems?
5. Is there anything else about this project that you'd like to tell us or think we should know?

Hacking in Darkness: Return-oriented Programming against Secure Enclaves

Abstract

Intel Software Guard Extensions (SGX) is a hardware-based Trusted Execution Environment (TEE) that is widely seen as a promising solution to traditional security threats. While SGX promises strong protection to bug-free software, decades of experience show that we have to expect vulnerabilities in any non-trivial application. In a traditional environment, such vulnerabilities often allow attackers to take complete control of vulnerable systems. Efforts to evaluate the security of SGX have focused on side-channels. So far, neither a practical attack against a vulnerability in enclave code nor a proof-of-concept attack scenario has been demonstrated. Thus, a fundamental question remains: *What are the consequences and dangers of having a memory corruption vulnerability in enclave code?*

To answer this question, we comprehensively analyze exploitation techniques against vulnerabilities inside enclaves. We demonstrate a practical exploitation technique, called Dark-ROP, which can completely disarm the security guarantees of SGX. Dark-ROP exploits a memory corruption vulnerability in the enclave software through return-oriented programming (ROP). However Dark-ROP differs significantly from traditional ROP attacks because the target code runs under solid hardware protection. We overcome the problem of exploiting SGX-specific properties and obstacles by formulating a novel ROP attack scheme against SGX under practical assumptions. Specifically, we build several oracles that inform the attacker about the status of enclave execution. This enables him to launch the ROP attack while both code and data are hidden. In addition, we exfiltrate the enclave's code and data into a shadow application to fully control the execution environment. This shadow application emulates the enclave under the complete control of the attacker, using the enclave (through ROP calls) only to perform SGX operations such as reading the enclave's SGX crypto keys.

The consequences of Dark-ROP are alarming; the attacker can completely breach the enclave's memory protections and trick the SGX hardware into disclosing the enclave's encryption keys and producing measurement reports that defeat remote attestation. This result strongly suggests that SGX research should focus more on traditional security mitigations rather than on making enclave development more convenient by expanding the trusted computing base and the attack surface (e.g., Graphene, Haven).

1 Introduction

Computer systems have become very complex. Even simple, security-sensitive applications typically inherit the huge trusted computing base (TCB) of the platforms they run on. Trusted execution environments such as ARM TrustZone [2] or Intel TXT [14] were invented to allow small programs to run in isolation from the much larger underlying platform software. However, the adoption of these systems has been limited, as they were either closed or required trusted hypervisors or operating systems that have not materialized in the mass market.

Intel Software Guard Extensions (SGX) [16] is a new processor feature that isolates security-critical applications from system software such as hypervisors, operating systems, or the BIOS. SGX has been integrated into recent Intel processor models and is seeing mass-market deployment. It is widely seen as the technology that can finally enable applications with a small TCB in the mass market. A number of systems have been using SGX to protect applications from threats ranging from untrusted cloud providers to compromised operating systems [3, 6, 17, 27, 30, 36, 39].

Recent work has explored the practical limitations of this vision. Several authors [26, 33, 38] have identified side channels that can leak large amounts of sensitive information out of the application's isolated execution

environment (*enclave*). A synchronization bug has been shown to lead to a breakdown in enclave security [37]. However, a fundamental question about the security of SGX remains unanswered: *What is the effect of having a memory-corruption vulnerability in an enclave and how dangerous is it?*

This question is important, as such vulnerabilities have been found in a wide range of applications, including security applications [4, 12, 13]. Furthermore, a major branch of SGX-based system design runs unmodified legacy applications and their complex operating system support inside enclaves [6, 36]. The enclave software of such systems is bound to have memory corruption vulnerabilities.

In a regular environment, such vulnerabilities often result in an attack that changes the control flow of a victim program to execute arbitrary code. However, enclaves in SGX differ from such environments in several important ways. In particular, SGX protects the entire memory contents of the enclave program. Memory values and registers that are required to launch an attack are completely hidden from attackers. More important, recent SGX-based systems even keep the enclave code secret from attackers. For example, under VC^3 [30], the program binaries are encrypted. This poses a problem for ROP attacks [8, 9, 32], as the attacker needs to find a vulnerability and gadgets in the victim's code.

In this paper, we comprehensively analyze the aftermath of exploiting a vulnerability in enclave code by demonstrating a practical attack, called Dark-ROP. Dark-ROP can completely disarm the security guarantees of SGX. In essence, Dark-ROP exploits a control-flow hijacking vulnerability in the enclave software through return-oriented programming (ROP). Since SGX prevents all access to enclave code and data from outside the enclave, we cannot directly apply typical ROP attacks.

To overcome these challenges, we construct a novel method for finding a vulnerability and useful ROP gadgets in fully encrypted binaries (unknown code) running under SGX. The method constructs three oracles that (a) detect the number of register pops before a ret instruction, (b) reveal enclave register values, and (c) leak the secret enclave memory contents. The method requires *no knowledge of the content* of the binary running in the enclave. Dark-ROP can chain the gadgets found in this way and utilize them to invoke security-critical functions such as data sealing and generating measurement reports for remote attestation.

In addition, we construct a *shadow application* (i.e., SGX Malware) that runs outside an enclave but fully emulates the environment of an SGX enclave. This demonstrates the ability of Dark-ROP to fully control the enclave program. Dark-ROP utilizes ROP chains to copy the complete enclave state, including both code and data to unprotected memory. In addition to breaching enclave confidentiality, this also enables Dark-ROP to emulate the enclave software. It can run the enclave's code outside the enclave, except for a small number of SGX instructions. The latter are used for attestation and for obtaining the enclave's crypto keys. Dark-ROP emulates these instructions by invoking ROP calls into the victim enclave.

The shadow application runs in unprotected memory under the control of the attacker. When a remote server requests a measurement report to check the integrity of the victim enclave, the shadow application first receives the request (as a man-in-the-middle), and then invokes an ROP call that generates the correct measurement report in the victim enclave and sends a reply to the remote party to complete the attestation protocol. This man-in-the-middle construction allows attackers to have complete flexibility in executing any code of their choice in the shadow application because it is not protected by SGX at all. At the same time, the remote party cannot detect the attack through the remote attestation because the shadow application can use the real enclave to generate the correct measurement report.

We summarize the contributions of the Dark-ROP attack as follows:

1. **First ROP demonstration against an SGX program on real hardware.** The Dark-ROP attack can completely disarm the security guarantees of SGX. This includes 1) exfiltrating secret code and data from enclave memory, 2) bypassing local and remote attestation, and 3) decrypting and generating the correctly sealed data.
2. **New ROP techniques.** We devise a new way to launch a code-reuse attack by 1) blindly finding a vulnerability and useful gadgets from an encrypted program in the enclave and 2) constructing a shadow enclave that poses as a man-in-the-middle to masquerade the entire application of the enclave.
3. **Informing the community.** There is a temptation to focus on convenience (e.g., running unmodified programs on SGX via library OSes [3, 6, 36]) rather than security (e.g., verification of enclave programs [34, 35]).
   While SGX-like execution environments may make exploitation more difficult, software vulnerabilities continue to be a real threat. Thus, there is a need for well-studied security mechanisms that are tailored to the SGX environment.

We organize the rest of the paper as follows. §2 provides background on SGX. §3 discusses the challenges and the threat model of Dark-ROP. §4 illustrates the design of Dark-ROP. §5 describes various ways to further

develop this attack for malicious uses. In §7, we discuss the feasibility and effectiveness of our attack. §8 covers related work. We conclude in §9.

2 Background

In this section, we present the background on SGX that is necessary to further the understanding of Dark-ROP.

Intel SGX. Intel Software Guard Extensions (SGX) is an extension of the x86 instruction set architecture (ISA), which enables the creation of trusted execution environments (TEE), called *enclaves*. An enclave has an isolated memory space and execution runtime. SGX protects programs running in enclaves from attacks that undermine the integrity and the confidentiality of code and data of the program. For example, SGX prevents enclaves from being tampered with by privileged software (e.g., kernel), and from many physical attacks such as the *cold-boot attacks*.

2.1 Security Features of SGX

Memory encryption/isolation in SGX. SGX provides hardware-based access control mechanism and memory encryption to strongly guarantee the confidentiality and integrity of the entire memory used by an enclave program (*Enclave Page Cache (EPC)*).

The SGX processor enforces an access control policy that restricts all access to an enclave's memory to code running inside that enclave. That is, no other software, including the operating system, can read or write enclave memory. This access restriction is enforced by the Memory Management Unit (MMU) integrated in the processor package, which cannot be manipulated by the system software. Specifically, page miss handler (PMH) [23] checks an access permission of the EPC pages when any software requests read or write access to the enclave memory.

In addition, a memory encryption engine (MEE) [11, 15] that is a extension of the memory controller encrypts enclave code and data before they are being written to main memory. This reduces the hardware TCB of SGX to the processor package and prevents a variety of attacks such as cold boot or DMA attacks.

Ensuring program integrity through attestation. Attestation is a secure assertion mechanism that confirms the correct application has been properly instantiated on a specific platform [1].

The purpose of attestation in SGX is twofold: ensuring that an enclave is running an expected program on a certified SGX platform with a correct configuration and securely sharing a secret to build a secure communication channel between an enclave and a remote entity (e.g., the owner of the enclave).

A complete end-to-end SGX attestation involves a long series of steps, most of which are not relevant for this paper. The one step that is relevant to Dark-ROP is that an enclave needs to obtain a cryptographic message authentication code (MAC) from the processor as part of the attestation. The enclave calls the *EREPORT* instruction to obtain the MAC. *EREPORT* computes the MAC over a data structure that includes the calling enclave's cryptographic identity (digest) with a processor key that is not revealed to the caller.

Data sealing. SGX provides the means for securely exporting sensitive data from an enclave by encryption (i.e. *data sealing*).

The processor provides each enclave with crypto keys that are unique to the enclave's cryptographic identity (digest). That is, different enclaves will receive different keys. Enclave code can use these keys to implement data sealing: It can cryptographically protect (e.g., encrypt, MAC) data before asking untrusted code to store them persistently. At a later time, a different instance of the same enclave (with the same enclave digest) can obtain the same key from the processor and decrypt the data. Enclaves can use the *EGETKEY* SGX leaf function to access their keys.

Deploying an encrypted binary in SGX. Several researchers have pointed out and built systems [5, 6, 24, 29, 30] that can deploy a completely encrypted program to the SGX platform. This can increase program security by preventing attackers from reverse engineering the program.

In short, the enclave owner builds the enclave with a simple plaintext loader binary. The loader will copy a second, encrypted binary into enclave memory and decrypt it inside the enclave with a key that it can obtain from the enclave owner using remote attestation. The loader then invokes the second binary. Optionally, the loader code can be erased from enclave memory to deprive attackers of known gadget building material.

This process requires memory that is at some time writable and at another time executable. Current SGX specification (*SGX1 [19]*) does not allow changing memory page permissions after an enclave has been created. Thus, the pages into which the second binary is loaded have to be made writable and executable. A new SGX specification *(SGX2 [20])*, promises to support the modification of page permissions of running enclaves. That would allow the deployment of encrypted binaries without requiring pages to be both executable and writable.

In summary, SGX makes it possible to deploy encrypted binaries, which means that attackers may never be able to see the code running inside the enclave they are

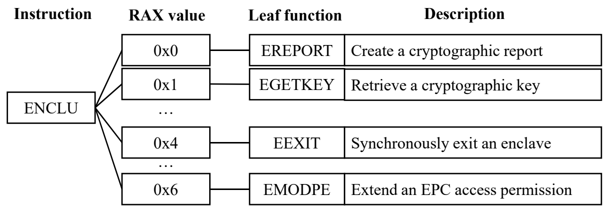

Figure 1: ENCLU instruction and its leaf functions. To invoke a leaf function of interest through the ENCLU instruction, an application developer can load the index of the function into the rax register and then execute ENCLU. For example, the value of rax is required to be 0x4 to invoke EEXIT.

trying to attack.

2.2 Instruction Specifications

SGX adds two new instructions, ENCLU and ENCLS, to the x86 ISA [19, 20]. ENCLU handles the user-level operations (i.e., Ring 3) such as deriving encryption keys and generating measurement reports. ENCLS, on the other hand, handles privileged level operations (i.e., Ring 0) such as creating enclaves, allocating memory pages. While SGX introduces many operations for creating enclaves and managing them, these two instructions work as gates that help dispatch a variety of functions, which are called *leaf functions* [19, 20].

Leaf functions. Figure 1 shows how a user-level process can invoke each leaf function through an ENCLU gate. To call a leaf function, a developer can load the index of a leaf function into the rax register and call ENCLU. For example, setting rax to 0x0 will call EREPORT, 0x1 will call EGETKEY, etc. Each leaf function requires different parameters, which are passed through the rbx, rcx, and rdx registers. For example, EEXIT, one of the leaf functions of ENCLU, requires two parameters: 1) a target address outside the enclave and 2) the address of the current Asynchronous Exit Pointer (AEP). These two parameters are passed through the rbx and rcx registers. After setting the required parameters, the developer can now set rax to the index of the leaf function (in this case, 0x4). Finally, executing the ENCLU instruction will execute the EEXIT leaf function. This calling convention for leaf functions is very similar to invoking a system call in Linux or Windows on the x86 architecture.

3 Overview

In this section, we present an overview of Dark-ROP with a simple enclave program that has a buffer overflow vulnerability as an example.

```
1  // EENTER can run this function
2  Data* import_data_to_enclave(char *out_of_enclave_memory)
3  {
4      // data to be returned
5      Data *data = new Data();
6      // a stack buffer in the enclave
7      char in_enclave_buffer[0x100];
8
9      // possible buffer overflow
10     strcpy(in_enclave_buffer, out_of_enclave_memory);
11
12     // ...
13     // do some processing
14     // ...
15     return data;
16 }
```

Figure 2: An example enclave program that has a buffer overflow vulnerability. The untrusted program can call an exported function import_data_to_enclave() in the enclave through the EENTER leaf function. The function will copy data from memory outside the enclave to an in-enclave stack buffer. However, the buffer can overflow during the copy because the size of data to be copied is not checked.

3.1 Launching the ROP attack in SGX

Figure 2 shows an example of a potentially exploitable vulnerability. In particular, the function import_data_to_enclave() reads the data from outside the enclave and creates a class object (i.e., Data in the code) by parsing the raw data. An untrusted program can invoke a function in the enclave (from outside the enclave) if an enclave program has exported the function. To call the function in the enclave, the untrusted program can set the rbx register as the address of the Thread Control Structure (TCS), which is a data structure that contains the entry point of the enclave (e.g., the import_data_to_enclave() function in this case) and its argument (i.e., the attack buffer as out_of_enclave_memory) as a pointer of the untrusted memory. Then, running EENTER will invoke the function in the enclave. In the function, the data at the untrusted memory will be copied (see line 10) using the strcpy() function, which does not check the size of the data to be copied so that the attacker can exploit this buffer overflow vulnerability. While the vulnerability does not have to be in this form specifically, the code is very simple to represent a general example of an enclave program that has an exploitable vulnerability.

To launch the ROP attack on the vulnerability, the attacker can fill the attack buffer to more than the size of the buffer in the enclave, which is 0x100, to overwrite the return address and then build the stack with ROP gadgets and function arguments to control the program execution at the attacker's will.

However, the ROP attack against enclaves will not simply work in the typical way because the information for the execution environment as well as the program itself is encrypted, so it is hidden to attackers.

Challenge: encrypted binary makes the ROP attack difficult. In the example, since we know the source code of the program, we can easily find the location and the triggering condition of the vulnerability. However, in the most secure configuration of the SGX platform (deploying an encrypted binary as in §2.1), the assumption that we know the location of the vulnerability and the condition that triggers vulnerability does not hold. This makes the launching of an ROP attack harder even if there is a buffer overflow vulnerability because attackers are required to find the vulnerability while having no knowledge of the target program.

Additionally, finding gadgets over the encrypted program is another challenge that is orthogonal to finding vulnerabilities. Suppose that an attacker could find the location and the condition for triggering a vulnerability. To successfully exploit the vulnerability and take control of the program, the attacker is required to launch a code reuse attack (if there is no code injection vulnerability) through return-oriented programming (ROP).

Unfortunately, chaining the ROP gadgets to execute an arbitrary function is exceptionally difficult in enclaves because the program binary is encrypted. Deploying a program binary in a fully encrypted form in SGX results in the code in the binary being completely unknown to the attacker. In other words, the attacker has to find gadgets for their execution and chain them together under the blindness condition.

Although a recent work on Blind ROP [7] demonstrates an ROP attack against unknown code, the attack relies critically on properties of certain server applications that are based on the `fork()` system call, which does not hold for SGX enclaves.

3.2 The Dark-ROP Attack

Consequently, to launch a successful ROP attack against the enclaves in SGX, the attacker must overcome the aforementioned challenges. In Dark-ROP attack, we resolve the challenges as follows.

Finding a buffer overflow vulnerability. To find a buffer overflow vulnerability in an encrypted enclave program, the Dark-ROP attack exploits the exception handling mechanism of SGX as follows.

For an enclave program, it has a fixed number of (exported) entry points (i.e., functions of enclave program) specified in the enclave configuration. Because these are the only point at which an untrusted OS can supply an input to the enclave program, we enumerate those functions and apply fuzzing to its argument to find any memory corruption vulnerability. In fuzzing functions, we can detect a vulnerability by exploiting the exception handling mechanism of the enclave. Since an enclave program runs as a user-level program, which cannot handle processor exceptions, when it encounters memory corruption (i.e., page fault) on its execution, the enclave gives back the execution to the untrusted operating system to handle the fault. This fall-back routine for handling the exception is called Asynchronous Enclave Exit (AEX). If we detect any AEX caused by a page fault on fuzzing, this means that there was a memory corruption so that we set the function and the argument that currently fuzzed as a candidate for the buffer overflow vulnerability.

Next, to detect vulnerability triggering conditions such as the size of the buffer and the location of the return address, we exploit the value of the CR2 register at the AEX handler, the register that stores the source address of a page fault. By constructing the fuzzing buffer to contain an invalid memory address (e.g. `0x41414000`) in the buffer, we can determine the potential target of the return address if the exception arose from the supplied value (i.e., if the value of CR2 is `0x41414000`).

Finding gadgets in darkness. After finding a buffer overflow vulnerability in an enclave program, the Dark-ROP attack finds gadgets to exploit the vulnerability. To overcome the challenge of finding gadgets against the unknown binary, we make the following assumptions on the code in the binary.

First, the code must have the `ENCLU` instruction. This is always true for the binaries in enclaves because the enclave program can call the leaf functions only with the `ENCLU` instruction. Without having the instruction, the enclave cannot enjoy the features provided by SGX.

Second, the code should have the ROP gadgets that consist of one or multiple "pop a register" (i.e., `pop rbx`) instructions before the return instruction, especially for the `rax`, `rbx`, `rcx`, `rdx`, `rdi`, and `rsi` registers. The reason we require pop gadgets for such registers is that these registers are used for the index of the leaf function (`rax`), for arguments passing (the other registers) for the leaf function, and a library function in the x86-64 architecture. For the `rbx`, `rcx`, and `rdx` registers, the `ENCLU` instruction uses them for passing the arguments. Similarly, for the `rdi` and `rsi` registers, the library functions use them for passing the arguments. To successfully call the leaf functions and library functions, the value of these registers must be under the control of the attacker.

The second assumption is also a very common case for the enclave binary because these registers are callee-saved registers. As mentioned above, the leaf functions and the library functions use them for passing the argument so that the callee must have a routine that restores the registers, and this is typically done by running multiple "pop a register" instructions before the return of the function. Thus, the code typically includes the "pop a register" gadget for these registers. Furthermore, since `rax` is reserved

for passing the return value of the function in the x86-64 architecture, having an instruction such as `mov rax, rbx` before the function epilogue is a very common case.

Third, we assume that the program in the enclave has a function that operates as a `memcpy` function (e.g., `memcpy`, `memmove`, or `strncpy`, etc.). The assumption still targets a typical condition because the isolated architecture of SGX memory requires frequent copying of memory between the trusted in-enclave area and the untrusted area.

We believe the assumptions we made for the gadgets targets a typical condition of enclave programs because without such gadgets, the programs will be broken or run unconventionally.

Based on the assumption of gadgets, we attempt to find the useful ROP gadgets without having any knowledge of the code in the binary, so we called this attack "Dark-" ROP. To this end, we construct three oracles that give the attackers a hint of the binary code to find the useful gadgets: 1) a page-fault-based oracle to find a gadget that can set the general purpose register values; 2) the `EEXIT` oracle can verify which registers are overwritten by the gadgets found by 1); and 3) the memory oracle that can find the gadget has a memory copy functionality to inject data from untrusted space to the enclave or to exfiltrate the data *vice versa*. For the details of the oracles, please refer to §4 for the further descriptions.

By utilizing these three oracles, the Dark-ROP attack achieves the ability to execute security-critical functions such as key derivation for data sealing and generating the correct measurement report for attestation, and arbitrarily read or write data between the untrusted memory and the memory of the enclaves.

3.3 Threat Model

To reflect the environment of SGX deployed in the real world, the Dark-ROP attack is based on the following assumptions:

1. The target system is equipped with the processor that supports SGX, and we assume that the hardware is not vulnerable. Additionally, we also exclude the case that requires physical access to the machine because the Dark-ROP attack is a pure software-based attack.
2. SGX and the enclave application are configured correctly. That is, we assume that all software settings that affect the enclave such as BIOS settings and the setting of page permissions for the enclave etc. are configured correctly, as described in the Intel manual [19–22] to guarantee the security promised by SGX if the application has no vulnerability.
3. The application harvests the entire security benefit of SGX. That is, the application that runs in the enclave is distributed in an encrypted format and removing the loader program after launching the payload, which makes it completely hidden to the attacker, and the application uses data sealing for protecting application data as well as remote attestation to verify the running status of the enclave.
4. However, the application that runs inside the enclave has an exploitable memory-corruption vulnerability.
5. The attacker has full control of all software of the system, including the operating system and the untrusted application that interacts with the enclave, etc., except the software that runs inside the enclave.
6. The target application is built with a standard compiler (e.g. Visual Studio for SGX, or `gcc`), with the standard SDK that is supplied by Intel.

The threat model of Dark-ROP is pragmatic because it assumes the standard, and secure configuration of SGX for the attack target, as well as assuming only the software-level attacker. The extra assumption that we add to the standard is that the software in the enclave has an exploitable vulnerability. Since removing all vulnerabilities from the software is an inextricable challenge, we believe that the assumptions depict the common best practices of using of SGX.

4 Attack Design

In this section, we illustrate how an attacker can launch the ROP attack by overcoming the challenges of the attack in the SGX environment. We first describe how an attacker can find the gadgets required for the Dark-ROP attack by exploiting the three oracles that can provide the hints with respect to the code in the unknown (encrypted) binary in the enclave. After that, we demonstrate a proof-of-concept example that invokes security-critical functions within the enclave through the vulnerability by chaining the ROP gadgets.

4.1 Finding gadgets in a hidden enclave program

To find gadgets from the completely hidden binary in an enclave, we devised three techniques that can turn an enclave into an oracle for finding a gadget: 1) Reading the `cr2` register at the page fault handler to find the gadget with multiple register pops to control the value of registers. 2) Leaking the register values at the page fault handler by calling the `EEXIT` leaf function to identify which registers are changed by 1. 3) Examining the memory outside the enclave to find a function in the `memcpy()` family to perform arbitrary read/write on the enclave.

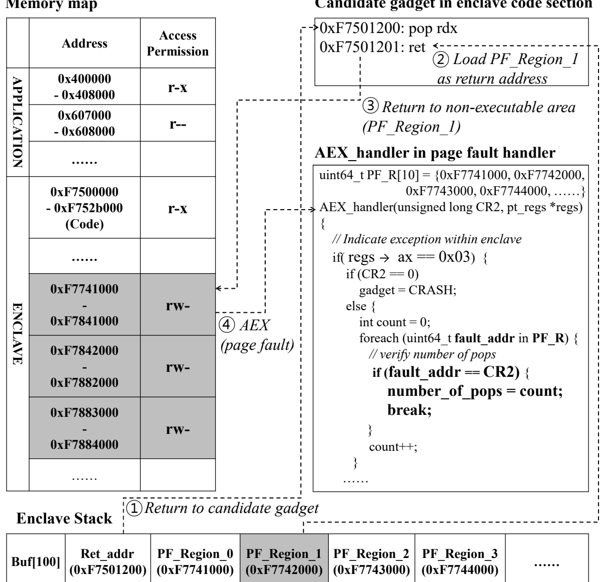

Figure 3: An overview of page fault oracle and the AEX handler. The workflow for identifying `pop` gadgets by using the *page fault oracle* is as follows: (1) The attacker sets an arbitrary address in the code section on the stack to probe if the address is for a `pop` gadget (e.g. `0xF7501200` in the figure) and then set several non-executable addresses in `PF_region`. (2) Because the probed address in the figure contains a single pop and a return instruction, the processor attempts to pop the first address in `PF_region` (i.e., `PF_region_0`) then return to the second address on the stack, `PF_region_1` (i.e., `0xF7742000`). (3) Returning to the `PF_region_1` address emits the page fault exception because the address is non-executable. (4) At the exception handler, the attacker can locate this address from the `cr2` register in the exception context so that the attacker can identify that only one pop is in the gadget.

Page fault oracle for changing register values. We first find gadgets that can set a value to a specific register from the values in the stack. For instance, a pop gadget like `pop rbx; pop rcx; pop rdx; retq;` can change the value of the `rbx`, `rcx`, and `rdx` registers at once if values are set at the attack stack by exploiting a buffer overflow vulnerability.

To find such gadgets, we turn the Asynchronous Enclave Exit (AEX) and page fault handler into an oracle for detecting the gadgets. An interesting property of the Intel processor is that when a page fault exception arises, the `cr2` register stores the address of the page that generated the fault. On the other hand, if a page fault arises in the enclave, the AEX happens and it clears the least 12 significant bits of the `cr2` register and overwrites the General Purpose Registers (GPRs) with the synthesized value to protect its execution context. Therefore, for the page fault that arises in the enclave, we can identify which address triggered the page fault in a page granularity by examining the value in the `cr2` register at the page fault handler (i.e., AEX handler in this paper).

To turn this into a gadget-finding oracle, we set the attack stack as in Figure 3. In essence, by exploiting the memory corruption bug, we set the return address to be the address that we want to probe whether it is a pop gadget or not. The probing will scan through the entire executable address space of the enclave memory. At the same time, we put several non-executable addresses, all of which reside in the address space of the enclave, on the stack.

Because the untrusted operating system manages all the memory allocations, the attacker knows the coarse-grained memory map of the enclave (on the left side of the Figure 3) so that the attacker can easily identify the non-executable enclave memory pages (e.g., enclave stack or heap pages). We call this memory region as `PF_region` and, `PF_R` array in the code contains the list of non-executable page addresses.

For instance, we put `0xf7741000`, `0xf7742000`, `0xf7743000`, and `0xf7744000`, etc. on the enclave stack to set the register values if it is a `pop` gadget (see at the bottom of the Figure 3. For example, if the gadget at the return address is `pop rdx; ret;`, then `0xf7741000` will be stored into the `rdx` register, and the processor will attempt to return to the address of `0xf7742000`. However, the address `0xf7742000` is a non-executable address; returning to such an address will cause the processor to generate the page fault. Then, the AEX handler will catch this page fault. At the AEX handler, the attacker is able to distinguish the number of `pops` in the gadget by examining the value in the `cr2` register. In the case of the example, the value is `0xf7742000`, the second value on the stack, which means that the gadget has only one pop before the return because the first value, `0xf7741000`, is popped. Taking another example, when the gadget has three pops, the first three values on the stack will be removed so that the value in the `cr2` register will be `0xf7743000`.

Using this method, the attacker can identify the number of pops before the return on the gadgets. However, the oracle does not allow the attacker to figure out which registers are being popped. Moreover, the gadget found by this method could not be a pop gadget because the page fault can be triggered in other cases such as `pop rax; mov rbx,QWORD PTR [rax+0x4]` (fault by `mov` instruction). In the next oracle, we will remove the uncertainty of the gadgets found by this oracle.

Identifying the gadgets and the registers on `EEXIT`. The second oracle we build is for identifying pop gadgets among the gadget candidates found from the first AEX oracle. The second oracle exploits the fact that the values in registers are not automatically cleared by the hardware on the execution of the `EEXIT` leaf function. As a result,

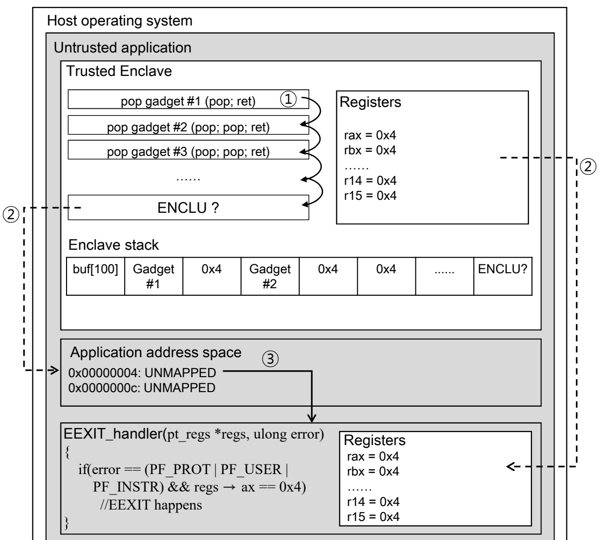

Figure 4: An overview of searching an `ENCLU` gadget and the behavior of `EEXIT`. (1) The attacker chains multiple pop gadgets found in Figure 3, as many as possible, and put the value `0x4` as the number of pops in the gadget. (2) If the probing address (the last return address) contains the `ENCLU` instruction, then it will invoke `EEXIT` and jump to the address specified in `rbx` (i.e., `0x4` because of the pop gadgets). (3) The execution of `EEXIT` generates the page fault because the exit address in `rbx` (`0x4`) does not belong to the valid address region. (4) At the page fault handler, the attacker can be notified that `EEXIT` is invoked accordingly by examining the error code and the value of the `rax` register. The error code of `EEXIT` handler contains the value that indicates the cause of page fault. In this case, the page fault is generated by pointing an invalid address `0x4` as jump address (i.e., the value of `rbx` register). So if the error code contains the flags for `PF_PROT` (un-allocated), `PF_USER` (userspace memory), and `PF_INSTR` (fault on execution), and the value of `rax` is `0x4` (the value for `EEXIT` leaf function), then the attacker can assume the probed address is where the `ENCLU` instruction is located.

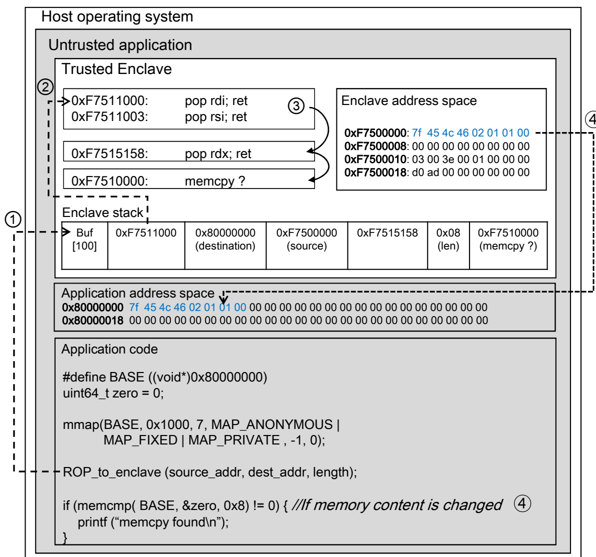

Figure 5: An overview of finding `memcpy()` gadget. (1) The attacker exploits a memory corruption bug inside the enclave and overwrites the stack with a gadget chain. (2) The gadgets in the chain sets the arguments (`rdi, rsi, rdx`) as the destination address (`0x80000000`) in `rdi`, the source address (`0x75000000`) in `rsi`, and the size (`0x8`) in `rdx` to discover the `memcpy()` gadget. (3) On the probing, if the final return address points to the `memcpy()` gadget, then it will copy the 8 bytes of enclave code (`0xf7500000`) to the pre-allocated address in application memory (`0x80000000`), which was initialized with all zero. (4) To check if the `memcpy()` gadget is found, the attacker (application code) compares the contents of the memory region (`0x80000000`) with zero after each probing. Any non-zero values in the compared area results the discovery of the `memcpy()`.

the attacker can identify the values of the registers that were changed by the pop gadget that is executed prior to `EEXIT`. This helps the attacker to identify the pop gadgets among the candidates and the registers that are popped by the gadgets.

To build this oracle, we need to find the `ENCLU` instruction first because the `EEXIT` leaf function can only be invoked by the instruction by supplying the index at the `rax` register as `0x4`. Then, at the `EEXIT` handler, we identify the pop gadgets and the registers popped by the gadget. To find the `ENCLU` instruction, we take the following strategy. First, for all of the pop gadget candidates, we set them as return addresses of a ROP chain. Second, we put `0x4`, the index of the `EEXIT` leaf function, as the value to be popped on that gadgets. For example, if the gadget has three pops, we put the same number (three) `0x4` on the stack right after the gadget address. Finally, we put the address to scan at the end to probe whether the address is a `ENCLU` gadget.

The mechanism behind the scene is like the following. The value `0x4` is the index for the leaf function `EEXIT`. What we aim to change the value for is the `rax` register because it is the selector of the `EEXIT` leaf function. For the combinations of pop gadget candidates and the address of probing, the enclave will trigger `EEXIT` if the address of a gadget that changes `rax` and the address of `ENCLU` sits on the stack. The attacker can catch this by using an `SIGSEGV` handler because the return address of `EEXIT` (stored in the `rbx` register) was not correct so that it will generate the exception. If the handler is invoked and the value of `rax` is `0x4`, then the return address placed at the end of the attack stack points to the `ENCLU` instruction.

After we find the method to invoke `EEXIT`, we exploit the `EEXIT` gadget to identify which registers are popped by the pop gadget. This is possible because, unlike AEX, the processor will not automatically clear the register values on running the `EEXIT` leaf function. Thus, if we put a pop gadget, and put some distinguishable values as its items to

be popped, for instance, 0x1, 0x2, and 0x3, and then run the EEXIT at the end, we can identify the popped registers by the values.

For example, if the pop gadget is pop rdi; pop rsi; pop rdx; ret, then at the handler, we can see the value of 0x1 at rdi, value of 0x2 at rsi, value of 0x3 at rdx. Accordingly, we can determine that the gadget pops the rdi, rsi, and rdx registers.

By using this oracle, we probe all candidates of pop gadgets until we can control all six registers that are required to launch the Dark-ROP attack.

Untrusted memory as a read/write gadget oracle. The last oracle we build is the memory-based one to find a function that can copy data between the enclave and the untrusted memory.

To find such a function, we build an ROP chain that copies data from the memory in the enclave to the untrusted area only if the probed address (set as a return address) is matched with the starting of the memcpy() function. In particular, we set the stack to have an address at the untrusted area for the first argument (i.e., the destination of memcpy()), an address in the enclave for the second argument (i.e., the source of memcpy()), and the size of data to be copied for the third argument in order to probe the return address as one of the functions in the memcpy() family. Then, we set the value of the destination address (at the untrusted area) with all zero bytes. After this, we probe each address of the enclave to find the memcpy() function. The probing finishes when we detect any change in the untrusted memory because the change proves that the memory copy is executed.

The memcpy() ROP gadget allows attackers to have an arbitrary read/write in both directions in between the enclave and the untrusted memory space because the attacker can set the source and destination addresses arbitrarily at the attack stack.

4.2 A proof-of-concept Dark-ROP attack

After finding all gadgets, including the register pop gadget, ENCLU, and memcpy(), an attacker can control the enclave in two ways. First, the attacker can run any leaf function through ENCLU by setting arbitrary values in the registers that are used for setting parameters. Second, the attacker can copy-in and copy-out the data from the untrusted memory to the trusted in-enclave memory by using the memcpy() gadget. In the Dark-ROP attack, we chain those two capabilities together to run the security-critical operations in SGX and then extract generated (secret) data from the enclave to the untrusted space solely based on launching the ROP attack. In particular, for the proof-of-concept demonstration, we execute EGETKEY, a leaf function for encryption key derivation, and extract the generated key from the enclave Note that EGETKEY must be executed in the enclave because the return value, which is an encryption key, is unique to the enclave and tied to the hardware.

Leaking the encryption key for data sealing. The EGETKEY leaf function handles the generation of the encryption key used for data sealing and verifying the REPORT in attestation. The requirement for calling the EGETKEY function is that, first, the value of rax register, which is the selector of ENCLU, should be set as 0x1. Second, the rbx register should point to the address of KEYREQUEST, which is a metadata that contains configurations for key generation, and the address must be aligned in 128 bytes. Third, the rcx register should point to a writable address in the enclave because the processor will store the generated key into that address.

To call EGETKEY through ROP gadgets correctly, we do use the following steps. We first construct a KEYREQUEST metadata object in the untrusted space and place a memcpy() gadget to the attack stack to copy this object to an 128-byte aligned in-enclave address that is both writable and readable. Finding such memory area in the enclave is not difficult. In the SGX security model, the attacker already knows the region of the memory that is used by the enclave because all the memory allocation is handled by the untrusted operating system. Even though the page permission in the page table entry could not be matched with the permission on EPCM, the attacker can scan the entire address space to find the in-enclave address that can be used for a buffer. Second, we place multiple pop gadgets to change the value of the registers. We set rbx to be the in-enclave destination address and rcx to be both a readable and writable region in the enclave. At the same time, we set the rax register to 0x1, the index of the EGETKEY leaf function. Third, we place the ENCLU gadget to execute the EGETKEY leaf function. Finally, we put the memcpy() gadget again by chaining the pop gadgets to set rdi to a writable untrusted memory address and rsi to the address of the generated key in the enclave, which is the value of rcx on the second step.

The chain of gadgets will first call memcpy() to copy the KEYREQUEST data from the untrusted space to the in-enclave memory, execute EGETKEY with the prepared KEYREQUEST as a parameter, and then call memcpy() again to copy the generated key from the enclave to the untrusted space. At the end of the chain, the attacker can extract the key at the untrusted memory address that is set on rdi at the final step of memcpy() chaining. Using the extracted key, the attacker can freely encrypt/decrypt the data as well as generate the MAC to seal the data at the untrusted space because SGX uses the standard encryption algorithm (e.g., AES-256-GCM), which can be replicated anywhere if the same encryption key is supplied.

5 The SGX Malware

In this section, we demonstrate how the Dark-ROP attack can be applied in the real world to completely disarm the security guarantees of SGX.

From the proof-of-concept attack, the attacker can obtain the ability to call any leaf functions of SGX within the enclave to extract the secret data and inject data into the (trusted) enclave space. In addition to calling leaf functions to invoke the security-critical functions of SGX, we present techniques to implement the SGX malware, which can perform the man-in-the-middle (MiTM) attack to mimic the real enclave program for running security-critical operations within the enclave and to freely run attackers' code outside the enclave without any restrictions.

To achieve full control of the enclave, we construct the SGX malware as follows: 1) By using the `memcpy()` gadget, the attacker can extract any secret data in the enclave, including the program binary and data. Additionally, the attacker runs the extracted program binary outside the enclave to replicate the enclave execution. Moreover, the attacker can inject any arbitrary code to this extracted binary because it runs outside the enclave, which is fully controllable by the attacker. 2) The attacker is able to launch the security-critical operations of SGX that must be run in the enclave at any time. This can be done by launching the Dark-ROP attack to call the target leaf function with arbitrary register values. 3) The remote party must not know that the enclave is under attack, even with the remote attestation feature provided by SGX. This can be achieved by hijacking remote attestation by calling the `EREPORT` leaf function and constructing the correct measurement data outside the enclave.

In the following, we illustrate how we construct the SGX malware with preserving such requirements so that the SGX malware can run at the attacker's discretion while bypassing attack detection using the remote attestation.

Extracting the hidden binary/data from the enclave. The Dark-ROP attack allows the attacker to call the `memcpy()` function with arbitrary source and destination addresses (i.e., arbitrary read/write functionality). By utilizing this, the attacker can set the source address to be the start address of the binary section of the enclave, the destination to be untrusted memory region, and the size to be the entire mapped space for the enclave. Then, an execution of the `memcpy()` gadget will copy the hidden content of the binary from the enclave to the untrusted area. After obtaining the binary by dumping the area, the attacker can analyze the dump and run it to mimic the real enclave program. Moreover, because this binary does not run in the protected space, the attacker can freely inject the code to alter the program for his/her own purpose.

Using a similar method, by setting the source address to be the address of the secret data in the enclave, the attacker can extract them to process them outside the enclave without being protected by SGX.

Man-in-the-Middle ROP for launching the leaf functions. While running extracted binary at the untrusted space can mimic the execution of the regular instructions, however, the leaf functions of SGX must be run inside the enclave. Thus, when the extracted binary requires calling the leaf functions, the SGX malware invokes the function by launching the Dark-ROP attack against the real enclave.

To this end, we construct the SGX malware as a Man-in-the-Middle (MitM) architecture. In particular, the general mechanism for calling the leaf function in the enclave by exploiting the ROP attack works as follows. The SGX malware first injects required data for the target leaf function into the enclave using the `memcpy()` gadget. Next, the SGX malware loads the required parameters of the leaf function at the general purpose registers by using pop gadgets, and then jumps into `ENCLU` to call the leaf function. Finally, the malware copies the generated data by the leaf function from the enclave to the untrusted memory.

After this process, the SGX malware can continue to execute the code in the extracted binary by supplying the (extracted) return values of the leaf function (e.g., a derived encryption key for `EGETKEY`) to the current (untrusted) execution. This shows that the attacker has full control over the binary because the untrusted execution can run the regular instructions as well as the leaf functions whenever they are required.

Bypassing remote attestation. The last attack target of the SGX malware is to bypass remote attestation while running the binary at the untrusted area. Since the attestation requires generating the report in the enclave, primarily, we call the `EREPORT` leaf function by the Dark-ROP attack to generate the measurement report, and we emulate the entire process of the remote attestation in the binary outside the enclave to reply the correct measurement report to the remote server.

Before describing the emulation step, we present the background on how remote attestation typically works, as in Intel SGX SDK.

Remote attestation in Intel SGX SDK. The purpose of remote attestation is to ensure the correct settings and running of the enclave before conducting secret operations such as provisioning secrets and establishing a secure communication channel with the enclave in the remote machine.

The Intel SGX SDK uses the protocol in Figure 6 for

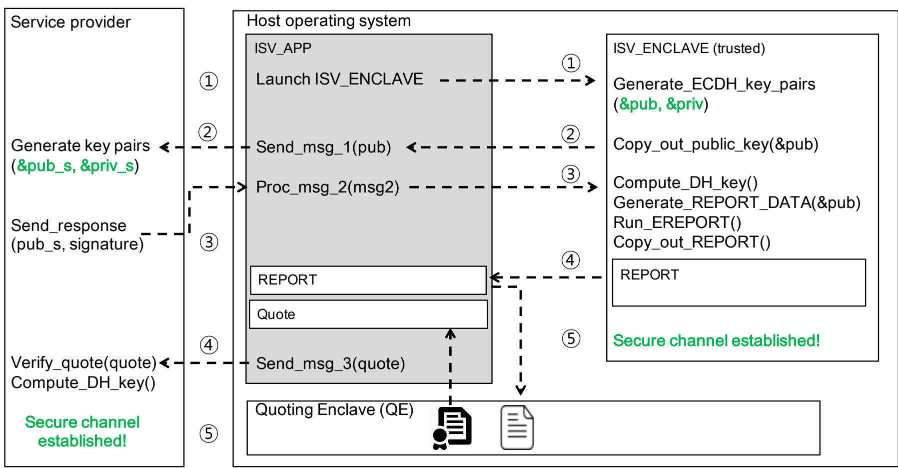

Figure 6: The (simplified) remote attestation protocol of SGX.

the remote attestation of the enclave and establishing a secure communication channel between the remote server and the enclave. First, (1) the untrusted part of the application deployed by an Independent Software Vendor (ISV, i.e., software distributor), called the *untrusted* program `isv_app`, launches the enclave program (we call this *trusted* program `isv_enclave`). On launching `isv_enclave`, `isv_app` requests the generation of Elliptic-Curve Diffie-Hellman (ECDH) public/private key pair to the enclave. The ECDH key pair will be used for sharing secret with the remote server. Then, the `isv_enclave` generates the key pair, securely stores the private key in the enclave memory and returns the public key to `isv_app`. This public key will be sent to the remote server for later use of sharing the secret for establishing a secure communication channel.

Second, on receiving the “hello” message from `isv_enclave`, (2) the remote server generates its own ECDH key pair that the server will use.

Third, (3) the server sends a quote request to the `isv_app`, to verify if the public key that the server received is from `isv_enclave`. Also, the server sends back the public key (of the remote server) to `isv_enclave`. To process the request, `isv_app` will invoke the function named `Compute_DH_Key` in `isv_enclave` to generate the shared secret and the measurement report (we refer this as `REPORT`). It contains the ECDH public key that `isv_enclave` uses as one of the parameters to bind the public key with the `REPORT`. Inside the enclave, `isv_enclave` uses the `EREPORT` leaf function to generate `REPORT`. On calling the leaf function, `isv_enclave` sets the `REPORTDATA`, an object that passed as an argument to the `EREPORT` leaf function, to bind the generated ECDH public key to the `REPORT`. After `isv_enclave` generates the `REPORT`, the untrusted `isv_app` delivers this to a *Quoting Enclave*(QE), a new enclave (trusted) for verifying the `REPORT` and then signs it with Intel EPID securely. As a result, the `REPORT` generated by `isv_enclave` contains the information for the ECDH public key that the enclave uses, and this information is signed by the QE.

Fourth, (4) the signed `REPORT` will be delivered to the remote server. The remote server can ensure that the `isv_enclave` runs correctly at the client side and then use the ECDH public key received at step (1) if the signed `REPORT` is verified correctly.

Finally, the server run `Compute_DH_Key` to generate the shared secret. (5) the remote server and `isv_enclave` can communicate securely because they securely shared the secret through the ECDH key exchange (with mutual authentication).

Controlling the REPORT generation. To defeat the remote attestation, and finally defeat the secure communication channel between the remote server and `isv_enclave`, in the SGX malware, we aim to generate the `REPORT` from `isv_enclave` with an arbitrary ECDH public key. For this, we especially focus on part (3), how `isv_enclave` binds the generated ECDH public key with the `REPORT` on calling the `EREPORT` leaf function.

The Dark-ROP attack allows the SGX malware to have the power of invoking the `EREPORT` leaf function with any parameters. Thus, we can alter the parameter to generate the `REPORT` that contains the ECDH public key that we chose, instead of the key that is generated by `isv_enclave`. On generating the `REPORT`, we prepare a `REPORTDATA` at the untrusted space using the chosen ECDH public key, and then chain the ROP gadgets to copy the `REPORTDATA` to the enclave space. Note that the `EREPORT` requires its parameters to be located in the enclave space. After copying the `REPORTDATA`, we call the `EREPORT` leaf function with copied data to generate the `REPORT` inside the `isv_enclave`. After this, we copy the generated `REPORT` from the `isv_enclave` to `isv_app` and delivers the `REPORT`

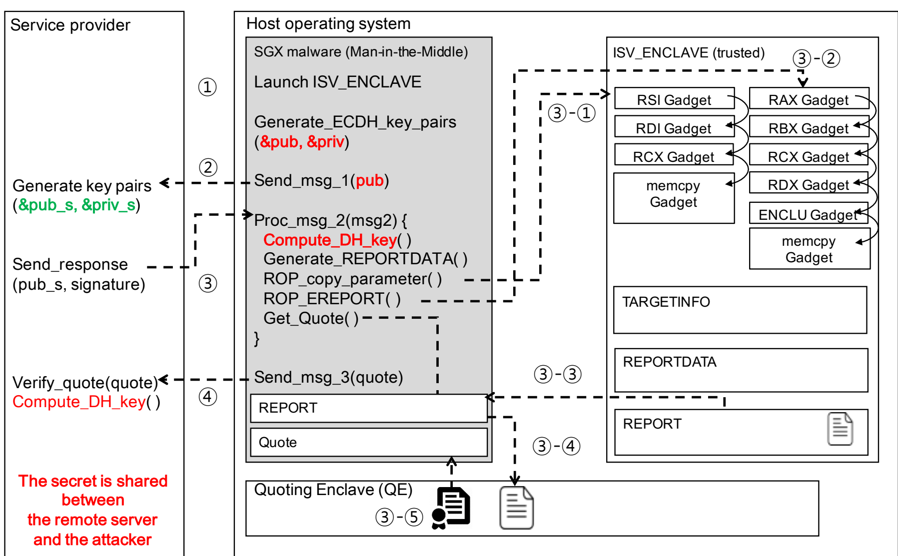

Figure 7: The Man-in-the-middle (MitM) attack of the SGX malware for hijacking the remote attestation in SGX.

to the QE to sign it.

As a result, at the untrusted space, the attacker can retrieve the `REPORT` that contains the ECDH parameter of his/her own choice, and the `REPORT` is signed correctly.

Hijacking remote attestation. The full steps of hijacking the remote attestation of an enclave are as follows (see Figure 7).

First, (1) instead of `isv_enclave`, the SGX malware generates an ECDH public/private key pair and own the private key. (2) the SGX malware sends the generated public key to the remote server.

Then, (3) on receiving the quote request from the server, the SGX malware calculates the shared secret corresponding to the parameters received by the remote server. Also, the SGX malware prepares `TARGETINFO` and `REPORTDATA` at `isv_app`. The `TARGETINFO` contains the information of the QE that enables the QE to cryptographically verify and sign the generated `REPORT`. The `REPORTDATA` is generated with the chosen public key as a key parameter to run `EREPORT` in the `isv_enclave`. After that, SGX malware launches the Dark-ROP attack (3-1, 3-2 and 3-3) to copy prepared parameters (`TARGETINFO` and `REPORTDATA`) from the untrusted app to the enclave and generate `REPORT` with the ECDH public key that the SGX malware generated at the first step. Moreover (3-4), the generated report will be copied out to the SGX malware from the `isv_enclave`, and the SGX malware sends the generated `REPORT` to the Quoting Enclave to sign this with the correct key. Because the `REPORT` is generated by the enclave correctly, the QE will sign this and return it to the attacker.

Finally, (4) the SGX malware sends this signed `REPORT` to the remote server. Now, the remote server shares the secret; however, it is not shared with the `isv_enclave`, but with the SGX malware so that the secure communication channel is hijacked by the SGX malware. Note that the remote server cannot detect the hijacking because all parameters and the signature are correct and verified.

6 Implementation

We implemented both the proof-of-concept attack and the SGX malware in the real SGX hardware. For the hardware setup, we use the Intel Core i7-6700 Skylake processor, which supports the first and only available specification of SGX, SGXv1. For the software, we run the attack on Ubuntu 14.04 LTS, running Linux kernel 4.4.0. Additionally, we use the standard Intel SGX SDK and compiler (`gcc-5`) to compile the code for the enclave for both attacks.

To launch the Dark-ROP attack on the real SGX hardware, we use the `RemoteAttestation` example binary in the Intel SGX SDK, which is a minimal program that only runs the remote attestation protocol, with slight modification, to inject an entry point that has a buffer overflow vulnerability, as mentioned in Figure 2.

Because the example is a very minimal one, we believe that if the Dark-ROP attack is successful against the `RemoteAttestation` example, then any other enclave programs that utilizes the remote attestation are exploitable by Dark-ROP if the program has memory corruption bugs.

Finding gadgets from standard SGX libraries. First, we search for gadgets from the example binary. To show the generality of finding gadgets, we find gadgets from the standard SGX libraries that are essential to run enclave

Table 1: Information for the length of ROP gadget chains for launching functions that breach the security of SGX.

Length of gadget chains (byte)			
memcpy	LEAF FUNCTION	EGETKEY	EREPORT
80	88	248	248

programs such as the library for controlling the enclave (*libsgx_trts.a*), the library that handles remote attestation protocol (*libsgx_tkey_exchange.a*), and the standard C library for SGX (*libsgx_tstdc.a*) because these libraries will be linked regardless of the program logic.

From the example binary, we found that four gadgets are enough to fulfill the gadget requirement described in §3 to launch the Dark-ROP attack against the `RemoteAttestation` example. Table 2 lists these four gadgets found in the example binary.

Constructing ROP chains for Dark-ROP. By chaining these gadgets, we construct ROP chains for calling the `memcpy()` function, and the `EREPORT` and `EGETKEY` leaf functions. To call the `memcpy()` function, we chained the four gadgets as follows. To set the registers for calling the memcpy function, we chained three gadgets, `pop rsi; pop r15; ret` and `pop rdi; ret` to set the destination and source address of memory copy, and `pop rdx; pop rcx; pop rbx; ret` to set the length of the data to be copied. As a result, we constructed an ROP chain for calling the `memcpy()` function. The total size of the gadget chain was 80 bytes, as shown in Table 1. To call the `EGETKEY` leaf function, we should call the `memcpy()` function to copy the `KEYREQUEST` structure first, set the register arguments for `EGETKEY`, and then call the `memcpy()` function again to move the generated key out to the untrusted area. By chaining two `memcpy()` gadgets and the leaf function gadgets, calling `EGETKEY` requires 248 bytes for gadget chaining. Similar to above, calling the `EREPORT` also requires 248 bytes for gadget chaining. Because the size of the chain is small enough (248 bytes as max) to fit into the overflowed stack (or heap area), we believe that the attack will work well in most cases.

7 Mitigation

We expect the adoption of traditional defense mechanisms in SGX to possibly mitigate Dark-ROP. However, since there are discrepancies between the normal execution environment and SGX, the specific features of SGX, which facilitate the attack in some aspects, need to be considered in the implementation of those defenses.

Gadget elimination. As shown in [28], the useful gadget that can be exploited to launch Dark-ROP can be eliminated before the enclave is deployed. For instance, we can transform the enclave code in a way to ensure that it does not contain any non-intended *ret* instructions. Moreover, we need to consider how to manage the non-removable SGX specific gadgets that contain the ENCLU instruction. For the transition between the host program and the enclave, at least one ENCLU instruction (for EEXIT leaf function) is required for the enclave, the requirement that makes it hard to completely remove the gadgets. We expect that implanting the register validation logic right after the ENCLU instruction could be a possible solution. Specifically, we can ensure that the ENCLU instruction in a certain location is tightly coupled with one of the pre-defined leaf functions. Besides, the way to remove the gadget that performs as a *memcpy* function, which is generally required to operate (un)marshalling the parameters between the host program and the enclave, should also be considered.

Control flow integrity. Deploying the CFI in the enclave also needs to consider the SGX-specific features. For instance, as shown in Figure 3, an attacker can arbitrarily incur the AEX to freeze the status (context) in the enclave. Then, he can create another thread to leak or manipulate the context (e.g., the saved general-purpose registers in the stack) of the trapped thread. Therefore, if the CFI implementation uses one of the general registers to point to the reference table that defines allowed target blocks, it can be easily bypassed by the attacker's manipulating the context saved in the stack of the trapped thread.

Fine-grained ASLR. Research projects that adopt fine-grained ASLR on enclave programs such as SGX-Shield [31] would possibly mitigate Dark-ROP. However, it should also accompany with enclave developer's careful configuration since Dark-ROP can still be effective by exploiting the number of state save area (NSSA) field that defines the number of allowed re-entrances to the enclave without reconstructing it. More specifically, SGX allows multiple synchronous entrances (EENTER) depending on the value configured in the NSSA field, even after the AEX happens (if ERESUME is executed instead of EENTER, the enclave crashes and thus the attacker needs to reconstruct the enclave). Therefore, if the value of the NSSA field is large enough, the attacker might be able to continuously reenter the enclave without reconstructing it, which enables the preservation of the previous memory layout. According to SGX specifications [20, 21], the value of NSSA can be up to a 4-byte integer, and we expect this to be enough to reliably locate all necessary gadgets.

8 Related work

In this section, we describe SGX-related prior works in the following respects: (1) application of SGX, (2) attacks

against SGX, (3) enclave confidentiality protection, and (4) comparison between BROP and Dark-ROP.

SGX application. Intel SGX has been utilized to secure various applications. Ryoan [17] ported Google NaCl in and SGX enclave to create a distributed sandbox that prevents sensitive data leakage. SCONE [3] leverages SGX to host a Docker container in the enclave, which specifically concerns the security enhancement and low overhead. Town Crier [39] isolates the crypto functions for the smart contract in the enclave. To prevent an Iago [10] attack, Haven [6] isolates the unmodified Windows application, library OS, and shielded module together in the enclave. Network services and protocols such as software-defined inter-domain routing are shown to possibly coordinate with SGX in Kim et al [25].

Attacks on SGX. Several research projects have explored potential attack surfaces on SGX. The controlled side-channel attack [33, 38] shows that the confidentiality of the enclave can be broken by deliberately introducing page faults. Asyncshock [37] presents how a synchronization bug inside the multi-threaded enclave can be exploited. Unfortunately, this work does not target the attacker who has full control over the enclave program. Instead, the work describes how the proposed attack can subvert the confidentiality and integrity of SGX.

Enclave confidentiality protection. As described in [18, 24, 30], an enclave binary can be distributed as a cipher text to preserve the confidentiality of the code and data deployed in the enclave. VC3 [30] shows a concrete implementation example that partitions the enclave code base as public (plaintext) and private (encrypted) and enables the public code to decrypt the private code. CONFIDENTIAL [34] provides a methodology that prevents the secret leakage from the enclave by enforcing the narrow interface between the user program and small library, and defining the formal model to verify the information release confinement. In addition, Moat [34, 35] tracks information flows by using static analysis to preserve the enclave confidentiality. Our work shows that, even with the protection of enclave confidentiality, Dark-ROP can be successfully deployed by exploiting a certain SGX hardware design and its functionality.

Revisiting BROP for Dark-ROP. Blind ROP [7] is an attack technique that can locate and verify the required gadgets in the restrictive environment where neither the target binaries nor the source code is known to the attacker. To this end, it depends on two primary gadgets, which are called the `trap gadget` and the `stop gadget`, both of which incur the program to be crashed or stopped when they are consumed (popped) as part of the input payload that is crafted by an attacker to specify the potential (and currently probed) gadget.

On the contrary, the Dark-ROP attack takes an orthogonal approach, which exploits the three oracles that allow the attacker to obtain hints of the gadgets by the features of SGX (i.e., page fault, `EEXIT`, and the memory) to identify required gadgets from a completely hidden environment. Additionally, the Dark-ROP attack can be applied to any application that runs in an enclave, whereas original Blind ROP is only applicable to server-like applications.

9 Conclusion

Dark-ROP is the first practical ROP attack on real SGX hardware that exploits a memory-corruption vulnerability and demonstrates how the security perimeters guaranteed by SGX can be disarmed. Despite the vulnerability in the enclave, realizing the attack is not straightforward since we assume the most restrictive environment where all the available security measures based on Intel SGX SDK and recent SGX-related studies are deployed in the enclave; thus, the code reuse attack and reverse engineering on the enclave binary may not be conducted. To overcome this challenge and accomplish the attack, Dark-ROP proposes the novel attack mechanism, which can blindly locate the required ROP gadgets by exploiting SGX-specific features such as enclave page fault and its handling by an asynchronous exception handler, ENCLU introduced as part of new SGX instructions, and shared memory for the communication between the enclave and the non-enclave part of program. Finally, as a consequence of Dark-ROP, we show that the attacker can successfully exfiltrate the secret from the enclave, bypass the SGX attestation, and break the data-sealing properties. We hope that our work can encourage the community to explore the SGX characteristic-aware defense mechanisms as well as an efficient way to reduce the TCB in the enclave.

Abstract

ARM TrustZone, a security extension that provides a secure world, a trusted execution environment (TEE), to run security-sensitive code, has been widely adopted in mobile platforms. With the increasing momentum of ARM64 being adopted in server markets like cloud, it is likely to see TrustZone being adopted as a key pillar for cloud security. Unfortunately, TrustZone is not designed to be virtualizable as there is only one TEE provided by the hardware, which prevents it from being securely shared by multiple virtual machines (VMs). This paper conducts a study on variable approaches to virtualizing TrustZone in virtualized environments and then presents vTZ, a solution that securely provides each guest VM with a virtualized guest TEE using existing hardware. vTZ leverages the idea of separating functionality from protection by maintaining a secure co-running VM to serve as a guest TEE, while using the hardware TrustZone to enforce strong isolation among guest TEEs and the untrusted hypervisor. Specifically, vTZ uses a tiny monitor running within the physical TrustZone that securely interposes and virtualizes memory mapping and world switching. vTZ further leverages a few pieces of protected, self-contained code running in a *Constrained Isolated Execution Environment (CIEE)* to provide secure virtualization and isolation among multiple guest TEEs. We have implemented vTZ on Xen 4.8 on both ARMv7 and ARMv8 development boards. Evaluation using two common TEE-kernels (secure kernel running in TEE) such as seL4 [1] and OP-TEE shows that vTZ provides strong security with small performance overhead.

1 Introduction

ARM TrustZone [20] has been widely used as an approach to providing a TEE for mobile devices including Samsung's Galaxy [14] and Huawei's Mate [17]. TEE has been used to protect security-critical data like cryptographic keys and payment information [45, 42, 54]. Generally, TrustZone provides hardware-based access control of hardware resources, by enabling a processor to run in two asymmetrically-isolated execution environments: a *secure world*, which is a trusted execution environment (TEE), can be configured to access all resources of a *normal world* but not vice versa. To enable TrustZone as a security pillar for ARM-based platform, there have been many secure kernels running in TEEs (called TEE-kernel), including Trustonic [11], Qualcomm's QSEE [7] and Linaro's OP-TEE [6], to host various Trusted Applications (TAs) with different functionalities [21, 55, 43, 42, 38, 66, 59, 8].

While currently TrustZone is mainly deployed on mobile platforms, AMD has integrated TrustZone in their first 64-bit ARM-based SoC solution named "Hierofalcon" [1]. There are also many ARM-based server SoC in the market, including AppliedMicro's "X-Gene 3" [12], Cavium's ThunderX [47], and AMD's "Opteron A1100" [2]. Internet companies like PayPal and Baidu have deployed ARM servers at scale for years [60, 52]. On the other hand, an increasing number of virtualization features have been incorporated into ARM platforms. For example, in ARMv7 architecture, a special CPU mode called *hyp mode* is added for hosting a hypervisor; two-stage address translation together with System Memory Management Unit (SMMU) are also provided to support address translation and secure DMA for virtualization. With such virtualization extensions, commercial virtualization softwares like Xen [37] and KVM [28] have provided built-in support for ARM platform.

With ARM gaining increasing momentum in the server market, one natural question to ask is: *can TrustZone, the security pillar of ARM platform, be leveraged by multiple VMs on a virtualized platform*? Unfortunately, as TrustZone currently provides almost no support for virtualization, all VMs have to share one secure world, which means one TEE-kernel in the secure world serves different TAs for all VMs. Meanwhile, it is known that TEE-kernels are not bug-free and there have been

multiple security vulnerabilities discovered from major TEE-kernel providers including Samsung, Huawei and Qualcomm [61, 62, 24]. Since the TEE-kernel has a higher privilege than any normal world software, once it gets compromised, attackers can access any resources of all VMs as well as the hypervisor, which makes the TEE-kernel the "single point of breach".

One straightforward way to virtualize TrustZone would be using a hypervisor in the normal world to simulate TrustZone without leveraging any features of the hardware TrustZone. However, such an approach heavily relies on the security of the hypervisor, which has a Trusted Computing Base (TCB) with millions of lines of code and usually hundreds of security vulnerabilities discovered [68, 23]. Hence, once a hypervisor is compromised, all guest TEEs (in the following paper, the *guest TEE* presents the virtual secure world for each guest and the *secure world* presents the hardware secure world) are also under attackers' control.

To address these issues, this paper introduces vTZ that provides transparent virtualization of TrustZone while still maintaining strong isolation among guest TEEs with minimal software TCB. The key idea is separating functionality from protection by maintaining one secure co-running VM serving as a guest TEE for each guest, while using the physical TrustZone to enforce strong isolation among them together with the hypervisor. Specifically, vTZ uses two secured modules running within the secure world that interpose memory mapping and world switching. Based on the interposition, vTZ further provides multiple *Constrained Isolated Execution Environments (CIEEs)* that protect self-contained code snippets running inside them by leveraging TrustZone-enabled same-privilege isolation [30, 21, 31] such that the hypervisor cannot tamper with the CIEE or break their execution integrity. The CIEEs are then used to contain the logic that virtualizes the functionalities of the physical TrustZone, including secure booting, secure configuration of memory and devices for each guest TEE. vTZ also provides *Control Flow Locking (CFLock)* to enforce that the CIEEs will be invoked at some specific point and cannot be bypassed. Building atop vTZ, we also provide various VM management operations including VM suspending and resuming while preserving the security properties.

We have implemented vTZ based on Xen-ARM 4.8 on both LeMaker Hikey ARMv8 development board as well as a Samsung's Exynos Cortex development board, and run two common TEE-kernels: seL4 [40, 39] and OP-TEE [6] from STMicroelectronics and Linaro in the guest TEE. The performance evaluation shows that the average applications overhead introduced by vTZ is about 3% compared with Xen.

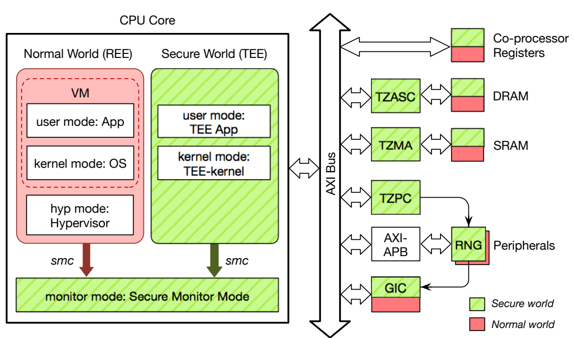

Figure 1: ARM with TrustZone and virtualization extensions: TrustZone splits CPU into normal world and secure world, all other hardware resources are split as well. Each world has its own user and kernel space, and can switch to each other by *smc* instruction. Only the normal world has virtualization support. TrustZone Address Space Controller (*TZASC*): configure DRAM as secure or non-secure (S/NS) partition. TrustZone Memory Adapter (*TZMA*): configure SRAM S/NS partition. TrustZone Protection Controller (*TZPC*): configure peripheral S/NS partition. General Interrupt Controller (*GIC*): control interrupt, can also configure interrupt S/NS partition. Random Number Generator (RNG): device for generating the random number.

2 Background and Motivation

We first give a detail introduction on ARM hardware extensions including TrustZone and virtualization. Then we introduce existing applications of TrustZone and discuss why virtualize it.

2.1 Overview of TrustZone

TrustZone [20] is a hardware security mechanism since ARMv6 architecture, which includes security extensions to ARM System-On-Chip (SoC) covering the processor, memory and peripherals. For processor, TrustZone splits it into two execution environments, a normal world and a secure world (as shown in Figure 1). Both worlds have their own user space and kernel space, together with cache, memory and other resources. It is noted that only the normal world has hyp mode.

The normal world cannot access the secure world's resources while the latter *can* access all the resources. Base on this asymmetrical permission, the normal world is used to run a commodity OS, which provides a *Rich Execution Environment (REE)*. Meanwhile, the secure world, always locates a secure small kernel (TEE-kernel). The two worlds can switch to each other under the strict supervision of a *Secure Monitor* running in monitor mode. Typically, a special instruction called "secure monitor call" (*smc*) is used for worlds switching.

TrustZone divides all memory into two parts: normal part and secure part, which are distributed into normal

world and secure world accordingly. Again, TrustZone ensures that the normal world cannot access the secure part of memory while the secure world can access the entire memory. With this feature, two worlds can communicate with each other by using a piece of shared memory. Besides, the memory partition can be dynamically controlled by the secure world, which gives secure services running in the secure world the ability to dynamically protect certain memory.

For I/O devices and interrupts, TrustZone also splits them into two worlds. An I/O device can be partitioned to one specific world. TrustZone ensures that the normal world cannot access the secure world's I/O devices while the secure world can control the whole system's devices. For each interrupt, TrustZone can designate which world to handle it. When a secure interrupt arrives, TrustZone will switch the processor to the secure world to handle it. Similar to memory, the partitioning of I/O devices and interrupts can be dynamically configured by the secure world.

2.2 Address Translation in ARM

The ARM virtualization extension not only adds a new *hyp mode* in CPU, but brings a complex address translation [4]. ARM architecture leverages translation table, which is pointed by a translation table base register, to perform address translation. There exist two different kinds of address translations: one-stage and two-stage. The one-stage translation simply maps virtual address (VA) to physical address (PA). It is used in the hyp mode (using a hyp-mode translation table) and the secure world (using a stage-1 translation table). Both of them have their own translation table base register. Two-stage translation includes stage-1 and stage-2, which is used by guest VMs. In stage-1, a VA is translated to an intermediate physical address (IPA); in stage-2, the IPA is further translated to the corresponding PA. The stage-1 page table is controlled by guest OS and the stage-2 page table is controlled by the hypervisor.

2.3 TrustZone-based Applications

TrustZone is getting increasing popularity and has been used in various scenarios to protect security-critical data and enhance the security of the normal world.

Secure Storage and Credential Protection: The isolation property of TrustZone makes it an ideal choice to store user's secret data, e.g., private keys, passwords, credit card numbers, etc. For example, a web server could put the private key and all the code accessing it into the secure world [55] so that the private key will never be accessed by the normal world, which can effectively defend against memory exposure attacks such as Heartbleed attack [16] or buffer overread attack [58]. The TrustOTP project [59] provides a secure one-time password (OTP) device on a mobile phone using TrustZone, which can keep working even if the REE OS crashes. Rubinov et al. [54] propose a method to automatically partition a Java application to two parts: one security-sensitive part in secure world and one feature-rich part in normal world. All these systems and technologies can be applied to the server platform in a seamless way.

Enforcing REE Security: TEE can be used to enhance the security of REE because the secure world has higher privilege than the normal world. For example, TZ-RKP [21] provides real-time protection for the normal world kernel from within the secure world. SPROBES [32] provides an introspection mechanism protected by TrustZone that can instrument any instruction of a REE OS, which is able to detect REE kernel rootkit. These technologies can also be used to enforce the security of server OS and applications.

2.4 The Need to Virtualize TrustZone

On mobile phone, the TEE-kernel is usually device dependent and is deployed by the phone manufacturer. For example, Apple [35], Samsung [14] and Huawei [36] use different TEE-kernels in their phones. A phone user is not allowed to install a third party TEE-kernel even after iOS jailbreak or Android root. Each TEE has one root key, which is controlled by the device manufacturer and used for TA authentication. A new TA needs to be signed by the root key before running in the TEE of corresponding device.

Since trustZone is not designed to be virtualizable, currently on a virtualized environment, e.g., cloud, all VMs on the same host have to share one TEE-kernel. Such solution is not only inefficient, but may also cause security issues, since there is no way for each VM to deploy its own TEE-kernel. It means that cloud users are restricted to use the root key controlled by the vender to sign their TAs, and have to trust the only TEE-kernel provided by the vender which is the single point of breach in software running inside TrustZone. Unfortunately, there have been various security vulnerabilities discovered in major vendors' TEE-kernel [62, 61, 63, 64, 15]. These motivate us to design vTZ to virtualize TrustZone to be seamlessly used by multiple virtual machines, while preserving the security properties offered by the hardware-based TrustZone, so that each virtual machine can run its own TEE-kernel in a secure and isolated environment.

3 Design Overview

In this section, we first discuss the goals and challenges of TrustZone virtualization, and present two intuitive de-

Table 1: Properties enforced by TrustZone which should also be enforced by vTZ. Meanwhile, shows how a malicious hypervisor can violate these properties as well as possible results. S/W means secure world. N/W means normal world.

TrustZone Features	System Properties	Properties Violation by Malicious Hypervisor → Consequence
Secure Boot	**P-1.1**: *S/W must boot before N/W.*	Violate boot order. → Secure configuration bypass.
	P-1.2: *Boot image of S/W must be checked.*	Violate integrity check of boot image. → Code injection in guest TEE.
	P-1.3: *S/W cannot be replaced.*	Replace a guest TEE with another one. → Providing malicious TEE.
CPU States Protection	**P-2.1**: *smc must switch to the correct world.*	Switch to a wrong guest TEE. → Providing malicious TEE.
	P-2.2: *Protect the integrity of N/W CPU states during switching.*	Tamper CPU states during switching. → Controlling execution of guest TEE.
	P-2.3: *Protect S/W CPU states.*	Tamper guest TEE's CPU states. → Controlling execution of guest TEE.
Memory Isolation	**P-3.1**: *Only S/W can access secure memory.*	Let arbitrary VM access guest secure memory. → Info leakage.
	P-3.2: *Only S/W can configure memory partition.*	Let arbitrary VM configure guest memory partition. → Reconfigure secure memory as normal.
Peripheral Assignment	**P-4.1**: *Secure interrupts must be injected into S/W.*	Forbid interrupt being injected into guest TEE. → Disturbing the execution of guest TEE.
	P-4.2: *N/W cannot access secure peripherals.*	Let guest N/W access secure peripherals. → Info leakage of secure peripherals.
	P-4.3: *Secure peripherals are trusted for S/W.*	Provide malicious peripherals for guest TEE. → Info leakage of guest TEE.
	P-4.4: *Only S/W can partition interrupt/peripherals.*	Let arbitrary VM configure guest interrupt/peripherals. → Reconfigure secure peripheral as normal.

signs. We then show our threat model, assumptions and the design of vTZ.

3.1 Goals and Challenges

The goal of vTZ is to embrace both strong security as well as high performance. We analyze a set of security properties that physical TrustZone provides, as shown in Table 1, which should be kept after TrustZone virtualization. To enforce these properties, vTZ needs to address the following challenges:

- *Challenge 1*: A compromised hypervisor may violate the booting sequence or booting a compromised or even a malicious guest TEE-kernel.
- *Challenge 2*: A compromised hypervisor may hijack a guest TEE's execution by tampering with its CPU states. It may even switch to a malicious TEE when performing world switching.
- *Challenge 3*: Once the hypervisor is compromised, there is no confidentiality and integrity guarantee for the secure memory owned by a guest TEE.
- *Challenge 4*: Guest TEEs trust peripherals that are configured as secure. A malicious hypervisor may provide a malicious virtual peripheral to a guest TEE.

3.2 Alternative Designs

Design-1: Dual-Hypervisor. This design uses a full-featured hypervisor to virtualize the secure world, which can be called a *TEE hypervisor*, as shown in Figure 2(a). Like the hypervisor in the normal world, the TEE hypervisor is in charge of multiplexing the secure world and offers a virtualized interface of TrustZone to the normal world. It also needs to associate a guest VM with its corresponding guest TEE. However, this design has several issues.

The first issue is its large TCB. A TEE hypervisor needs to virtualize a full-featured execution environment as the physical TrustZone provides, which requires non-trivial implementation complexity due to the lack of virtualization support in the secure world. This leads to a large code base for the TEE hypervisor. Further, since the TEE hypervisor needs to work together with the REE hypervisor to bind one guest TEE for each guest, the TCB of such a design includes not only the TEE hypervisor but also the REE hypervisor. Otherwise, a malicious REE hypervisor may let one guest VM in the normal world switch to another guest's TEE.

The second issue is the poor compatibility with existing TEE-kernels. The TEE-kernel cannot run in the kernel mode, since only the TEE hypervisor can reside at the highest privilege level. While "trap and emulate" may be a viable solution, there are some sensitive but unprivileged instructions, which will silently fail instead of trapping into the hypervisor when being executed in user mode. For example, modifying some privileged bits in *CPSR* register in user mode will just be ignored. Para-virtualization is also possible, but it may lead to compatibility and security problems since existing TEE-kernels have to be modified and the TEE hypervisor has to weaken isolation due to exposing more states and interfaces to guest TEE-kernels.

The third issue is the large overhead due to costly world switching, which involves two hypervisors to trap

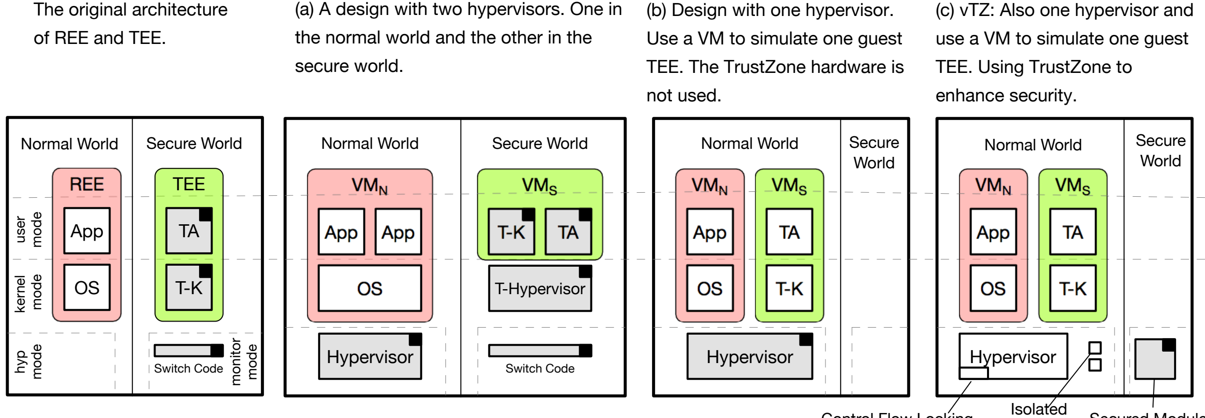

Figure 2: Different designs of TrustZone virtualization. VM_n and VM_s mean the normal world and secure world of a VM, respectively. T-K means TEE-kernel.

and emulates the world switching. An *smc* (secure monitor call) will first be trapped in the REE hypervisor and then transferred to the TEE hypervisor, which in turn transfer the call to the designated guest TEE. This results in a long call path and several privilege level crossings.

Design-2: Full Simulation of TrustZone. This design fully simulates multiple guest TEEs by using the hypervisor running in the normal world to virtualize the guest TEEs along with the normal world guest VMs and to handle their interaction, as shown in Figure 2(b). All switches between two virtualized worlds are simulated by switching between two different VMs (called VM_n and VM_s). This also means that the physical TrustZone is not essential (not used).

Comparing with the first design, this design can achieve better performance, less complexity, and better compatibility. The main problem is its large TCB of a commodity hypervisor, which includes not only the hypervisor but also the management VM (for Xen) or the host OS (for KVM). Either contains millions of lines of code (LoC). There have been 236 and 103 security vulnerabilities uncovered in Xen [19] and KVM [18] respectively, not to mention those in Linux itself.

3.3 Threat Model and Assumptions

vTZ assumes an ARM-based platform that implements the TrustZone extension together with the virtualization extension. All the hardware implementations are correct and trustworthy. vTZ also assumes that the whole system is loaded securely, including both the secure world's and the normal world's code, which is ensured by *secure boot* technology of TrustZone. Intuitively, secure boot only guarantees the integrity of the system during the boot-up process, but not the integrity thereafter. We do not consider side channel attacks or physical attacks to the memory and SoC, like cold boot or bus snooping. We also do not consider the vulnerabilities within a guest TEE.

We assume that any guest VM or guest TEE can be malicious. Like prior work using same privilege level protection [30, 21, 31], we assume the hypervisor itself is not malicious, which is trust during system booting to do initialization correctly. After booting, the hypervisor can be compromised.

3.4 Our Design: vTZ

vTZ adopts the principle of separating functionality from protection [68]. Specifically, vTZ relies on the normal world hypervisor to virtualize functionality of guest TEEs but leverages the physical TrustZone to enforce protection, as shown in Figure 2(c).

To enforce the booting integrity, vTZ uses the secure world to check the booting sequence as well as perform integrity checking (Section 5.1). To provide efficient memory protection, vTZ uses Secured Memory Mapping (SMM), a module in the secure world, to control all the stage-2 translation tables as well as hypervisor's translation table (Section 4.1). Based on that, vTZ can set security policies to, e.g., ensure that any of the guest TEE's secure memory will never be mapped to other VMs or the hypervisor, and the hypervisor cannot map any new executable pages in hyp mode after booting up.

To protect the CPU states during context switching and guest TEE's execution, Secured World Switching (SWS) hooks and checks all the switches in the secure world, which alternatively saves and restores guest CPU states for each guest TEE (Section 4.3). The virtual peripherals are also isolated through securely virtualizing resource partitioning of peripherals and interrupts (Section 5.3).

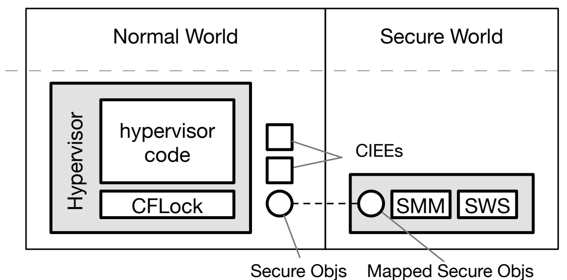

Figure 3: System Architecture: Two secured modules (Secured World Switching (SWS) and Secured Memory Mapping (SMM)) are located in secure world. Constrained Isolated Execution Environment (CIEE) is running in hyp mode in the normal world. Control-flow Lock (CFLock) provides non-bypassable hook for CIEE and secured modules when an exception happens.

The key to achieving the above interposition and protection is efficiency and vTZ achieves these by extending prior work with same privilege isolation [30, 21, 31] to virtualized environments. Specifically, vTZ provides a set of Constrained Isolated Execution Environments (CIEEs) in hyp mode (Section 4.4). CIEE is isolated from each other as well as from the hypervisor. To prevent sophisticated attacks like ROP [53], vTZ ensures the control flow and data flow integrity for code snippets within each CIEE. Control Flow Locking (CFLock) (Section 4.2) is used to provide non-bypassable hook for CIEE and secured modules (SMM and SWS) in the secure world. CIEE is not part of TCB since a compromised CIEE cannot affect the security of other CIEEs or guest TEEs.

The TCB of vTZ contains only the secured modules running in the secure world, which has less than 2k LoC. In contrast, the TCB for design-1 contains the huge REE hypervisor as well as a smaller TEE hypervisor containing tens of thousands of LoC (e.g., NOVA [57] contains a 9k LoC microhypervisor and 29k LoC VMM, OKL4 [33] contains 9.8k LoC). The TCB for design-2 includes a whole commodity hypervisor, which contains several millions of LoC.

4 Protection Mechanisms

As mentioned in Section 3.4, vTZ leverages four mechanisms: SMM, CFLock, SWS and CIEE to enforce the security properties for guest TEEs, as demonstrated in Figure 3. This section will describe all these mechanisms in details.

4.1 SMM: Secured Memory Mapping

The Secured Memory Mapping (SMM) module runs in the secure world for memory isolation. SMM controls the VA-to-PA mapping in the hyp mode as well as IPA-to-PA mappings for guest VMs in an exclusive way. It provides two interfaces to the hypervisor, one for loading a translation table and the other for modifying entries of a translation table. Based on that, SMM manages and enforces different security policies on every memory mapping operation. It only provides one interface to some specific CIEEs which contain virtual partitioning controller emulator (introduced in Section 5.3) to configure security policies.

Exclusive Control of Memory Mapping: To ensure that only the SMM can load or change memory mapping, vTZ enforces that the hypervisor does not contain any instruction to do so. There are three ways for a hypervisor to modify memory mapping: changing the base register to a new translation table [2], changing the entries of translation table, or disabling the address translation [3]. In vTZ, the hypervisor is modified so that is no instruction that loads new translation table or disables translation. Meanwhile, all the page tables are set as read-only to the hypervisor. The corresponding operations are replaced to invocations to SMM.

SMM maps the code pages of the hypervisor as read-only so that the code will not be changed at runtime. It also controls the swapping of hypervisor code and ensures the integrity of code during swapping in process. To prevent return-to-guest attack, SMM ensures that no guest memory will be mapped as executable in hypervisor's space. Moreover, SMM forbids to map any new page as executable in the hypervisor's address space after system booting. vTZ also ensures that there is no ROP gadget that can be used to form new instructions to operate the translation table (which is relatively trivial on ARM platform since instruction alignment is required). We also consider all the ISAs with different length.

4.2 CFLock: Control Flow Locking

Locking the control flow means enforcing a control flow transfer to specific code at some certain event, so that the code will not be bypassed to handle the event. CFLock can "lock" the control flow when any exception happens, which is used to ensure the non-bypassability of the SWS and CIEEs (described in following sections). We force the control flow at the entry of different exception handlers. The ARM architecture uses a special register to point to the base address of exception table, and each table entry will correspond to one exception handler. We deprive the hypervisor of ability to modify this base register by replacing all the modification instructions with invocations to secure world, similar as Section 4.1. The exception table will also be marked as read-only by SMM, to enforce that each exception will eventually reach to one specific handler. After that, certain control flow transfer instructions (e.g., an uncondi-

tional jump to the entry of a CIEE) will be implanted in these handlers. Since SMM ensures the code of hypervisor is read-only, such instruction will never be modified.

4.3 SWS: Secured World Switching

Secured World Switching (SWS) is a module running in the secure world enforcing the security properties of guest's world switching. SWS interposes two types of switching: between one guest's VM_n and VM_s, as well as between a virtual machine and the hypervisor. In vTZ, these two types can be handled uniformly since the former is also handled by the hypervisor. To achieve complete interposition, SWS ensures that each switching will first trap to SWS itself.

Complete Interposition: On ARM architecture, there are two situations causing switching from a guest VM to the hypervisor. One is *IRQ/FIQ interrupt* which is caused by hardware interrupts, the other is *guest sync exception* (hyp trap in ARM32), which is caused by any trapping instructions (like *smc*, co-processor accessing, hypercall, etc.) or data abort (like stage-2 translation table abort). In both situations, switching is caused by exception. Hence, CFLock can be used to enforce that the control flow will eventually be transferred to SWS.

If the hypervisor needs to switch to a guest, it must change the current exception level from the hyp mode to kernel mode. There are three methods for the hypervisor to do so: by executing *eret* instruction, by executing *movs pc, lr* instruction, or directly setting the exception level (e.g., by executing *CPS* instruction); In order to enforce a single exit point, SWS requires the hypervisor to remove all these instructions and replace them with corresponding invocations to SWS. Thus, SWS ensures that its interposition will be non-bypassable for each control transfer between guest VMs and the hypervisor.

4.4 CIEE: Constrained Isolated Execution Environment

CIEE is an environment in the hyp mode, which is used to implement some key logics that emulate the functionalities of TrustZone, e.g., virtualizing partition controller (see Section 5.3). Each CIEE has its own translation table, stack page and secure objects, and contains a piece of code with a strong control flow integrity as well as data flow integrity. Meanwhile, SMM and SWS will assign different capabilities to different CIEEs, so that one CIEE can only access its own secure objects. Each CIEE has different copies of secure objects for different guests, and one CIEE can only serve one caller guest at a time.

Enforce Security of CIEE: In order to protect CIEE from a compromised hypervisor and ensure that it cannot be bypassed, it must satisfy following requirements:

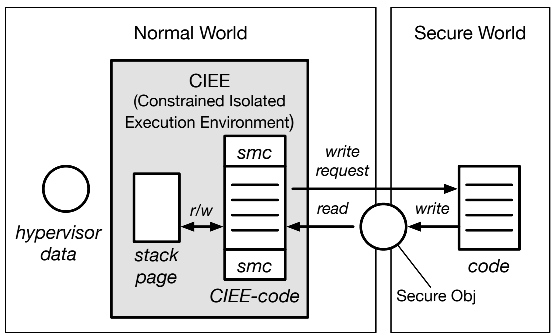

Figure 4: Constrained Isolated Execution Environment (CIEE): an execution environment which is fixed on memory location to identify itself to the secured modules running in the secure world. Its execution only depends on the stack page and secure objects. Interrupts are disabled when in CIEE.

1. **Single entry point**: It is illegal to jump to the middle of a CIEE.
2. **Run-to-completion**: Once starting to run, it must run to the completion without being interrupted.
3. **No dependence on the hypervisor's data**: Otherwise a compromised hypervisor can affect CIEE's execution.
4. **No data exposure to the hypervisor**: Otherwise a compromised hypervisor may tamper with CIEE's running states.
5. **Unforgeable to the secure world**: A CIEE needs to identify itself to the modules running in the secure world; otherwise the hypervisor may impersonate to be CIEE.

Figure 4 shows the design of *CIEE* in vTZ. Each CIEE's code is loaded to a fixed memory address during initialization. The secure world is aware of CIEE's metadata, which includes {*entry_addr, exit_addr*}, to meet the requirement-⑤. The code pages of CIEE are mapped as read-only by SMM to ensure the code integrity. By default, the code pages of CIEE are mapped as non-executable. The first and last instructions of a CIEE are always *smc*. After the first *smc* (on a different executable page) trapping to the secure world, vTZ will check the trapping address stored in *LR_mon* [4] and to identify the specific CIEE by the address. Then SMM will remap the corresponding CIEE's code body to be executable, and map stack pages as read/write. The remapping is done only on the current CPU core; thus on other cores the CIEE is still non-executable and its stack is not accessible. In this way, the execution must start from the first *smc*, and the requirement-① is satisfied.

vTZ will disable any interrupt before transferring control to a CIEE. The code in CIEE must be self-contained,

and will keep running till the last *smc* instruction. Thus, the requirement-② is met. When trapping due to the last *smc*, SMM will again remap the code body to non-executable and clean the stack page to meet requirement-④. There is no need for the hypervisor to access CIEE's code, secure objects or CIEE's stack page.

To further enforce the control flow integrity, protecting the code page alone is not enough. We also ensure that CIEE's code only depends on either local data in stack page or secure objects. The former is only mapped when CIEE is executed, and the latter is mapped as read-only in the hyp mode and can only be modified by invoking the secured modules. So that we can satisfy requirement-③, and hypervisor cannot tamper with CIEE's control flow.

Since a CIEE contains code which serves the guest or the hypervisor, vTZ enables a CIEE to write results back to them. The memory used to store results for a guest is marked as secure object, and the CIEE needs to ask the SMM to write it. The hypervisor's data is mapped to the CIEE, so that the CIEE can directly write results to the hypervisor's memory. For example, the CIEE for VM suspending (Section 5.4) could directly return the encrypted snapshot of a VM_s back to the hypervisor.

Privilege Isolation: CIEE is not in the TCB of vTZ. vTZ isolates the privilege of different CIEEs from two dimensions. First, one CIEE cannot access any sensitive data not belonging to it. This is enforced by SMM which ensures one CIEE's own secure object and stack page will never be mapped into other's address space. Second, one CIEE can only provide service to the current guest. One CIEE will have different secure objects for different guests. SWS can identify the current guest and then only allows a CIEE to access current guest's secure objects.

5 TrustZone Virtualization

In this section, we present how to virtualize TrustZone features listed in Table 1 by using the four mechanisms described in last section. We also demonstrate the process of suspending and resuming a guest with its guest TEE.

5.1 Virtualizing Secure Boot

Secure boot is used to ensure the integrity of booting. The booting process of a TrustZone-enabled device includes following steps: 1) Loading a bootloader from ROM, which is tamper resistant. 2) The bootloader initializes the secure world and loads a TEE-kernel to memory. 3) The TEE-kernel does a full initialization of the secure world, including the secure world translation table, vector table and so on. 4) The TEE-kernel switches to the normal world and executes a kernel-loader. 5) The kernel-loader loads a non-secure OS and runs it.

During the process, each time a loader loads a binary image, it will calculate the checksum of the image to verify its integrity. Meanwhile, the booting order is also fixed: the TEE-kernel is the first to run so that it can initialize the platform first. To virtualize the secure boot process, vTZ is required to enforce the following properties:

- **P-1.1**: *S/W must boot before N/W.*
- **P-1.2**: *Boot image of S/W must be checked.*
- **P-1.3**: *S/W cannot be replaced.*

The virtualized secure boot process of vTZ is shown in the top part of Figure 5. The hypervisor initializes the data structure and allocates memory for both guest VM_n and its corresponding VM_s, loads the TEE-kernel image and guest normal world OS image to the memory, respectively. Then the hypervisor will register the two VMs in the Secured World Switching (SWS) module. Since SWS controls all the world switches between the *hyp mode* and a VM, it can ensure that only registered VM can be executed. During registration, SWS first asks the Secured Memory Mapping (SMM) module to remove all the mapping of memory pages allocated to the guest from the hypervisor's translation table and checks the integrity of a guest's TEE-kernel. Then SWS creates a binding between the guest VM_n and VM_s by recording their VMID, and marks their context data as read-only to hypervisor. SMM will also initialize the stage-2 translation tables of these two VMs and set the VMID in the stage-2 translation table base register. So the **P-1.2** and **P-1.3** are enforced. The scheduling of VM is done by the hypervisor. SWS will ensure that the VM_s must run before the corresponding VM_n to enforce **P-1.1**.

5.2 Protecting CPU states

vTZ needs to enforce following properties to provide the same CPU states protection of TrustZone.

- **P-2.1**: *smc must switch to the correct world.*
- **P-2.2**: *Protect the integrity of N/W CPU states during switching.*
- **P-2.3**: *Protect S/W CPU states.*

SWS intercepts all the switching between a guest VM and the hypervisor, A switching includes saving states of the current VM, finding the next VM, and restoring its states. The states saving and restoring are done by SWS in the secure world, while the finding of next VM is done by the hypervisor, as shown in the bottom half of Figure 5. Then SWS can check the restored target VM

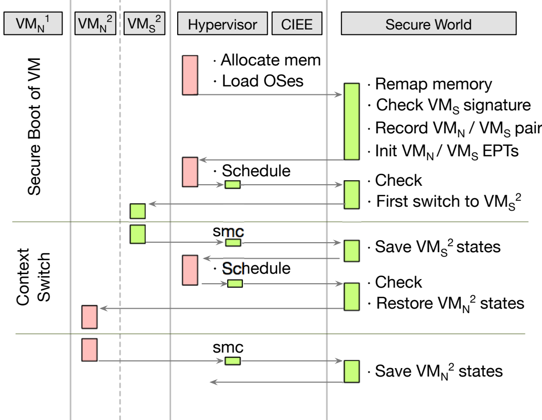

Figure 5: Boot and context switch process: Hypervisor is responsible to build VM for each guest. SWS verifies every guest before hypervisor can execute it, including initializing guest EPT and checking image integrity. Let hypervisor switch between VM_s and VM_n. SWS checks all entering to a VM.

to ensure **P-2.1** and **P-2.2** are satisfied. During execution, SWS also prevents the hypervisor from stealing or tampering with VM_s's context to achieve **P-2.3**. For example, if one VM is exited because of the scheduling, then its CPU states cannot be modified. Further, VM_s's system control registers also cannot be modified by the normal world hypervisor.

5.3 Virtualizing Resource Partitioning

TrustZone can split hardware resources to the normal world or the secure world. Three different resource partitions are provided, together with three different controllers which are used to configure the partition:

- **Memory partitioning**, which is configured by TrustZone Address Space Controller (*TZASC*).
- **Peripheral partitioning**, which is configured by TrustZone Protection Controller (*TZPC*).
- **Interrupt partitioning**, which is configured by General Interrupt Controller (*GIC*).

Once set as secure, the resource can only be accessed by the secure world. A secure interrupt must be injected to the secure world and will lead to a world switching if it happens in the normal world. All the three controllers can be used to repartition the resource only by the secure world.

It is needed for a guest to dynamically partition some critical virtual devices such as virtual Random Number Generator (vRNG), vGIC and so on. For example, a guest may only allow its guest TEE to configure the vGIC, or first initialize a vRNG in VM_s and then use it in VM_n. To support these requirements, vTZ provides the same semantic of resource partitioning as a real TrustZone, which includes the configuration of partitioning and the enforcement of partitioning.

Virtualizing Partitioning Controllers: Following two properties should be satisfied:

- **P-3.2**: *Only S/W can configure memory partition.*
- **P-4.4**: *Only S/W can partition interrupt/peripherals.*

The virtualization of partitioning configuration is done by the classic "trap and emulate" method. vTZ provides three virtual controllers (*vTZASC*, *vTZPC* and *vGIC*) for each guest. ARM only provides memory mapped I/O, all devices are operated by accessing their device memory region. By mapping all the three controllers' memory regions as read-only in each guest's stage-2 translation table, any write to them will cause a trap to the hypervisor. The CFLock enforces that the trap will be handled by a handler in a CIEE. The handler first checks whether the trap is raised by a VM_s, and will ignore it if not, which enforce **P-3.2** and **P-4.4**. The handler then invokes a corresponding controller emulator to do the configuration. The emulator runs in another CIEE and can only repartition for the guest who performs the write operation.

Secure Memory Partitioning: The following property is a fundamental one:

- **P-3.1**: *Only S/W can access secure memory.*

This property is enforced by the SMM module through the following policy: any guest's secure memory region can only be mapped in its VM_s but not any other VMs or the hypervisor.

Secure Device Partitioning: In secure device part, vTZ must enforce the following two properties:

- **P-4.2**: *N/W cannot access secure peripherals.*
- **P-4.3**: *Secure peripherals are trusted for S/W.*

We have implemented commonly used secure devices for existing TEE-kernel, like *TZASC*, *TZPC*, *GIC*, *uart*, *RTIC* and so on. We virtualize these devices for each guest by "trap and emulate". Since all ARM devices use memory mapped I/O, access to a virtual secure device can be easily trapped by controlling stage-2 translation table. When a virtual secure device is accessed, the CPU will get trapped. The trap will be handled by a corresponding emulator, which runs in a CIEE. The device states are stored as secure objects belonging to the CIEE. vTZ keeps different copies of devices state for different guests, so that the emulator can virtualize the secure device for different guests. If the device is marked as a secure peripheral by one guest, the emulator will enforce

that it cannot be accessed by this guest's VM_n, so the **P-4.2** is enforced. One guest's configuration will not influence others. The entire process is also protected by CFLock, so that all the operations on virtual secure device will eventually be handled by the emulator in CIEE, and **P-4.3** is satisfied.

Secure Interrupt Partitioning: For interrupts, vTZ needs to ensure the following property:

- **P-4.1**: *Secure interrupts must be injected into S/W.*

Each time when an interrupt happens, it will be handled by a secure interrupt dispatcher. The dispatcher can decide whether the interrupt is secure or not according to a virtual interrupt partition list which is managed by trusted virtual GIC. The CFLock enforces that the dispatcher cannot be bypassed and the CIEE ensures the security of it. These work together to enforce **P-4.1**.

5.4 Supporting TEE Management Operations

Suspending and resuming are two important operations of virtualization. vTZ enforces the correctness and security of these operations, as shown in Figure 6.

Guest TEE Suspension/Resumption: The hypervisor needs to ask a suspend CIEE to save all secure states of one guest. The suspend CIEE will first invoke the SWS to encrypt and hash guest's vTZ related data, including CPU states, memory partition, interrupt partition, device partition, etc. Then it asks the SMM to encrypt and hash all guest's secure pages and share them with the hypervisor. The hypervisor stores all these encrypted data and hash value together with guest VM_n's states into a snapshot file. Resuming process is similar with that for suspending but in the opposite direction.

6 Performance Evaluation

We evaluate the performance of vTZ on both a Hikey ARMv8 development board (64-bit) and an Exynos Cortex ARMv7 development board (32-bit). The Hikey board enables eight 1.2 GHz cores together with 2GB memory. The Exynos board enables one 1.7 GHz core and 1GB memory. We use Xen 4.4 [13] as the hypervisor and Linux 4.1 as the guest normal world kernel and Dom0 kernel. For guest TEE-kernel, We ported two widely used TEE-kernels, namely seL4 [9] and OP-TEE [6], to vTZ. On the Exynos board, each guest together with Dom0 has one virtual CPU. On the Hikey board, each guest, as well as Dom0, has one virtual CPU and each virtual CPU is pinned on one physical CPU. We leverage ARM's performance monitor unit (PMU) to measure the clock cycles.

Running Existing TEE-kernel: Running a TEE-kernel on vTZ needs three steps. First, vTZ leverages Xen's multi-boot loader to load TEE-kernel's image, so we need to add a multi-boot header in the image. Second, we add a new description file (e.g., platform_config.h in OP-TEE) to describe the memory layout of our guest TEE. Finally, since vTZ already provides a secure context switch, we remove the context switching logic in TEE-kernel.

6.1 Micro-benchmark

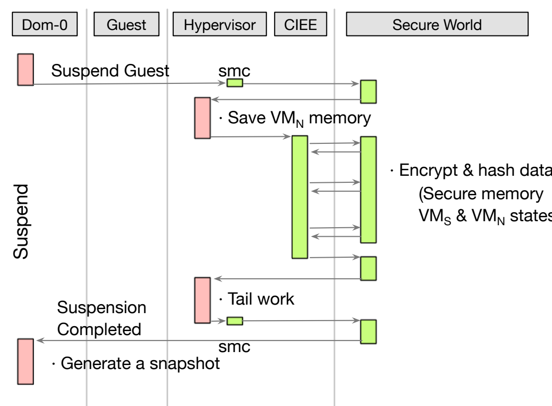
World Switch Overhead: For the physical TrustZone, the time of switching between two worlds is about 17,840 cycles on Exynos board and 1,294 cycles on Hikey board. The cost includes context saving and restoring in the monitor mode (shown in Table 2). In vTZ, one switching between guest's normal world and guest TEE is about 34,164 cycles on Exynos and 6,837 cycles on Hikey. The overhead is still acceptable since world switching happens rarely and thus has little effect on TrustZone-based applications.

Secure Configuration Overhead: A TEE-kernel usually configures system resource partitioning during initialization or occasional run-time protection. Table 2 shows the overhead of these configurations in vTZ. The native value is performing configuration by hardware in the real secure world. Since HiSilicon, the vender of hikey's SoC, does not publish the register mapping of *TZASC* or *TZPC*, the native time of Hikey is not provided. Same as world switching, secure configuration operations happen rarely, so the overhead will have limited effect on the whole system.

Run-Time Integrity Checker: Besides virtualizing secure devices like *vTZASC*, *vTZPC* and *virtual GIC* (virtual devices used to perform resource partition), we also virtualize and use Run-Time Integrity Checker (RTIC) to evaluate the overhead of vTZ's virtual secure devices. *RTIC* is a commonly used security-related device which can calculate hash values of at most five different memory regions. TEE-kernel can leverage it to detect whether some memory regions have been tampered with. We leverage RTIC to perform SHA1 hashing on five memory regions with sizes from 1K to 128K. Figure 7(a) shows the overhead of *vRTIC* (virtual RTIC) emulated by vTZ in CIEE. It only incurs overhead from 0.3% to 4%.

Table 2: Single operation overhead (unit: *cycle*). Native means real TrustZone and vTZ is our system.

	Native (ARMv7)	**vTZ** (ARMv7)	**Native** (ARMv8)	**vTZ** (ARMv8)
World Switching	17840	34164	1294	6837
Memory Partition	5798	10341	n/a	7918
Device Partition	1886	10395	n/a	7289
Interrupt Partition	1073	4031	755	2903



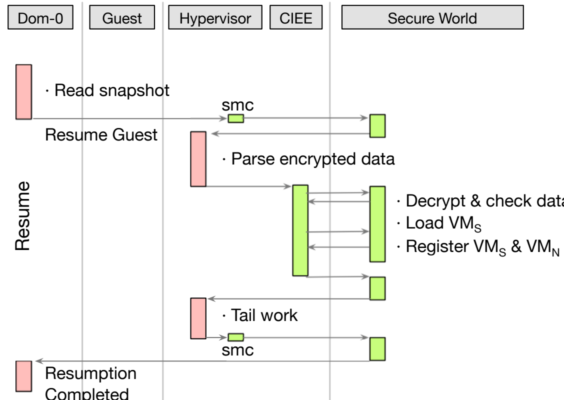


Figure 6: TEE suspension and resumption: During suspension operation, all VM_s's memory and CPU states are encrypted in secure world, and a hash value is computed as well. During resumption operation, such states are decrypted in secure world and SWS will then verify the integrity.

6.2 Application Overhead

Single Guest: We test four real applications (ccrypt, mcrypt, GnuPG and GoHttp) and compare them with original Xen on ARMv7 and ARMv8 platform. We use these applications to encrypt/transfer file about 1KB, and protect the encryption logic in real secure world/guest TEE. The application/guest VM is pinned on one physical core in native environment/virtualization environment, respectively. Figure 7(b) and Figure 7(c) show the overhead. Our system has little overhead compared with original Xen on both ARMv7 and ARMv8 platform.

Multi-Guest: We compare the concurrent performance of vTZ with native environment, real TrustZone and original virtualization environment (Xen). The GoHttp server is used to do the evaluation, and we protect its encryption logic in secure world/guest TEE. In native environment (including protection with TrustZone), each GoHttp server runs as a normal process. In virtualization environment (including protected by vTZ), each of them runs in one guest VM. The client, which sends the https request, runs in the same guest with the server to bypass the network overhead. Each client downloads a 20M file from the server. We do not evaluate more applications concurrently because the memory on the board limits the number of VMs. The results are shown in Figure 8.

On ARMv7 platform, which only has one core enabled, the virtualization (Xen hypervisor) itself brings non-negligible (about 40%) performance slowdown. While on ARMv8 platform, the overhead is remitted with the benefit of 8 enabled cores. The overhead of virtualization becomes larger compared with the single case because that the GoHttp server transfers a big file (20 MB) for each request. Such transferring time is larger than Xen scheduler's time slices (30ms), and then the scheduler will influence the performance. Finally, vTZ has about a 5% performance slowdown compared with original Xen on ARMv8 implementation, and less than 30% performance slowdown compared with native environment.

6.3 Server Application Overhead

We also evaluate two widely used server applications, MongoDB [5] and Apache [3] on Hikey board. Same as the multi-guest evaluation, we run applications on four different environments. Meanwhile, the clients are executed together with the server to bypass the network overhead. One difference is that the guest has eight virtual cores instead of one.

Figure 9(a) shows the insert operation throughput of MongoDB. The client continually inserts object to the server. We evaluate the throughput with different sizes of objects. The result shows that vTZ has little overhead compared with virtualization environment. For Apache (shown in Figure 9(b)), we evaluate the downloading throughput by downloading a file (size is 100MB) from the server with https protocol. The result shows that using virtual TrustZone caused less than 5% overhead in virtualization environment.

7 Security Analysis

In this section, we assume a strong adversary who can directly boot a malicious guest (including a malicious guest TEE) and even compromise the hypervisor.

7.1 Breaking TrustZone Properties

Booting Protection: A compromised hypervisor can tamper with the system image loaded in guest TEE. The Secured World Switching (SWS) module will check the integrity of the image before execution, and only allow the hypervisor to enter a registered guest TEE. Meanwhile, the attacker may want to boot a guest VM_n before

its guest VM_s, and then tries to bypass the security configuration. SWS will defend against it by ensuring that guest TEE must be executed first.

CPU States Protection: When a guest switches between its two worlds, a compromised hypervisor may switch to another malicious world. SWS will check every world switch operation issued by guest and ensure that the target world must be executed thereafter. This will also forbid the hypervisor to ignore the world switch operation or to make one guest's two worlds being executed at the same time. During the world switch, the attacker may also try to tamper with the CPU states. Since SWS is responsible for saving and restoring each VM's CPU states and synchronizing general registers between guest's two worlds, it will check and refuse the tampering.

Memory Protection: A compromised hypervisor may want to map one guest's secure memory to a compromised VM or the hypervisor itself. Secured Memory Mapping (SMM) prevents these malicious behaviors by controlling and checking all the mapping to the physical address and ensuring that one guest's secure memory can only be mapped to its guest TEE.

vTZ allows a guest TEE to dynamically repartition its memory through a virtual memory configuration device, which invokes SMM to update the security policy. A compromised hypervisor may try to configure a guest's secure memory to normal memory by sending a faked request to SMM or the configuration device. In vTZ, SMM will only handle requests from the virtual configuration device, which can be identified by its CIEE entry address, and will deny the fake requests from the hypervisor. Meanwhile, the configuration device also verifies whether the request is from one guest TEE.

Peripheral Protection: vTZ enables guest TEE to configure interrupts as secure or normal. A compromised hypervisor may try to inject it into a compromised VM. CFLock ensures all the interrupts will first be handled in a CIEE which identifies the type of interrupt and injects it to guest TEE. The interrupt will be later handled by the hypervisor if it is non-secure. The hypervisor may also provide some malicious virtual devices to guest TEE. Guest TEE only trusts the virtual devices provided by vTZ, and all other devices must be treated as untrusted.

7.2 Hacking vTZ

Tampering with System Code: During system initialization, the attacker may try to modify the code of hyper-

visor, CIEEs or even the secured modules in real secure world. The secure boot technology provided by hardware enables vTZ to ensure the integrity of all secured modules, hypervisor and all CIEEs during system boot. After that, the SMM will ensure that all codes in hyp mode are write-protected. Meanwhile, the SMM never allows mapping any new executable memory in the hyp mode after system boot to forbid code injection into the hyp mode. A benign hypervisor also does not need to load code dynamically.

Code-reuse or Return-to-guest Attacks: Attacker may try to reuse code of the hypervisor or let the hypervisor jump to some code region of a guest VM to execute critical instructions (e.g., switching translation table) and bypass the SMM. ARM has several ISAs (e.g., aarch64, aarch32), the instructions of them are fix-byte aligned. vTZ ensures there is no key instruction under any ISAs in the hyp mode's text section, so that there is no ROP gadget in the code to reuse. Meanwhile, the SMM ensures that only the code of the hypervisor can be mapped as executable in the hyp mode, thus return-to-guest attack also can be prevented.

DMA Attack: An attacker may try to access guest secure memory or inject code into hypervisor's memory by leveraging Direct Memory Access (DMA). vTZ defends this attack by controlling System Memory Management Unit (SMMU), which performs address translation for DMA. SMMU is controlled by certain memory mapped registers. It is ensured that these memory regions are only mapped in the secure world. After exclusively controlling the SMMU, we can ensure that all DMAs cannot access guest's secure memory, hypervisor's text section or CIEE's memory.

Debugging Attack: The attacker may also want to bypass the SWS or CFLock by setting debug checkpoint on the *smc* instruction. Then she can perform some operations before switching to SWS or CFLock works. vTZ controls the entry points of all limited exception handlers, and the debug procedure is also under control. Thus, the debug point on *smc* instruction in the hyp mode will trigger an infinite iteration, since the first instruction a debug exception handler executed is also *smc*. This is a kind of DoS attack and is not considered in this paper.

Security of CIEEs: While CIEE contains some logic which provides critical services for guest TEE, e.g., virtualizing TZPC (TrustZone Protection Controller), vTZ still excludes it from the system TCB. Although there is work which can verify some small piece of privileged code (e.g., Jitk [65]), vTZ currently does not formally verify the code in CIEE. Hence, even all CIEEs are small and virtuous, they may still contain bugs. For example, the attacker first compromises the CIEE responsible for virtualizing memory configuration device. Then she tries to configure other guest's memory partition or compromise other CIEEs. vTZ prevents these attacks by constraining a CIEE's abilities. First, SWS can identify current guest TEE and SMM will forbid a CIEE to access any data belonging to other guests. Second, SMM ensures that different CIEEs have different memory mapping and can only access their own secure objects.

7.3 Security Limitations

As described in the threat model, vTZ does not consider hardware-based attacks, e.g., the cold-boot attack, or side-channel attacks. Meanwhile, vTZ can not prevent DoS attacks, e.g., a hypervisor may never execute a guest TEE. But note that vTZ can ensure that if a guest VM uses *smc* instruction to switch to its guest TEE, such switching cannot be ignored.

TEE-kernels may have bugs [61, 62, 24]. Such bugs enable an attacker to directly get data from a guest TEE or even to get control of it. Defending against these attacks is not the goal of vTZ, as the real TrustZone also cannot handle it. However, vTZ does ensure that a compromised TEE-kernel can only affect its corresponding guest while cannot bypass the isolation or attack other TEE-kernels. In all, vTZ aims to achieve the same security level with TrustZone, but no more.

8 Related Work

ARM-based servers are increasingly getting more attentions [50, 51, 25]. It can be expected that virtualization, as one of the most important enabling technologies in the cloud, will also be prevalent on ARM-based servers. There have already been many TrustZone based systems [55, 59, 54, 21, 32, 14], as mentioned in Section 2.3. Many of these designs are not specific for mobile devices, which can be used on ARM servers. vTZ paves the way for the use of TrustZone guarantees in similar environments.

Virtualization of Security Hardware: Similar as TrustZone, Trusted Platform Module (TPM) is a hardware extension for security. vTPM [48] makes TPM functions available to virtual machines by virtualizing the TPM hardware to multiple virtual vTPM instances, which supports suspending and resuming operations. vTZ shares a similar goal with vTPM but is harder since the interaction between the secure world and the normal world is much more complex than TPM. fTPM [49] presents a design and implementation of a TrustZone-based TPM-2.0, which is a pure software solution without the need of a real TPM chip. It can be seen as an application of TrustZone, and by using vTZ fTPM can now inherently support virtualization as well.

Other Hardware-based TEE: Intel's Software Guard eXtension (SGX) [10] offers a strongly isolated execu-

tion environment that can defend against physical attacks. AMD has also announced two security features [34] named Secure Memory Encryption (SME) for defending against physical attack and Secure Encrypted Virtualization (SEV) for protecting VM against hypervisor. Unlike TrustZone, an SGX-TEE does not have higher privilege and can only run in user mode, which makes it not suitable for certain scenarios like security monitoring. Meanwhile, these technologies focus more on memory isolation while TrustZone can also support peripheral partitioning (e.g., random number generator, trust timer, secure co-processors, etc.) Further, currently on ARM platform there is no extension like SGX or SME/SEV while TrustZone has already been widely deployed and has various applications.

Software-based TEE: There are many types of TEE that are based on hypervisor [68, 56, 26, 67, 44, 41, 46], or based on Linux kernel [31, 22, 27], or based on compiler [30, 29], to name a few. These researches are orthogonal to our work. vTZ does not try to provide a new abstraction of TEE but aims to virtualize the existing TrustZone hardware and let all the guests have their own TEE without trusting a large TCB.

9 Hardware Design Discussion

In this section we discuss how to modify TrustZone hardware to support virtualization. One design choice is adding virtualization extension (e.g., hyp mode) in the secure world. After that, software developers can run a TEE hypervisor inside the secure world to virtualize multiple TEEs for different guests (similar with Design-1 in Section 3.2). Although this design simplifies the implementation of the TEE hypervisor, the whole system's security still depends on the interaction between two hypervisors.

Another design is to make the hypervisor unware of the TrustZone. When a virtual machine executes a *smc* instruction, it will directly switch from the normal world to secure world or vice versa, without trapping to the hypervisor. The CPU states are protected by the hardware as before. Both the secure world and the normal world share the same guest physical address space, so that the secure world can still access all the memory of its VM, but cannot access other VM's memory. All the hardware resource partition devices (e.g., TZASC) are virtualized (e.g., by trap-and-emulate) for multiplexing. For example, a vTZASC can only be configured by a VM when the VM is running in its secure world. In this design, only one hypervisor is needed. The secure world and normal world runs as a single VM, which also simplifies the scheduling of VCPU.

10 Conclusion

This paper described vTZ, a design aiming at virtualizing TrustZone in ARM architecture. vTZ provides each guest with an isolated guest TEE, which has the same functionalities and security with the physical secure world. vTZ uses a few modules running in the secure world to securely interpose memory mapping, world switching and device accesses. vTZ further leverages Constrained Isolated Execution Environments (CIEEs) in the normal world to virtualize the functionality of TrustZone. vTZ's TCB only contains the secured modules in the secure world together with system's bootloader. The performance overhead incurred by vTZ is shown to be small.

Inferring Fine-grained Control Flow Inside SGX Enclaves with Branch Shadowing

* *Microsoft Research*

Abstract

Intel has introduced a hardware-based trusted execution environment, Intel Software Guard Extensions (SGX), that provides a secure, isolated execution environment, or enclave, for a user program without trusting any underlying software (e.g., an operating system) or firmware. Researchers have demonstrated that SGX is vulnerable to a page-fault-based attack. However, the attack only reveals page-level memory accesses within an enclave.

In this paper, we explore a new, yet critical, side-channel attack, *branch shadowing*, that reveals fine-grained control flows (branch granularity) in an enclave. The root cause of this attack is that SGX does not clear branch history when switching from enclave to non-enclave mode, leaving fine-grained traces for the outside world to observe, which gives rise to a branch-prediction side channel. However, exploiting this channel in practice is challenging because 1) measuring branch execution time is too noisy for distinguishing fine-grained control-flow changes and 2) pausing an enclave right after it has executed the code block we target requires sophisticated control. To overcome these challenges, we develop two novel exploitation techniques: 1) a last branch record (LBR)-based history-inferring technique and 2) an advanced programmable interrupt controller (APIC)-based technique to control the execution of an enclave in a fine-grained manner. An evaluation against RSA shows that our attack infers each private key bit with 99.8% accuracy. Finally, we thoroughly study the feasibility of hardware-based solutions (i.e., branch history flushing) and propose a software-based approach that mitigates the attack.

1 Introduction

Establishing a trusted execution environment (TEE) is one of the most important security requirements, especially in a hostile computing platform such as a public cloud or a possibly compromised operating system (OS). When we want to run security-sensitive applications (e.g., processing financial or health data) in the public cloud, we need either to fully trust the operator, which is problematic [16], or encrypt all data before uploading them to the cloud and perform computations directly on the encrypted data. The latter can be based on fully homomorphic encryption, which is still slow [42], or on property-preserving encryption, which is weak [17, 38, 43]. Even when we use a private cloud or personal workstation, similar problems exist because no one can ensure that the underlying OS is robust against attacks given its huge code base and high complexity [2, 18, 23, 28, 36, 54]. Since the OS, in principle, is a part of the trusted computing base of a computing platform, by compromising it, an attacker can fully control any application running on the platform.

Industry has been actively proposing hardware-based techniques, such as the Trusted Platform Module (TPM) [56], ARM TrustZone [4], and Intel Software Guard Extension (SGX) [24], that support TEEs. Specifically, Intel SGX is receiving significant attention because of its recent availability and applicability. All Intel Skylake and Kaby Lake CPUs support Intel SGX, and processes secured by Intel SGX (i.e., processes running inside an *enclave*) can use almost every unprivileged CPU instruction without restrictions. To the extent that we can trust the hardware vendors (i.e., if no hardware backdoor exists [61]), it is believed that hardware-based TEEs are secure.

Unfortunately, recent studies [50, 60] show that Intel SGX has a noise-free side channel—a *controlled-channel attack*. SGX allows an OS to fully control the page table of an enclave process; that is, an OS can map or unmap arbitrary memory pages of the enclave. This ability enables a malicious OS to know exactly which memory pages a victim enclave attempts to access by monitoring page faults. Unlike previous side channels, such as cache-timing channels, the page-fault side channel is deterministic; that is, it has no measurement noise.

The controlled-channel attack has a limitation: It reveals only coarse-grained, page-level access patterns. Fur-

ther, researchers have recently proposed countermeasures against the attack such as balanced-execution-based design [50] and user-space page-fault detection [10, 49, 50]. However, these methods prevent only the page-level attack; hence, a fine-grained side-channel attack, if it exists, would easily bypass them.

We have thoroughly examined Intel SGX to determine whether it has a critical side channel that reveals fine-grained information (i.e., finer than page-level granularity) and is robust against noise. One key observation is that Intel SGX *leaves branch history uncleared during enclave mode switches*. Knowing the branch history (i.e., taken or not-taken branches) is critical because it reveals the fine-grained execution traces of a process in terms of basic blocks. To avoid such problems, Intel SGX hides all performance-related events (e.g., branch history and cache hit/miss) inside an enclave from hardware performance counters, including precise event-based sampling (PEBS), last branch record (LBR), and Intel Processor Trace (PT), which is known as anti side-channel interference (ASCI) [24]. Hence, an OS is unable to directly monitor and manipulate the branch history of enclave processes. However, since Intel SGX does not clear the branch history, an attacker who controls the OS can infer the fine-grained execution traces of the enclave through a branch-prediction side channel [3, 12, 13].

The branch-prediction side-channel attack aims to recognize whether the history of a targeted branch instruction is stored in a CPU-internal branch-prediction buffer, that is, a branch target buffer (BTB). The BTB is shared between an enclave and its underlying OS. Taking advantage of the fact that the BTB uses only the lowest 31 address bits (§2.2), the attacker can introduce set conflicts by positioning a shadow branch instruction that maps to the same BTB entry as a targeted branch instruction (§6.2). After that, the attacker can probe the shared BTB entry by executing the shadow branch instruction and determine whether the targeted branch instruction has been taken based on the execution time (§3). Several researchers exploited this side channel to infer cryptographic keys [3], create a covert channel [12], and break address space layout randomization (ASLR) [13].

This attack, however, is difficult to conduct in practice because of the following reasons. First, an attacker cannot easily guess the address of a branch instruction and manipulate the addresses of its branch targets because of ASLR. Second, since the capacity of a BTB is limited, entries can be easily overwritten by other branch instructions before an attacker probes them. Third, timing measurements of the branch misprediction penalty suffer from high levels of noise (§3.3). In summary, an attacker should have 1) a permission to freely access or manipulate the virtual address space, 2) access to the BTB anytime before it is overwritten, and 3) a method that recognizes branch misprediction with negligible (or no) noise.

In this paper, we present a new branch-prediction side-channel attack, *branch shadowing*, that accurately infers the fine-grained control flows of an enclave without noise (to identify conditional and indirect branches) or with negligible noise (to identify unconditional branches). A malicious OS can easily manipulate the virtual address space of an enclave process, so that it is easy to create shadowed branch instructions colliding with target branch instructions in an enclave. To minimize the measurement noise, we identify alternative approaches, including Intel PT and LBR, that are more precise than using `RDTSC` (§3.3). More important, we find that the LBR in a Skylake CPU allows us to obtain the most accurate information for branch shadowing because it reports whether each conditional or indirect branch instruction is correctly predicted or mispredicted. That is, we can *exactly* know the prediction and misprediction of conditional and indirect branches (§3.3, §3.5). Furthermore, the LBR in a Skylake CPU reports elapsed core cycles between LBR entry updates, which are very stable according to our measurements (§3.3). By using this information, we can precisely infer the execution of an unconditional branch (§3.4).

Precise execution control and frequent branch history probing are other important requirements for branch shadowing. To achieve these goals, we manipulate the frequency of the local advanced programmable interrupt controller (APIC) timer as frequently as possible and make the timer interrupt code perform branch shadowing. Further, we selectively disable the CPU cache when a more precise attack is needed (§3.6).

We evaluated branch shadowing against an RSA implementation in mbed TLS (§4). When attacking sliding-window RSA-1024 decryption, we successfully inferred each bit of an RSA private key with 99.8% accuracy. Further, the attack recovered 66% of the private key bits by running the decryption *only once*, unlike existing cache-timing attacks, which usually demand several hundreds to several tens of thousands of iterations [20, 35, 65].

Finally, we suggest hardware- and software-based countermeasures against branch shadowing that flush branch states during enclave mode switches and utilize indirect branches with multiple targets, respectively (§5).

The contributions of this paper are as follows:

- **Fine-grained attack.** We demonstrate that branch shadowing successfully identifies fine-grained control flow information inside an enclave in terms of basic blocks, unlike the state-of-the-art controlled-channel attack, which reveals only page-level accesses.
- **Precise attack.** We make branch shadowing very precise by 1) exploiting Intel PT and LBR to correctly identify branch history and 2) adjusting the

local APIC timer to precisely control the execution inside an enclave. We can deterministically know whether a target branch was taken without noise for conditional and indirect branches and with negligible noise for unconditional branches.

- **Countermeasures.** We design proof-of-concept hardware- and software-based countermeasures against the attack and evaluate them.

The remainder of this paper is organized as follows. §2 explains SGX and other CPU features our attack exploits. §3 and §4 describe our attack and evaluate it. §5 proposes our countermeasures. §6 discusses our attack's limitations and considers some advanced attacks. §7 introduces related work and §8 concludes this paper.

2 Background

We explain Intel SGX and two other processor features, branch prediction and LBR, closely related to our attack.

2.1 Intel SGX

An Intel CPU supports a hardware-based TEE through a security extension, Intel SGX. SGX provides a set of instructions to allow an application to instantiate an *enclave* that secures the code and data inside it against privileged software such as an OS or a hypervisor, hardware firmware, and even hardware units except for the CPU. To provide such protection, SGX enforces a strict memory access mechanism: allow only enclave code to access memory of the same enclave. In addition, SGX leverages an on-chip memory-encryption engine that encrypts enclave content before writing it into physical memory and decrypts the encrypted content only as it enters the CPU package during enclave execution or enclave mode.

Enclave context switch. To support context switching between enclave and non-enclave mode, SGX provides instructions such as `EENTER`, which starts enclave execution, and `EEXIT`, which terminates enclave execution. Also, `ERESUME` resumes enclave execution after an asynchronous enclave exit (AEX) occurs. The causes of an AEX include exceptions and interrupts. During a context switch, SGX conducts a series of checks and actions to ensure security, e.g., flushing the translation lookaside buffer (TLB). However, we observe that SGX does not clear all cached system state such as branch history (§3).

2.2 Branch Prediction

Branch prediction is one of the most important features of modern pipelined processors. At a high level, an instruction pipeline consists of four major stages: fetch, decode, execute, and write-back. At any given time, there are a number of instructions in-flight in the pipeline. Processors exploit instruction-level parallelism and out-of-order execution to maximize the throughput while still maintaining in-order retirement of instructions. Branch instructions can severely reduce instruction throughput since the processor cannot execute past the branch until the branch's target and outcome are determined. Unless mitigated, branches would lead to pipeline stalls, also known as bubbles. Hence, modern processors use a branch prediction unit (BPU) to *predict* branch outcomes and branch targets. While the BPU increases throughput in general, it is worth noting that in the case of a misprediction, there is a pretty high penalty because the processor needs to clear the pipeline and roll back any speculative execution results. This is why Intel provides a dedicated hardware feature (the LBR) to profile branch execution (§2.3).

Branch and branch target prediction. *Branch prediction* is a procedure to predict the next instruction of a conditional branch by guessing whether it will be taken. *Branch target prediction* is a procedure to predict and fetch the target instruction of a branch before executing it. For branch target prediction, modern processors have the BTB to store the computed target addresses of taken branch instructions and fetch them when the corresponding branch instructions are predicted as taken.

BTB structure and partial tag hit. The BTB is an associative structure that resembles a cache. Address bits are used to compute the set index and tag fields. The number of bits used for set index is determined by the size of the BTB. Unlike a cache that uses all the remaining address bits for the tag, the BTB uses a subset of the remaining bits for the tag (i.e., a partial tag). For example, in a 64-bit address space, if ADDR[11:0] is used for index, instead of using ADDR[63:12] for a tag, only a partial number of bits such as ADDR[31:12] is used as the tag. The reasons for this choice are as follows: First, compared to a data cache, the BTB's size is very small, and the overhead of complete tags can be very high. Second, the higher-order bits typically tend to be the same within a program. Third, unlike a cache, which needs to maintain an accurate microarchitectural state, the BTB is just a predictor. Even if a partial tag hit results in a false BTB hit, the correct target will be computed at the execution stage and the pipeline will roll back if the prediction is wrong (i.e., it affects only performance, not correctness.)

Static and dynamic branch prediction. *Static branch prediction* is a default rule for predicting the next instruction after a branch instruction when there is no history [25]. First, the processor predicts that a forward conditional branch—a conditional branch whose target address is higher than itself—will *not be taken*, which means the next instruction will be directly fetched (i.e., a fall-through path). Second, the processor predicts that a backward conditional branch—a conditional branch whose target address is lower than itself—will *be taken*; that is, the specified target will be fetched. Third, the processor predicts that an indirect branch will *not be taken*, similar to the forward conditional branch case. Fourth,

the processor predicts that an unconditional branch will *be taken*, similar to the backward conditional branch case. In contrast, when a branch has a history in the BTB, the processor will predict the next instruction according to the history. This procedure is known as *dynamic branch prediction*.

In this paper, we exploit these two conditional branch behaviors to infer the control flow of a victim process running inside Intel SGX (§3).

2.3 Last Branch Record

The LBR is a new feature in Intel CPUs that logs information about recently *taken* branches (i.e., omitting information about not-taken branches) without any performance degradation, as it is separated from the instruction pipeline [26, 32, 33]. In Skylake CPUs, the LBR stores the information of up to 32 recent branches, including the address of a branch instruction (from), the target address (to), whether the branch direction or branch target was mispredicted (it does not independently report these two mispredictions), and the elapsed core cycles between LBR entry updates (also known as the timed LBR). Without filtering, the LBR records all kinds of branches, including function calls, function returns, indirect branches, and conditional branches. Also, the LBR can selectively record branches taken in user space, kernel space, or both.

Since the LBR reveals detailed information of recently taken branches, an attacker may be able to know the fine-grained control flows of an enclave process if the attacker can directly use the LBR against it, though he or she still needs mechanisms to handle not-taken branches and the limited capacity of the LBR. Unfortunately for the attacker and fortunately for the victim, an enclave does not report its branch executions to the LBR unless it is in a debug mode [24] to prevent such an attack. However, in §3, we show how an attacker can *indirectly* use the LBR against an enclave process while handling not-taken branches and overcoming the LBR capacity limitation.

3 Branch Shadowing Attacks

We explain the branch shadowing attack, which can infer the fine-grained control flow information of an enclave. We first introduce our threat model and depict how we can attack three types of branches: conditional, unconditional, and indirect branches. Then, we describe our approach to synchronizing the victim and the attack code in terms of execution time and memory address space.

3.1 Threat Model

We explain our threat model, which is based on the original threat model of Intel SGX and the controlled-channel attack [60]: an attacker has compromised the operating system and exploits it to attack a target enclave program.

First, the attacker knows the possible control flows of a target enclave program (i.e., a sequence of branch instructions and their targets) by statically or dynamically analyzing its source code or binary. This is consistent with the important use case of running unmodified legacy code inside enclaves [5,6,51,57]. Unobservable code (e.g., self-modifying code and code from remote servers) is outside the scope of our attack. Also, the attacker can map the target enclave program into specific memory addresses to designate the locations of each branch instruction and its target address. Self-paging [22] and live re-randomization of address-space layout [15] inside an enclave are outside the scope of our attack.

Second, the attacker infers which portion of code the target enclave runs via observable events, e.g., calling functions outside an enclave and page faults. The attacker uses this information to synchronize the execution of the target code with the branch shadow code (§3.8).

Third, the attacker interrupts the execution of the target enclave as frequently as possible to run the branch shadow code. This can be done by manipulating a local APIC timer and/or disabling the CPU cache (§3.6).

Fourth, the attacker recognizes the shadow code's branch predictions and mispredictions by monitoring hardware performance counters (e.g., the LBR) or measuring branch misprediction penalty [3, 12, 13].

Last, the attacker prevents the target enclave from accessing a reliable, high-resolution time source to avoid the detection of attacks because of slowdown. Probing the target enclave for every interrupt or page fault slows the enclave down such that the attacker needs to hide it. SGX version 1 already satisfies such a requirement, as it disallows `RDTSC`. For SGX version 2 (not yet released), the attacker may need to manipulate model-specific registers (MSRs) to hook `RDTSC`. Although the target enclave could rely on an external time source, it is also unreliable because of the network delay and overhead. Further, the attacker can intentionally drop or delay such packets.

3.2 Overview

The branch shadowing attack aims to obtain the fine-grained control flow of an enclave program by 1) knowing whether a branch instruction has been taken and 2) inferring the target address of the taken branch. To achieve this goal, an attacker first needs to analyze the source code and/or binary of a victim enclave program to find all branches and their target addresses. Next, the attacker writes shadow code for a set of branches to probe their branch history, which is similar to Evtyushkin et al.'s attack using the BTB [13]. Since using the BTB and BPU alone suffers from significant noise, branch shadowing exploits the LBR, which allows the attacker to precisely identify the states of all branch types (§3.3, §3.4, §3.5). Because of the size limitations of the BTB, BPU, and LBR, the branch shadowing attack has to synchronize the execution of the victim code and the shadow code in terms of execution time and memory address space. We ma-

```
1 if (a != 0) {
2   ++b;
3   ...
4 }
5 else {
6   --b;
7   ...
8 }
9 a = b;
10 ...
```

(a) Victim code executed inside an enclave. According to the value of a, either if-block or else-block is executed.

```
1  ⋆ if (c != c) {
2      nop; // never executed
3      ...
4    }
5  ⋆ else {
6  ⋆   nop; // execution
7  ⋆   ...
8  ⋆ }
9  ⋆ nop;
10 ⋆ ...
```

(b) Shadow code aligned with **(a)**. The BPU predicts which block will be executed according to the branch history of **(a)**.

Figure 1: Shadow code (b) against a victim's conditional branch (a). The execution time (i.e., running [1, 5-10], marked with ⋆ in (b)) of the shadowing instance depends on the branching result (i.e., taken or not at [1] in (a)) of the victim instance.

nipulate the local APIC timer and the CPU cache (§3.6) to frequently interrupt an enclave process execution for synchronization, adjust virtual address space (§3.7), and run shadow code to find a function the enclave process is currently running or has just finished running (§3.8).

3.3 Conditional Branch Shadowing

We explain how an attacker can know whether a target conditional branch inside an enclave has been taken by shadowing its branch history. For a conditional branch, we focus on recognizing whether the branch prediction is correct because it reveals the result of a condition evaluation for `if` statement or loop. Note that, in this and later sections, we mainly focus on a *forward* conditional branch that will be predicted as not taken by a static branch prediction rule (§2.2). Attacking a backward conditional branch is basically the same such that we skip the explanation of it in this paper.

Inferring through timing (RDTSC). First, we explain how we can infer branch mispredictions with `RDTSC`. Figure 1 shows an example victim code and its shadow code. The victim code's execution depends on the value of `a`: if `a` is not zero, the branch will not be taken such that the `if`-block will be executed; otherwise, the branch will be taken such that the `else`-block will be executed. In contrast, we make the shadow code's branch always be taken (i.e., the `else`-block is always executed). Without the branch history, this branch is always mispredicted because of the static branch prediction rule (§2.2). To make a BTB entry collision [13], we align the lower 31 bits of the shadow code's address (both the branch instruction and its target address) with the address of the victim code.

When the victim code has been executed before the shadow code is executed, the branch prediction or misprediction of the shadow code depends on the execution of the victim code. If the conditional branch of the victim code has been taken, i.e., if `a` was zero, the BPU predicts that the shadow code will also take the conditional branch, which is a correct prediction so that no rollback will occur. If the conditional branch of the victim code either has not been taken, i.e., if `a` was not zero, or has not been executed, the BPU predicts that the shadow code will not take the conditional branch. However, this is an incorrect prediction such that a rollback will occur.

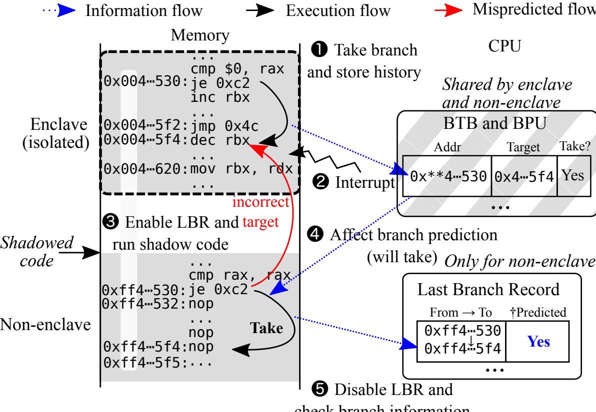
	Correct prediction		Misprediction	
	Mean	σ	Mean	σ
RDTSCP	94.21	13.10	120.61	**806.56**
Intel PT CYC packets	59.59	14.44	90.64	**191.48**
LBR elapsed cycle	25.69	9.72	35.04	**10.52**

Table 1: Measuring branch misprediction penalty with `RDTSCP`, Intel PT CYC packet, and LBR elapsed cycle (10,000 times). We put 120 `NOP` instructions at the fall-through path. The LBR elapsed cycle is less noisy than `RDTSCP` and Intel PT. σ stands for standard deviation.

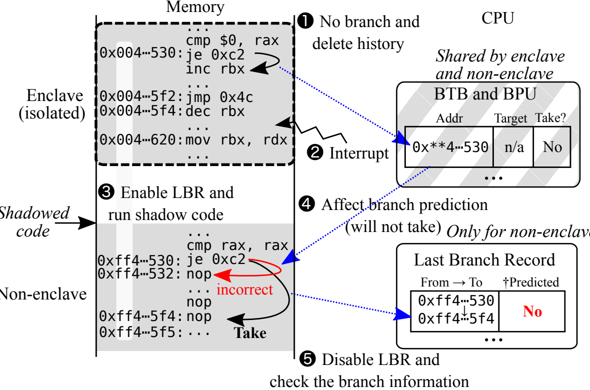
Previous branch-timing attacks try to measure such a rollback penalty with the `RDTSC` or `RDTSCP` instructions. However, our experiments show (Table 1) that branch misprediction timings are quite noisy. Thus, it was difficult to set a clear boundary between correct prediction and misprediction. This is because the number of instructions that would be mistakenly executed because of the branch misprediction is difficult to predict given the highly complicated internal structure of the latest Intel CPUs (e.g., out-of-order execution). Therefore, we think that the `RDTSC`-based inference is difficult to use in practice and thus we aim to use the LBR to realize precise attacks, since it lets us know branch misprediction information, and its elapsed cycle feature has little noise (Table 1).

Inferring from execution traces (Intel PT). Instead of using `RDTSC`, we can use Intel PT to measure a misprediction penalty of a target branch, as it provides precise elapsed cycles (known as a CYC packet) between each PT packet. However, CYC packets cannot be used immediately for our purpose because Intel PT aggregates a series of conditional and unconditional branches into a single packet as an optimization. To avoid this problem, we intentionally insert an indirect branch right after the target branch, making all branches properly record their elapsed time in separate CYC packets. Intel PT's timing information about branch misprediction has a much smaller variance than `RDTSCP`-based measurements (Table 1).

Precise leakage (LBR). Figure 2 shows a procedure for conditional branch shadowing with the BTB, BPU, and LBR. We first explain the case in which a conditional branch has been taken (Case 1). ❶ A conditional branch of the victim code is taken and the corresponding information is stored into the BTB and BPU. This branch taken occurs inside an enclave such that the LBR does not report this information unless we run the enclave process in a debug mode. ❷ Enclave execution is interrupted and



(a) Case 1: The target conditional branch has been taken.



(b) Case 2: The target conditional branch has not been taken (i.e., either not been executed or been executed but not taken).

Figure 2: Branch shadowing attack against a *conditional branch* (i.e., Case 1 for taken and Case 2 for non-taken branches) inside an enclave († LBR records the result of *misprediction*. For clarity, we use the result of *prediction* in this paper.)

the OS takes control. We explain how a malicious OS can frequently interrupt an enclave process in §3.6. ❸ The OS enables the LBR and then executes the shadow code. ❹ The BPU correctly predicts that the shadowed conditional branch will be taken. At this point, a branch target prediction will fail because the BTB stores a target address inside an enclave. However, this target misprediction is orthogonal to the result of a branch prediction though it will introduce a penalty in CPU cycles (§3.4). ❺ Finally, by disabling and retrieving the LBR, we learn that the shadowed conditional branch has been *correctly predicted*—it has been taken as predicted. We think that this correct prediction is about branch prediction because the target addresses of the two branch instructions are different; that is, the target prediction might be failed. Note that, by default, the LBR reports all the branches (including function calls) that occurred in user and kernel space. Since our shadow code has no function calls and is executed in the kernel, we use the LBR's filtering mechanism to ignore every function call and all branches in user space.

Next, we explain the case in which a conditional branch has not been taken (Case 2). ❶ The conditional branch of the victim code is not taken, so either no information is stored into the BTB and BPU or the corresponding old information might be deleted (if there are conflict missed in the same BTB set.) ❷ Enclave execution is interrupted and the OS takes control. ❸ The OS enables the LBR and then executes the shadow code. ❹ The BPU incorrectly predicts that the shadowed conditional branch will not been taken, so the execution is rolled back to take the branch. ❺ Finally, by disabling and retrieving the LBR, we learn that the shadowed conditional branch has been *mispredicted*—it has been taken unlike the branch prediction.

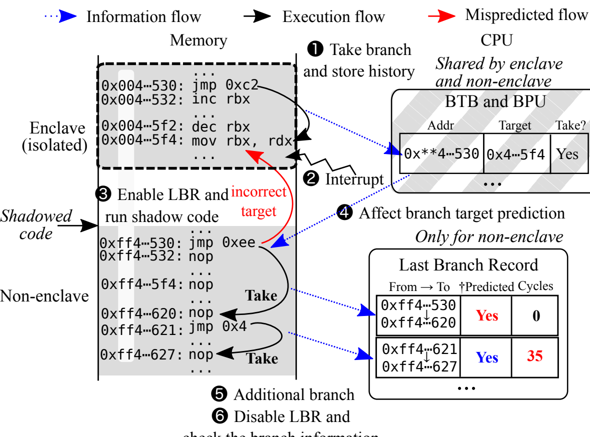
Initializing branch states. When predicting a conditional branch, modern BPUs exploit the branch's several previous executions to improve prediction accuracy. For example, if a branch had been taken several times and then not taken only once, a BPU would predict that its next execution would be taken. This would make the shadow branching infer incorrectly a target branch's execution after it has been executed multiple times (e.g., inside a loop). To solve this problem, after the final step of each attack iteration, we additionally run the shadow code multiple times while varying the condition (i.e., interleaving taken and not-taken branches) to initialize branch states.

3.4 Unconditional Branch Shadowing

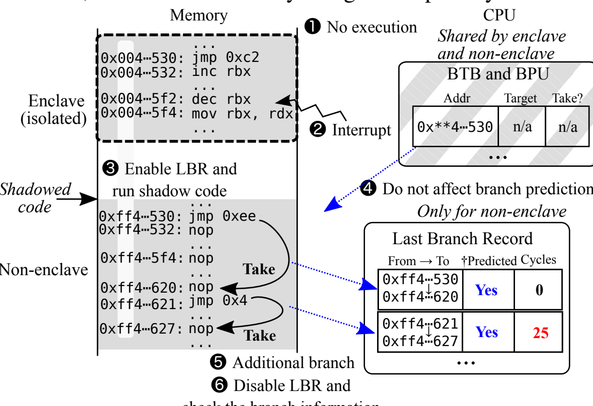
We explain how an attacker can know whether a target unconditional branch inside an enclave has been executed by shadowing its branch history. This gives us two kinds of information. First, an attacker can infer where the instruction pointer (IP) inside an enclave currently points. Second, an attacker can infer the result of the condition evaluation of an `if-else` statement because an `if` block's last instruction is an unconditional branch to skip the corresponding `else` block.

Unlike a conditional branch, an unconditional branch is always taken; i.e., a branch prediction is not needed. Thus, to recognize its behavior, we need to divert its target address to observe branch target mispredictions, not branch mispredictions. Interestingly, we found that the LBR does not report the branch target misprediction of an unconditional branch; it always says that each taken unconditional branch was correctly predicted. Thus, we use the elapsed cycles of a branch that the LBR reports to identify the branch target misprediction penalty, which is less noisy than `RDTSC` (Table 1).

Attack procedure. Figure 3 shows our procedure for unconditional branch shadowing. Unlike the conditional branch shadowing, we make the target of the shadowed unconditional branch differ from that of the victim uncon-



(a) Case 3: The target unconditional branch has been taken. The LBR does not report the misprediction of unconditional branches, but we can infer it by using the elapsed cycles.



(b) Case 4: The target unconditional branch has not been taken.

Figure 3: Branch shadowing attack against an unconditional branch inside an enclave.

ditional branch to recognize a branch target misprediction. We first explain the case in which an unconditional branch has been executed (Case 3). ❶ An unconditional branch of the victim code is executed and the corresponding information is stored into the BTB and BPU. ❷ Enclave execution is interrupted, and the OS takes control. ❸ The OS enables the LBR and then executes the shadow code. ❹ The BPU mispredicts the branch target of the shadowed unconditional branch because of the mismatched branch history, so execution is rolled back to jump to the correct target. ❺ The shadow code executes an additional branch to measure the elapsed cycles of the mispredicted branch. ❻ Finally, by disabling and retrieving the LBR, we learn that a branch target misprediction occurred because of the large number of elapsed cycles.

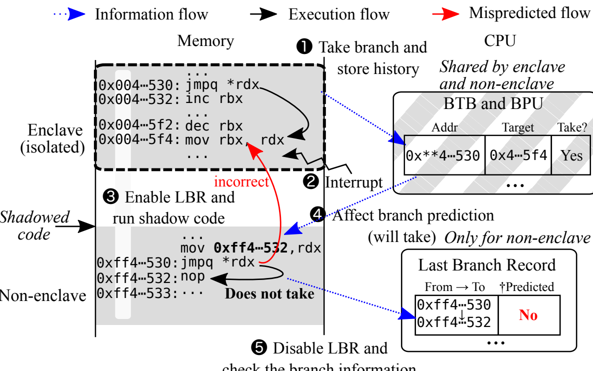
Next, we explain the case in which an unconditional branch has not been taken (Case 4). ❶ The enclave has not yet executed the unconditional branch in the victim code, so the BTB has no information about the branch. ❷ Enclave execution is interrupted, and the OS takes control. ❸ The OS enables the LBR and then executes the shadow code. ❹ The BPU correctly predicts the shadowed unconditional branch's target, because the target unconditional branch has never been executed. ❺ The shadow code executes an additional branch to measure the elapsed cycles. ❻ By disabling and retrieving the LBR, we learn that no branch target misprediction occurred because of the small number of elapsed cycles.

No misprediction of unconditional branch. We found that the LBR always reports that every taken unconditional branch has been predicted irrespective of whether it mispredicted the target (undocumented behavior). We think that this is because the target of an unconditional branch is fixed such that, typically, target mispredictions should not occur. Also, the LBR was for facilitating branch profiling to reduce mispredictions for optimization. However, programmers have no way to handle mispredicted unconditional branches that result from the execution of the kernel or another process—i.e., it does not help programmers improve their program and just reveals side-channel information. We believe these are the reasons the LBR treats every unconditional branch as correctly predicted.

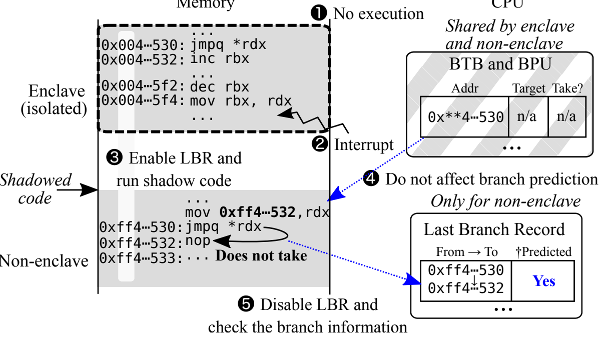
3.5 Indirect Branch Shadowing

We explain how we can infer whether a target indirect branch inside an enclave has been executed by shadowing its branch history. Like an unconditional branch, an indirect branch is always taken when it is executed. However, unlike an unconditional branch, an indirect branch has no fixed branch target. If there is no history, the BPU predicts that the instruction following the indirect branch instruction will be executed; this is the same as the indirect branch not being taken. To recognize its behavior, we make a shadowed indirect branch jump to the instruction immediately following it to monitor a branch target misprediction because of the history. The LBR reports the mispredictions of indirect branches such that we do not need to rely on elapsed cycles to attack indirect branches.

Attack procedure. Figure 4 shows a procedure of indirect branch shadowing. We make the shadowed indirect branch jump to its next instruction to observe whether a branch misprediction occurs because of the branch history. We first explain the case in which an indirect branch has been executed (Case 5). ❶ An indirect branch of the victim code is executed and the corresponding information is stored into the BTB and BPU. ❷ Enclave execution is interrupted, and the OS takes control. ❸ The OS enables the LBR and then executes the shadow code. ❹ The BPU mispredicts that the shadowed indirect branch will be taken to an incorrect target address, so the execution is rolled back to not take the branch. ❺ Finally, by disabling and retrieving the LBR, we learn that the shadow



(a) Case 5: The target indirect branch has been taken.



(b) Case 6: The target indirect branch has not been taken

Figure 4: Branch shadowing attack against an indirect branch inside an enclave.

code's indirect branch has been incorrectly predicted—it has not been taken, unlike the branch prediction.

Next, we explain the case in which an indirect branch has not been taken (Case 6). ❶ The enclave does not execute the indirect branch of the victim code, so that the BTB has no information about the branch. ❷ Enclave execution is interrupted, and the OS takes control. ❸ The OS enables the LBR and then executes the shadow code. ❹ The BPU correctly predicts that the shadowed indirect branch will not be taken because there is no branch history. ❺ Finally, by disabling and retrieving the LBR, we learn that the shadow code's indirect branch has been correctly predicted—it has not been taken, as predicted.

Inferring branch targets. Unlike conditional and unconditional branches, an indirect branch can have multiple targets such that just knowing whether it has been executed would be insufficient to know the victim code's execution. Since the indirect branch is mostly used for representing a `switch-case` statement, it is also related to a number of unconditional branches (i.e., `break`) as an `if-else` statement does. This implies that an attacker can identify which case block has been executed by probing the corresponding unconditional branch. Also, if an attacker can repeatedly execute a victim enclave program with the same input, he or she can test the same indirect

Branch	State	BTB/BPU	LBR		Inferred
			Pred.	Elapsed Cycl.	
Cond.	Taken	✓	✓	-	✓

	Not-exec.	-	-	✓	✓
Indirect	Exec.	✓	✓	-	✓
	Not-exec.	-	✓	-	✓

Table 2: Branch types and states the branch shadowing attack can infer by using the information of BTB, BPU, and LBR.

branch multiple times while changing candidate target addresses to eventually know the real target address by observing a correct branch target prediction.

Table 2 summarizes the branch types and states our attack can infer and the necessary information.

3.6 Frequent Interrupting and Probing

The branch shadowing attack needs to consider cases that change (or even remove) BTB entries because they make the attack miss some branch histories. First, the size of the BTB is limited such that a BTB entry could be overwritten by another branch instruction. We empirically identified that the Skylake's BTB has 4,096 entries, where the number of ways is four and the number of sets is 1,024 (§5.1). Because of its well-designed index-hashing algorithm, we observed that conflicts between two branch instructions located at different addresses rarely occurred. But, no matter how, after more than 4,096 different branch instructions have been taken, the BTB will overflow and we will lose some branch histories. Second, a BTB entry for a conditional or an indirect branch can be removed or changed because of a loop or re-execution of the same function. For example, a conditional branch has been taken at its first run and has not been taken at its second run because of the changes of the given condition, removing the corresponding BTB entry. A target of an indirect branch can also be changed according to conditions, which change the corresponding BTB entry. If the branch shadowing attack could not check a BTB entry before it has been changed, it would lose the information.

To solve this problem, we interrupt the enclave process as frequently as possible and check the branch history by manipulating the local APIC timer and the CPU cache. These two approaches slow the execution of a target enclave program a lot such that an attacker needs to carefully use them (i.e., selectively) to avoid detection.

Manipulating the local APIC timer. We manipulate the frequency of the local APIC timer in a recent version of Linux (details are in Appendix A.) We measured the frequency of our manipulated timer interrupts in terms of how many `ADD` instructions can be executed between two timer interrupts. On average, about 48.76 `ADD` instructions were executed between two timer interrupts (standard

deviation: 2.75)[1]. ADD takes only one cycle in the Skylake CPU [25] such that our frequent timer can interrupt a victim enclave per every ∼50 cycles.

Disabling the cache. If we have to attack a branch instruction in a short loop taking < 50 cycles, the frequent timer interrupt is not enough. To interrupt an enclave process more frequently, we selectively disable the L1 and L2 cache of a CPU core running the victim enclave process by setting the cache disable (CD) bit of the CR0 control register. With the frequent timer interrupt and disabled cache, about 4.71 ADD instructions were executed between two timer interrupts on average (standard deviation: 1.96 with 10,000 iterations). Thus, the highest attack frequency we could achieve was around five cycles.

3.7 Virtual Address Manipulation

To perform the branch shadowing attack, an attacker has to manipulate the virtual addresses of a victim enclave process. Since the attacker has already compromised the OS, manipulating the page tables to change virtual addresses is an easy task. For simplicity, we assume the attacker disables the user-space ASLR and modifies the Intel SGX driver for Linux (vm_mmap) to change the base address of an enclave (Appendix B). Also, the attacker puts an arbitrary number of NOP instructions before the shadow code to satisfy the alignment.

3.8 Attack Synchronization

Although the branch shadowing probes multiple branches in each iteration, it is insufficient when a victim enclave program is large. An approach to overcome this limitation is to apply the branch shadowing attack at the function level. Namely, an attacker first infers functions a victim enclave program either has executed or is currently executing and then probes branches belonging to these functions. If these functions contain entry points that can be invoked from outside (via EENTER) or that rely on external calls, the attacker can easily identify them because they are controllable and observable by the OS.

However, the attacker needs another strategy to infer the execution of non-exported functions. The attacker can create special shadow code consisting of always reachable branches of target functions (e.g., branches located at the function prologue). By periodically executing this code, the attacker can see which of the monitored functions has been executed. Also, the attacker can use the page-fault side channel [60] to synchronize attacks in terms of pages.

3.9 Victim Isolation

To minimize noise, we need to ensure that only a victim enclave program and shadow code will be executed in an isolated physical core. Each physical core has the BTB and BPU shared by multiple processes. Thus, if another

[1]The number of iterations was 10,000. We disabled Hyper-Threading, SpeedStep, TurboBoost, and C-States to reduce noise.

```

25 +          mpi_montmul(X, X, N, mm, &T);
26
27 +        mpi_montmul(X, &W[wbits], N, mm, &T);
28          state--; nbits = wbits = 0;
29        }
30      }
31      ...
32    }
```

Figure 5: Sliding-window exponentiation of mbed TLS. Branch shadowing can infer every bit of the secret exponent.

process runs in the core under the branch shadowing attack, its execution would affect the overall attack results. To avoid this problem, we use the isolcpus boot parameter to specify an isolated core that will not be scheduled without certain requests. Then, we use the taskset command to run a victim enclave with the isolated core.

4 Evaluation

In this section, we demonstrate the branch shadowing attack against an implementation of RSA and also describe our case studies of various libraries and applications that are vulnerable to our attack but mostly secure against the controlled-channel attack [60]. The branch shadowing attack's goal is not to overcome countermeasures against branch-prediction side-channel attacks, e.g., exponent blinding to hide an exponent value, not branch executions [34]. Thus, we do not try to attack applications without branch-prediction side channels.

4.1 Attacking RSA Exponentiation

We launch the branch shadowing attack against a popular TLS library, called mbed TLS (also known as PolarSSL). mbed TLS is a popular choice of SGX developers and researchers because of its lightweight implementation and portability [47, 49, 62, 63].

Figure 5 shows how mbed TLS implements sliding-window exponentiation, used by RSA operations. This function has two conditional branches (jne) marked with ⋆ whose executions depend on each bit (ei) of an exponent. These branches will be taken only when ei is not

zero (i.e., one). Thus, by shadowing them and checking their states, we can know the value of `ei`. Note that the two branches are always executed no matter how large the sliding window is. In our system, each loop execution (Lines 7–30) took about 800 cycles such that a manipulated local APIC timer was enough to interrupt it. Also, to differentiate each loop execution, we shadow unconditional branches that jump back to the loop's beginning.

We evaluated the accuracy of branch shadowing by attacking RSA-1024 decryption with the default key pair provided by mbed TLS for testing. By default, mbed TLS's RSA implementation uses the Chinese Remainder Theorem (CRT) technique to speed up computation. Thus, we observed two executions of `mbedtls_mpi_exp_mod` with two different 512-bit CRT exponents in each iteration. The sliding-window size was five.

On average, the branch shadowing attack recovered approximately 66% of the bits of each of the two CRT exponents from *a single run* of the victim (averaged over 1,000 executions). The remaining bits (34%) correspond to loop iterations in which the two shadowed branches returned different results (i.e., predicted versus mispredicted). We discarded those measurements, as they were impacted by platform noise, and marked the corresponding bits as unknown. The remaining 66% of the bits were inferred correctly with an accuracy of 99.8%, where the standard deviation was 0.003.

The events that cause the attack to miss about 34% of the key bits appear to occur at random times. Different runs reveal different subsets of the key bits. After at most 10 runs of the victim, the attack recovers virtually the entire key. This number of runs is small compared to existing cache-timing attacks, which demand several hundreds to several tens of thousands of runs to reliably recover keys [20, 35, 65].

Timing-based branch shadowing. Instead of using the LBR, we measured how long it takes to execute the shadow branches using `RDTSCP` while maintaining other techniques, including the modified local APIC timer and victim isolation. When the two target branches were taken, the shadow branches took 55.51 cycles on average, where the standard deviation was 48.21 cycles (1,000 iterations). When the two target branches were not taken, the shadow branches took 93.89 cycles on average, where the standard deviation was 188.49 cycles. Because of high variance, finding a good decision boundary was challenging, so we built a support vector machine classifier using LIBSVM (with an RBF kernel and default parameters). Its accuracy was 0.947 (10-fold cross validation)—i.e., we need to run this attack at least two times more than the LBR-based attack to achieve the same level of accuracy.

Controlled-channel attack. We also evaluated the controlled channel attack against Figure 5. We found that `mbedtls_mpi_exp_mod` conditionally called `mpi_montmul`

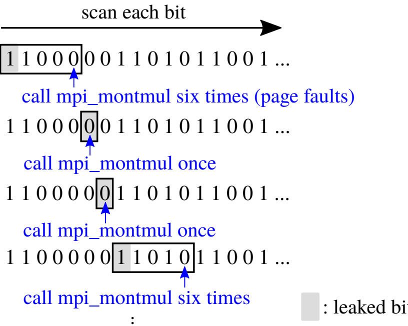

Figure 6: Controlled-channel attack against sliding-window exponentiation (window size: 5). It only knows the first bit of each window (always one) and skipped bits (always zero).

(marked with +) according to the value of `ei` and both functions were located on different code pages. Thus, by carefully unmapping these pages, an attacker can monitor when `mpi_montmul` is called. However, as Figure 6 shows, because of the sliding-window technique, the controlled-channel attack cannot identify every bit unless it knows `W[wbits]`—i.e., this attack can only know the first bit of each window (always one) and skipped bits (always zero). The number of recognizable bits completely depends on how the bits of an exponent are distributed. Against the default RSA-1024 private key of mbed TLS, this attack identified 334 bits (32.6%). Thus, we conclude that the branch shadowing attack is better than the controlled-channel attack for obtaining fine-grained information.

4.2 Case Study

We also studied other sensitive applications that branch shadowing can attack. Specifically, we focused on examples in which the controlled-channel attack cannot extract any information, e.g., control flows within a single page. We attacked three more applications: 1) two libc functions (`strtol` and `vfprintf`) in the Linux SGX SDK, 2) LibSVM, ported to Intel SGX, and 3) some Apache modules ported to Intel SGX. We achieved interesting results, such as how long an input number is (`strtol`), what the input format string looks like (`vfprintf`), and what kind of HTTP request an Apache server gets (`lookup_builtin_method`), as summarized in Table 3. Note that the controlled-channel attack cannot obtain the same information because those functions do not call outside functions at least in the target basic blocks. Detailed analysis with source code is in Appendix C.

5 Countermeasures

We introduce our hardware-based and software-based countermeasures against the branch shadowing attack.

5.1 Flushing Branch State

A fundamental countermeasure against the branch shadowing attack is to flush all branch states generated inside an enclave by modifying hardware or updating mi-

Program/Library	Function	Description	Obtainable information
mbed TLS	`mbedtls_mpi_exp_mod`	sliding-window exponentiation	✓each bit of an exponent
	`mpi_montmul`	Montgomery multiplication	✓whether a dummy subtraction has performed
libc	`strtol`	convert a string into an integer	✓the sign of an input number
			✓the length of an input number
			✓whether each hexadecimal digit is larger than nine
	`vfprintf`	print a formatted string	✓the input format string
			✓the type of each input argument (e.g., int, double)
LIBSVM	`k_function`	evaluate a kernel function	✓the type of a kernel (e.g., linear, polynomial)
			✓the length of a feature vector (i.e., # of features)
Apache	`lookup_builtin_method`	parse the method of an HTTP request	✓HTTP request method (e.g., `GET`, `POST`)

Table 3: Summary of example sensitive applications and their functions attacked by branch shadowing.

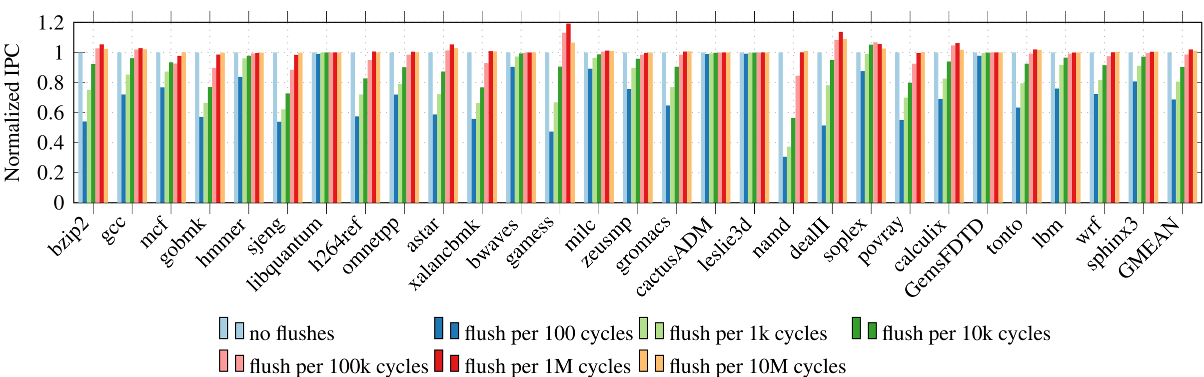

Figure 7: Instructions per cycle of SPEC benchmark in terms of frequency of BTB and BPU flushing.

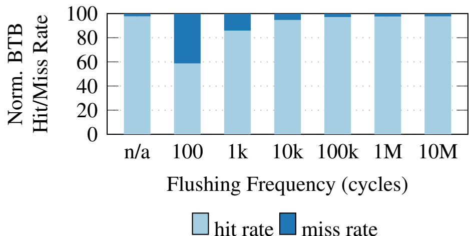

Figure 8: Average BTB hit/miss rate according to frequency of BTB and BPU flushing.

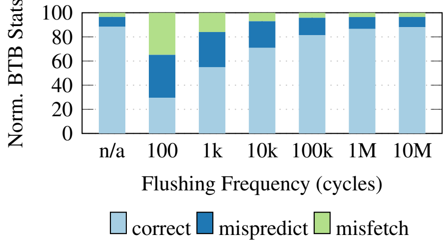

Figure 9: Average BTB statistics according to frequency of BTB and BPU flushing.

crocode. Whenever an enclave context switch (via the `EENTER`, `EEXIT`, or `ERESUME` instructions or AEX) occurs, the processor needs to flush the BTB and BPU states. Since the BTB and BPU benefit from local and global branch execution history, there would be a performance penalty if these states were flushed too frequently.

Parameter	Value
CPU	4 GHz out of order core, 4 issue width, 256 entry ROB
L1 cache	8 way 32 KB I-cache + 8 way 32 KB D-cache
L2 cache	8 way 128 KB
L3 cache	32 way 8 MB
BTB	4 way 1,024 sets
BPU	gshare, branch history length 16

Table 4: MacSim simulation parameters.

We estimate the performance overhead of our countermeasure at different enclave context switching frequencies using a cycle-level out-of-order microarchitecture simulator, MacSim [30]. To simulate branch history flushing for every enclave context switch, we modified MacSim to flush BTB and BPU for every 100 to 10 million cycles; this resembles enclave context switching for every 100 to 10 million cycles. The details of our simulation parameters are listed in Table 4. The BTB is modeled after the BTB in Intel Skylake processors. We used a method similar to that in [1, 58] to reverse engineer the BTB parameters. From our experiments, we found that the BTB is organized as a 4-way set associative structure with a total of 4,096 entries. We model a simple branch predictor, gshare [37], for the simulation. We use traces

that are 200 million instructions long from the SPEC06 benchmark suite for simulation.

Figure 7 shows the normalized instructions per cycle (IPC) for different flush frequencies. We found that if the flush frequency is higher than 100k cycles, it has negligible performance overhead. At a flush frequency of 100k cycles, the performance degradation is lower than 2% and at 1 million cycles, it is negligible. Figure 8 shows the BTB hit rate, whereas Figure 9 shows the BPU *correct*, *incorrect* (direction prediction is wrong), and *misfetch* (target prediction is wrong) percentages. The BTB and BPU statistics are also barely distinguishable beyond a flush frequency of 100k cycles.

According to our measurements with a 4GHz CPU, about 250 and 1,000 timer interrupts are generated per second in Linux (version 4.4) and Windows 10, respectively—i.e., a timer interrupt is generated for every 4M and 1M cycles, respectively. Therefore, if there is no I/O device generating many interrupts and an enclave program generates less frequent system calls, which would be desired to avoid the Iago attack [9], flushing branch states for every enclave context switch will introduce negligible overhead.

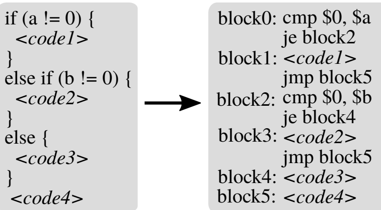
5.2 Obfuscating Branch

Branch state flushing can effectively prevent the branch shadowing attack, but we cannot be sure when and whether such hardware changes will be realized. Especially, if such changes cannot be done with micro code updates, we cannot protect the Intel CPUs already deployed in the markets.

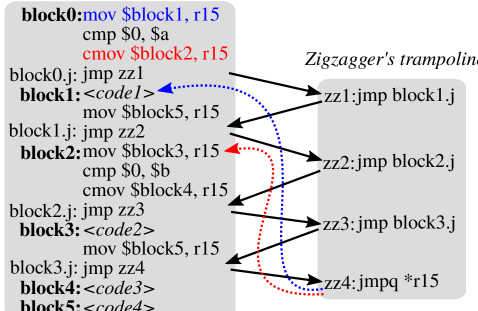
Possible software-based countermeasures against the branch shadowing attack are to remove branches [39] or to use the state-of-the-art ORAM technique, Raccoon [44]. Data-oblivious machine learning algorithms et al. [39] eliminate all branches by using a conditional move instruction, `CMOV`. However, their approach is algorithm-specific, i.e., it is not applicable to general applications. Raccoon [44] always executes both paths of a conditional branch, such that no branch history will be leaked. But, its performance overhead is high (21.8×).

Zigzagger. We propose a practical, compiler-based mitigation against branch shadowing, called *Zigzagger*. It obfuscates a set of branch instructions into a single indirect branch, as inferring the state of an indirect branch is more difficult than inferring those of conditional and unconditional branches (§3.5). However, it is not straightforward to compute the target block of each branch without relying on conditional jumps because conditional expressions could become complex because of nested branches. In Zigzagger, we solved this problem by using a `CMOV` instruction [39, 44] and introducing a sequence of non-conditional jump instructions in lieu of each branch.

Figure 10 shows how Zigzagger transforms an example code snippet having `if`, `else-if`, and `else` blocks. It



(a) An example code snippet. It selectively executes a branch block according to `a` and `b` variables.



(b) The protected code snippet by Zigzagger. All branch instructions are executed regardless of `a` and `b` variables. An indirect branch in the trampoline and `CMOV`s in the translated code are used to obfuscate the final target address. `r15` is reserved to store the target address.

Figure 10: An example of Zigzagger transformation.

converts all conditional and unconditional branches into unconditional branches targeting Zigzagger's trampoline, which jumps back-and-forth with the converted branches. The trampoline finally jumps into the real target address stored in a reserved register `r15`. Note that reserving a register is only for improving performance. We can use the memory to store the target address when an application needs to use a large number of registers. To emulate conditional execution, the `CMOV` instructions in Figure 10b update the target address in `r15` only when `a` or `b` is zero. Otherwise, they are treated as `NOP` instructions. Since all of the unconditional branches are executed almost simultaneously in sequence, recognizing the current instruction pointer is difficult. Further, since the trampoline now has five different target addresses, inferring real targets among them is not straightforward.

Zigzagger's approach has several benefits: 1) security: it provides the first line of protection on each branch block in an enclave program; 2) performance: its overhead is at most 2.19× (Table 5); 3) practicality: its transformation demands neither complex analysis of code semantics nor heavy code changes. However, it does not ensure perfect security such that we still need ORAM-like techniques to protect very sensitive functions.

Implementation. We implemented Zigzagger in LLVM 4.0 as an LLVM pass that converts branches in each function and constructs the required trampoline. We also mod-

Benchmark	Baseline (iter/s)	Zigzagger #Branches (overhead)				
		2	3	4	5	All
numeric sort	967.25	1.05×	1.11×	1.12×	1.13×	1.15×

GEOMEAN		1.17×	1.22×	1.24×	1.26×	1.34×

Table 5: Overhead of the Zigzagger approach according to the number of branches belonging to each Zigzagger.

ified the LLVM backend to reserve a register. The number of branches a single trampoline manages affects the overall performance, so our implementation provides a knob to configure it to trade the security for performance.

Our proof-of-concept implementation of Zigzagger, merging every branch in each function, imposed a 1.34× performance overhead when evaluating it with the `nbench` benchmark suite (Table 5). With optimization (i.e., merging ≤ 3 branches into a single trampoline), the average overhead became $\leq 1.22\times$. Note that reserving a register resulted in a 4%–50% performance improvement.

6 Discussion

In this section, we explain some limitations of the branch shadowing attack and discuss possible advanced attacks.

6.1 Limitations

The branch shadowing attack has limitations. First, it cannot distinguish a not-taken conditional branch from a not-executed conditional branch because, in both cases, the BTB stores no information; the static branch prediction rule is applied. Second, it cannot distinguish an indirect branch to the next instruction from a not-executed indirect branch because their predicted branch targets are the same. Therefore, an attacker has to probe a number of correlated branches (e.g., unconditional branches in `else-if` or `case` blocks) to overcome these limitations. Third, as with the controlled-channel attack, the branch shadowing attack needs repetitions to increase attack accuracy, which can be prohibited by a state continuity solution [55]. However, this requires persistence storage such as that provided by a trusted platform module (TPM).

6.2 Advanced Attacks

We consider how branch shadowing can be improved: hyperthreading and blind approaches.

Hyperthreaded branch shadowing. Since two hyperthreads simultaneously running in the same physical core share the BTB and BPU, a malicious hyperthread can attack a victim enclave hyperthread by using BTB entry conflicts if a malicious OS gives the address information of the victim to it. We observed that branch instructions with the same low 16-bit address were mapped into the same BTB set. Thus, a malicious hyperthread can monitor a BTB set for evictions by filling the BTB set with four branch instructions (§5.1). The BTB flushing cannot prevent this attack because it demands no enclave mode switch, so disabling hyperthreading or preventing the hyperthreads from sharing the BTB and BPU is necessary.

Blind branch shadowing. A blind branch shadowing attack is an attempt to probe the entire or selected memory region of a victim enclave process to detect any unknown branch instructions. This attack would be necessary if a victim enclave process has self-modifying code or uses remote code loading, though this is outside the scope of our threat model (§3.1). In the case of unconditional branches, blind probing is easy and effective because it does not need to infer target addresses. However, in the case of conditional and indirect branches, blind probing needs to consider branch instructions and their targets simultaneously such that the search space would be huge. We plan to consider an effective method to minimize the search space to know whether this attack is practical.

7 Related Work

Intel SGX. The strong security guarantee provided by SGX has drawn significant attention from the research community. Several security applications of SGX are proposed, including secure and distributed data analysis [7, 11, 39, 46, 66] and secure networking service [31, 41, 48]. Also, researchers implemented SGX layers [5, 6, 51, 57] to run existing applications inside an enclave without any modifications. The security properties of SGX itself are also being intensively studied. For example, Sinha et al. [52, 53] develop tools to verify the confidentiality of enclave programs.

However, researchers find security attacks against Intel SGX. Xu et al. [60] and Shinde et al. [50] demonstrate the first side-channel attack on SGX by leveraging the fact that SGX relies on an OS for memory resource management. The attack is done by intentionally manipulating the page table to trigger a page fault and using a page-fault sequence to infer the secret inside an enclave. Weichbrodt et al. [59] also show how a synchronous bug can be exploited to attack SGX applications. Further, concurrently with our work, Hähnel et al. [21] exploit a frequent timer in Windows to realize a precise cache side-channel attack against the Intel SGX simulator.

To address the page-fault-based side-channel attack, Shinde et al. [50] obfuscate the memory access pattern of an enclave. Shih et al. [49] propose a compiler-based solution using Intel TSX to detect suspicious page faults inside an enclave. Also, Costan et al. [10] propose a new en-

clave design to prevent both page-fault and cache-timing side-channel attacks. Finally, Seo et al. [47] enforce fine-grained ASLR on enclave programs, which can raise the bar of exploiting any vulnerabilities and inferring control flow with page-fault sequences. However, all of these solutions heavily use branch instructions and do not clear branch states, such that they would be vulnerable to our attack.

Microarchitectural side channel. Researchers considered the security problems of microarchitectural side channels. The most popular and well-studied microarchitectural side channel is a CPU cache timing channel first developed by [29, 34, 40] to break cryptosystems. This attack is further extended to be conducted in the public cloud setting to recognize co-residency of virtual machines [45, 64]. Several researchers further improved this attack to exploit the last level cache [27, 35] and create a low-noise cache storage channel [19]. The CPU cache is not the sole source of the microarchitectural side channel. For example, to break kernel ASLR, researchers exploit a TLB timing channel [23], an Intel TSX instruction [28], a `PREFETCH` instruction [18], and a BTB timing channel [13]. Ge et al. [14] conducted a comprehensive survey of microarchitectural side channels.

8 Conclusion

A hardware-based TEE such as Intel SGX demands thorough analysis to ensure its security against hostile environments. In this paper, we presented and evaluated the branch shadowing attack, which identifies fine-grained execution flows inside an SGX enclave. We also proposed hardware-based countermeasure that clears the branch history during enclave mode switches and software-based mitigation that makes branch executions oblivious.

Responsible disclosure. We reported our attack to Intel and discussed with them to find effective solutions against it. Also, after having a discussion with us, the authors of Sanctum [10] revised their eprint paper that coped with our attack.

A Manipulating Local APIC Timer

The local APIC is a component of Intel CPUs to configure and handle CPU-specific interrupts [26, §10]. An OS can program it through memory-mapped registers (e.g., device configuration register) or model-specific registers (MSRs) to adjust the frequency of the *local APIC timer*, which generates high-resolution timer interrupts, and deliver an interrupt to a CPU core (e.g., inter-processor interrupt (IPI) and I/O interrupt from the I/O APIC).

Intel CPUs support three local APIC timer modes: periodic, one-shot, and timestamp counter (TSC)-deadline modes. The periodic mode lets an OS configure the initial-count register whose value is copied into the current-count register the local APIC timer uses. The current-count register's value decreases at the rate of the bus frequency, and when it becomes zero, a timer interrupt is generated and the register is re-initialized by using the initial-count register. The one-shot mode lets an OS configure the initial-count counter value whenever a timer interrupt is generated. The TSC-deadline mode is the most advanced and precise timer mode allowing an OS to specify when the next timer interrupt will occur in terms of a TSC value. Our target Linux system (kernel version 4.4) uses the TSC-deadline mode, so we focus on this mode.

Figure 11 shows how we modified the `lapic_next_deadline()` function specifying the next TSC deadline and the `local_apic_timer_interrupt()` function called whenever a timer interrupt is fired. We made and exported two global variables and function pointers to manipulate the behaviors of `lapic_next_deadline()` and `local_apic_timer_interrupt()` with a kernel module: `lapic_next_deadline_delta` to change the delta; `lapic_target_cpu` to specify a virtual CPU running a victim enclave process (via a CPU affinity); and `timer_interrupt_hook` to specify a function to be called whenever a timer interrupt is generated. In our evaluation environment having an Intel Core i7 6700K CPU (4GHz), we were able to have 1,000 as the minimum delta value; i.e., it fires a timer interrupt about every 1,000 cycles. Note that, in our environment, a delta value lower than 1,000 made the entire system freeze because a timer interrupt was generated before an old timer interrupt was handled by the interrupt handler.

B Modifying SGX Driver

Figure 12 shows how we modified the Intel SGX driver for Linux to manipulate the base address of an enclave.

```
1  /* linux-4.4.23/arch/x86/kernel/apic/apic.c */
2  ...
3  // manipualte the delta of TSC-deadline mode
4  unsigned int lapic_next_deadline_delta = 0U;
5  EXPORT_SYMBOL_GPL(lapic_next_deadline_delta);
6
7  // specify the virtual core under attack
8  int lapic_target_cpu = -1;
9  EXPORT_SYMBOL_GPL(lapic_target_cpu);
10
11 // a hook to launch branch shadowing attack
12 void (*timer_interrupt_hook)(void*) = NULL;
13 EXPORT_SYMBOL_GPL(timer_interrupt_hook);
14 ...
15 // update the next TSC deadline
16 static int lapic_next_deadline(unsigned long delta,
17                                struct clock_event_device *evt) {
18   u64 tsc;
19   tsc = rdtsc();
20 * if (smp_processor_id() != lapic_target_cpu)
21     wrmsrl(MSR_IA32_TSC_DEADLINE,
22         tsc + (((u64) delta) * TSC_DIVISOR));
23 * else
24 *   wrmsrl(MSR_IA32_TSC_DEADLINE,
25 *       tsc + lapic_next_deadline_delta); // custom deadline
26   return 0;
27 }
28 ...
29 // handle a timer interrupt
30 static void local_apic_timer_interrupt(void) {
31   int cpu = smp_processor_id();
32   struct clock_event_device *evt = &per_cpu(lapic_events, cpu);
33
34 * if (cpu == lapic_target_cpu && timer_interrupt_hook)
35 *   timer_interrupt_hook((void*)&cpu); // call attack code
36   ...
37 }
```

Figure 11: Modified local APIC timer code. We changed `lapic_next_deadline()` to manipulate the next TSC deadline and `local_apic_timer_interrupt()` to launch attack code.

```
1  /* isgx_ioctl.c */
2  ...
3  static long isgx_ioctl_enclave_create(struct file *filep,
4                              unsigned int cmd, unsigned long arg) {
5    ...
6    struct isgx_create_param *createp =
7      (struct isgx_create_param *) arg;
8    void *secs_la = createp->secs;
9    struct isgx_secs *secs = NULL;
10   // SGX Enclave Control Structure (SECS)
11   long ret;
12   ...
13   secs = kzalloc(sizeof(*secs), GFP_KERNEL);
14   ret = copy_from_user((void *)secs, secs_la, sizeof (*secs));
15   ...
16 * secs->base = vm_mmap(file, MANIPULATED_BASE_ADDR, secs->size,
17 *                 PROT_READ | PROT_WRITE | PROT_EXEC,
18 *                 MAP_SHARED, 0);
19   ...
20 }
```

Figure 12: Modified Intel SGX driver to manipulate the base address of an enclave

C Case Study in Detail

We study other sensitive applications the branch shadowing can attack. Specifically, we focus on examples in which the controlled-channel attack cannot extract any information, e.g., control flows within a single page.

mbed TLS. We checked mbed TLS's another function: the Montgomery multiplication (`mpi_montmul`). As shown

```
1  /* bignum.c */
2  static int mpi_montmul(mbedtls_mpi *A, const mbedtls_mpi *B,
3                         const mbedtls_mpi *N, mbedtls_mpi_uint mm,
4                         const mbedtls_mpi *T) {
5    size_t i, n, m;
6    mbedtls_mpi_uint u0, u1, *d;
7
8    d = T->p; n = N->n; m = (B->n < n) ? B->n : n;
9
10   for (i = 0; i < n; i++) {
11     u0 = A->p[i];
12     u1 = (d[0] + u0 * B->p[0]) * mm;
13
14     mpi_mul_hlp(m, B->p, d, u0);
15     mpi_mul_hlp(n, N->p, d, u1);
16
17     *d++ = u0; d[n+1] = 0;
18   }
19
20 * if (mbedtls_mpi_cmp_abs(A, N) >= 0) {
21 *   mpi_sub_hlp(n, N->p, A->p);
22 *   i = 1;
23 * }
24 * else { // dummy subtraction to prevent timing attacks
25 *   mpi_sub_hlp(n, N->p, T->p);
26 *   i = 0;
27 * }
28   return 0;
29 }
```

Figure 13: Montgomery multiplication (`mpi_montmul()`) of mbed TLS. The branch shadowing attack can infer whether a dummy subtraction has performed or not.

in Figure 13, this function has a dummy subtraction (Lines 24–27) to prevent the well-known remote timing attack [8]. The branch shadowing attack was able to detect the execution of this dummy branch. In contrast, the controlled-channel cannot know whether a dummy subtraction has happened because both real and dummy branches execute the same function: `mpi_sub_hlp()`.

Linux SGX SDK. We attacked two libc functions, `strtol()` and `vfprint()`, Linux SGX SDK provides. Figure 14a shows `strtol()` converting a string into an integer. The branch shadowing can infer the sign of an input number by checking the branches in Lines 7–12. Also, it infers the length of an input number by checking the loop branch in Lines 14–24. When an input number was hexadecimal, we were able to use the branch at Line 16 to know whether each digit was larger than nine.

Figure 14b shows `vfprintf()` printing a formatted string. The branch shadowing was able to infer the format string by checking the `switch-case` statement in Lines 4–13 and the types of input arguments to this function according the `switch-case` statement in Lines 15–23. In contrast, the controlled-channel attack cannot infer this information because the functions called by `vfprint()`, including `ADDSARG()` and `va_arg()`, are inline functions. No page fault sequence will be observed.

LIBSVM. LIBSVM is a popular library supporting support vector machine (SVM) classifiers. We ported a classification logic of LIBSVM to Intel SGX because it would be a good example of machine learning as a service [39]

```
1     /* linux-sgx/sdk/tlibc/stdlib/strtol.c */
2     long strtol(const char *nptr, char **endptr, int base) {
3       ...
4       s = nptr;
5       do { c = (unsigned char) *s++; } while (isspace(c));
6
7  ⋆    if (c == '-') {
8  ⋆      neg = 1; c = *s++;
9  ⋆    } else {
10 ⋆      neg = 0;
11 ⋆      if (c == '+') c = *s++;
12 ⋆    } // infer the sign of an input number
13
14 ⋆    for (acc = 0, any = 0;; c = (unsigned char) *s++) {
15 ⋆      if(isdigit(c)) c -= '0';
16 ⋆      else if (isalpha(c)) c -= isupper(c) ? 'A'-10 : 'a'-10;
17 ⋆      //  infer hexademical
18        else break;
19
20        if (!neg) {
21          acc *= base; acc += c;
22        }
23        ...
24 ⋆    } // infer the length of an input number
25      ...
26    }
```

(a) Simplified `strtol()`. The branch shadowing attack can infer the sign and length of an input number.

```
1     /* linux-sgx/sdk/tlibc/stdio/vfprintf.c */
2     int __vfprintf(FILE *fp, const char *fmt0, __va_list ap) {
3       ...
4       for (;;) {
5         ch = *fmt++;
6         switch (ch) {
7         ...
8  ⋆      case 'd': case 'i': ADDSARG(); break;
9  ⋆      case 'p': ADDTYPE_CHECK(TP_VOID); break;
10 ⋆      case 'X': case 'x': ADDUARG(); break;
11        ...
12        }
13      } // infer input format string
14      ...
15      for (n = 1; n <= tablemax; n++) {
16        switch (tyypetable[n]) {
17 ⋆      case T_INT:
18 ⋆        (*argtable)[n].intarg = va_arg(ap, int); break;
19 ⋆      case T_DOUBLE:
20 ⋆        (*argtable)[n].doublearg = va_arg(ap, double); break;
21        ...
22        }
23 ⋆    } // infer the types of input arguments
24      ...
25    }
```

(b) Simplified `vfprintf()`. The branch shadowing attack can infer the format string and variable arguments.

Figure 14: libc functions attacked by the branch shadowing

```
1     /* svm.cpp */
2     double Kernel::k_function(const svm_node *x,
3             const svm_node *y, const svm_parameter& param) {
4       switch(param.kernel_type) {
5  ⋆    case LINEAR:
6  ⋆      return dot(x,y);
7  ⋆    case POLY:
8  ⋆      return powi(param.gamma*dot(x,y)+param.coef0,
9                   param.degree);
10 ⋆    case RBF:
11        double sum = 0;
12        while (x->index != -1 && y->index != -1) {
13 ⋆        if (x->index == y->index) {
14 ⋆          double d = x->value - y->value;
15 ⋆          sum += d*d; ++x; ++y;
16 ⋆        }
17 ⋆        else {
18 ⋆          ...
19 ⋆        }
20          ...
21 ⋆      } // infer the lengths of x and y
22 ⋆      return exp(-param.gamma*sum);
23 ⋆    case SIGMOID:
24 ⋆      return tanh(param.gamma*dot(x,y)+param.coef0);
25 ⋆    case PRECOMPUTED:
26 ⋆      return x[(int)(y->value)].value;
27      default:
28        return 0;
29 ⋆    } // infer the kernel type
30    }
```

Figure 15: Kernel function of LIBSVM. The branch shadowing attack can infer the kernel type.

```
1     /* http_protocol.c */
2     static int lookup_builtin_method(const char *method,
3                                      apr_size_t len) {
4       ...
5       switch (len) {
6  ⋆    case 3:
7         switch (method[0]) {
8  ⋆      case 'P': return (method[1] == 'U' && method[2] == 'T'
9  ⋆        ? M_PUT : UNKNOWN_METHOD);
10 ⋆      case 'G': return (method[1] == 'E' && method[2] == 'T'
11 ⋆        ? M_GET : UNKNOWN_METHOD);
12        default: return UNKNOWN_METHOD;
13        }
14      ..
15 ⋆    case 5:
16        switch (method[2]) {
17 ⋆      case 'T': return (memcmp(method, "PATCH", 5) == 0
18 ⋆        ? M_PATCH : UNKNOWN_METHOD);
19 ⋆      case 'R': return (memcmp(method, "MERGE", 5) == 0
20 ⋆        ? M_MERGE : UNKNOWN_METHOD);
21        ...
22        }
23      ...
24 ⋆    }
25    }
```

Figure 16: Apache HTTP method lookup function. The branch shadowing infers the type of HTTP method sent by clients.

while hiding the detailed parameters. Figure 15 shows the LIBSVM's kernel function code running inside an enclave. The branch shadowing attack can recognize the kernel type such as linear, polynomial, and radial basis function (RBF) because of the `switch-case` statement in Lines 4–28. Also, when a victim used an RBF kernel, we were able to infer the number of features (i.e., the length of a vector) he or she used (Lines 11–20).

Apache. We ported some modules of Apache to SGX. Figure 16 shows its lookup function to parse the method of an HTTP request. Because of its `switch-case` statements, we can easily identify the method of a target HTTP request, such as `GET`, `POST`, `DELETE`, and `PATCH`. Since this function invokes either no function or `memcmp()`, the controlled-channel attack has no chance to identify the method.

AuthentiCall: Efficient Identity and Content Authentication for Phone Calls

Abstract

Phones are used to confirm some of our most sensitive transactions. From coordination between energy providers in the power grid to corroboration of high-value transfers with a financial institution, we rely on telephony to serve as a trustworthy communications path. However, such trust is not well placed given the widespread understanding of telephony's inability to provide end-to-end authentication between callers. In this paper, we address this problem through the AuthentiCall system. AuthentiCall not only cryptographically authenticates both parties on the call, but also provides strong guarantees of the integrity of conversations made over traditional phone networks. We achieve these ends through the use of formally verified protocols that bind low-bitrate data channels to heterogeneous audio channels. Unlike previous efforts, we demonstrate that AuthentiCall can be used to provide strong authentication before calls are answered, allowing users to ignore calls claiming a particular Caller ID that are unable or unwilling to provide proof of that assertion. Moreover, we detect 99% of tampered call audio with negligible false positives and only a worst-case 1.4 second call establishment overhead. In so doing, we argue that strong and efficient end-to-end authentication for phone networks is approaching a practical reality.

1 Introduction

Telephones remain of paramount importance to society since their invention 140 years ago, and they are especially important for sensitive business communications, whistleblowers and journalists, and as a reliable fallback when other communication systems fail. When faced with critical or anomalous events, the default response of many organizations and individuals is to rely on the telephone. For instance, banks receiving requests for large transfers between parties that do not generally interact call account owners. Power grid operators who detect phase synchronization problems requiring careful remediation speak on the phone with engineers in adjacent networks. Even the Federal Emergency Management Agency (FEMA) recommends that citizens in disaster areas rely on phones to communicate sensitive identity information (e.g., social security numbers) to assist in recovery [29]. In all of these cases, participants depend on telephony networks to help them validate claims of identity and integrity.

However, these networks were never designed to provide end-to-end authentication or integrity guarantees. Adversaries with minimal technical ability regularly take advantage of this fact by spoofing Caller ID, a vulnerability enabling over $7 billion in fraud in 2015 [34]. More capable adversaries can exploit weaknesses in core network protocols such as SS7 to reroute calls and modify content [15]. Unlike the web, where mechanisms such as TLS protect data integrity and allow experts to reason about the identity of a website, the modern telephony infrastructure simply provides no means for anyone to reason about either of these properties.

In this paper, we present AuthentiCall, a system designed to provide end-to-end guarantees of authentication and call content integrity over modern phone systems (e.g., landline, cellular, or VoIP). While most phones have access to some form of data connection, that connection is often not robust or reliable enough to support secure VoIP phone calls. AuthentiCall uses this often low-bitrate data connection to mutually authenticate both parties of a phone call with strong cryptography *before* the call is answered. Even in the worst case, this authentication adds at most a negligible 1.4 seconds to call establishment. Once a call is established, AuthentiCall binds the call audio to the original authentication using specialized, low-bandwidth digests of the speech in the call. These digests protect the integrity of call content and can distinguish legitimate audio modifications attributable to the network from

99% of maliciously tampered call audio even while a typical user would expect to see a false positive only once every six years. Our system is the first to use these digests to ensure that received call audio originated from the legitimate source and has not been tampered with by an adversary. Most critically, AuthentiCall provides these guarantees for standard telephone calls without requiring changes to any core network.

Our work makes the following contributions:

- **Designs Channel Binding and Authentication Protocols:** We design protocols that bind identities to phone numbers, mutually authenticate both parties of a phone call, and protect call content in transit.
- **Evaluates Robust Speech Digests for Security:** We show that proposed constructions for digesting speech data in systems that degrade audio quality can be made effective in adversarial settings in real systems.
- **Evaluates Call Performance in Real Networks:** Our prototype implementation shows that the techniques pioneered in AuthentiCall are practical and performant, adding at most only 1.4 seconds to phone call establishment in typical settings.

We are not the first to address this problem [2, 9, 17, 21, 43, 47, 56, 77]. However, other approaches have relied upon weak heuristics, fail to protect phone calls using the public telephone network, are not available to end users, neglect to protect call content, are trivially evaded, or add significant delay to call establishment. AuthentiCall is the only system that authenticates phone calls and content with strong cryptography in the global telephone network with negligible latency and overhead. We compare AuthentiCall to other existing or proposed systems in Section 9.

The remainder of this paper is organized as follows: Section 2 provides background information about the challenges underlying authentication in telephony networks; Section 3 describes our assumptions about adversaries and our security model in detail; Section 4 gives a formal specification of the AuthentiCall system; Section 5 discusses how analog speech digests can be used to achieve call content integrity; Section 6 provides details of the implementation of our system; Section 7 shows the results of our experiments; Section 8 offers additional discussion; Section 9 analyzes related work; and Section 10 provides concluding remarks.

2 Background

Modern telephony systems are composed of a mix of technologies. As shown in Figure 1, the path between a caller and callee may transit through multiple networks consisting of mobile cores, circuit-switched connections and packet-switched backbones. While the flow of a call across multiple network technologies is virtually invisible to customers, significant transformations occur to call audio between source and destination. Whereas the content of data packets on the Internet should not be modified between source and destination, call audio is transcoded by gateways to ensure that it is compatible with the underlying network. As such, *users of the global telephony infrastructure can only be guaranteed that an approximate but not bitwise identical representation of their voice will be delivered to the other end of the call.*

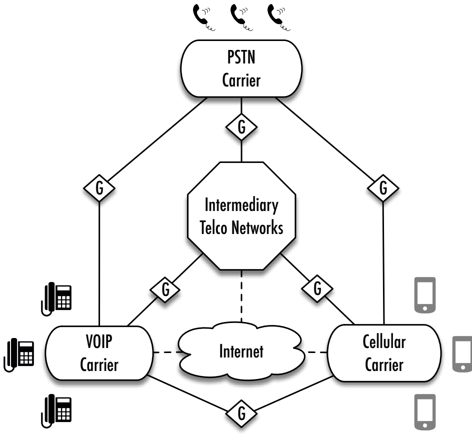

Figure 1: In the modern phone network, calls are often routed through gateways at network boundaries that remove authentication information and modify call audio.

Any other data that may be generated by a user or their home network is not guaranteed to be delivered or authenticatable end-to-end. That is, because the underlying technologies are heterogeneous, there is no assurance that information generated in one system is passed (much less authenticated) to another. This has two critical implications. The first is that any proofs of identity a user may generate to their provider are not sent to the other end of the call. For instance, a mobile phone on a 4G LTE connection performs strong cryptographic operations to prove its identity to its provider. However, there exists no means to share such proofs with a callee within this system let alone one in another provider's network. Second, claims of identity (e.g., Caller ID) are sent between providers with no means of verifying said claims. As evidenced by greater than $7 billion in fraud in 2015 [34], it is extremely simple for an adversary to trick a receiver into believing any claim of identity. There is no simple solution as calls regularly transit multiple intermediate networks between the source and destination.

It is increasingly common that modern phones have simultaneous access to at least low-bitrate data channels. VoIP phones naturally have a secondary data channel, the majority of mobile phones allow users to both talk and use data networks simultaneously, and even some circuit-switched connections (e.g., ISDN) provide phones with

a data connection. The presence of these data services does *not* mean that all calls can be simply converted to VoIP. For example, cellular data in many places does not support the high data-rate or quality of service necessary for intelligible calls. Moreover, it is unlikely that any provider will entirely scrap their non-VoIP infrastructure. Accordingly, we argue that the presence of this low-bitrate data channel creates opportunities to develop a uniform means of end-to-end authentication across the heterogeneous mechanisms for delivering call audio.

3 Security Model

In order to authenticate voice calls and content, AuthentiCall will face adversaries with a range of capabilities. The simplest adversary will attempt to commit phone fraud by spoofing Caller ID when calling a target [59, 60]. An equivalent form of this attack may occur by the adversary tricking their target to call an arbitrary number under their control (e.g., via spam or phishing) and claiming to represent some other party (e.g., a financial institution) [46]. Additionally, this adversary may perform a call forwarding attack, which forces a target calling a legitimate number to be redirected to the adversary. Lastly, the adversary may place a voice call concurrent with other legitimate phone calls in order to create a race condition to see which call arrives at the destination first. In all of these cases, the goal of the adversary is to claim another identity for the purpose of extracting sensitive information (e.g., bank account numbers, usernames, and passwords).

A more sophisticated adversary may gain access to a network core via vulnerabilities in systems such as SS7 [15], or improperly protected legal wiretapping infrastructure [74]. This adversary can act as a man-in-the-middle, and is therefore capable of redirecting calls to an arbitrary endpoint, acting as an arbitrary endpoint, hanging up one side of a call at any point in time, and removing/injecting audio to one or both sides. Such an adversary is much more likely to require nation-state level sophistication, but exists nonetheless. Examples of both classes of adversary are shown in Figure 2.

Given that the bitwise encoding of audio is unlikely to be the same at each endpoint, end-to-end encryption is not a viable means of protecting call content or integrity across the heterogeneous telephony landscape. Moreover, while we argue that the majority of phones have access to at least a low-bandwidth data connection, solutions that demand high-speed data access at all times (i.e., pure VoIP calls) do not offer solutions for the vast majority of calls (i.e., cellular calls). Finally, we claim no ability to make changes throughout the vast and disparate technologies that make up the core networks of modern telephony and instead focus strictly

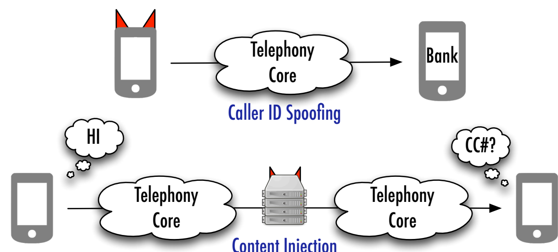

Figure 2: Broad overview of attacks possible on Caller ID and call content in current telephony landscape.

on addressing this problem in an end-to-end fashion.

We define four participants: the Caller (R), the Callee (E), the Server (S), and the Adversary (Adv). Callers and Callees will register with the AuthentiCall service as described in the next section and will generate credentials[1] that include a public key. AuthentiCall will achieve the following security goals in the presence of the above-described adversaries:

1. **(G1) Proof of Number Ownership:** During the process of registration, R will actively demonstrate ownership of its claimed Caller ID to S before it receives a signed certificate.
2. **(G2) Authentication of the Caller:** E will be able to cryptographically verify the identity of R prior to accepting an incoming call.
3. **(G3) Authentication of the Callee:** R will be able to cryptographically verify the identity of E as soon as the call begins.
4. **(G4) Integrity Protection of Call Content:** R and E will be able to verify that the analog voice content has not been meaningfully altered, or that new content has not been injected by a man in the middle. Additionally, both will also be protected against concurrent call attacks.
5. **(G5) Proof of Liveness:** Both R and E will be able to detect if the other party is no longer on the call, perhaps as the result of a man in the middle attempting to engage in the call after the initial authentication.

We note that AuthentiCall does not provide confidentiality guarantees. While recent work has shown how to build systems that support anonymous calling [31], encrypting call audio end-to-end in lossy, heterogeneous telephone networks remains an open problem.

4 Protocol Design and Evaluation

Previously, we saw that AuthentiCall has five security goals to meet, and this section describes the three protocols that AuthentiCall uses to achieve these goals. These

[1] The details of which are described in depth in Section 4.

are the *Enrollment*, *Handshake*, and *Call Integrity* protocols.

These protocols make use of certificates issued to each client that indicate that a particular client controls a specific phone number. In prior work we proposed a full public key infrastructure for telephony [56] called a "TPKI" that would have as its root the North American Numbering Plan Administration with licensed carriers acting as certificate authorities. This PKI would issue an authoritative certificate that a phone number is owned by a particular entity, and AuthentiCall could enforce that calls take place between the entities specified in those certificates. While AuthentiCall can leverage the proposed TPKI, a fully-deployed TPKI is not necessary as AuthentiCall can act as its own certificate authority (this is discussed further in the enrollment protocol).

All of these protocols make use of a client-server architecture, where an AuthentiCall server acts as either an endpoint or intermediary between user clients. There are several reasons for this design choice. First, having a centralized relay simplifies the development of AuthentiCall. Although there are risks of adding a centralized point on a distributed infrastructure, our design minimizes them by distributing identity verification to a certificate authority and only trusting a central server to act as a meeting point for two callers. Second, it allows the server to prevent abuses of AuthentiCall like robodialing [71] by a single party by implementing rate limiting. The server can authenticate callers before allowing the messages to be transmitted, providing a mechanism for banning misbehaving users. Finally, all protocols (including handshake and enrollment) implement end-to-end cryptography. Assuming the integrity of the AuthentiCall certificate authority infrastructure and the integrity of the client, no other entity of the AuthentiCall network can read or fabricate protocol messages. We also assume that all communications between clients and servers use a secure TLS configuration with server authentication.

Our protocols have another goal: no human interaction except for choosing to accept a call. There are two primary reasons for this. First, it is well established that ordinary users (and even experts) have difficulty executing secure protocols correctly [76]. Second, in other protocols that rely on human interaction, the human element has been shown to be the most vulnerable [63].

The following subsections detail the three protocols in AuthentiCall. First, the enrollment protocol ensures that a given AuthentiCall user actually controls the phone number they claim to own (G1). The enrollment protocol also issues a certificate to the user. Second, the handshake protocol mutually authenticates two calling parties at call time (G2 and G3). Finally, the call integrity protocol ensures the security of the voice channel and the content it carries (G4 and G5).

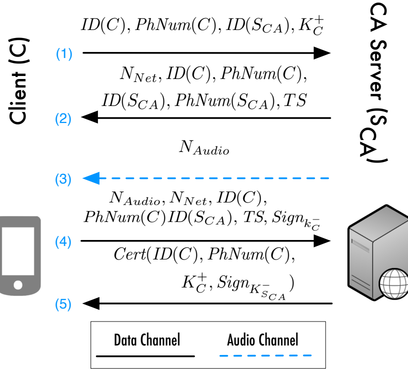

Figure 3: Our enrollment protocol confirms phone number ownership and issues a certificate.

4.1 Enrollment Protocol

The enrollment protocol ensures that a client controls a claimed number and establishes a certificate that binds the identity of the client to a phone number. For our purposes, "identity" may be a user's name, organization, or any other pertinent information. Binding the identity to a phone number is essential because phone numbers are used as the principal basis of identity and routing in phone networks, and they are also used as such with AuthentiCall. The enrollment protocol is similar to other certificate issuing protocols but with the addition of a confirmation of control of the phone number.

Figure 3 shows the details of the enrollment protocol. The enrollment protocol has two participants: a client C and an AuthentiCall enrollment server S_{CA}. In message 1, C sends an enrollment request with S_{CA}'s identity, C's identity info, C's phone number, and C's public key. In message 2, the server sends a nonce N_{Net}, the identities of C and S_{CA} and the phone numbers of C and S_{CA} with a timestamp to ensure freshness, liveness, and to provide a "token" for this particular authentication session.

In message 3, the server begins to confirm that C controls the phone number it claims. The number is confirmed when S_{CA} places a call to C's claimed phone number. When the call is answered, S_{CA} transmits a nonce *over the voice channel*. Having S_{CA} call C is a critical detail because intercepting calls is far more difficult than spoofing a source number.[2] Using a voice call is important because it will work for any phone – including VoIP devices that may not have SMS access.

In message 4, C sends both N_{Net} and N_{Audio} along with the IDs of server, clients, a timestamp, and a signature covering all other fields. This final message concludes the proof of three things: possession of N_{Net}, the ability

[2] We will revisit the threat of call interception later in this subsection.

to receive a call by providing N_{Audio} and possession by C of the private key K_C^- by virtue of signing the message.

In message 5, S_{CA} replies with a signed certificate issued to C. This completes the enrollment protocol.

We note that this protocol is subject to the same limitations on certifying identity as every other Internet certificate authority. In particular, we will require an out-of-band process to verify identity for high-value certificates, and will require the ability to authenticate supporting documentation. AuthentiCall can also use other authoritative information sources like CNAM[3] lookups to verify number ownership in some cases. While no system or process is perfect, these types of policies have been largely effective on the Internet.

We also note that this is a trust-on-first-use (TOFU) protocol. While the protocol is secure in the presence of passive adversaries on both the data and voice networks, if an adversary can actively intercept a call addressed to a victim phone number (and also supply any out-of-band identity confirmation), they may be able to obtain a certificate for a number they illicitly control. If a TPKI were deployed, this attack would not be possible. Even without a TPKI, the likelihood of a successful attack is limited. Success is limited because the attack would eventually be detected by the legitimate owner when they attempt to register or authenticate using the legitimate number. To further protect against the prior attack, our protocol meets an additional goal: human interaction is not required for enrollment and confirming control of the claimed phone number. This means that automatic periodic reverification of phone number control is possible. This is important to prevent long-term effects of a brief phone number compromise, but also for more mundane issues like when phone numbers change ownership.

4.2 Handshake Protocol

The handshake protocol takes place when a caller intends to contact a callee. The caller places a voice call over the telephone network while simultaneously using a data connection to conduct the handshake protocol.

The handshake protocol consists of two phases. The first indicates to the AuthentiCall server and the calling party that a call is imminent. The second phase authenticates both parties on the call and establishes shared secrets. These secrets are only known end-to-end and are computed in a manner that preserves perfect forward secrecy. Figure 4 shows the handshake protocol.

Prior to the start of the protocol, we assume that C has

[3]CNAM is the distributed database maintained by carriers that maps phone numbers to the names presented in traditional caller ID. While spoofing a number is trivial, CNAM lookups occur out-of-band to call signaling and results could only be spoofed by a carrier, not a calling party.

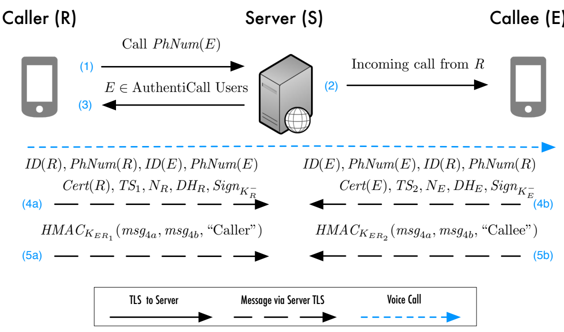

Figure 4: Our handshake protocol mutually authenticates both parties.

connected to S via TLS, meaning S has properly authenticated itself to C. After connecting C authenticates itself to S, by either presenting a username/password pair or by signing a challenge with its private key.

The first phase consists of messages 1–3. In message 1, a caller R indicates to an AuthentiCall server S that R would like to place a call to the callee E. In message 2, S informs the callee E that an authenticated voice call is incoming.

In message 3, S informs R whether E is an AuthentiCall user or not, but does not provide information about E's presence or availability. Message 3 has several aims. The first is to protect the privacy of E. A strawman mechanism to protect privacy is for AuthentiCall to provide no information about E until E agrees to accept the call. However, this presents a problem: if an adversary tampers or blocks messages from E, it prevents E from participating in the handshake, and R would have to assume (in the absence of outside knowledge) that E is not a participant in AuthentiCall. This would allow an adversary to evade AuthentiCall. To solve this problem, S simply indicates to R whether or not R should expect to complete an AuthentiCall handshake for this call if E is available and chooses to accept the call. This reveals only E's preference to authenticate a phone call, and nothing about her availability or whether she has even chosen to accept or reject a call. Protecting this information is important because if an unwanted callee knows that a user is available, they may call repeatedly or use that information in other undesirable ways (e.g., harassment or telemarketing). If message 3 indicates that E is not an AuthentiCall user but E does not choose to accept the call, R must simply wait for the call request to time out. From R's perspective, this is no different from dialing and waiting for a busy signal or voicemail and should add little to no latency to the call. If message 3 indicates that E is not an AuthentiCall user, the protocol ends at this step and R is forced to fallback to an insecure call.

The second handshake phase authenticates R and E and consists of messages 4A-B and 5A-B. These messages are indicated by letters A and B because the messages contain the same fields for caller and callee respectively. They can be computed independently and sent in parallel, reducing round trip latencies.

Message 4 contains all information necessary for a Diffie-Hellman key establishment authenticated with a signature key defined in the certificate of R or E. It also contains identity information for R or E, the calling or called phone number, a timestamp, and a nonce. Each side also provides a Diffie-Hellman share, and the entire message is signed with the public key in the certificate issued by AuthentiCall.

After message 4, both sides combine their Diffie-Hellman secret with the share they received to generate the derived secret. Each client then generates keys using the Diffie-Hellman result, the timestamps of both parties, and the nonces of both parties. These keys are used to continue the handshake and to provide keys for the integrity protocol.

Message 5A and 5B contain an HMAC of messages 4A and 4B along with a string to differentiate message 5A from message 5B. The purpose of this message is to provide key confirmation that both sides of the exchange have access to the keys generated after messages 4A and 4B. This message concludes the handshake protocol.

4.3 Call Integrity Protocol

The call integrity protocol binds the handshake conducted over the data network to the voice channel established over the telephone network. Part of this protocol confirms that the voice call has been established and confirms when the call ends. The remainder of the messages in this protocol exchange content authentication information for the duration of the call. This content integrity takes the form of short "digests" of call audio (we discuss these digests in detail in the following section). These digests are effectively heavily compressed representations of the call content; they allow for detection of tampered audio at a low bit rate. Additionally, the digests are exchanged by both parties and authenticated with HMACs.

Figure 5 shows the details of the call integrity protocol. The protocol begins *after the voice call is established.* Both caller R and callee E send a message indicating that the voice call is complete. This message includes a timestamp, IDs of the communicating parties and the HMAC of all of these values. The timestamp is generated using the phone clock which is often synchronized with the carrier.[4] These messages are

[4] In this setting, loose clock synchronization (approximately one minute) is sufficient; if necessary, S can also provide a time update at login.

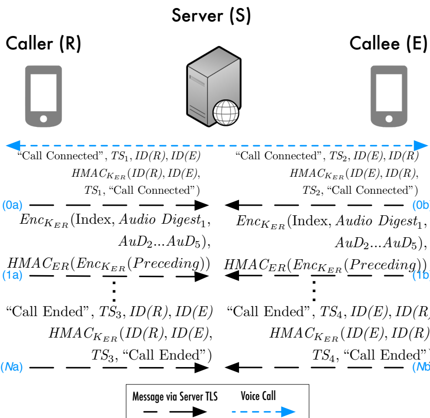

Figure 5: Our call integrity protocol protects all speech content.

designed to prevent attacks where a call is redirected to another phone. One possible attack is an adversary maliciously configuring call forwarding on a target; the handshake would be conducted with the target, but the voice call would be delivered to the adversary. In such a case, the target would not send a "call established" message and the attack would fail.

Once the voice call begins, each side will encrypt and send the other audio digests at a regular interval. It is important to note that we use unique keys generated during the handshake for encryption, message authentication codes, and digest calculation. The messages also guarantee freshness because the index is effectively a timestamp, and the message authentication codes are computed under a key unique to this call. Timestamps in messages 1-N are indexed against the beginning of the call, negating the need for a synchronized clock. In order to prevent redirection attacks, the messages are bound to the identities of the communicating parties by including the IDs in the HMACs and by using keys for the HMACs that are unique to the call.

When the voice call ends, each side sends a "call concluded" message containing the client IDs, a timestamp, and their HMAC. This alerts the end point to expect no more digests. It also prevents a man-in-the-middle from continuing a call that the victim has started and authenticated.

4.4 Evaluation

Our protocols use standard constructions for certificate establishment, certificate-based authentication, authenticated key establishment, and message authentication. We therefore believe our protocols are secure based on inspection. Nevertheless, we used ProVerif [20] to

further analyze the handshake and enrollment protocols. Our ProVerif code can be found in our technical report [55]. The analysis verified that our handshake protocol establishes and never leaks the secret key. The protocol also provides authentication and perfect forward secrecy for both the caller and callee. The enrollment protocol is verified to never leak the private keys of either party. This property allows us to assert that both signatures and certificates cannot be forged.

5 Speech Digest Design and Evaluation

The previous section describes how AuthentiCall enrolls and authenticates users prior to a call. During a call, AuthentiCall needs a way to summarize speech content in order to authenticate audio using a low-bandwidth data connection. To accomplish this goal, we leverage research from an area of signal processing that produces techniques that are known as "perceptual hashes" or "robust hashes." Robust digests have been developed for a wide domain of inputs, including music, images, and speech, but their applicability has remained limited. Unlike cryptographic hashes, which change drastically with small changes in input, robust hashes give very similar outputs for similar inputs. By definition, a robust digest cannot provide collision resistance (or second preimage resistance) because collisions are the property that make them useful. In this paper, we call these techniques "speech digests" to avoid confusion with cryptographic hashes. To our knowledge, this work presents one of the first uses of robust speech digests for security.

A speech digest has two goals. First, it must accurately summarize the content of the call. However, it is not necessary for this summary to be lossless or meaningful for human interpretation. We are also concerned more with semantics (i.e., words spoken) than we are with speaker voice characteristics (e.g., tone, identity) or extraneous features like noise. Second, the digest must be robust to non-semantic changes in audio.

Because of ambient or electronic noise, intermittent loss, and the use of differing encodings throughout the phone network, the audio transmitted by a phone will not be the same as the audio received. In particular, the audio received is practically guaranteed to *not* be identical on a bit level to the audio sent by the phone. This means that common data digest approaches like cryptographic hashes will fail.

While the original phone system used analog transmission of voice, it is now common in every telephone network (landline, VoIP, cellular, etc.) for speech to be digitized and compressed using an audio codec. At network boundaries, it is common for audio to be decoded and recoded into a different codec (known as transcoding). Codecs used in the phone network are highly lossy and drastically distort the call audio, and so have the potential to significantly impact audio digest performance. Because some phone systems (especially cellular and VoIP) use lossy networks for transmission, frames are routinely lost. For example, loss rates of 4% are considered nominal for cellular voice [12].

These legitimate modifications caused by the phone network must be distinguished from changes to audio induced by an adversary. The following subsections provide a description of the speech digests we use in AuthentiCall and a thorough analysis of the performance of these digests for telephone calls.

5.1 Construction and Properties

There are a number of constructions of speech digests, and they all use the following basic process. First, they compute derived features of speech. Second, they define a compression function to turn the real-valued features into a bit string. We use the construction of Jiao et al. [36] called `RSH`. We chose this technique over others because it provides good performance on speech at a low-bitrate, among other properties. We note that the original work did not evaluate the critical case where an adversary can control the audio being hashed. Our evaluation shows that `RSH` maintains audio integrity in this crucial case. The construction also selects audio probabilistically; we show in Appendix B that the digest indeed covers all of the semantic content in the input audio. Finally, to our knowledge we are the first to use any robust speech digest for an authentication and integrity scheme.

For space reasons, and because we do not claim the design of the `RSH` digest as a research contribution, we provide a detailed description of the actual computation of an `RSH` digest in Appendix A. However, the remainder of this subsection will provide details necessary for the rest of this paper. `RSH` computes a 512-bit digest for each 1 second of audio, and the digest can be thought of as a heavily compressed version of the audio in the call. The digest is computed probabilistically using a keyed pseudorandom number generator with a key derived during the handshake (Section 4.2) in AuthentiCall. The probabilistic nature of the digest ensures that digests of the same phrase (e.g., "Hello") differ and cannot simply be replayed. Digests are computed by the caller and are received and verified by the callee. The verifying party computes the digest of the received audio and the Hamming distance between the calculated and received digests. Because degradation of audio over a phone call is expected, digests will not match exactly. However, the Hamming distance between two audio digests (equivalent to the bit error rate (BER)) quantifies the change in the audio. By setting an appropriate threshold on BER, maliciously modified audio can be detected.

5.2 Implementation and Evaluation

Now that we have seen how RSH digests are computed, we can evaluate properties of RSH digests. This includes effects of legitimate transformations and the results of comparing digests of unrelated audio samples (as might be generated by an adversary). We also describe how we use digests to detect tampered audio.

We implement RSH using Matlab, and we deploy it in our AuthentiCall prototype by using the Matlab Coder toolbox to generate C code that is compiled as an Android native code library. We use the TIMIT audio corpus [30] which is a standard test dataset for speech processing systems. It consists of high-fidelity recordings of 630 male and female speakers reading 10 English sentences constructed for phonetic diversity. Because RSH computes hashes of one second of audio, we split the TIMIT audio data into discrete seconds of audio corresponding to a unique section of audio from a speaker and sentence. This resulted in 22,487 seconds of unique audio.

5.2.1 Robustness

Robustness is one of the most critical aspects of our speech digests, and it is important to show that these digests will not significantly change after audio undergoes any of the normal processes that occur during a phone call. These include the effects of various audio encodings, synchronization errors in audio, and noise. To test robustness, we generate modified audio from the TIMIT corpus and compare the BER of digests of standard TIMIT audio to digests of degraded audio. We first downsample the TIMIT audio to a sample rate of 8kHz, which is standard for most telephone systems. We used the `sox` [5] audio utility for downsampling and adding delay to audio to model synchronization error. We also used `sox` to convert the audio to two common phone codecs, AMR-NB (Adaptive Multi-Rate Narrow Band) and GSM-FR (Groupe Spécial Mobile Full-Rate). We used GNU Parallel [67] to quickly compute these audio files. To model frame loss behavior, we use a Matlab simulation that implements a Gilbert-Elliot loss model [32]. Gilbert-Elliot models bursty losses using a two-state Markov model parameterized by probabilities of individual and continued losses. We use the standard practice of setting the probability of an individual loss (p) and probability of continuing the burst ($1-r$) to the desired loss rate of 5% for our experiments. We also use Matlab's `agwn` function to add Gaussian white noise at a 30 decibel signal to noise ratio.

Figure 6 shows boxplots representing the distribution of BER rates of each type of degradation tested. All degradations show a fairly tight BER distribution near the median with a long tail. We see that of the effects

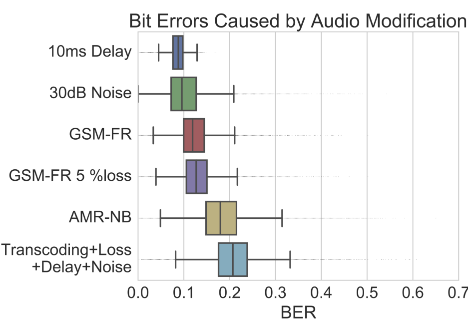

Figure 6: These box plots show the distribution of digests bit error rates as a result of various audio degradations. These error rates are well below the rates seen by adversarial audio, shown in Figure 7

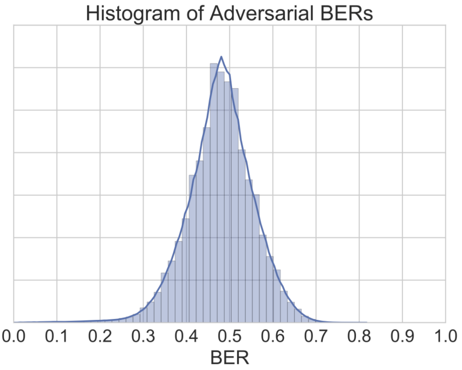

Figure 7: This graph shows the histogram and kernel density estimate of digest of adversarial audio on over 250 million pairs of 1-second speech samples. While the majority of legitimately modified audio has digest errors less than 35%, adversarial audio has digest BERs averaging 47.8%.

tested, 10ms delay has the least effect; this is a result of the fact that the digest windows the audio with a high overlap. For most digests, addition of white noise also has little effect; this is because LSF analysis discards all frequency information except for the most important frequencies. We see higher error rates caused by the use of audio codecs like GSM-FR and AMR-NB; these codecs significantly alter the frequency content of the audio. We can also see that a 5% loss rate has negligible effect on the audio digests. Finally, we see that combining transcoding, loss, delay, and noise has an additive effect on the resulting digest error — in other words, the more degradation that takes place, the higher the bit error. These experiments show that RSH is robust to common audio modifications.

5.2.2 Adversarial Audio

While robustness is essential, the ultimate goal of these digests is to detect maliciously tampered or injected audio, which we term "adversarial audio." Such an analysis has not been previously performed. To validate the ability of RSH to detect adversarial audio we compute the BER of digests of every pair of seconds of TIMIT audio discussed in the previous section. This dataset includes 252,821,341 pairs of single seconds of audio. For this test, we use the same key for every hash; this models the situation where an adversary can cause the target to receive audio of its choice but not modify the associated digest.

We find that the mean BER between two distinct audio pairs is 0.478. A histogram and kernel density estimate of these values is also shown in Figure 7. This plot shows that the bit error is normally distributed with a mean and median of 0.478 and 0.480 (respectively). The expected bit error for two random bit strings is 50%, and the mean seen for RSH bit error is close to the optimal, best possible distance between two adversarial digests.

Because the TIMIT corpus contains speakers speaking several identical sentences, we can investigate the resilience of the digest to more specific adversarial scenarios in two important ways. First, we can look at whether using different speech from the same speaker can create a false positive. If so, this would be a serious problem because an adversary could use recorded words from the target speaker undetected. Second, we can determine if a different speaker uttering the same words causes false positives. This test indicates to what extent the digest is protecting *content* instead of speaker characteristics.

We found that digests from the same speaker speaking different content are accepted at practically the same rate as audio that differs in speaker and content. At a BER detection threshold of 0.384 (derived and discussed in the following subsection), the detection rate for different content spoken by the same speaker is 0.901482, while the detection rate for different content spoken by a different speaker is 0.901215. However, identical phrases spoken by different speakers results in a much higher rate of collision and a detection rate of 0.680353. This lower detection rate is not a problem for AuthentiCall because it is still high enough to detect modified call audio with high probability. More importantly, it indicates that RSH is highly sensitive to changes in call content.

5.2.3 Threshold selection and performance

Distinguishing legitimate and illegitimate audio requires choosing a BER threshold to detect tampered audio. Because the extreme values of these populations overlap, a tradeoff between detection and false positives must be made. The tradeoff is best depicted in a ROC curve in

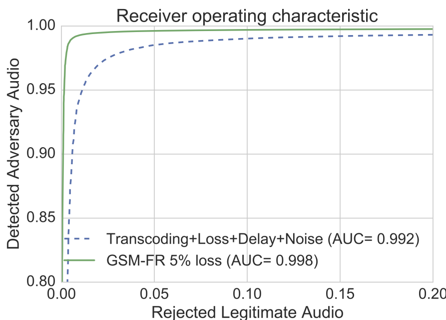

Figure 8: The digest performance ROC graph shows that digests can easily distinguish between legitimate and substituted audio, even in the presence of transcoding, loss, delay, and noise. These results are computed over digests of a single second. The graph is scaled to show the extreme upper corner.

Figure 8. This figure shows the true positive/false positive tradeoff measured on the adversarial audio and two legitimate modifications – GSM encoding and a combination of GSM, AMR-NB, 5% frame loss, 10ms delay, and 30dB of white noise. This combination represents an approximate "worst case" of legitimate audio. Figure 8 shows excellent performance in terms of distinguishing audio. For GSM-only audio, we see an area-under-curve of 0.998, and for the "worst case" audio, we see an area-under-curve of 0.992. However, because digests will be used at a high rate (one per second), even with a very small false positive rate, alerting users for every individual detection will likely result in warning fatigue. As a result, the most important metric for evaluating a threshold is minimizing the user's likelihood of a false positive. This problem suggests trading off sensitivity to short changes in call content for a lower false positive rate. To reduce overhead and network load, AuthentiCall sends digests in groups of five. To provide high detection rates while limiting false positives, AuthentiCall alerts the user if any 3 out of 5 digests are greater than the BER threshold. We model true and false performance of this scheme as a set of five Bernoulli trials — successful authentication for true positives and successful digest collision for false positives. Thus, we can compute 3-out-of-5 performance using the binomial distribution.

After this analysis, we selected an individual-digest BER threshold of 0.384. This corresponds to an individual adversary audio true positive detection rate of 0.90, while presenting a 0.0058 false positive rate against our "worst-case" audio and a 0.00089 false positive rate against clean GSM-FR encoded audio. Using our "three-out-of-five" alerting scheme, the probability of detecting 3 or more seconds of tampered audio is 0.992. The false positive rate is drastically reduced: the false positive rate

is 1.96×10^{-6}, and for clean GSM-FR audio the false positive rate is 7.02×10^{-9}. This corresponds to a false alert on average every 425.1 hours of talk time for worst case audio, and for GSM-FR audio one false positive every 118,766 hours. The average British mobile phone user only places 176 minutes per month of outbound calls [65]; assuming inbound and outbound talk time are roughly equal, the average user only places 70.4 hours of calls per year. This means that the average AuthentiCall user would only see a false alert *once every six years.*

5.2.4 Limitations

No security solution is perfect, and our use of audio digests have some limitations. The chief limitation is that audio digests cannot detect altered audio less than one second in length. This limitation is simply a result of the constraints of doing low-bitrate authentication of mutable and analog data.

While the digests are not perfect, we argue that they are secure against most adversaries. We note that audio digests have two purposes: 1) to provide a guarantee that the voice call established was the one that was negotiated in the handshake and 2) that the voice content has not significantly changed during the call. These two goals deal with adversaries of different capabilities. In particular, intercepting and modifying call audio requires far more advanced access and capability than simply spoofing a caller ID during a handshake already occurring. Audio digests will detect the first scenario within five seconds of audio, and it will also quickly detect changes that effect any three seconds in five for the second scenario.

In limited circumstances, it may be possible for a man-in-the-middle adversary to make small modifications to the received audio. For the second attack to be successful in the presence of these digests, a number of conditions must hold: First, the adversary can change no more than two seconds out of every five seconds of audio. Second, the adversary must change the audio in a way that would sound natural to the victim. This would mean that the changed audio would have to conform to both the current sentence pattern as well as the speaker's voice. While voice modification algorithms exist (e.g., Adobe VoCo [10] and Lyrebird [11]), modifying an existing sentence in an ongoing conversation is beyond the abilities of current natural-language processing. Also, since our digests depend on the semantic call content, changes to the structure of a sentence (and not necessary audible voice) would alert the user. Finally, in addition to the substantial difficulty of these limits, the adversary must also do all of this in soft-real-time.

Additionally, our threat model assumes the adversary has access to the audio (but not the keys) that generated the digest and thus second preimage resistance is a relevant property. Note that our security argument rests in the computational difficulty of finding a series of collisions in real-time using semantically relevant audio. The protection that RSH would provide for preimage resistance (given an arbitrary digest but no corresponding audio) depends primarily on the security of the keyed-pseudorandom selection of audio segments for each digest. Evaluating this property is interesting but not immediately relevant to the security of our system.

Nevertheless, a user is still not defenseless against such an attack. While we believe such attempts would likely be noticeable and suspicious to the human ear, users could also receive prompts from AuthentiCall when individual digests fail. These prompts could recommend that the user ask the opposing speaker to elaborate their prior point or to confirm other details to force the adversary to respond with enough tampered audio that the attack could be detected.

6 System Implementation

The previous sections described the protocol design and characterized our speech digests. In this section, we describe our AuthentiCall client and server implementation, and in the following section evaluate its performance.

Server: Our server was implemented in Java, using Twilio's Call API to call clients during the registration phase to share the audio nonce that confirms control of a phone number. Google Cloud Messaging (GCM) is used to generate a push notification to inform clients of incoming calls.

Client: Our prototype AuthentiCall client consists of an Android app, though we anticipate that in the future AuthentiCall will be available for all telephony platforms, including smartphones, VoIP phones, PBXs, and even landlines (with additional hardware similar in concept to legacy Caller ID devices that uses a wireless or wired LAN data connection).

A TLS connection is used to establish a secure channel between client and server. We implement the AuthentiCall protocol in Java using the Spongy Castle library [1]. The audio digests were implemented in Matlab, compiled to C, and linked into the app as native code. In our implementation, digest protocol messages contain five seconds of audio digests.

We use RSA-4096 to as our public key algorithm and SHA-3 for the underlying hash function for HMACs. To reduce handshake time, we use a standard set of NIST Diffie-Hellman parameters hardcoded into the client. These are NIST 2048-bit MODP group with a 256-bit prime order subgroup from RFC5114 [41]. We also use the HMAC-based key derivation algorithm used by TLS 1.2 described in RFC 5869 [39]. Upon registration, the

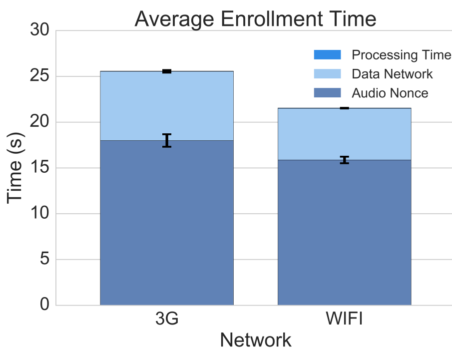

Figure 9: Enrollment takes less than 30 seconds and is a one time process that may be done in the background.

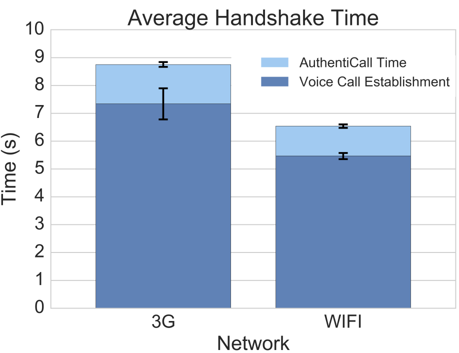

Figure 10: AuthentiCall adds 1 to 1.41 seconds to the phone call establishment, making the overhead effectively unnoticeable to users.

server issues the client an X509 certificate. This consists of a user's claimed identity, phone number, validity, public key and signature of the CA.

Audio Nonces: As described in Section 4, the AuthentiCall enrollment protocol sends a nonce through the voice channel to ensure that an client can receive a voice call. We use a 128-bit random nonce. In our implementation, the nonce is encoded as touch-tones (DTMF[5]). DTMF tones were used because they are faithfully transmitted through every telephone system and were simple to send and detect. There are 16 possible touch-tone digits [6], so each tone can represent an encoded hexadecimal digit. These tones are transmitted for 200ms each with a 100ms pause between tones. This provides a bit rate of 13.3 bits per second for a nonce transmission time of 9.6 seconds. This transmission time comprises the bulk of the time spent in the enrollment protocol.

7 Results

Our AuthentiCall implementation allows us to test its performance in enrollment, call handshakes, and detecting modified call audio in real phone calls.

7.1 Experiment Setup

Before describing individual experiments, we describe our experiment testbed. The AuthentiCall server was placed on an Amazon Web Services (AWS) server located in Northern Virginia. We used the same network provider, AT&T, and the same cellular devices, Samsung Galaxy Note II N7100s, across all experiments. The enrollment and handshake experiments were carried out 20 times over both WiFi and 3G, and digest exchange tests were done 10 times using WiFi. Digest exchange was done over WiFi as this experiment was used to validate content protection, not delivery speed. In all experiments, calls used a 3G voice channel.

We evaluate 3G and WiFi because our research phones do not support 2G-only operation. We note that not all wireless access is created equal, and actual speeds depend on many factors including network congestion, transmission power, and interference.

7.2 Enrollment Protocol

Our first experiments measure the user enrollment time. We measure the time from the instant a user begins enrollment to when the user receives the last protocol message, including all protocol messages and the audio nonce. For clients, enrollment is a one-time process that is done before the first call can be placed, analogous to activating a credit card. Figure 9 shows the average time of enrollment using 3G and WiFi to exchange protocol messages. The main contributor to the enrollment time comes from the transmission of the audio nonce which is used to establish ownership. Though the enrollment times over 3G and WiFi are 25 and 22 seconds respectively, this protocol requires no user interaction.

7.3 Handshake Protocol

We next measure the time to complete an entire handshake, including data messages and voice call setup. We note that voice call setup time is substantial, and requires many seconds even without AuthentiCall. We believe the most important performance metric is additional latency experienced by the end user. As shown in Figure 10, AuthentiCall only adds 1.07 seconds for WiFi or 1.41 seconds on 3G data to the total call establishment time (error bars indicate standard error). We believe that

[5]Dual-Tone Multi-Frequency tones are the sounds made by dialing digits on a touch-tone phone.

[6]Four DTMF tones are not available on consumer phones but provide additional functionality in some special phone systems

this will be unnoticeable to the user for several reasons. First, call establishment time varies significantly. This is normal network behavior, not an artifact introduced by AuthentiCall. In our 3G experiments our additional handshake time is approximately equal to the standard error in voice call establishment. We also note that our test phones were in the same location connected to the same tower, so the voice call setup time is likely lower than a typical call. In fact, our measured times are very close to the published estimates of 6.5 seconds for call setup by the tower between both phones [4]. Finally, we note that this is substantially faster than Authloop [56] which takes nine seconds to perform authentication *after call delivery*.

7.4 Speech Digest Performance

Our final experiments evaluate our speech digest accuracy over real call audio. In these 10 calls, we play 10 sentences from 10 randomly selected speakers in the TIMIT corpus through the call, and our AuthentiCall implementation computed the sent and received digests. In total this represented 360 seconds of audio. For simplicity, a caller sends audio and digests, and a callee receives the audio and compares the received and locally computed digests. We also compared these 10 legitimate call digests with an "adversary call" containing different audio from the hashes sent by the legitimate caller. To compare our live call performance to simulated audio from Section 5, we first discuss our individual-hash accuracy.

Figure 11 shows the cumulative distribution of BER for digests of legitimate audio calls and audio sent by an adversary. The dotted line represents our previously established BER threshold of 0.348.

First, in testing with adversarial audio, we see that 93.4% of the individual fraudulent digests were detected as fraudulent. Our simulation results saw an individual digest detection rate of 90%, so this means that our real calls see an even greater performance. Using our 3-out-of-5 standard for detection, we detected 96.7%. This test shows that AuthentiCall can effectively detect tampering in real calls. Next, for legitimate calls, 95.5% of the digests were properly marked as authentic audio. Using our 3-out-of-5 standard, we saw no five-second frames that were marked as tampered.

While our individual hash performance false positive rate of 4.5% was low, we were surprised that the performance differed from our earlier evaluation on simulated degradations. Upon further investigation, we learned that our audio was being transmitted using the AMR-NB codec set to the lowest possible quality setting (4.75kbps); this configuration is typically only used when reception is exceptionally poor, and we anticipate this case will be rare in deployment. Nevertheless, there are several mechanisms that can correct for this. One option would be to digest audio *after* compression for transmission (our prototype uses the raw audio from the microphone); such a scheme would reduce false positives partially caused by known-good transformation of audio. Another option is to simply accept these individual false positives. Doing so would result in a false alert on average every 58 minutes, which is still acceptable as most phone calls last only 1.8 minutes [3].

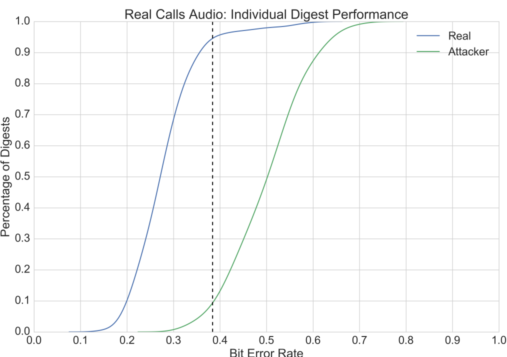

Figure 11: This figure shows that 93.4% of individual digests of adversarial audio are correctly detected while 95.5% of individual digests of legitimate audio are detected as authentic. Using a 3-out-of-5 detection scheme, 96.7% of adversarial audio is detected.

8 Discussion

We now discuss additional issues related to AuthentiCall.

Applications and Use Cases: AuthentiCall provides a mechanism to mitigate many open security problems in telephony. The most obvious problems are attacks that rely on Caller ID fraud, like the perennial "IRS scams" in the United States. Another problem is that many institutions, including banks and utilities, use extensive and error-prone challenge questions to authenticate their users. These challenges are cumbersome yet still fail to stop targeted social engineering attacks. AuthentiCall offers a strong method to authenticate users over the phone, increasing security while reducing the authentication time and effort.

Another valuable use case is emergency services, which have faced "swatting" calls that endanger the lives of first responders [73] as well as denial of service attacks that have made it impossible for legitimate callers to receive help [8]. AuthentiCall provides a mechanism to allow essential services to prioritize authenticated calls in

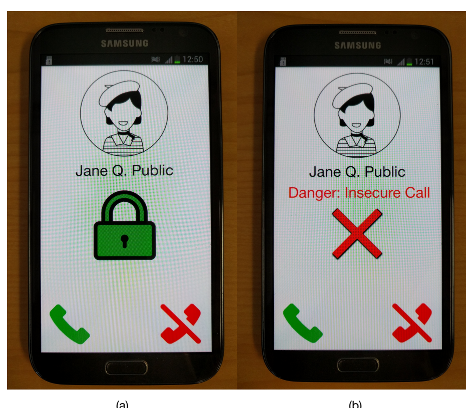

Figure 12: Before the call is answered, AuthentiCall indicates if the call is authenticated or unauthenticated

such a scenario while answering other calls opportunistically. While such a proposal would need to be reviewed by public policy experts and stakeholders, we provide a mitigation to a problem with no clear solution.

Server Deployment: AuthentiCall relies on a centralized server infrastructure to facilitate authenticated calls while minimizing abuse. AuthentiCall, including server infrastructure, could be provided by a carrier or an independent organization. While a centralized model is simplest to test our hypothesis that auxiliary data channels can be used to authenticate traditional voice calls, we intend to study decentralized and privacy-preserving architectures in future work.

Cellular Network Load: Systems that make use of the cellular network must be careful not to increase signaling load on the network in a harmful way [26, 40, 62]. We believe that AuthentiCall will not cause network harm because in modern networks (3G and 4G), data signaling is no longer as expensive as a voice call, and simultaneous voice and data usage is now commonplace.

Certificate Management: Any system that relies on certificates must address certificate revocation and expiration. AuthentiCall's centralized model allows the server to deny use of any revoked certificate, drastically simplifying revocation compared to CRLs or protocols like OCSP. Similar to Let's Encrypt [7], AuthentiCall certificates can have short lifetimes because certificate renewal using our enrollment protocol is fast and requires no human interaction. Our certificate authority proposal is one of many possible designs. As mentioned in Section 4, AuthentiCall could also make use of the proposed Telephony PKI [56]. In this scenario, certificate lifetime would be determined by the TPKI, which would also issue a certificate revocation list.

Why IP data: We chose IP data over other channels because it provides reliable and fast data transmission for most existing devices including smartphones, VoIP phones, and even landlines if provided with suitable hardware. As an example, SMS as a transmission carrier would be impractical. Bandwidth is low, and delivery is slow and not guaranteed [69]. In particular, the average time to send one SMS message is 6.4 seconds [53], meaning that AuthentiCall using SMS would require a minimum of *38.4 seconds* — effectively increasing call setup time by a factor of 5. If data connections are not available, users could use a system like Authloop to authenticate their calls. [56]

Why Not Biometrics: Robust speech digests are a superior solution for content integrity than voice biometrics for several reasons. First, voice authentication is simply not secure in adversarial settings [38]. Second, voice biometrics would assume that the call would only consist of a single party (e.g., speakerphones would not be supported). By contrast, audio digests are speaker independent and can be computed locally with no additional knowledge about the other party.

Denial of Service Adversaries may attempt to break the security of AuthentiCall by selectively dropping protocol messages, but AuthentiCall can detect these attacks and fail to complete a call or end an in-progress call. In the handshake, the client will not accept a voice call until the all authentication messages are complete. During the integrity protocol, the client can enforce tight timeouts of all messages and alert the user of an attack if expected messages do not arrive.

User Interface We have developed a complete working prototype of AuthentiCall for Android, including a preliminary simple user interface as shown in Figure 12. Along with previous research [72], this is one of the first interfaces to indicate secure Caller-ID, our prototype interface is intended to simply and clearly alert the user to the safety of the call. We note that indicating security in a user interface requires great care [13, 16], and we intend to formally study interface design for AuthentiCall in future work.

9 Related Work

Authentication has long been a concern in telephony networks. Chiefly motivating that concern has been the need to identify customers to bill for service usage [69]. The strength of such authentication mechanisms have varied widely, from easily breakable or weak authentication (e.g., 1G and 2G cellular) [18, 54] and authorization [42, 70, 75] to strong mutual authentication (e.g., LTE). However, all of these mechanisms do not provide authentication end-to-end.

Researchers have attempted to address the problem through one of two classes of solutions: heuristics or cryptography. In the case of the former, researchers have

explored a wide range of solutions: blacklists of phone numbers [6, 44, 52], call-back verification [47], channel characterization [57], call data analysis [35, 45, 48, 58], carrier level ID extraction [68], timing [47], call provenance [17], name registries [22] and biometrics [14, 19, 27, 37]. The difficulty with these is that their defenses are probabilistic in nature and may be weak in various adversarial settings. Given the increasing number of attacks on machine learning algorithms [33,49,50], such techniques offer uncertain security properties.

As for cryptographic solutions, most have been VoIP-only (e.g., Zfone and Redphone) [2, 9, 21, 43, 77]. Such solutions not only require high bandwidth at all times, but also *cannot be extended to the heterogeneous global telephone network*. Additionally, they are susceptible to man-in-the-middle attacks [28, 63] and are difficult to use [25, 51, 61, 64]. Tu et al. have described how to modify SS7, the core telephony signaling protocol, to support authenticated Caller ID [72]. This protocol is not end-to-end (so the protocol is vulnerable to malicious network endpoints like IMSI-catchers [23, 24]), requires both endpoints to call from an SS7-speaking network, and most importantly would also require modifying core network entities throughout every network.

The solution closest to our own is Authloop [56]. Authloop uses a codec agnostic modem and a TLS-inspired protocol to perform authentication solely over the audio channel. While Authloop provides end-to-end authentication for heterogeneous phone calls, it has a number of limitations compared to AuthentiCall. The constrained bandwidth of the audio channel means that the handshakes are slow (requiring 9 seconds on average), authentication is one-sided, and content authentication is not possible. While Authloop can prevent some forms of man-in-the-middle attacks, it is vulnerable to attacks that replace content. Finally, because Authloop relies on the audio channel, users must answer all calls before they can be authenticated. AuthentiCall overcomes all of these limitations.

10 Conclusion

Telephone networks fail to provide even the most basic guarantees about identity. AuthentiCall protects voice calls made over traditional telephone networks by leveraging now-common data connections available to call endpoints. AuthentiCall cryptographically authenticates both call parties while only adding a worst case 1.4 seconds of overhead to the call setup time. Unlike other solutions that use voice calls, AuthentiCall also protects the content of the voice call with high accuracy. In so doing, AuthentiCall offers a solution to the constant onslaught of illicit or fraudulent bulk calls plaguing the telephone network.

A RSH Digest Construction

In this appendix, we describe the construction of the RSH digest used by AuthentiCall for channel binding and content integrity.

There are a number of constructions of speech digests, and they all use the following basic process. First, they compute derived features of speech. Second, they define a compression function to turn the real-valued features into a bit string. In this paper, we use the construction of Jiao et al. [36], which they call RSH. We chose this technique over others because it provides good performance on speech at a low-bitrate, among other properties. We note that the original work did not evaluate the critical case where an adversary can control the audio being hashed. Our evaluation shows that RSH maintains audio integrity in this crucial case. The construction also selects audio probabilistically; we show in Appendix B that the digest indeed protects all of the semantic content in the input audio. Finally, to our knowledge we are the first to use any robust speech digest for an authentication and integrity scheme.

Figure 13 illustrates how RSH computes a 512-bit digest for one second of audio. In the first step of calculating a digest, RSH computes the Line Spectral Frequencies (LSFs) of the input audio. LSFs are used in speech compression algorithms to represent the major frequency components of human voice, which contain the majority of *semantic* information in speech.

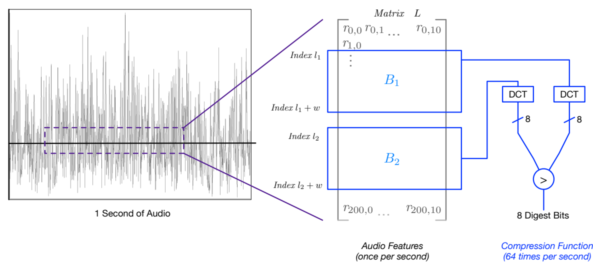

Figure 13: This figure illustrates the digest construction described in Section 5.1. Audio digests summarize call content by taking one second of speech data, deriving audio features from the data, and compressing blocks of those features into a bit string.

That is, LSFs represent phonemes – the individual sound units present in speech. While pitch is useful for speaker recognition, LSFs are not a perfect representation of all of the nuances of human voice. This is one reason why it is sometimes difficult for humans to confidently recognize voices over the phone. This means that the digest more accurately represents *semantic* content rather than the speaker's voice characteristics. This is important because a number of techniques are able to synthesize new speech that evades speaker recognition from existing voice samples [38,66]. Finally, LSFs are numerically stable and robust to quantization — meaning that modest changes in input yield small changes in output. In RSH, the input audio is grouped into 30ms frames with 25ms audio overlap between frames, and 10 line spectral frequencies are computed for each frame to create a matrix L.

The second phase of digest computation involves compressing the large amount of information about the audio into a digest. Because audio rarely changes on millisecond time scales, the representation L is highly redundant. To compress this redundant data, RSH uses the two-dimensional discrete cosine transform (DCT). The DCT is related to the Fourier transform, is computationally efficient, and is commonly used in compression algorithms (e.g., JPEG, MP3). RSH computes the DCT over different sections of the matrix L to produce the final digest. RSH only uses first eight DCT coefficients (corresponding to the highest energy components and discarding high-frequency information).

The second phase of digest computation – the compression function – uses the DCT algorithm in the computation of the bitwise representation of the audio sample. The following process generates 8 bits of a digest; it is repeated 64 times to generate a 512-bit digest.

1. Obtain a window size w and two window start indexes l_1 and l_2 from the output of a keyed pseudorandom function.
2. Select from L two blocks of rows. These blocks B_1 and B_2 contain all columns from $l_1 : l_1 + w$ and $l_2 : l_2 + w$ respectively.
3. Compress these individual blocks into eight coefficients each using the DCT.
4. Set eight digest bits by whether the corresponding coefficients of the first block (B_1) are greater than the coefficients

of the second block (B_2).

We note that sections of audio are selected probabilistically; we show in Appendix B that the probability that a section of audio is not used in a digest is negligible.

An important consideration is to note that the digest is *keyed*. By using a keyed pseudorandom function, repeated phrases generate verifiable unique digests. It also has the advantage that it makes it difficult to compute digests for audio without knowledge of the key, which in AuthentiCall is derived during the handshake for each call. In AuthentiCall, digests themselves are also authenticated using an HMAC to guarantee digest integrity in transit.

Digests of spoken audio are sent by both parties. The verifying party computes the digest of the received audio, then computes the hamming distance between the calculated and received digests. Because degradation of audio over a phone call is expected, digests will not match exactly. However, the Hamming distance between two audio digests — or bit error rate (BER) — is related to the amount of change in the audio. By setting an appropriate threshold on BER, legitimate audio can be distinguished from incorrect audio.

B Probabilistic Analysis of Robust Hashing

AuthentiCall uses the RSH speech digest algorithm [36], which probabilistically selects sections of audio for inclusion. The initial research did not establish whether all audio was included in every hash. In this appendix, we bound the probability that one or more 5ms sections of audio (which are individual rows in the matrix L) are not included. The analysis shows that it is possible for a few milliseconds of audio to be excluded – less than 25 milliseconds of audio. This is less than an individual phoneme, could not change semantic meaning of the audio, and losses of 25 milliseconds or more are common in audio transmission and typically go unnoticed by users. Accordingly, the digests effectively cover call content.

Fix an even integer $N > 0$, and fix a block width $w \in [2..N/2]$. Let $r \in [1..N]$ be a row index of the matrix L. We begin by computing the probability that in any particular trial, the r-th row is *not* covered by at least one of the two blocks B_1, B_2 used in the robust hashing algorithm. Recall that the "top" row of B_1 and B_2 are randomly selected each trial. Thus, let ℓ_1, ℓ_2 be uniform integers in the range $[1..N+1-w]$.

Let $X_r^{(i)}$ be an indicator random variable for the event that row f is covered by at least one of these blocks in the i-th trial. Then we observe that $X_r^{(i)} = 0$ iff the event $r \notin [\ell_1..\ell_1+w-1] \wedge r \notin [\ell_2..\ell_2+w-1]$ occurs. We have

$$\begin{aligned}\Pr\left[X_r^{(i)} = 0\right] &= \Pr\left[r \notin [\ell_1..\ell_1+w-1]\right] \cdot \\ &\quad \Pr\left[r \notin [\ell_2..\ell_2+w-1]\right] \\ &= \Pr\left[r \notin [\ell_1..\ell_1+w-1]\right]^2\end{aligned}$$

since ℓ_1, ℓ_2 are independent and identically distributed. There are two cases to consider. When $r \in [1..w-1]$ we have

$$\Pr\left[X_r^{(i)} = 0\right] = \left(1 - \frac{r}{N+1-w}\right)^2 \leq e^{-2r/(N+1-w)}$$

because there are only r values for ℓ_1 (resp. ℓ_2) that cause block B_1 (resp. B_2) to include the r-th row of L. When $r \geq w$, which is the common case when $N \gg w$, we have

$$\Pr\left[X_r^{(i)} = 0\right] = \left(1 - \frac{w}{N+1-w}\right)^2 \leq e^{-2w/(N+1-w)}.$$

To build some intuition for these probabilities, take $N = 200$ and $w = 51$ (the average value if w were selected uniformly from its range), $\Pr\left[X_1^{(i)} = 0\right] \leq 0.98$, i.e., the first row is almost certainly not covered in any particular trial. But this quickly decreases as r grows, and when $r = w$ (and beyond) we have $\Pr\left[X_r^{(i)} = 0\right] \leq 0.51$. Keep in mind that the robust hashing algorithm runs $t = 64$ independent trials, thus, defining the indicator $X_r = 1$ iff $\bigvee_{i=1}^{t} X_r^{(i)} = 1$, we have

$$\Pr[X_r = 0] \leq \begin{cases} e^{-t(2r)/(N+1-w)} & \text{when } r < w \\ e^{-t(2w)/(N+1-w)} & \text{when } r \geq w \end{cases}$$

Thus $\Pr[X_1 = 0] \leq (0.98)^{64} \approx 0.43$, and for $r \geq w$ we have $\Pr[X_r = 0] \leq (0.51)^{64} \approx 2^{-64}$. It is apparent that the first few rows of L are unlikely to be covered, but that the remaining rows are covered in some trial with overwhelming probability.

Continuing, let $X = \sum_{r=1}^{N} X_r$, i.e., the number of rows covered across all t trials. Additionally, let W be a uniform value in $[2..N/2]$. (Recall that in the robust hashing algorithm, the parameter w is chosen this way for each trial.) By linearity of expectation we have

$$\begin{aligned}\mathbb{E}[X \mid W = w] &= \sum_{r=1}^{N} \mathbb{E}[X_r \mid W = w] \\ &= \sum_{r=1}^{N} \Pr[X_r = 1] \\ &= N - \sum_{r=1}^{N} \Pr[X_r = 0] \\ &= N - \left(\sum_{r=1}^{w-1} \Pr[X_r = 0] + \sum_{r=w}^{N} \Pr[X_r = 0]\right) \\ &\geq N - \left(\sum_{r=1}^{w-1} e^{-t(2r)/(N+1-w)}\right. \\ &\qquad \left. + (N+1-w)e^{-t(2w)/(N+1-w)}\right)\end{aligned}$$

Again, when $N = 200, w = 51, t = 64$, we have $\mathbb{E}[X \mid W = 51] \geq 198.4$; on average, the number of rows missed is less than two. Finally, we define $f(w) = \mathbb{E}[X \mid W = w]$ and consider $\mathbb{E}[f(W)]$, which is the average number of rows covered over random choices of block width and block-starting rows. When $N = 200, t = 64$ we have $\mathbb{E}[f(W)] \geq 195.4$; thus fewer than five rows are completely missed, on average, across all trials. With overwhelming probability, it will be the first few rows that are missed. As we discussed at the beginning of this section, this audio would could not affect the semantics of the transmitted speech.

Picking Up My Tab: Understanding and Mitigating Synchronized Token Lifting and Spending in Mobile Payment

Abstract

Mobile *off-line* payment enables purchase over the counter even in the absence of reliable network connections. Popular solutions proposed by leading payment service providers (e.g., Google, Amazon, Samsung, Apple) rely on direct communication between the payer's device and the POS system, through Near-Field Communication (NFC), Magnetic Secure Transaction (MST), audio and QR code. Although pre-cautions have been taken to protect the payment transactions through these channels, their security implications are less understood, particularly in the presence of unique threats to this new e-commerce service.

In the paper, we report a new type of over-the-counter payment frauds on mobile off-line payment, which exploit the designs of existing schemes that apparently fail to consider the adversary capable of actively affecting the payment process. Our attack, called *Synchronized Token Lifting and Spending* (STLS), demonstrates that an *active* attacker can sniff the payment token, halt the ongoing transaction through various means and transmit the token quickly to a colluder to spend it in a different transaction while the token is still valid. Our research shows that such STLS attacks pose a realistic threat to popular off-line payment schemes, particularly those meant to be backwardly compatible, like Samsung Pay and AliPay.

To mitigate the newly discovered threats, we propose a new solution called *POSAUTH*. One fundamental cause of the STLS risk is the nature of the communication channels used by the vulnerable mobile off-line payment schemes, which are easy to sniff and jam, and more importantly, unable to support a secure mutual challenge-response protocols since information can only be transmitted in one-way. POSAUTH addresses this issue by incorporating one unique ID of the current POS terminal into the generation of payment tokens by requiring a quick scanning of QR code printed on the POS terminal. When combined with a short valid period, POSAUTH can ensure that tokens generated for one transaction can only be used in that transaction.

1 Introduction

The pervasiveness of mobile devices has profoundly changed the ways commercial activities are conducted. Particularly, mobile payment, in which a payment transaction is carried out between a smartphone and a point of sale (POS) system, becomes increasingly popular, with over 1 trillion dollars revenue projected for 2019 [49]. Leading e-commerce providers (e.g., PayPal, Amazon, Google, Alibaba) and smartphone manufacturers (e.g., Samsung, Apple) all come up with their own solutions and competing with each other for market shares. Most of these schemes are designed for *online* use originally, which requires both the payer and the payee to stay connected to the Internet during a transaction, so both parties are notified by the payment service provider once the transaction succeeds. A problem for this approach is that the payer (who in many cases is a grocery shopper) is expected to have a decent network connection (or enough mobile data) whenever she pays. To avoid the delay and extra cost introduced during this process, recently *off-line* payment schemes are gaining traction, which allow a transaction to go through even when the payer's network connection is less reliable. This is achieved by establishing a direct connection between the smartphone and the POS system through Near-Field Communication (NFC), Bluetooth, electromagnetic field, 2D-QR code or even audio signal, and delivering a payment token over this channel. Already many prominent payment schemes have offered this off-line support, including PayPal, Google Wallet, Apple Pay, Samsung Pay and AliPay. What is less clear, however, is the security guarantee they can provide.

Security of mobile off-line payment. Unlike the online payment, in which the payer and the payee do the

*The two lead authors are ordered alphabetically.
†Corresponding author.

transaction through the service provider, the off-line approach relies on the direct communication between the smartphone and the POS system, and therefore can be vulnerable to the eavesdropping attack from a bystander. This is less of an issue for the NFC channel, due to its extremely short communication distance, making the sniffing difficult. More importantly, both NFC and Bluetooth allow convenient bidirectional interactions between the payer (smartphone) and the payee (POS), which helps strengthen the protection: a typical approach is for the POS device to challenge the phone with an "unpredictable number"; the number is then used by the phone to generate a payment token with a short validity period. This thwarts the attempt to use the token in a different transaction.

In practice, however, the POS systems armed with NFC or Bluetooth are expensive and less deployed, and cheaper and more backwardly compatible alternatives are widely adopted. For example, Samsung Pay supports *Magnetic Secure Transmission* (MST), which can work on those using magnetic stripes, like credit-card readers. PayPal and AliPay (an extremely popular Chinese payment service, with 190 million users) both transmit the token through QR scanning, an approach widely supported by POS machines. Also, AliPay and ToneTag [51] utilize audio signals, a low-cost solution that needs only a sound recorder on the payee side. A problem here is that all such channels (electromagnetic field, QR code and audio) are one-way in nature, making the above challenge-response approach hard to implement. To address this issue, these schemes employ *one-time payment token*, together with a short valid time, to defend against the eavesdropping attack. The idea is that once the token is observed, it cannot be used again and will soon expire, and is therefore useless to the adversary. The effectiveness of this protection, however, becomes questionable in the presence of an *active* attacker, who is capable of disrupting a transaction to prevent the token from being spent, which allows him to use it in a different transaction within the validity period. This was found to be completely realistic in our study.

Our attacks. In this paper, we report our security analysis of two leading mobile off-line payment schemes: Samsung Pay and AliPay. Our study reveals surprising security vulnerabilities within these high-profile schemes, affecting hundreds of millions of users around the world: we found that both approaches are subject to a new type of over-the-counter payment frauds, called *Synchronized Token Lifting and Spending* (STLS), in which an adversary sniffs the payment token, manages to halt the ongoing transaction and transmits the token to a colluder to spend it in a different transaction while the token is still valid. Oftentimes, such an attack can also seamlessly trigger a retry from the payer to let the original transaction go through without arousing any suspicion. More specifically, in Samsung Pay, we show that the attacker can pick up the magnetic signals 3 meters away using a sensor, and then automatically *jam* the wireless signals produced by a mobile POS (mPOS) using a jammer (a commercial device), causing a disruption between its communication with the payment provider. As a result, the payment token is prevented from being delivered to the provider and instead, recovered, demodulated and then spent in a different transaction (at a different location). After this is done, the attacker stops the jamming, which enables a retry from the shopper to complete the transaction. We found that this attack can be realistically implemented, as demonstrated in a video we posted online [1] (Section 3.1). A similar attack also succeeds on Alipay, over the audio channel: we utilized a recorder to capture the token transferred through sound and again the jammer to disrupt the payment transaction, before using the token for another transaction (Section 3.2).

Alipay also supports payment through QR code scan. In our research, we studied two payment scenarios: peer-to-peer transfer and pay through POS. In the first case, the payer uses his phone to scan the payee's QR code displayed by her phone. Our study shows that a malicious payer device or the one infected with an attack app can not only steal the token from the payee's screen, which can later be used for over-the-counter payment (through POS), but also stealthily force the payee device to refresh its screen, causing it to generate a new token, therefore preserving the original one for an unauthorized purchase (Section 3). When it comes to POS-based payment, we discovered that a malicious app running on the payer's device can stealthily halt the transaction by strategically covering a few pixels on the screen when it is displaying the QR token to the POS machine. In the meantime, we found that it is feasible to acquire the image of the code from the reflection on the glass of the QR scanner's scan window (captured by the phone's front camera) (Section 3.3). Again, the demos of these attacks are available online [1].

Mitigation. Our findings highlight the fundamental weaknesses of today's mobile off-line payment schemes: one-time token is insufficient for defending against an active adversary capable of stealthily disrupting a payment transaction (which is found to be completely realistic); also given the error-prone nature of the channels (magnetic field, sound, QR scan) those schemes use, the validity period of their payment tokens needs to be sufficiently long to allow multiple retries, which leaves the door open for the STLS attack. To mitigate the newly discovered threats and enhance the security protection of the off-line payment, we designed and implemented a new solution, called *POSAUTH*, which authorizes the payer to use a payment token only at a specific transaction. POSAUTH is meant to be easily deployed, without changing hard-

ware of today's POS systems. More specifically, each POS terminal presents a QR code carrying its unique ID. For each transaction, the payer is supposed to scan the code to generate the payment token, which is bound to the terminal. This binding, together with the valid period, ensures that the token can only be used in the current transaction (see Figure 1).

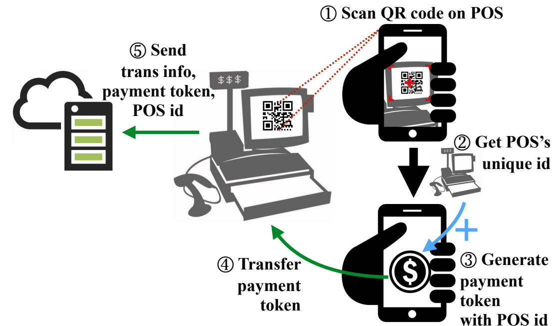

Figure 1: The work-flow of POSAUTH

Contributions. The contributions of the paper are outlined as follows:

• *New findings and understandings*. We report the first study on the STLS threat to mobile off-line payment. Our research brings to light surprising security vulnerabilities within high-profile payment solutions, which subject these schemes to the new type of payment frauds. Such STLS attacks are found to be completely realistic, with serious consequences, leading to unauthorized spending of the payer's token. The findings demonstrate the challenges in protecting these off-line payment schemes in the presence of an *active* adversary.

• *New protection*. We made a first step towards practically mitigating these STLS attacks through a new design that binds the payer's payment token to a specific POS terminal, without changing the hardware of existing systems. We implemented this design, which is found to be effective and efficient in defending against the threat.

Roadmap. The rest of the paper is organized as follows: Section 2 provides background information for our study; Section 3 elaborates the STLS threats on Samsung pay and Alipay; Section 4 presents our protection mechanism; Section 5 discusses the limitations of our study and potential future research; Section 6 compares our work with related prior studies and Section 7 concludes the paper.

2 Background

In this section, we describe how mobile payment works, the current protection in place and potential security risks. Further we present the assumptions made in our research.

Mobile off-line payment. Since 1999, when Ericsson and Telnor Mobil phones were first used to purchase movie tickets, mobile payment has gained considerable popularity in the past decades, and is expected to be used by 90 percent of smartphone users in 2020[42]. Today, a typical payment transaction through mobile devices includes three parties: the payer, the payee and the payment service provider. Depending on the role played by the provider, a payment transaction can be *online* or *off-line*. Figure 2 illustrates the work-flows of both payment methods. A prominent example of mobile online payment is *Mobile wallet*, a scheme provided by PayPal, Amazon and Google. A payment process through Mobile wallet involves registration of a user's phone number and acquisition of a PIN for authentication. In a transaction, the user enters the PIN to validate the payment that will be charged to her account based upon the credit card or other information (stored in her mobile device) given to the service provider during the transaction.

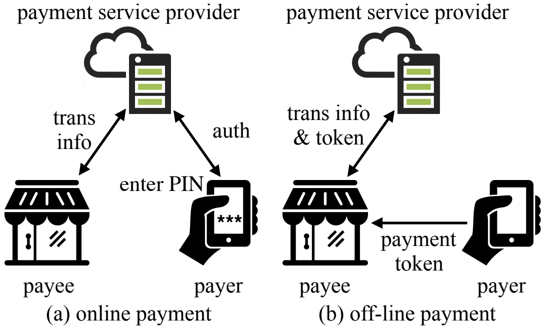

Figure 2: The work-flows of online and off-line mobile payment methods

By comparison, a mobile off-line payment happens directly between the payer and the payee, with the provider communicating with only one of these two parties in the transaction. Oftentimes, the payer is a grocery shopper, with a smartphone carrying a shared secret with the provider and the payee controls a POS device for communicating with the provider. An off-line transaction starts when the payee creates a charge request through entering payment information (e.g., amount, payment method) into a POS terminal. Then, the payer is supposed to run her payment app to establish a communication channel with the POS for transmitting a token. Some of these channels are described in Table 1. Such a token is generated using a secret in the payer's mobile digital wallet, the current time and the challenge from the payee when it is available, and other credential data.

Upon receiving the token, the POS terminal forwards the token as well as other transaction information to the payment service provider for verification. From the token, the provider first recovers the owner information and then verifies its authenticity (whether it is issued by the owner) and liveness (whether it has been used before and whether

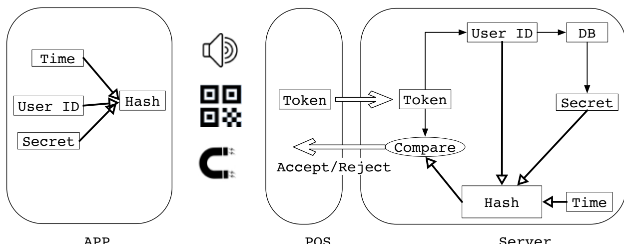

Figure 3: Mobile off-line payment transaction flow.

Channel	Provider Examples

it is issued recently, within the validity period) of the token. If so, the provider continues to check the balance of the owner's account to determine whether the transaction can proceed. A transaction approval or denial is then issued to the POS terminal, depending on whether all these checks are passed. The process is shown in Figure 3.

Payment security. The security guarantee of an off-line payment scheme is mainly built upon the protection of the payment token, which is essentially the proof for a payment request, typically in the form of a hash-based message authentication code (HMAC) over its generation time and other information. The token is delivered to the provider by the payee through a secure channel. Less protected here is the direct link between the payer and the payee, which could be monitored by the adversary present at the scene of the payment. For the transaction going through NFC and Bluetooth (see Table 1), a random number generated by the payee can serve to challenge the payer and ensure that the token is bound to a specific POS terminal. For other channels, however, existing payment schemes do not use this challenge-response approach (due to the complexity and unreliability of the channels) and instead, rely on one-time token: a token, once received by the provider, is recorded to make sure that it will not be used again. Also, each token is ephemeral, with a short valid period attached to it, based upon its generation time specified in its content.

This protection apparently only considers the threat from a passive adversary, who does nothing to interfere with the execution of a transaction. The situation can be very different for an active one. In the case that the transaction can actually be disrupted, which stops the delivery of the token to the provider, the observed one-time token can then be stolen and used for a different transaction. Also this attack cannot be prevented by checking the liveness of the token, since the validity period often has to be set sufficiently long to tolerate the errors in a normal token transmission. As an example, a payer needs 5 -10 seconds to place her phone before the QR code can be reliably recognized. As a result, often a payment token has more than one minute of living time, which as shown in our study (Section 3), is often long enough for successfully spending it on a different transaction, with the help of a colluder in the attack.

Adversary model. In our study on the payment through electromagnetic field (Samsung Pay) and audio signals, we consider an adversary who is either physically present at the payment scene or capable of placing her attack devices (including sniffer and jammer) there. This is completely realistic, given the small sizes of the devices, as illustrated in Figure 7(a). In QR-code based payment, we no longer require the presence of attack devices. Instead, we assume that the payer's phone is infected with an attack app, which *does not* have system privileges but needs camera, Bluetooth and network permissions, which are commonly requested by legitimate apps.

3 STLS Attacks

In this section, we report our security analysis on Samsung Pay as well as the Audio Pay and QR Pay techniques utilized by other popular mobile off-line payment services such as Alipay and Wechat. Our study shows that they are all subject to the STLS attacks: an adversary can realistically disrupt payment transactions, steal payment tokens and spend them without proper authorization. This security hazard affects hundreds of millions of mobile users worldwide. We contacted all affected service providers and some of them have already acknowledged the importance of the findings. We are now helping them fix the discovered problems and enhance their protection. Following we elaborate this study.

3.1 Samsung Pay

Samsung Pay is a popular token based mobile payment service available on the smartphones manufactured by Samsung Electronics. It is characterized by a unique POS-device communication technique, when compared with other payment services like Apple Pay and Android Pay, called *Magnetic Secure Transmission (MST)*, which has been acquired from LoopPay in 2015 [44]. In this paper we focus on the security protection of MST, even though Samsung Pay also supports NFC.

Samsung Pay features a high compatibility to existing POS terminals which work with magnetic-stripe card. Merchants need no modification to their out-dated POS

terminal to support this kind of innovative mobile phone payment. A Samsung phone stores a piece of secret key inside KNOX, a secure container. When the Samsung Pay user (the payer) is going to pay at a POS, she launches the app and chooses a card she is going to pay with and then passes the app's verification with either password or fingerprint. Then the app (inside KNOX) immediately generates a token for the user by HMAC a piece of message containing the transaction counter, the primary account number (PAN) [1] using the secret key, assembles all information in the same format as the magnetic tracks on conventional credit cards, and starts to broadcast that information over the MST channel by modulating electric current passing through a MST antenna. Any POS terminal, if magnetic card is supported, will receive the token through its magnetic head and then process it in the exact same way as if the user is swiping a magnetic-stripe credit card. The track data with token and other information encapsulated will be passed to the service provider via POS's network for further transaction processes including token verification, translating to real PAN, balance verification, and the transaction result will be returned to the POS terminal to notify the payee if the transaction is approved or not.

Understanding MST. MST is a patented technique (US8814046 [20]) that first appears in LoopPay Fob and LoopPay CardCase and it is compatible with any existing POS terminal.

The security protection of MST pretty much depends on the property of electromagnetic field, which is considered to be a near-field communication channel. Specifically, the strength of electromagnet signal quickly attenuates as the distance to the source r grows, at the rate of $1/r^3$. On LoopPay's home page, it is claimed: "LoopPay works within a 3-inch distance from the read head. The field dissipates rapidly beyond that point, and only exists during a transmission initiated by the user" [33]. A similar claim is also made by Samsung Pay: "Due to the short-range nature of MST, it is difficult to capture the payment signal" [43].

Eavesdropping MST signal. However, we found in our research that this distance based protection does not work as stated by those claims, which has also been reported by other research [6, 3]. Fundamentally, the distance that allows electromagnetic field signal sniffing feasible is determined by a signal-noise-ratio (SNR) at that distance and the capability for the sniffing antenna to pick up the signal. Our study shows that instead of 3 inches (< 0.08 meters) as claimed by the MST document, a small loop antenna at the size of a small bag (as illustrated in Figure 4) can effectively collect the signal at least 2 meters away from the source. More importantly, the signal captured at this distance still carry enough information for decoding, in a realistic noise environment. For example, Figure 5 a) and b) compare the signal received by our loop antenna (2 meters away from the source) with the theoretically received ones, as discovered in a real-world grocery store. As we can see here, the signal still largely preserved the coding information and can therefore be used for decoding using our later proposed decoding method.

[1] a virtualized one instead of original credit card number.

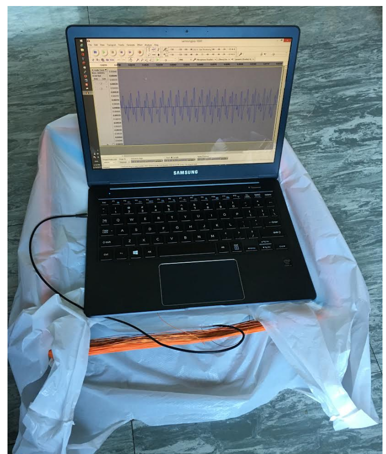

Figure 4: Sniffing devices.

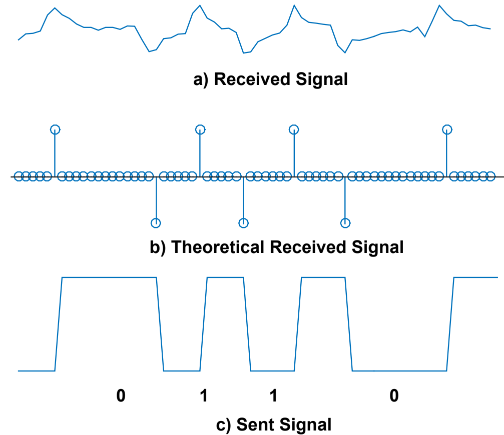

Figure 5: Comparison between original signal and our received one in 2 meters.

Signal decoding. In our research, we decode such signal according to impulse polarity changes. Specifically, MST uses differential Manchester encoding, in which the polarity flips once for the symbol '0' while twice for the symbol '1' (Figure 5 c)). Although our antenna cannot directly sense the magnetic field, it is able to capture the polarity flips, because the current generated by the antenna is the derivative of the magnetic filed (a flip's derivative is an impulse, as compared in the Figure 5 b) and c)).

The captured signal is then decoded using a band pass filter (BPF), a synchronization detection module and a symbol judgment module. BPF allows only frequency

components from 0.3 kHz to 10 kHz to pass, which effectively reduces the out-of-band noise. The synchronization detection module identifies the start and the end positions of each symbol. It sequentially enumerates all the sample points and determines whether a given sample point is an apex and whether it exceeds a threshold: if so, the point is chosen as the start point of the first symbol. Then the module chooses an apex with maximum strength around its theoretical end position (based upon the symbol duration) as the end point of the first symbol (also the start point of the second symbol). The process repeats until the apex's strength is under the threshold, which indicates that the valid signal ends. In this way, all the symbols' start and end positions are determined. The symbol judgment module decides whether a given symbol represents '0' or '1' by comparing the polarities of the start and end point. If the start point and end point have the same polarity, the symbol represents '1', otherwise, it is '0'.

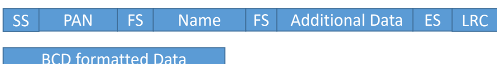

Figure 6: The track format Samsung Pay uses.

The symbols generated by the symbol judgment can be easily translated to a text string in accordance with the ANSI/ISO ALPHA data format (designed for magnetic card track 1) or the ANSI/ISO BCD data format (for track 2 and 3) [2], as shown in Figure 6.

Figure 7: A commercial jammer and a mPOS.

mPOS jamming. As mentioned earlier, Samsung Pay and LoopPay utilize one-time token, which effectively defends against passive attacks: up to our knowledge, none of the prior exploit attempts [6, 3] can succeed, because a used token cannot be used again. A fundamental issue here, however, is that the protection does not work against an *active* adversary and interfering with an ongoing transaction is much more realistic than one thought, as discovered in our research. Specifically, we found that mobile POS systems, as shown in Figure 7(b) and Figure 7(c), with over 3.2 million already installations and a over 27 million installations in 2021 by expectation [21], can be easily jammed using a portable commercial device. For example, the device in Figure 7(a) can easily block either WiFi or cellular signal or both at a distance of 3

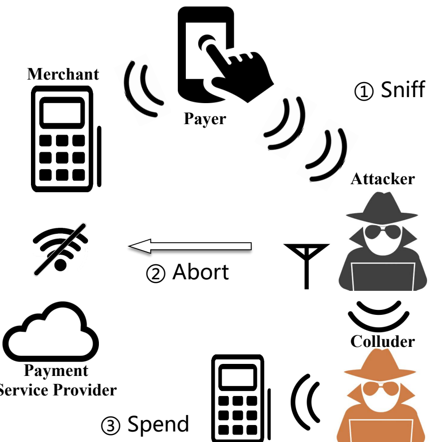

Figure 8: Attack flow for Samsung Pay.

meters, which causes all mPOS transaction to abort. Such a jammer simply broadcasts white noise over the same frequencies as those used by the targeted channels to interfere with legitimate communications. It can be easily switched on and off to target a specific payment step. Note that such jamming does not need to be blind: most mPOS systems are using WiFi, and a temporary disruption of its service, within a few meters, will not affect other mobile users, such as those using smartphones through 3G or 4G; even for the mPOS running on cellular networks, the adversary can jam only their specific cellular formats, e.g., Verizon (CDMA format), without interfering with others, e.g., AT&T users (UMTS format), in a 3-meter peripheral. Further, given the delay for the POS system to restore its connection, the adversary can quickly stop jamming: for example, he can turn on the device for 30 seconds and then leave, and gives his colluder, who receives the token from an unblocked channel, at least 1 minute to spend the token.

The attack. Putting pieces together, the flow for the whole STLS attack on Samsung Pay is illustrated in Figure 8. The attacker runs a small antenna (small enough to be hidden in his backpack) connected to a laptop (also hidden) to monitor the electromagnetic signal around an mPOS terminal. Once a customer opens her digital wallet (on her smartphone) for a payment transaction, the antenna captures the token and in the meantime, the jammer is switched on (which does not affect the communication between the wallet and the mPOS) to block the mPOS's network. The acquired token is then automatically decoded and forwarded through an unjammed channel to a colluder (who might run an app to alert him to the arrival of a token that needs to be spent within a time frame[2]). Such a token is automatically written to a magnetic stripe card, which can be used just like a normal credit card, or

[2] Actually we found that Samsung Pay has a one day time limit for its token [25].

to a MagSpoof device (e.g., for a purchase at an automatic vending machine) to replay the token. The adversary can stop the jamming and walk away after a short period of time, which allows the mPOS to restore its network connection and receive a payment error from the server (which often comes without details). As a result, the payer has to retry with an automatically generated new token to complete the transaction. We are communicating with Samsung to help them address this threat.

3.2 Audio Pay

Similar to MST-based payment, the schemes based upon the audio channel are equally vulnerable to the STLS attack. Following we elaborate the attack on these schemes.

Analysis of audio pay. Audio is an emerging channel for near-field inter-device communication. Compared to other channels like Bluetooth, Wi-Fi Direct, or NFC, the audio channel is cheap and easy to use, given the fact that every phone is equipped with a microphone and a speaker. The main weakness of this channel is its bandwidth because of its narrow frequency spectrum. Nevertheless, it remains an efficient and convenient way to exchange a small amount of information. In particular, it has been used by multiple payment schemes, including Alipay and ToneTag, to transmit a payment token (from the payer's device to the payee).

Specifically, the payer is supposed to encode her payment information into an audio clip using a modulation scheme like audio frequency-shift keying (AFSK). During the payment transaction, she can play the clip to the merchant's POS device. Upon receiving the audio, the merchant decodes it to recover the payment token from, and then sends the token as well as transaction information to the payment service provider. The provider verifies the payment token and replies with an acknowledgement response if successful. This payment process is illustrated in Figure 9.

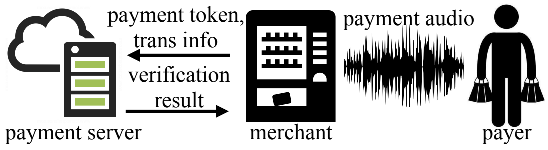

Figure 9: The process of audio pay.

Alipay has widely adopted audio pay on mobile vending machines. In this scenario, after the payer selects an item, the vending machine will ask the payer to play her payment audio. Upon receiving the audio, the machine decodes the payment token from the audio and sends it to the payment service provider through cellular network to proceed the transaction. To produce the payment audio, Alipay encodes the payment token into a carrier sound by AFSK. While the carrier sound can be heard by a human being, the payment token is encoded at the frequency of 17.2kHz - 18.4kHz, which is beyond the absolute threshold of human hearing. But such a modulation scheme also enables the sniffing attack since there is nearly no noise at this frequency range, and the token can be broadcast with low lost. Here, we elaborate our attack to audio pay as below.

The attack. Again, this payment scheme is vulnerable to an STLS attack involving audio recording and WiFi or cellular signal jamming with the device shown in Figure 7(a). Specifically, before the payment transaction starts, a nearby attacker turns on a signal jamming device to block signals and prevents the merchant from communicating with the payment service provider. When the payer plays her payment sound to the merchant (mobile vending machine in Alipay), the attacker records the sound within a proper distance. Since the transaction is aborted by the signal jamming, the recorded payment token is not spent. Then the attacker can replay the recorded sound to make another purchase. The attack is illustrated in Figure 10.

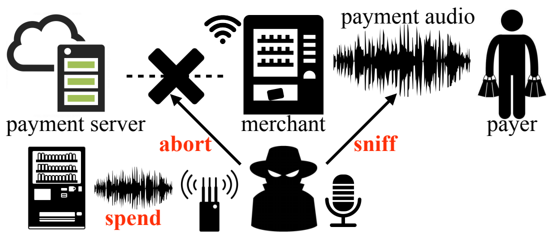

Figure 10: The attack against audio pay.

We implemented this attack against a real-world vending machine. The attack demo is posted online [1]. In this attack, the attacker uses a free iOS app called SpectrumView[35] to record the payment audio signal at a distance of 30cm from the payer's phone. [3] With such low cost, the attacker is still able to successfully launch the STLS attack. Although the the token has a limited valid period (90 seconds), our attack demonstration shows that such time window is sufficient for attackers.

3.3 QR Pay

Mobile payment through QR code is quickly gaining popularity in recent years. A plenty of retailers (like Walmart and Starbucks), financial organizations (like Chase, Paypal and Alibaba) and social network apps (like WeChat) have developed or adopted QR payment. So far, three payment schemes have been proposed to support different payment scenarios [13]:

[3] The attack device is small and can be placed stealthily and closely to merchant device, e.g., within 30cm to a vending machine. Token recording and transmitting can be fully automated without attacker's attendance. Hence, the threat is realistic.

•*Buyer-to-Large retailer transactions (B2L)*. A QR code representing the payment token is generated by the payer's mobile payment app (like WeChat, ChasePay and AliPay) and then picked up by payee's POS scanner and transferred to service provider (see Figure 11). Since a special POS scanner has to be deployed by the payee, this scheme is usually seen in large retailers, like Walmart, Target and Starbucks.

Figure 11: The work-flow of QR pay.

•*Buyer-to-Small business transactions (B2S)*. The payer scans the QR code presented by the payee using a mobile app to get payee's merchant ID, inputs the right amount and then authorizes the payment. In this case, the QR code can be printed on a paper as the merchant ID is usually permanent.

•*Peer-to-Peer transactions (P2P)*. A user (or payer) with payment app wants to transfer money to another user (or payee). The payee generates a QR code to be scanned by the payer. After the scanning process, the money is transferred [4].

In this work, we evaluate whether STLS attack can succeed for the first and third transaction scenario, i.e., whether the payment token can be stolen at one place and spared at another place. We skipped the second scenario, as no payment token is generated by the user (payment is sent directly to the service provider). We focus on the off-line mode, for which the token is generated off-line and no confirmation by the payer is required when the token is about to be consumed. We discuss the online payment option in Section 5.

Security analysis of payment app. Different from the native payment apps, like Samsung Pay and Apple Pay, which protect the payment token through hardware means (e.g., Secure Enclave for Apple Pay and KNOX for Samsung Pay), the third-party payment apps, like WeChat and Alipay, cannot shield the payment token against the OS-level attack (e.g., malicious app with root privilege). Though the OS-level attacks can cause devastating consequences, their victim base is usually small.

As a result, the defense employed by the third-party apps is largely targeting malicious apps with non-root permissions. For instance, AliPay claims that it can prevent another app from taking screenshot to steal the QR code [5]; its payment token is one-time and short-lived; it is capable of detecting mobile trojan app and phishing QR code.

Challenges for STLS attack on QR code. Unlike the MST and audio channels, QR code is a visual sign, which cannot be jammed and sniffed by the nearby physical device. Carrying out STLS attack under this scenario seems impossible at first sight, but through a set of novel techniques, we show such attack is completely realistic. Our only assumption is that a malicious app has been installed on the payer's mobile device with camera, bluetooth and network permissions granted. This app plays a similar role as the nearby physical device used in MST and audio attack. More importantly, our app is a **non-root app** and **does not trigger any abnormal behavior** vetted by the payment app (e.g., taking screenshots of QR code). The key stage of this attack is stealing the payment token while halting the ongoing transaction, and we elaborate two approaches for this step, one attacking the QR scanner of the POS machine and another attacking the payment app during P2P transactions.

3.3.1 Attack POS-based Payment

Attack overview. Our attack can be launched when a user shows the payment QR code to the POS scanner. In particular, the malicious app attempts to steal the QR code from the glass reflection of the POS scanner when the payer's screen is close to it. In the meantime, it disrupts the display of the original QR code to abort the ongoing transaction, by masking the payer's screen. The token (stored in photos captured by the front camera of payer's phone) is exfiltrated to attacker through network and spent at another store after unmasking, like MST and audio attack. To avoid arousing payer's suspicion, the attack app actively profiles the context (e.g., the foreground app and activity) and the actual attack is initiated when the context matches the payment context. We elaborate the four key attack components (sniff, abort, profile and exfiltration) below. A demo of this attack can be found in [1].

Sniffing QR code. For the attack app, direct capture of QR code is not feasible as screen scraping is prevented by the payment app. However, the reflection of the QR code on other objects cannot be controlled by the payment app and we exploit this observation to build this attack component. It turns out the glass window of the POS scanner can serve our purpose perfectly. As illustrated in Figure 12, a typical scanner is composed of a glass window, a camera and a light source. When the screen of payer's phone is close enough to the scanner, the reflection

[4] Some payment app reverses the scheme (payer shows QR code to payee). Our attack is valid for both case.

[5] For example, an Android app can set a window flag `FLAG_SECURE` when initiating an activity window to avoid screen scraping [15]. AliPay uses this flag to protect its QR code.

of the QR code will appear on the scanner glass and the attack app can capture it by taking photos with phone's front camera. The scanner glass is an ideal object here because of its brightness is significantly different from payer's screen: mobile payment apps always increase screen brightness to ease the recognition of the QR code while the light source of the scanner is much darker to avoid glare. As such, a "one-way mirror" is constructed for attack app to pick up the QR code.

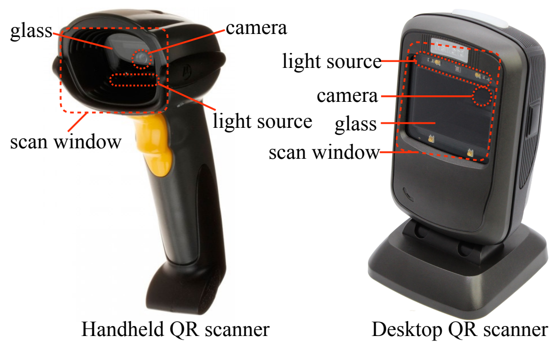

Figure 12: A QR Scanner.

•*Assessment of sniffing.* Whether QR code can be successfully captured by the phone's front camera depends on several factors, including the horizontal distance between the QR code and the front camera (d_{cq}), the side length of the QR code (l_q), the vertical distance between the glass and the phone screen (d_{gs}), and the front camera's angle of view (AOV). Figure 13 illustrates these factors for the most common case that the scanner and the phone are parallel. The ideal approach to assess these factors is to run experiments by simulating all their possible combinations and check whether the QR code can be recovered, which cannot be done within reasonable time. Instead, we compute their theoretical value range for the successful attack.

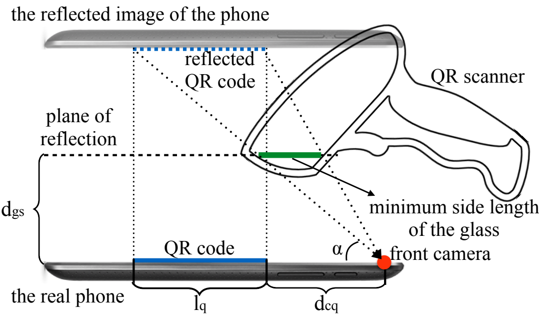

Figure 13: The side view of the phone and the QR scanner during POS-based payment.

In summary, three conditions have to be satisfied. First, the scanner glass should be large enough to reflect the whole QR code. Hence, the minimum side length of the glass should be $d_{cq}/2 + l_q - (d_{cq} + l_q)/2$, or $l_q/2$. Second, the horizontal position of the glass should be about the middle point between the QR code and the front camera. Third, the glass should be vertically far enough so it would be within front camera's AOV. In other words, d_{gs} should be at least $(tan(90 - AOV/2) \times (l_q + d_{cq}))/2$.

It turns out all the three conditions can be met for the normal payment scenario. For the tested mobile phone (MI 3W), l_q is 3.2cm and d_{cq} is 5.8cm. For Alipay on the tested scanners (Symbol DS-6708SR[50] and NLS-FR40[10]), their glass side lengths are 2.3cm and 4.3cm respectively, which are much larger than the minimum requirement $l_q/2$ (1.6cm). Placing the scanner glass in the middle point is also natural for the payee (as illustrated in Figure 15). Assume AOV for the front camera is 60 degrees, the minimum d_{gs} would be 7.8cm, which is within the suggested working range of the scanner [50, 10].

Aborting ongoing transaction. Signal jamming cannot be used here to disrupt the normal payment process. Instead, we instruct the malicious app to mask the QR code for the disruption.

A QR code has to embed three *positioning markings* (or PM) at its three corners. They are used to ensure that a reader can correctly identify the region and direction of the QR code. If one of these PMs is not displayed, the QR code will not be readable. Our attack app is developed to mask one PM. To this end, the app pops up a floating window covering one PM only. However, showing floating window on top of another app requires a system permission `SYSTEM_ALERT_WINDOW` since Android 6.0 [17]. So, we choose a different approach by commanding the attack app to create an activity which is transparent except the PM region (filled with white pixels) and overlay it on top of the payment app. Such design yields the similar visual effect without asking for any additional permission. When the reflected QR code is captured, the attack app will dismiss the transparent activity and bring back the original QR code window. Figure 14 illustrates an example of the original and masked QR. Figure 15 shows how the masked QR code is scanned and the reflection image of the masked QR code captured by the malicious app with front camera.

Inferring payment activity. To keep the sniffing and jamming process stealthy, our attack app actively infers the running context and moves to the next stage when the context is matched. We exploit a set of side-channel information to learn the context, including the foreground app, its displayed activity and payer's action. The details are described below:

•*Foreground app*. The attack app needs to know when the foreground app is identical to the targeted payment app. The information is not directly available due to the separation between apps. However, it can be inferred by

Figure 14: An example of the original and masked QR.

Figure 15: The masked QR code is being scanned and the reflection image of the masked QR code is captured by the malicious app with front camera.

reading a public Linux procfile `/proc/net/tcp6` which logs the opened TCP sockets per app [6]. As long as the targeted payment app is activated , TCP sockets to the servers will be established and the IP addresses expose the app's running status.

•*Displayed activity*. We use the brightness of the screen to determine if the payment app is displaying QR code. Our key observation is that mobile payment apps always increase the screen brightness (say B_{QR}) to the maximum level when showing the QR code. B_{QR} is even higher than the maximum brightness that can be configured by the user. As such, we create a `FileObserver` [14] to monitor the file `/sys/class/leds/lcd-backlight/brightness`. If the brightness logged within the file reaches B_{QR}, the targeted activity is recognized.

[6]We did not use `/proc/net/tcp` since socket information is no longer displayed. `/proc/net/tcp6` shows both IP v6 sockets and IP v4 sockets. The IP v4 addresses are mapped to the IP v6 space in the file.

•*Payer's action*. We use onboard sensors, including accelerometer, gyroscope, and magnetometer, to infer whether the payer is showing her QR code to the merchant. Usually, such action incurs a drastic change of rotation angle of the phone, therefore we can measure the change rate to infer it. In particular, we employ the algorithm in [22] to compute the angles on all axes compared to a fixed position. We begin to monitor the angles when prior conditions are satisfied and record the first observed angle as $A_{initial}$. When the difference between the current angle and $A_{initial}$ exceeds a threshold, the user is recognized as rotating the phone to show the QR code to the merchant.

Exfiltrating QR code. In order to increase the success rate, a series of photos of the reflected QR code are taken during the scanning process. Recovering the QR code from the distorted images on the cell phone is time- and battery-consuming. Therefore, the images are exfiltrated to attackers' server through cellular or WiFi network for further analysis, i.e., mask removal.

Evaluation. We tested our attacks on Alipay (version 10.0.2) and Wechat (version 6.5.4). The testing phone is MI 3W with Android 4.4. The testing QR scanners are Symbol DS-6708SR[50] (hand-held) and NLS-FR40[10] (desktop). And we are able to carry out STLS attack as shown in the demo [1]. We further examined the success rate of our attack by asking 14 users to show the masked QR code (the QR code is masked for 60s) to a desktop QR scanner (NLS-FR40). Among them, 6 (43%) are successfully attacked, suggesting retrieving payment token from the reflected QR code on the scanner's glass window is completely feasible. Some attempts are failed when the user positioned the phone too close to the scanner. The average time of the whole attack is 55s. In particular, the average time to sniff a valid QR code is 16s, and the average time to exfiltrate QR code is 39s. The time to transfer photos to remote server is negligible. Actually, the validity period of a QR code is configured to 90s, based our examination on Alipay and Wechat. This time is sufficient for the attacker to launch the attack and spend the QR code in a different transaction.

Since the attack app does not require any system permissions or any unique system features, the attack is applicable to all Android versions. We are working to implement this attack on other platforms, e.g., iOS. But several issues have to be addressed a priori, e.g., how to mask one PM of the QR code and how to infer the foreground activity, which might need new design of the attack app.

3.3.2 Attack Peer-to-peer Transfer

Attack overview. A user may be attacked even if her device is not infected with any malware. In addition to being used in B2L transaction, a payment QR code

can also be used in P2P transaction, in which the payee presents her QR code to the payer. In this scenario, if there is a malicious app installed on the payer's phone and taking pictures during a P2P transaction, the payee's QR code can be directly harvested. Then the attacker can spend the sniffed QR code in the B2L transaction in another place.

In particular, the malicious app on payer's phone brings itself to the foreground and takes picture when it discovers that the payment app on the same phone is in the QR code scanning mode. The original P2P transaction is disrupted by the malicious app by initiating a bluetooth paring process. The QR code is decoded in the payer's phone and transfered to the remote attacker to be spared (different from the prior attack, the QR code of the payee is not masked and therefore can be directly decoded on the phone). We elaborate the steps for activity inference and transaction disruption below (the other steps are straightforward or similar to the prior attack). Figure 16 and Figure 17 illustrate the normal process for P2P transaction and the attack scenario.

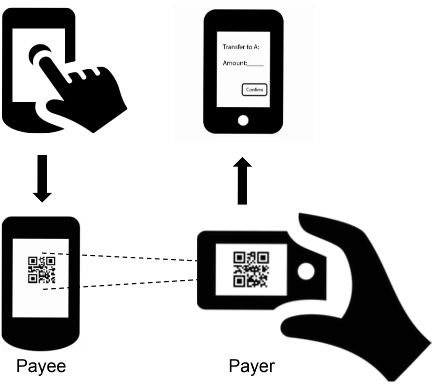

Figure 16: Work flow of P2P transfer.

Inferring payment activity. The attack app on payer's phone needs to learn whether the payment app is on top and in scanning mode. We use the same methodology to infer the foreground app. To detect the scanning mode, our app frequently pings the status of the back camera by invoking a system API `camera.open()` at every 100 milliseconds. If the API returns an error code, the back camera is highly likely occupied by the payment app and the scanning mode is identified (only this mode uses camera).

Interfering P2P transaction. Once the scanning mode is inferred, the attack app will bring an activity (with identical UI to the payment app) to the foreground by sending an intent. Different from the prior attack in which we have no control over the POS scanner, we can block payer's app scanner through intent injection. The attack app keeps scanning QR code until it is successfully decoded. Finally, the malicious app destroys its scan activity to restore interface of the payment app. Though the payment token can be obtained by the attacker, it might be invalid to be spent by the attacker in a B2L transaction as the same token could be used earlier by the P2P transaction. We address this problem by forcing the payee's app to refresh the payment token. Since the payment app works in offline mode, both the old and new payment tokens are valid (if used within its lifetime, e.g., around 90 seconds for Alipay). A big challenge here is to alter the behavior of payer's phone without being discovered where there is no attack app installed. In the end, we found that bluetooth pairing could be used for this purpose.

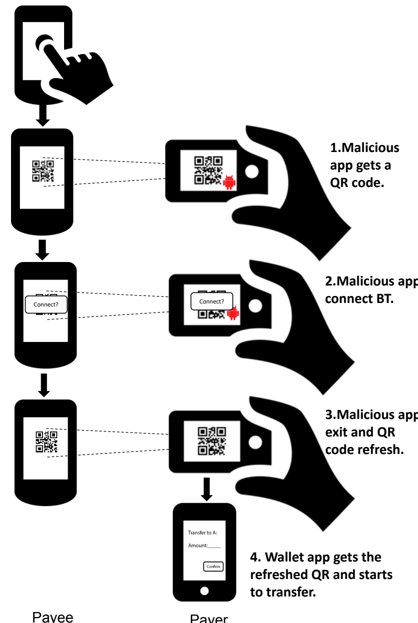

Figure 17: Work flow of attack against P2P transfer.

Specifically, the attack app launches a pairing request to a nearby bluetooth device (highly likely to be the payer's phone) by calling an API `createBond()`. A window asking the user to confirm the pairing will be prompted on payee's phone. The attack app immediately cancels the pairing process by calling `cancelPairingUserInput()` API[7]. The pairing process is interrupted and the confirmation window on the payee's phone will disappear. The duration for this step is very short and it is nearly impossible to be observed by the user, as shown in our demo[1]. When the pairing confirmation window disappears, the payment app is brought to foreground and it will refresh the UI together with the token based on its logic.

Evaluation. We successfully launched the attack on a Samsung GT-S7562 (as payee) and a Galaxy Nexus (as payer). The total attacking time is 8s, including activity starting, QR code capturing (5s), bluetooth pairing

[7]This is a hidden API which can be invoked by java reflection.

requesting (3s), and activity exiting. During the bluetooth pairing, the confirmation window showed less than 1 second. We reported the attack to Alipay, and after that, they removed the functionality of payment QR code P2P transfer.

4 Transaction Point Authorization

Our study shows that STLS threat is completely realistic to mobile off-line payment schemes. The fundamental problem behind today's mobile off-line payment schemes is: one-time token is insufficient to protect against an active attacker who is not only able to sniff payment tokens but also capable of disrupting an ongoing legitimate transaction. In addition, our attacks have demonstrated that the validity period of offline payment tokens is sufficiently long for the adversary to transmit the token to a colluder to spend it in a different transaction. To mitigate the STLS thread and enhance the security of the off-line payment schemes, we propose a new solution called POSAUTH. In this section, we elaborate the design and implementation of POSAUTH, and evaluate its effectiveness and efficiency.

Design and implementation. The indispensable steps in a STLS attack include sniffing the payment token, halting the ongoing transaction, and spending the sniffed token in a different transaction. If any one of these steps fails, the STLS attack cannot succeed, which means that we can defend by undermining any step. Due to the broadcast nature of audio and MST channels, it is difficult to defend against sniffing on these channels. Though QR code is a unicast channel, it is still feasible for an adversary to sniff in certain scenarios (like in our attacks). As a result, our defense cannot rely on preventing the payment token from being sniffed. Similarly, it is difficult to prevent an active attacker from halting the ongoing transaction in mobile payment scenes, especially those with mobile POS systems. The only option left is to prevent a token from being used in a different transaction other than the original transaction between the payer and the merchant.

This observation inspires the design of POSAUTH, which binds a payment token to a specific transaction and authorizes the payer to use it only in the same transaction. Actually, we bind the payment token to the POS terminal on which it is going to be spent by the payer. POSAUTH is meant to make such binding easily deployable without changing the hardware. In particular, each POS terminal is attached with a QR code that contains its unique ID (PID). Before the payer starts to transmit her payment token to the POS terminal, she is required to scan the QR code. Upon receiving the POS terminal's unique ID, the payer encodes the PID into her payment token. In this way, the payment token is indeed bound to the terminal. As stated in Section 2, the payment token in the mobile off-line payment schemes is typically in the form of a HMAC over timestamp and other identity information. To prevent an attacker from replacing the encoded PID in the sniffed payment token, we encode the PID by integrating it within the one-way HMAC computation.

When the POS terminal receives the payment token, it sends the payment token as well as its PID to the payment service provider. The provider checks the consistency between the payment token and the PID. If they are bound, the transaction is allowed. If not, the transaction is supposed to be halted and the token's owner (the payer) should be warned about the risks of token being stolen. In this way, even if the payment token is stolen, it can not be spent on another POS terminal. It is unrealistic to assume that the attacker could pay to the same POS terminal in the mean time when the payer is still paying. We can further require that, if a payment token is spent, the payer's tokens with earlier timestamp should be invalid, in order to prevent a stolen payment token being spent on the bound POS terminal in the short period after the payer finishes payment with a refreshed payment token.

To understand whether POSAUTH can properly protect current mobile off-line payment schemes, we implemented a prototype of POSAUTH on Alipay QR Pay. More specifically, in Alipay QR Pay, the payment token is a string of 18 decimal numbers, consisting of a constant prefix of 2 digits, a suffix of 6-digit Time-based One-time Password (TOTP) computed from a pre-configured seed and the current timestamp, and a middle-10-digit encrypted identity (EID), which is generated by encrypting the payer's unique identity (or account number) in a customized symmetric encryption algorithm with the TOTP as its encryption key. In our POSAUTH implementation, we encode a PID into the QR Pay payment token by concatenating it with the timestamp in the TOTP computation. Upon receiving the payment token and PID, the server computes a set of valid TOTPs with the pre-configured seed, a set of valid timestamps, and the PID. And it checks whether the TOTP in the received payment token belongs to a valid one. If valid, the token is then bound to the POS terminal.

Evaluation. We mainly evaluate the time overhead during each transaction introduced by POSAUTH, because obviously POSAUTH does not introduce much other overhead like upgrading costs, power consumption etc.

Comparing with the existing transaction schemes, POSAUTH adds only one QR scanning step and slightly modifies the token generation algorithm while the remaining steps are all the same, which brings extra time consumption in 2 steps. For the time consumed by token generation (modifying algorithms), we consider it negligible since it is a simple operation to integrate the PID into a token generation algorithm (e.g., concatenating it with the timestamp during the TOTP computation in Alipay),

therefore we focus on the extra scanning step. To assess the extra time overhead introduced by POSAUTH, we implemented an app to scan a QR code and recorded the time spent between user clicking the button and QR code decoding module returning result. We prepared a QR code containing 18 digits that is enough to accommodate the POS terminal ID. Then we measure how much time a scan costs. We scanned 10 times and the average time is 3.8 seconds for a Galaxy Nexus.

For a mobile transaction, this time overhead is small, comparing to the time the cashier spends on manipulating the POS terminal, which usually costs 10 or even more seconds. As a result, we conclude that the POSAUTH is a practical defense scheme against the STLS attacks.

5 Discussion

Comparison with online scheme. In most online mobile payment schemes, users are required to confirm the transaction with brief transaction detail prompted, by inputing the password or by pressing their fingerprints. Therefore, our attacks fail in this scenario since such information is usually unavailable to a remote attacker.

However, online schemes are recommended for small business who could not afford a POS terminal. In addition, it requires decent network connection on payer device. Comparing to the off-line schemes which are provided by many large merchants[13] and are able to able to work regardless of payer's connection quality, their adoption is limited so far.

Root Cause. After a careful analysis of all vulnerable payment schemes having been discovered, we conclude that the root cause for STLS attack is the missing of bidirectional communication capabilities when transmitting tokens through near field communication channels. Without such capabilities, mobile off-line payment schemes have to rely on time-restricted one-time token for security, which, as shown in this work, turns out to be ineffective to active attackers. The threat could be mitigated by our defense scheme POSAUTH which provides a light-weight bidirectional communication capability by only requiring a quick scanning of QR code printed on POS terminal.

Comparison between POSAUTH and B2S. Similar to POSAUTH, in the B2S scenario, the merchant also presents a QR code for the payer to scan and pay. The main difference here is that the QR code in B2S is still used as a one-way communication channel, which is vulnerable in the presence of an active attacker. By replacing the merchant's QR code with a malicious one, an attacker can make unauthorized payment with the payer's account [27]. However, POSAUTH is immune to such attacks since the payment token is indeed bound to the ID of a POS terminal (via QR code scanning), and any discrepancy between the POS ID and the payment token would raise an alarm of such attacks to the payment service providers.

6 Related Work

Samsung Pay security. We studied the security of Samsung Pay and showed that it is vulnerable to our STLS attack. Before our work, the security aspect of Samsung Pay was studied by two groups recently as well [6, 3]. These studies showed that sniffing payment token from the MST channel by a passive attacker is feasible, but the proposed techniques did not lead to the successful attack under the real-world settings, as the payment token is one-time and the payer could spend it ahead of the attacker. Instead, our STLS attack employs a jamming device to disrupt the normal transaction to prevent the payment token from being spent by the payer, which ensures that an active attacker is able to spend the victim's payment token in a different transaction.

Data transfer over audio. Several communication products have realized data transmission through audio channel [34, 16]. These techniques encode data into audio signals distinguished by amplitude, frequency, or phase modulation [4]. Our study is the first to investigate the usage of the audio communication channel in mobile payment settings and proposed a realistic attack against such channel.

QR code security. QR code is one of the earliest channel for mobile payment and there have been many works demonstrating how to build a secure payment scheme on top of it [11, 28, 39, 31, 7, 36]. In these payment schemes, QR code is used to encode transaction information [28, 7] or users' payment token [11]. And a user can pay by showing her QR code to the merchant, or scanning the merchant's QR code, or both. In the mean time, attacks [27] have been proposed against QR Pay in B2S transaction, e.g., replacing the merchant's QR code with one associated with the attacker. In this paper, we mainly focus on the scenarios in which a user shows her QR code to the merchant or another user (B2L and P2P transaction). Different from the existing attacks, we are the first to investigate the STLS threats on these scenarios.

Since QR code can carry different types of data, whether and how it can be used to deliver malicious content have been investigated [26, 23]. In fact, an attacker is able to launch attacks including phishing [53], SQL injection [46], and even malicious app installation [55], by encoding malicious content into QR code. In these attacks, an attacker can either use a new malicious QR code or partially modify an existing QR code [24]. In our attack against POS-based payment, we also partially modify the QR code. The difference is that prior attacks still keep the QR code readable but our attack prevents it from being read. In the meantime, defense techniques [54] were

proposed to protect users when scanning an untrusted QR code. Such techniques can not prevent our attacks since the modified QR code has no malicious content.

Similar to POSAUTH, QR code has also been employed to transfer information for authentication schemes [48, 30, 29], given its high usability and low deployment cost. In this work, we show that QR code can be used to protect payment security. Such direction has not been explored before.

Security on other mobile payment schemes. The security of other mobile payment schemes, including contactless NFC payment [40, 41] and online mobile wallet payment [52, 12], has been studied. NFC-based payment has been adopted by the major phone vendors, like Google and Apple. Attack [37, 8, 9] and defense [18, 38, 47] techniques regarding this channel have been investigated, but none of them are similar to our STLS attack. Due to its extremely short communication distance and the challenge-response based bidirectional communication pattern, NFC payment is not affected here.

Users' perception of the emerging mobile payment techniques is also investigated and studied. These studies show that several factors could impede the adoption of mobile payment methods, including their security, usability, and cost [32, 45, 19].

7 Conclusion

In this paper, we present a new threat called STLS which can enable adversaries to attack off-line payment schemes by sniffing payment token, aborting current transaction, and spending the stolen token at other places. We have investigated some leading off-line payment systems in real world and demonstrated that such STLS attacks are completely realistic. We also carreid out security analysis, which reveals some major limitations of existing token protection techniques. Contrary to the closed settings of traditional payment systems, off-line mobile payment solutions have larger attacking surface. Channels between smartphone and POS terminal are susceptible to sniffing attack. Communications between mobile POS and back-end servers are built on WiFi or 3G/4G network, thus the ongoing transactions can be disrupted. More importantly, most token delivering channels are one-way only, so tokens cannot be bound to the POS terminal of current transaction. Meanwhile, shortening the token valid period only still cannot guarantee adequate payment security. To mitigate STLS threats, we propose POSAUTH which forces a payment token to include the unique ID of current POS terminal and, when combined with short valid period, is able to confine a token to be used in legitimate transactions only. In the future, we plan to work with merchants and deploy POSAUTH in real-world POS systems.

Abstract

The current state of certificate-based authentication is messy, with broken authentication in applications and proxies, along with serious flaws in the CA system. To solve these problems, we design TrustBase, an architecture that provides certificate-based authentication as an operating system service, with system administrator control over authentication policy. TrustBase transparently enforces best practices for certificate validation on all applications, while also providing a variety of authentication services to strengthen the CA system. We describe a research prototype of TrustBase for Linux, which uses a loadable kernel module to intercept traffic in the socket layer, then consults a userspace policy engine to evaluate certificate validity using a variety of plugins. We evaluate the security of TrustBase, including a threat analysis, application coverage, and hardening of the Linux prototype. We also describe prototypes of TrustBase for Android and Windows, illustrating the generality of our approach. We show that TrustBase has negligible overhead and universal compatibility with applications. We demonstrate its utility by describing eight authentication services that extend CA hardening to all applications.

1 Introduction

Server authentication on the Internet currently relies on the certificate authority (CA) system to provide assurance that the client is connected to a legitimate server and not one controlled by an attacker. Unfortunately, certificate validation is challenged by significant problems. First, applications frequently do not properly validate the server's certificate [20, 17, 5, 35]. This is caused by failure to use validation functions, incorrect usage of libraries, and also developers who disable validation during development and forget to enable it upon release. Second, TLS interception, used by numerous firewall appliances and software (as well as malware), compromises the integrity of end-to-end encryption [24, 34], with many firewalls having significant implementation bugs that break authentication [7, 11]. Third, the CA system itself is vulnerable to being hijacked even when applications and proxies are implemented correctly. This is largely due to the fact that most CAs are able to sign certificates for any host, reducing the strength of the CA system to that of the weakest CA [12]. This weakness was exploited in the 2011 DigiNotar hack [25], and is exacerbated by CAs that do not follow best practices [31, 10] and by governmental ownership and access to CAs [13, 40].

Due to these problems, there are a number of recent proposals to improve or replace the current CA trust model. These include multi-path probing [31, 41, 1, 23] or other systems that vouch for the authenticity of a certificate [15, 2, 3], DNS-based authentication [21], certificate pinning [16, 32], and audit logs [27, 39, 14, 26]. Unfortunately, the majority of applications have not yet integrated these improvements. Even relatively simple fixes, such as certificate revocation, are beset with problems [29]. The result is that there is no de facto standard regarding where and how certificate validation should occur, and it is currently spread between applications, TLS libraries, and interception proxies [11].

Several projects have tried to address these issues, fixing broken authentication in existing applications, while providing a means to deploy improved authentication services. Primary among these is CertShim, which uses the `LD_PRELOAD` environment variable to replace functions in dynamically-loaded security libraries [4]. However, this approach does not provide universal coverage of all existing applications, does not provide administrators singular control over certificate authentication practices, does not protect against several important attacks, and has significant maintenance issues. Fahl takes a different approach that rewrites the library used for authentication by Android applications [18], while also including pluggable authentication modules. This approach is well-suited for Android because all applications are written in Java, but

it is difficult to extend this approach to operating systems that provide more general programming language support.

In this paper, we explore a different avenue for fixing these problems by centralizing authentication as an operating system (OS) service and giving system administrators and OS vendors control over authentication policy. These two motivating principles result in TrustBase, an architecture for certificate authentication that secures existing applications, provides simple deployment of improved authentication services, and overcomes shortcomings of previous approaches. TrustBase provides universal coverage of existing applications, supports both direct and opportunistic TLS[1], is hardened against unprivileged local adversaries, is supported on both mobile and desktop operating systems, and has negligible overhead.

To centralize authentication as an operating system service, TrustBase uses a combination of traffic interception to harden certificate validation for existing applications and a validation API to simplify authentication for new or modified applications. TrustBase intercepts network traffic between the socket layer and the transport layer, where it detects the initiation of TLS connections, extracts handshake information, validates the server's certificate using a variety of configurable authentication services, and then allows or blocks the connection based on the results of this additional validation. This allows TrustBase to harden certificate validation in an application-agnostic fashion, irrespective of what TLS library is employed. TrustBase also includes a simple certificate validation API that applications call directly, which extends authentication services to new or modified applications, while also providing compatibility with TLS 1.3.

To provide system administrator control, TrustBase provides a policy engine that enables an administrator to choose how certificate authentication is performed on the host, with a variety of authentication services that can be used to harden the CA system. The checks performed by authentication services are complementary to any existing certificate validation performed by applications. This approach both protects against insecure applications and transparently enables existing applications to be strengthened against failures of the CA system. For example, a browser that validates the extended validation (EV) certificate of a bank is doing the best it currently can, but it is still vulnerable to a compromised CA, allowing a man-in-the-middle (MITM) to present fake but valid certificates. One possible use of TrustBase is to configure the use of notaries that check whether hosts across the Internet are exposed to the same certificate for the bank.[2]

[1] Opportunistic TLS is TLS initiated via an optional upgrade from a plaintext protocol.

[2] Keys for notaries can be pinned in advance, so they are not vulnerable to the MITM.

TrustBase enables system administrators and OS vendors to enforce a number of policies regarding TLS. For example, an administrator could require revocation status checking, disallow weak cipher suites, or mandate that Certificate Transparency be used to protect against active man-in-the-middle (MITM) attacks. An OS vendor could ship TrustBase with strong default protections against broken applications, such as enforcing best practices for validating a certificate chain, requiring hostname validation, and pinning certificates for the most popular web sites and applications. As TLS becomes more widespread, TrustBase could easily be extended to provide the capability to report on the use of all applications that do *not* use TLS, so that an organization could better manage or even block insecure applications. All of these improvements can be made without requiring user interaction or configuration.

Our contributions include:

- **An architecture for certificate validation that prioritizes operating system centralization and system administrator control:** TrustBase offers standard certificate validation procedures and optionally adds additional authentication services, both of which are enforced by the operating system and controlled by the administrator or OS vendor. This repairs broken validation for poorly-written applications and can strengthen the validation done by all applications. TrustBase provides a policy engine that enables an administrator to use policies that define how multiple authentication services cooperate, for example using unanimous consent or threshold voting.

- **A research prototype of TrustBase:** We develop a loadable kernel module that provides general traffic interception and TLS handling for Linux. This module communicates via the Netlink API to the policy engine residing in user space for parsing and validation of certificates. We describe how this same architecture can be implemented on other operating systems and give details of our current Android and Windows versions. We provide source code and developer documentation for our prototypes, with licensing for both commercial and non-commercial purposes.

- **A security analysis of TrustBase:** We provide a security analysis of TrustBase, including its centralization, application coverage, and the hardening we have done on the Linux implementation. We describe a threat analysis and demonstrate how TrustBase can thwart attacks that include a hacked CA, a subverted local root store, and a STARTTLS downgrade attack. We also demonstrate the ability of

TrustBase to fix applications that do not validate hostnames or skip certificate validation altogether.

- **An evaluation of TrustBase:** We evaluate the TrustBase prototype for performance, compatibility, and utility. (1) We show that TrustBase has negligible performance overhead, with no measurable impact on latency. (2) We demonstrate that TrustBase enforces correct certificate validation on all popular Linux libraries and tools and on the most popular Android applications. (3) We describe eight authentication services that we have developed and report on how simple and straightforward it was to develop these services for TrustBase.

2 Related Work

Three systems aim to tackle similar problems as TrustBase.

Fahl et al. proposed a new framework for Android applications that would help developers correctly use TLS [18]. Their work follows a similar principle to ours—instead of letting developers implement their own certificate validation code, validation is a service, and it incorporates a pluggable framework for authentication schemes. Fahl's approach is well-suited to mobile operating systems such as Android, where all applications are written in Java, but it is difficult to extend this approach to operating systems that provide more general programming language support.

Another Android system, MITHYS, was developed to protect Android applications from MITM attacks [6]. It first attempts to MITM applications that establish TLS connections and, if successful, continues using the MITM and provides certificate validation using a notary service hosted in the cloud. MITHYS only works for HTTPS traffic, adds significant delays to all TLS connections that it protects (one to ten seconds), and only supports the current CA system.

The most closely related system to TrustBase is CertShim [4]. Like TrustBase, CertShim is an attempt to immediately fix TLS problems in existing apps and also support new authentication services. CertShim works by utilizing the `LD_PRELOAD` environment variable to replace functions in dynamically-loaded security libraries with their own wrappers for those functions. This method has an advantage over TrustBase in that CertShim does not need to perform double validation for cases where an application is already performing certificate validation correctly. Because TrustBase uses traffic interception to enforce proper certificate validation, its checks are in addition to what applications may already do (either correctly or incorrectly). In addition, CertShim's wrapping of validation functions means that it can more easily override the CA system in the case where administrators want an application to accept alternative certificates, though this will only work with applications that CertShim supports and that do not validate against hard-coded certificates or keys.

TrustBase has advantages that set it apart from CertShim in several notable ways:

(1) **Coverage.** TrustBase intercepts all secure traffic and thus can independently validate certificates for all applications, regardless of what library they used, how they were compiled, what user ran them, or how they were spawned. CertShim does not support browsers, and it cannot perform validation for applications in all scenarios. For example, applications using custom or unsupported security libraries (e.g., BoringSSL, NSS, MatrixSSL, more-recent GnuTLS, etc.), applications statically linked with any security library, and applications spawned without being passed CertShim's path in the `LD_PRELOAD` environment variable (e.g., spawned by `execv` or spawned by a user without that environment setting) will not have their certificates validated by CertShim.

(2) **Maintenance.** TrustBase only needs to maintain compatibility with the TLS specification and the signatures of high-level functions of TCP in the Linux kernel. As a datapoint, the latter has had only two minor changes since Linux 2.2 (released 1999)—one change was to add a parameter, the other was to remove it. In contrast, CertShim relies on data structures internal to the security libraries it supports, and libraries change their internals with surprising frequency. The current versions of PolarSSL (now mbed TLS) and GnuTLS were no longer compatible with CertShim, one year after its release.

(3) **Administrator Control.** TrustBase ensures that only system administrators can load, unload, bypass, or modify its functionality, so that every secure application is subject to its configured policies. With CertShim, guest users and applications can easily opt out of its security policies by removing CertShim from their `LD_PRELOAD` environment variable, and developers can bypass CertShim by statically-linking with security libraries, using an unsupported TLS library, or spawning child processes without CertShim in their environment.

(4) **Local Adversary Protection.** TrustBase uses a trust model that protects against a local adversary, wherein a nonprivileged, local, malicious application attempts to bypass or alter certificate validation. Recent studies of TLS MITM behavior suggest that local malware acting as a MITM is more prevalent than remote MITM attackers [24, 34]. TrustBase protects against this case by using a protected Netlink protocol, privileged policy engine, protected files, and kernel module that cannot be removed by a nonprivileged user. CertShim's attack model does not address this case. In fact, malware uses the same `LD_PRELOAD` mechanism [28].

(5) **Opportunistic TLS Enforcement.** TrustBase can enforce the use of TLS in plaintext protocols that optionally allow upgrades to TLS, such as STARTTLS, significantly reducing the attack surface for downgrade attacks. Since CertShim hooks into TLS library calls, it cannot be invoked if no calls occur.

3 TrustBase

TrustBase is motivated by the need to fix broken authentication in applications and strengthen the CA system, using the two motivating principles that authentication should be centralized in the operating system and system administrators should be in control of authentication policies on their machines. In this section, we discuss the threat model, design goals, and architecture of the system.

3.1 Threat Model

In our threat model, an active attacker attempts to impersonate a remote host by providing a fake certificate. Our attacker includes remote hosts as well as MITM attackers located anywhere along the path to a remote host. The goal of the attacker is to establish a secure connection with the client.

The application under attack may accept the fake certificate for the following reasons:

- The application employs incorrect certificate validation procedures (e.g., limited or no validation) and the attacker exploits his knowledge of this to trick the application into accepting his fake certificate.

- The attacker or malware managed to place a rogue certificate authority into the user's root store (or another trust store used by the application) so that he has become a trusted certificate authority. The fake certificate authority's private key was then used to generate the fake certificate used in the attack.

- Non-privileged malware has altered or hooked security libraries the application uses to force acceptance of fake certificates (e.g., via malicious OpenSSL hooks and LD_PRELOAD).

- A legitimate certificate authority was compromised or coerced into issuing the fake certificate to the attacker.

Local attackers (malware) with root privilege are outside the scope of our threat model. In addition, we consider only certificates from TLS connections directly made from the local system to a designated host, and not those that may be present in streams higher up in the OSI stack or indirectly from other hosts or proxies via protocols like onion routing.

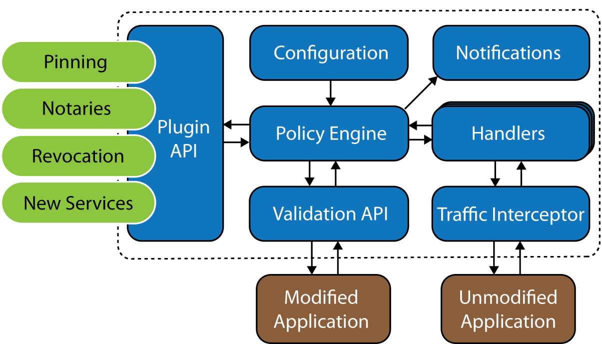

Figure 1: TrustBase architecture overview

3.2 Design Goals

The design goals for TrustBase are: **(1) Secure existing applications.** TrustBase should override incorrect or absent validation of certificates received via TLS in current applications. **(2) Strengthen the CA system.** TrustBase should provide simple deployment of authentication services that strengthen the validation provided by the CA system. **(3) Full application coverage.** All incoming certificates should be validated by TrustBase, including those provided to both existing applications and future applications. However, this does not include certificates from connections not made directly by the system, such as certificates delivered through onion routing. **(4) Universal deployment.** The TrustBase architecture should be designed to work on any major operating system, including both desktop and mobile platforms. **(5) Negligible overhead.** TrustBase should have negligible performance overhead. This includes ensuring that the user experience for applications is not affected in any way, except when TrustBase prevents an application from establishing an insecure connection.

3.3 Architecture

The architecture for TrustBase is given in Figure 1. These components are described below:

3.3.1 Traffic Interceptor

The traffic interceptor intercepts all network traffic and delivers it to registered handlers for further processing. The interceptor is generic, lightweight, and can provide traffic to any type of handler. Traffic for any specific stream is intercepted only as long as a handler is interested in it. Otherwise, traffic is routed normally.

The traffic interceptor is needed to secure existing applications. If a developer is willing to modify her application to call TrustBase directly for certificate validation, then she can use the validation API. Administrators can con-

figure TrustBase to not intercept traffic from applications using this API.

3.3.2 Handlers

Handlers are state machines that examine a traffic stream to isolate data used for authenticating connections and then pass this data to the policy engine. Data provided to the policy engine includes everything from the relevant protocol that is intercepted.[3] For example, with TLS this includes the `ClientHello` and `ServerHello` data in addition to the server certificate chain and the server hostname. The handler will allow or abort the connection, based on the policy engine's response.

TrustBase currently has both a TLS handler and an opportunistic TLS handler (e.g., STARTTLS), and due to the design of the traffic interceptor it is easy to add support for new secure transport protocols as they become popular (e.g., QUIC, DTLS).

3.3.3 Policy Engine

The policy engine is responsible for using the registered authentication services to validate the server certificate extracted by the handler. The policy engine also aggregates validation responses if there are multiple active authentication plugins. The policy is configured by the system administrator, with sensible operating system defaults for ordinary users.

When the policy engine receives a validation request from a handler, it will query each of the registered authentication services to validate the server's certificate chain and host data. Authentication services can respond to this query in one of four ways: *valid*, *invalid*, *abstain*, or *error*. Abstain and error responses are mapped to the valid or invalid responses, as defined in a configuration file.

To render a decision, the policy engine classifies plugins as either "necessary" or "voting", as defined in the configuration file. All plugins in the "necessary" category must indicate the certificate is valid, otherwise the policy engine will mark the certificate as invalid. If the necessary plugins validate a certificate, the responses from the remaining "voting" plugins are tallied. If the aggregation of valid votes is above a preconfigured threshold, the certificate is deemed valid by the policy engine. A write-protected configuration file lists the plugins to load, assigns each plugin to an aggregation group ("necessary" or "voting"), defines the timeout for plugins, etc.

3.3.4 Plugin API

TrustBase defines a robust plugin API that allows a variety of authentication services to be used with TrustBase. The policy engine queries each authentication service by supplying host data and a certificate chain, and the authentication service returns a response. We provide both an asynchronous plugin API and a synchronous plugin API to facilitate the needs of different designs.

The synchronous plugin API is intended for use by simple authentication methodologies. Plugins using this API may optionally implement `initialize` and `finalize` functions for any setup and cleanup they need to perform. For example, a plugin may want to store a cache or socket descriptor for long-term use during runtime. Each plugin must also implement a `query` function, which is passed a data object containing a query ID, hostname, IP address, port, certificate chain, and other relevant context. The certificate chain is provided to the plugin DER encoded and in openssl's `STACK_OF(X509)` format for convenience. The `query` function returns the result of the plugin's validation of the query data (valid, invalid, abstain, or error) back to the policy engine.

The asynchronous plugin API allows for easier integration with more advanced designs, such as multithreaded and event-driven architectures. This API supplies a callback function through the `initialize` function that plugins must use to report validation decisions, using the query ID supplied by the data supplied to `query`. Thus the `initialize` function is required so that plugins may obtain the callback pointer (the `finalize` function is still optional). Asynchronous plugins also implement the `query` function, but return a status code from this function immediately and instead report their validation decision using the supplied callback.

3.3.5 Validation API

The validation API provides a direct interface to the policy engine for certificate validation. New or modified applications can use this API to simplify validation, avoid common developer mistakes, and take advantage of TrustBase authentication services. Applications can use the API to validate certificates or request pinning for a self-signed certificate. The API also allows the application to receive validation error messages from TrustBase, allowing it to display errors directly in the application (TrustBase displays notifications through the operating system).

3.4 Addressing Certificate Pinning

Some applications have implemented certificate pinning to provide greater security in cases where the hosts that the application visits are static and known, rather than using the CA system for certificate validation. TrustBase wants to avoid the situation where its authentication services declare a certificate to be invalid when the application has validated it with pinning, but should also adhere to its core

[3] This enables plugins to provide authentication methods that utilize TLS extensions and cipher suite information.

tenant that the system administrator should have ultimate control over how certificates are validated. Our measurements indicate that this circumstance is rare and affects relatively few applications, since the problem only arises when a certificate offered by a host does not also validate by the CA system (e.g., a self-signed certificate). In the short term, TrustBase solves this problem by using the configuration file to allow whitelisting of programs that should bypass TrustBase's default policies. In the long term, this problem is solved by applications migrating to the validation API.

3.5 TLS 1.3 and Overriding the CA System

There are two situations where TrustBase cannot use default traffic interception to accomplish its primary goals. First, when an application uses TLS 1.3, the certificates that are exchanged are encrypted, preventing TrustBase from using passive traffic interception to independently validate certificates. Second, in some cases a system administrator may want to distrust the CA system entirely and rely solely on alternative authentication services. For example, the administrator may want to force applications currently using CA validation to accept self-signed certificates that have been validated using a notary system such as Convergence[31], or she may want to use DANE[21] with trust anchors that differ from those shipped with the system. When this occurs, TrustBase will use the new authentication service and determine the certificate is valid and allow a connection as configured by the administrator, but applications using the CA system may reject the certificate and terminate the connection. We stress that such a policy would not be intended to override strong certificate checks done by a browser (e.g., when communicating with a bank), but to provide a path for migrating away from the CA system as stronger alternatives emerge.

To handle both TLS 1.3 and overriding the CA system, TrustBase provides two options. The preferred option is to modify applications to rely on TrustBase for certificate validation, rather than performing their own checks. This is facilitated by the validation API described above. This enables new or modified applications to use the full set of authentication services provided by TrustBase in a natural manner.

A second option is to employ a local TLS proxy that can coerce existing applications that rely on the CA system to use new authentication services instead. The use of a proxy also allows TrustBase plaintext access to the server's certificate under TLS 1.3. TrustBase gives the administrator the option of running such a proxy, but it is activated only in those cases where it is needed, namely when the policy engine determines a certificate is valid but the CA system would reject it. The proxy employed is a modified fork of `sslsplit` [38] and has shown itself to be scalable and performant in our experimentation. Note that in most cases this is not needed—for example, under Convergence, the certificates validated by notaries would likely also be validated by the CA system unless the certificate was self-signed, which is a situation likely to exist until CA alternatives gain significant traction. Given the vulnerabilities noted recently with proxies [11] administrators should exercise caution using this feature. Due to the features of the Windows root store, TrustBase on Windows can override the CA system without the use of a local proxy, as explained in Section 6.4.

3.6 Operating System Support

We designed the TrustBase architecture so that it could be implemented on additional operating systems. The main component that may need to be customized for each operating system is the traffic interception module. We are optimistic that this is possible because the TCP/IP networking stack and sockets are used by most operating systems.

Our Linux implementation is described in the following section. We also have a working prototype of TrustBase for Windows, which uses the Windows Filtering Platform API.

Mac OSX provides a native interface for traffic interception between the TCP and socket levels of the operating system. Apple's Network Kernel Extensions suite provides a "Socket Filter" API that could be used as the traffic interceptor.

For iOS, Apple provides a Network Extension framework that includes a variety of APIs for different kinds of traffic interception. The App Proxy Provider API allows developers to create a custom transparent proxy that captures application network data. Also available is the Filter Data Provider API that allows examination of network data with built-in "pass/block" functionality.

Because Android uses a variant of the Linux kernel, we believe our Linux implementation could be ported to Android with relative ease. We have a prototype of TrustBase on Android that instead uses the `VPNService` to intercept traffic.

4 Linux Implementation

We have designed and built a research prototype of TrustBase for Linux. The source code is available at `owntrust.org`.

We have developed a loadable kernel module (LKM) to intercept traffic at the socket layer, as data transits between the application and TCP handling kernel code. No modification of native kernel code is required, and the LKM can be loaded and unloaded at runtime. Similarly to

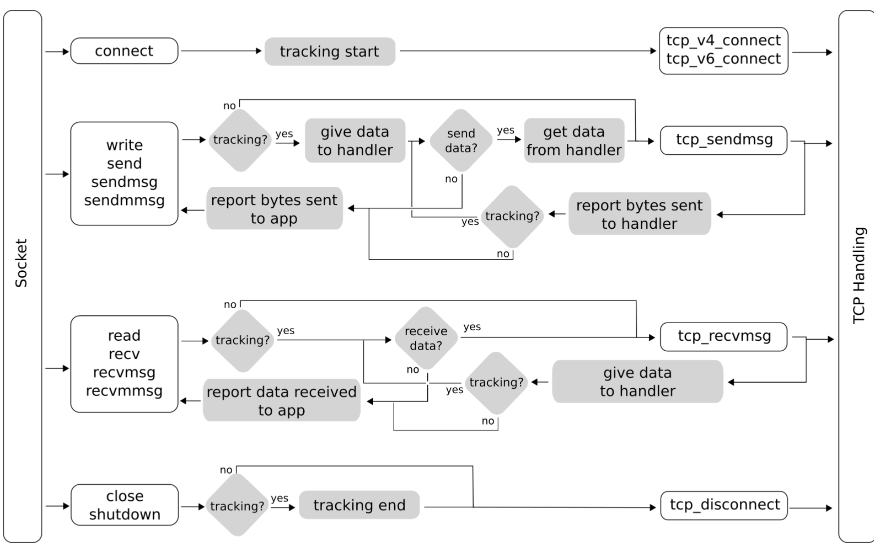

Figure 2: Linux Traffic Interceptor simplified flowchart. Grey boxes correspond to hooks for handlers, white boxes are native system calls and kernel functions

how Netfilter operates at the IP layer, TrustBase can intercept traffic at the socket layer, before data is delivered for TCP handling, and pass it to application-level programs, where it can be (optionally) modified and then passed back to the native kernel code for delivery to the original TCP functionality. Likewise, interception can occur after data finishes TCP processing and before it is delivered to the application. This enables TrustBase to efficiently intercept TLS connections in the operating system and validate certificates in the application layer.

The following discussion highlights the salient features of our implementation.

4.1 Traffic Interceptor

TrustBase provides generic traffic interception by capturing traffic between sockets and the TCP protocol. This is done by hooking several kernel functions and wrapping them to add traffic interception as needed. An overview of which functions are hooked and how they are modified is given in Figure 2. Items in white boxes on the left side of the figure are system calls. Items in white boxes on the right side of the figure are the wrapped kernel functions. The additional logic added to the native flow of the kernel is shown by the arrows and gray boxes in Figure 2.

When the TrustBase LKM is loaded, it hooks into the native TCP kernel functions whose pointers are stored in the global kernel structures `tcp_prot` (for IPv4) and `tcpv6_prot` (for IPv6). When a user program invokes a system call to create a socket, the function pointers within the corresponding protocol structure are copied into the newly-created kernel socket structure, allowing different protocols (TCP, UDP, TCP over IPv6, etc.) to be invoked by the same common socket API. The function pointers in the protocol structures correspond to basic socket operations such as sending and receiving data, and creating and closing connections. Application calls to `read`, `write`, `sendmsg`, and other system calls on that socket then use those protocol functions to carry out their operations within the kernel. Note that within the kernel, all socket-reading system calls (`read`, `recv`, `recvmsg`, and `recvmmsg`) eventually call the `recvmsg` function provided by the protocol structure. The same is true for the corresponding socket write system calls, as each result in calling the kernel `sendmsg` function. When the LKM is unloaded, the original TCP functionality is restored in a safe manner.

From top to bottom in Figure 2, the functionality of the traffic interceptor is as follows. First, a call to `connect` informs the handler that a new connection has been created, and the handler can choose to intercept its traffic.

Second, when an application makes a system call to send data on the socket, the interceptor checks with the handler to determine if it is tracking that connection. If so, it forwards the data to the handler for analysis, and the handler chooses what data (potentially modified by the handler), if any, to relay to native TCP-sending code. After attempting to send data, the interceptor informs the handler how much of that data was successfully placed into the kernel's send buffer and provides notification of any errors that occurred. At this point the interceptor allows the handler to send additional data, if desired. This process continues until the handler indicates it no longer wishes to send data. The interceptor then queries the handler for the return values it wishes to report to the

application (such as how many bytes were successfully sent or an error value) and these values are returned to the application.

Third, a similar, reversed process is followed for the reception of data from the network. If the interceptor is tracking the connection it can choose whether to receive data processed by TCP handling. Any data received is reported to the handler, which can choose whether to report a different value to the application. Note that handlers are allowed to report arbitrary values to applications for the amount of data sent or received, including false values, to allow greater flexibility in connection handling, or to maintain application integrity when injecting additional bytes into a stream. For example, to provide more time to obtain and parse a message, a handler may indicate to an application that zero bytes have been received on a nonblocking socket, even though some or all of the data may have already been received. After the handler has completed its operation it can report to a subsequent receive call from the application that bytes were received, and fill the application's provided buffer with relevant data. As another example, if a handler wishes to append data to a message successfully transferred to the OS by an application using the `send` system call, it should enforce that the return value of this function be the number of bytes the application expects to have been sent, rather than a higher number that includes the added bytes.

Finally, a call to `close` (on the last remaining socket descriptor for a connection) or `shutdown` informs the handler that the connection is closed. Note that the handler may also choose to abandon tracking of connections before this point.

Handlers for various network observation and modification can be constructed by implementing a small number of functions, which will be invoked by the traffic interceptor at runtime. These functions roughly correspond to the grey boxes in Figure 2. For example, handlers must implement functions to send and receive data, indicate whether to continue or cease tracking of a connection, etc. The traffic interceptor calls these functions to provide the handler with data, receive data from the handler to be forwarded to applications or remote hosts, and other tasks. Such an architecture allows developers to implement arbitrary protocol handlers as simple finite state machines, as demonstrated by the TLS handler and opportunistic TLS handlers described in the following subsections.

Another option for implementing traffic interception would have been to use the Netfilter framework, but this is not an optimal approach. TrustBase relies on parsing traffic at the application layer, but Netfilter intercepts traffic at the IP layer. For TrustBase to be implemented using Netfilter, TrustBase would need to transform IP packets into application payloads. This could be done either by implementing significant portions of TCP, including out-of-order handling and associated buffers, or passing traffic through the network stack twice, once to parse the IP packets for TrustBase and once for forwarding the traffic to the application. Both of these options are problematic, creating development and performance overhead, respectively.

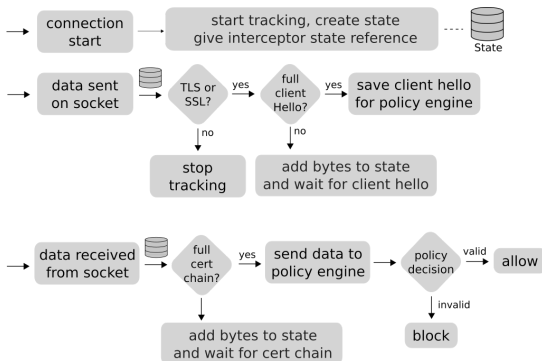

Figure 3: Simplified view of TLS handler

4.2 TLS Handler

TrustBase includes a handler for the traffic interceptor dubbed the "TLS handler". The TLS handler extracts certificates from TLS network flows and forwards them to the policy engine for validation.

Figure 3 provides a high-level overview of how this handler operates. When a new socket is created, the handler creates state to track the connection, which the handler will have access to for all subsequent interactions with the interceptor. The destination IP address and port of the connection and PID of the application owning the connection are provided to the handler during connection establishment by the interceptor. Since the handler is implemented in a LKM, the PID of the socket can be used to obtain any further information about the application such as the command used to run it, its location, and even memory contents.

When data is sent on the socket, the handler checks state data to determine whether the connection has initiated a TLS handshake. If so, then it expects to receive a `ClientHello`; the handler saves this message for the policy engine so that it can obtain the hostname of the desired remote host, if the message contains a Server Name Indication (SNI) extension. If SNI is not used, a log of applications' DNS lookups can be used to infer the intended host,[4] similar to work by Bates et al. [4]

When data is received on the socket, the TLS handler waits until it has received the full certificate chain, then

[4]Our experimentation showed that all popular TLS implementations and libraries now use SNI, and Akamai reports HTTPS SNI global usage at over 98% [33], so this fallback mechanism is almost never needed.

it sends this chain and other data to the policy engine for parsing and validation.

Note, the TLS handler understands the TLS record and handshake protocols but does not perform interpretations of contained data. This minimizes additions to kernel-level code and allows ASN.1 and other parsing to be done in userspace by the policy engine.

4.3 Opportunistic TLS Handler

We have also implemented an opportunistic TLS handler, which provides TrustBase support for plaintext protocols that may choose to upgrade to TLS opportunistically, such as STARTTLS. This handler performs passive monitoring of plaintext protocols (e.g., SMTP), allowing network data to be fast-tracked to and from the application and does not store or aggressively process any transiting data. If at some point the application requests to initiate a TLS connection with the server (e.g., via a STARTTLS message), the handler processes acknowledgments from the server and then delivers control of the connection to the normal TLS handler, which is free to handle the connection as if it were conducting regular TLS.

It should be noted that the use of opportunistic TLS protocols by applications is subject to active attackers who perform stripping attacks to make the client believe the server does not support TLS upgrades, an existing vulnerability well documented by recent work [9, 19, 22]. TrustBase can prevent this type of attack, as discussed in Section 5.

4.4 Policy Engine

The policy engine receives raw certificate data from the TLS handler and then validates the certificates using the configured authentication services. To avoid vulnerabilities that may arise from performing parsing and modification of certificates in the kernel, all such operations are carried out in user space by the policy engine.

Communication between TrustBase kernel space and user space components is conducted via Netlink, a robust and efficient method of transferring data between kernel and user space, provided natively by the Linux kernel. The policy engine asynchronously handles requests from the kernel module, freeing up the kernel threads to handle other connections while a response is constructed.

Native plugins must be written in either C or C++ and compiled as a shared object for use by the policy engine. However, in addition to the plugin API, TrustBase supports an addon API that allows plugins to be written in additional languages. Addons provide the code needed to interface between the native C of the policy engine and the target language it supports. We have implemented an addon to support the Python language and have created several Python plugins.

5 Security Analysis

The TrustBase architecture, prototype implementation, and sample plugins have many implications for system security. In this section we provide a security analysis of the centralized system design, application coverage, protection of applications from attackers, and protection of TrustBase itself from attackers.

5.1 Centralization

Concentrating certificate validation in an operating system service has some risks and benefits. Any vulnerability in the service has the potential to impact all applications on the system. An exploit that grants an attacker root permission leads to compromise of the host. An exploit that causes a certificate to be rejected when it should be accepted is a type of denial-of-service attack. We note that if an attacker is able to get TrustBase to accept a certificate when it should not, any application that does its own certificate authentication correctly will be unaffected. If the application is broken, the TrustBase failure will not make the situation any worse than it already was. The net effect is a lost opportunity to make it better.

The risks of centralization are common to any operating system service. However, centralization also has a compelling upside. For instance, all of our collective effort can be centered on making the design and implementation correct, and all applications can benefit.[5] Securing a single service is more scalable than requiring developers to secure each application or library independently. It also enforces an administrator's preferences regardless of application behavior. Additionally, when a protocol flaw is discovered, it can be more rapidly tested and patched, compared to having to patch a large number of applications.

5.2 Coverage

Since one of the goals of TrustBase is to enforce proper certificate validation on all applications on a system, the traffic interceptor is designed to stand between the transport and application layers of the OS so that it can intercept and access all TLS flows from local applications. The handlers associated with the traffic interception component are made aware of a connection when a `connect` call is issued and can associate that connection with all data flowing through it. Applications that utilize their own

[5] All applications would likewise benefit from caching among authentication services.

custom TCP/IP stack must utilize raw sockets, which require administrator privileges and are therefore implicitly trusted by TrustBase.

To obtain complete coverage of TLS, our handlers need only monitor initial TLS handshakes (standard TLS) and the brief data preceding them (STARTTLS). The characteristics of TLS renegotiation and session termination are compatible with our approach.

In TLS renegotiation, subsequent handshakes use key material derived using the master secret of the first handshake. Thus if the policy engine correctly authenticates and validates the first handshake, TLS renegotiations are implicitly verified as well. Attackers who obtained sufficient secrets to trigger a renegotiation, through some other attack on the TLS protocol or implementation (outside our threat model), have no need to take advantage of renegotiation as they have complete control over the connection already. We also note that renegotiation is rare and typically used for client authentication for an already authenticated server, and has become less relevant for SGC or refreshing keys [37].

Session termination policies for TLS allow us to associate each TLS session with only one TCP connection. In TLS, a close notify must be immediately succeeded by a responding close notification and a close down of the connection [8]. Subsequent reconnects to the target host for additional TLS communication are detected by the TrustBase traffic interceptor and presented to the handlers. We have found that TLS libraries and applications do indeed terminate a TCP session when ending a TLS session, although many of them fail to send an explicit TLS close notification and rely solely on TCP termination to notify the remote host of the session termination.

5.3 Threat Analysis

The coverage of TrustBase enables it to enforce both proper and additional certificate validation procedures on TLS-using applications. There are a variety of ways that attackers may try perform a TLS MITM against these applications. A selection of these methods and discussion of how TrustBase can protect against them follows. For each, we verified our solution utilizing an "attacker" machine acting as a MITM using sslsplit [38], and a target "victim" machine running TrustBase. For some scenarios, the victim machine was implanted with our own CA in the distribution's shipped trust store or the store of a local user or application. Applications tested utilize the tools and libraries mentioned in section 6.2.

- **Hacked or coerced certificate authorities:** Attackers who have received a valid certificate through coercion, deception, or compromise of CAs are able to subvert even proper CA validation. Under TrustBase, administrators can choose to deploy pinning or notary plugins, which can detect the mismatch between the original and forged certificate, preventing the attacker from initiating a connection. We have developed plugins that perform these actions and verified that they prevent such attacks.

- **Local malicious root:** Attackers utilizing certificates that have been installed into an application or user trusted store will be trusted by many target applications. Even Google Chrome will ignore certificate pins in the presence of a certificate that links back to a locally-installed root certificate. TrustBase can protect against this by utilizing similar plugins to the preceding scenario.

- **Absence of status checking:** Many applications still do not check OCSP or Certificate Revocation Lists to determine if a received certificate is valid [29]. In these cases, attackers utilizing stolen certificates that have been reported can still perform a MITM. Administrators who want to prevent this from happening can add an OCSP or CRL plugin to the policy engine and ensure these checks for all applications on the machine. We have developed both OCSP and CRLSet plugins and verified that they perform status checks where applicable. For example, the OSCP plugin can be used to check certificates received by the Chrome browser, which does not do this natively.

- **Failure to validate hostnames:** Some applications properly validate signatures from a certificate back to a trusted root but do not verify that the hostname matches the one contained in the leaf certificate. This allows attackers to utilize any valid certificate, including those for hosts they legitimately control, to intercept traffic [20]. The TrustBase policy engine strictly validates the common name and all alternate names in a valid certificate against the intended hostname of the target host to eliminate this problem.

- **Lack of validation:** For applications that blindly accept all certificates, attackers need only send a self-signed certificate they generate on their own, or any other for which they have the private key, to MITM a connection. TrustBase prohibits this by default, as the policy engine ensures the certificate has a proper chain of signatures back to a trust anchor on the machine and performs the hostname validation described previously.

- **STARTTLS downgrade attack:** Opportunistic TLS begins with a plaintext connection. A downgrade attack occurs when an active attacker suppresses STARTTLS-related messages, tricking the endpoints into thinking one or the other does not

support STARTTLS. The net result is a continuation of the plaintext connection and possible sending of sensitive data (e.g., email) in the clear. TrustBase mitigates this attack by an option to enforce STARTTLS use. When STARTTLS is used to communicate with a given service, TrustBase records the host information. Future connections to that host are then required to upgrade via STARTTLS. If the host omits STARTTLS and prohibits its use, the connection is severed by TrustBase to prevent leaking sensitive information to a potential attacker.[6] TrustBase also allows the system administrator to configure a strict TLS policy, which disallows plaintext connections even if it has no prior data about whether a remote host supports STARTTLS.

5.4 Hardening

The following design principles strengthen the security of a TrustBase implementation. First, the traffic interceptor and handler components run in kernel space. Their small code size and limited functionality—handlers are simple finite state machines—make it more likely that formal methods and source code auditing will provide greater assurance that an implementation is correct. Second, the policy engine and plugins run in user space. This is where error-prone tasks such as certificate parsing and validation occur. The use of privilege separation [36] and sandboxing [30] techniques can limit the potential harm when any of these components is compromised. Third, plugins can only be installed and configured by an administrator, which prohibits unprivileged adversaries and malware from installing malicious authentication services. Finally, communications between the handlers, policy engine, and plugins are authenticated to prevent local malware from spoofing a certificate validation result.

TrustBase is designed to prevent a local, nonprivileged user from inadvertently or intentionally compromising the system. (1) Only privileged users can insert and remove the TrustBase kernel module, prohibiting an attacker from simply removing the module to bypass it. The same is true for plugins. (2) The communication between the kernel module component of TrustBase and the user space policy engine is performed via a custom Generic Netlink protocol that protects against nonprivileged users sending messages to the kernel. The protocol definition takes advantage of the Generic Netlink flag `GENL_ADMIN_PERM`, which enforces that selected operations associated with the custom protocol can only be invoked by processes that have administrative privileges for networking (the capability mapped to `CAP_NET_ADMIN` in Linux systems). This prevents a local attacker from using a local Netlink-utilizing process to masquerade as the policy engine to the kernel. (3) The policy engine runs as a nonroot, `CAP_NET_ADMIN` process that can be invoked only by a privileged user. (4) The configuration files, plugin directories, and binaries for TrustBase are write-protected to prevent unauthorized modifications from nonprivileged users. This protects against weakening of the configuration, disabling of plugins, shutting down or replacing the policy engine, or enabling of bogus plugins.

TrustBase stops traffic interception for a given flow as soon as it is identified as a non-TLS connection. Experimental results show that TrustBase has negligible overhead with respect to memory and time while tracking connections. Thus it is unlikely that an attacker could perform a denial-of-service attack on the machine by creating multiple network connections, TLS or otherwise, any easier than in the non-TrustBase scenario. Such an attack is more closely associated with firewall policies.

An attacker may seek to compromise TrustBase by crafting an artificial TLS handshake that results in some type of TrustBase failure, hoping to cause some kind of application error or termination. We reduce this attack surface by performing no parsing in the kernel except for TLS handshake records, which involves just the message type, length, and version headers. ASN.1 and other data sent to the policy engine are evaluated and parsed by standard openssl functions, which have undergone widespread scrutiny and use for many years. The TrustBase code has been made publicly available, and we invite others to audit the code. We note that, in the absence of the local proxy, TrustBase will not coerce an application to accept a certificate that the application would normally reject.

6 Evaluation

We evaluated the prototype of TrustBase to measure its performance, ensure compatibility with applications, and test its utility for deploying authentication services that can harden certificate validation.

6.1 Performance

To measure the overhead incurred by TrustBase, we instrumented our implementation to record the time required to establish a TCP connection, establish a TLS connection, and transfer a file of varying size (2MB - 500 GB). We tested TrustBase with two plugins, CA Validation and Certificate Pinning (see Section 6.5). The target host for these connections was a computer on the same local network as the client machine, to reduce the effect of latency and network noise. The host presented a valid certificate

[6] This could be further strengthened by checking DANE records to determine if the server supports STARTTLS. We are likewise interested in pursuing whether this technique can be used to protect against other types of downgrade attacks.

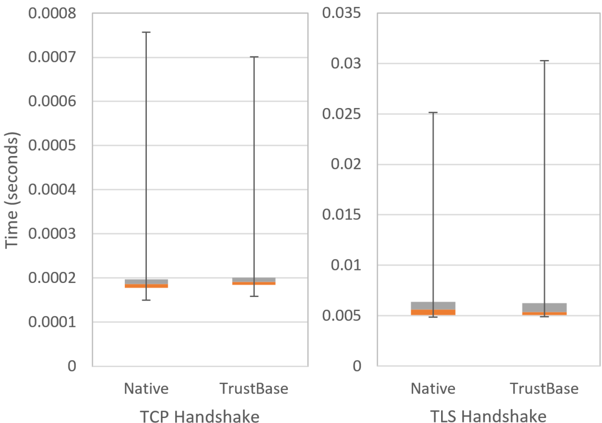

Figure 4: Handshake Timings for TCP (left) and TLS (right) handshakes with and without TrustBase running.

chain that also employed an intermediate authority, representing a realistic circumstance for web browsing and forcing plugins to execute all of their validity checks. Our testing used a modern PC running Fedora 21 and averaged across 1,000 trials.

Figure 4 shows boxplots that characterize the timing of TCP and TLS handshakes, with and without TrustBase active. There is no discernible difference for TCP handshake timings and the average difference is less than 10 microseconds, with neither configuration consistently beating the other in subsequent experiments. This is expected behavior because the traffic interceptor is extremely light-weight for TCP connections. Average TLS handshake times with and without TrustBase also have no discernible difference, with average handshake times for this experiment of 5.9 ms and 6.0 ms, respectively. Successive experiments showed again that neither average consistently beat the other. This means that the inherent fluctuations in system and network conditions account for more time than the additional control paths TrustBase introduces. This is also expected, as the brevity of TLS handling code, its place in the kernel, the use of efficient Netlink transport and other design choices were made with performance in mind.

Our experimentation with varying file sizes also exhibited no difference between native and TrustBase cases. Note that the TrustBase timings for the TLS handshake may increase if a particular plugin is installed that requires more processing time or relies on Internet queries to function, and that this overhead is inherent to that service and not the TrustBase core.

The memory footprint in our Linux prototype is also negligible. For each network connection, TrustBase temporarily stores less than 300 bytes of data, plus the length of any TLS handshake messages encountered. Connections not using TLS use even less memory than this and carry a zero-byte memory overhead once their nature has been determined and TrustBase ceases to monitor them.

6.2 Compatibility

One goal of TrustBase is to strengthen certificate authentication for existing, unmodified applications and to provide additional authentication services that strengthen the CA system. To meet this goal, TrustBase must be able to enforce proper authentication behavior by applications, as defined by the system administrator's configuration.

There are three possible cases for the policy engine to consider. (1) If a certificate has been deemed valid by both TrustBase and the application, the policy engine allows the original certificate data to be forwarded on to the application, where it is accepted naturally. (2) In the case where the application wishes to block a connection, regardless of the decision by TrustBase, the policy engine allows this to occur, since the application may have a valid reason to do so. We discuss in Section 3.5, the special case when a new authentication service is deployed that wishes to accept a certificate that the CA system normally would not. (3) In the case where validation with TrustBase fails, but the application would have allowed the connection to proceed, the policy engine blocks the connection by forwarding an intentionally invalid certificate to the application, which triggers any SSL application validation errors an application supports, and then subsequently terminates the connection.

We tested TrustBase with 34 popular applications and libraries and tools, shown in Table 1.[7] TrustBase successfully intercepted and validated certificates for all of them. For each library tested, and where applicable, we created sample applications that performed no validation and improper validation (bad checking of signatures, hostnames, and validity dates). We then verified that TrustBase correctly forced these applications to reject false certificates despite those vulnerabilities in each case. In addition, we observed that TrustBase caused no adverse behavior, such as timeouts, crashes, or unexpected errors.

6.3 Android Prototype

To verify that the TrustBase approach works on mobile platforms and is compatible with mobile applications, we built a prototype for Android. Source code can be found at `owntrust.org`.

Our Android implementation uses the `VPNService` so that it can be installed on an unaltered OS and without root permissions. The drawback of this choice is that only one VPN service can be active on the Android at a time. In the long-term, adding socket-level interception to the Android kernel would be the right architectural choice,

[7] These are a superset of the tools and libraries tested with CertShim

Library	Tool
C++	gnutls-cli
libcurl	curl
libgnutls	sslscan
libssl	openssl s_client
libnss	openssl s_time
JAVA	lynx
SSLSocketFactory	fetchmail
PERL	firefox
socket::ssl	chrome/chromium
PHP	mpop
fsockopen	w3m
php_curl	ncat
PYTHON	wget
httplib	steam
httplib2	thunderbird
pycurl	kmail
pyOpenSSL	pidgin
python ssl	
urllib, urllib2, urllib3	
requests	

Table 1: Common Linux libraries and tools compatible with TrustBase

and then TrustBase could use similar traffic interception techniques as with the Linux implementation.

The primary engineering consequence of using the `VPNService` on Android is that TrustBase must intercept IP packets from applications but emit TCP (or UDP) packets to the network. If it could use raw sockets, then TrustBase could merely transfer IP packets between the `VPNService` and the remote server. Unfortunately, the lowest level socket endpoint an Android developer can create is the Java `Socket` or `DatagramSocket`, which encapsulate TCP and UDP payloads respectively. Therefore, we must emulate IP, UDP and TCP to facilitate communication between the `VPNService` and the sockets used to communicate with remote hosts. For TCP, this involves maintaining connection state, emulating reliability, and setting appropriate flags (SYN, ACK, etc.) for TCP traffic.

To verify compatibility with mobile applications, we tested 16 of the most popular Android applications: Chrome, YouTube, Pandora, Gmail, Pinterest, Instagram, Facebook, Google Play Store, Twitter, Snapchat, Amazon Shopping, Kik, Netflix, Google Photos, Opera, and Dolphin. TrustBase on Android successfully intercepted and strengthened certificate validation for all of them.

6.4 Windows Prototype

To demonstrate that the TrustBase approach works on Windows, we also built a prototype for Windows 10. Source code can be found at `owntrust.org`.

The traffic interceptor component of TrustBase on Windows is implemented utilizing the native Windows Filtering Platform (WFP) API, acting as a kernel-mode driver. Reliance on the WFP reduced the code necessary to provide traffic interception capabilities and also made them easy to maintain, given that the Windows kernel code is not open source. As on Linux, this kernel code is event-driven, collects connection information, and transmits it to a userspace policy engine for processing and decision making. The policy engine is patterned after its Linux counterpart, supports both Python and C plugins, and uses native Windows libraries where possible (e.g., Microsoft's CryptoAPI and native threading APIs).

The nature of the Windows root certificate store allows TrustBase to avoid utilizing a TLS Proxy in cases where overriding the CA system is desired (see Section 3.5). Windows has the ability to dynamically alter the root certificate store during runtime, and applications using the CA system will be immediately subject to those changes. This allows TrustBase to dynamically add self-signed certificates to the root store when the policy engine deems them trustworthy. Through this mechanism TrustBase can override the CA system by placing a validated certificate in the root store before the application obtains and validates it against the root store. TrustBase maintains identifying hashes of all the certificates added to the root store and removes them when the connections using them are terminated. As on Linux, applications that use their own private certificate stores cannot have their validation rejections overridden using this methodology.

6.5 Utility

To validate the utility of TrustBase, we implemented eight useful authentication services. Table 2 describes each of these services. These services illustrate the types of control that TrustBase can provide to an administrator in securing TLS on a system. The CA validation plugin ensures that all applications on the system perform appropriate checks when validating certificates received through TLS (hostname, basic constraints, expiration, etc.). The whitelist represents a more manual, customized approach to validation, likely to be used in conjunction with other services to handle edge cases. Our certificate pinning and certificate revocation services enforce more advanced checks that are usually reserved for individual applications but can now be deployed system-wide. Note that this includes the deployment of Google's CRLSets checks, which are normally reserved for Chromium browsers only. This addresses the limitation noted by [11] concerning the isolation of newer validation technologies in browser code. The Notary and DANE services can be leveraged to trust additional channels of information aside from CA signatures and revocation lists. Finally, our cipher suite auditor service allows system administrators to pre-

CA Validation	Enforces standard certificate validation using `openssl` functions and standard practices for validating hostnames, Basic Constraints, dates, etc.
Whitelist	Stores a set of certificates that are always considered valid for their respective hosts, such as self-signed certificates.
Certificate Pinning	Uses Trust On First Use to pin certificates for any host; expired certificates are replaced by the next certificate received by a connection to that domain.
Certificate Revocation	Checks OCSP to determine whether the certificate has been revoked.
CRLSet Blocking	Checks Google's CRLSet to determine whether the certificate has been blocked, extending Chrome's protection to all apps.
DANE	Uses the DNS system to distribute public keys in a TLSA record [21].
Notary	Based on ideas presented by Perspectives [41] and Convergence [31], it connects securely to one or more notary servers to validate the certificate received by the client is the same one that is seen by the notaries.
Cipher Suite Auditor	Uses Client Hello and Server Hello information, along with a configuration with secure defaults, to disallow weak cipher suites. It can also require that certain TLS extensions be employed (e.g., TACK[32]).

Table 2: Authentication and Security services implemented with TrustBase

vent connections that attempt to utilize weak cipher suites and signing algorithms, using the additional handshake information provided to all plugins.

7 Future Work

TrustBase explores the benefits and drawbacks of providing authentication as an operating system service and giving administrators control over how all authentication decisions on their machines are made. In doing so, a step has been taken toward empowering administrators to control secure connections on their machines. However, some drawbacks have been noted, such as the reliance on a local proxy to support TLS 1.3 interception and CA overriding in some cases on Linux. These issues are caused by applications dictating the security of the machine's connections, using their own (or third party) security features and keys, reducing operating system and administrator control.

We are currently investigating further steps into this territory to provide great administrator control of security without some of these drawbacks. One such step is providing TLS as an operating system service, meaning that the operating system provides encryption for applications, not just authentication. Current TLS libraries are a burden on application developers, who are often not security experts. In addition, developers do not necessarily share the same security goals as the vendors or administrators who configure the systems upon which applications run. By providing TLS as an operating system service, application developers are relieved of this burden and the OS can invoke the TrustBase validation API natively. This removes the need for developers to explicitly invoke the validation API, and provides the OS with visibility and control over all TLS data, including TLS 1.3 handshakes, as the OS becomes the de facto TLS client. Such a measure enables system-wide deployment of security measures, such as cipher suite customization, TLS extension deployment, and responses to CVEs. This also allows OS vendors and system administrators an easier upgrade path for TLS versions.

Since network application developers are already familiar with the POSIX socket API, we are working on providing TLS as a protocol type in the socket API, the same way the OS provides TCP and UDP protocols as a service. In contrast to using a userspace library, this approach allows network application developers unfamiliar with security to operate in a well-known environment, utilizes an existing OS API that can be shared by many different platform implementations, and allows strict configuration and control by administrators. By creating a socket using a new `IPPROTO_TLS` parameter (as opposed to `IPPROTO_TCP`), developers can use the `bind`, `connect`, `send`, `recv`, and other socket API calls with which thy are already familiar, focusing solely on application data and letting the OS handle all TLS functionality. The generalized `setsockopt` and `getsockopt` are available to specify remote hostnames and additional options to the OS TLS service without violating the existing socket API.

8 Conclusion

We have explored how to fix broken authentication in existing applications, while also providing a platform for improved authentication services. To solve these problems we used two guiding principles—centralizing authentication as an operating system service and giving system administrators control over authentication policy. Following these two principles, we designed the TrustBase architecture for certificate authentication, meeting our design goals of securing existing applications, strengthening the CA system, providing full application coverage, enabling universal deployment, and imposing negligible overhead. We have presented a research prototype for TrustBase on Linux, discussed how we hardened this implementation, provided a security analysis, and evaluated its performance. We have provided source code for Linux, Android, and Windows prototypes. Finally, we have written eight authentication services to demonstrate the utility of this approach, extending CA hardening to all applications.

Abstract

Building machine learning models of malware behavior is widely accepted as a panacea towards effective malware classification. A crucial requirement for building sustainable learning models, though, is to train on a wide variety of malware samples. Unfortunately, malware evolves rapidly and it thus becomes hard—if not impossible—to generalize learning models to reflect future, previously-unseen behaviors. Consequently, most malware classifiers become unsustainable in the long run, becoming rapidly antiquated as malware continues to evolve. In this work, we propose Transcend, a framework to identify aging classification models *in vivo* during deployment, much before the machine learning model's performance starts to degrade. This is a significant departure from conventional approaches that retrain aging models retrospectively when poor performance is observed. Our approach uses a statistical comparison of samples seen during deployment with those used to train the model, thereby building metrics for prediction quality. We show how Transcend can be used to identify concept drift based on two separate case studies on Android and Windows malware, raising a red flag before the model starts making consistently poor decisions due to out-of-date training.

1 Introduction

Building sustainable classification models for classifying malware is hard. Malware is mercurial and modeling its behavior is difficult. Codebases of commercial significance, such as Android, are frequently patched against vulnerabilities and malware attacking such systems evolve rapidly to exploit new attack surfaces. Consequently, models that are built through training on older malware often make poor and ambiguous decisions when faced with modern malware—a phenomenon commonly known as *concept drift*. In order to build sustainable models for malware classification, it is important to identify when the model shows signs of aging whereby it fails to recognize new malware.

Existing solutions [12, 15, 23] aim to periodically retrain the model. However, if the model is retrained too frequently, there will be little novelty in the information obtained to enrich the classifier. On the other hand, a loose retraining frequency leads to periods of time where the model performance cannot be trusted. Regardless, the retraining process requires manual labeling of all the processed samples, which is constrained by available resources. Once the label is acquired, traditional metrics such as precision and recall are used to retrospectively indicate the model performance. However, these metrics do not assess the decision of the classifier. For example, hyperplane-based learning models (e.g., SVM) only check the side of the hyperplane where the object lies while ignoring its distance from the hyperplane. This is a crucial piece of evidence to assess non-stationary test objects that eventually lead to concept drift.

A well known approach for qualitative assessment of decisions of a learning model is the probability of fit of test object in a candidate class. Previous work has relied on using fixed probability thresholds to identify best matches [19]. Standard algorithms compute the probability of a sample fitting into a class as a by-product of the classification process. However, since probabilities need to sum up to 1.0, it is likely that for previously unseen test objects which do not belong to any of the classes, the probability may be artificially skewed. To mitigate this issue, Deo et al. propose ad-hoc metrics derived from the two probabilities output by Venn-Abers Predictors (VAP) [5], one of which is perfectly calibrated. Although promising, the approach is unfortunately still in its infancy and does not reliably identify drifting objects (as further elaborated in § 6).

The machine learning community has developed tech-

[*]Research carried out entirely while Post-Doctoral Researchers at Royal Holloway, University of London.

niques that look at objects statistically rather than probabilistically. For example, Conformal Predictor [20] makes predictions with statistical evidence. However, as discussed by Fern and Dietterich[1], this method is not tailored to be used in presence of concept drift.

Nevertheless, statistical assessments seem to overcome the limitations of probabilistic approaches, as outlined in § 2. Still, there are two key issues that need to be addressed before statistical assessments can be used to detect concept drift. First, the assessments have to be agnostic to the algorithm used to build the learning model. This is non-trivial as different algorithms can have different underlying classification mechanisms. Any assessment has to abstract away from the algorithm and identify a universal criteria that treats the underlying algorithm as a black box. Second, and more importantly, auto-computation of thresholds to identify an aging model from an abstract assessment criteria requires a brute force search among scores for the training objects.

In this work, we address both these issues by proposing both meaningful and sufficiently abstract assessment metrics as well as an assessment criteria for interpreting the metrics in an automated fashion. We propose Transcend—a fully parametric statistical framework for assessing decisions made by the classifier to identify concept drift. Central to our contribution, is the translation of the decision assessment problem to a constraint optimization problem which enables Transcend to be parametric with diverse operational goals. It can be bootstrapped with pre-specified parameters that tune its sensitivity to varying levels of concept drift. For example, in applications of critical importance, Transcend can be pre-configured to adopt a strict filtering policy for poor and unreliable classification decisions. While previous work has looked at decision assessment [4, 19], this is the first work that looks at identifying untrustworthy predictions using decision assessment techniques. Thereby, Transcend can be deployed in existing detection systems with the aim of identifying aging models and ameliorating performance in the face of concept drift.

In a nutshell, we make the following contributions:

- We propose conformal evaluator (CE), an evaluation framework to assess the quality of machine learning tasks (§ 2). At the core of CE is the definition of non-conformity measure derived from the ML algorithm under evaluation (AUE) and feature set (§ 2.1). This measure builds statistical metrics to quantify the AUE quality and statistically support goodness of fit of a data point into a class according to the AUE (§ 2.4).

[1] A. Fern and T. Dietterich. "Toward Explainable Uncertainty". https://intelligence.org/files/csrbai/fern-slides-1.pdf

- We build assessments on top of CE's statistical metrics to evaluate the AUE design and understand statistical distribution of data to better capture AUE's generalization and class separations (§ 3).
- We present Transcend, a fully tunable classification system that can be tailored to be resilient against concept drift to varying degrees depending on user specifications. This versatility enables Transcend to be used in a wide variety of deployment environments where the cost of manual analysis is central to classification strategies. (§ 3.3)
- We show how CE's assessments facilitate Transcend to identify suitable statistical thresholds to detect decay of ML performance in realistic settings (§ 4). In particular, we support our findings with two case studies that show how Transcend identifies concept drift in binary (§ 4.1) and multi-class classification (§ 4.2) tasks.

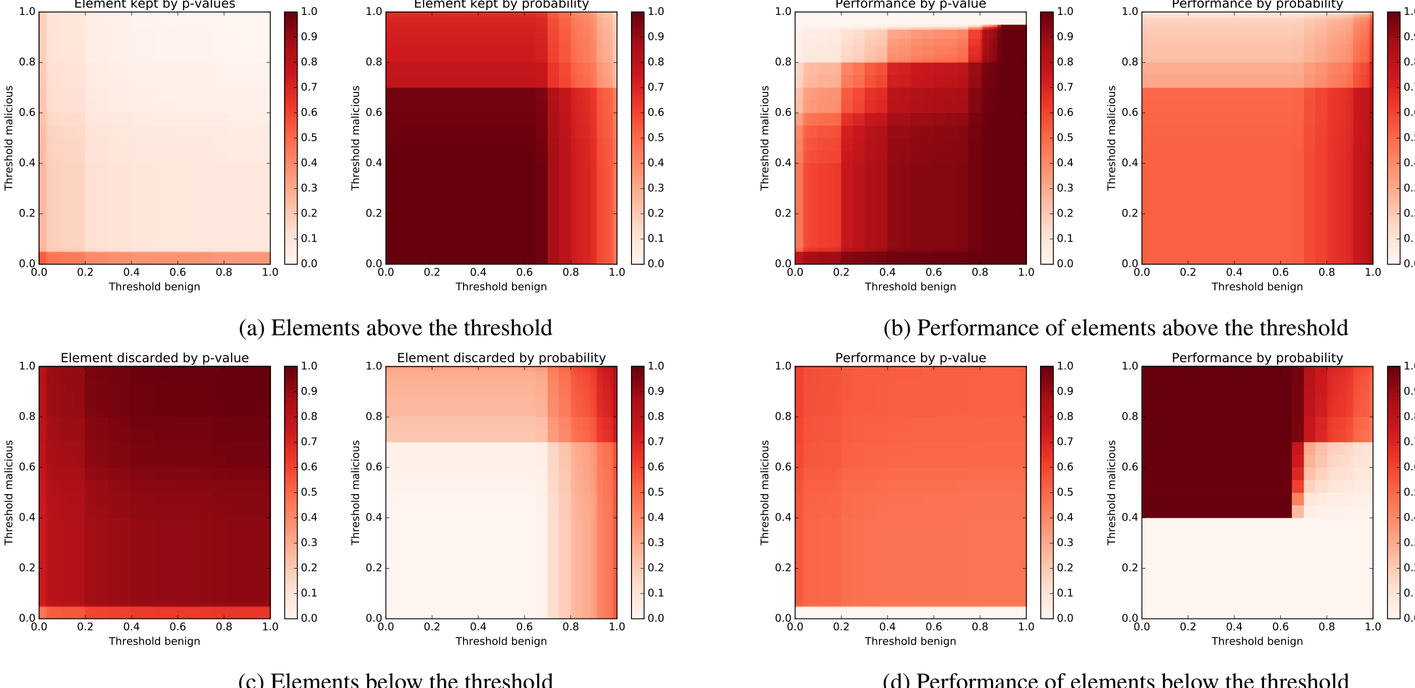
2 Statistical Assessment: Why and How?

In this section we discuss the significance of statistical techniques for decision assessment, which form the core of conformal evaluator. A statistical approach to decision assessment considers each decision in the context of previously made decisions. This is different to a probabilistic assessment where the metric is indicative of how likely a test object is to belong to a class. In contrast, statistical techniques answer the question: *how likely is the test object to belong to a class compared to all of its other members?* The contextual evidence produced by statistical evidence is a step beyond standard probabilistic evidence and typically gives stronger guarantees on the quality of the assessment. Our work dissects Conformal Predictor (CP) [24] and extracts its sound statistical foundations to build conformal evaluator (CE). In the following section, we provide further details, while we forward the reader to § 6 for a full comparison between CP and CE.

2.1 Non-conformity Measure

Classification is usually based on a *scoring function* which, given a test object z^*, outputs a *prediction score* $F_{\mathcal{D}}(l, z^*)$, where $\mathcal{D}$ is the dataset of training objects and l is a label from the set of possible object labels $\mathcal{L}$.

The scoring function can be used to measure the difference between a group of objects belonging to the same class (e.g., malware belonging to the same family) and a new object (i.e., a sample). In Transcend, the *non-conformity measure* (NCM) is computed directly from the scoring function of the algorithm. Thus, conformal



(a) Elements above the threshold

(b) Performance of elements above the threshold

(c) Elements below the threshold

(d) Performance of elements below the threshold

Figure 1: Performance comparison between *p-value* and *probability* for the objects above and below the threshold used to accept the algorithm's decision. The p-values are given by CE with SVM as non-conformity measure, the probabilities are given directly by SVM. As we can see from the graph, p-values tend to contribute to a higher performance of the classifier, identifying those (drifting) objects that would have been erroneously classified.

evaluation is agnostic to the algorithm, making it versatile and compatible with multiple ML algorithms; it can be applied on top of any classification or clustering algorithm that uses a score for prediction.

We note that some algorithms already have built-in quality measures (e.g., the distance of a sample from the hyperplane in SVM). However, these are algorithm specific and cannot be directly compared with other algorithms. On the other hand, Transcend unifies such quality measures through uniform treatment of non-conformity in an algorithm-agnostic manner.

2.2 P-values as a Similarity Metric

At the heart of conformal evaluation is the non-conformity measure—a real-valued function $A_{\mathcal{D}}(C \backslash z, z)$, which tells how different an object z is from a set C. The set C is a subset of the data space of object $\mathcal{D}$. Due to the real-valued range of non-conformity measure, conformal evaluator can be readily used with a variety of machine learning methods such as support-vector machines, neural networks, decision trees and Bayesian prediction [20] and others that use real-valued numbers (i.e., a similarity function) to distinguish objects. Such flexibility enables Transcend to assess a wide range of algorithms.

Conformal evaluation computes a notion of similarity through p-values. For a set of objects $\mathcal{K}$, the p-value $p^{C}_{z^*}$ for an object z^* is the proportion of objects in class $\mathcal{K}$ that are at least as dissimilar to other objects in C as z^*. There are two standard techniques to compute the p-values from $\mathcal{K}$: *Non-Label-Conditional* (employed by *decision* and *alpha* assessments outlined in § 3.1 and § 3.2), where $\mathcal{K}$ is equal to $\mathcal{D}$, and *Label-Conditional* (employed by the concept drift detection described in § 3.3), where $\mathcal{K}$ is the set of objects C with the same label. The calculations for the non-conformity measures for the test object and the set of objects in $\mathcal{K}$ is shown in equation 1 and 2 respectively. The computation of p-value for the test object is shown in equation 3.

$$\alpha_{z^*} = A_{\mathcal{D}}(C, z^*) \quad (1)$$

$$\forall i \in \mathcal{K}. \alpha_i = A_{\mathcal{D}}(C \setminus z_i, z_i) \quad (2)$$

$$p^{C}_{z^*} = \frac{|\{j : \alpha_j \geq \alpha_{z^*}\}|}{|\mathcal{K}|} \quad (3)$$

P-values compute an algorithm's credibility and confidence, crucial for decision assessments (§ 2.4).

2.3 P-values vs. Probabilities

One might question the utility of p-value over probability of a test object belonging to a particular class. Probabilities are computed by most learning algorithms as qualitative feedback for a decision. SVM uses Platt's scaling to compute probability scores of an object belonging to a class while a random forest averages the decision of individual trees to reach a final prediction [3]. In this section, we discuss the shortcomings of using probabilities for decision assessment as shown in §4.1.1 and §4.2. Additionally, we also provide empirical evidence in favor of p-values as a building block for decision assessment.

P-values offer a significant advantage over probabilities when used for decision assessment. Let us assume that the test object z^* has p-values of $p^1_{z^*}, p^2_{z^*} \cdots p^k_{z^*}$ and probability of $r^1_{z^*}, r^2_{z^*} \cdots r^k_{z^*}$ of belonging to classes $l_1, l_2 \cdots l_k$ (which is the set of all classes in $\mathcal{L}$). In the case of probabilities, $\Sigma_i r^i_{z^*}$ must sum to 1.0. Now, lets consider a 2-class problem. If z^* does not belong to either of the classes, and the algorithm computes a low probability score $r^1_{z^*} \sim 0.0$, then $r^2_{z^*}$ would artificially tend to 1.0. In other words, if we use probabilities for decision assessment it is likely that we might reach an incorrect conclusion for previously unseen samples. P-values on the other hand are not constrained by such limitations. It is possible for both $p^1_{z^*}$ and $p^2_{z^*}$ to be a low value for the case of a previously unseen sample. This is true also when p-values are built using probability as NCM. To calculate the probability of a test sample, only information belonging to the test samples are used (e.g., distance to the hyperplane in the case SVM or ratio of decisions for one class in the case of random forest). Instead, a p-value is computed comparing the scores of all the samples in a class (see equation 1 and 2).

We further elaborate on this by training an SVM classifier with Android malware objects from the Drebin dataset [2] and by testing it using objects from a drifted dataset (the Marvin dataset [14], see § 4 for details). Then, we apply a threshold to accept the decision of the classifier only if a certain level of certainty is achieved. Figure 1 shows the average of F1-score for malicious and benign classes after the application of the threshold for the objects that fall above (Figure 1b) and below it (Figure 1d). Figure 1 also shows the ratio of objects retained (Figure 1a) and rejected (Figure 1c). Figure 1b shows that the use of p-values produces better performance as it identifies more objects to reject than probabilities (Figure 1a). Here, filtering out a high number of objects is correct as they are drifting from the trained model. Keeping them would degrade the performance of the algorithm (Figures 1c and 1d). The threshold is applied to the testing objects; we present case studies in § 4.1, which show how to derive it from the training dataset.

2.4 Statistical Decision Assessment

This section introduces and discusses CE metrics used to assess the classification decisions. The techniques for interpreting these metrics are discussed in § 3.

Algorithm Credibility. The first evaluation metric for assessing classification decision on a test object is *algorithm credibility*. $A_{Cred}(z^*)$ is defined as the p-value for the test object z^* corresponding to the label chosen by the algorithm under analysis. As discussed, the p-value measures the fraction of objects within $\mathcal{K}$, that are at least as different from the set of objects C as the new object z^*. A high credibility value means that z^* is very similar to the objects in the class chosen by the classifier. Although credibility is a useful measure of classification quality, it only tells a partial story. There may potentially be high p-values for multiple labels indicating multiple matching labels for the test object which the classification algorithm has ignored. On the other hand, a low credibility value is an indicator of either z^* being very different from the objects in the class chosen by the classifier or the object being poorly identified. These two observations show that credibility alone is not sufficient for reliable decision assessment. Hence, we introduce another measure to gauge the non-performance of the classification algorithm—*algorithm confidence*.

Algorithm Confidence. For a given choice (e.g., assigning z to a class l_i), confidence tells how certain or how committed the evaluated algorithm is to the choice. Formally, it measures how distinguishable is the new object $z^* \in l_i$ from other classes l_j with $j \neq i$. We define the algorithm confidence as 1.0 minus the maximum p-value among all p-values except the *p-value* chosen by the algorithm (i.e., algorithm credibility): $A_{Conf}(z^*) = 1 - \max(P(z^*) \setminus A_{Cred}(z^*))$ where, $P(z^*) = \{p^{l_i}_{z^*} : l_i \in \mathcal{L}\}$

$P(z^*)$ is the set of p-values associated to the possible choices for the new object z^*. The highest value of confidence is reached when the algorithm credibility is the highest p-value. It may happen that the choice made by the algorithm is not attached to the highest p-value, suggesting that the confidence is sub-optimal. Results in § 4 show that this provides valuable insights, especially when the method under assessment makes choices with low values of confidence and credibility. Low algorithm confidence indicates that the given object is similar to other classes as well. Depending on the algorithm credibility, this indication may imply that the decision algorithm is not able to uniquely identify the classes or, that the new object looks similar to two or more classes.

Finally, we note that algorithm confidence and credibility are not biased by the number of classes in a dataset as popular measures, such as precision and recall [13]. Thus CE's findings are more robust to dataset changes.

3 Framework Description

Previous section introduced conformal evaluation along with the two metrics that we use for decision assessment: algorithm confidence and algorithm credibility. Transcend uses two techniques to evaluate the quality of an algorithm employed on a given dataset: (*i*) *Decision assessment*—evaluates the robustness of the predictions made by the algorithm; and (*ii*) *Alpha assessment*—evaluates the quality of the non-conformity measure. We combine these assessments to enable the detection of concept drift (§3.3).

3.1 Decision Assessment

Conformal evaluator qualitatively assesses an algorithm's decision by assigning a class $l \in \mathcal{L}$ as predicted by the algorithm to each new object z^* and computing its algorithm credibility and confidence.

Hence, four possible scenarios unfold: (*i*) High algorithm confidence, high algorithm credibility—the best situation, the algorithm is able to correctly identify a sample towards one class and one class only. (*ii*) High algorithm confidence, low algorithm credibility—the algorithm is not able to correctly associate the sample to any of the classes present in the dataset. (*iii*) Low algorithm confidence, low algorithm credibility—the algorithm gives a label to the sample but it seems to be more similar to another label. (*iv*) Low algorithm confidence, high algorithm credibility—according to the algorithm, it seems that the sample is similar to two or more classes.

The measures are then grouped into two sets —correct or wrong— which represents values for correctly and wrongly classified objects. Subsequently, values are averaged and their standard deviation is also computed, this is done for every class $l \in \mathcal{L}$, to study whether the algorithm works consistently for all classes or if there are difficult classes that the algorithm has trouble dealing with. This assessment, performed during the design phase of the algorithm, helps us to decide the cutoff threshold for a deployed scenario to separate the samples with enough statistical evidence of correctness.

Comparing the results obtained for correct and wrong choices produces interesting results. For correct choices it would be desirable to have high credibility and confidence. Conversely, for wrong choices it would be desirable to have low credibility and high confidence. The divergence from these scenarios helps understand whether the algorithm takes strong decisions, meaning that there is a strong statistical evidence to confirm its decisions, or, in contrast, if the decisions taken are easily modified with a minimal modification of the underlying data.

By looking at the outcome of decision assessment, it is possible to understand whether the choices made by an algorithm are supported with statistical evidence. Otherwise, it is possible to get an indication where to look for possible errors or improvements, i.e., which classes are troublesome, and whether further analysis is needed, e.g. by resorting to the alpha assessment.

3.2 Alpha Assessment

In addition to the decision assessment, which evaluates the output of a similarity-based classification/clustering algorithm, another important step in understanding the inner workings and subtleties of the algorithm includes analyzing the data distribution of the algorithm under evaluation. Owing mainly to practical reasons, malware similarity-based algorithms are developed around a specific dataset. Hence there is often the possibility of the algorithm to over-fit its predictions to the dataset. Overfitting results in poor performance when the algorithm analyses new or unknown datasets [13]. Despite employing techniques to avoid over-fitting, the best way to answer this question is to try the algorithm against as many datasets as possible. We show that conformal evaluator can help solve this problem, when no more than one dataset is available.

The *alpha assessment* analysis takes into account how appropriate is the similarity-based algorithm when applied to a dataset. It can detect if the final algorithm results still suffer from over-fitting issues despite the efforts of minimizing it using common and well known techniques (e.g., cross validation).

Furthermore, the assessment enables us to get insights on classes (e.g., malware families), highlighting how the similarity-based method works against them. Researchers may gather new insights on the peculiarities of each class, which may eventually help to improve feature engineering and the algorithm's performance, overall.

First, for each object $z_j \in D$, where l_j is z_j's true class, we compute its p-values against every possible $l \in \mathcal{L}$. We then plot the boxplot [10], containing the p-values for each decision. By aligning these boxplots and grouping them by class/cluster, we can see how much an element of class/cluster j resembles that of another one, allowing for reasoning about the similarity-based algorithm itself.

In § 4 we present case studies where we statistically evaluate the quality behind performances of algorithms within the conformal evaluator framework.

3.3 Concept Drift

We now describe the core of Transcend's concept drift detection and object filtering mechanism. It must be stressed here that we look at concept drift from the perspective of a malware analysis team. Consequently, the

severity of the drift is a subjective issue. For critical applications, even a few misclassifications can cause major issues. Consequently, the malware analysis team would have a high standard for abandoning an aging classification model. Therefore, we make the concept drift detection in Transcend parametric in two dimensions: the desired performance level (ω) and the proportion of samples in an epoch that the malware analysis team is willing to manually investigate (δ). The analyst selects ω and δ as degrees of freedom and Transcend will detect the corresponding concept drift point constrained by the chosen parameters. The goal is to find thresholds that best separate the correct decisions from the incorrect ones based on the quality metrics introduced by our analysis. These thresholds are computed on the training dataset but are enforced on predictions during deployment (for which we do not have labels). The rationale is very simple: predictions with p-values above such thresholds would identify objects that likely fit (from a statistical perspective) in the model; such classifications should be trusted. Conversely, objects out of predictions with p-values smaller than such thresholds should not be trusted as there is lack of statistical evidence to support their fit in the model.

What happens to untrustworthy predictions (and related test—likely drifted—objects) is out of the scope of this work. It is reasonable to envision a pipeline that would label drifted objects to retrain the machine learning model, eventually. While this raises several challenges (e.g., how many objects need to be labeled, how much resources can be invested in the process), we would like to remark the fact that is only possible once concept drift is detected: the goal of this research. Not only, Transcend plays a fundamental role in the identification of drifting objects and thus in the understanding of when a prediction should be trusted or not, but its metrics can also aid in selecting what drifted objects should be labeled first (e.g., those with low p-values as are the one that have drifted the most from the trained model).

The following discussion assumes two classes of data, malicious and benign, but it is straightforward to extend it to a multiclass scenario.

We define the function $f : \mathbb{B} \times \mathbb{M} \rightarrow \Omega \times \Delta$ that maps a pair of thresholds in the benign and malicious class and outputs the performance achieved and the number of decisions accepted. Here, the number of decisions accepted refers to the percentage of the algorithm outputs with a p-value (for benign or malicious classes, depending on the output itself) greater than the corresponding threshold; performance means the percentage of correct decisions amongst the accepted ones. $\mathbb{B}$, $\mathbb{M}$, Ω and Δ are the domains of the possible thresholds on benign samples, malicious samples, desired performance and classification decisions accepted, respectively. During training of our classifier, we iterate over all values of the benign threshold t'_b and the malicious threshold t'_m, at a pre-specified level of granularity, in the domain of $\mathbb{B}$ and $\mathbb{M}$, respectively. Let us assume f gives the output $f\!:\!f(t'_b, t'_m) = (\omega', \delta')$

To detect concept drift during deployment with a pre-specified threshold of either ω or δ, we need to define an inverse of f which we call $f^{-1} : \Lambda \rightarrow \mathbb{B} \times \mathbb{M}$ where $\Lambda = \Omega \cup \Delta$. When supplied with either ω or δ, f^{-1} would give us two thresholds t_b and t_m which would help Transcend decide when to accept the classifier's decision and when to ignore it. Notice that with a conjoined domain Λ, which only accepts either ω or δ, it is not trivial to reconstruct the values of t_b and t_m. For every value of ω, there could be multiple values for δ. Therefore, we adopt a simple heuristic to compute t_b and t_m whereby we maximize the second degree of freedom given the first. For example, given ω, we find t_b and t_m for every possible value of δ and pick the t_b and t_m that maximizes δ. The formulation is exactly the same when δ is used as an input. The formal equations for the inverse functions are:

$$
\begin{aligned}
\Gamma &= \{x : x \in \forall t'_b \forall t'_m . f(t'_b, t'_m))\} \\
f^{-1}(\omega) &= \{(t_b, t_m) : \delta \in f(t_b, t_m) = max(\forall \delta' \in \Gamma)\} \\
f^{-1}(\delta) &= \{(t_b, t_m) : \omega \in f(t_b, t_m) = max(\forall \omega' \in \Gamma)\}
\end{aligned}
$$

Comparison with Probability. The algorithm used as inner non-conformity measure (NCM) in CE may have a pre-defined quality metric to support its own decision-making process (e.g., probability). Hence, we also compare the ability of detecting concept drift of the algorithm's internal metric with CE metrics. The thresholds are extracted from the true positive samples, because we expect the misclassified samples to have a lower value of the quality metric: it seems rather appropriate to select a higher threshold to highlight decisions the algorithm would likely make wrong. We compare our metrics with probability metrics derived from two different algorithms for our case studies. In the first case study (see, § 4.1), we compare our metrics with SVM probabilities derived from Platt's scaling [17]; on the other hand, the second case study (see, § 4.2) uses the probabilities extracted from a random forest [3] model. This comparison shows the general unsuitability of the probability metric to detect concept drift. For example, the threshold obtained from the first quartile of the true positive p-value distribution is compared with that of the first quartile of the true positive probability distribution, and so forth.

The reasoning outlined above still holds when a given algorithm, adapted to represent the non-conformity measure, uses raw score as its decision-making criteria. For instance, the transformation of a raw score to a probability value is often achieved through a monotonic transformation (e.g., Platt's scaling, for SVM) that does not affect the p-value calculation. Such algorithms do not

provide a raw score for representing the likelihood of an alternative hypothesis (e.g., that the test object does not belong to any of the classes seen in the training). Moreover, a threshold built from a raw score lacks context and meaning; conversely, combining raw scores to compute p-values provides a clear statistical meaning, able of quantifying the observed drift in a normalized scale (from 0.0 to 1.0), even across different algorithms.

CE can also provide quality evaluation that allows switching the underlying ML-based process to a more computationally intensive one on classes with poor confidence [4]. Our work details the CE metrics used by Dash et al. [4] and extends it to identify concept drift.

4 Evaluation

To evaluate the effectiveness of Transcend, we introduce two case studies: a binary classification to detect malicious Android apps [2], and a multi-class classification to classify malicious Windows binaries in their respective family [1]. The case studies were chosen to be representative of common supervised learning settings (i.e., binary and multi-class classification), easy to reproduce[2], and of high quality[3].

Binary Classification Case Study. In [2], Arp et al. present a learning-based technique to detect malicious Android apps. The approach, dubbed Drebin, relies on statically extracting features, such as permissions, Intents, APIs, strings and IP addresses, from Android applications to fuel a linear SVM. Hold-out validation results (66-33% split in training-testing averaged over ten runs) reported TPR of 94% at 1% FPR. The Drebin dataset was collected from 2010 to 2012 and the authors released the feature set to foster research in the field.

To properly evaluate a drifting scenario in such settings, we also use Marvin [14], a dataset that includes benign and malicious Android apps collected from 2010 and 2014. The rationale is to include samples drawn from a timeline that overlaps with Drebin as well as newer samples that are likely to drift from it (duplicated samples were removed from the Marvin dataset to avoid biasing the results of the classifier). Table 1 provides details of the datasets.

Section 4.1 outlines this experiment in detail; however, without any loss of generality, we can say models are trained using the Drebin dataset and tested against the Marvin one. In addition, the non-conformity measure we instantiate CE with is the distance of testing objects from the SVM hyperplane, as further elaborated in § 4.1.1.

Multiclass Classification Case Study. Ahmadi et al. [1] present a learning-based technique to classify Windows malware in corresponding family of threats. The approach builds features out of machine instructions' opcodes of Windows binaries as provided by Microsoft and released through the Microsoft Malware Classification Challenge competition on Kaggle [11]—a well-known platform that hosts a wide range of machine learning-related challenges. Ahmadi et al. rely on eXtreme Gradient Boosting (XGBoost) [21] for classification. It is based on gradient boosting [18] and, like any other boosting technique, it combines different weak prediction models to create a stronger one. In particular, the authors use XGBoost with decision trees.

Table 2 provides details of the Microsoft Windows Malware Classification Challenge dataset. To properly evaluate a drifting scenario we omit the family Tracur from the training dataset, as further elaborated in § 4.2. In this setting, a reasonable conformity measure that captures the likelihood of a test object o to belong to a given family $l \in \mathcal{L}$ is represented by the probability p that o belongs to $l \in \mathcal{L}$, as provided by decision trees. We initialize conformal evaluator with $-p$ as non-conformity measure, because it captures the dissimilarities. Please note we do not interpret $-p$ as a probability anymore (probability ranges from 0 to 1), but rather as a (non-conformity) score CE builds p-values from (see § 2).

We would like to remark that these case studies are chosen because they are general enough to show how concept drift affects the performance of the models. This is not a critique against the work presented in [1, 2]. Rather, we show that even models that perform well in closed world settings (e.g., k-fold cross validation), eventually decay in the presence of non-stationary data (concept drift). Transcend identifies *when* this happens in operational settings, and provides indicators that allow to establish whether one should *trust* a classifier decision or not. In absence of retraining, which requires samples relabeling, the ideal net effect would then translate to having high performance on non-drifting objects (i.e., those that fit well into the trained model), and low performance on drifting ones.

In a nutshell, our experiments aim to answer the following research questions:

RQ1: *What insights do CE statistical metrics provide?* Intuitively, such metrics provide a quantifiable level of quality of the predictions of a classifier.

RQ2: *How can CE statistical metrics detect concept drift in binary and multiclass classification?* Intuitively, we can interpret quality metrics as thresholds: predictions of tested objects whose quality fall below such

[2]The work in [2] released feature sets and details on the learning algorithm, while we reached out to the authors of [1], which shared datasets and the learning algorithm's implementation with us.

[3]The work in [2] was published in a top-tier venue, while the work in [1] scored similar to the winner of the Kaggle's Microsoft Malware Classification Challenge [11].

thresholds should be marked as untrustworthy, as they drift away from the trained model (see §3.3).

We elaborate this further in § 4.1 and § 4.2 for binary and multiclass classification tasks, respectively.

4.1 Binary Classification Case Study

This section assesses the quality of the predictions of Drebin[4], the learning algorithm presented in [2]. We reimplemented Drebin and achieved results in line with those reported by Arp et al. in absence of concept drift (0.95 precision and 0.92 recall, and 0.99 precision and 0.99 recall for malicious and benign classes, respectively on hold out validation with 66-33% training-testing Drebin dataset split averaged on ten runs).

Figure 2a shows how CE's decision assessment supports such results. In particular, the average algorithm credibility and confidence for the correct choices are 0.5 and 0.9, respectively. This reflects a high prediction quality: correctly classified objects are very different (from a statistical perspective) to the other class (and an average p-value of 0.5 as algorithm credibility is expected due to mathematical properties of the conformal evaluator). Similar reasoning applies for incorrect predictions, which are affected by a poor statistical support (average algorithm credibility of 0.2).

Figure 2b shows CE's alpha assessment of Drebin. We plot this assessment as a boxplot to show details of the p-value distribution. The plot shows that the p-value distribution for the wrong predictions (i.e., second and third column) is concentrated in the lower part of the scale (less than 0.1), with few outliers; this means that, on average, the p-value of the class which is not the correct one, is much lower than the p-value of the correct predictions. Benign samples (third and fourth columns) seem more stable to data variation as the p-values for benign and malicious classes are well separated. Conversely, the p-value distribution of malicious samples (first and second columns) is skewed towards the bottom of the plot; this implies that the decision boundary is loosely defined, which may affect the classifier results in the presence of concept drift. A direct evaluation of the confusion matrix and associated metrics does not provide the ability to see decision boundaries nor predictions (statistical) quality.

[4]Unless otherwise stated, we refer to Drebin as both the learning algorithm and the dataset outlined in [2].

4.1.1 Detecting Concept Drift

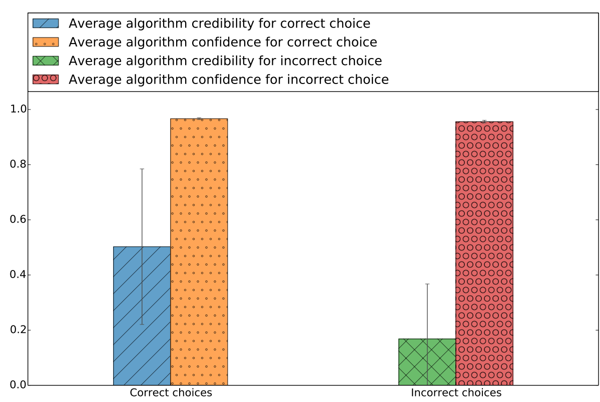
This section presents a number of experiments to show how Transcend identifies concept drift and correctly marks as untrustworthy the decisions the NCM-based classifier predicts erroneously.

We first show how the performance of the learning model introduced in [2] decays in the presence of concept drift. To this end, we train a model with the Drebin dataset [2] and we test it against 9,000 randomly selected malicious and benign Android apps (with equal split) drawn from the Marvin dataset [14]. The confusion matrix in Table 3a clearly shows how the model is affected by concept drift as it reports low precision and recall for the positive class representing malicious objects[5]. This is further outlined in Figure 3a, which shows how the p-value distribution of malicious objects is pushed towards low values (poor prediction quality).

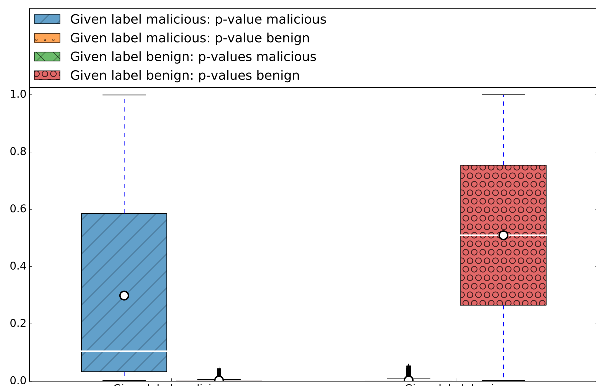
Table 3b shows how enforcing cut-off quality thresholds affect—by improving—the performance of the same learning algorithm. For this experiment, we divided the Drebin dataset in training and calibration sets with a 90-10% averaged over 10 rounds. This ensures that each object in the dataset has a p-value. We then asked Transcend to identify suitable quality thresholds (cfr § 3.3) with the aim to maximize the F1-score as derived by the calibration dataset, subject to a minimum F1-score of 0.99 and a minimum percentage of kept element of 0.76[6]. It is worth noting that such thresholds are derived from the calibration dataset but are enforced to detect concept drift on a testing dataset. Results show how flagging predictions of testing objects with p-values below the cut-off thresholds as unreliable improves precision and recall for the positive (malicious) class, from 0.61 to 0.89 and from 0.36 to 0.76, respectively.

[5]Drebin spans the years 2010–2012 while Marvin covers from 2010 to 2014. Most of the Drebin's features capture information (e.g., string and IP addresses) that is likely to change over time, affecting the ability of the classifier to identify non-stationary data.

[6]In [2], Arp et al. report a TPR of 94% at a FPR of 1%. Such metrics do not rule out the possibility of having 0.99 as F1-score; if that is a plausible constraint, Transcend's parametric framework will find a suitable solution.



(a) Decision assessment for the binary classification case study (Drebin [2]) with the original dataset. Correct predictions are supported by a high average algorithm credibility and confidence, while incorrect ones have a low and a high algorithm credibility and confidence, respectively. Overall, positive results supported by a strong statistical evidence.



(b) Alpha assessment for the binary classification case study (Drebin [2]) with the original dataset. Benign samples are well separated from malicious ones, especially when the assigned label is benign; this provides a clear statistical support that positively affect the quality of predictions.

Figure 2: Binary Classification Case Study (Drebin [2]): Decision assessment and Alpha assessment.

(a)

	Assigned label		
Sample	Benign	Malicious	**Recall**
Benign	4 498	2	1
Malicious	2 890	1 610	0.36
Precision	0.61	1	

(b)

	Assigned label		
Sample	Benign	Malicious	**Recall**
Benign	4 257	2	1
Malicious	504	1 610	0.76
Precision	0.89	1	

(c)

	Assigned label		
Sample	Benign	Malicious	**Recall**
Benign	4 413	87	0.98
Malicious	255	4 245	0.94
Precision	0.96	0.98	

Table 3: Binary classification case study ([2]). Table 3a: confusion matrix when the model is trained on Drebin and tested on Marvin. Table 3b: confusion matrix when the model is trained on Drebin and tested on Marvin with p-value-driven threshold filtering. Table 3c: retraining simulation with training samples of Drebin as well as the filtered out element of Marvin of Table 3b (2386 malicious samples and 241 benign) and testing samples coming from another batch of Marvin samples (4500 malicious and 4500 benign samples). The fate of the drifting objects is out of scope of this paper as that would require to solve a number of challenges that arise *once* concept drift is identified (e.g., randomly sampling untrustworthy samples according to their p-values, effort of relabeling depending on available resources, model retraining). We nonetheless report the result of a realistic scenario in which objects drifting from a given model, correctly identified by Transcend, represent important information to retrain the model and increase its performance (assuming a proper labeling as briefly sketched above).

	TPR of kept elements		FPR of kept elements		TPR of discarded elements		FPR of discarded elements		MALICIOUS kept elements		BENIGN kept elements	
	p-value	probability	p-value	probability	p-value	probability	p-value	probability	p-value	probability	p-value	probability
1st quartile	0.9045	0.6654	0.0007	0.0	0.0000	0.3176	0.0000	0.0013	0.3956	0.1156	0.6480	0.6673
Median	0.8737	0.8061	0.0000	0.0	0.3080	0.3300	0.0008	0.0008	0.0880	0.0584	0.4136	0.4304
Mean	0.8737	0.4352	0.0000	0.0	0.3080	0.3433	0.0008	0.0018	0.0880	0.1578	0.4136	0.7513
3rd quartile	0.8723	0.6327	0.0000	0.0	0.3411	0.3548	0.0005	0.0005	0.0313	0.0109	0.1573	0.1629

Table 4: Binary classification case study ([2]): examples of thresholds. From the results we can see that increasing the threshold will lead to keep only the sample where the algorithm is sure about. The number of discarded samples is very subjective to the severity of the shift in the dataset, together with the performance of those sample it is clear the advantage of the p-value metric compared to the probability one.

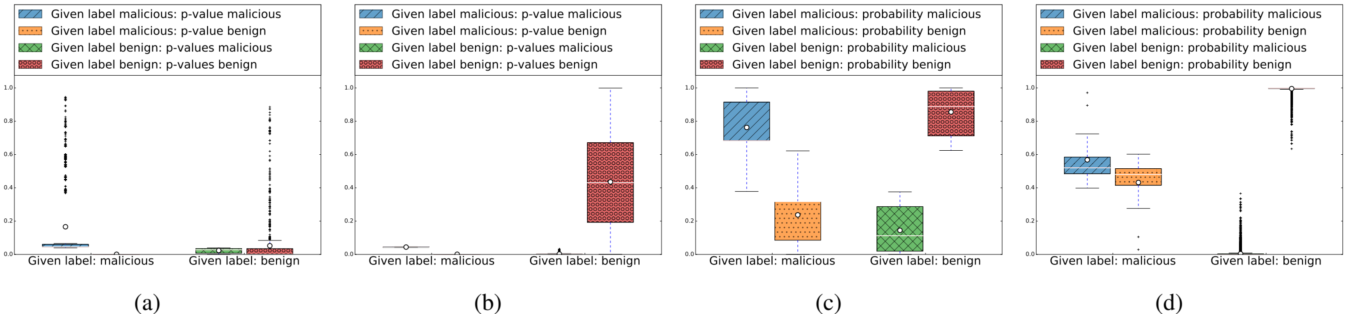


Figure 3: Binary Classification Case Study: p-value and probability distribution for true malicious and benign samples when the model is trained on Drebin dataset and tested on Marvin. Graph (a): p-value distribution for true malicious samples. Graph (b): p-value distribution of true benign samples. Graph (c): probability distribution of true malicious samples. Graph (d): probability distribution of true benign samples.

We would like to remark that drifting objects are still given a label as the output of a classifier prediction; Transcend flags such predictions as untrustworthy, de-facto limiting the mistakes the classifier would likely make in the presence of concept drift. It is clear that one needs to deal with such objects, eventually. Ideally, they would represent an additional dataset that, once labeled properly, would help retraining the classifier to predict similar objects. This opens a number of challenges that are out of the scope of this work; however, one could still rely on CE's metrics to prioritize objects that should be labeled (e.g., those with low p-values as they are the one the drift the most from the model). This might require to randomly sample drifting objects once enough data is available as well as understanding how much resources one can rely on for data labeling. It is important to note that Transcend plays a fundamental role in this pipeline: it identifies concept drift (and, thus, untrustworthy predictions), which gives the possibility of start reasoning on the open problems outlined above.

The previous paragraphs show the flexibility of the parametric framework we outlined in § 3.3, on an arbitrary yet meaningful example, where statistical cut-off thresholds are identified based on an objective function to optimize, subject to specific constraints. Such goals are however driven by business requirements (e.g., TPR vs FPR) and resource availability (e.g., malware analysts available vs number of likely drifting samples—either benign or malicious—for which we should not trust a classifier decision) thus providing numerical example might be challenging. To better outline the suitability of CE's statistical metrics (p-values) in detecting concept drift, we provide a full comparison between p-values and probabilities as produced by Platt's scaling applied to SVM. We summarize a similar argument (with probabilities derived from decision trees) for multiclass classification tasks in § 4.2.

Comparison with Probability. In the following, we compare the distributions of p-values, as derived from CE, and probabilities, as derived from Platt's scaling for SVM, in the context of [2] under the presence of concept drift (i.e., training on Drebin, testing on Marvin as outlined). The goal of this comparison is to understand which metric is better-suited to identify concept drift.

Figure 3a shows the alpha assessment of the classifications shown in Table 3a. The figure shows the distribution of p-values when the true label of the samples is malicious. Correct predictions (first and second columns), reports p-values (first column) that are are slightly higher than those corresponding to incorrect ones (second column), with a marginal yet well-marked separation as compared to the values they have for the incorrect class (third and fourth columns). Thus, when wrong predictions refer to the benign class, the p-values are low and show a poor fit to both classes. Regardless of the classifier outcome, the p-value for each sample is very low, a likely indication of concept drift.

Figure 3b depicts the distribution of p-values when true label of the samples is benign. Wrong predictions (first and second columns) report p-values representing benign (second column) and malicious (first column) classes to be low. Conversely, correct predictions (third and fourth columns) represent correct decisions (fourth column) and have high p-values, much higher compared to the p-values of the incorrect class (third column). This is unsurprising as benign samples have data distributions that do not drift with respect to malicious ones.

A similar reasoning can be followed for Figures 3c and 3d. Contrary to the distribution of p-values, probabilities are constrained to sum up to 1.0 across all the classes; what we observe is that probabilities tend to be skewed towards high values even when predictions are wrong. Intuitively, we expect to have poor quality on *all* the classes of predictions in the presence of a drifting

scenario: while probabilities tend to be skewed, CE's statistical metrics (p-values) seem better-suited at this task.

So far, we have seen how Transcend produces statistical thresholds to detect concept drift driven by predefined goals under specific constraints. In addition, the analysis of p-value and probability distributions highlighted how the former seem to be better-suited than probabilities to identify concept drift. In the following paragraphs, we show how CE's statistical metrics provide thresholds that *always outperform* probabilities in detecting concept drift. Figure 6 in Appendix 7 provides a thorough comparison. For simplicity, here, we focus the attention on the 1st and 3rd quartile, the median and the average of the distribution of p-values and probabilities as potential cut-off thresholds, as shown in Table 4.

Intuitively speaking, a successful technique not only would achieve high performances on correct predictions, but it would also report poor performances on drifting objects. This is evident from Table 4, where a cut-off threshold at the 1st quartile reports a high performance for the objects that fit the trained model (0.9045 TPR at 0.0007 FPR), and a poor performance for those drifting away (0 TPR and 0 FPR); this means that at this threshold, CE's statistical metrics suggest to consider as untrustworthy only objects the classifier would have predicted incorrectly. Conversely, probabilities also tend to be skewed when predictions are wrong, affecting the ability to rely on such metrics to correctly identify concept drift. Table 4 shows 0.6654 TPR and 0 FPR for objects whose quality fall above the 1st quartile of the probability distribution, and 0.3176 TPR and 0.0013 FPR for those who fall below; this means that probabilities marked as unreliable also make predictions that would have been classified correctly.

As we move up towards more conservative thresholds, CE's statistical metrics start discarding objects that would have been classified correctly. This is unsurprising as we have defined a threshold that is more selective of the desired quality. Regardless, at each point p-values still outperform probabilities (higher TPR and FPR of objects with a quality higher than the cut-off, and lower for those below the threshold). These results further show how relying on detecting concept drift is a challenging problem that cannot be easily addressed by relying on a prefixed 50% threshold [19].

Note that the number of untrustworthy predictions on the testing dataset is a function of the number of drifting objects. If the entire dataset drifts, we would expect Transcend to flag as untrustworthy all (or most of) the predicted objects that do not fit the trained model.

Adapting to Concept Drift. Once drifting objects are identified, the next step would require data relabeling and model retraining, as outlined throughout the paper. Table 3c shows the results of these steps, which take precision for benign samples to 0.89 and recall for malicious ones to 0.76. We would like to remark that this work focuses on the construction of statistical metrics to *identify* concept drift as outlined so far. While relabeling is out of scope for this work, it is clear that an approach that identifies drifting objects is well-suited to address such a challenge in the pipeline as resources can be focused on analyzing samples that do not fit in the trained model.

4.2 Multiclass Classification Case Study

In this section we evaluate the algorithm proposed by Ahmadi et al. [1] as a solution to Kaggle's Microsoft Malware Classification Challenge; the underlying rationale is similar to that outlined in the previous section, thus, we only report insightful information and takeaways. In this evaluation, we train the classifier with seven out of eight available malware families; Trucur, the excluded family, represents our drifting testing dataset.

The confusion matrix reports a perfect diagonal[7]; in this case, the decision assessment gives us no additional information because we cannot analyze the distribution of p-values of incorrect choices. From a quality perspective, drawing upon the alpha assessment of Figure 4, two families, Vundo and Ramnit, have significant differences. The Ramnit family has p-values that are much higher than those of the interfering families. However, for Vundo the p-values of interfering families are closer to the correct ones. These details can be only be observed through the alpha assessment, suggesting that the identification of the Ramnit samples would be more robust when the data distribution changes.

Family Discovery. Below, we show how we identify a new family based on CE's statistical metrics.

The testing samples coming from Tracur are classified as follows: 5 as Lollipop, 6 as Kelihos_ver3, 358 as Vundo and 140 as Kelihos_ver1. Looking at the distribution of probabilities and p-values it is easy to relate to the case of binary classification, i.e., for each family there is only one class with high p-values corresponding to the class of the true label. For the test objects of Tracur, we observe that the p-values for all the classes are close to 0. This is a clear pattern which shows that the samples are coming from an unknown distribution. In a scenario changing gradually, we will observe an initial concept drift (as shown in the binary classification case study in § 4.1.1), characterized by a gradual decrease of the p-values for all the classes, which ends up in a situation where we have p-values very close to 0 as observed here. These results clearly show that even in multiclass classification settings, CE provides metrics that are better-suited

[7] We reached out to the authors who provided us with the dataset and the implementation of the learning algorithm to replicate the results presented in [1].

to identify concept drift than probabilities[8]. The comparison between p-values and probabilities is reported in Figures 7 to 10 in Appendix 7 and follow a reasoning similar to that of the binary classification case study.

5 Discussion

Security community has grappled with the challenge of concept drift for some time now [12, 23, 25]. The problem commonly manifests itself in most malware detection/classification algorithm tasks and models perform poorly as they become dated. Literature [12, 15, 16] recommends retraining the model periodically (see § 6) to get around this. However, retraining periodicity is loosely defined and is an expensive process that leads to sub-optimal results. Consequently, there are periods where the model performance cannot be trusted. The problem is further exacerbated as concept drift is hard to identify without manual intervention. If the model is retrained too frequently, there will be little novelty in information obtained through retraining to enrich the model. Regardless of the periodicity, the retraining process requires manual labeling of all the processed objects. Transcend selectively identifies the drifted objects with statistical significance[9], thus is able to restrict the manual labeling process to the objects that are substantially different than the ones in the trained model (see §3.3 and §4.1.1).

[8] The algorithm in [1] relies on probabilities (decision trees).

[9] The p-value for an object o with label l is the statistical support of the null hypothesis H_0, i.e., that o belongs to l. Transcend finds the significance level (the per-class threshold) to reject H_0 for the alternative hypothesis H_a, i.e., that o does not belong l (p-values for wrong hypotheses are smaller than those for correct ones, e.g., Figure 2b).

Adversarial ML and Model Fortification. Our work aims to detect concept drift as it occurs in an existing model. Concept drift can occur due to various reasons. Common causes being malware polymorphism or evasion but adversarial data manipulation (adversarial drift) can also be a reason. Approaches have been proposed to fortify models against drift [12, 15, 23], however such solutions deal with specific domains and do not provide a generalized solution. Transcend is agnostic to the machine learning algorithm under consideration. This let us leverage the strength of the algorithm while detecting concept drift. Therefore, if the algorithm is more resilient to concept drift, drift will be detected later on in time. If it is less resilient, drift will be detected as sooner.

Comparison with Probability. Probabilities have been known to work well in some scenarios but as demonstrated in § 4.1.1 and § 4.2 they are not as effective as compared to p-values which are more versatile, especially in the presence of concept drift. When probabilities are reported to be low it is difficult to understand if the sample does not belong to any class or if the sample is actually just *difficult* to classify while still belonging to one of the known classes. In other words, the p-value metric offers a natural *null option* when the p-values calculated for all the classes are low. Instead, as shown in the case of SVM (see, § 4.1.1), the probability metric is bounded to one of the options in the model.

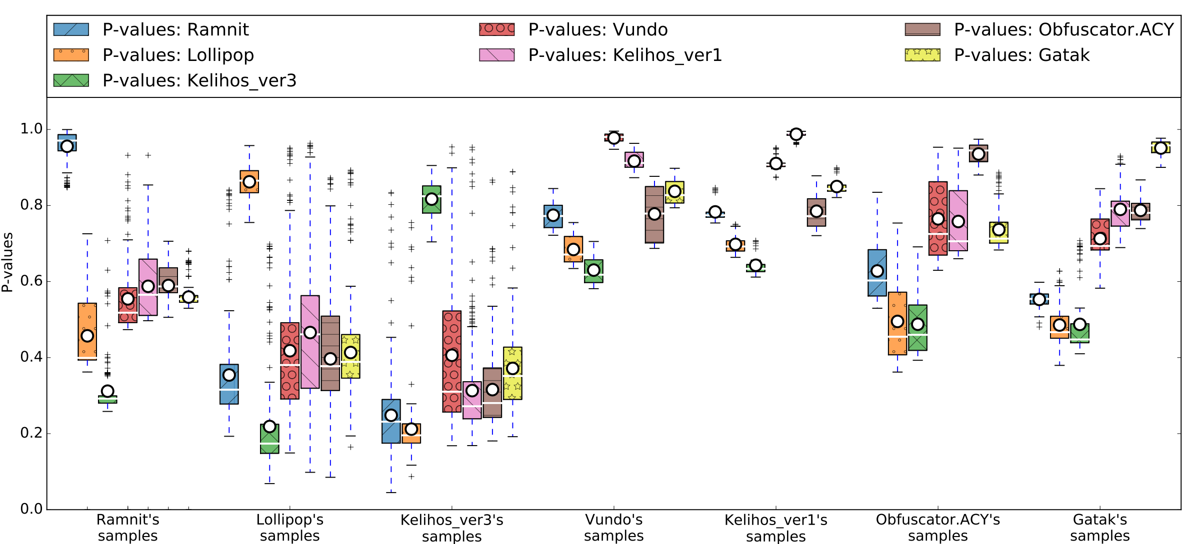

Figure 4: Multiclass Classification Case Study: Alpha assessment for the Microsoft classification challenge showing the quality of the decision taken by the algorithm. Although, perfect results are observed on the confusion matrix , the quality of those results vary a lot across different families.

It does not matter if the probabilities are well calibrated or not, the limitation is inherent to the metric. As discussed, the work by Rieck et al. [19] faces similar challenges when choosing the probability threshold. Moreover, the p-value metric provided by our framework, can be calculated from algorithms that do not provide probabilities, e.g., custom algorithms like [22], thus extending the range of algorithms that can benefit from a statistical evaluation.

Performance. Calculation of p-values is a computationally intensive process—for each sample z in a class $c \in C$, the calculation of a p-value requires computation of a non-conformity measure for every element in the dataset. This can be further exacerbated by non-conformity measures that rely on distances that are complex to compute. The computational complexity in relation to the number of the times that the non-conformity measure needs to be computed is $O(C \cdot N^2)$, where N represents the total number of samples and C represent the number of classes. Calculations can be sped up by computing a whole set of non-conformity scores in one single algorithm run. For example, SVM used in Drebin [2] can directly supply the total non-conformity scores for the calculation of one p-value in only one run of the algorithm, thus reducing the complexity to $O(C \cdot N)$. Further optimizations can be made for algorithms that treat each class separately; in such a scenario we can run the algorithm just for the class under analysis.

6 Related Work

Solutions to detect concept drift, specific to security domains, have been proposed [12, 15, 23], in contrast our framework provides a generic solution which is algorithm agnostic. On the other hand, solutions [6, 7] developed by the ML community have constrains that are not suitable for security applications (e.g., retrospective detection of concept drift when the classification decision has already been made).

Thomas et al. [23] present *Monarch* a real-time system that crawls URLs as they are submitted to web services and determines whether the URLs direct to spam. The system uses machine-learning to classify URLs as malicious or benign. The authors suggest training the model continuously to keep classification error low as the nature of malicious URLs keeps evolving. Kantchelian et al. [12] propose fusing human operators with the underlying machine-learning based security system to address concept drift in adversarial scenarios. Maggi et al. [15] present a machine-learning based system to classify malicious web applications. They use techniques specific to web application to detect concept drift and thus retrain their model to reduce false positives. Mariconti et al. [16] show how models decay over time and propose ways to resist longer. Our model unifies these techniques as it generalizes to both the area of application and machine-learning algorithm used. The presented model can not only accurately predict when to retrain a model but also provides a quality estimate of the decisions made. These results can reduce human intervention and make it more meaningful thus decreasing the cost of operation. Transcend can be plugged on top of any such approach to provide a clear separation between non-drifting and drifting objects.

Deo et al. [5] propose using Venn-Abers predictors for assessing the quality of binary classification tasks and identifying concept drift. The Venn-Abers predictors offer automatically well calibrated and probabilistic guidance to detect change in distribution of underlying samples. Although useful, the approach has limitations and cannot draw concrete conclusions on sample clusters which are outliers. Also, Venn-Abers outputs multiple probabilities of which one is perfectly calibrated but it is not possible to know which. Our approach provides a simple mechanism to compare predictions through p-values and does not suffer from the discussed shortcomings. CE also works on multi-class prediction tasks, while this is not currently supported by Venn-Abers predictors.

Other works try to detect change point detection when the underlying distribution of data samples changes significantly, e.g., in case of evolving malware which is observed as a disruption in ex-changeability [25]. Martingales have often been used to detect drift of multidimensional data sequences using ex-changeability [8, 9]. Prior works [6, 7] use conformal prediction to detect deviation of the data sequence from independent and identically distributed (iid) assumption which could be caused by concept drift. The drift is measured by creating a martingale function. If the data is not iid, then the conformal predictor outputs an invalid result. Some p-values assigned to the true hypotheses about data labels are too small (or have another deviation from uniformity), and this leads to high values of the martingale. However, this martingale approach does not use p-values assigned to *wrong* hypotheses, which is another cause of wrong classification, e.g., malicious samples being classified as benign. We consider this information to be important because in the case of malware evolution, malicious samples are often specially designed to be indistinguishable from benign samples, therefore they tend to get high p-values assigned to wrong hypotheses. Additionally, the martingale approach uses true labels to study the drift of data without making any predictions, in contrast our approach does not have access to true labels and analyses the predictions made by a given model.

Comparison with Conformal Predictor. Although

conformal evaluator is built on top of conformal predictor (CP), it does not share the same weaknesses as that of other solutions based on it [6, 7]. Fern and Dietterich[10] also show that CP is not suited for anomaly detection as it outputs a set of labels and hence needs to be modified to predict quality of predictions. We further highlight the differences between CP and CE that makes CE better-suited to the concept drift detection task.

Conformal Predictor [24] (CP) is a machine learning classification algorithm. It relies on a non-conformity measure (NCM) to compute p-values in a way similar to CE. For each classification task, CP builds on such p-values to introduce credibility—the class, in a classification problem, with the highest p-value and confidence—defined as one minus the class with the second highest p-value (these metrics are different from CE metrics, see § 2.4). The CP algorithm then outputs either a single class prediction with the identified credibility and confidence, or, given a fixed confidence level $1-\varepsilon$ (where ε represents the significance level), a prediction set that includes classes that are above it. This set is proven to cover the true class with probability not lower than $1-\varepsilon$.

CE dissects CP metrics and to extract its p-values calculation. The p-values are used together with the output labels provided by the algorithm under evaluation, to build CE metrics. CP ignores these labels as it tries to predict them. Conversely, CE uses this information to provide quality metrics to assess the quality of the encapsulated algorithm. This change is of paramount importance to derive the thresholds (computed by Transcend) used to accept or reject a prediction.

The *posterior* use of the labels is a key feature that enables CE to detect concept drift. On the contrary, CP is designed as a predictive tool making only use of prior information. Since labels are important pieces of information, CE uses them to build its metrics and assessments (see, § 2.4 and § 3). The labels used by CE are the ones of the training samples and not the labels of the testing samples that are unavailable at the time of classification.

7 Conclusions

We presented Transcend—a fully tunable tool for statistically assessing the performance of a classifier and filtering out unreliable classification decisions. At the heart of Transcend, CE's statistical confidence provides evidence for better understanding model generalization and class separation; for instance, CE has been successfully adopted to selectively invoke computationally expensive learning-based algorithms when predictions choose classes with low confidence [4], trading off performance for accuracy. Our work details the CE metrics used in [4] and extend it to facilitate the identification of concept drift, thus bridging a fundamental research gap when dealing with evolving malicious software.

We present two case studies as representative use cases of Transcend. Our approach provides sound results for both binary and multi-class classification scenarios on different datasets and algorithms using proper training, calibration and validation, and testing datasets. The diversity of case studies presents compelling evidence in favor of our framework being generalizable.

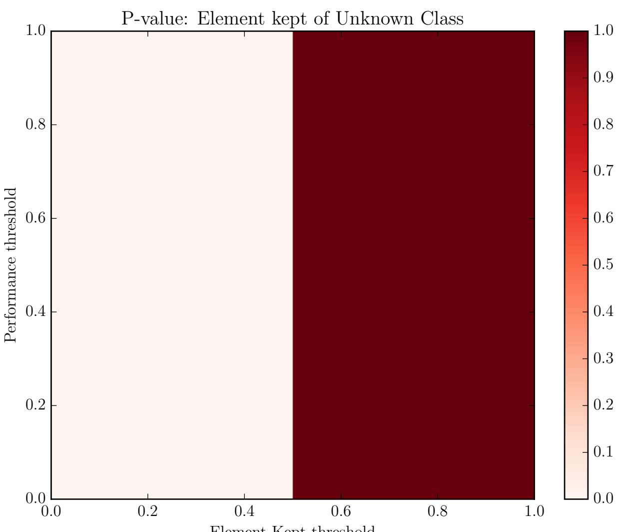

Figure 5: Multiclass Classification Case Study: Element kept during the test of the new class. The test elements belong to a new class so every samples kept will be miss-classified. The net separation between good and bed performance comes from the perfect classification of training samples used to derived the thresholds.

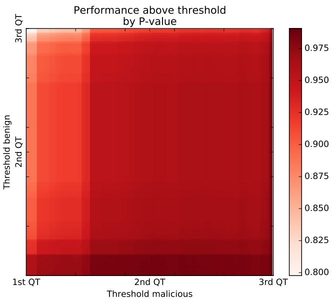
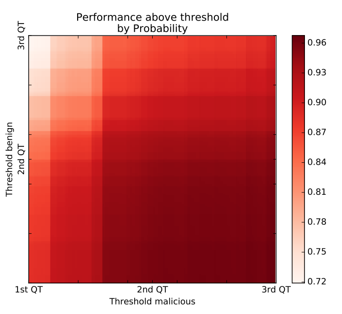
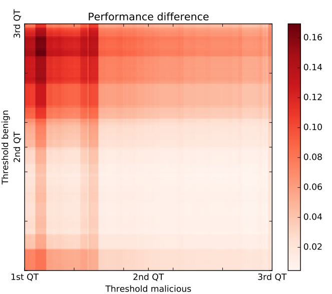


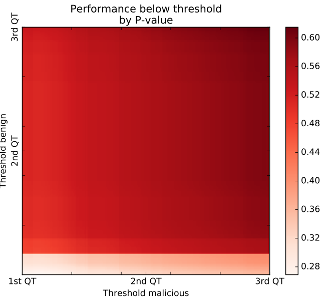
(a) Performance of p-value driven threshold for element above the threshold.



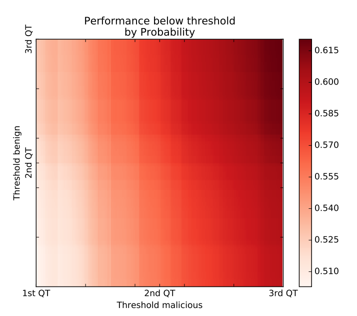
(b) Performance of probability driven threshold for element above the threshold.



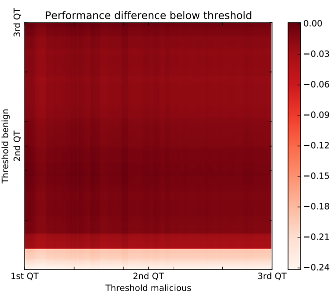
(c) Performance difference between p-value and probability for element above the threshold.



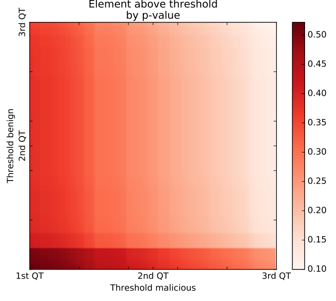
(d) Performance of p-value driven threshold for element below the threshold.



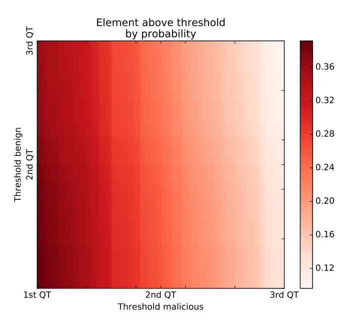
(e) Performance of probability driven threshold for element below the threshold.



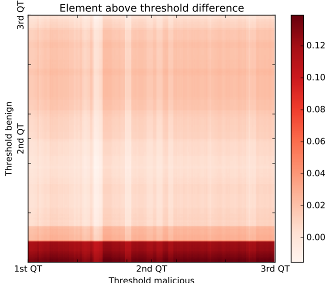
(f) Performance difference between p-value and probability for element below the threshold.



(g) Number of element above the p-value threshold.



(h) Number of element above the probability threshold.



(i) Difference between the number of element above the threshold between p-value and probability.

Figure 6: Binary Classification Case Study [2]: complete comparison between p-value and probability metrics. Across all the threshold range we can see that the p-value based thresholding is providing better performance than the probability one, discarding the samples that would have been incorrectly classified if kept.

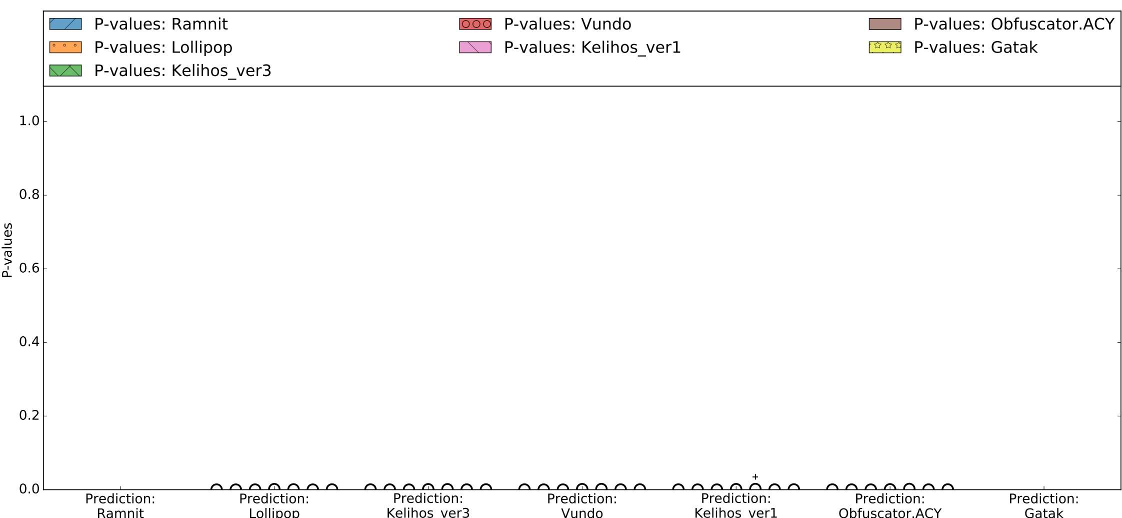


Figure 7: Multiclass Classification Case Study [1]: P-value distribution for samples of Tracur family omitted from the training dataset; as expected, the values are all close to zero.

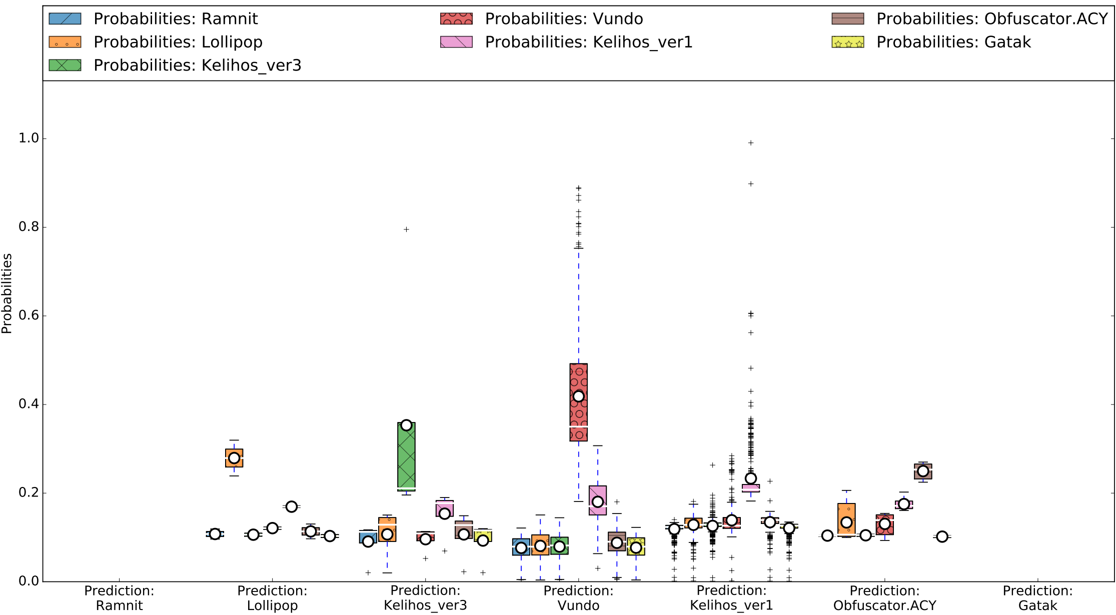

Figure 8: Multiclass Classification Case Study [1]: probability distribution for samples of Tracur family omitted from the training dataset. Probabilities are higher then zero and not equally distributed across all the families, making the classification difficult. It is worth noting some probabilities are skewed towards large values (i.e., greater than 0.5) further hindering a correct classification result.

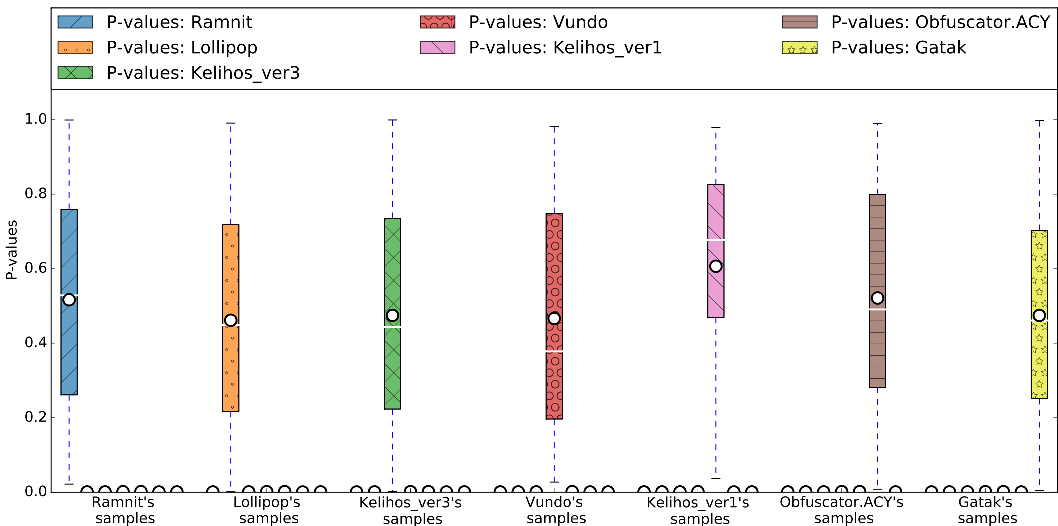

Figure 9: Multiclass Classification Case Study [1]: a new family is discovered by relying on the p-value distribution for known malware families. The figure shows the amount of conformity each sample has with its own family; for each sample, there is only one family with high p-value.

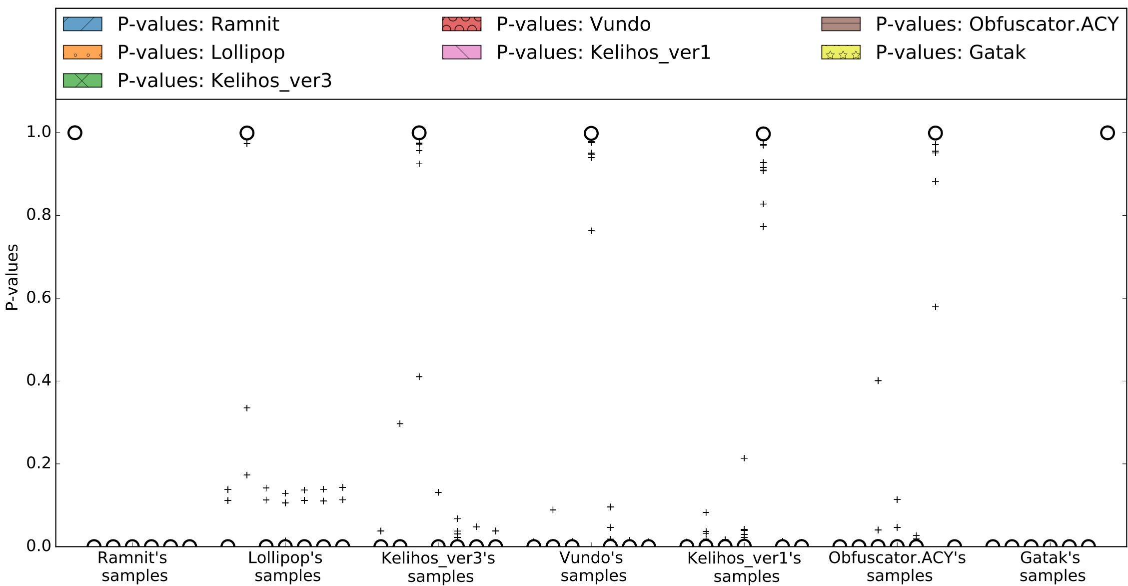

Figure 10: Multiclass Classification Case Study [1]: probability distribution for samples of families included in the training dataset. High probabilities support the algorithm classification choice.

Syntia: Synthesizing the Semantics of Obfuscated Code

Tim Blazytko, Moritz Contag, Cornelius Aschermann, Thorsten Holz

Ruhr-Universität Bochum, Germany
{firstname.lastname}@rub.de

Abstract

Current state-of-the-art deobfuscation approaches operate on instruction traces and use a mixed approach of symbolic execution and taint analysis; two techniques that require precise analysis of the underlying code. However, recent research has shown that both techniques can easily be thwarted by specific transformations.

As program synthesis can synthesize code of arbitrary code complexity, it is only limited by the complexity of the underlying code's *semantic*. In our work, we propose a generic approach for automated code deobfuscation using program synthesis guided by Monte Carlo Tree Search (MCTS). Specifically, our prototype implementation, Syntia, simplifies execution traces by dividing them into distinct trace windows whose semantics are then "learned" by the synthesis. To demonstrate the practical feasibility of our approach, we automatically learn the semantics of 489 out of 500 random expressions obfuscated via Mixed Boolean-Arithmetic. Furthermore, we synthesize the semantics of arithmetic instruction handlers in two state-of-the art commercial virtualization-based obfuscators (VMProtect and Themida) with a success rate of more than 94%. Finally, to substantiate our claim that the approach is generic and applicable to different use cases, we show that Syntia can also automatically learn the semantics of ROP gadgets.

1 Introduction

Code obfuscation describes the process of applying an obfuscating transformation to an input program to obtain an obfuscated copy of the program. Said copy should be more complex than the input program such that an analyst cannot easily reason about it. An obfuscating transformation is further desired to be *semantics-preserving*, i. e., it must not change observable program behavior [12]. Code obfuscation can be leveraged in many application domains, for example in software protection solutions to prevent illegal copies, or in malicious software to impede the analysis process. In practice, different kinds of obfuscation techniques are used to hinder the analysis process. Most notably, industry-grade obfuscation solutions are typically based on *Virtual Machine (VM)*-based transformations [38, 55, 57, 58], which are considered one of the strongest obfuscating transformations available [2]. While these protections are not perfect and in fact are broken regularly, attacking them is still a time-consuming task that requires highly specific domain knowledge of the individual Virtual Machine implementation. Consequently, for example, this gives game publishers a head-start in which enough revenue can be generated to stay profitable. On the other hand, obfuscated malware stays under the radar for a longer time, until concrete analysis results can be used to effectively defend against it.

To deal with this problem, prior research has explored many different approaches to enable deobfuscation of obfuscated code. For example, Rolles proposes static analysis to aid in deobfuscation of VM-based obfuscation schemes [44]. However, it incorporates specific implementation details an attacker has to know a priori. Further, static analysis of obfuscated code is notoriously known to be intractable in the general case [12]. Hence, recent deobfuscation proposals have shifted more towards dynamic analysis [13, 61, 62]. Commonly, they produce an execution trace and use techniques such as (dynamic) taint analysis or symbolic execution to distinguish input-dependent instructions. Based on their results, the program code can be reduced to only include relevant, input-dependent instructions. This effectively strips the obfuscation layer. Even though such deobfuscation approaches sound promising, recent work proposes several ways to effectively thwart underlying techniques, such as symbolic execution [2]. For this reason, it suggests itself to explore distinct techniques that may be leveraged for code deobfuscation.

In this paper, we propose an approach orthogonal to prior work on approximating the underlying semantics

of obfuscated code. Instead of manually analyzing the instruction handlers used in virtualization-based (VM) obfuscation schemes in a complex and tedious manner [44] or learning merely the bytecode decoding (not the semantics) of these instruction handlers [53], we aim at learning the *semantics* of VM-based instruction handlers in an automated way. Furthermore, our goal is to develop a generic framework that can deal with different use cases. Naturally, this includes constructs close to obfuscation, such as Mixed Boolean-Arithmetic (MBA), different kinds of VM-based obfuscation schemes, or even analysis of code chunks (so called *gadgets*) used in Return-oriented Programming (ROP) exploits.

To this extend, we explore how *program synthesis* can be leveraged to tackle this problem. Broadly speaking, program synthesis describes the task of automatically constructing programs for a given specification. While there exists a variety of program synthesis approaches [21], we focus on SMT-based and stochastic program synthesis in the following, given its proven applicability to problem domains close to trace simplification and deobfuscation. SMT-based program synthesis constructs a loop-free program based on first-order logic constraints whose satisfiability is checked by an SMT solver. For *component-based* synthesis, components are described that build the instruction set of a synthesized program; for instance, components may be bitwise addition or arithmetic shifts. The characteristics of a well-formed program such as the interconnectivity of components are defined and the semantics of the program are described as a logical formula. Then, an SMT solver returns a permutation of the components that forms a well-encoded program following the previously specified intent [22, 24], if it is satisfiable, i. e., such a permutation *does* exist.

Instead of relying on a logical specification of program intent, *oracle-guided* program synthesis uses an input-output (I/O) oracle. Given the outputs of an I/O oracle for arbitrary program inputs, program synthesis learns the oracle's semantics based on a finite set of I/O samples. The oracle is iteratively queried with *distinguishing* inputs that are provided by an SMT solver. Locating distinguishing inputs is the most expensive task in this approach. The resulting synthesized program has the same input-output behavior as the I/O oracle [24]. Contrary to SMT-based approaches that only construct semantically correct programs, stochastic synthesis *approximates* program equivalence and thus remains faster. In addition, it can also find partial correct programs. Program synthesis is modeled as heuristic optimization problem, where the search is guided by a cost function. It determines, for instance, output similarity of the synthesized expression and the I/O oracle for same inputs [50].

As program synthesis is indifferent to code complexity, it can synthesize arbitrarily obfuscated code and is only limited by the underlying code's *semantic* complexity. We demonstrate that a stochastic program synthesis algorithm based on Monte Carlo Tree Search (MCTS) achieves this in a scalable manner. To show feasibility of our approach, we automatically learned the semantics of 489 out of 500 MBA-obfuscated random expressions. Furthermore, we synthesize the semantics of arithmetic instruction handlers in two state-of-the art commercial virtualization-based obfuscators with a success rate of more than 94%. Finally, to show applicability to areas more focused on security aspects, we further automatically learn the semantics of ROP gadgets.

Contributions In summary, we make the following contributions in this paper:

- We introduce a generic approach for trace simplification based on program synthesis to obtain the semantics of different kinds of obfuscated code. We demonstrate how Monte Carlo Tree Search (MCTS) can be utilized in program synthesis to achieve a scalable and generic approach.
- We implement a prototype of our method in a tool called Syntia. Based on I/O samples from assembly code as input, Syntia can apply MCTS-based program synthesis to compute a simplified expression that represents a deobfuscated version of the input.
- We demonstrate that Syntia can be applied in several different application domains such as simplifying MBA expressions by learning their semantics, learning the semantics of arithmetic VM instruction handlers and synthesizing the semantics of ROP gadgets.

2 Technical Background

Before presenting our approach to utilize program synthesis for recovering the semantics of obfuscated code, we first review several concepts and techniques we use throughout the rest of the paper.

2.1 Obfuscation

In the following, we discuss several techniques that qualify as an obfuscating transformation, namely virtualization-based obfuscation, Return-oriented Programming and Mixed Boolean-Arithmetic.

2.1.1 Virtualization-based Obfuscation

Contemporary software protection solutions such as VMProtect [58], Themida [38], and major game copy protections such as SecuROM base their security on the concept

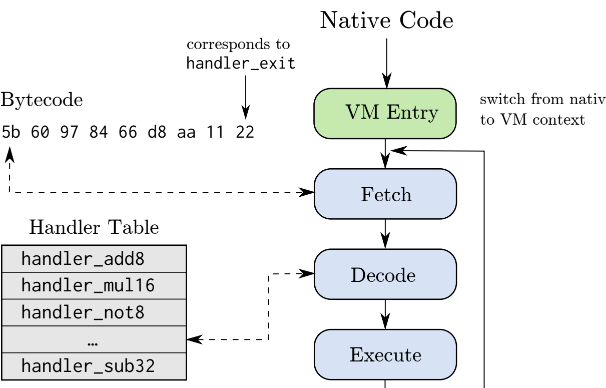

Figure 1: The Fetch–Decode–Execute cycle of a Virtual Machine. Native code calls into the VM, upon which startup code is executed (VM entry). It performs the context switch from native to VM context. Then, the next instruction is fetched from the bytecode stream, mapped to the corresponding handler using the handler table (decoding) and, finally, the handler is executed. The process repeats for subsequent VM instructions in the bytecode until the exit handler is executed, which returns back to native code.

of *Virtual Machine-based* obfuscation (also known as *virtualization-based* obfuscation [44]).

Similar to system-level Virtual Machines (VMs) that emulate a whole system platform, process-level VMs emulate a foreign instruction set architecture (ISA). The core idea is to translate parts of a program, e. g., a function f containing intellectual property, from its native architecture—say, Intel x86—into a custom VM-ISA. The obfuscator then embeds both the *bytecode* of the virtualized function (its instructions encoded for the VM-ISA) along with an *interpreter* for the new architecture into the target binary whilst removing the function's original, native code. Every call to f is then replaced with an invocation of the interpreter. This effectively thwarts any naive reverse engineering tool operating on the native instruction set and forces an adversary to analyze the interpreter and re-translate the interpreted bytecode back into native instructions. Commonly, the interpreter is heavily obfuscated itself. As VM-ISAs can be arbitrarily complex and generated uniquely upon protection time, this process is highly time-consuming [44].

Components. The *(VM) context* holds internal variables of the VM-ISA such as general-purpose registers or the virtual instruction pointer. It is initialized by sequence called *VM entry*, which handles the context switch from native code to bytecode.

After initialization, the *VM dispatcher* fetches and decodes the next instruction and invokes the corresponding *handler* function by looking it up in a global *handler table* (depicted in Figure 1). The latter maps indices, obtained from the instruction's bytecode in the decoding step, to handlers addresses. In its most simple implementation, all handler functions return to a central dispatching loop which then dispatches the next handler. Eventually, execution flow reaches a designated handler, *VM exit*, which performs the context switch back to the native processor context and transfers control back to native code.

Custom ISA. The design of the target VM-ISA is entirely up to the VM designer. Still, to maximize the amount of handlers an analyst has to reverse engineer, VMs often opt for reduced complexity for the individual handlers, akin to the RISC design principle. To exemplify, consider the following Intel x86 code:

```
1 mov eax, dword ptr [0x401000 + ebx * 4]
2 pop dword ptr [eax]
```

This might get translated into VM-ISA as follows:

```
1  vm_mov   T0, vm_context.real_ebx
2  vm_mov   T1, 4
3  vm_mul   T2, T0, T1
4  vm_mov   T3, 0x401000
5  vm_add   T4, T2, T3
6  vm_load  T5, dword(T4)
7  vm_mov   vm_context.real_eax, T5
8  vm_mov   T6, T5
9  vm_mov   T7, vm_context.real_esp
10 vm_add   T8, T7, T1
11 vm_mov   vm_context.real_esp, T8
12 vm_load  T9, dword(T7)
13 vm_store dword(T6), T9
```

It favors many small, simple handlers over fewer more complicated ones.

Bytecode Blinding. In order to prevent global analysis of instructions, the bytecode *bc* of each VM instruction is blinded based on its instruction type, i. e., its corresponding handler h, at protection time. Likewise, each handler *unblinds* the bytecode before decoding its operands: $(bc, vm_key) \leftarrow \mathsf{unblind}_h(blinded_bc, vm_key)$.

The routine is parameterized for each handler h and updates a global key register in the VM context. Consequently, instruction decoding can be *flow-sensitive*: An adversary is unable to patch a single VM instruction without re-blinding all subsequent instructions. This, in turn, requires her to extract the unblinding routines from every handler involved. The individual unblinding routines commonly consist of a combination of arithmetic and logical operations.

Handler Duplication. In order to easily increase analysis complexity, common VMs *duplicate* handlers such

that the same virtual instruction can be dispatched by multiple handlers. In presence of bytecode blinding, these handlers' semantics only differ in the way they unblind the bytecode, but perform the same operation on the VM context.

Architectures. In his paper about interpretation techniques, Klint denotes the aforementioned concept using a central decoding loop as the "classical interpretation method" [28]. An alternative is proposed by Bell with *Threaded Code* (TC) [4]: He suggests inlining the dispatcher routine into the individual handler functions such that handlers execute in a chained manner, instead of returning to a central dispatcher. Nevertheless, the dispatcher still indexes a global handler table.

In Klint's paper, however, he describes an extension of TC, *Direct Threaded Code* (DTC). As in the TC approach, the dispatcher is appended to each handler. The handler table, though, is inlined into the *bytecode* of the instruction. Each instruction now directly specifies the address of its corresponding handler. This way, in presence of bytecode blinding, not all handler addresses are exposed immediately, but only those used on a certain path in the bytecode.

Attacks. Several academic works have been published that propose novel attacks on virtualization-based obfuscators [13, 44]. Section 6.3 discusses and classifies them. In addition, it draws a comparison to our approach.

2.1.2 Return-oriented Programming

In *Return-oriented Programming* (ROP) [30, 52], shellcode is expressed as a so-called ROP chain, a list of references to *gadgets* and parameters for those. In the preliminary step of an attack, the adversary makes `esp` point to the start of the chain, effectively triggering the chain upon function return. Gadgets are small, general instruction sequences ending on a `ret` instruction; other flavors propose equivalent instructions. Concrete values are taken from the ROP chain on the stack. As an example, consider the gadget `pop eax; ret`: It takes the value on top of the stack, places it in `eax` and, using the `ret` instruction, dispatches the next gadget in the chain. By placing an arbitrary immediate value `imm32` next to this gadget's address in the chain, an attacker effectively encodes the instruction `mov eax, imm32` in her ROP shellcode. Depending on the gadget space available to the attacker, this technique allows for arbitrary computations [39, 51].

Automated analysis of ROP exploits is a desirable goal. However, its unique structure poses various challenges compared to traditional shellcode detection. In their paper, Graziano et al. outline them and propose an analysis framework for code-reuse attacks [19]. Amongst others, they mention challenges such as verbosity of the gadgets, stack-based chaining, lack of immediates, and the distinction of function calls and regular control flow. Further, they stress how an accurate emulation of gadgets is important for addressing these challenges. Considering the aforementioned challenges, at its core, Return-oriented Programming can be seen as an albeit weaker flavor of obfuscated code. In particular, the chained invocation of gadgets is reminiscent of handlers in VM-based obfuscation schemes following the threaded code principle.

In addition to its application to exploitation, ROP has seen other fields of applications such as rootkit development [59], software watermarking [34], steganography [33], and code integrity verification [1], which reinforces the importance of automatic ROP chain analysis.

2.1.3 Mixed Boolean-Arithmetic

Zhou et al. propose transformations over Boolean-arithmetic algebras to hide constants by turning them into more complex, but semantically equivalent expressions, so called MBA expressions [14, 63]. In Section 6.2, we provide details on their proposal of MBA expressions and show how our approach is still able to simplify them.

2.2 Trace Simplification

Due to the complexity of static analysis of obfuscated code, many deobfuscation approaches proposed recently make use of dynamic analysis [13, 19, 19, 53, 62]. Notably, they operate on *execution traces* that record instruction addresses and accompanying metadata, e. g., register content, along a concrete execution path of a program. Subsequently, trace simplification is performed to strip the obfuscation layer and simplify the underlying code. Depending on the approach, multiple traces are used for simplification or one single trace is reduced independently.

Coogan et al. [13] propose *value-based dependence* analysis of a trace in order to track the flow of values into system calls using an equational reasoning system. This allows them to reduce the trace to those instructions *relevant* to the previously mentioned value flow.

Graziano et al. [19] mainly apply standard compiler transformations such as dead code elimination or arithmetic simplifications to reduce the trace.

Yadegari et al. [62] use bit-level taint analysis to identify instructions relevant to the computation of outputs. For subsequent simplification, they introduce the notion of *quasi-invariant* locations with respect to an execution. These are locations that hold the same value at every use in the trace and can be considered constants when performing constant propagation. Similarly, they use several other compiler optimizations and adapt them to make use

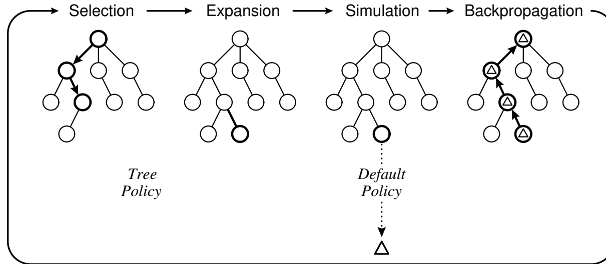

Figure 2: Illustration of a single MCTS round (taken from Browne et al. [5]).

of information about *quasi-invariance* to prevent oversimplification.

2.3 Monte Carlo Tree Search

Monte Carlo Tree Search (MCTS) is a stochastic, best-first tree search algorithm that directs the search towards an optimal decision, without requiring much domain knowledge. The algorithm builds a search tree through reinforcement learning by performing random simulations that estimate the quality of a node [5]. Hence, the tree grows asymmetrically. MCTS has had significant impact in artificial intelligence for computer games [16, 35, 49, 56], especially in the context of Computer Go [17, 54].

In an MCTS tree, each node represents a game state; a directed link from a parent node to its child node represents a move in the game's domain. The core algorithm iteratively builds the decision tree in four main steps that are also illustrated in Figure 2: (1) The *selection* step starts at the root node and successively selects the most-promising child node, until an *expandable* leaf (i. e., a non-terminal node that has unvisited children) is reached. (2) Following, one or more unvisited child nodes are added to the tree in the *expansion* step. (3) In the *simulation* step, node rewards are determined for the new nodes through random playouts. For this, consecutive game states are randomly derived until a terminal state (i. e., the end of the game) is reached; the game's outcome is represented by a reward. (4) Finally, the node rewards are propagated backwards through the selected nodes to the root in the *backpropagation* step. The algorithm terminates if either a specified time/iteration limit is reached or an optimal solution is found [5, 8].

Selecting the most-promising child node can be treated as a so called *multi-armed bandit problem*, in which a gambler tries to maximize the sum of rewards by choosing one out of many slot machines with an unknown probability distribution. Applied to MCTS, the *Upper Confidence Bound for Trees* (UCT) [5, 17, 29] provides a good balance between exploration and exploitation. It is obtained by

$$\overline{X}_j + C\sqrt{\frac{\ln n}{n_j}}, \tag{1}$$

where $\overline{X}_j$ represents the average reward of the child node j, n the current node's number of visits, n_j the visits of the child node and C the exploration constant. The average reward is referred to as *exploitation parameter*: if C is decreased, the search is directed towards nodes with a higher reward. Increasing C, instead, leads to an intensified exploration of nodes with few simulations.

2.4 Simulated Annealing

Simulated Annealing is a stochastic search algorithm that has been used to effectively solve NP-hard combinatorial problems [27]. The main idea of Simulated Annealing is to approximate a global optimum by iteratively improving an initial candidate and exploring the local neighborhood. To avoid a convergence to local optima, the search is guided by a falling temperature T that decreases the probability of accepting worse candidates over time [25]; in the following, we assume that a falling temperature depends on a decreasing loop counter.

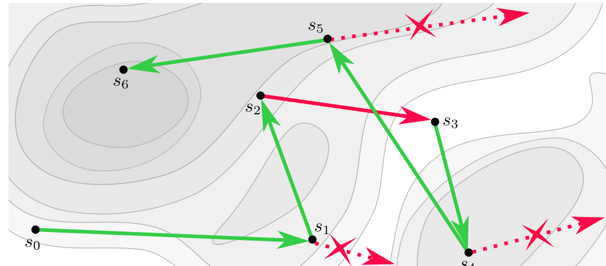

Figure 3: Simulated Annealing approximates a global optimum (the darkest area in the map).

Figure 3 illustrates this process on the example of finding the darkest area in a given map. Starting in an initial state (s_0), the algorithm always accepts a candidate that has a better score than the current one (green arrows). If the score is worse, we accept the worse candidate with some probability (the red arrow from s_2 to s_3) that depends on the temperature (loop counter) and how much worse the candidate is. The higher the temperature, the more likely the algorithm accepts a significantly worse candidate solution. Otherwise, the candidate is discarded (e. g., the crossed out red arrow at s_4); in this case, we pick another one in the local neighborhood. This allows the algorithm to escape from local optima while the temperature is high; for low temperatures (loop counters closer to 0), it mainly accepts better candidate solutions. The algorithm terminates after a specified number of iterations.

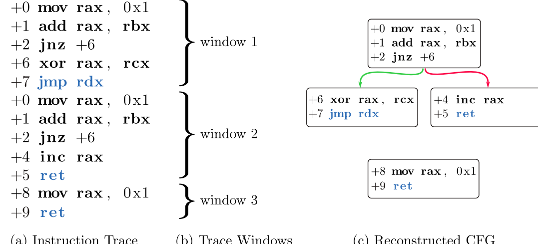

Figure 4: Dissecting a given trace (a) into several trace windows (b). The trace windows can be used to reconstruct a (possibly disconnected) control-flow graph (c).

3 Approach

Given an instruction trace, we dissect the instruction trace into *trace windows* (i. e., subtraces) and aim at learning their high-level semantics which can be used later on for further analysis. In the following, we describe our approach which is divided into three distinct parts:

1. *Trace Dissection.* The instruction trace is partitioned into unique sequences of assembly instructions in a (semi-)automated manner.

2. *Random Sampling.* We derive random input-output pairs for each trace window. These pairs describe the trace window's semantics.

3. *Program Synthesis.* Expressions that map all provided inputs to their corresponding outputs are synthesized.

3.1 Trace Dissection

The choice of trace window boundaries highly impacts later analysis stages. Most notably, it affects synthesis results: if a trace window ends at an *intermediary* computation step, the synthesized formula is not necessarily succinct or meaningful at all, as it includes spurious semantics.

Yet, we note how trace dissection of ROP chains and VM handlers lends itself to a simple heuristic. Namely, we split traces at indirect branches. In the ROP case, this describes the transition between two gadgets (commonly, on a `ret` instruction), whereas for VM handlers it distinguishes the invocation of the next handler (cf. Section 6.3). Figure 4 illustrates the approach. Given concrete trace window boundaries, we can reconstruct a control-flow graph consisting of multiple connected components. A *trace window* then describes a particular path through a connected component.

3.2 Random Sampling

The goal of random sampling is to derive input-output relations that describe the semantics of a trace window. This happens in two steps: First, we determine the inputs and outputs of the trace window. Then, we replace the inputs with random values and obverse the outputs.

Generally speaking, we consider register and memory reads as inputs and register and memory writes as outputs. For inputs, we apply a read-before-write principle: inputs are only registers/memory locations that are read before they have been written; for outputs, we consider the last writes of a register/memory location as output.

```
1 mov rax, [rbp + 0x8]
2 add rax, rcx
3 mov [rbp + 0x8], rax
4 add [rbp + 0x8], rdx
```

Following this principle, the code above has three inputs and two outputs: The inputs are the memory read M_0 in line 1, `rcx` (line 2) and `rdx` (line 4). The two outputs are o_0 (line 2) and o_1 (line 4).

In the next step, we generate random values and obverse the I/O relationship. For instance, we obtain the outputs $(7,14)$ for the input tuple $(2,5,7)$; for the inputs $(1,7,10)$, we obtain $(8,18)$.

By default, we use register locations as well as memory locations as inputs and outputs. However, we support the option to reduce the inputs and outputs to either register or memory locations. For instance, if we know that registers are only used for intermediate results, we may ignore them since it reduces the complexity for the synthesis.

3.3 Synthesis

This section demonstrates how we synthesize the semantics of assembly code; we discuss the inner workings of our synthesis approach in the next section.

After we obtained the I/O samples, we combine the different samples and synthesize each output separately. These synthesis instances are mutually independent and can be completely parallelized.

To exemplify, for the I/O pairs above, we search an expression that transforms $(2,5,7)$ to 7 and $(1,7,10)$ to 8 for o_0; for o_1, the expression has to map $(2,5,7)$ to 14 and $(1,7,10)$ to 18. Then, the synthesizer finds $o_0 = M_0 + \texttt{rcx}$ and $o_1 = M_0 + \texttt{rcx} + \texttt{rdx}$.

4 Program Synthesis

In the last section, we demonstrated how we obtain I/O samples from assembly code and apply program synthesis to that context. This section describes our algorithm in detail; we show how we find an expression that maps all inputs to their corresponding outputs for all observed

samples. We use Monte Carlo Tree Search, since it has been proven to be very effective when working on infinite decision trees without requiring much domain knowledge.

We consider program synthesis as a single-player game whose purpose is to synthesize an expression whose input-output behavior is as close as possible to given I/O samples. In essence, we define a context-free grammar that consists of terminal and non-terminal symbols. (Partially) derived words of the grammar are *game states*; the grammar's production rules represent the *moves* of the game. *Terminal nodes* are expressions that contain only terminal symbols; these are *end states* of the game.

Given a maximum number of iterations and I/O samples, we iteratively apply the four MCTS steps (cf. Section 2.3), until we find a solution or we reach the timeout. Starting with a non-terminal expression as *root node*, we *select* the most-promising expandable node. A node is *expandable*, if there still exist production rules that have not been applied to this node. We choose a production rule randomly and expand the selected node. To evaluate the quality of the new node, we perform a *random playout*: First, we randomly derive a terminal expression by successively applying random production rules. Then, we evaluate the expressions based on the inputs from the I/O pairs and compare the output similarity. The similarity score is the node *reward*. A reward of 1 ends the synthesis, since the input-output behavior is the same for the provided samples. Finally, we *propagate* the reward back to the root.

In the following, we give details on node selection, our grammar, random playouts and backpropagation. Finally, we discuss the algorithm configuration and parameter tuning. To demonstrate the different steps of our approach, we use the following running example throughout this section:

Example 1 (I/O relationship)**.** *Working with bit-vectors of size* 3 *(i. e., modulo* 2^3*), we observe for an expression with two inputs and one output the I/O relations:* $(2,2) \rightarrow 4$ *and* $(4,5) \rightarrow 1$*. A synthesized expression that maps the inputs to the corresponding outputs is* $f(a,b) = a+b$*.*

4.1 Node Selection

Since we have an infinite search space for program synthesis, node selection must be a trade-off between exploration and exploitation. The algorithm has to explore different nodes such that several promising and non-promising candidates are known. On the other hand, it has to follow more promising candidates to find deeper expressions. As described in Section 2.3, the UCT (cf. Equation 1) provides a good balance between exploitation and exploration for many MCTS applications.

However, we observed that it does not work for our use case: if we set the exploration constant C to a higher value (focus on exploration), it does not find deeper expressions; if we set C to a lower value, MCTS gets lost in deep expressions. To solve this problem, we use an adaption of UCT that is known as *Simulated Annealing UCT* (SA-UCT) [47]. The main idea of SA-UCT is to use the characteristics of Simulated Annealing (cf. Section 2.4) and apply it to UCT. SA-UCT is obtained by replacing the exploration constant C by a variable T with

$$T = C\frac{N-i}{N}, \tag{2}$$

where N is the maximum number of MCTS iterations and i the current iteration. Then, SA-UCT is defined as

$$\overline{X}_j + T\sqrt{\frac{\ln n}{n_j}}. \tag{3}$$

T decreases over time, since $\frac{N-i}{N}$ converges to 0 for increasing values of i. As a result, MCTS places the emphasis on exploration in the beginning; the more T decreases, the more the focus shifts to exploitation.

4.2 Grammar

Game states are represented by sentential forms of a context-free grammar that describes valid expressions of our high-level abstraction. We introduce a terminal symbol for each input (which corresponds to a variable that stores this input) and each valid operator (e. g., addition or multiplication). For every data type that can be computed we introduce one non-terminal symbol (in our running example, we only use a single non-terminal value U that represents an unsigned integer). The production rules describe how we can derive expressions in our high-level description. Since the sentential forms represent partial expressions, we will use the term expression to denote the (partial) expression that is represented by a given sentential form. Sentences of the grammar are final states in the game since they do not allow any further moves (derivations). They represent expressions that can be evaluated. We represent expressions in *Reverse Polish Notation* (RPN).

Example 2. *The grammar in our previous example has two input symbols* $V = \{a,b\}$*, since each I/O sample has two inputs. If the grammar supports addition and multiplication* $O = \{+,*\}$*, there are four production rules:* $R = \{U \rightarrow U\ U\ +\ |\ U\ U\ *\ |\ a\ |\ b\}$*. An unsigned integer expression* U *can be mapped to an addition or multiplication of two such expressions or a variable. The final grammar is* $(\{U\}, \Sigma = V \cup O, R, U)$*.*

Synthesis Grammar. Our grammar is designed to synthesize expressions that represent the semantics of bit-vector arithmetic, especially for

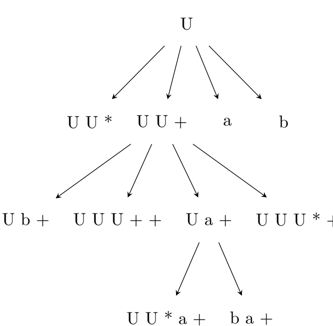

Figure 5: An MCTS tree for program synthesis that grows towards the most-promising node $b\ a\ +$, the right-most leaf in layer 3.

the x86 architecture. For every data type (U_8, U_{16}, U_{32} and U_{64}), we define the set of operations as $O = \{+,-,*,/_s,/,\%_s,\%,\wedge,\vee,\oplus,\ll,\gg,\gg_a,-_1,\neg,$ `sign_ext`, `zero_ext`, `extract`, $++$, $1\}$, where the operations are binary addition, subtraction, multiplication, signed/unsigned division, signed/unsigned remainder, bitwise and/or/xor, logical left shift, logical/arithmetic right shift as well as unary minus and complement. The unary operations `sign_ext` and `zero_ext` extend smaller data types to signed/unsigned larger data types. Conversely, the unary operator `extract` transforms larger data types into smaller data types by extracting the respective least significant bits. Since the x86 architecture allows register concatenation (e. g., for division), we employ the binary operator $++$ to concatenate two expressions of the same data type. Finally, to synthesize expressions such as increment and decrement, we use the constant 1 as niladic operator. The input set V consists of $|V| = n$ variables, where n represents the number of inputs.

Tree Structure. The sentential form U is the root node of the MCTS tree. Its child nodes are other expressions that are produced by applying the production rules to a single non-terminal symbol of the parent. The expression depth (referred to as *layer*) is equivalent to the number of derivation steps, as depicted in Figure 5.

Example 3. *The root node U is an expression of layer 0. Its children are a, b, $U\ U\ +$, and $U\ U\ *$, where a and b are terminal expressions of layer 1. Assuming that the right-most U in an expression is replaced, the children of $U\ U\ +$ are $U\ b\ +$, $U\ a\ +$, $U\ U\ U\ +\ +$, and $U\ U\ U\ *\ +$. To obtain the layer 3 expression $b\ a\ +$, the following derivation steps are applied: $U \Rightarrow U\ U\ + \Rightarrow U\ a\ + \Rightarrow b\ a\ +$.*

To direct the search towards outer expressions, we replace the *top-most-right-most* non-terminal. If we, instead, substitute always the *right-most* non-terminal only, then the search would be guided towards most-promising subexpressions. If the expression is too nested, the synthesizer would find the partial subexpression but not the whole expression. The top-most-right-most derivation is illustrated in Figure 6, which shows the abstract syntax tree (AST) of an expression.

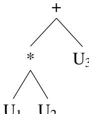

Figure 6: The left-most U in $U_3\ U_2\ U_1\ *\ +$ is the top-most-right-most non-terminal in the abstract syntax tree. (The indices are provided for illustrative purposes only.)

Example 4. *The expression $(U + (U * U))$ is represented as $U\ U\ U\ *\ +$. If we successively replace the right-most U, the algorithm is unlikely to find expressions such as $((a+b)+(b*(b*a)))$, since it is directed into the subexpression with the multiplication. Instead, replacing the top-most-right-most non-terminal directs the search to the top-most addition and then explores the subexpressions.*

4.3 Random Playout

One of the key concepts of MCTS are random playouts. They are used to determine the outcome of a node; this outcome is represented by a reward. In the first step, we randomly apply production rules to the current node, until we obtain a terminal expression. To avoid infinite derivations, we set a maximum playout depth. This maximum playout depth defines how often a non-terminal symbol can be mapped to rules that contain non-terminal symbols; at the latest we reached the maximum, we map non-terminals only to terminal expressions. This happens in a top-most-right-most manner. Afterwards, we evaluate the expression for all inputs from the I/O samples.

Example 5. *Assuming a maximum playout depth of 2 and the expression $U\ U\ *$, the first top-most-right-most U is randomly substituted with $U\ U\ *$, the second one with $U\ U\ +$. After that, the remaining non-terminal symbols are randomly replaced with variables: $U\ U\ * \Rightarrow U\ U\ U\ *\ * \Rightarrow U\ U\ +\ U\ U\ *\ * \Rightarrow \cdots \Rightarrow a\ a\ +\ b\ a\ *\ *$. A random playout for $U\ U\ +$ is $a\ b\ b\ +\ +$.*

For the I/O sample $(2,2) \rightarrow 4$, we evaluate $g(2,2) = 0$ for $g(a,b) = ((a+a)*(b*a)) \mod (2^8)$ and $h(2,2) = 6$ for $h(a,b) = (a+(b+b)) \mod 2^8$.

We set terminal nodes to inactive after their evaluation, since they already are end states of the game; there is no possibility to improve the node's reward by random playouts. As a result, MCTS will not take these nodes

into account in further iterations. The node's reward is the similarity of the evaluated expressions and the outputs from the I/O samples. We describe in the following section how to measure the similarity to the outputs.

4.4 Measuring Similarity of Outputs

To measure the similarity of two outputs, we compare values with different metrics: arithmetic distance, Hamming distance, count leading zeros, count trailing zeros, count leading ones and count trailing ones. While the numeric distance is a reliable metric for arithmetic operations, it does not work well with overflows and bitwise operations (e. g., xor and shifts). In turn, the Hamming distance addresses these operations since it states in how many bits two values differ. Finally, the leading/trailing zeros/ones are strong indicators that two values are in the same range. We scale each result between a value of 0 and 1. Since the different metrics compensate each other, we set the total similarity reward to the average reward of all metrics.

Example 6. *Considering I/O pair* $(2,2) \rightarrow 4$*, the output similarities for g and h (as defined in Example 5) are* $\text{similarity}(4,0)$ *and* $\text{similarity}(4,6)$*. Limiting to the metrics of Hamming distance and count leading zeros (*`clz`*), we obtain* $\text{hamming}(4,0) = \text{hamming}(4,6) = 0.67$*,* $\text{clz}(4,0) = 0$ *and* $\text{clz}(4,6) = 1.0$*. Therefore, the average similarities are* $\text{similarity}(4,0) = 0.335$ *and* $\text{similarity}(4,6) = 0.835$*. Related to the random playouts, the evaluated node* $U\ U\ +$ *has a higher reward than* $U\ U\ *$*.*

During a random playout, we calculate the similarity for all I/O samples. The final node reward is the average score of all similarity rewards. A reward of 1 finishes program synthesis, since the evaluated expression produces exactly the outputs from the I/O samples.

4.5 Backpropagation

After obtaining a score by random playout, we do the following for the selected node and all its parents, up to the root: (1) We update the node's average reward. This reward is averaged based on the node's and its successors' total number of random playouts. (2) If the node is fully expanded and its children are all inactive, we set the node to inactive. (3) Finally, we set the current node to its parent node.

4.6 Expression Simplification

Since MCTS performs a stochastic search, synthesized expressions are not necessary in their shortest form. Therefore, we apply some basic standard expression simplification rules. For example, if the synthesizer constructs integer values as $((1 \ll 1) \ll (1 + (1 \ll 1)))$, we can reduce them to the value 16.

4.7 Algorithm Configuration

Two main factors define the algorithm's success that cannot be influenced by the user: the number of input variables and the complexity (e. g., depth) of the expression to synthesize. Contrary, there exist four parameters that can be configured by a user to improve the effectiveness and speed: the initial SA-UCT value, the number of I/O samples, the maximum number of MCTS iterations and the maximum playout depth.

The SA-UCT parameter T configures the trade-off between exploration and exploitation and depends on the maximum number of MCTS iterations; if the maximum number of MCTS iterations is low, the algorithm focuses on exploiting promising candidates within a small period of time. The same holds for small initial values of T.

A large number of variables or a higher expression depth requires more MCTS iterations. Besides the maximum number of MCTS iterations, the maximum playout depth provides more accuracy since it is more probable to hit deeper expressions or more influencing variables with deeper playouts. On the other hands, deeper playouts have an impact on the execution time.

Since random playouts are performed for every node and for every I/O pair, the number of I/O samples has a significant impact on the execution time. In addition, it effects the number of false positives, since there are less expressions that have the same I/O behavior for a larger number of I/O samples. Finally, the MCTS synthesis is more precise since the different node rewards are expected to be informative.

Since the search space for finding good algorithm configurations for different complexity classes is large, we approximate an optimal solution by Simulated Annealing. We present the details and results in Section 6.1.

5 Implementation

We implemented a prototype implementation of our approach in our tool *Syntia*, which is written in Python. For trace generation and random sampling, we use the *Unicorn Engine* [43], a CPU emulator framework. To analyze assembly code (e. g., trace dissection), we utilize the disassembler framework *Capstone* [42]. Furthermore, we use the SMT solver *Z3* [36] for expression simplification.

Initially, Syntia expects a memory dump, a start and an end address as input. Then, it emulates the program and outputs the instruction trace. Then, the user has the opportunity to define its own rules for trace dissection; otherwise, Syntia dissects the trace at indirect control

Table 1: Initial Simulated Annealing configuration and the parameter's lower/upper bounds.

parameter	initial	lower bound	upper bound
SA-UCT	1.0	0.7	2.0
# MCTS iterations	2,000	500	50,000
# I/O samples	30	10	60
playout depth	1	0	2

transfers. Additionally, the user has to decide if register and/or memory locations are used as inputs/outputs and how many I/O pairs shall be sampled. Syntia traces register and memory modifications in each trace window, derives the inputs and outputs and generates I/O pairs by random sampling. The last step can be parallelized for each trace window. Finally, the user defines the synthesis parameters. Syntia creates a synthesis tasks for each (trace window, output) pair. The synthesis tasks are performed in parallel. The synthesis results are simplified by Z3's term-rewriting engine.

6 Experimental Evaluation

In the following, we evaluate our approach in three areas of application. The experiments have been evaluated on a machine with two Intel Xeon E5-2667 CPUs (in total, 12 cores and 24 threads) and 96 GiB of memory. However, we never have used more than 32 GiB of memory even though parallel I/O sampling for many trace windows can be memory intensive; synthesis itself never used more than 6 GiB of memory.

6.1 Parameter Choice

As described in Section 4.7, we approximate an optimal algorithm configuration with Simulated Annealing. To compute preferably representative results, we generate a set of $1,200$ *randomly* generated expressions. We divide this set into three classes with 400 expressions each; to prevent overfitting the parameters on a fixed set of inputs, the experiments of each class are performed with distinct input samples.

In each iteration, Simulated Annealing synthesizes the $1,200$ expressions under the same configuration. We set a timeout of 120 seconds for each synthesis task and prune non-successful tasks by a constant factor of the timeout. As a result, Simulated Annealing optimizes towards a high success rate for synthesis tasks and a minimal average time. Table 1 lists the initial algorithm configuration and the parameter boundaries.

We aim at determining optimal parameters for different complexity classes. Classes are distinguished by the number of variables and by the expression's layer. Table 2 illustrates the final configurations for 12 different complexity classes after 50 Simulated Annealing iterations. While the I/O samples and the playout depth are mostly in a similar range (0 and 20), there is a larger scope for the SA-UCT parameter and the maximum number of MCTS iterations. Especially for higher complexity classes, this is due to the optimization towards a high success rate within 120 seconds. The latter parameters strive towards larger values without this timeout.

Generally, the parameter configurations set a focus on exploration instead of exploitation. We follow this observation and adapt the configuration based on our problem statements. To describe a configuration, we provide a configuration vector of the form (SA-UCT, #iter, #I/O, PD).

6.2 Mixed Boolean-Arithmetic

Zhou et al. proposed the concept of *MBA expressions* [63]. By transforming simpler expressions and constants into MBA expressions over Boolean-arithmetic algebras, they can generate semantically-equivalent, but much more complex code which is arguably hard to reverse engineer. Effectively, this obfuscating transformation allows them to hide formulas and constants in plain code. In their paper, they define a Boolean-arithmetic algebra as follows:

Definition 1 (Boolean-arithmetic algebra [63])**.** *With n a positive integer and $\mathsf{B} = \{0,1\}$, the algebraic system* $(\mathsf{B}^n, \wedge, \vee, \oplus, \neg, \leq, \geq, >, <, \leq^s, \geq^s, >^s, <^s, \neq, =, \gg^s, \gg, \ll, +, -, \cdot)$, *where $\ll, \gg$ denote left and right shifts, $\cdot$ (or juxtaposition) denotes multiply, and signed compares and arithmetic right shift are indicated by ^{s}, is a* Boolean-arithmetic algebra (BA-algebra), $\mathsf{BA}[n]$. *n is the* dimension *of the algebra.*

Specifically, they highlight how $\mathsf{BA}[n]$ includes, amongst others, the Boolean algebra $(\mathsf{B}^n, \wedge, \vee, \neg)$ as well as the integer modular ring $\mathbb{Z}/(2^n)$. As a consequence, Mixed Boolean-Arithmetic (MBA) expressions over B^n are hard to simplify in practice. In general, we note that reducing a complex expression to an equivalent, but simpler one by, e. g., removing redundancies, is considered NP-hard [31].

Zhou et al. represent MBA expressions as polynomials over $\mathsf{BA}[n]$. While polynomial MBA expressions are conceptually not restricted in terms of complexity, Zhou et al. define *linear MBA expressions* as those polynomials with degree 1. In particular, $f(x,y) = x - (x \oplus y) - 2(x \vee y) + 12564$ is a linear MBA expression, whereas $f(x,y) = x + 9(x \vee y)yx^3$ is not.

Implementation in Tigress. In practice, MBA expressions are used in the Tigress C Diversifier/Obfuscator by

Table 2: Parameter choices for different complexity classes that depend on the expression layer and the number of variables. The parameters are the SA-UCT parameter (SA), the maximum number of MCTS iterations (# iter), the number of I/O samples (# I/O) and the playout depth (PD).

	# variables

Collberg et al. [9] which uses the technique to encode integer variables and expressions in which they are used [11]. Further, Tigress also supports common arithmetic encodings to increase an expression's complexity, albeit not based on MBAs [10].

For example, the rather simple expression $x+y+z$ is transformed into the layer 23 expression $(((x \oplus y)+((x \wedge y) \ll 1)) \vee z)+(((x \oplus y)+((x \wedge y) \ll 1)) \wedge z)$ using its arithmetic encoding option. In a second transformation step, Tigress encodes it into a linear MBA expression of layer 383 (omitted due to complexity). Such expressions are hard to simplify symbolically.

Table 3: Trace window statistics and synthesis performance for Tigress (MBA), VMProtect (VMP), Themida (flavor Tiger White, TM), and ROP gadgets.

	MBA	VMP	TM	ROP
#trace windows	500	12,577	2,448	78
#unique windows	500	449	106	78
#instructions per window	116	49	258	3
#inputs per window	5	2	15	3
#outputs per window	1	2	10	2
#synthesis tasks	500	1,123	1,092	178
I/O sampling time (s)	110	118	60	17
overall synthesis time (s)	2,020	4,160	9,946	829
synthesis time per task (s)	4.0	3.7	9.1	4.7

Evaluation Results. We evaluated our approach to simplify MBA expressions using Syntia. As a testbed, we built a C program which calls 500 *randomly* generated functions. Each of these random functions takes 5 input variables and returns an expression of layer 3 to 5. Then, we applied the arithmetic encoding provided by Tigress, followed by the linear MBA encoding. The resulting program contained expressions of up to $2,821$ layers, the average layer being 156. The arithmetic encoding is applied to highlight that our approach is invariant to the code's increased *symbolic* complexity and is only concerned with semantical complexity.

Based on a concrete execution trace it can be observed that the 500 functions use, on average, 5 memory inputs (as parameters are passed on the stack) and one register output (the register containing the return value). Table 3 shows statistics for the analysis run using the configuration vector $(1.5, 50000, 50, 0)$. The first two components indicate a strong focus on *exploration* in favor of exploitation; due to the small number of synthesis tasks, we used 50 I/O samples to obtain more precise results.

The sampling phases completed in less than two minutes. Overall, the 500 synthesis tasks were finished in about 34 minutes, i.e., in 4.0 seconds per expression. We were able to synthesize 448 out of 500 expressions (89.6%). The remaining expressions are not found due to the probabilistic nature of our algorithm; after 4 subsequent runs, we synthesized 489 expressions (97.8%) in total.

To get a better feeling for this probabilistic behavior, we compared the cumulative numbers of synthesized MBA expressions for 10 subsequent runs. Figure 7 shows the results averaged over 15 separate experiments. On average, the first run synthesizes 89.6% (448 expressions) of the 500 expressions. A second run yields 22 new expressions (94.0%), while a third run reveals 10 more expressions (96.0%). While converging to 500, the number of newly synthesized expressions decreases in subsequent runs. Comparing the fifth and the eighth run, we only found 5 new expressions (from 489 to 494). After the ninth run, Syntia synthesized 495 (99.0%) of the MBA expressions.

6.3 VM Instruction Handler

As introduced in Section 2.1.1, an instruction handler of a Virtual Machine implements the effects of an atomic instruction according to the custom VM-ISA. It operates on the VM context and can perform arbitrarily complex tasks. As handlers are heavily obfuscated, manual analysis of a handler's semantics is a time-consuming task.

Attacking VMs. When faced with virtualization-based obfuscations, an attacker typically has two options. For one, she can analyze the interpreter and, for each handler, extract all information required to *re-translate* the bytecode back to native instruction. Especially in face of handler duplication and bytecode blinding, this requires

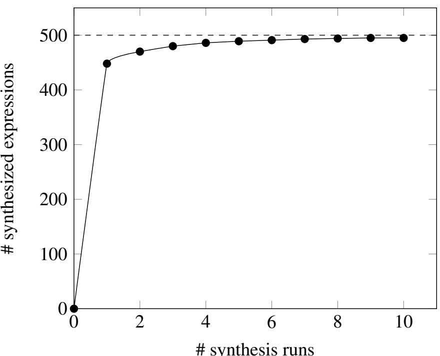

Figure 7: Subsequent synthesis runs increase the number of synthesized MBA expressions. Each point represents the average cumulative number of synthesized expressions from 15 separate experiments.

her to precisely capture all effects produced by the handlers. This includes both the high-level semantics with regard to input and output variables *as well as* the individual unblinding routines. In his paper, Rolles discusses how this type of attack requires complete understanding of the VM and therefore has to be repeated for each virtualization obfuscator [44]. Thus, we note that this attack does not lend itself easily to full automation. Another approach is to perform analyses on the *bytecode level*. The idea is that while an attacker cannot learn the full semantics of the original code, the analysis of the interaction of handlers itself reveals enough information about the underlying code. This allows the attacker to skip details like bytecode blinding as she only requires the high-level semantics of a handler. Sharif et al. successfully mounted such an attack to recover the CFG of the virtualized function [53], but do not take semantics other than virtual instruction pointer updates into account.

We recognize the latter approach as promising and note how Syntia allows us to *automatically* extract the high-level semantics of arithmetical and logical instruction handlers. This is achieved by operating on an execution trace through the interpreter and simplify its individual handlers—as distinguished by trace window boundaries—using program synthesis. Especially, we highlight how obtaining the semantics of *one* handler automatically yields information about the underlying native code at *all points* of the trace where this specific handler is used to encode equivalent virtualized semantics.

Evaluation Setup. We evaluated Syntia to learn the semantics of arithmetic and logical VM instruction handlers in recent versions of VMProtect [58] (v3.0.9) and Themida [38] (v2.4.5.0). To this end, we built a program that covers bit-vector arithmetic for operand widths of 8, 16, 32, and 64 bit. Since we are interested in analyzing effects of the VM itself, using a synthetic program does not distort our results. For verification, we manually reverse engineered the VM layouts of VMProtect and Themida. Note that the commercial versions of both protection systems have been used to obfuscate the program. These are known to provide better obfuscation strength compared to the evaluation versions.

We argue that our evaluation program is representative of *any* program obfuscated with the respective VM-based obfuscating scheme. As seen in Section 2.1.1, common instructions map to a plethora of VM handlers. Consequently, if we succeed in recovering the semantics of these integral building blocks, we are at the same time able to recover other variations of native instructions using these handlers as well.

This motivates the design of our evaluation program, which aims to have a wide coverage of all possible arithmetic and logical operations. We note that this may not be the case for *real-world* test cases, which may not trigger all interesting VM handlers. To this extent, our evaluation program is, in fact, *more representative* than, e. g., malware samples.

6.3.1 VMProtect

In its current version, VMProtect follows the *Direct Threaded Code* design principle (cf. Section 2.1.1). Each handler directly invokes the next handler based on the address encoded directly in the instruction's bytecode. Hence, reconstructing the handlers requires an instruction trace. Also, this impacts trace dissection: since VM handlers dispatch the next handler, they end with an indirect jump. Unsurprisingly, Syntia could automatically dissect the instruction trace into trace windows that represent a single VM handler. As evident from Table 3, there are 449 *unique* trace windows out of a total of 12,577 in the instruction trace.

Further, VMProtect employs *handler duplication*. For example, the 449 instruction handlers contain 12 instances performing 8-bit addition, 11 instances for each of addition (for each flavor of 16-, 32-, 64-bit), `nor` (8-, 64-bit), left and right shift (32-, 64-bit); amongst multiple others. If Syntia is able to learn one instance in each group, it is safe to assume that it will successfully synthesize the full group, as supported by our results.

Similarly, the execution trace is made up of all possible handlers and some of them occur multiple times. Hence, if we correctly synthesize semantics for, e. g., a 64-bit addition, this immediately yields semantics for 772 trace windows (6.2% of the full trace, 32.0% of all arithmetic and logical trace windows in the trace). Equivalent reasoning applies to 16-bit `nor` operations in our trace (3.6% of the full trace, 18.8% of all arithmetic and logical trace windows). In total, our results reveal semantics for 19.7% of the full execution trace (2,482 out of 12,577 trace win-

dows). Manual analysis suggests that the remaining trace semantics mostly consists of control-flow handling and stack operations. These are especially used when switching from the native to the VM context and amount for a large part of the execution trace.

On average, an individual instruction handler consists of 49 instructions. As VMProtect's VM is stack-based, binary arithmetic handlers pop two arguments from the stack and push the result onto the stack. This tremendously eases identification of inputs and outputs. Therefore, we mark memory operands as inputs and outputs and use the configuration vector $(1.5, 30000, 20, 0)$ for the synthesis. The sampling phase finished in less than two minutes. Overall, the $1,123$ synthesis tasks completed in less than an hour, which amounts to merely 3.7 seconds per task. In total, in our first run, we automatically identified 190 out of 196 arithmetical and logical handlers (96.9%). The remaining 6 handlers implement 8-bit divisions and shifts. Due to their representation in x86 assembly code, Syntia needs to synthesize more complex expressions with nested data type conversions. As the analysis is probabilistic in nature, we scheduled five more runs which yielded 4 new handlers. Thus, we are able to automatically pinpoint 98.9% of all arithmetic and logical instruction handlers in VMProtect.

6.3.2 Themida

The protection solution Themida supports three basic VM flavors, namely, Tiger, Fish, and Dolphin. Each flavor can further be customized to use one of three obfuscation levels, in increasing complexity: White, Red, and Black. We note that related work on deobfuscation does not directly mention the exact configuration used for Themida. In hopes to be comparable, we opted to use the default flavor Tiger, using level White, in our evaluation. Unlike VMProtect, Tiger White uses an explicit handler table while inlining the dispatcher routine; i. e., it follows the *Threaded Code* design principle (cf. Section 2.1.1). Consequently, trace dissection again yields one trace window per instruction handler. Even though the central handler table lists $1,111$ handlers, we identified 106 *unique* trace windows along the concrete execution trace.

Themida implements a register-based architecture and stores intermediate computations in one of many register available in the VM context. This, in turn, affects the identification of input and output variables. While in the case of VMProtect, inputs and outputs are directly taken from two slots on the stack, Themida has a significantly higher number of potential inputs and outputs (i. e., all virtual registers in the VM context, 10 to 15 in our case).

Tiger White supports handlers for addition, subtraction, multiplication, logical left and right shift, bitwise operations and unary subtraction; each for different operand widths. In contrast to VMProtect, handlers are neither duplicated nor do they occur multiple times in the execution trace. Hence, the trace itself is much more compact, spanning $2,448$ trace windows in total; roughly 5 times shorter than VMProtect's. Still, Themida's handlers are much longer, with 258 instructions on average.

We ran the analysis using the configuration vector $(1.8, 50000, 20, 0)$. Due to the higher number of inputs, this configuration—in comparison to the previous section—sets a much higher focus on exploration as indicated by higher values chosen for the first two parameters. Sampling finished in one minute, whereas the synthesis phase took around 166 minutes. At $1,092$ synthesis tasks, this amounts to roughly 9.1 seconds per task. Eventually, we automatically learned the semantics of 34 out of 36 arithmetic and logical handlers (94.4%). The remaining handlers (8-bit subtraction and logical or) were not found as we were unable to complete the sampling phase due to crashes in Unicorn engine.

6.4 ROP Gadget Analysis

We further evaluated Syntia on ROP gadgets, specifically, on four samples that were thankfully provided by Debray [62]. They implement bubble sort, factorials, Fibonacci, and matrix multiplication in ROP. To have a larger set of samples, we also used a CTF challenge [41] that has been generated by the ROP compiler `Q` [51] and another Fibonacci implementation that has been generated with `ROPC` [39].

Syntia automatically dissected the instruction traces into 156 individual gadgets. Since many gadgets use exactly the same instructions, we unified them into 78 unique gadgets. On average, a gadget consists of 3 instructions with 3 inputs and 2 outputs (register and memory locations).

Due to the small numbers of inputs and synthesis tasks, we chose the configuration vector $(1.5, 100000, 50, 0)$ that sets a very strong focus on exploration while accepting a higher running time. Especially, we experienced both effects for the maximum number of MCTS iterations.

Syntia synthesized partial semantics for 97.4% of the gadgets in less than 14 minutes; in total, we were successful in 163 out of the 178 (91.5%) synthesis tasks. Our synthesis results include 58 assignments, 17 binary additions, 5 ternary additions, 4 unary minus, 4 binary subtractions, 4 register increments/decrements, 2 binary multiplications and 1 bitwise and. In addition, we found 68 stack pointer increments due to `ret` statements. The results do not include larger constants or operations such as `ror` as they are not part of our grammar.

7 Discussion

In the following, we discuss different aspects of program synthesis for trace simplification and MCTS-based program synthesis. Furthermore, we point out limitations of our approach as well as future work.

Program Synthesis for Trace Simplification. Current research on deobfuscation [13, 53, 61, 62] operates on instruction traces and uses a mixed approach consisting of symbolic execution [61] and taint analysis [60]; two approaches that require a precise analysis of the underlying code. While techniques exist that defeat taint analysis [6, 48], recent work shows that symbolic execution can similarly be attacked [2].

Program synthesis is an orthogonal approach that operates on a purely semantical level as opposed to (binary) code analysis; it is oblivious to the underlying code constructs. As a result, syntactical aspects of code complexity such as obfuscation or instruction count do not influence program synthesis negatively. It is merely concerned with the complexity of the code's *semantics*. The only exception where code-level artifacts matter is the generation of I/O samples; however, this can be realized with small overhead compared to regular execution time using dynamic binary instrumentation [37, 40].

Commonly, instruction traces contain repetitions of unique trace windows that can be caused by loops or repeated function calls to the same function. By synthesizing these trace windows, the synthesized semantics pertain for all appearances on the instruction trace; the more frequently these trace windows occur in the trace, the higher the percentage of *known* semantics in the instruction trace. We stress how VM-based obfuscation schemes do this to the extreme: a relatively small number of unique trace windows are used over the whole trace.

In general, the synthesis results may not be precise semantics since we approximate them based on I/O samples. If these do not reflect the full semantics, the synthesis misses edge cases. For instance, we sometimes cannot distinguish between an arithmetic and a logical right shift if the random inputs are no *distinguishing* inputs. We point out that this is not necessarily a limitation, since a human analyst might still get valuable insights from the approximated semantics.

As future work, we consider improving trace simplification by a stratified synthesis approach [23]. The main idea is to incrementally synthesize larger parts of the instruction trace based on previous results and successively approximate high-level semantics of the entire trace. Further, we note that the work by Sharif et al. [53] is complementary to our synthesis approach and would also allow us to identify control flow. Likewise, extending the grammar by control-flow operations is another viable approach to tackle this limitation.

MCTS-based Program Synthesis. Compared to SMT-based program synthesis, we obtain *candidate* solutions, even if the synthesizer does not find an *exact* result. This is particularly beneficial for applications such as deobfuscation, since a human analyst can sometimes infer the full semantics. We decided to utilize MCTS for program synthesis since it has been proven very effective when operating on large search trees without domain knowledge. However, our approach is not limited to MCTS, other stochastic algorithms are also applicable.

Drawn from the observations made in Section 6, we infer that the MCTS approach is much more effective with a configuration that focuses on exploration instead of exploitation. The SA-UCT parameter ensures that paths with a higher reward are explored in-depth in later stages of the algorithm. We still try to improve exploration strategies, for instance with *Nested Monte Carlo Tree Search* [35] and *Monte Carlo Beam Search* [7].

Limitations. In general, limits of program synthesis apply to our approach as well. Non-determinism and point functions—Boolean functions that return 1 for exactly one input out of a large input domain—cannot be synthesized practically. This also holds for semantics that have strong confusion and diffusion properties, such as cryptographic algorithms. These are inherently very complex, non-linear expressions with a deep nesting level. Our approach is also limited by the choice of trace window boundaries; ending a trace window in intermediate computation steps may produce formulas that are not *meaningful* at all.

8 Related Work

We now review related work for program synthesis, Monte Carlo Tree Search and deobfuscation. Furthermore, we describe how our work fits into these research areas.

Program Synthesis. Gulwani et al. [22] introduced an SMT-based program synthesis approach for loop-free programs that requires a logical specification of the desired program behavior. Building on this, Jha et al. [24] replaced the specification with an I/O oracle. Upon generation of *multiple* valid program candidates, they derive *distinguishing inputs* that are used for subsequent oracle queries. They demonstrated their use case by simplifying a string obfuscation routine of MyDoom. Godfroid and Taly [18] used an SMT-based approach to learn the formal semantics of CPU instruction sets; for this, they use the CPU as I/O oracle.

Schkufza et al. [50] proved that stochastic program synthesis often outperforms SMT-based approaches. This is mostly due to the fact that common SMT-based approaches effectively enumerate *all* programs of a given size or prove their non-existence. On the other hand, stochastic approaches focus on promising parts of the search space without searching exhaustively. Schkufza et al. use this technique for stochastic superoptimization on the basis of their tool *STOKE*. Recent work by Heule et al. [23] demonstrates a stratified approach to learn the semantics of the x86-64 instruction set, based on STOKE. Their main idea is to re-use synthesis results to synthesize more complex instructions in an iterative manner. To the best of our knowledge, STOKE is the only other stochastic synthesis tool that is able to synthesize low-level semantics. By design, their code only produces Intel x86 code.

In our case, stochastic techniques have additional properties that are not achieved by previous tools: we obtain partial results that are often already "close" to a real solution and might be helpful for a human analyst who tries to understand obfuscated code. Furthermore, we can encode arbitrary complex function symbols in our grammar (e. g., complex encoding schemes or hash functions); a characteristic that is not easily reproduced by SMT-based approaches.

In the context of non-academic work, Rolles applied some of the above mentioned SMT-based approaches to reverse engineering and deobfuscation [45]. Amongst others, he learned obfuscation rules by adapting peephole superoptimization techniques [3] and extracted metamorphic code using an oracle-guided approach. In his recent work, he performs SMT-based shellcode synthesis [46].

Monte Carlo Tree Search. MCTS has been widely studied in the area of AI in games [16, 35, 49, 56]. Ruijl et al. [47] combine Simulated Annealing and MCTS by introducing SA-UCT for expression simplification. Lim and Yoo [32] describe an early exploration on how MCTS can be used for program synthesis and note that it shows comparable performance to genetic programming. We extend the research of MCTS-based program synthesis by applying SA-UCT and introducing node pruning. For our synthesis approach, we designed a context-free grammar that learns the semantics of Intel x86 code.

Deobfuscation. Rolles provides an academic analysis of a VM-based obfuscator and outlines a possible attack on such schemes in general [44]. He proposes using static analysis to re-translate the VM's bytecode back into native instructions. This, however, requires minute analysis of *each* obfuscator and hence is time-consuming and prone to minor modifications of the scheme. Kinder is also concerned with (static) analysis of VMs [26]. Specifically, he lifts a *location-sensitive* analysis to be usable in presence of virtualization-based obfuscation schemes. His work highlights how the execution trace of a VM, while performing various computations, always exhibits a recurring set of addresses. As seen in Section 6, our approach actually benefits from this side effect. In contrast, Sharif et al. [53] analyze VMs in a *dynamic* manner and record execution traces. In contrast to the work of Rolles, their goal is not to re-translate, but to directly analyze the bytecode itself. Specifically, they aim to reconstruct parts of the underlying code's control flow from the bytecode. This approach is closest to our work as we are, in turn, mostly concerned with arithmetic and logical semantics of a handler.

More recent results include work by Coogan et al. [13] as well as Yadegari et al. [62]. Both approaches seek to deobfuscate code based on execution traces by further making use of symbolic execution and taint tracking. The former approach is focused on the *value flow* to system calls to reduce a trace whereas Yadegari et al. propose a more general approach and aim to produce fully deobfuscated code. However, to counteract symbolic execution-based deobfuscation approaches, Banescu et al. propose novel obfuscating transformations that specifically target their deficiencies [2]. For one, they propose a construct akin to *random opaque predicates* [12] that deliberately explodes the number of paths through a function. A second technique preserves program behavior of the obfuscated program for specific input invariants *only*, effectively increasing the input domains and thus the search space for symbolic executors.

Guinet et al. present *arybo*, a framework to simplify MBA expressions [20]. In essence, they perform bit-blasting and use a Boolean expression solver that tries to simplify the expression symbolically. Eyrolles [15] describes a symbolic approach that uses pattern matching. Furthermore, she suggests improvements of current MBA-obfuscated implementations that impede these symbolic deobfuscation techniques [14]. To this effect, we also argue that symbolic simplification is inherently limited by the complexity of the input expression. However, we demonstrated that a synthesis-based approach allows fine-tuned simplification, irrespective of *syntactical* complexity, while producing approximate intermediate results.

9 Conclusion

With our prototype implementation of Syntia we have shown that program synthesis can aid in deobfuscation of real-world obfuscated code. In general, our approach is vastly different in nature compared to proposed deobfuscation techniques and hence may succeed in scenarios where approaches requiring precise code semantics fail.

Predicting the Resilience of Obfuscated Code Against Symbolic Execution Attacks via Machine Learning

Technische Universität München

Abstract

Software obfuscation transforms code such that it is more difficult to reverse engineer. However, it is known that given enough resources, an attacker will successfully reverse engineer an obfuscated program. Therefore, an open challenge for software obfuscation is estimating the time an obfuscated program is able to withstand a given reverse engineering attack. This paper proposes a general framework for choosing the most relevant software features to estimate the effort of automated attacks. Our framework uses these software features to build regression models that can predict the resilience of different software protection transformations against automated attacks. To evaluate the effectiveness of our approach, we instantiate it in a case-study about predicting the time needed to deobfuscate a set of C programs, using an attack based on symbolic execution. To train regression models our system requires a large set of programs as input. We have therefore implemented a code generator that can generate large numbers of arbitrarily complex random C functions. Our results show that features such as the number of community structures in the graph-representation of symbolic path-constraints, are far more relevant for predicting deobfuscation time than other features generally used to measure the potency of control-flow obfuscation (e.g. cyclomatic complexity). Our best model is able to predict the number of seconds of symbolic execution-based deobfuscation attacks with over 90% accuracy for 80% of the programs in our dataset, which also includes several realistic hash functions.

1 Introduction

Software developers often protect premium features and content using cryptography, if secure key storage is possible. However, there are some risks regarding the use of cryptography in this context, i.e. code and data must be decrypted in order to be executable, respectively consumable by the end-user device. If end-users are malicious, then they can get access to the unencrypted code or data, e.g. by dumping the memory of the device on which the client software is running. Malicious end-users are called man-at-the-end (MATE) attackers and their capabilities include everything from static analysis to dynamic modification of the executable code and memory (e.g. debugging, tampering with code and data values, probing any hardware data bus, etc.).

In order to raise the bar against MATE attackers, obfuscation tools use code transformations to modify the original code such that it is harder to analyze and tamper with, while preserving the functionality of the program. Provably secure code obfuscation has been proposed in the literature, however, it is still impractical [3, 6, 7]. On the other hand, dozens of practical obfuscation transformations have been proposed since the early 1990s [14], however, their security guarantees are unclear.

Researchers and practitioners alike have struggled with evaluating the strength of different obfuscating code transformations. Many approaches have been proposed (see Section 2), however, despite the numerous efforts in this area, a recent survey on common obfuscating transformations and deobfuscation attacks indicates that after more than two decades of research, we are still lacking reliable concepts for evaluating the resilience of code obfuscation against attacks [42].

This paper makes the following contributions:

- A general framework for selecting program features which are relevant for predicting the resilience of software protection against automated attacks.
- A free C program generator, which was used to create a dataset of over 4500 different programs in order to benchmark our approach.
- A case study involving over 23000 obfuscated programs, where we build and test regression models to predict the resilience of the obfuscated programs against symbolic execution attacks.

- A set of highly relevant features for predicting the effort of attacks based on symbolic execution.
- A model that can predict the resilience of several code obfuscating techniques against an attack based on symbolic execution, with over 90% accuracy for 80% of the programs in our dataset.

The remainder of this paper is organized as follows. Section 2 describes related work. Section 3 describes our framework and the C program generator. Section 4 describes the case-study. Section 5 presents conclusions and future work. Acknowledgements are expressed in Section 6. Details regarding the availability our dataset and software tools are given in Section 7.

2 Related Work

Collberg et al. [15] proposed a general taxonomy for evaluating the quality of obfuscating transformations. This taxonomy states that code obfuscation should be evaluated with respect to: *potency* against human-assisted attacks, *resilience* against automated attacks, *cost* (in terms of performance overhead) added by the obfuscating transformation and *stealth*, which measures the difficulty of identifying parts of obfuscated code in a given program. Collberg et al. [15] also proposed using several existing software features to evaluate potency, namely: program length, cyclomatic complexity, nesting complexity, data flow complexity, fan-in/-out complexity, data structure complexity and object oriented design metrics. However, in their empirical studies Ceccato et al. [11] have found that potency does not always correlate with the previous software metrics. Dalla Preda [17] proposes using abstract interpretation to model attackers, which can either break a certain obfuscation transformation or not. However, they do not propose any fine-grained features for measuring resilience. On the other hand, there have also been works that propose measures for resilience. Udupa et al. [46] propose using the edit distance between control flow graphs of the original code and deobfuscated code. Mohsen and Pinto [33] propose using Kolmogorov complexity. Banescu et al. [5] propose using the effort needed to run a deobfuscation attack. However, they do not attempt to predict the effort needed for deobfuscation, which has been identified as a gap in this field [45]. In this paper we focus on predicting the effort needed by an automated deobfuscation attack.

Our work is complementary to the *Obfuscation Executive* (OE) proposed by Heffner and Collberg [23]. The OE uses software complexity metrics and performance measurements to choose a sequence of obfuscating transformations, that should be applied to a program in order to increase its potency, while our paper is solely concerned with resilience. Moreover, the OE also proposes restrictions regarding which obfuscating transformations can follow each other. Our work focuses on prediction of resilience, which is something that the OE does not do. However, our approach could be integrated into the OE to improve the decision making process (see Section 4.4).

Karnick et al. [26] proposed to measure the quality of Java obfuscators by summing up potency and resilience and subtracting cost of memory consumption, file storage size and execution time from the sum. They measure potency with a subset of the features proposed by Collberg et al. [15]. They measure resilience by using concrete implementations of deobfuscators, measuring whether they were successful or if they encountered errors and averaging the measurements across the total number of deobfuscators. We acknowledge that using multiple concrete implementations of a deobfuscation attack (e.g. disassembly, CFG simplification) is important to weed out any issues specific to a particular implementation. However, in this work we aim to provide a more fine-grained measure of deobfuscation effort, instead of a categorical classification such as *succeeded* or *failed* for each deobfuscation attack implementation, as done in [26]. Moreover, we also predict this fine-grained effort.

Anckaert et al. [2] propose applying concrete software complexity metrics on four program properties (i.e. instructions, control flow, data flow and data), to measure resilience. Similarly to our work, Anckaert et al. measure resilience of different obfuscating transformations against concrete implementations of deobfuscation attacks. However, they apply deobfuscation attacks which are specific to different obfuscating transformations, while we use a general deobfuscation attack (based on symbolic execution) on all obfuscating transformations. Moreover, they disregard the effort needed for deobfuscation and measure the effect of different obfuscating transformations on software complexity metrics and the subsequent effect of deobfuscation on these metrics. In this paper we are chiefly concerned with predicting the effort needed to run a successful deobfuscation attack.

Wu et al. [48] propose using a linear regression model over a fixed set of features, for measuring the potency of obfuscating transformations. In contrast to our work, they do not provide any evaluation of their approach. They suggest obtaining the ground truth for training and testing a linear regression model, from security experts who manually deobfuscate the obfuscated programs and indicate the effort required for each program, which is far more expensive compared to our approach of using automated attacks. We obtain our ground truth by running an automated attack and recording the effort (measured in execution time), needed to deobfuscate programs. Moreover, we also propose a way of selecting which features to use for building a regression model.

In sum, Collberg's taxonomy [15] proposes evaluating

obfuscation using four dimensions. Most of the related work focuses on simply *measuring* potency, resilience and cost. Wu et al. [48] discuss estimating potency. Zhuang and Freiling [50] propose using a naive Bayes algorithm to estimate the optimal sequence of obfuscating transformations, from a performance point of view. Kanzaki et al. [25] propose code artificiality as a measure to estimate stealth. However, there is a gap in estimating resilience, which we fill in this work.

3 Approach

Resilience is defined as a function of *deobfuscator effort*[1] and *programmer effort* (i.e. the time spent building the deobfuscator) [15]. However, in many cases we can consider the effort needed to build the deobfuscator to be negligible, because an attacker needs to invest the effort to build a deobfuscator only once and can then reuse it or share it with others. Our general approach is illustrated as a work-flow in Figure 1, where ovals depict inputs and outputs of the software tools, which are represented by rectangles. The work-flow requires a dataset of original (un-obfuscated) programs to be able to start (step 0 in Figure 1). To generate these programs we have developed a C code generator presented in Section 3.1. Afterwards, an obfuscation tool is then used to generate multiple obfuscated (protected) versions of each of the original programs (step 1 in Figure 1). Subsequently, an implementation of a deobfuscation attack (e.g. control-flow simplification [49], secret extraction [5], etc.) is executed on all of the obfuscated programs, and the time needed to successfully complete the attack for each of the obfuscated programs is recorded (step 2 in Figure 1). In parallel, feature values (e.g. source code metrics) are extracted from the obfuscated programs.

Once the *attack times* are recorded and software features are extracted from all programs, one could directly use this information to build a regression model for predicting the time needed for deobfuscation. However, some features could be irrelevant to the deobfuscation attack and/or they could be expensive to compute. Moreover, for most regression algorithms the resource usage during the training phase grows linearly or even exponentially with the number of different features used as predictors. Therefore, we add an extra step to our approach, namely a *Feature Selection Algorithm*, which selects only the subset of features which are most relevant to the attack (step 3 in Figure 1). Feature selection can be performed in many ways. Section 3.2 briefly describes how we approached feature selection. After the relevant

[1] In this paper we quantify deobfuscator effort via the time it takes to run a successful attack on a certain hardware platform; however, note that we could easily map time to CPU cycles, to provide a hardware independent measure of attack effort.

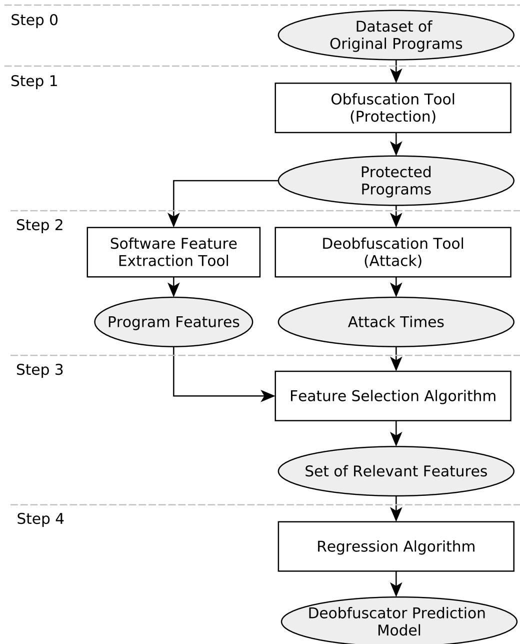

Figure 1: General attack time prediction framework.

features are selected, the framework uses this subset of features to build a regression model via a machine learning algorithm (step 4 in Figure 1).

Note that the proposed approach is not limited to obfuscation and deobfuscation. One can substitute the obfuscation tool in Figure 1, with any kind of software protection mechanism (e.g. code layout randomization [38]) and the deobfuscation tool by any known attack implementation corresponding to that software protection mechanism (e.g. ROPeme [27]). This way the set of relevant features and the output prediction model will estimate the strength of the chosen protection mechanism against the chosen attack implementation.

3.1 C Program Generator

One important challenge of the proposed approach is obtaining a dataset of unobfuscated (original) programs for the input to the framework. This dataset should be large enough to serve as a training set for the regression model in the last step of the framework, because the quality of the model depends on the training set. Ideally, we would have access to a large corpus of open source programs that contain a security check (such as a license check) that needed to be protected against discovery and tampering, as presented in [4]. For example, we could select a collection of such programs from popular code sharing sites such as GitHub. Unfortunately, open source programs tend not to contain the sorts of security checks required by our study. To mitigate this we could manu-

```
1   void f(int *in, int *out) {
2     long s[2], local1 = 0;
3     // Expansion phase
4     s[0] = in[0] + 762;
5     s[1] = in[0] | (9 << (s[0] % 16 | 1));
6     // Mixing phase
7     while (local1 < 2) {
8       s[1] |= (s[0] & 15) << 3;
9       s[(local1 + 1) % 2] = s[local1];
10      local1 += 1;
11    }
12    if (s[0] > s[1]) {
13      s[0] |= (s[1] & 31) << 3;
14    } else {
15      s[1] |= (s[0] & 15) << 3;
16    }
17    s[0] = s[1];
18    // Compression phase
19    out[0] = (s[0] << (s[1] % 8 | 1));
20  }
21  void main(int ac, char* av[]) {
22    int out;
23    f(av[1], &out);
24    if (out == 0xa199abd8)
25      printf("You win!");
26  }
```

Figure 2: Randomly generated program example.

ally insert a security check into a few carefully chosen open source programs. While this would have the advantage of using real code for the study, it does not scale for a large enough dataset. Moreover, we have noticed that in *capture the flag* (CTF) competitions, attackers always seem to locate the license checking code via pattern recognition or taint analysis [41], in order to reduce the part of the code which needs to be symbolically executed. Afterwards, they apply symbolic execution on the license checking code snippet, not on the whole executable code (e.g. built from a GitHub project), which removes the utility of using open source projects in the first place. Since we only want to focus on the second part of this attack (i.e. symbolically executing the license checking code snippet), our C program generator produces a large number of simple programs with diverse license checking algorithms, having a variety of control- and data-flows.

The code generator operates at the function level. Each generated function takes an array of primitive type (e.g. char, int) as input (i.e. `in`) and outputs another array of primitive type (i.e. `out`), as shown in Figure 2. Each function first expands the input array into a (typically larger) state array via a sequence of assignment statements containing operations (e.g. arithmetic, bitwise, etc.) involving the inputs (lines 3-5). After input expansion, the values in the state array are processed via control flow statements containing various operations on the state variables (lines 6-17). Finally, the state array is compressed into the (typically smaller) output array via assignment statements (lines 18-19). These three phases represent a generic way to map data from an input domain to an output domain, as a license check would do.

```
exp := (bb n)
     | (if exp exp)
     | (for exp)
```

Figure 3: `RandomFunsControlStructures` grammar

We implemented this approach as the `RandomFuns` transformation as part of the Tigress C Diversifier/Obfuscator [13]. This transformation offers multiple options[2] that can be tuned by the end user in order to control the set of generated programs. However, here we only provide a description of those options which have been used to generate the dataset of programs used in the experiments from Section 4, i.e.:

- `RandomFunsTypes` indicates the data type of the input, output and state arrays. The current implementation supports the following primitive types: char, short, int, long, float and double.
- `RandomFunsForBound` indicates the type of upper bound in a for loop. The possible types are: (1) a constant value, (2) a value from the input array and (3) a value from the input array modulo a constant.
- `RandomFunsOperators` indicates the allowable operators in the body of the function. Possible values include: arithmetic operators (addition `PlusA`, subtraction `MinusA`, multiplication `Mult`, division `Div` and modulo `Mod`), left shift `Shiftlt`, right shift `Shiftrt`, comparison operators (less than `Lt`, greater than `Gt`, less or equal `Le`, greater or equal `Ge`, equal `Eq`, different `Ne`) and bitwise operators (and `BAnd`, or `BOr` and xor `BXor`).
- `RandomFunsControlStructures` indicates the control structure of the function. If this option is not set, a random structure will be chosen. The value of this option is a string, which follows a simple grammar depicted in Figure 3, where (bb *n*) specifies that the structure should be a basic block with *n* statements, where *n* is an integer. Note that the branch conditions are implicit and randomly generated.
- `RandomFunsPointTest` adds an *if*-statement in the *main* function, immediately after the call to the random function (lines 24-25 in Figure 2). This if statement compares the output of the random function with a constant. If the two values are equal then "You win!" is printed on standard output, indicating that the random function was given an input which led it to execute the true branch of the *if*-statement. Few inputs of the random function take this path, hence, finding such an input is equivalent to finding a valid license key.

[2]For a full list of options and features visit the webpage of `RandomFuns` at `http://tigress.cs.arizona.edu/transformPage/docs/randomFuns`.

The reason why we chose to implement these features is that we suspect them to be relevant for the deobfuscation attack presented in [5], which is used in our case study presented in Section 4. An important limitation of the C code generator is that it does not add system calls inside the generated code. We plan to add this feature in future work.

3.2 Selecting Relevant Features

Given a set of several software features (e.g. complexity metrics), it is unclear which software features one should aim to change (by applying various obfuscating transformations), such that the resulting obfuscated program is more resilient against certain automated deobfuscation attacks. A conservative approach would be to simply use all available software features in order to build a prediction model. However, this approach does not scale for several regression algorithms, because of the large amount of hardware resources needed and also the time needed to train the model. There are several approaches for feature selection published in the literature, e.g. using genetic algorithms [8] or simulated annealing [29]. From our experiments we noticed that such feature extraction algorithms are time-consuming, i.e. even with datasets of the order of tens of thousands of entries and a few dozen features it takes weeks of computation time. We have experimented also with principal component analysis [40], however, this approach did not yield better results for our dataset. Therefore, in this section we describe a few light-weight approaches for selecting a subset of features, which are most relevant for a particular deobfuscation attack. The first approach is based on computing correlations and the second approach is based on variable importance in regression models. In Section 4 we compare these approaches by building regression models using the features selected by each approach.

3.2.1 First approach: Pearson Correlation

One intuitive way to select relevant features, first proposed by Hall [22], is by computing the Pearson correlation [39] between each of the software features and the attack time. The Pearson correlation is a value in the range $[-1,1]$. A positive value means that both the time needed for deobfuscation and the software feature tend to have the same increasing trend, while a negative value indicates that the deobfuscation time decreases as the software feature increases. If the absolute value of this correlation is in the range $[0.8,1]$ the variables are said to be *very strongly correlated*. Furthermore, the range $[0.6,0.8)$ corresponds to *strong correlation*, [0.4, 0.6) to *moderate correlation*, $[0.2,0.4)$ to *weak correlation*, and $(0,0.2)$ to *very weak correlation*. Finally, a value of 0 indicates the absence of correlation. After computing the correlation, we sort the features by their absolute correlation values in descending order and store them in a list L. The caveat in selecting the top ten features with the highest correlation is that several of those top ten features may contain couples which are highly correlated with each other. This means that we could discard one of them and still obtain about the same prediction accuracy. To avoid this issue, for each pair of highly correlated features in L, we remove the one with a lower correlation to the deobfuscation attack time. Afterwards, we select the remaining features with the highest correlations.

3.2.2 Second approach: Variable Importance

Another way of selecting relevant features from a large set of features is to first build a regression model (e.g. via random forest, support vector machines, neural networks, etc.), using all available features and record the prediction error. Concretely, we would:

1. Check the importance of each variable (i.e. feature) using the technique described in [9], i.e. add random noise by permuting values for the i-th variable and average the difference between the prediction error after randomization and before.
2. Repeat this for all $i = \{1,\ldots,n\}$, where n is the total number of variables.
3. Rank the variables according to their average difference in prediction error, i.e. the higher the prediction error, the more important the variable is for the accuracy of the regression model.

Similarly, to the previous approach based on Pearson correlation, we select those features which have the highest importance. In order to reduce over-fitting the regression model to our specific dataset, we employ 10-fold-cross-validation, i.e. the dataset is partitioned into 10 equally sized subsets, training is performed on 9 subsets and testing is performed on the remaining subset, for each combination of 9 subsets. Variable importance is averaged over all of these 10 regression models. Then the features are ranked according to their average importance, i.e. difference in prediction error when the values of that variable are permuted. This procedure is called *recursive feature elimination* [21].

4 Case-Study

This section presents a case-study in which we evaluate the approach proposed in Section 3. We are interested in answering the following research questions:

RQ1 Which features are most relevant for predicting the time needed to successfully run the symbolic-execution attack presented in [5]?

RQ2 Which regression algorithms generate models that can predict the attack effort with the lowest error?

Due to space constraints, in this paper we will focus on the deobfuscation attack based on symbolic execution presented in [5], which is equivalent to extracting a secret license key hidden inside the code of the program via obfuscation. However, in future work we plan to apply the approach proposed in Section 3, to other types of automated attacks, such as control-flow simplification [49]. Note that even for other attacks the work-flow from Figure 1 remains unchanged. However, the attack implementation and the software features will change.

4.1 Experimental Setup

All steps of the experiment were executed on a physical machine with a 64-bit version of Ubuntu 14.04, an Intel Xeon CPU having 3.5GHz frequency and 64 GB of RAM. Subsequently we describe the tools that we have used and how we have used them. The following subsections correspond to the steps from 0 to 4 in Figure 1.

4.1.1 Dataset of Original Programs

We have used the code generator described in Section 3.1 to generate a dataset of 4608 unobfuscated C programs. The following is a list of parameters and their corresponding values we used to generate this dataset:

- The random seed value: `Seed` $\in \{1,2,4\}$ (3 values).
- The data type of variables: `RandomFunsTypes` $\in$ {char, short, int, long} (4 values).
- The bounds of *for*-loops: `RandomFunsForBound` $\in$ {constant, input, boundedInput} (3 values).
- The operators allowed in expressions: `RandomFunsOperators` presented in Table 1 (4 values), which also describes each parameter value.
- The control structures: `RandomFunsControlStructures` presented in Table 2 (16 values), which also shows the depth of the control flow.
- The number of statements per basic block was changed via the value of $n \in \{1,2\}$ from Table 2.

The total number of combinations is therefore: $3 \times 4 \times 3 \times 4 \times 16 \times 2 = 4608$. All other parameters were kept to their default values, except for the `RandomFunsPointTest`, which was set to true, meaning that the return value of the randomly generated function is checked against a constant value and if they are equal the program prints a distinctive message, i.e. "You win!" to standard output. We have set this constant value to be equal to the output of the randomly generated function when its input is equal to "12345". Therefore, all of the 4608 programs will print "You win!" on the standard output if their input argument is "12345". The reason for doing this will become clear when we explain the deobfuscation attack in Section 4.1.3.

`RandomFunsOperators` **Parameter Value**	**Description**
`PlusA, MinusA, Lt, Gt, Le, Ge, Eq, Ne`	Simple arithmetic and comparison operators
`PlusA, MinusA, Mult, Div, Mod, Lt, Gt, Le, Ge, Eq, Ne`	Harder arithmetic and comparison operators
`Shiftlt, Shiftrt, BAnd, BXor, BOr, Lt, Gt, Le, Ge, Eq, Ne`	Shift, bitwise and comparison operators
`PlusA, MinusA, Mult, Div, Mod, Lt, Gt, Le, Ge, Eq, Ne, Shiftlt, Shiftrt, BAnd, BXor, BOr`	Harder arithmetic, shift, bitwise and comparison operators

Table 1: *Operator* parameter values given to C code generator used for generating dataset.

`RandomFunsControlStructures` **Parameter Value (see grammar in Figure 3)**	**Ctrl-flow depth**	**Num. of *if*-stmts**	**Num. of Loops**
(if (bb *n*) (bb *n*))	1	1	0
(if (bb *n*))(if (bb *n*))	1	2	0
(if (bb *n*))(if (bb *n*))(if (bb *n*))	1	3	0
(if (if (bb *n*) (bb *n*)) (bb *n*))	2	2	0
(if (if (bb *n*) (bb *n*)) (if (bb *n*) (bb *n*)))	2	3	0

(for (if (if (bb *n*) (bb *n*)) (if (bb *n*) (bb *n*))))	3	3	1
(for (for (if (bb *n*) (bb *n*))))	3	1	2

Table 2: *Control structure* parameter values given to C code generator used for generating dataset.

Since this set of 4608 programs might seem too homogeneous for building a regression model, we used another set of 11 non-cryptographic hash functions[3] in our experiments. Similarly to the randomly generated functions, these hash functions, process the input string passed as an argument to the program and it compares the result to a fixed value. In the case of the hash functions we print a distinctive message on standard output whenever the input argument is equal to "my_license_key". Table 3 shows the minimum, median, average and maximum values of various code metrics of only the original (un-obfuscated) set of programs, as computed by the *Unified Code Counter* (UCC) tool [37] and the total number of lines of code (LOC). Each metric was computed on the entire C file of each program, which includes the randomly generated function and the main function. Note that by summing up the metrics on the first 6 rows we obtain the total number of lines of code in our C programs. The important thing to note from Table 3 is that

these 4608 programs vary in size and complexity, as was intended, in order to capture a representative range of license checking algorithms.

To increase the number of programs in this set, we generated 275 different variants for each of the non-cryptographic hashes using combinations of multiple obfuscation transformations. The point which we aim to show here is that even if we add a small heterogeneous subset to our larger homogeneous set of programs, the smaller subset is going to be predicted with the same accuracy as the programs from the larger set. Table 4 shows the minimum, median, average and maximum values of various code metrics of only the original (un-obfuscated) non-cryptographic hash functions, as computed by the UCC tool and the total number of lines of code (LOC). Each metric was computed on the entire C file of each program, which includes the hash function and the main function, but no comment lines or empty lines.

4.1.2 Obfuscation Tool

We have used five obfuscating transformations offered by Tigress [13], in order to generate five obfuscated versions of each of the 4608 programs generated by our code generator and the 11 non-cryptographic hash functions. The obfuscating transformations we have used are:

- *Opaque predicates*: introduce branch conditions in the original code, which are either always true or always false for any possible program input. However, their truth value is difficult to learn statically.
- *Literal encoding*: replaces integer/string constants by code that generates their value dynamically.
- *Arithmetic encoding*: replaces integer arithmetic with more complex expressions, equivalent to the original ones.
- *Flattening*: replaces the entire control-flow structure by a flat structure of basic blocks, such that it is unclear which basic block follows which.
- *Virtualization*: replaces the entire code with bytecode that has the same functional semantics and an emulator which is able to interpret the bytecode.

We obfuscated each of the generated programs using these transformations with all the default settings (except for opaque predicates where we set the number of inserted predicates to 16), we obtained $5 \times 4608 = 23040$ obfuscated programs[4]. We obfuscated each of the non-cryptographic hash functions with every possible pair of these 5 obfuscation transformations and obtained $25 \times 11 = 275$ obfuscated programs.

Table 5 and Table 6 show the minimum, median, average and maximum values of various code metrics of the obfuscated set of randomly generated programs, respectively the obfuscated programs involving simple hash functions, as computed by the UCC tool. Each metric was computed on the entire C file of each program, which includes the randomly generated function, the main function and other functions generated by the obfuscating transformation which is applied. For instance, the encode literals transformation generates another function which dynamically computes the values of constants in the code using a switch statement with a branch for each constant. Due to this reason we also notice that after applying the encode literals transformation to a program, its average cyclomatic complexity (CC) is slightly reduced because this function has CC=1 and it is averaged with two other functions with higher CCs. Comparing the numbers in these two table with those from Tables 3 and 4, it is important to note that the size and complexity of the obfuscated programs have increased by one order of magnitude on average, w.r.t. un-obfuscated programs.

4.1.3 Deobfuscation Tool

Since all of the original programs print a distinctive message (i.e. “You win!”) when a particular input value is entered, we can define the deobfuscation attack goal as: *finding an input value that leads the obfuscated program to output “You win!”, without tampering with the*

[4] Tigress transforms have multiple options that affect the generated code, and makes it more or less amenable to analysis. For this study, we avoid transformations and options that would generate obfuscated code not analyzable by KLEE, which we use as our deobfuscation tool.

Code Metric	Min	Med	Avg	Max
Calculations	22.00	98.00	183.36	870.00

Table 6: Overview of obfuscated simple hash programs.

program. As presented in [4], this deobfuscation goal is equivalent to finding a hidden secret key and can be achieved by employing an automated test case generator. A state of the art approach for test case generation is called *dynamic symbolic execution* (often it is simply called symbolic execution). Such an approach is implemented by several free and open source software tools such as KLEE [10], angr [44], etc. The first step of symbolic execution is to mark a subset of program data (e.g. variables) as symbolic, which means that they can take any value in the range of its type. Afterwards, the program is interpreted and whenever a symbolic value is involved in an instruction, its range is constrained accordingly. Whenever a branch based on a symbolic value is encountered, symbolic execution forks the state of the program into two different states corresponding to each of the two possible truth values of the branch. The ranges of the symbolic variable in these two forked states are disjoint. This leads to different constraints on symbolic variables for different program paths. The symbolic execution engine sends these constraints to an SMT solver, which tries to find a concrete set of values (for the symbolic variables), which satisfy the constraints. Giving the output of the SMT solver as input to the program will lead the execution to the path corresponding to that constraint.

Since we have the C source code for the obfuscated programs, we chose to use KLEE as a test case generator in this study. We ran KLEE with a symbolic argument length of 5 characters, on all of the un-obfuscated and obfuscated programs generated by our code generator, for 10 times each. All of the symbolic executions successfully generated a test case where the input was "12345", which is the input needed to achieve the attacker goal. Similarly we ran KLEE with a symbolic argument length of 16 characters, on all of the un-obfuscated and obfuscated non-cryptographic hash functions, for 10 times each. Again the correct test cases were generated on all symbolic executions, but this time the input was "my_license_key". Note that this is only one way to attack an obfuscated program, and that it does not produce a simplified version of the obfuscated code as in [49]. Rather, it extracts a hidden license key value from the obfuscated code. We computed the mean (M) and the standard deviation (SD) of the reported times across all the 10 runs of KLEE and obtained that 83% of the programs have a relative standard deviation ($RSD = SD/M$) under 0.25 and 94% have $RSD \leq 0.50$. This means that the difference between multiple runs of KLEE on the same program is small.

4.1.4 Software Feature Extraction Tools

Many papers [32, 43, 1, 4] suggest that the complexity of branch conditions is a program characteristic with high impact on symbolic execution. However, these papers do not clearly indicate how this complexity should be measured. One way to do this is by first converting the C program into a *boolean satisfiability problem* (SAT instance), and then extracting features from this SAT instance. There are several tools that can convert a C program into a SAT instance, e.g. the C bounded model checker (CBMC) [12] or the low-level bounded model checker (LLBMC) [31], etc. However, the drawback of these tools is that the generated SAT instances may be as large as 1GBs even for programs containing under 1000 lines of code, because they are not optimized. Hence, for our dataset, the generated SAT instances would require somewhere in the order of 10TBs of data and several weeks of computational power, which is prohibitively expensive.

Instead, we took a faster alternative approach for obtaining an optimized SAT instance from a C program, which we describe next. KLEE generates a *satisfiability modulo theories* (SMT) instance for each execution path of the C program. We selected the SMT instance corresponding to the difficult execution path that prints out the distinctive message on standard output[5]. These SMT

[5]Note that it is not necessary to execute KLEE to obtain the SMT instance corresponding to the difficult execution path. The developer knows the correct license key, therefore s/he can give the correct license key and record the instruction trace of the execution. Afterwards, the developer can substitute the constant input argument in the trace, with a symbolic input and then extract the path constraint by combining all expressions in the trace. This path constraint does not need to be solved by the SMT solver, but simply converted to SAT.

instances (corresponding to the difficult path), were the most time-consuming to solve by KLEE's SMT solver, STP [19]. Many SMT solvers, including Microsoft's Z3 [18], internally convert SMT instances to SAT instances in order to solve them faster. Therefore, we modified the source code of Z3 to output the internal SAT instance, which we saved in separate files for each of the programs in our dataset. For extracting features from these SAT instances we used SATGraf [36], which computes graph metrics for SAT instances, where each node represents a variable and there is an edge between variables if they appear in the same clause. SATGraf computes features such as the number of community structures in the graph, their modularity (Q value), and also the minimum, maximum, mean and standard deviation of nodes and edges, inside and between communities. Such features have been shown to be correlated with the difficulty of solving SAT instances [35]. Therefore, since symbolic execution includes many queries to an SMT/SAT solver, as shown in [4], these features are expected to be good predictors of the time needed for a symbolic execution based deobfuscation attack. In sum, we transform the path that corresponds to a successful deobfuscation attack into a SAT instance (via an SMT instance), and then compute characteristics of this formula, to be used as features for predicting the effort of deobfuscating the program.

For computing source code features often used in software engineering, on both the original and obfuscated programs, we used the *Unified Code Counter* (UCC) tool [37]. This tool outputs a variety of code metrics including three variations of the McCabe cyclomatic complexity, their average and the number of: calculations, conditional operations, assignments, logical operations, loops at three different nesting levels, pointer operations, mathematical operations, logarithmic operations and trigonometric operations. For the programs in our dataset the last four metrics are all zeros, therefore, in our experiments we only used the other eleven metrics. Additionally, we also propose using four other program features, namely: the execution time of the program, the maximum RAM usage of the program, the compiled program file size and the type of obfuscating transformation.

In total we have 64 features out of which 49 are SAT features which characterize the complexity of the constraints on symbolic variables and 15 are program features which characterize the structure and size of the code. In the following we show that not all of these features are needed for good prediction results.

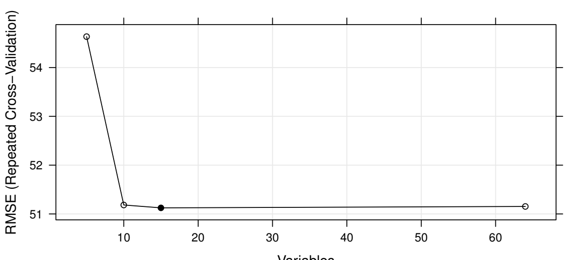

Figure 4: RF models with different feature subsets.

4.1.5 Regression Algorithms

For the purpose of regression we have used the R software environment[6] for statistical computing. R provides several software packages for regression algorithms out of which we used *e1071, randomForest, rgp* and *h2o*:

- The "e1071" package for regression via the *support vector machine* (SVM) algorithm.
- The "randomForest" package for regression via the *random forest* (RF) algorithm.
- The "rgp" package for regression via *genetic programming* (GP).
- The "h2o" package for regression via *neural networks* (NNs).

4.2 Feature Selection Results

This section presents the results for the *Feature Selection Algorithms* presented in Section 3.2. However, before selecting the most relevant features, we identify how many features (predictor variables) are needed to get good prediction results. For this purpose we performed a 10-fold-cross validation with linear and random forest (RF) regression models using all combinations of 5, 10 and 15 metrics, as well as a model with all metrics. The results in Figure 4 show that using 15 variables is enough to obtain an RF model with *root-mean-squared-error* (RMSE) values which are as good as those from RF models built using all variables. Similar results were obtained for linear models, except that the overall RMSE was higher w.r.t. that of the RF models. Therefore, in the experiments presented in the following sections, we will only select the top best 15 features in both of the two approaches described in Section 3.2.

4.2.1 First approach: Pearson Correlation

After employing the algorithm described in Section 3.2.1, we were left with a set of 25 features, with their Pearson correlation coefficients ranging from

[6] `https://www.r-project.org/`

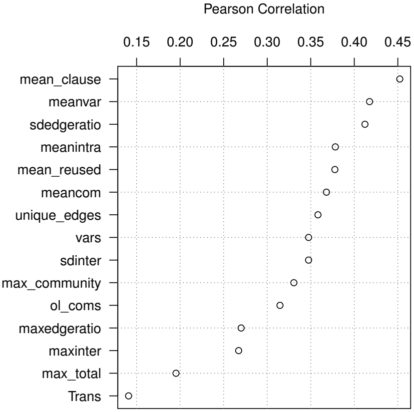

Figure 5: Top 15 features via first approach.

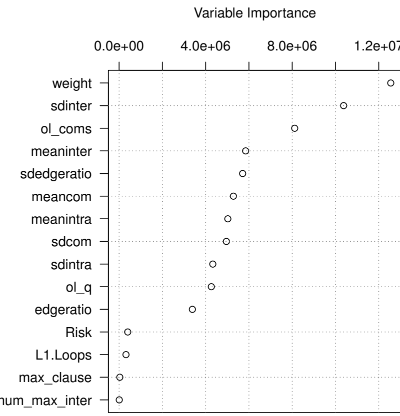

Figure 6: Top 15 features via second approach.

0.4523 to -0.0302. The top 15 metrics in this range are shown in Figure 5. The strongest Pearson correlation of the time needed for running the deobfuscation attack is with the average size of clauses in the SAT instance (*mean_clause*), followed by: the average number of times any one variable is used (*meanvar*), the standard deviation of the ratio of inter to intra community edges (*sdedgeratio*), the average number of intra community edges (*meanintra*), the average number of times a clause with the same variable (but different literals) is repeated (*mean_reused*), the average community size (*meancom*), the number of unique edges (*unique_edges*), the number of variables (*vars*), the standard deviation of the number of inter community edges (*sdinter*), the maximum number of distinct communities any one community links to (*max_community*), the number of communities detected with the online community detection algorithm (*ol_coms*), the maximum ratio of inter to intra community edges within any community (*maxedgeratio*), the maximum number of inter community edges (*maxinter*), the maximum number of edges in a community (*max_total*) and finally the type of obfuscation transformation employed.

None of the previous features are very strongly correlated to deobfuscation time. The first three features are moderately correlated, the following ten features are weakly correlated and finally the last two features are very weakly correlated. However, notice that the top fourteen features are all SAT features, and none are code metrics from the UCC tool or program features such as execution time, memory usage or file size.

4.2.2 Second approach: Variable Importance

To rank our features according to variable importance we performed recursive feature elimination via random forests, as indicated in Section 3.2.2. Figure 6 shows the top 15 features sorted by their variable importance.

The features selected using this approach are quite different from those selected in Section 4.2.1. The common features between these two approaches are: *sdinter, ol_coms, sdedgeratio, meancom* and *meanintra*. The first two common features are ranked 2nd and 3rd according to variable importance, however, the most important feature w.r.t. variable importance is the weight of the graph (*weight*), computed as the sum of positive literals minus the sum of negative literals. The 4th most important variable in Figure 6 is the average number of inter community edges (*meaninter*), followed by: *sdedgeratio, meancom, meanintra* (see descriptions of these 3 features in Section 4.2.1), the standard deviation of community sizes (*sdcom*), the standard deviation of intra community edges (*sdintra*), the modularity of the SAT graph structure (*ol_q*), the overall ratio of inter to intra community edges (*edgeratio*), the category of the McCabe cyclomatic complexity [30] (*Risk*), the number of outer-loops (*L1.Loops*), the size of the longest clause (*max_clause*) and the number of communities that have the maximum number of inter community edges (*num_max_inter*).

Similarly, to the first approach, the majority of selected features are SAT features. The only two features which are not SAT features are *Risk* and *L1.Loops* which are computed by the UCC tool. The number of loops was indeed indicated also in [4] as being an important feature. The *Risk* has four possible values depending on the value of the cyclomatic complexity (CC), i.e. low if CC $\in [1,10]$, moderate if CC $\in [11,20]$, high if CC $\in [21,50]$ and very high if CC is above 50. CC gives a measure of the complexity of the branching structure in programs (including if-statements, loops and jumps). However, it is remarkable that the CC value was ranked lower than the *Risk*.

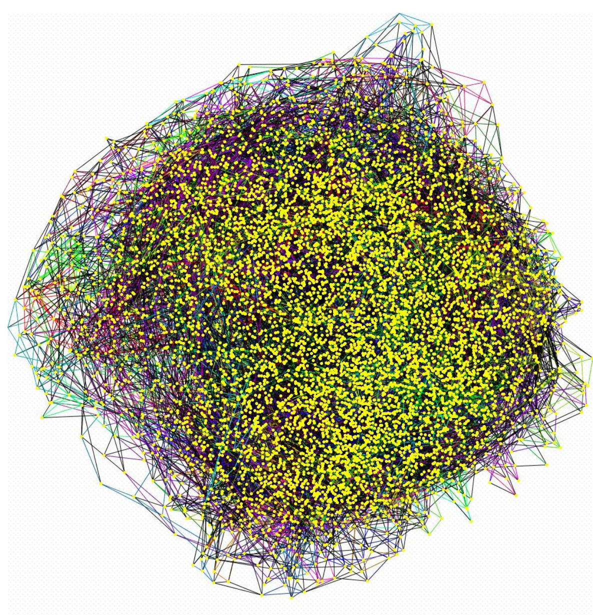

Figure 7: Graph representation of SAT instance corresponding to an MD5 hash with 27 rounds. Solving this instance takes approximately 25 seconds on our testbed.

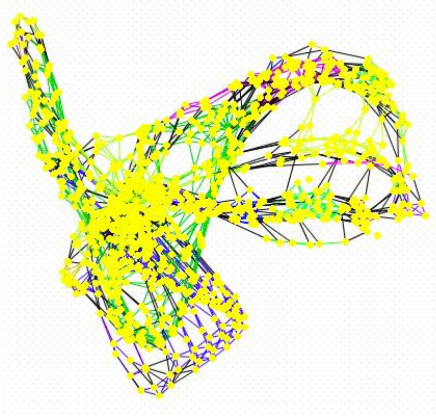

Figure 8: Graph representation of SAT instance corresponding to a program whose symbolic execution time is under 1 second.

4.2.3 Insights from Feature Selection Results

SAT features are important for symbolic execution, because most of the time of the attack is spent waiting for the SAT solver to find solutions for path constraints [4]. Taking a closer look at the common SAT features of both feature selection approaches, we can characterize those SAT instances, which are harder to solve. The graph representation of such an instance has a large number of *balanced* community structures, i.e. a similar number of intra- and inter-community edges. On the other hand, easy to solve instances tend to have *established* community structures, i.e. many more intra-community, than inter-community edges. To check this observation, we downloaded the Mironov-Zhang [32] and the Li-Ye [28] benchmark suites for SAT solvers, containing solvable versions of more realistic hash functions such as MD5 and SHA. All of these instances had *balanced* community structures. For example, Figure 7 illustrates the graph representation of the SAT instance[7] of the MD5-27-4 hash function of the Li-Ye benchmark suite[28] proposed during the 2014 SAT Competition. It is visible – from the number of yellow dots – that this graph has a high number of variables. More importantly it is also visible that one cannot easily distinguish graph community structures, because they are relatively small and well connected with other communities. This kind of structure is hard to solve, because each assignment of a variable has a large number of connections and therefore ramifications inside the graph at the time when *unit propagation* is performed by the SAT solver. However, note that if the graph is fully connected, then it is easy to solve. Therefore, there is a fine line between having too many connections and too few, where the difficulty of SAT instances increases dramatically. This last observation is similar to the *constrainedness of search* employed by Gent et al. [20], when analyzing the likelihood of finding solutions to different instances of the same search problem. This makes sense since a SAT solver is executing a search when it is trying to solve a SAT instance.

On the other hand, many of our randomly generated C programs which were fast to deobfuscate, had *established* community structures. For example, Figure 8 illustrates the graph representation of a program generated using our C code generator. This program was generated with the following parameter values:

- `RandomFunsTypes` was set to int.
- `RandomFunsForBound` was set to a constant value.
- `RandomFunsOperators` was set to `Shiftlt`, `Shiftrt`, `Lt`, `Gt`, `Le`, `Ge`, `Eq`, `Ne`, `BAnd`, `BOr` and `BXor`.
- `RandomFunsControlStructures` was set to (if (if (if (bb n) (bb n)) (if (bb n) (bb n))) (if (bb n) (bb n))).
- $n = 1$.
- `RandomFunsPointTest` was set to true.

Given these parameter values, this instance is expected to be fast to solve, because it does not involve any loops dependent on symbolic inputs and it only involves logical and bitwise operators.

[7]These graph representations were generated using the SATGraf tool [36].

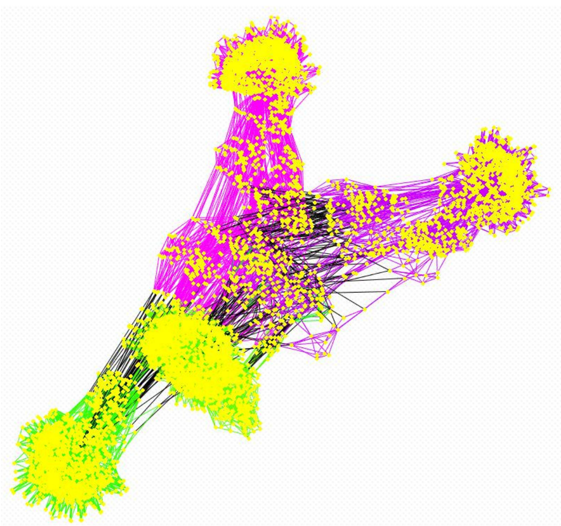

Figure 9: Graph representation of SAT instance corresponding to a non-cryptographic hash function which is solved in about 7.5 seconds.

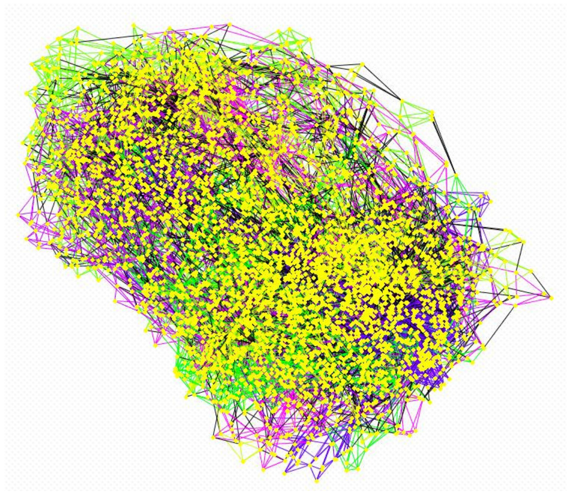

Figure 10: Graph representation of SAT instance corresponding to same non-cryptographic hash function from Figure 9, after being obfuscated with *virtualization* and subsequently control-flow *flattening*. This instance is solved in about 438 seconds.

In this context of representing SAT instances as graphs, it is interesting to note the effect of obfuscation transformations on SAT instances. For instance, Figure 9 illustrates the SAT instance of a non-obfuscated, non-cryptographic hash function from our dataset. The community structures of this hash function are *established*, hence, the instance can be solved in about 7.5 seconds. However, after applying two layers of obfuscation, first using the *virtualization* and then the *flattening*, transforms the SAT instance of this program into the one illustrated in Figure 10. This instance, has a *balanced* community structure, hence, slower to solve (438 seconds) and shares a resemblance to the MD5 instance from Figure 7. We have also noticed that the *arithmetic encoding* transformation has this effect on SAT instances. However, the *opaque predicate* and *literal encoding* alone do not have such an effect.

As a conclusion of this section we observe that balanced community structures translate to a high diffusion of the symbolic input to output bits, i.e. affecting any bit of the input license key will affect the result of the output. This is the case for collision-resistant hash functions, as well as the effect of obfuscation transformations like *virtualization*, *flattening* and *arithmetic encoding*.

4.3 Regression Results

For each of the regression algorithms presented next, we have used several different configuration parameters. Due to space limitations, we only present the configuration parameters which gave the best results. We randomly shuffled the programs in our 2 datasets of programs into one single dataset and performed 10-fold cross-validation for each experiment. To interpret the *root-mean-squared-error* (RMSE) we normalize it by the range between the fastest and slowest times needed to run the deobfuscation attack on any program from our dataset. Since our dataset contains outliers (i.e. either very high and very low deobfuscation times), the normalized RMSE (NRMSE) values are very low for all algorithms, regardless of the selected feature subsets, as shown in Table 7. This could be misinterpreted as extremely good prediction accuracy regardless of the regression algorithm and feature set. However, we provide a clearer picture of the accuracy of each regression model by computing the NRMSEs after removing 2% and 5% of outliers from both the highest and the lowest deobfuscation times in the dataset. This means that in total we remove 4%, respectively 10% of outliers. Instead of showing just the numeric values of the NRMSE for each these three cases (0%, 4% and 10% of outliers removed), we show cumulative distribution functions of the relative (normalized) error in the form of line plots, e.g. Figure 11. These line plots show the maximum and the median errors for all the three cases, where the x-axis represents the percentage of programs for which the relative error (indicated on the y-axis) is lower than the plotted value.

Note that in addition to the following regression algorithms we have also employed both linear models and generalized linear models [34]. However, the results of the models generated by these algorithms were either much worse compared to the models presented in the following, or the models did not converge after 24 hours.

	SVM	RF	GP	NN
UCC (11 features)	0.019	0.016	0.018	0.018
Pearson (15 features)	0.017	0.013	0.015	0.015
Var. Importance (15 features)	0.019	0.013	0.015	0.015

Table 7: The NRMSE between model prediction and ground truth (average over NRMSE of 10 models)

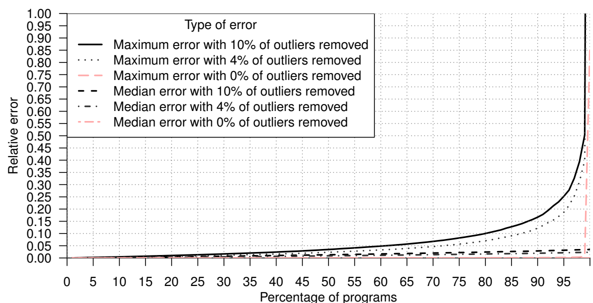

Figure 11: Relative prediction error of RF model.

4.3.1 Random Forests (RFs)

Random forests (RFs) were proposed by Breiman [9] as an extension of random feature extraction, by including the idea of "bagging", i.e. computing a mean of the prediction of all random decision trees. In our experiments we constructed a RF containing 500 decision trees.

Figure 11 shows the maximum and median relative errors for 0%, 4% and 10% of outliers removed. As more outliers are removed the relative error increases due to a decrease in the range of deobfuscation times in the dataset. However, even when 10% of outliers are removed, the maximum error is under 17% and the median error is less than 4% for 90% of the programs, which seems acceptable for most use cases.

Note that the model in Figure 11 was built using the 15 features selected via variable importance, presented in Section 4.2.2. We chose to show the results from the model built using these features because, they are better than those produced by models built using other subsets of features. As we can see from Figure 12, the relative error values when building models with UCC metrics only and with the Pearson correlation approach, give worse results in terms of both maximum and median error rates.

4.3.2 Support Vector Machines (SVMs)

Support vector machines (SVMs) were proposed by Cortes and Vapnik [16] to classify datasets having a high number of dimensions, which are not linearly separable.

Figure 13 shows the relative errors for the SVM model built using the features selected via the second approach (see Section 4.2.2). The accuracy of this model is lower than the RF model from Figure 11, i.e. the maximum relative error is just below 35% for 90% of the programs, when we remove 10% of the outliers. However, the median error is less than 7% in the same circumstances. The reason why SVM performs worse than RF is due to the bagging technique applied by RF, whereas SVM uses a single non-linear function.

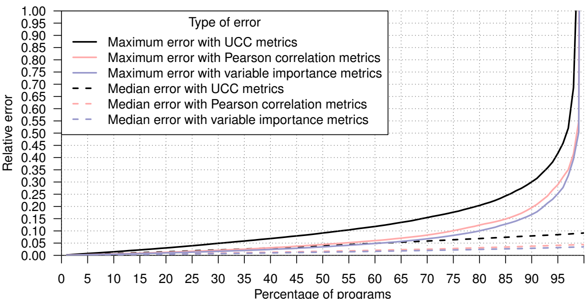

Figure 12: RF models with different feature sets.

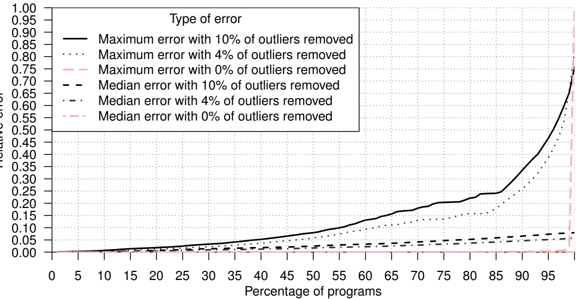

Figure 13: Relative prediction error of SVM model.

Again we chose to show the SVM model built using the features selected via variable importance in Figure 13, because, as we can see from Figure 14, the maximum and median error rates for this model are much lower than the SVM models built using only UCC metrics or the features selected via Pearson correlation. However, note that the maximum error of the model built using variable importance surpasses that of the other two models around the 90% mark on the horizontal axis. This means that for 10% of the programs the maximum error of the model built using the features selected by variable importance, is higher that the error of the other two models. However, note that the median error is around 10% lower in the same circumstances.

4.3.3 Genetic Programming (GP)

Given the set of all code features as a set of *input variables*, GP [24] searches for models that combine the input variables using a given *set of functions* used to process and combine these variables, i.e. addition, multiplication, subtraction, logarithm, sinus and tangent in our experiments. GP aims to optimize the models such that a

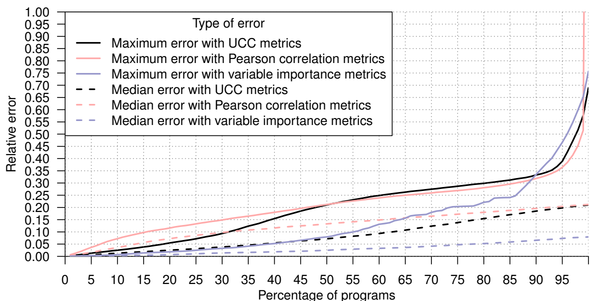

Figure 14: SVM models with different feature sets.

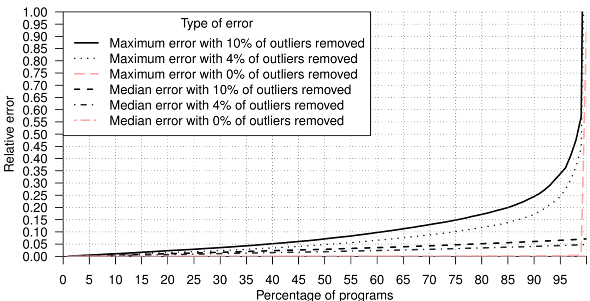

Figure 16: Relative prediction error of NN model.

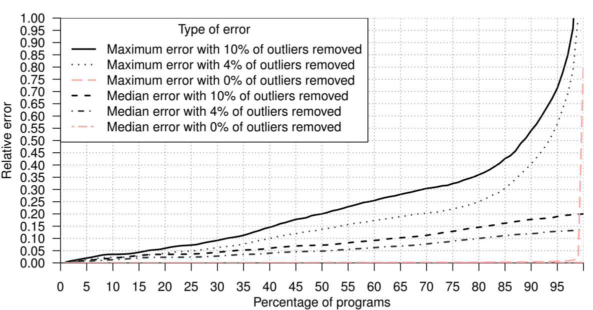

Figure 15: Relative prediction error of GP model.

given *fitness function* is minimized. For our experiments, we used the *root-mean-square error* (RMSE) between the actual time needed for deobfuscation and the time predicted by the model, as a fitness function. The output of GP is one of the generated models with the best fitness value. In our case this member is a function of the code features, which has the smallest error in predicting the time needed to execute the deobfuscation attack on every program. For instance, the best GP model built using the features selected via variable importance is presented in equation 1:

$$\begin{aligned} time = {} & (\text{edgeratio} + cos(\text{ol_coms}) \\ & + cos(cos(\text{sdcom} + \text{num_max_inter}) + \text{L1.Loops})) \\ & * (\text{sdinter} * (\text{sdedgeratio} - sin(\text{meanintra} * -1.27))) \\ & * (\text{sdedgeratio} - sin(\text{meanintra} * -1.27)) \\ & * (1.03 - sin(0.04 * \text{sdinter})) \\ & * \text{sdedgeratio} + 10.2 \end{aligned} \tag{1}$$

Note that only seven distinct features were selected by the GP algorithm for this model, from the subset of 15 features. Figure 15 shows the maximum and median error values for the GP model from equation 1. Note that the maximum and median error levels for the dataset where 10% of outliers are removed, are 55%, respectively 19% for 90% of the programs. This error rate is much higher than both RFs and SVMs and is due to the fact that the GP model is a single equation.

4.3.4 Neural Networks (NNs)

Multi-layer neural networks (NNs) were introduced by Werbos [47] in the 1970s. Recently, the interest in NNs has been revived due to the increase in computational resources available in the cloud and in graphical processing units. A neural network has three characteristics. Firstly, the *architecture* which describes the number of neuron layers, the size of each layer and connection between the neuron layers. In our experiments we used a NN with five hidden layers each containing 200 neurons. The input layer consists of the set of code features and the output of the NN is a single value that predicts the time needed to run the deobfuscation attack on a program. Secondly, the *activation function* which is applied to the weighted inputs of each neuron. This function can be as simple as a binary function, however it can also be continuous such as a Sigmoid function or a hyperbolic tangent. In our experiments we use a ramp function. Thirdly, the *learning rule* which indicates how the weights of a neuron's input connections are updated. In our experiment we used the *Nesterov Accelerated Gradient* as a learning rule.

Figure 16 shows the maximum and median error of the NN model built using all metrics. Note that in the case of NNs it is feasible to use all metrics without incurring large memory usage penalties such as is the case for SVMs. The performance of this model is better than the SVM and GP models, but not better than the RF model.

4.4 Summary of Results

Based on the results presented above, we answer the research questions elicited in the beginning of Section 4. Firstly, in Figure 4 we have seen that given our large set of 64 program features, using only 15 is enough to obtain regression models with RMSEs as low as the regression models where all the features are used. From Figures 5 and 6 we have seen that both approaches to feature selection ranked SAT features above code metrics commonly used to measure resilience, namely cyclomatic complexity or the size of the program. This means that the most

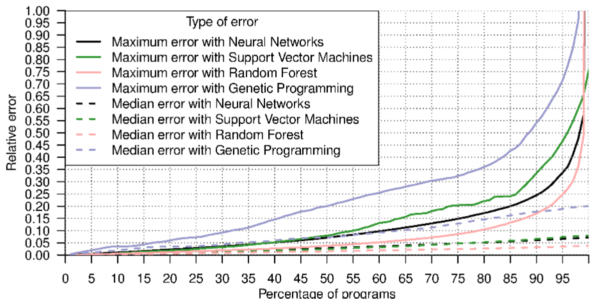

Figure 17: Comparison of regression algorithms.

important characteristics for symbolic execution based attacks is the complexity of the constraints on symbolic variables. The reason why SAT features have a higher impact on symbolic execution is that most of the time during symbolic execution is spent waiting for the SMT solver and these features indicate the time that is needed by the SMT solver to find a counter example for path constraints.

Secondly, Table 7 shows the RMSE for different regression models normalized by the fastest and slowest deobfuscation attacks in our dataset. Since our dataset contains outliers, the results from Table 7 are misleading. Therefore we removed 4% and 10% of the outliers from our dataset and plotted the cumulative distribution of the errors for each of the regression models. From Figures 12 and 14 we observe that the second approach to feature selection, based on variable importance, gives better results than the first approach, based on Pearson correlation. Therefore, in Figure 17 we plot the maximum and median errors of the models from the four different regression algorithms, where 10% of outliers are removed from the dataset. From this figure we observe that RF has the lowest overall maximum error rate, followed by NN, SVM and GP. However, the median error of the RF, NN and SVM models are all lower than 8% for all programs. This indicates that if the median error is the key performance indicator, it is much less important whether we pick RF, NN or SVM as the regression algorithm.

Another observation is that the size of the prediction models from RF models are generally smaller than those of SVM models. However, models obtained from GP and NN are one, respectively two orders of magnitude smaller than RF models. The size of SVM, RF and GP models grows proportionally to the number of features used. An advantage of NN models is their relatively small size of around 50 Kilobytes is constant for any number of features used. This is understandable because the number of weights and neurons is negligibly influenced by the number of features used to build the model.

In sum, the most relevant features for characterizing

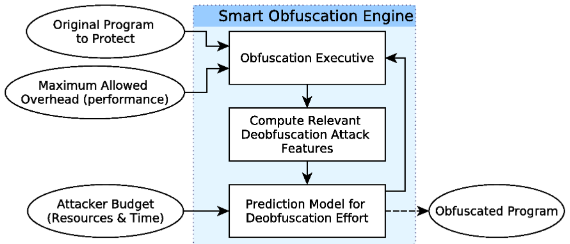

Figure 18: Combining results with obfuscation tools.

the deobfuscation attack based on symbolic execution, are SAT features (RQ1). Moreover, the regression algorithm which yields the highest prediction accuracy is random forest (RQ2).

These results can be used to build the *Smart Obfuscation Engine* (SObE) shown in Figure 18, where the ovals represent inputs and outputs. SObE takes three inputs: (1) the original program source code, (2) the maximum allowed performance overhead of the resulting obfuscated program and (3) the resource and time available to the attacker (attacker budget). SObE first gives the original program to the *Obfuscation Executive* (OE) [23] (see Section 2), which applies a set of obfuscation transformations that satisfy the maximum allowed overhead. Afterwards, SObE computes the relevant features (determined in Section 4.2) on the obfuscated program and then uses the best prediction model from Section 4.3 to estimate the effort needed by the deobfuscation attack. If the effort is less than the attacker's budget, then this is signaled to the OE and the process restarts, otherwise the obfuscated program is output.

4.5 Threats to Validity

In our case study, we have generated a dataset of unobfuscated programs of up to a few 100s of lines of code (LOC). Obfuscating these programs generates programs having up to a few 1000s of LOC. Therefore, the regression models generated in the case study may not be accurate for all possible programs. However, in our ex-

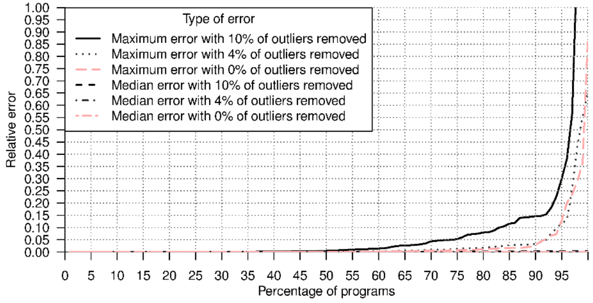

Figure 19: Relative error of hash functions only.

periments we have found that the size of the program is very weakly correlated with the time needed to run the deobfuscation attack based on symbolic execution. We show that the prediction accuracy of our best RF model (from Figure 11) is high even when including a small non-artificial dataset of programs containing non-cryptographic hash functions. Figure 19 shows the prediction error of our best RF model (trained using 10-fold-cross-validation on both datasets), for the samples in the smaller dataset alone, has similar levels to the prediction error of the entire dataset.

We also performed a reality check, i.e. we verified that the SAT features we identified are also relevant for the realistic hash functions from the Mironov-Zhang [32] and the Li-Ye [28] benchmark suites for SAT solvers. We selected the top 10 SAT metrics from Section 4.2 and trained a random forest (RF) model using the SAT instances corresponding to the C programs in our obfuscated dataset of randomly generated programs and non-cryptographic hash functions. Afterwards, we applied this RF model to a set of more realistic hash functions from the Mironov-Zhang [32] and the Li-Ye [28] benchmark suites for SAT solvers, containing solvable versions of more realistic hash functions such as MD5 and SHA. Table 8 shows the results obtained from applying the RF model to the hash functions, which were solvable by the *minisat* solver used by STP (KLEE's SMT solver), on our machine. Note that the Li-Ye [28], suite contains many other instances of MD5 with more rounds, however, those could not be solved within a 10 hour time limit on our test machine. The last column of Table 8 gives the ratio between the predicted and the actual time needed to solve each instance. Except for the *mizh-md5-47-4* and *mizh-md5-47-5* SAT instances, which are the most over- and respectively under-estimated, the rest of the predictions are quite encouraging, given that we have not trained the RF model with any such realistic SAT instances. Therefore, we obtained encouraging results with a median prediction error of 52%, which is quite remarkable given the fact that our model was not trained using these realistic instances.

Instance Name	Solver(s)	Predicted(s)	$\frac{Predicted}{Solver}$
MD5-27-4	25.37	71.56	2.82
mizh-md5-47-3	681.29	950.43	1.39
mizh-md5-47-4	235.53	1069.19	4.53
mizh-md5-47-5	1832.96	437.98	0.23
mizh-md5-48-2	445.19	523.70	1.17
mizh-md5-48-5	227.05	644.38	2.83
mizh-sha0-35-2	330.48	158.57	0.47
mizh-sha0-35-3	139.93	213.03	1.52
mizh-sha0-35-4	97.62	214.61	2.19
mizh-sha0-35-5	164.71	193.49	1.17
mizh-sha0-36-2	85.44	222.07	2.59

5 Conclusions

This paper presents a general approach towards building prediction models that can estimate the effort needed by an automated deobfuscation attack. We evaluated our approach using a dataset of programs produced by our C code generator. For programs that our generated dataset is representative, features such as the complexity of path constraints (measured via SAT features), are more important than cyclomatic complexity, size of the program, number of conditional operations, etc. With a median error of 4% our best model can accurately predict the time it takes to deobfuscate a program using a symbolic execution based attack, for programs in our dataset. Moreover, we have also obtained encouraging results with realistic hash functions such as MD5 and SHA instances used in SAT competitions.

Note however, that our framework is not specific to symbolic execution and can be used for other attacks, other programs and other obfuscators. Finally, we compared different regression algorithms both in terms of prediction error and memory consumption and conclude that the choice of regression algorithm is less important than the choice of features when it comes to predicting the effort needed by the attack. However, we obtained the lowest maximum error using a random forest model, built with features selected using variable importance. In terms of memory usage genetic algorithms and neural networks have a lower memory footprint, however their training times may be much higher.

In future work we plan to use datasets consisting of real-world programs, additional obfuscation tools and deobfuscation attacks. We believe that obtaining representative datasets of programs would also be of paramount importance for benchmarking both new and existing obfuscation and deobfuscation techniques. Therefore, we believe this area of research needs much more work, since it could be a driving factor for the field of software protection.

Another avenue for future work is to employ other machine learning techniques in order to derive better prediction models for deobfuscation attacks. An interesting idea in this direction is deriving attack resilience features using deep neural networks. However, such a task would also require a set of representative un-obfuscated programs, which stresses the importance of future work in this direction.

6 Acknowledgments

The authors would like to thank the anonymous reviewers, Prof. Vijay Ganesh and Zack Newsham for the feedback regarding the SATGraf tool and tips for converting SMT instances into SAT instances. This work was partially supported by NSF grants 1525820 and 1318955.

7 Availability

Our code generator is part of the Tigress C Diversifier/Obfuscator tool. Binaries are freely available at:

`http://tigress.cs.arizona.edu/transformPage/docs/randomFuns`

Source code is available to researchers on request. Our dataset of original (unobfuscated) programs, as well as all scripts and auxiliary software used to run our experiments, are available at:

`https://github.com/tum-i22/obfuscation-benchmarks/`

Extension Breakdown: Security Analysis of Browsers Extension Resources Control Policies

Abstract

All major web browsers support browser extensions to add new features and extend their functionalities. Nevertheless, browser extensions have been the target of several attacks due to their tight relation with the browser environment. As a consequence, extensions have been abused in the past for malicious tasks such as private information gathering, browsing history retrieval, or passwords theft — leading to a number of severe targeted attacks.

Even though no protection techniques existed in the past to secure extensions, all browsers now implement defensive countermeasures that, in theory, protect extensions and their resources from third party access. In this paper, we present two attacks that bypass these control techniques in *every* major browser family, enabling enumeration attacks against the list of installed extensions. In particular, we present a timing side-channel attack against the *access control settings* and an attack that takes advantage of poor programming practice, affecting a large number of Safari extensions. Due to the harmful nature of our findings, we also discuss possible countermeasures against our own attacks and reported our findings and countermeasures to the different actors involved. We believe that our study can help secure current implementations and help developers to avoid similar attacks in the future.

1 Introduction

Browser extensions are the most popular technique currently available to extend the functionalities of modern web browsers. Extensions exist for most of the browser families, including major web browsers such as Firefox, Chrome, Safari, and Opera. They can be easily downloaded and installed by users from a central repository (such as the Chrome Web Store [15] or the Firefox Add Ons [26]).

Unfortunately, extensions are also prone to misuse. In fact, due to their close relationship to the browser environment, they can be abused by an adversary in order to gather a wide range of private information — such as cookies, browsing history, system-level data, or even user passwords [7]. Due to this raising concern, the amount of research studying the security implications and vulnerabilities of browser extensions has rapidly increased in the last years [3, 4, 8, 10, 18, 21, 25].

When browser extensions were first introduced, websites were able to access all their local resources. As a consequence, malicious actors started to use that freely-accessible data to enumerate the extensions a user has installed in her system, or even to exploit vulnerabilities within installed extensions [23]. To mitigate this increasing threat, Firefox introduced the `contentaccessible` flag and Chrome a new manifest version [16] to implement some form of access control over the extension resources. In the rest of the paper we will refer to these security measures as *access control settings*. Developers of Safari decided to adopt a different mechanism, which consists in randomizing at runtime part of the extension URI [2]. We will refer to this second class of protection technique as *URI randomization*.

Information of the web browser has been used for a number of malicious or "questionable" purposes. For example, *Panopticlick* [12] creates a unique browser fingerprint using the installed fonts, among other features. *PluginDetect* [14] retrieves instead the list of plugins installed in the browser. Even worse, this technique has recently been used in two reported *fingerprinting-driven malware* campaigns [33, 37].

Thanks to the existing browser security countermeasures described above, so far extensions were protected against these fingerprinting techniques. Two very simple enumeration attacks were recently proposed to retrieve a small number of installed extensions in the browsers that adopted access control settings [6, 20]. These techniques

took advantage of accessible resources of the extensions present in Chrome and Firefox to identify a small number of popular extensions. In addition, XHOUND [34] was also recently proposed to enumerate extensions and perform fingerprinting, by measuring the changes in the DOM of the website.

In this paper we present the first in-depth security study of all the extensions resource control policies used by modern browsers. Our analysis show that **all browsers families** that currently support extensions are vulnerable to some form of enumeration attack. In particular, while the two design choices (i.e., access control settings or URI randomization) are both secure from a theoretical point of view, their practical implementation suffers from many different problems.

We discuss two offensive techniques to subvert these control policies, one based on a timing side-channel attack and one based on an involuntary leakage of the random URI token that affects many extensions. At the time of writing, these attacks undermine the extension security of all browsers. We also discuss a set of attacks based on these techniques, which allow third-parties to perform precise user fingerprinting, or to perform various types of targeted attacks, performing proof-of-concept tests of some of them.

We already reported the discovered problems to the involved browsers and extensions developers and we are currently discussing with them about possible fixes.

In summary, this paper makes the following contributions:

- We propose the first time-based extension enumeration attack that can retrieve the complete list of extensions installed in browsers that use access control settings. This method largely outperforms any previous extension fingerprinting methodology presented to date.

- We design a static analysis tool for Safari extensions, and use it to flag hundreds of potentially vulnerable cases in which the developers leaked the random extension URI. Through an exhaustive manual code analysis on a subset of the extensions, we confirm that this is indeed a very widespread problem affecting a large fraction of all Safari extensions.

- We show that browsers extension resources control policies are very difficult to properly design and implement, and they are prone to subtle errors that undermine their security. Our research led to numerous discussions with the developers of all major browsers and extensions, including the ones vulnerable to our attacks and the ones that are still in the design or testing phase. As a result, our study is helping to secure all browsers against these common errors.

The remainder of this paper is organized as follows. §2 provides the background on extension control methods. §3 describes the problems and two different attacks to subvert them. §4 describes the impact of the problems in a broad set of scenarios. We then discuss possible countermeasures and summarize the outcome of our research in §5. Finally, §6 discusses related work and §7 concludes the paper.

2 Background

All browsers that support extensions implement some form of protection to prevent arbitrary websites from enumerating the installed extensions and freely accessing their resources. After an extensive survey of several traditional and mobile browser families, we identified two main classes of protection mechanisms currently in use: *access control settings* (§2.1), and *URI randomization* (§2.2).

2.1 Access Control Settings

The most popular approach to protect extension resources from unauthorized accesses consists in letting the extensions themselves specify which resources they need to be kept private and which can be made publicly available. All browsers that adopt this solution rely on a set of configuration options included in a manifest file that is shipped with each extension. For security reasons, by default all the resources are considered private. However, developers can specify in the manifest a list of accessible resources.

This solution is currently used by all browsers based on Chromium, all the ones based on Firefox and Microsoft Edge.

Chromium family

The Chromium family includes all versions of Chromium (such as Google Chrome), and all browsers based on the Chromium engine (e.g., Opera, Comodo Dragon, and the Yandex browser).

Extensions in this family are written using a combination of HTML, CSS, and JavaScript [17]. They are not required to use any form of native code, as it is instead the case for plugins or other forms of browser extensions. Each Chromium extension includes a JSON file called `manifest.json` that defines a set of properties such as the extension name, description, and version number (see Figure 1 for an example of manifest). The

```

  "https://ajax.googleapis.com/"],

"web_accessible_resources": [
  "images/*.png",
  "style/double-rainbow.css",
  "script/double-rainbow.js",
  "script/main.js",
  "templates/*"], ...
```

Figure 1: Snippet of a Chrome Extension `manifest.json` file.

manifest is used by the browser to know the functionality offered by the extension and the permissions required to perform those actions [16].

In the first version of the manifest, there was no restriction over the resources of the extensions accessible from third-party websites. Because of that, different tools were released to take advantage of this weakness to enumerate user extensions and exploit their vulnerabilities [23]. To mitigate this threat, Google decided to introduce dedicated access control settings in the second version of the manifest file. This extension uses a parameter (`web_accessible_resources`) to specify the paths of packaged resources that can be used in the context of a website. Resources are available through the URL `chrome-extension://[extID]/[path]`. However, any navigation access to an extension or its resources is blocked by the browser, unless the extension resource has been previously listed as accessible in its `manifest.json`. This solution was explicitly designed to minimize the attack surface while protecting users' privacy.

Firefox family

Firefox family extensions (or Add-ons, as they are called in the Mozilla jargon) can add new functions to the web browser, change its behavior, extend the GUI, or interact with the content of websites. Add-ons have access to a powerful API called XPCOM [30], that enables the use of several built-in services and applications through the XPConnect interface. In the Firefox family (which includes for example Firefox Mobile, Iceweasel and Pale Moon), extensions are written in a combination of JavaScript and XML User Interface Language (XUL). Extensions are also allowed to use functionality from third-party binaries or create their own binary components. Recently, Mozilla changed its extension development framework, introducing the Add-on SDK of the JetPack project [28]. This development kit provides a high-level API, easing the development process and addressing some of the security issues of previous Firefox extensions.

The registration and allocation of the different extensions is performed through the *Chrome Registry* [27] which is also in charge of customizing user interface elements of the application window that are not in the windows content area (such as toolbars, menu bars, progress bars, or windows title bars). Each extension contains a `chrome.manifest` file that specifies options related to three main categories — content, locale, and skin — as exemplified in the following snippet:

```
content  ext                    src/content/
skin     ext  classic           src/skin/
locale   ext  en-US             src/locale/en-US/
content  pck  chrome/ext/pck contentaccessible=yes
```

As it was the case for Chromium extensions, originally there was no control performed to prevent external websites from accessing the different resources of an extension. And also in this case, developers decided to solve the problem by including a new option in the `chrome.manifest` (called `contentaccessible` and depicted in the last line of the previous example) that specifies which resources can be publicly shared. However, resources have a restricted access by default, unless `contentaccessible=yes` is specified in the manifest.

Firefox is now developing a new way of handling Add-ons called WebExtensions [29]. This technology is designed mainly for cross-browser compatibility, supporting the extension API of Chromium. Porting extensions between the two platforms will require few changes in the code of the Add-on. The new extensions will also use a `manifest.json`, including some extra data specific for Firefox (see Figure 2). In order to access the different resources of the extension, Firefox will use the `moz-extension://` schema.

As WebExtensions are currently in an early stage we are not including them in our tests, but we notified their developers and we will discuss more about them in §5.

Microsoft Edge

Edge will be the first Microsoft browser to fully support extensions. It will follow a Chrome-compatible extension model based on HTML, JavaScript and CSS. This means that the migration process to Microsoft Edge for

```
"applications": {
  "gecko": {
    "id": "{the-addon-id}",
    "strict_min_version": "40.0.0",
    "strict_max_version": "50.*"
    "update_url": "https://foo/bar"
  }
} ...
```

Figure 2: Snippet of a Firefox WebExtension manifest's new data.

Chrome extension developers will require minimal effort.

Beside the general web APIs, a special extension API will provide a deeper integration with the browser, making possible to access features such as tab and window manipulation. The manifest will be named `manifest.json` and will use the same JSON-formatted structure and general properties of the Chromium implementation. The URL to access the extension resources follows the `ms-browser-extension://[extID]/[path]` schema.

As the design is in its preliminary stages and it is not yet fully working, we are not including it in our analysis.

2.2 URI Randomization

As Safari was one of the last major browsers to adopt extensions, its developers implemented a resource control from the beginning to avoid enumeration or vulnerability exploitations of installed extensions. Instead of relying on settings included in a manifest file like all the other major browsers, Apple developers adopted a URI randomization approach. In this solution there is no distinction between private or public resources, but instead the base URI of the extension is randomly re-generated in each session.

Safari extensions are coded using a combination of HTML, CSS, and JavaScript. To interact with the web browser and the page content, a JavaScript API is provided and each extension runs within its own "sandbox" [1]. To develop an extension, a developer has to provide: (i) the global HTML page code, (ii) the content (HTML, CSS, JavaScript media), (iii) the menu items (label and images), (iv) the code of the injected scripts, (v) the stylesheets, and (vi) the required icons.

These components are grouped into two categories: the first including the global page and the menu items, and the second including the content, and the injected scripts and stylesheets. This second group cannot access any resource within the extension folder using relative URLs as the first group does. Instead, these extension components are required to use JavaScript

```
1 <script type = "text/javascript">
2 var myImage = safari.extension.baseURI +
3 "Images/paper.jpg";
4 document.body.style.cssText =
5 "background-image: url(" +myImage+ ")";
6 </script>
```

Figure 3: Example of background image load in CSS using absolute URLs in Safari extension.

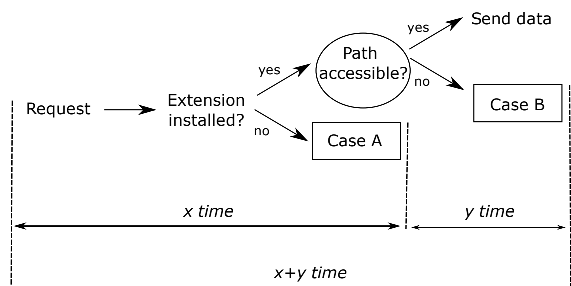

Figure 4: Resource accessibility control schema.

to access the randomized URI that changes each time Safari is launched. Absolute URIs are stored in the `safari.extension.baseURI` field, as shown in Figure 3.

3 Security Analysis

In the previous section we presented the two complementary approaches adopted by all major browser families to protect the access to extension resources. The first solution relies on a public resource URI, whose access is protected by a centralized code in the browser according to settings specified by the extension developers in a manifest file. The second solution replaces the centralized check by randomizing the base URI at every execution. In this case, the extension needs to access its own resources by using a dedicated Javascript API.

While their design is completely different, both solutions provide the same security guarantees, preventing an attacker from enumerating the installed extensions and accessing their resources. We now examine those two approaches in more detail and discuss two severe limitations that often undermine their security. It is important to note that these attacks can also be used in any type of device with a browser with extension capability, such as smartphones or smartTVs.

3.1 Timing Side-Channel on Access Control Settings Validation

As already mentioned, the vast majority of browsers adopt a centralized method to prevent third parties from

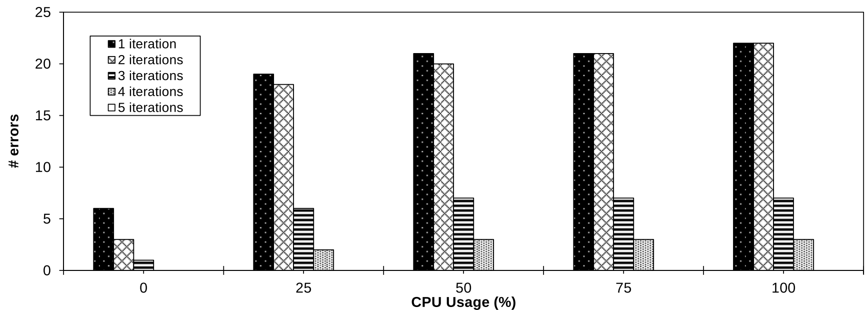

Figure 5: Comparison between number of iterations and errors with different CPU usages (%), .

accessing any resource of the extensions that have not been explicitly marked as public. Therefore, when a website tries to load a resource not present in the list of accessible resources, the browser will block the request. Despite the fact that, from a design point of view, this solution may seem secure, we discovered that all their implementations suffer from a serious problem that derives from the fact that these browsers are required to perform two different checks: (i) to verify if a certain extension is installed and (ii) to access their control settings to identify if the requested resource is publicly available (see Figure 4 for a simple logic workflow for the enforcement process). When this two-step validation is not properly implemented, it is prone to a timing side-channel attack that an adversary can use to identify the actual reasons behind a request denial: the extension is not present or its resources are kept private. To this end, we used the *User Timing API*[1], implemented in every major browser, in order to measure the performance of web applications.

As an example, an attacker can code few lines of Javascript to measure the response time when invoking a fake extension (refer to case A in Figure 4). For instance, in Chromium the requested URI could look like this:

```
chrome-extension://[fakeExtID]/[fakePath]
```

Then, the attacker can generate a second request to measure the response time when requesting an extension that actually exists, but using a non-existent resource path (case B in Figure 4):

```
chrome-extension://[realExtID]/[fakePath]
```

By comparing the two timestamps, the attacker can easily determine whether an extension is installed or not in the browser. Similar response times mean that the central validation code followed the same execution path on the two requests and, therefore, the extension is not installed in the browser. Otherwise, significantly different execution times mean that only the second test failed and, therefore, that the requested extension is present in the browser.

[1] https://www.w3.org/TR/user-timing/

We performed an experiment in order to empirically tune the time difference threshold and the number of correct requests required to ensure the correctness of our attack. In particular, the following configuration was used:

- We configured 5 different CPU usages: 0%, 25%, 50%, 75%, and 100%. The experiment was executed on a 2.4GHz Intel Core 2 Duo with 4 GB RAM commodity computer.
- The attack was configured to be repeated from 1 to 10 iterations. Note that each iteration performs two calls to the browser: one that asks for the fake extension and one that asks for the actual extension with a fake path.
- We repeated each attack testing 500 times to avoid any bias. In this way, we performed: 2 calls $\times$ 10 iteration configurations $\times$ 500 times $\times$ 5 CPU usages, resulting in a total number of 275,000 calls.

We observed that, when the execution paths were different, the response times differed by more than 5%. It is important to remark that our method exploits the proportional timing difference between two different calls rather than using a pre-computed time for a specific device. Figure 5 shows the precision across different CPU loads and different numbers of iterations. Five iterations were sufficient enough to achieve a 100% success rate even under a 100% CPU usage.

Affected Browsers

We tested our timing side-channel attack on the two browser families (Chromium-based and Firefox-based) that use extensions access control settings.

Table 1: Percentage extension detected by previous methods.

	Chrome	Firefox	Total
# Extensions Tested	10,620	10,620	21,240
% Previous Approaches	12.73%	8.17%	10.45%
% Our Approach	*100.00%*	*100.00%*	*100.00%*

Our experiments confirm that all versions of Chromium are affected by this vulnerability. Browsers such as Chrome, Opera, the browser of Yandex (largest search engine in Russia) and the browser of Comodo (largest issuer of SSL certificates) are included in this group. As aforementioned, we are not including Edge and Firefox WebExtensions because they are still in early stages of development. However, as they follow the same extension control mechanism as Chromium, they are also likely to be vulnerable to our timing side-channel attack.

Surprisingly, non-WebExtensions in Firefox suffer from a different bug that makes even easier to detect the installed extensions. The browser raises an exception if a webpage requests a resource for non-installed extension (case A in Figure 4), but not in the case when the resource path does not exist (case B in Figure 4). While the exception does not cause any visible effect in the page, an attacker can simply encapsulate the invocation in a `try-catch` block to distinguish between the two execution paths and reliably test for the presence of a given extension.

Extensions Enumeration

By telling apart the two centralized checks that are part of the extension settings validation (either because of the side-channel or because of the different exception behaviors), it is possible to completely enumerate all the installed extensions. It is sufficient for an attacker to simply probe in a loop all existing extensions to precisely enumerate the ones installed in the system.

In comparison, previous bypassing techniques [6, 20] were only able to detect a small subset of the existing extensions. In order to precisely assess the accuracy improvement over these previous techniques, we conducted an experiment on a set of 21,240 extensions. For this test, we decided to focus on the two browsers with the highest number of available extensions: Chrome and Firefox (Opera also has its own extension store, but the number of popular extensions is very low compared with the other browsers). In the case of Chrome, extensions are divided in three different groups: extensions, apps, and games. Although one of the groups is explicitly called extensions, all of them are installed as a `chrome-extension` and follow the same access control settings model.

At the time of writing, the number of recommended extensions in the games category (the smallest of the three) was 3,540. To keep a balanced dataset, we therefore selected also the top 3,540 of the remaining two categories, resulting in a balanced dataset of the 10,620 most recommended extensions.

For Firefox, the selection process was easier because its store makes no distinction among different categories. Therefore, we selected the 10,620 most popular Firefox extensions to keep our complete dataset equally balanced between the two browsers.

To measure the coverage of previous bypassing methods and compare it with the full coverage of our bypass technique, we combined the methods described in [6,20]. These methods are, to the best of our knowledge, the only ones that exist capable of enumerating extensions by subverting access control settings. These methods are based on checking the existence of externally accessible resources in extensions. To test them, we analyzed the manifest files of all extensions we downloaded, looking for any accessible resources.

Table 1 shows the obtained coverage using previous methods. Chrome extensions were easier to enumerate than the ones in the Firefox store. However, the coverage of these old methods is very low compared to the full coverage achieved by our method.

3.2 URI Leakage

Even if URI randomization control is completely centralized, it strongly depends on developers to keep resources away from any third-party access. In fact, extensions are often used to inject additional content, controls, or simply alert panels into a website. This newly generated content can unintentionally leak the random extension URI, thus bypassing the security control measures and opening access to all the extension resources to any other code running in the same page. In addition, the leaked random URI may be used by third-parties to unequivocally identify the user while browsing during the same session.

A simple example taken from the Web of Trust[2] extension is shown in Figure 6. The code snippet creates a new `iframe` (line #11), sets its `src` attribute to the `baseURI` random address of the extension (line #14), and adds the frame to the document body (line #19). As a result, any other JavaScript code running in the same page (and therefore potentially under control of an attacker) can retrieve the address of the injected `iframe` and use it to access any resource of the extension. In fact, once the random token is known, the browser offers no other

[2] `https://www.mywot.com/`

```
1  wot.rating = {
2  toggleframe: function(id, file, style){
3   try {
4     var frame = document.getElementById(
          id);
5     if (frame) {
6      frame.parentNode.removeChild(frame);
7      return true;
8     } else {
9      var body = document.
           getElementsByTagName("body");
10     if (body && body.length) {
11      frame = document.createElement("
            iframe");
12      if (frame) {
13       frame.src = safari.extension.
             baseURI+file;
14       frame.setAttribute("id", id);
15       frame.setAttribute("style", style)
            ;
16       if (body[0].appendChild(frame))
17        {return true;}
18      }
19     }
20    }
21   } catch (e) {
22     console.log("failed with"+e+"\n");}
23   return false;
24  }
```

Figure 6: Web Of Trust Safari extension function that creates an iframe in the website with the baseURI random variable as source.

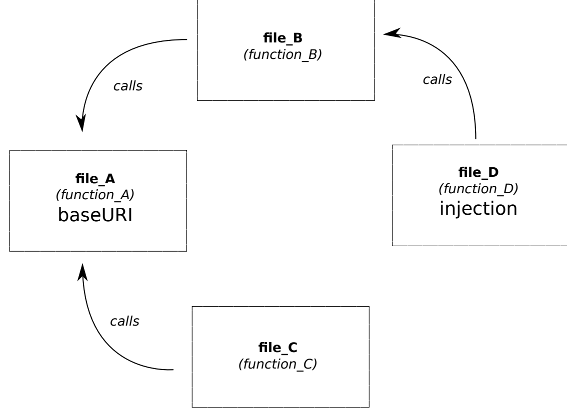

Figure 7: Simplified example schema of an extension that leaks the baseURI.

security mechanism to protect the access to an extension resources.

While this may seem like a simple bug in the extension development, our experiments show that it is instead a very widespread phenomenon. The entire security of the extension access control in Safari relies on the secrecy of the randomly generated token. However, the token is part of the extension URI which is often used by the extensions to reference public resources injected in the page. As a result, we believe that this design choice makes it very easy for developers to unintentionally leak the secret token.

Estimating the Scale of the Problem

The Web-of-Trust example discussed above consists of a single function of 30 lines of code, but not all the cases are so obvious to identify without a complex static analysis of the extension.

To estimate how prevalent the problem is, we implemented a prototype analyzer that reports candidate cases of URI leakage in all Safari extensions. Our tool is based on Esprima[3] to perform a static analysis based on the Abstract Syntax Trees (ASTs) of all the different JavaScript components of the extension under analysis. Source and sinks are located by just looking for the specific code in the nodes of the tree, while the information flow is computed by following the different pieces of code that actually have access to the data along the different execution paths. In particular, the analysis is performed in three steps:

1. In the first step, the tool identifies the *source* locations where the code accesses the random extension URI (looking for calls to the baseURI method).

2. The tool then separately analyzes all the components that can use the retrieved value. Following the information flow (i.e., functions that are are called or are calling), this process is performed recursively until no more connections are found.

3. For every identified components, the tool locates the *sinks*, i.e., the location where new content is injected in the webpage (e.g., through the createElement and appendChild methods). If there is a connection between the baseURI access and the injection of an element in the website, the extension is flagged as suspicious and reported for further analysis.

The schema in Figure 7 shows a simplified example of an extension that leaks the baseURI using function_A of file_A to obtain the value, function_B of file_B as an intermediate phase, and function_D of file_D to finally make the injection on the website.

This technique is designed to act as a screening filter and NOT as a precise detection method. Indeed, the fact that an extension retrieves the baseURI and then uses it to create some content is not sufficient to identify if the full information is actually leaked. For instance, we

[3] https://github.com/jquery/esprima

Table 2: Percentage of potential baseURI leakage in safari extensions.

Category	# Total Ext.	# P. Leak

found an extension that used the `baseURI` to retrieve its version number and then injected an `iframe` with the version number included directly as part of its URL, but without leaking the complete `baseURI`.

To evaluate our tool, we downloaded and analyzed all the available extensions within the Safari Extension Gallery[4]. The 718 extensions belonged to 15 different categories (e.g., security, shopping, news, social networking, and search tools).

Table 2 shows the obtained results. In general, more than 40% of the Safari Extension Gallery were potentially vulnerable to our enumeration technique. We decided to manually analyze some of the results to determine whether the reported extensions actually performed the leak or not. Since the security category is among the ones with the highest percentage of extensions with a potential leak and it is also particularly sensitive due to the type of information these extensions usually deal with (such as user passwords), we decided to manually verify all the results for the extensions in this category.

With a considerable effort, we performed an exhaustive manual code review of all the security extensions, selecting those that were completely functional, excluding the ones that required payment for their services. Among the 68 extensions in this group, 29 were flagged as suspicious of making the leakage and 39 were not leaking it. From the suspicious ones, 20 out of 29 actually leaked the secret `baseURI`. In addition, we only identified one false negative that leaked the information but was not identified by our static analysis tool. In particular, this extension obtained the complete `URL`, including `baseURI`, but stored it locally. Within the extensions that are vulnerable to our attack, we found popular protection extensions such as Adblock[5], Ghostery[6], Web Of Trust[7], and Adguard[8]. The list also includes password managers, such as LastPass[9], Dashline[10], Keeper[11], and TeedyID[12] and combinations of the two functionalities (e.g., Blur from Abine[13]).

In summary, a relevant number of Safari extensions are vulnerable to our technique, including several important and very popular security-related extensions. As explained in §5, we are now in the process of validating all the results and contacting the developers of the affected extensions to fix their code.

4 Impact

In the previous section we discussed the security of access control settings and URI randomization, and we showed how every mechanism adopted by current browsers can be easily bypassed in practice. There are several possible consequences of abusing the information provided by our two techniques.

4.1 Fingerprinting & Analytics

The most accurate and controversial form of fingerprinting aims at building a unique identifier for each user device, such as *Panopticlick* [12]. It is considered a *stateless* technique, because in order to build and share the unique identifier, these techniques do not require to store anything on the user machine (in contrast with *stateful* techniques such as *Cookies*). To build a unique identifier, several features are retrieved from the user's machine and combined in a unique fingerprint. This process can be repeated across multiple websites and the identifier will always be the same for the same machine, allowing trackers to determine users' browsing history, among other tasks. Using the set of installed extensions can increase the uniqueness of the resulting fingerprint. To measure the exact fingerprinting ability of extension enumerations, a study should be performed to measure the discriminatory power of the most popular extensions available for each browser. To this end, we have conducted a preliminary study of this type of analysis in §4.3.

The techniques proposed in this paper can also be used to perform a completely accurate browser finger-

printing without checking the `User-Agent`. To this end, our method can be used to check for **built-in extensions**. These extensions are pre-installed and present in nearly every major web browser and there is no possibility for the user to uninstall them. Therefore, if we configure our techniques to check one of these built-in extensions that does not exist in other browsers, a website can precisely identify the browser family with 100% accuracy.

The installed extensions enumeration combined with the aforementioned browser identification can be used to determine users' demographics. The extensions that a particular user utilizes can be easily discovered by websites or third-party services. Installed extensions provide information about a particular user's interests, concerns, and browsing habits. For example, users with security and privacy extensions installed in their browsers such as *Ghostery* or *PrivacyBadger* are potentially more aware about their privacy than other users. The same happens with personalizing extensions, games, or any possible combinations of other extensions categories. In order to measure the feasibility of performing analytics through extensions, we have conducted a proof-concept test described in §4.3.

4.2 Malicious Applications

The information retrieved from the installed extensions can also be used for malicious purposes, as the information gathering phase about potential victims is usually the first step to perform a targeted attack. For instance, attackers can inject the extension enumeration code in a compromised website and search for users with shopping management extensions and password managers to narrow down their attack surface to only those users whose credit card information has a higher likelihood to be stolen. Another possibility would be to identify the presence of a major antivirus vendor extension to personalize an exploit kit or to decide whether the malicious payload should be delivered or not to a certain user.

In addition to the attacks already presented, in a recent work, Buyukkayhan et al. [7] presented *CrossFire*, a technique that allows attacker to perform malicious actions using legitimate extensions. The part that was left unanswered by the paper is how the attacker can identify a set of installed extensions to use for her purpose. By using our enumeration technique, an attacker can create completely functional malicious extensions by knowing all installed victim's extensions in beforehand.

Due to the variability of possible extensions, the information of a particular user can be exploited in different social-driven attacks (automated or not). For example, a malicious website can exploit the information about particular extensions being installed to impersonate and fake legitimate messages about that extensions, with the intention of deceiving the user and leading her to install malicious software. As an example, if a malicious website discovers that the user is using a concrete password management extension, it can create a fake window to ask the user to re-type her password. This attack is particularly severe in the case of Safari, since the attacker can actually access all the resources of an extension that leaks its `baseURI`. Hence, even a careful user who decides to analyze the website source cannot easily understand if a certain window or frame is created by an installed extension or by the site reusing the extension resources.

Table 3: Top 10 most Popular Extension Categories in the Chrome Store.

Category	% Usage
productivity	29.90
fun	10.45
communication	9.76
web development	7.74
accessibility	4.65
search tools	4.44
shopping	3.46
photos	3.12
news	2.40
sports	1.80

While the URI randomization control bypass does not provide a complete enumeration capability, when an extension leaks its random token it opens all its internal resources to the attacker. This is potentially very harmful as it increases the attack surface, allowing the attacker to access and exploit any vulnerability in one of the internal extension components. For example, Kotowicz and Osborn [23] presented a Chrome extension exploitation framework[14] that could be used when it was still possible to access all the different extension resources.

4.3 Viability Study

We have studied the viability of the estimated impact for several of the cases discussed before. In particular, we have analyzed their potential for performing analytics as well as the fingerprinting capability of extensions. We have omitted the malicious case studies due to their inherent ethical concerns. In addition, we believe that their implementations are more straightforward than in the proof-of-concept cases we tested and evaluated.

Analytics

In the case of the analytics capability of extensions, we have computed the popularity of the different categories

[14] `https://github.com/koto/xsschef`

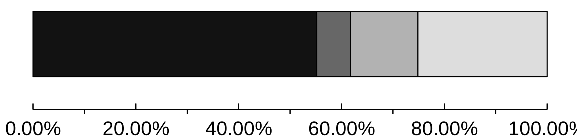

Figure 8: Distribution of anonymity set sizes regarding extensions.

established in the Chrome Web Store for each of the extensions that we previously analyzed in §3.1. In particular, we analyzed the 63 categories present in the 10,620 most popular Chrome extensions (Table 3 shows the 10 most popular categories).

The most popular category was "productivity" with 29.90% usage. Nevertheless, the definition of this category is not clear because it includes a wide-range of types of extensions such as ad blockers, schedulers, or office-related tools. Anyhow, a possible sub-categorization may be possible by means of the available description of each extension. The rest of the 10 most popular are more precise and may be helpful in order to perform analytics related tasks such as targeted advertisement or website personalization. For instance, the number of visitors with "shopping", "web development", or "sports" extensions, may help the website owner to personalize her content or ads accordingly, thus improving her number of visitors or ad revenues.

However, not only the most popular extensions may help the website owner to get a better understanding of her visitors and act accordingly. Indeed, less popular extensions, because their higher power of discrimination among users, can also be used for this task. For example, the usage of extensions from the "creative tools" category indicates that the visitor is prone to create content, the presence of extensions within "academic resources" category would likely indicate that the visitor is near the academic environment, "teacher tools" may imply that the visitor deliver at least some lectures, and "blogging" implies that the visitor is a blogger.

In summary, we believe that extensions are a powerful tool to perform fine-grained user analytics because of their diversity. Moreover, the information derived from the installed extensions of a web visitor, combined with the classical analytics information may lead to a better user analytics for website owners.

Device Fingerprinting

In order to understand and measure the capability of extensions for device fingerprinting, we implemented a page that checks the users' installed extensions among the top 1,000 most popular from the Chrome Web Store and the Add-ons Firefox websites, using the timing side-channel extension enumeration attack described in §3.1. Since our study involved the enumeration of several users' installed extensions, we informed the users about the procedure including the information gathered. Only after the user agrees to perform the experiment and share the collected information, the enumeration of her extensions is conducted. We also set a cookie on the user browser to prevent multiple resubmissions from the same user. In addition, to protect the user privacy, we only collected anonymous data.

Table 4: Comparison between Extensions with other Fingerprinting Attributes.

Method	**Entropy**
Extensions	0.869
List of Plugins	0.718
List of Fonts	0.548
User Agent	0.550
Canvas	0.475
Content Language	0.344
Screen Resolution	0.263

We disseminate the URL of the page through social networks and friends, asking them to participate in the study and further re-disseminate the link among their contacts. This way we collected the list of installed extensions from 204 participants from 16 different countries. Even though this number is smaller than in previous studies, we would like to remark that fingerprinting is not the actual goal of the paper but just a possible application of our attacks. In fact, this analysis is simply designed to determine the viability of our technique for device fingerprinting, either as a method by itself or by complementing other existing fingerprinting techniques.

Following the standard adopted in previous works [12, 24], we analyzed the extension anonymity sets of the fingerprinted users, which is defined as the number of users with the same fingerprint i.e., same extension set (the distribution of anonymity sets is shown in Figure 8). Overall, from the 204 users that participated in our study, 116 users presented a unique set of installed extensions, which means that 56.86% of the participants are uniquely identifiable just by using their set of extensions.

In addition, we also compare the discriminatory level of this proof-of-concept fingerprinting technique by computing its normalized Shannon Entropy [24] and comparing it with other fingerprinting attributes proposed in previous studies. In particular, Table 4 compares the different entropy values of the top six fingerprinting methods or attributes measured in the work by Laperdrix et al. [24] with our extensions-based fingerprinting method. We can notice that extensions pre-

sented the highest entropy of the analyzed fingerprinting attributes — making them more precise than using the list of fonts or canvas-based techniques.

5 Vulnerability Disclosure and Countermeasures

5.1 Attack Coverage & Effects

In this paper we presented two different classes of attacks against the resource control policies adopted by all families of browsers on the market. Table 5 summarizes the overall impact of our methods.

As already mentioned, the coverage of our enumeration attack is complete in the case of the timing side-channel attack to access-control-based browser families (i.e., Chromium and Firefox Families) while approximately around 40% in URL randomization browsers (Safari).

Effects of Private Mode

"Incognito" or private mode is present in most of the modern browsers and it protects and restricts several accesses to the browser resources such as cookies or browsing history. Therefore, we decided to analyze if our attacks can enumerate extensions even when this mode is activated.

We discovered that all of our attacks accurately identified the list of installed extensions also within the private mode. This fact is due to several reasons. In the case of Chromium family browser, the browser checks for extensions in incognito mode, even though extensions are not allowed to access the websites [9]. Firefox and Safari did not include any check for extensions and, therefore, both websites and extensions are able to access each other.

5.2 Timing Side-Channel Attack

The first class of attacks is the consequence of a poor implementation of the browser access control settings: Firefox-family browsers usage of extensions can be exploited to recognize the reason behind a failed resolution, and Chromium family timing-side channel allows an attacker to precisely tell apart the two individual checks performed by the browser engine.

The consequence, in both cases, is a perfect technique to enumerate all the extensions installed by the user. Given the open-source nature of these two browsers, we manually identified the functions responsible of the problem and indicated how to fix each of them.

Chromium family

We contacted the Chromium team to report the timing problem. The developers were quite surprised about the attack, because they believed that the time differences in

the checking phase were not significant enough to allow this type of timing side-channel attack. By inspecting the function responsible of checking the accessibility of a concrete extension path (see Figure 10), the two different steps described in section 3 can be clearly identified. First, the browser tests the existence of the extension (line #4) and finishes if the extension does not exist. If the extension does exist, it performs different checks to make sure that the path is accessible, returning a error message if it is not. These checks are the ones that permit the timing difference exploited in the attack.

We suggested a possible way to fix the code to avoid the time measurement by modifying the extension control mechanism to combine the internal extension verification and the resource check together in a single atomic operation (i.e., by modifying the extension existence check of line #4). This requires to replace the extension list with a hashtable containing the extensions and the full path of their resources.

While it may seem simple to fix the problem by making the check atomic, the problem remains if the attack is performed with real extension paths (easily obtainable) instead of fake paths. The timing difference would be the same as the one presented in Figure 4, with the only difference that the first check would validate the full path and not just the extension. At the time of writing, as it is a design-related problem, it is still not fixed.

In addition, as the new Firefox WebExtensions and Microsoft Edge (both currently in their early stages) use the same extension control mechanisms proposed by Chromium, we also notified their developers to make them aware of the issue described in this paper. We hope that our effort will help these two new versions to integrate by-design the necessary countermeasures to avoid these security problems since the beginning.

Firefox family

We also responsibly reported the Firefox non-WebExtensions problem that makes our enumeration attack possible to its developers, who acknowledged the issue and are currently discussing how to proceed. Specifically, Figure 9 show the function that causes the response difference regarding the extension existence.

The error returned when the resource path does not exist (line #4 and line #12 in Figure 9) does not raise any exception. Therefore, the solution is straightforward: return a `NS_ERROR_DOM_BAD_URI` error (i.e., the same one that is thrown when extension is not installed). This fix will not cause any issue to websites using extension paths, maintaining the functionality intact.

Regarding WebExtensions, the Firefox developers recently changed the way extensions are accessed in order to solve the timing side-channel and other related attacks. In particular, they changed the initial scheme (`moz-extension://[extID]/[path]`) to `moz-extension://[random-UUID]/[path]`. Unfortunately, while this change makes indeed more difficult to enumerate user extensions, it introduces a far more dangerous problem. In fact, the `random-UUID` token can now be used to precisely fingerprint users if it is leaked by an extensions. A website can retrieve this UUID and use it to uniquely identify the user, as once it is generated the random ID never changes. We reported this design-related bug to Firefox developers as well.

5.3 URI Leakage

The second class of attacks presented in the paper is quite different. In fact, the method that Safari's extension control employs to assure the proper accessibility of resources is, in principle, correct. However, Safari delegates to the extension developers the responsibility to keep the random URI secret. We believe that this is a very risky decision because most of the developers lack a proper understanding of the problem. As a consequence, our experiments confirm that a relevant number (40% in our preliminary experiments) of the extensions are likely to leak the `baseURI`, undermining the entire security solution. In particular, we discovered that important security extensions such as multiple password managers or advertisement blockers suffer from this `baseURI` leakage vulnerability and, hence, they are vulnerable to this attack. In the case of security extensions, this is particularly worrying due to the type of information they manage is usually very sensitive.

In this case the problem is even harder to solve, because it is not a consequence of an error in the extension control but of hundreds of errors spread over different extensions. Reaching out and training all the extension developers is a difficult task but Apple should provide more information on the proper way to handle the `baseURI` and about the security implications of this process.

In addition, we believe that Safari could benefit from adopting a lightweight static analysis solution (similar to the one we discuss in §3) to analyze the extensions in their market and flag those that leak the random token. This would allow to immediately identify potentially leaking extensions that may need a more accurate manual verification. In the meantime, we started reporting the problem to some security extensions we already manually confirmed, to help them solve their URI leakage problem.

5.4 Extension Security Proposal

In order to improve the security and privacy of browser extensions, we propose a solution that solves all the dif-

ferent problems presented in this paper.

1. All browsers should follow an extension schema that includes a random generated value in the URL: `X-extension://[randomValue]/[path]`. This random value should be modified across and during the same session and should be independent for each extension installed. For example, the browser should change it in every extension in every access. In this way, the random value cannot be used to fingerprint users.

2. Browsers should also implement an access control (such as `web_accessible_resource`) to avoid any undesirable access to all extensions resources even when the random value is unintentionally leaked.

3. Extensions should be analyzed for possible leakages before making them public to the users. Moreover, developer manuals should specifically discuss the problems that can cause the leakage of any random value generated.

6 Related Work

Security of Browser Extensions

The research community has made a large number of contributions analyzing the security properties of browsers extensions. A number of recent studies have focused on monitoring the runtime execution of browser extensions. Louw et al. [35, 36] proposed an integrity checker and a policy enforcement for Firefox legacy extensions. A more recent framework, Sentinel [31, 32], provided a fine-grained control to the users over legacy extensions, allowing them to define custom security policies while blocking common attacks to these extensions.

Other approaches have focused on providing security analysis of browsers extensions in order to discover security flaws. On the static analysis side, IBEX [18] is a framework to analyze security properties by means of a static methodology and it also allows developers to create a fine-grained access control and data-flow policies. VEX [3] is instead a static analyzer for Firefox JavaScript extensions that applies information flow analysis to identify browser extension vulnerabilities.

Dynamic extensions analysis includes the work of Djeric et al. [11], in which the authors proposed the use of dynamic analysis to track data inside the browser and detect malicious extensions. Dhawan et al. [10] proposed a similar approach to detect extensions that compromised the browser environment. In a similar vein, Wang et al. [39] used an instrumented browser to analyze Firefox Extensions. Hulk [21] is a dynamic analysis framework that controlled the activity of the browsing extensions, employing fuzzing techniques and HoneyPages adapted to the extensions. Hulk was used to analyze more than 48,000 Chrome extensions, discovering several malicious ones.

Despite the fact that these approaches are useful to detect malicious or compromised extensions, they are unfortunately useless against external attacks or information leakages. Our analysis has lead to the most complete set of attacks against resource accessibility control and `baseURI` randomization, allowing in both cases extension enumeration attacks that can be used as part of larger threats.

Similar to our own work, XHOUND [34] recently showed that the changes extensions perform on the DOM are enough to enumerate extensions. Using this technique, the authors also developed a new device fingerprinting technique and measured its impact. However, this approach has a much more limited applicability. In comparison, our techniques achieve a larger coverage, successfully enumerating 100% of the extensions for *access control* browsers and around 40% for those using *URI randomization*.

Web Timing Attacks

Web Timing attacks have been used for many different purposes, both in the client side and server side. Felten and Schneider [13] introduced this type of attacks as a tool to compromise users' private data and, specifically, their web-browsing history. In this way, a malicious attacker might obtain this information by leveraging the different forms of web browser cache techniques. By measuring the time needed to access certain data from an unrelated website, the researchers could determine if that specific data was cached or not, indicating a previous access.

Later, Bortz et al. [5] organized timing attacks in two different types of attacks: (i) direct timing, consisting in measuring the time difference in HTTP requests to websites and (ii) cross-site timing, which allows to obtain data from the client-side. The first type could expose website data that may be used to prove the validity of a username in certain secure website. The second type of attacks follow the same line of work of previous work by Felten and Schneider. They also performed some experiments that suggested that these timing vulnerabilities were more common than expected. In addition, Kotcher et al. [22] discovered that besides from the attacks previous discussed, the usage of CSS filters made possible the revelation of sensitive information such as text tokens exploiting time differences to render various DOM trees.

Two recent studies show that these attacks are far from being solved. Jia et al. [19] analyzed the possibility of determining the geo-locations of users thanks

to the customization of services performed by websites. Location-sensitive content is cached the same way as any other content. Therefore, a malicious actor can determine the victim's location by checking this concrete data and without relying in any other technique. Besides, Van Goethem et al. [38] proposed new timing techniques based on estimating the size of cross-origin resources. Since the measurement starts after the resources are downloaded, it does not suffer from unfavorable network conditions. The study also shows that these attacks could be used in various platforms, increasing the attack surface and the number of potential victims.

However, none of these timing techniques have been previously used to identify components of the web browser itself. Our new timing side-channel attacks are the first attacks capable of determining with 100% accuracy which extensions are installed in the browser, independently of the CPU usage.

7 Conclusions

Many different threats against the users security and privacy can benefit from a precise fingerprint of the extensions installed in the browser.

In this paper, we show that the current countermeasures adopted by all browser families are insufficient or erroneously implemented. In particular, we present a novel time side-channel attack against the access control settings used by the Chromium browser family. This technique is capable of correctly identifying any installed extension. Firefox WebExtensions and Microsoft Edge (early states) follow the same API and design, indicating that they may be prone to be vulnerable to the attack.

We also discuss a URI leakage technique that subverts the URI randomization mechanism implemented in Safari, that emerges from inappropriate extension implementations that leak the value of a random token. We implemented a new method to identify extensions with this potential leakage and we found out that up to 40% of Safari extensions could be vulnerable to this problem. After a manual inspection of security-related extensions, we discovered that many popular extensions are vulnerable to this attack. In addition, in the case of this attack, not only the extension is identified but also its resources can be accessed, posing as a more dangerous threat.

We also presented applications for our extension enumeration attacks. First, we propose different fingerprinting and user analytics techniques, demonstrating their feasibility in a real-world scenario. Second, we also proposed technique to use our enumeration techniques for malicious applications such as targeted malware, social engineering, or vulnerable extension exploitation.

We responsibly disclosed all our findings and we are now discussing with the developers of several browsers and extensions to propose the correct countermeasures to mitigate these attacks in both current and future versions.

CCSP: Controlled Relaxation of Content Security Policies by Runtime Policy Composition

Stefano Calzavara, Alvise Rabitti and Michele Bugliesi
Università Ca' Foscari Venezia

Abstract

Content Security Policy (CSP) is a W3C standard designed to prevent and mitigate the impact of content injection vulnerabilities on websites by means of browser-enforced security policies. Though CSP is gaining a lot of popularity in the wild, previous research questioned one of its key design choices, namely the use of static white-lists to define legitimate content inclusions. In this paper we present Compositional CSP (CCSP), an extension of CSP based on runtime policy composition. CCSP is designed to overcome the limitations arising from the use of static white-lists, while avoiding a major overhaul of CSP and the logic underlying policy writing. We perform an extensive evaluation of the design of CCSP by focusing on the general security guarantees it provides, its backward compatibility and its deployment cost. We then assess the potential impact of CCSP on the web and we implement a prototype of our proposal, which we test on major websites. In the end, we conclude that the deployment of CCSP can be done with limited efforts and would lead to significant benefits for the large majority of the websites.

1 Introduction

Content Security Policy (CSP) is a W3C standard introduced to prevent and mitigate the impact of content injection vulnerabilities on websites [11]. It is currently supported by all modern commercial web browsers and deployed on a number of popular websites, which justified a recently growing interest by the research community [20, 5, 13, 1, 18, 10].

A content security policy is a list of directives supplied in the HTTP headers of a web page, specifying browser-enforced restrictions on content inclusion. Roughly, the directives associate different content types to lists of sources (web origins) from which the CSP-protected web page can load contents of that specific type. For instance, the following policy:

```
script-src  https://example.com;
img-src     *;
default-src 'none'
```

specifies these restrictions: scripts can only be loaded from `https://example.com`, images can be loaded from any web origin, and contents of different type, e.g., stylesheets, cannot be included. Moreover, CSP prevents by default the execution of inline scripts and bans a few dangerous JavaScript functions, like `eval`; these restrictions can be explicitly deactivated by policy writers to simplify deployment, although they are critical for the security of CSP.

Simple as it looks, however, CSP is typically hard to deploy correctly on real websites [19, 20, 1, 18] and there are several, diverse reasons for this:

1. an effective content security policy must not relax the default restrictions which forbid inline scripts and `eval`-like functions. However, removing inline scripts from existing websites proved to require a significant effort [19, 20], hence relaxing the default restrictions of CSP is a common routine even for major websites [18, 1];

2. white-lists are hard to get right. On the one hand, if a white-list is too liberal, it can open the way to security breaches by allowing the communication with JSONP endpoints or the inclusion of libraries for symbolic execution, which would enable the injection of arbitrary malicious scripts [18]. On the other hand, if a white-list is too restrictive, it can break the intended functionality of the protected web page [1]. The right equilibrium is difficult to achieve, most notably because it is hard for policy writers to predict what needs to be included by active contents (scripts, stylesheets, etc.) loaded by their web pages;

3. many web contents have a dynamic nature, which is not easily accommodated by means of the static white-lists available in CSP. For instance, writing appropriate content security policies may be hard when using CDNs for load balancing, when including advertisement libraries based on real-time bidding, or in presence of HTTP redirects [20, 1].

The industry was relatively quick in realizing that the pervasive presence of inline scripts is a serious obstacle to the widespread adoption of CSP and more recent versions of the standard introduced controlled mechanisms based on hashes and nonces to white-list individual inline scripts [15]. This is an interesting approach to deal with the first problem we mentioned: by selectively enabling only a few known inline scripts, web developers can significantly improve the security of their websites against script injection, while avoiding a major overhaul of their code base by moving inline scripts to external files.

However, the other two problems which hinder a wider and more effective deployment of CSP are still largely unsolved, since they both stem from the inherent complexity of accurately predicting the capabilities dynamically needed by real, content-rich web applications. The recent *Strict* CSP proposal [4] based on CSP Level 3 [16] may help in dealing with these challenges in some practical cases, but unfortunately it only provides a very partial solution to them (see Section 2 for a discussion).

1.1 Goals and Contributions

The goal of the present paper is proposing a simple extension of CSP which naturally and elegantly solves the delicate issues discussed above. The most important design goal of our proposal is to avoid both a major overhaul of the existing CSP specification and a dramatic change to the logic behind policy writing, so as to simplify its practical adoption by web developers who are already familiar with CSP.

Our proposal builds on the pragmatic observation that static white-lists are inherently complex to write down for modern web applications and do not really fit the dynamic nature of common web interactions, so we devise Compositional CSP (CCSP), an extension of CSP based on *runtime policy composition*. In CCSP an initial, simple content security policy is incrementally relaxed via the interactions between the protected page and its content providers. More precisely, content providers can loosen up the policy of the protected page to accommodate behaviours which were not originally admitted by the latter, although the protected page reserves itself the last word on its security by specifying suitable upper bounds for policy relaxation. Notably, by introducing a dynamic dimension to CSP and by delegating part of the policy specification efforts to the content providers, it is possible to come up with white-lists which are much more precise than those which could be realistically written by the developers of the protected page alone, since they often lack an in-depth understanding of the externally included contents and their dependencies.

Concretely, we make the following contributions:

1. we provide a precise specification of CCSP and we discuss two realistic use cases which may benefit from this extension of the CSP standard. We show CCSP policies for these use cases and we discuss how the enforcement model of CCSP supports desirable security guarantees (Section 3);

2. we perform an extensive evaluation of the design of CCSP by focusing on the general security guarantees it provides, its backward compatibility and its deployment cost (Section 4);

3. we assess the potential impact of CCSP in the wild by building and analysing a dataset of CSP violations found on the Alexa Top 100k websites. Specifically, we show that violations are pervasive and mostly caused by behaviours which are hard to accommodate in CSP, which confirms the need for a more expressive mechanism like CCSP. We also establish that only a few selected players need to embrace CCSP to provide a significant benefit to the majority of the websites (Section 5);

4. we develop a proof-of-concept implementation of CCSP as a Chromium extension and we test it by manually writing CCSP policies for a few popular websites which normally trigger CSP violations. Our experiments show that CCSP is easy to deploy and fully supports the intended functionality of the tested websites (Section 6).

2 Motivations

2.1 Example

Consider a web page *w* including the following script tag in its HTML contents:

```
<script src="https://a.com/stats.js"/>
```

The `stats.js` script, in turn, is implemented as follows:

```
// load dependency.js from https://b.com
var s = document.createElement('script');
s.src = 'https://b.com/dependency.js';
document.head.appendChild(s);
...
// load banner.jpg from https://c.com
var i = document.createElement('img');
i.src = 'https://c.com/banner.jpg';
document.body.appendChild(i);
```

This script includes another script from `https://b.com` and an image from `https://c.com` and all these contents must be allowed by the content security policy of *w* to let the web page work correctly.

CSP 1.0 and CSP Level 2. Both CSP 1.0 [14] and CSP Level 2 [15] restrict the inclusion of external contents purely by means of a white-listing approach. This means that the content security policy of *w* must not only white-list `https://a.com` as a valid source for script inclusion to load `stats.js`, but it must also white-list all the dependencies of `stats.js` with their correct type. An appropriate content security policy for *w* would thus be:

```
script-src https://a.com https://b.com;
img-src    https://c.com
```

This approach has two significant problems. First, the definition of the policy is complex, since it requires one to carefully identify all the dependencies of the scripts included by *w*, including those recursively loaded, like `dependency.js`. Second, the policy above is brittle: if the developers of `stats.js` or `dependency.js` change the implementation of their scripts, for instance to include additional libraries from other sources, the policy of *w* must correspondingly be updated to white-list them.

In principle, these limitations pay off in terms of security, since the developers of *w* have full control on which contents can be included by scripts loaded by their page. Unfortunately, previous research showed that web developers typically write an overly liberal white-list to avoid issues with their websites, for instance by allowing the inclusion of scripts from any domain [20, 1, 18].

CSP Level 3 (Strict CSP). Recently, the CSP community realized that the white-list approach advocated by CSP 1.0 and CSP Level 2 is often inconvenient to use, because it may be hard to write white-lists which are neither too liberal, nor too restrictive. The latest version of the standard, called CSP Level 3 [16], thus added new mechanisms which support a different policy specification style, known as *Strict* CSP [4]. Strict CSP drives away from the complexities of white-lists and simplifies the process of recursive script inclusion by transitively propagating trust. Concretely, the example web page *w* must be changed to bind a randomly generated *nonce* to its script tag as follows:

```
<script src="https://a.com/stats.js"
        nonce="ab3f5k"/>
```

Correspondingly, its content security policy is adapted as follows:

```
script-src 'nonce-ab3f5k' 'strict-dynamic';
img-src     https://c.com
```

Under this policy, only those scripts whose tag includes the nonce `ab3f5k` are allowed to be loaded, irrespective of the web origin where they are hosted. Since the nonce value is random and unpredictable, an attacker cannot inject malicious scripts with a valid nonce on *w*. Since nonce-checking may break benign scripts which are dynamically inserted without a valid nonce, the `'strict-dynamic'` source expression is included in the policy: this ensures that any script request triggered by a non-parser-inserted script element like `stats.js` is also allowed by CSP [16].

Besides making policy specification simpler, nonces also make the resulting policies stronger against script injection attacks. Since a valid nonce is only bound to the script tag loading `https://a.com/stats.js`, other dangerous contents hosted on `https://a.com` cannot be unexpectedly loaded and abused by an attacker. Moreover, the use of `'strict-dynamic'` simplifies the definition of policies when recursive script inclusion is needed. In our example, the script `dependency.js` can be relocated from `https://b.com` to `https://d.com` without any need of updating the content security policy of *w*. Also, both `stats.js` and `dependency.js` can include new libraries without violating the policy of *w*, again thanks to the presence of `'strict-dynamic'`.

2.2 Criticisms to Strict CSP

Limited Scope. The `'strict-dynamic'` source expression only targets the problem of recursive script inclusion, but it does not solve similar issues for other content types. In our example, if the script `stats.js` is updated to load its image from `https://d.com` rather than from `https://c.com`, or if the script is left unchanged but the image is relocated to `https://d.com` by means of a HTTP redirect, the content security policy of *w* must also be updated to ensure a correct rendering of the website. This means that the developers of *w* must change their content security policy to deal with something which is unpredictable and not under their control.

Generalizing `'strict-dynamic'` to deal with these cases would have a negative "snowball effect" on the effectiveness of CSP, since basically all the content restrictions put in place by the policy would need to be ignored.

Poor Granularity. The `'strict-dynamic'` source expression uniformly applies to all the scripts loaded by a web page, thus offering an all-or-nothing relaxation mechanism. We believe there are two sound motivations underlying this design: ease of policy specification and the fact that the main security goal of Strict CSP is protecting against XSS. The key observation justifying the design of `'strict-dynamic'` is that, if a script loaded by a web page is malicious, it can already attack the page,

without any need of abusing 'strict-dynamic' to load other malicious scripts from external domains.

However, it is worth noticing that the design of 'strict-dynamic' does not support the *principle of least privilege*, since it gives all scripts with a valid nonce the ability of putting arbitrary relaxations on script inclusion, even though not every script requires this capability. As a matter of fact, most scripts included in a trusted website are not actually malicious, but they may have bugs or be developed by programmers who are not security experts, and there is no way for a benign script to declare that it only needs limited policy relaxation capabilities to perform its intended functionalities, thus limiting the room for unintended harmful behaviours.

Use of Nonces. Nonces are a convenient specification tool, but they also have severe drawbacks. First, the security of nonces is questionable: it is now recognized that the protection offered by their use can be sidestepped, most notably because nonces are still included in the DOM. This leaves room for attacks, for instance when script injection happens in the scope of a valid nonce[1] or when nonces are exfiltrated by means of *scriptless* attacks[2]; also other attacks have been found recently[3].

Moreover, the use of nonces makes the security review of a page deploying CSP much harder to carry out: one cannot just inspect the content security policy of the page to understand which security restrictions are put in place, but she must also check the code of the page to detect which scripts are bound to a valid nonce. (In fact, the use of nonces makes particularly troublesome to compare the permissiveness of two content security policies, which instead is a fundamental building block of the upcoming CSP Embedded Enforcement mechanism [17].) Finally, nonces are not easily assigned to dynamically generated script tags in legacy code: 'strict-dynamic' is just one way to circumvent this issue, but it comes with the limitations we previously discussed.

Discussion. Strict CSP provides significant improvements over CSP 1.0 and CSP Level 2 in terms of both security and ease of deployment, and there is pragmatic evidence about the effectiveness of 'strict-dynamic' at major websites [18]. Nevertheless, we discussed practical cases where 'strict-dynamic' is not expressive enough to fix CSP violations and web developers still need to account for these behaviors by means of extensive white-listing. This complicates policy specification and maintenance, because policy changes may be dictated by elements which are not under the direct control of the policy writers, such as script dependencies and HTTP redirects. We confirm the existence of these expressiveness issues of Strict CSP in the wild in Section 5.

CCSP complements Strict CSP with more flexible tools for policy specification, while supporting the principle of least privilege and removing security-relevant information from the page body, thus simplifying policy auditing and preventing subtle security bypasses. Moreover, its design is backward compatible to ensure a seamless integration with the existing CSP deployment.

3 Compositional CSP (CCSP)

3.1 Overview

In our view, web developers should be able to keep their content security policies as simple as possible by focusing only on the direct dependencies required by their web pages, largely ignoring other dependencies needed by the contents they include. In CCSP, direct dependencies are specified by means of *fine-grained white-lists* reminiscent of CSP 1.0 and CSP Level 2, since these dependencies are relatively easy to identify for web developers and it is feasible to come up with reasonably strict and secure white-lists for them. Indirect dependencies, instead, are dealt with by *dynamically composing* the policy of the protected web page with additional content security policies which define the dependencies of the included contents. These policies are written and served by the content providers, who are the only ones who can accurately know the dependencies of the contents they serve and keep them constantly updated. Ideally, only the least set of dependencies required to work correctly should be white-listed to respect the principle of least privilege and avoid weakening protection unnecessarily. To keep under control the power on policy specification delegated to external content providers, CCSP grants web developers the ability of putting additional restrictions on the policy relaxation mechanism.

Concretely, let us move back to our example. In our proposal, the web page w would send to the browser the following headers:

```
CSP-Compose
   script-src https://a.com/stats.js;

CSP-Intersect
   scope       https://a.com/stats.js;
   script-src  https://*;
   img-src     *;
   default-src 'none'
```

The CSP-Compose header contains the initial content security policy of the protected page: in this case, it specifies that only the script https://a.com/stats.js can

be included in the page. The `CSP-Intersect` header, instead, tracks that the script `https://a.com/stats.js` is entitled to relax the content security policy of *w* up to the specified upper bound, expressed again in terms of CSP. For instance, in this case the script can relax the content security policy of the protected page to white-list any HTTPS script and any image, but nothing more. Different scripts can be assigned different upper bounds on policy relaxation.

When delivering `stats.js`, the script provider can attach it the following header:

```
CSP-Union
   script-src https://b.com/dependency.js;
   img-src    https://c.com
```

The `CSP-Union` header includes what `stats.js` needs to operate correctly. In this case, the additional script dependency is white-listed very precisely, while there is much more liberality on images, since any image from `https://c.com` is white-listed by the policy.

A CCSP-compliant web browser would join together the original policy of the page and the policy supplied by the script provider before including `stats.js`, while enforcing the upper bounds on policy relaxation specified by the developers of the protected page. In this case, the policy supplied by the script provider is compliant with said upper bounds, hence the browser would update the content security policy of the page as follows:

```
script-src https://a.com/stats.js
           https://b.com/dependency.js;
img-src    https://c.com
```

This policy is reminiscent of the policy we would write using CSP 1.0 or CSP Level 2, but it is assembled dynamically by interacting with the content providers. This significantly simplifies the specification of the original policy for the page developers and makes it naturally robust to changes in the included contents, as long as the capabilities required by the updated contents still comply with the original upper bounds on policy relaxation specified by the page developers. This flexibility is crucial to appropriately deal with highly dynamic web contents, which can hardly be accommodated by static white-lists, and with complex chains of dependencies, which may be difficult to predict for page developers.

It is also worth noticing that, since the burden of policy specification is now split between page developers and content providers, CCSP makes it feasible in practice to white-list individual contents rather than entire domains, which makes the resulting policy stricter and more secure. In the end, the resulting policy can realistically be as strict and precise as a nonce-based policy, but all the security information is available in the HTTP headers, thus overcoming the typical limitations associated with the use of nonces. Finally, observe that the dynamically enforced policy is much tighter than the upper bound for policy relaxation specified by the protected web page. Though the page developers could deploy a standard CSP policy which is as liberal as the upper bound, that policy would be significantly more permissive than the enforced CCSP policy built at runtime.

3.2 Example Use Cases

We discussed how our proposal overcomes some important limitations of CSP, but we now observe that these improvements come with a cost on the content providers, which in our proposal become actively involved in the policy specification process. We believe that many major content providers would be happy to contribute to this process, because mismatches between the capabilities required by their contents and the content security policies of their customers may lead to functionality issues resulting in economic losses, like in the case of broken advertisement. To further exemplify the benefits of CCSP, however, we discuss now two concrete use cases.

As a first use case, we pick a provider of JavaScript APIs, for example Facebook. The lead developer of the Facebook APIs may stipulate that all the developers in her team are allowed to use external libraries in the scripts they write, but only if they are hosted on `https://connect.facebook.net`, because libraries which are put there are always updated, subject to a careful security scrutiny and delivered over a secure channel. The lead developer can thus ensure that the following header is attached to all the available JavaScript APIs:

```
CSP-Union
   script-src https://connect.facebook.net
```

This way, Facebook can make its customers aware of the fact that the API code only needs to access internal contents to operate correctly, which may increase its level of trust and simplify a security auditing. If a Facebook API contained a bug or was developed by an uncaring developer who did not respect the indications of the lead developer, a sufficiently strong content security policy on the pages using the API may still prevent the unintended inclusion of dangerous contents.

As a second use case, we consider an advertisement library. Web advertisement may involve delicate trust relationships: it is not uncommon for web trackers to collaborate and share information about their visitors[4]. For instance, an advertisement library developed by `a.com` may actually import an external advertisement library by `b.com`. Developers at `a.com` may want to mitigate the impact of vulnerabilities in the `b.com` library, since the

[4] `https://blog.simeonov.com/2013/04/17/anatomy-of-an-online-ad/`

end user of the advertisement library may be unaware of the inclusion of external contents and just blame the developers of a.com for any security issue introduced by the advertisement system. The a.com developers can thus attach the following headers to their library:

```
CSP-Union
   script-src https://b.com/adv.js;

CSP-Intersect
   scope        https://b.com/adv.js;
   img-src      *://b.com;
   default-src 'none'
```

This way, the developers at a.com declare their need of including a script by b.com, but they only grant it enough capabilities to relax the content security policy of the embedding page to white-list more images from its own domain (using any protocol) and nothing more. This significantly reduces the impact of bugs in the script by b.com, as long as the page using the advertisement library deploys a reasonably strong content security policy in the first place.

3.3 Specification

Preliminaries. We start by reviewing some terminology from the original CSP specification. A content security policy is a list of *directives*, defining content restrictions on *protected resources* (web pages or iframes) by means of a white-listing mechanism. White-lists are defined by binding different content types (images, scripts, etc.) to lists of *source expressions*, noted as $\vec{se}$, which are a sort of regular expressions used to succinctly express sets of URLs. The inclusion of a content of type t from a protected resource r is only allowed if the URL u of the content *matches* any of the source expressions bound to the type t in the content security policy of r. We abstract from the details of the matching algorithm of CSP and we just write $matches(u, \vec{se})$ if u matches any of the source expressions in the list $\vec{se}$.

We let P stand for the set of the content security policies and we let p range over it. We let $\sqsubseteq$ stand for the binary relation between content security policies such that $p_1 \sqsubseteq p_2$ if and only if all the content inclusions allowed by p_1 are also allowed by p_2. It can be proved that $(P, \sqsubseteq)$ is a *bounded lattice* and there exist algorithmic ways to compute the *join* $\sqcup$ and the *meet* $\sqcap$ of any two content security policies. The join $\sqcup$ allows a content inclusion if and only if it is allowed by at least one of the two policies (union of the rights), while the meet $\sqcap$ allows a content inclusion if and only if it is allowed by both policies (intersection of the rights). We let $\top$ and $\bot$ stand for the top and the bottom elements of the lattice respectively. In the following, we do not discuss how the join and the meet of two policies are actually computed, but we provide an abstract specification of CCSP which uses these operations as a black box. The formal metatheory is presented in Appendix A for the sake of completeness.

Security Headers. The CCSP specification is based on three new security headers:

1. CSP-Compose: only used by the web developers of the protected resource. It includes a content security policy specifying the initial content restrictions to be applied to the protected resource;
2. CSP-Union: only used by the content providers. It includes a content security policy which should be joined with the content security policy of the protected resource to accommodate the intended functionality of the supplied contents;
3. CSP-Intersect: (optionally) used by both the web developers of the protected resource and the content providers. It includes a list of bindings between a source expression list (a *scope*) and a content security policy, expressing that contents retrieved from a URL matching a given scope are entitled to relax the policy of the protected resource only up to the specified upper bound.

The next paragraph makes these intuitions more precise.

Enforcement Model. Conceptually, each protected resource needs to keep track of two elements: the enforced content security policy p and the upper bounds on policy relaxation $R = \{(\vec{se}_1, p_1), \ldots, (\vec{se}_n, p_n)\}$ collected via the CSP-Intersect headers. We call R a *relaxation policy* and we refer to the pair (p, R) as the *protection state* of the protected resource.

In the protection state (p, R), a content inclusion is allowed if and only if it is allowed by the content security policy p, whose weakening is subject to the relaxation policy R. Initially, the protection state is set so that p is the policy delivered with the CSP-Compose header of the protected resource and $R = \{(\vec{se}_1, p_1), \ldots, (\vec{se}_n, p_n)\}$ is the CSP-Intersect header originally attached to it. The protection state can be dynamically updated when the protected resource includes contents with a CSP-Union header. To formalise the update of the protection state, it is convenient to introduce a few auxiliary definitions. First, we define the set of the upper bounds for policy relaxation given to the URL u by the relaxation policy R.

Definition 1 (Specified Upper Bounds)**.** Given a URL u and a relaxation policy R, we define the *specified upper bounds* for u under R as:

$$bnds(u, R) = \{p \mid \exists \vec{se} : (\vec{se}, p) \in R \wedge matches(u, \vec{se})\}.$$

Using this auxiliary definition, we can define the upper bound for policy relaxation as follows:

Definition 2 (Upper Bound)**.** Given a URL u and a relaxation policy R, we define the *upper bound* for u under R as:

$$ub(u,R) = \begin{cases} p_1 \sqcup \ldots \sqcup p_n & \text{if } bnds(u,R) = \{p_1,\ldots,p_n\} \\ & \quad \text{with } n > 0 \\ \bot & \text{if } bnds(u,R) = \emptyset \end{cases}$$

Though simple, this definition is subtle. If no upper bound for a given URL u is defined in a relaxation policy R, then $ub(u,R) = \bot$ and no policy relaxation is possible when processing a response from u. However, if multiple upper bounds are specified for u, then their *join* is returned. This means that, if multiple content providers specify different, possibly conflicting upper bounds on policy relaxation, then all of them will be honored, which is the most liberal behaviour. This design choice is crucial to ensure the functionality of the protected resource, as we extensively discuss in Section 4.

We are now ready to explain how the protection state of a resource gets updated. Let (p,R) be the current protection state and assume that a content is loaded from the URL u. Assume also that the corresponding HTTP response attaches the following headers: a `CSP-Union` header including the content security policy p' and a `CSP-Intersect` header defining the relaxation policy R'. Then, the protection state (p,R) is updated to:

$$\begin{aligned} &(p \sqcup (p' \sqcap ub(u,R)), \\ &\quad R \cup \{(\vec{se}_i, p_i \sqcap ub(u,R)) \mid (\vec{se}_i, p_i) \in R'\}). \end{aligned} \tag{1}$$

In words, the protection state of the protected resource is updated as follows:

1. the content security policy p is relaxed to allow all the content inclusions allowed by p' which are compatible with the restrictions $ub(u,R)$ enforced on u by the relaxation policy R. This means that all the content inclusions allowed by p' are also allowed to the protected resource, unless the relaxation policy R specifies a tighter upper bound for u;

2. the relaxation policy R is extended to allow all the behaviours allowed by R' which are compatible with the restrictions $ub(u,R)$ enforced on u by the relaxation policy R. This prevents trivial bypasses of the relaxation policy R, where u specifies a more liberal upper bound than $ub(u,R)$ for other contents recursively loaded by itself.

Observe that CCSP gives web developers the possibility of granting different capabilities on policy relaxation to different content providers, but content security policies are still enforced per-resource (web page or iframe), rather than per-content. Though certainly useful in principle, enforcing different content security policies on different contents is not possible without deep browser changes, whose practical feasibility and backward compatibility are unclear.

3.4 Example

To exemplify the enforcement model of CCSP, we show our proposal at work on the advertisement library example of Section 2. Recall the example focuses on a library developed by `a.com` and importing an external library from `b.com`. Since the users of the `a.com` library are not necessarily aware of the inclusion of contents from `b.com`, the developers at `a.com` are careful in limiting the capabilities granted to the imported library. In particular, they deploy the following CCSP policy declaring the need of importing a script from `b.com`, which in turn should only be allowed to load images from the same domain, using any protocol:

```
CSP-Union
   script-src https://b.com/adv.js;

CSP-Intersect
   scope       https://b.com/adv.js;
   img-src     *://b.com;
   default-src 'none'
```

A user of the `a.com` library may not know exactly what the library needs to work correctly. However, since she trusts the provider of the library, she may deploy the following CCSP policy on her homepage:

```
CSP-Compose
   script-src https://a.com/lib.js;

CSP-Intersect
   scope       https://a.com/lib.js;
   script-src  https://*;
   img-src     https://*;
   default-src 'none'
```

Hence, in the initial protection state, the page is only allowed to load the `a.com` library, but the library is also granted the capability of relaxing the content security policy of the page to include more scripts and images over HTTPS. After loading the `a.com` library and processing its CCSP headers, the content security policy of the protected page is updated as follows:

```
script-src https://a.com/lib.js
           https://b.com/adv.js;
```

This allows the inclusion of the external script from `b.com`. What is more interesting, however, is how the

relaxation policy of the homepage is updated after processing the response from `a.com`. Specifically, the relaxation policy will include a new entry for `b.com` of the following format:

```
scope       https://b.com/adv.js;
img-src     https://b.com;
default-src 'none'
```

This entry models the combined requirement that the imported script from `b.com` can only relax the content security policy of the protected page to load images from its own domain (as desired by `a.com`), but only using the HTTPS protocol (as desired by the protected resource and originally enforced on the importer at `a.com`).

Assume now that the script from `b.com` sends the following CCSP header:

```
CSP-Union
   img-src *
```

When processing the response from `b.com`, the page will further relax its content security policy as follows:

```
script-src https://a.com/lib.js
           https://b.com/adv.js;
img-src    https://b.com
```

Hence, even though `b.com` asked for the ability of loading arbitrary images from the web, the restrictions put in place by `a.com` actually ensured that the content security policy of the protected page was only relaxed to load images from `b.com`. At the same time, the protected page successfully enforced that these images are only loaded over HTTPS.

4 Design Evaluation

4.1 Security Analysis

Threat Model. CCSP is designed to assist *honest* content providers in making their end users aware of the capabilities needed by the contents they make available and simplify their robust integration with the content security policy of the embedding resource. As such, CCSP aims at mitigating the impact of *accidental* security vulnerabilities, whose threats can be prevented by the mismatch between the unintended harmful behaviours and the expected capabilities requested in the CCSP headers. If we assume that both the initial content security policy of the protected resource and the following relaxations (by honest content providers) comply with the principle of the least privilege, imported contents can only recursively load additional contents served from sources which were white-listed to implement a necessary functionality: this greatly reduces the room for dangerous behaviours.

However, CCSP is *not* designed to protect against malicious content providers. If a protected resource imports malicious contents, the current CSP standard offers little to no protection against data exfiltration and serious integrity threats [13]. Since CCSP ultimately relies on CSP to implement protection, the same limitations apply to it, though attackers who are not aware of the deployment of (C)CSP on the protected resource may see their attacks thwarted by the security policy.

Policy Upper Bounds. In CCSP, the initial protection state (p,R) is entirely controlled by the developers of the protected resource. If $R = \emptyset$, no policy relaxation is possible and the security guarantees offered to the protected resource are simply those provided by the initial content security policy p. Observe that no policy relaxation is allowed even if a content provider at u sends its own relaxation policy $R' \neq \emptyset$, since all the relaxation bounds in R' will be set to $ub(u,R) = \bot$ when updating the protection state, thanks to the use of the meet operator in Equation 1. Otherwise, let $R = \{(\vec{se}_1, p_1), \ldots, (\vec{se}_n, p_n)\}$ with $n > 0$ be the initial relaxation policy. In this case, the most liberal content security policy eventually enforced on the protected resource can be $p \sqcup p_1 \sqcup \ldots \sqcup p_n$, again because the initial upper bounds on policy relaxation can never be weakened when the protection state is updated, due to the use of the meet operator in Equation 1. Remarkably, this bound implies that the developers of the protected resource still have control over the most liberal content security policy enforced on it and may reliably use CCSP to rule out undesired behaviours, e.g., loading images over HTTP, just by writing an appropriate initial policy and upper bounds on policy relaxation.

Notice that the upper bounds defined by the initial relaxation policy may be way more permissive than the actual policy enforced on the protected resource, since the policy relaxation process happens dynamically and depends on the responses of the different content providers. In particular, if all the content providers are honest and prudent, they should comply with the principle of the least privilege, hence the enforced policy will realistically be much tighter than the original upper bounds.

4.2 Compatibility Analysis

Legacy Browsers. Legacy browsers lacking support for CCSP will not recognise the new security headers defined by our proposal, hence these headers will just be ignored by them. If we stipulate that CCSP-compliant browsers should only enforce standard content security policies in absence of CCSP policies, which is a reasonable requirement being CCSP an extension of CSP, developers of protected resources can provide support for legacy browsers just by sending both a CCSP policy

(enforced by CCSP-compliant browsers) and a standard content security policy (enforced by legacy browsers).

Clearly, the latter policy would need to white-list all the legitimate content inclusions, though, as we said, these are often hard to predict correctly. Luckily, there is a simple way to build a working content security policy from a CCSP policy, which is including all the upper bounds specified by the relaxation policy directly in the content security policy. This can be done automatically by a server-side proxy and it will produce a policy which is typically more liberal than necessary, yet permissive enough to make the protected resource work correctly (and not necessarily weaker than the policy the average web developer would realistically write using CSP).

Legacy Content Providers. Legacy content providers will not attach any `CSP-Union` header to the contents they serve, although developers of resources protected by CCSP may expect them to supply this information to relax their policies. There are two alternative ways to deal with the absence of a `CSP-Union` header, both of which are plausible and worth discussing:

1. perform no policy relaxation: this conservative behaviour can break the functionality of protected resources, but it ensures that, whenever policy relaxation happens, both the developers of the protected resource and the content providers agreed on the need of performing such a sensitive operation;

2. relax the policy to the upper bound specified for the content provider: this alternative choice privileges a correct rendering of contents served by legacy content providers, at the cost of enforcing a policy which may be more permissive than necessary. Notice, however, that this still takes into account the (worst case) expectations of the developers of the protected resource.

Though both choices are sensible, we slightly prefer the first option as the default in CCSP, most notably because it is consistent with a similar design choice taken in the latest draft of CSP Embedded Enforcement [17], where the lack of an expected header on an embedded content triggers a security violation on the embedding resource. We do not exclude, however, that it could be useful to extend CCSP to give developers a way to express which of these two choices should be privileged.

Compatibility Issues from Security Enforcement. In CCSP, the content security policy of the protected resource can never be restricted by an interaction with a content provider, but it can only be made more liberal, hence it can never happen that a content provider forbids a content inclusion which is needed and allowed by the protected resource. It is also important to remark that different content providers can specify different, possibly conflicting upper bounds for policy relaxation with the same scope, but conflicts cannot lead to compatibility issues in practice, because all bounds are joined together (see Definition 2) and taken into account upon policy relaxation. This choice privileges the correct rendering of contents over security, but the opposite choice of taking the meet of the upper bounds would make the integration of contents from different providers too difficult to be practical, because these providers are not necessarily aware of the presence of each other in the same protected resource and may disagree on the relaxation needs. Moreover, taking the meet of the upper bounds would open the room to "denial of service" scenarios, where two competitor content providers could maliciously put unduly restrictions on each other.

If the content security policy of the protected resource is not liberal enough to let a content be rendered correctly, there are only two possibilities:

1. the original content security policy of the protected resource was not permissive enough in the first place and was never appropriately relaxed;

2. the content was loaded by a provider enforcing overly tight restrictions on policy relaxation for contents recursively loaded by another provider.

The first possibility may already occur in CSP and it is inherent to the nature of any whitelist-based protection mechanism. The second possibility, instead, is specific to CCSP, but it is not really a compatibility issue, because providers are not forced to put restrictions on policy relaxation and they are assumed to behave rationally, i.e., they do not deliberately put restrictions to break contents which are recursively loaded from other providers as part of their intended functionality.

4.3 Deployment Considerations

Deployment on Websites. Two actors must comply with CCSP to benefit of its protection: developers of protected resources and content providers. Assuming a reasonably large deployment of CCSP by content providers, developers who are willing to deploy a standard content security policy on their websites would have a much simpler life if they decided to run CCSP instead, because the policies written in the `CSP-Compose` headers are a subset of the policies which would need to be written using the standard CSP; moreover, the direct dependencies of the protected resource are much simpler to identify than the indirect ones. Writing accurate `CSP-Intersect` headers for controlled policy relaxation might be more complex for the average web developer, but quite liberal policies

would be easy to write and still appropriate for content providers with a high level of trust.

Content providers, instead, would need to detect the (direct) dependencies of the contents they serve and write appropriate `CSP-Union` headers. We think this a much simpler task for them rather than for the end users of their contents, because they have a better understanding of their implementation. We also believe that pushing part of the policy specification effort on the content providers is beneficial to a wide deployment of CCSP, because in practice few selected providers supply a lot of contents to the large majority of the websites. Configuring correctly the `CSP-Union` headers of these providers would thus provide benefits to a significant fraction of the web, which is a much more sensible practice than hoping that most web developers are able to identify correctly the dependencies of the contents they include. We substantiate these claims with the experiments in Section 5.

Deployment in Browsers. CCSP does not advocate any major change to the CSP specification and uses it as a black box, because the content restrictions applied to a CCSP-protected page follow exactly the semantics of a standard content security policy. The only difference with respect to CSP is that the protection state of the protected resource is not static, but can change dynamically, so that different content security policies are applied on the same protected resource at different points in time. This means that CCSP should be rather easy to deploy on existing browsers, because the implementation of CSP available therein could be directly reused.

Incremental Deployment. Given that CCSP is an extension of CSP, it naturally supports the coexistence of CCSP-compliant and legacy content providers in the same policy. Developers of protected resources can write `CSP-Intersect` headers for CCSP-compliant providers and trust that they provide appropriate `CSP-Union` headers for their contents; at the same time, however, developers can also include the dependencies of legacy content providers directly in the `CSP-Compose` header. This allows an incremental deployment of CCSP on the web, which is particularly important because not all content providers may be willing to deploy CCSP.

4.4 Criticisms to CCSP

CCSP is more expressive than Strict CSP, because it extends the possibility of relaxing the white-listed content inclusions beyond what is allowed by the use of `'strict-dynamic'`. In this section, we argued for the security, the backward compatibility and the ease of deployment of CCSP. Still, there are a few potential criticisms to CCSP that we would like to discuss.

Practical Adoption. A first criticism to CCSP is fundamental to its design: achieving the benefits of CCSP requires adoption by third-party content providers. One may argue that it is difficult enough to get first parties to adopt CSP, let alone convince third parties to write CCSP policies. Two observations are in order here.

First, as anticipated, content providers typically have an economic interest on the correct integration between the contents they supply and the CSP policies of the embedding pages, such as in the case of advertisements, hence content providers often do not need further convincing arguments to deploy CCSP. Moreover, one may argue that the challenges faced by the first-party adoption of CSP may actually depend on the lack of third-party support for policy deployment, which proved to be difficult for web developers [9, 20, 1, 18]. If content providers could provide the correct policies for the content they supply, then also the first parties might be more willing to adopt CCSP, because they will encounter significantly less challenges upon deployment. Major content providers supporting CSP, such as Google, could play an important role in pushing the adoption of CCSP.

Increased Complexity. We acknowledge that CCSP is more complex than CSP and its enforcement model is subtle, because it aims at reconciling security, flexibility and backward compatibility. Complexity may be a concern for the practical adoption of CCSP, though one may argue that the simplicity of CSP bears limits of expressiveness which may actually complicate its deployment when `'strict-dynamic'` is not enough, e.g., in the presence of complex script dependencies or HTTP redirects.

That said, we designed CCSP as an extension of CSP exactly to ensure that web developers who do not need the additional expressive power of CCSP can ignore its increased complexity. On the contrary, web developers who need more flexibility in policy writing can find in CCSP useful tools to accommodate their needs.

Complex Debugging. A peculiarity of CCSP is that the enforced security policy changes dynamically, which can make policy debugging more complex than for CSP. This is a legitimate concern: even if content providers write appropriate `CSP-Union` headers for their resources, policy violations may arise due to some additional restrictions enforced by the `CSP-Intersect` headers sent by the protected resource.

We propose to make these conflicts apparent by extending the monitoring facilities of CCSP so that all the policy relaxations performed by a protected resource are reported to web developers. However, we acknowledge that designing a robust reporting system for CCSP is a

complex and delicate problem, which we plan to investigate further as future work.

5 Impact of CCSP

To evaluate the benefits offered by CCSP, we built and extensively analyzed a dataset of CSP violations collected in the wild, finding a number of cases which are difficult to accommodate in CSP (and, indeed, were not correctly supported by policy writers). Our investigation confirms the need for a more expressive mechanism like CCSP. We then quantitatively assess that only few content providers need to deploy CCSP to fix most of the policy violations on the websites we visited, which substantiates the practical importance of our proposal.

5.1 Methodology

We developed a simple Chromium extension which intercepts the CSP headers of incoming HTTP(S) responses and changes them to report the detected CSP violations to a web server run by us (we do this by leveraging the `report-uri` directive available in CSP). We then used Selenium to guide Chromium into accessing the homepages of the 1,352 websites from the Alexa Top 100k running CSP[5]. This way, we were able to collect a dataset of CSP violations from existing websites. Notice that this is only a subset of all the CSP violations which may be triggered on these websites, since our crawler does not exercise any website functionality besides page loading.

We then performed a breakdown of the collected CSP violations. In particular, we focused on two categories of violations which are difficult to fix robustly in CSP, but are simple to address with CCSP: (*i*) violations triggered by the recursive inclusion of contents by any of the scripts loaded on the website, and (*ii*) violations triggered by HTTP redirects towards URLs which are not white-listed in the content security policy of the website. Both these scenarios are common, but challenging for CSP, since they involve elements which are not under the direct control of the developers of the websites.

To detect the violations in the first category, we relied on the structure of the collected violation reports, which includes both the URI of the website (named `document-uri`) and the URI of the element triggering the violation (named `source-file`); if there is a mismatch between the two, we put the violation into the first category. As to the second category of violations, we kept track of the detected HTTP redirects using our extension, storing the content of their `Location` header, and we performed a cross-check between this information and the dataset of violations: if there is a violation due to the inclusion of a content located at a URL found in a `Location` header, we put the violation in the second category. Violations can belong to both categories.

[5] We only focus on websites running CSP in enforcement mode. There are way more websites running CSP in report-only mode, but we excluded them from our analysis, because their policies are not necessarily accurate and intended to be eventually enforced [1].

5.2 Results

Overall, we found 959 CSP violations in 154 websites. We assigned 231 violations from 51 websites to the first category and 199 violations from 73 websites to the second category; we found only 7 violations belonging to both categories.

Table 1 provides the breakdown of the 231 violations due to script dependencies with respect to the violated CSP directive. One can readily observe that scripts often need to recursively include other scripts as expected, but they also typically load a bunch of other contents of different nature, most notably fonts, frames and images. The use of `'strict-dynamic'` can fix the 96 violations related to the `script-src` directive, which however represent only the 41.6% of the total number of violations in this category. To properly fix the other 135 cases in CSP, one would need to identify the missing dependencies of the included scripts and adapt the content security policy of the website accordingly, but this is not always easy for web developers, as testified by the fact that these violations occurred on popular websites.

Violated Directive	*Violations*	*Sites*
`script-src`	96	30
`font-src`	72	3
`frame-src`	32	25
`img-src`	17	5
`connect-src`	12	6
`style-src`	2	2

Table 1: Violations triggered by script dependencies

Table 2 reports the top 10 script providers by number of violations produced by the scripts they serve, as well as the number of websites where these violations are triggered. An interesting observation here is that, by writing appropriate CCSP headers for these 10 providers, one could fix 88 violations, which amount to the 38.1% of all the violations due to script dependencies we observed in the wild. Remarkably, this would fix violations in 37 websites, which amount to the 72.5% of all the websites which presented a violation in the first category. This suggests that the use of CCSP by the top script providers could provide a benefit to the majority of the websites.

As to the 199 violations due to HTTP redirects, we noticed that they were caused by redirectors from 46 different domains. Table 3 shows the top 10 redirectors by

Script Provider	*Violations*	*Sites*
www.googletagmanager.com	26	9
apis.google.com	13	13
pagead2.googlesyndication.com	11	2
api.dmp.jimdo-server.com	8	4
assets.jimstatic.com	7	4
vogorana.ru	7	2
www.googleadservices.com	7	6
www.googletagservices.com	4	2
s.adroll.com	3	3
js-agent.newrelic.com	2	2

Table 2: Top script providers by number of violations

number of violations, as well as the number of websites where these violations are triggered. It is worth noticing that, by writing appropriate CCSP headers for these 10 redirectors, one could already prevent 136 violations, which amount to the 68.3% of all the violations due to redirects. This would fix violations in 61 websites, which amount to the 83.6% of all the websites which presented a violation in the second category. This confirms again that a limited deployment of CCSP at major services could have a significant impact on the entire Web.

Redirector	*Violations*	*Sites*
www.google.com	47	38
www.ingbank.pl	20	2

6 Implementation and Testing

6.1 Prototype Implementation

We developed a proof-of-concept implementation of CCSP as a Chromium extension. The extension essentially works as a proxy based on the webRequest API[6]. It inspects all the incoming HTTP(S) responses looking for CCSP headers: if they are present, the extension parses them following the syntax described in the present paper and then strips away standard CSP headers (if any) to avoid conflicts. The extension internally keeps track of the protection state of all the open pages, closely following the CCSP enforcement model described in Section 3.3. Outgoing requests are then inspected to check whether they are allowed by the content security policy enforced in the current protection state of the page sending them: if this is not the case, the request is blocked.

Our prototype does not support any source expression which does not deal with outgoing requests, like `'unsafe-inline'`, since they are not trivial to handle via a browser extension (assuming it is even possible). The goal of the prototype is just providing a way to get hands-on experience with CCSP on existing websites and testify that it is possible to write accurate CCSP policies for them. On the long run, we would like to implement a more mature prototype of CCSP directly in Chromium: this should be relatively easy to do, because CCSP can use the existing CSP implementation as a black box.

[6] `https://developer.chrome.com/extensions/webRequest`

6.2 Testing in the Wild

In our experiments, we fixed CSP violations found on two popular websites by using CCSP. We started by stipulating that their `CSP-Compose` headers should contain exactly the original content security policy and we then wrote appropriate `CSP-Union` and `CSP-Intersect` headers to fix the observed CSP violations. We finally injected these CCSP headers in the appropriate HTTP(S) responses via a local proxy.

Twitter. On Jan 13th 2017 we found that the content security policy of `twitter.com` was broken by the inclusion of a script from `https://cdn5.userzoom.com`, loaded by a script from `https://abs.twimg.com`.

Since `twimg.com` is controlled by Twitter, we decided to assume a high level of trust for all its sub-domains and we wrote the following `CSP-Intersect` header for the homepage of `twitter.com`:

```
CSP-Intersect:
   scope       *.twimg.com;
   script-src  https://*;
   default-src 'none';
```

This gives contents hosted on `twimg.com` the ability of relaxing the content security policy of Twitter to load arbitrary scripts over HTTPS. This is a very liberal behaviour, but it may be a realistic possibility if the team working at `abs.twimg.com` develops products independently from their final users at Twitter.

We then injected the following `CSP-Union` header in the script provided by `abs.twimg.com`:

```
CSP-Union:
   script-src https://cdn5.userzoom.com;
```

In this specific case, we cannot white-list the exact script, `QzI2OVQxNDQg.js`, as its name is taken from the DOM and cannot be known by the server. However, the domain `https://cdn5.userzoom.com` is hard-coded in the script at `abs.twimg.com`, so we can reliably use that information for white-listing.

These two CCSP headers fixed the policy violation we found and allowed the script from `abs.twimg.com` to change its imported scripts without any intervention from the Twitter developers, as long as it correctly updates its `CSP-Union` header.

Orange. On Jan 23rd 2017 we detected three CSP violations at `www.orange.sk`, a national website of the popular telecommunication provider Orange.

The first violation was due to a script imported from `static.hotjar.com`, which was trying to create an iframe including contents from `vars.hotjar.com`. We fixed it by writing the following `CSP-Intersect` header for the homepage of `www.orange.sk`:

```
CSP-Intersect:
   scope       static.hotjar.com;
   frame-src   *.hotjar.com;
   default-src 'none';
```

We then attached the following `CSP-Union` header to the script from `vars.hotjar.com`:

```
CSP-Union:
   frame-src https://vars.hotjar.com/rcj-b2
      c1bce0a548059f409c021a46ea2224.html
```

Notice that this time we were able to white-list exactly the required contents, since the whole URL is readily available in the script code.

The other two violations were triggered by two images imported from `www.google.com` for tracking purposes, which were redirected to a national Google website not included in the content security policy. The web developers at `www.orange.sk` probably noticed these violations and tried to fix them by adding `www.google.sk` to the `img-src` directive, but since we were visiting the website from Italy, we got redirected to `www.google.it` and this domain was not included in the content security policy of `www.orange.sk`.

We then fixed these issues by adding the following information to the headers sent by `www.orange.sk`:

```
CSP-Intersect:
   scope       www.google.com;
   img-src     *;
   default-src 'none';
```

and by including the following headers to the redirect sent from `www.google.com`:

```
CSP-Union:
   img-src www.google.it
```

Notice that the correct top-level domain is known to the server, because it is also issuing the redirect request.

Other Websites. We discussed two practical examples of CCSP deployment, but one may wonder how difficult it is to write CCSP headers for other websites. To get a rough estimate about the challenges of the CCSP deployment more in general, we inspected our dataset of CSP violations and we collected for the top 10 script providers (by number of violations) the following information: the number of scripts they serve, the number of CSP violations triggered by these scripts, and the type of these violations. The results are in Table 4.

We think that the perspective offered by the table is pretty encouraging, because it suggests that even popular script providers only serve a small number of scripts to their customers, which means that the number of CCSP headers to write for them is typically limited. Moreover, scripts often load a very limited number of resources and only few of them need to load contents of variegate type. These two factors combined suggest that writing policies for scripts should be relatively easy on average, because these policies would have limited size and complexity.

7 Related Work

Several studies analysed the extent and the effectiveness of the CSP deployment in the wild and highlighted that web developers have troubles at configuring CSP correctly [9, 20, 1, 18]. Indeed, there have been a number of complementary proposals, with different level of complexity, on how to automatically generate content security policies for existing websites [2, 3, 7, 8]. The effectiveness of these proposals is still unclear, since automatically generating content security policies which are at the same time accurate and secure turned out to be extremely challenging, requiring a combination of static analysis, runtime monitoring and code rewriting. However, even a perfect policy generation algorithm can still lead to functionality problems upon content inclusion, due to unanticipated changes in the behaviour of included contents due to, e.g., the use of HTTP redirects or the relocation of script dependencies. CCSP was designed to support these behaviours under the assumption that most content providers are not actually malicious. It is also worth mentioning that CCSP is naturally effective at simplifying the policy specification process for web developers, assuming that content providers are willing

Script Provider	*Scripts*	*Violations*	*Types of Violations*

to dedicate some efforts to foster the integration between their contents and the content security policies of the embedding resources.

The idea of dynamically changing the enforced CSP policy advocated in CCSP is also present in the design of COWL, a confinement system for JavaScript code [12]. COWL assigns information flow labels to contexts (e.g., pages and iframes) and restricts their communication based on runtime label checks. Labels are allowed to change dynamically using meet and join operators, and implemented on top of CSP, which makes runtime policy composition part of COWL. However, COWL targets more ambitious security goals than (C)CSP by enforcing non-interference on labeled contexts and, as such, it is less flexible and harder to retrofit on existing websites. For these reasons, we believe that COWL and (C)CSP are complementary: one system may be better than the other one, depending on the desired security properties.

CSP Embedded Enforcement is a draft specification by the W3C which allows a protected resource to embed an iframe only if the latter accepts to enforce upon itself an embedder-specified set of restrictions expressed in terms of CSP [17]. The embedder advertises the restrictions using a new `Embedding-CSP` header including a content security policy, while the embedded content must attach a `Content-Security-Policy` header including a policy with at least the same restrictions to declare its compliance. It is worth noticing that CSP Embedded Enforcement is a first step towards making the CSP enforcement depend upon an interaction between the protected resource and the content providers, though the problems it addresses are orthogonal to CCSP. Similarly to CSP, CSP Embedded Enforcement asks web developers to get a thorough understanding of the contents they include to write a content security policy for them.

Other papers on CSP studied additional shortcomings of the standard, touching on a number of different issues: ineffectiveness against data exfiltration [13], difficult integration with browser extensions [5], unexpected bad interactions with the Same Origin Policy [10] and sub-optimal protection against code injection [6].

8 Conclusion

We proposed CCSP, an extension of CSP based on runtime policy composition. By shifting part of the policy specification process to content providers and by adding a dynamic dimension to CSP, CCSP reconciles the protection offered by fine-grained white-listing with a reasonable policy specification effort for web developers and a robust support for the highly dynamic nature of common web interactions. We analysed CCSP from different perspectives: security, backward compatibility and deployment cost. Moreover, we assessed its potential impact on the current web and we implemented a working prototype, which we tested on major websites. Our experiments show that popular content providers can deploy CCSP with limited efforts, leading to significant benefits for the large majority of the web.

As future work, we plan to implement CCSP directly in Chromium and carry out a large-scale analysis of its effectiveness, including a performance evaluation. We would also like to investigate automated ways to generate CCSP policies for both websites and content providers: since CCSP splits policy specification concerns between these two parties, we hope there is room for simplifying the automated policy generation process and making it more effective than for CSP. Finally, we would like to investigate the problem of supporting robust debugging facilities for CCSP in web browsers.

A Theory

Our theory of joins and meets is based on a core fragment of CSP called CoreCSP. This fragment captures the essential ingredients of the standard and defines their (denotational) semantics, while removing uninspiring low-level details.

A.1 CoreCSP

We presuppose a denumerable set of strings, ranged over by *str*. The syntax of *policies* is shown in Table 5, where we use dots (...) to denote additional omitted elements of a syntactic category (we assume the existence of an arbitrary but finite number of these elements).

This a rather direct counterpart of the syntax of CSP. The most notable points to mention are the following:

Content types	t	::=	$\texttt{script} \mid \texttt{style} \mid \ldots$
Schemes	sc	::=	$\texttt{http} \mid \texttt{https} \mid \texttt{data}$
		$\mid$	$\texttt{blob} \mid \texttt{filesys} \mid \texttt{il}$
		$\mid$	$\ldots$
Policies	p	::=	$\vec{d} \mid p + p$
Directives	d	::=	$t\texttt{-src}\ v$
		$\mid$	$\texttt{default-src}\ v$
Directive values	v	::=	$\{se_1, \ldots, se_n\}$
Source expressions	se	::=	$h \mid \texttt{unsafe-inline}$
		$\mid$	$\texttt{inline}(str)$
Hosts ($sc \neq \texttt{il}$)	h	::=	$\texttt{self} \mid sc \mid he \mid (sc, he)$
Host expressions	he	::=	$* \mid *.str \mid str$

Table 5: Syntax of CoreCSP

1. we assume the existence of a distinguished scheme `il`, used to identify inline scripts and stylesheets. This scheme cannot occur inside policies, but it is convenient to define their formal semantics;

2. we do not discriminate between hashes and nonces in source expressions, since this is unimportant at our level of abstraction. Rather, we uniformly represent them using the source expression $\texttt{inline}(str)$, where str is a string which uniquely identifies the white-listed inline script or stylesheet;

3. we define directive values as sets of source expressions, rather than lists of source expressions. This difference is uninteresting in practice, since source expression lists are always parsed as sets;

4. for simplicity, we do not model ports and paths in the syntax of source expressions.

To simplify the formalization, we only consider *well-formed* policies, according to the following definition.

Assumption 1 (Well-formed Policies)**.** We assume that policies are *well-formed*, i.e., for each directive value v occurring therein, we have that $\texttt{unsafe-inline} \in v$ implies $\texttt{inline}(str) \notin v$.

The syntax of CSP is more liberal, because it allows one to write policies violating the constraint above. However, there is no loss of generality in focusing only on well-formed policies, since if both `unsafe-inline` and $\texttt{inline}(str)$ occur in the same directive, only one of them is enforced: browsers supporting CSP 1.0 would ignore $\texttt{inline}(str)$, while browsers implementing more recent versions of CSP would ignore `unsafe-inline`.

The definition of the semantics of CoreCSP is based on three main entities: *locations* are uniquely identified sources of contents; *subjects* are HTTP(S) web pages enforcing a CSP policy; and *objects* are contents available for inclusion by subjects.

Definition 3 (Locations)**.** A *location* is a pair $l = (sc, str)$. We let $\mathscr{L}$ stand for a denumerable set of locations and we let L range over subsets of $\mathscr{L}$.

Definition 4 (Subjects)**.** A *subject* is a pair $s = (l, str)$ where $l = (sc, str')$ with $sc \in \{\texttt{http}, \texttt{https}\}$.

Definition 5 (Objects)**.** An *object* is a pair $o = (l, str)$. We let $\mathscr{O}$ stand for a denumerable set of objects and we let O range over subsets of $\mathscr{O}$.

We use the projection functions $\pi_1(\cdot)$ and $\pi_2(\cdot)$ to extract the components of a pair (location, subject or object). We also make the following typing assumption.

Assumption 2 (Typing of Objects)**.** We assume that objects are *typed*. Formally, this means that $\mathscr{O}$ is partitioned into the subsets $\mathscr{O}_{t_1}, \ldots, \mathscr{O}_{t_n}$, where $t_1, \ldots, t_n$ are the available content types. We also assume that, for all objects $o = ((\texttt{il}, str'), str)$, we have $o \in \mathscr{O}_{\texttt{script}} \cup \mathscr{O}_{\texttt{style}}$.

The judgement $se \rightsquigarrow_s L$ defines the semantics of source expressions. It reads as: the source expression se allows the subject s to include contents from the locations L. The formal definition is given in Table 6, where we let $\triangleright$ be the smallest reflexive relation on schemes such that $\texttt{http} \triangleright \texttt{https}$. The judgement generalizes to values by having: $v \rightsquigarrow_s \{l \mid \exists se \in v, \exists L \subseteq \mathscr{L} : se \rightsquigarrow_s L \wedge l \in L\}$.

$$\texttt{self} \rightsquigarrow_s \{\pi_1(s)\} \qquad sc \rightsquigarrow_s \{l \mid \pi_1(l) = sc\}$$

$$* \rightsquigarrow_s \{l \mid \pi_1(l) \notin \{\texttt{data}, \texttt{blob}, \texttt{filesys}, \texttt{il}\}\}$$

$$str \rightsquigarrow_s \{l \mid \pi_1(s) \triangleright \pi_1(l) \wedge \pi_2(l) = str\}$$

$$*.str \rightsquigarrow_s \{l \mid \pi_1(s) \triangleright \pi_1(l) \wedge \exists str' : \pi_2(l) = str'.str\}$$

$$(sc, str) \rightsquigarrow_s \{(sc, str)\}$$

$$(sc, *.str) \rightsquigarrow_s \{l \mid \pi_1(l) = sc \wedge \exists str' : \pi_2(l) = str'.str\}$$

$$(sc, *) \rightsquigarrow_s \{l \mid \pi_1(l) = sc\}$$

$$\texttt{unsafe-inline} \rightsquigarrow_s \{l \mid \pi_1(l) = \texttt{il}\}$$

$$\texttt{inline}(str) \rightsquigarrow_s \{(\texttt{il}, str)\}$$

Table 6: Semantics of Source Expressions ($se \rightsquigarrow_s L$)

We then define operators to get the value bound to a directive in a policy. Given a list of directives $\vec{d}$ and a

content type t, we define $\vec{d} \downarrow t$ as the value bound to the first t-`src` directive, if any; otherwise, the value bound to the first `default-src` directive, if any; and in absence of both, we let it be the wildcard $\{*\}$.

Definition 6 (Lookup)**.** Given a list of directives $\vec{d}$ and a content type t, we define $\vec{d}.t$ as follows:

$$\vec{d}.t = \begin{cases} v & \text{if } \vec{d} = \vec{d}_1, t\texttt{-src}\ v, \vec{d}_2 \wedge \\ & \quad \forall d \in \{\vec{d}_1\} : d \neq t\texttt{-src}\ v' \\ \bot & \text{otherwise} \end{cases}$$

We then define the *lookup* operator $\vec{d} \downarrow t$ as follows:

$$\vec{d} \downarrow t = \begin{cases} \vec{d}.t & \text{if } \vec{d}.t \neq \bot \\ v & \text{if } d.t = \bot \wedge \vec{d} = \vec{d}_1, \texttt{default-src}\ v, \vec{d}_2 \wedge \\ & \quad \forall d \in \{\vec{d}_1\} : d \neq \texttt{default-src}\ v' \\ \{*\} & \text{otherwise} \end{cases}$$

The judgement $p \vdash s \hookleftarrow_t O$ defines the semantics of policies. It reads as: the policy p allows the subject s to include as contents of type t the objects O. The formal definition is given in Table 7.

$$\text{(D-VAL)}\quad \frac{\vec{d} \downarrow t = v \qquad v \rightsquigarrow_s L}{\vec{d} \vdash s \hookleftarrow_t \{o \in \mathscr{O}_t \mid \pi_1(o) \in L\}}$$

$$\text{(D-CONJ)}\quad \frac{p_1 \vdash s \hookleftarrow_t O_1 \qquad p_2 \vdash s \hookleftarrow_t O_2}{p_1 + p_2 \vdash s \hookleftarrow_t O_1 \cap O_2}$$

Table 7: Semantics of Policies ($p \vdash s \hookleftarrow_t O$)

The semantics of a CSP policy depends on the subject restricted by the policy. This makes reasoning on CSP policies quite complicated, hence we introduce a class of policies, called *normal policies*, whose semantics does not depend on a specific subject. The restriction to normal policies does not bring any loss of generality in practice, since any policy can be translated into an equivalent normal policy by using a subject-directed compilation.

The syntax of normal policies is obtained by replacing the occurrences of h in Table 5 with $\overline{h}$, where:

$$\overline{h} ::= sc \mid * \mid (sc, he).$$

We define normal source expressions and normal directive values accordingly.

Definition 7 (Normalization)**.** Given a source expression se and a subject s, we define the *normalization* of se under s, written $\langle se \rangle_s$, as follows:

$$\langle se \rangle_s = \begin{cases} \{\pi_1(s)\} & \text{if } se = \texttt{self} \\ \{(sc, str) \mid \pi_1(s) \rhd sc\} & \text{if } se = str \\ \{(sc, *.str) \mid \pi_1(s) \rhd sc\} & \text{if } se = *.str \\ \{se\} & \text{otherwise} \end{cases}$$

The normalization of a directive value v under s is defined as $\langle v \rangle_s = \bigcup_{se \in v} \langle se \rangle_s$. The normalization of a policy p under s, written $\langle p \rangle_s$, is obtained by normalizing under s each directive value occurring in p.

Lemma 1 (Properties of Normalization)**.** *The following properties hold true:*

1. *for all policies p and subjects s, $\langle p \rangle_s$ is normal;*
2. *for all policies p, subjects s and content types t, we have $p \vdash s \hookleftarrow_t O$ if and only if $\langle p \rangle_s \vdash s \hookleftarrow_t O$;*
3. *for all normal policies p, subjects s_1, s_2 and content types t, we have that $p \vdash s_1 \hookleftarrow_t O_1$ and $p \vdash s_2 \hookleftarrow_t O_2$ imply $O_1 = O_2$.*

A.2 Technical Preliminaries

We now introduce the technical ingredients needed to implement our proposal. We start by defining a binary relation $\sqsubseteq_{src}$ on normal source expressions. Intuitively, we have $se_1 \sqsubseteq_{src} se_2$ if and only if se_1 denotes no more locations than se_2 (for all subjects).

Definition 8 ($\sqsubseteq_{src}$ Relation)**.** We let $\sqsubseteq_{src}$ be the least reflexive relation on normal source expressions defined by the following rules:

$$\frac{sc \notin \{\texttt{data}, \texttt{blob}, \texttt{filesys}, \texttt{il}\}}{sc \sqsubseteq_{src} *}$$

$$\frac{sc \notin \{\texttt{data}, \texttt{blob}, \texttt{filesys}, \texttt{il}\}}{(sc, he) \sqsubseteq_{src} *} \qquad sc \sqsubseteq_{src} (sc, *)$$

$$(sc, he) \sqsubseteq_{src} sc \qquad (sc, str) \sqsubseteq_{src} (sc, *)$$

$$(sc, *.str) \sqsubseteq_{src} (sc, *) \qquad (sc, str'.str) \sqsubseteq_{src} (sc, *.str)$$

$$\texttt{inline}(str) \sqsubseteq_{src} \texttt{unsafe-inline}$$

To compare policy permissiveness, however, there are a couple of issues left to be addressed:

1. a policy p may enforce multiple restrictions on the same content type t, specifically when $p = p_1 + p_2$ for some p_1, p_2. In this case, multiple directive values must be taken into account when reasoning about the inclusion of contents of type t;

2. a policy p may enforce restrictions on the inclusion of contents of type t by using directives of two different formats, namely t-src v or default-src v'. One has then to ensure that the appropriate directive value is chosen when reasoning about the inclusion of contents of type t.

We address these issues by defining a *smart* lookup operator $p \Downarrow t$ which, given a policy p and a content type t, returns a directive value which captures all the restrictions put in place by p on t. This operator is based on the following definition of *meet* of directive values.

Definition 9 (Meet of Values)**.** Given two normal directive values v_1, v_2, we define their *meet* $v_1 \bowtie v_2$ as follows:

$$\begin{aligned} v_1 \bowtie v_2 &= \{se \in v_1 \mid \exists se' \in v_2 : se \sqsubseteq_{src} se'\} \\ &\cup \{se \in v_2 \mid \exists se' \in v_1 : se \sqsubseteq_{src} se'\}. \end{aligned}$$

Lemma 2 (Correctness of Meet)**.** *For all normal directive values v_1, v_2 and subjects s, we have $v_1 \rightsquigarrow_s L_1$ and $v_2 \rightsquigarrow_s L_2$ if and only if $v_1 \bowtie v_2 \rightsquigarrow_s L_1 \cap L_2$.*

Definition 10 (Smart Lookup)**.** Given a normal policy p and a content type t, we define $p \Downarrow t$ as follows:

$$p \Downarrow t = \begin{cases} \vec{d} \downarrow t & \text{if } p = \vec{d} \\ (p_1 \Downarrow t) \bowtie (p_2 \Downarrow t) & \text{if } p = p_1 + p_2 \end{cases}$$

Lemma 3 (Correctness of Smart Lookup)**.** *For all normal policies p, subjects s and content types t, we have:*

$$p \vdash s \hookleftarrow_t \{o \in \mathscr{O}_t \mid \exists L \subseteq \mathscr{L} : p \Downarrow t \rightsquigarrow_s L \wedge \pi_1(o) \in L\}.$$

A.3 Join and Meet

The *join* of two policies allows a subject to include some content if and only if at least one of the two policies does.

Definition 11 (Join of Policies)**.** Given two policies p_1, p_2 and a subject s, we define the *join* $p_1 \sqcup_s p_2$ as the least policy s.t. $(p_1 \sqcup_s p_2).t = (\langle p_1 \rangle_s \Downarrow t) \cup (\langle p_2 \rangle_s \Downarrow t)$.

Theorem 1 (Correctness of Join)**.** *$p_1 \vdash s \hookleftarrow_t O_1$ and $p_2 \vdash s \hookleftarrow_t O_2$ iff $p_1 \sqcup_s p_2 \vdash s \hookleftarrow_t O_1 \cup O_2$.*

Proof. Let $p_1 \vdash s \hookleftarrow_t O_1$, $p_2 \vdash s \hookleftarrow_t O_2$ and $p_1 \sqcup_s p_2 \vdash s \hookleftarrow_t O$, we show that $O = O_1 \cup O_2$ by proving $O \subseteq O_1 \cup O_2$ and $O \supseteq O_1 \cup O_2$:

($\subseteq$) Let $o \in O$, then there exists v such that $(p_1 \sqcup_s p_2).t = v$ and $v \rightsquigarrow_s L$ for some L such that $\pi_1(o) \in L$. By definition, this means that there exists $se \in v$ such that $se \rightsquigarrow_s L'$ for some L' such that $\pi_1(o) \in L'$. By definition of join, we have $v = (\langle p_1 \rangle_s \Downarrow t) \cup (\langle p_2 \rangle_s \Downarrow t)$. Hence, we have either $se \in \langle p_1 \rangle_s \Downarrow t$ or $se \in \langle p_2 \rangle_s \Downarrow t$. Assume that $se \in \langle p_1 \rangle_s \Downarrow t$, then $o \in O_1$ by using Lemma 3 and the observation that normalization does not change the semantics of policies. The case $se \in \langle p_2 \rangle_s \Downarrow t$ is symmetric;

($\supseteq$) Let $o \in O_1 \cup O_2$, then either $o \in O_1$ or $o \in O_2$. Assume that $o \in O_1$, the other case is symmetric. By using Lemma 3 and the observation that normalization does not change the semantics of policies, there exists v such that $\langle p_1 \rangle_s \Downarrow t = v$ and $v \rightsquigarrow_s L$ for some L such that $\pi_1(o) \in L$. By definition of join, we have $(p_1 \sqcup_s p_2).t = v'$ for some v' such that $v' \rightsquigarrow_s L'$ with $L \subseteq L'$. This implies $o \in O$.

□

The *meet* of two policies allows a subject to include some content if and only if both policies do. Defining the meet is more complicated in CSP, because not all browsers correctly handle the conjunction of two policies [1]. The key idea of the definition is to reuse the meet operator $\bowtie$ defined for directive values, since we proved that $v_1 \rightsquigarrow_s L_1$ and $v_2 \rightsquigarrow_s L_2$ if and only if $v_1 \bowtie v_2 \rightsquigarrow_v L_1 \cap L_2$ (see Lemma 2).

Definition 12 (Meet of Policies)**.** Given two policies p_1, p_2 and a subject s, we define the *meet* $p_1 \sqcap_s p_2$ as the least policy s.t. $(p_1 \sqcap_s p_2).t = (\langle p_1 \rangle_s \Downarrow t) \bowtie (\langle p_2 \rangle_s \Downarrow t)$.

Theorem 2 (Correctness of Meet)**.** *$p_1 \vdash s \hookleftarrow_t O_1$ and $p_2 \vdash s \hookleftarrow_t O_2$ iff $p_1 \sqcap_s p_2 \vdash s \hookleftarrow_t O_1 \cap O_2$.*

Proof. Let $p_1 \vdash s \hookleftarrow_t O_1$, $p_2 \vdash s \hookleftarrow_t O_2$ and $p_1 \sqcap_s p_2 \vdash s \hookleftarrow_t O$, we show that $O = O_1 \cap O_2$ by proving $O \subseteq O_1 \cap O_2$ and $O \supseteq O_1 \cap O_2$:

($\subseteq$) Let $o \in O$, then there exists v such that $(p_1 \sqcap_s p_2).t = v$ and $v \rightsquigarrow_s L$ for some L such that $\pi_1(o) \in L$. By definition of meet, we have $v = (\langle p_1 \rangle_s \Downarrow t) \bowtie (\langle p_2 \rangle_s \Downarrow t)$. Let $\langle p_1 \rangle_s \rightsquigarrow_s L_1$ and $\langle p_1 \rangle_s \rightsquigarrow_s L_2$, then $\pi_1(o) \in L_1 \cap L_2$ by Lemma 2. This implies $\pi_1(o) \in L_1$ and $\pi_1(o) \in L_2$ by definition of intersection. Hence, we have $o \in O_1$ and $o \in O_2$ by using Lemma 3 and the observation that normalization does not change the semantics of policies;

($\supseteq$) Let $o \in O_1 \cap O_2$, then $o \in O_1$ and $o \in O_2$. By using Lemma 3 and the observation that normalization does not change the semantics of policies, there exist v_1, v_2 such that $\langle p_1 \rangle_s \Downarrow t = v_1$, $\langle p_2 \rangle_s \Downarrow t = v_2$, $v_1 \rightsquigarrow_s L_1$ for some L_1 such that $\pi_1(o) \in L_1$, and $v_2 \rightsquigarrow_s L_2$ for some L_2 such that $\pi_1(o) \in L_2$. This implies that $\pi_1(o) \in L_1 \cap L_2$. By definition of meet, we have $(p_1 \sqcap_s p_2).t = v_1 \bowtie v_2$ and we know that $v_1 \bowtie v_2 \rightsquigarrow_s L_1 \cap L_2$ by Lemma 2, hence $o \in O$.

□

Observe that both the definitions of join and meet are parametric with respect to a subject. In the case of normal policies, however, this subject can be dropped. Since all policies can be transformed into equivalent normal policies (Lemma 1), in the body of the paper we just write $\sqcup$ and $\sqcap$ for simplicity.

Same-Origin Policy: Evaluation in Modern Browsers

Jörg Schwenk, Marcus Niemietz, and Christian Mainka
Horst Görtz Institute for IT Security, Chair for Network and Data Security
Ruhr-University Bochum

Abstract

The term *Same-Origin Policy (SOP)* is used to denote a complex set of rules which governs the interaction of different *Web Origins* within a web application. A subset of these SOP rules controls the interaction between the host document and an embedded document, and this subset is the target of our research (SOP-DOM). In contrast to other important concepts like Web Origins (RFC 6454) or the Document Object Model (DOM), there is no formal specification of the SOP-DOM.

In an empirical study, we ran 544 different test cases on each of the 10 major web browsers. We show that in addition to Web Origins, access rights granted by SOP-DOM depend on at least three attributes: the type of the embedding element (EE), the sandbox, and CORS attributes. We also show that due to the lack of a formal specification, different browser behaviors could be detected in approximately 23% of our test cases. The issues discovered in Internet Explorer and Edge are also acknowledged by Microsoft (MSRC Case 32703). We discuss our findings in terms of *read*, *write*, and *execute* rights in different access control models.

1 Introduction

The *Same-Origin Policy (SOP)* is perhaps the most important security mechanism for protecting web applications, and receives high attention from developers and browser vendors.

Complex Set of SOP Rules. Today there is no formal definition of the SOP itself. Web Origins as described in RFC 6454 are the basis for the SOP, but they do not formally define the SOP. Documentation provided by standardization bodies [1] or browser vendors [2] is still incomplete. Our evaluation of related work has shown that the SOP does not have a consistent description – both in the academic and non-academic world (e.g., [15, 16, 5]). Therefore, recurrent browser bugs enabling SOP bypasses are not surprising.

SOP rules can roughly be classified according to the problem areas which they were designed to solve (cf. Table 1). It is impossible to cover all these subsets in a single research paper and even may be impossible to find a "unifying formula" which covers all subsets.[1] However, it is possible to cover single subsets, as previous work on HTTP cookies has shown [12]. Thus, we restricted our attention to the following research questions:

- *How is SOP for DOM access (SOP-DOM) implemented in modern browsers?*
- *Which parts of the HTML markup influences SOP-DOM?*
- *How does the detected behavior match known access control policies?*

More precisely, we concentrate on a subset of SOP rules according to the following criteria:

- **Web Origins.** We use RFC 6454 as a foundation.
- **Browser Interactions.** We concentrate on the interaction of web objects once they have been loaded.

It is a difficult task to select a test set for SOP-DOM that has constantly evolved over nearly two decades. The SOP-DOM has been adapted several times to include new features (e.g., CORS) and to prevent new attacks. 15 out of 142 HTML elements have a URL attribute and may thus have a different Web Origin [17]. Additionally, sandbox and CORS attributes also modify SOP-DOM.

The Need for Testing. Amongst web security researchers, SOP-DOM is partially common knowledge, but not thoroughly documented. Although this means

[1] For example, the SOP rules for DOM access and HTTP cookies are inconsistent, because their concept of "origin" differs.

SOP Subset	Description	Related Work
DOM access (this paper)	This subset describes if JavaScript code loaded into one "execution context" may access web objects in another "execution context". This includes modifications of the standard behavior by changing the Web Origin, for example, using `document.domain`.	[1], [2], [3], [4], [5] , [6]
Local storage and session storage	This subset defines which locally stored web object ([name,value] pairs) may be accessed from a JavaScript execution context.	[7], [8]
XMLHttpRequest	This subset imposes restrictions on cross-origin HTTP network access. It contains many ad-hoc rules and its main concepts have been standardized in CORS.	[9], [7], [8], [10]
Pseudo-protocols	Browsers may use Pseudo-protocols like `about:`, `javascript:` and `data:` to denote locally generated content. A complex set of rules applies for the definition of Web Origins here.	[8], [10]
Plugins	Many plugins like Java, Flash, Silverlight, PDF come with their own variants of a SOP.	[11], [8]
Window/Tab	Cross-window communication functions and properties: `window.opener`, `open()` and `showModalDialogue()`.	[8], [10]
HTTP Cookies	This subset, with an extension of the Web Origin concept (path), defines to which URLs HTTP cookies will be sent. This defines their accessibility in the DOM for non-httpOnly cookies.	[12], [13], [14]

Table 1: Different subsets of SOP rules.

that most researches are familiar with many edge cases in SOP-DOM, especially those relating to attacks and countermeasures, it is likely that some of those edge cases will not be covered in this paper. Additionally, each individual researcher will be unaware of other edge cases, which may include novel vulnerabilities. For example, it is well known that JavaScript code from a different web origin has full read and write access to the host document; nevertheless, recently Lekies et al. [5] pointed our that there is also read access from the host document to JavaScript code, which may constitute a privacy problem.

Additionally, HTML5 has brought greater diversity to seemingly well-known HTML elements. For instance, the term "authority" used in RFC 6454 [18] may not be sufficient any more if we compare the power of SVG images [19] with the following quote from RFC 6454: "an image is passive content and, therefore, carries no authority, meaning the image has no access to the objects and resources available to its origin". Our evaluation shows that this statement is true for all image types if they are embedded via <**img**>. This statement does not hold if SVG images are embedded via <**iframe**> or <**object**>. Novel standards like Cross-Origin Resource Sharing (CORS, [9]) also influence access rights granted by the SOP. To be able to keep the implementation of the SOP consistent through all these extensions, a formal model is needed.

Our Approach. The aim of this paper is to develop a comprehensive testing framework for SOP-DOM (see Figure 1). The SOP restricts access of active content like JavaScript on other components of a web page. We also apply it to CSS code by interpreting the style changes

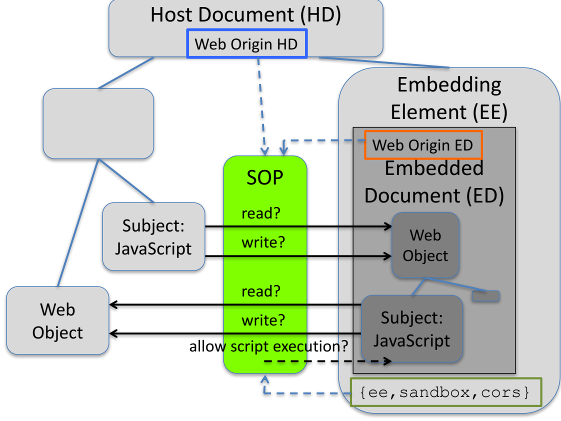

Figure 1: Setup for our test cases for SOP DOM access. The embedding element (`EE`) itself belongs to the host document (`HD`).

imposed by CSS code as write access on certain DOM elements.

We define "comprehensive" by meaning the coverage of all *interesting* edge cases. We thus do not cover all 15 elements with URI attributes but only a selected subset according to importance and interesting properties. Instead, we include "URL-attribute-like" constructions in the <**canvas**> element. We also do not restrict the test set to full DOM read or write access (which easily could have been automated to cover more test cases) but instead, also concentrate on the more interesting cases of *partial* read and write access.

Our tests thus cover only a representative sample of SOP-DOM, but this sample was chosen to cover each

known edge case of SOP-DOM. To cover these edge cases, many of the 544 test cases were designed manually. We use these representative test results to discuss if classical access control models like DAC, RBAC and ABAC are applicable to SOP-DOM. We reformulate access restrictions in terms of read, write, and execute rights granted to an embedded document (ED) contained in the HD and vice versa. We thus highlight the importance of the EE in defining the access rules of the SOP.

Testbed. We show the applicability of our test methodology for SOP implementations in current web browsers by providing a testbed at www.your-sop.com, where proof-of-concept HTML, JavaScript, and CSS code is given for each test case. Our tool consists of more than 10,000 lines of code covering 544 test cases with five types of ED and ten types of EE. The tests are created in a semi-automatic manner. For each EE to be tested, we automatically load the ED with possible CORS/sandbox attributes successively. We did not choose a fully-automatic test creation because this would lead to an overwhelming number of errors. Combining each EE with all possible attributes would lead to errors; for example, neither <img data=".."> nor <object src="..."> are semantically correct. In addition, there is no universal access from HD to ED and vice versa; for example, accessing the SVG ED can be achieved with a dedicated getSVGDocument() method.

Limitations. We describe a subset of the SOP for the interaction of web objects that are loaded into the browser. Zalweski describes other contexts such as cookie, local storage, Flash, XMLHttpRequest, Java, Silverlight, and Gears [8]. For each of them a different SOP is used. For example, Zheng et al. [12] have analyzed the SOP for HTTP cookies in-depth; here the SOP takes the path contained in an URI into account, which is an extension of the Web Origin concept. An in-depth discussion of the limitations of our approach can be found in Section 5.

Contributions. We make the following contributions:

- We systematically test edge cases of the SOP that have not been previously documented like the influence of the embedding element, and the CORS and sandbox attributes.
- We provide a testbed where the SOP implementation of a browser can be automatically tested and visualized.
- We used this testbed to extensively evaluate our model in 544 test cases on 10 modern browsers. More than 23% of the test cases revealed different SOP-DOM access rights implemented in at least one of the tested browsers. Our ABAC model provides a systematic way to describe these differences.
- We prove that a better understanding of SOP-DOM is useful by describing a novel CSS-based login oracle attack for IE and Edge, which we found using the ABAC rules for cross-origin access to CSS.
- We critically discuss the applicability of standard access control models like DAC, RBAC, and ABAC to SOP-DOM.

2 Foundations

Document Object Model (DOM). DOM is the standardized application programming interface (API) for scripts running in a browser to interact with the HTML document. It defines the "environment" in which a script operates. The first standard (DOM Level 1) was published in 1998 and the latest published version is DOM Level 3 (2004). The DOM standard is now a "living standard" since it has to be adapted to each new HTML5 feature, resulting the DOM Level 4 to remain in the "work in progress" stage.[2]

A browser's DOM includes more objects and properties than just the pure HTML markup, as shown in Figure 2. These objects can be accessed through a variety of different methods. For example, the iFrame element can be accessed through predefined selector methods like document.getElementByID("ID1"). The DOM structure does not necessarily match the markup structure. Although the <iframe> element from Figure 2 is a child element of the HTML document, there is no property document.frames[0]; instead, there is only window.frames[0].

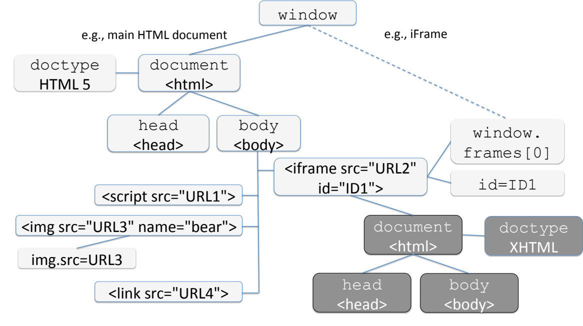

Figure 2: Small extract from the DOM.

[2] https://dom.spec.whatwg.org/

To access and modify the DOM, JavaScript code can be used. Each JavaScript script runs in a specific DOM *execution context*. Consider Listing 1 as an example. If this small HTML file is opened in a web browser, first the <**iframe**> element will be parsed. After that the iFrame's source code from Listing 2 will be loaded and the `alert` function contained therein will be executed. The <**script**> element will then be parsed and the (second) `alert` function will be executed.

```
1 <html><head><title>a.html</title></head>
2 <body><iframe src="b.html" />
3 <script>alert(document.location)</script>
4 </body></html>
```

Listing 1: Code of `http://a.org/a.html`

The two `alert` pop-up windows, triggered by the two `script` elements, will display different URLs because they are acting in different DOMs. The alert window called in Listing 1 will display the URL `http://a.org/a.html`, whereas the alert window in Listing 2 will display the URL `http://a.org/b.html`.

```
1 <html><head><title>b.html</title></head>
2 <body><script>alert(document.location)</
    script>
3 </body></html>
```

Listing 2: Code of `http://a.org/b.html`

Cross-Origin Resource Sharing (CORS). Using XMLHttpRequest, a web page may send arbitrary HTTP requests to any webserver. This is different from just opening an URL or submitting an HTML form since with XMLHttpRequest the web page has full control over all HTTP headers. To restrict such potentially dangerous queries, XMLHttpRequest is restricted by default to the domain from which the calling document was loaded (same-domain). To enable controlled cross-domain requests, the CORS standard [9] was developed. It works as follows: *a)* in a preflight request,[3] the browser sends an origin header (`Origin: http://a.com`) to the target web service requesting CORS privileges. *b)* the target server may now answer with an error message (access denied) or with a CORS header, such as `Access-Control-Allow-Origin: http://a.com`, to grant the access. Instead of a domain name, the CORS header may contain a wildcard (`*`) to grants access from arbitrary domains.[4] Although CORS is designed to relax the Same-Origin Policy (SOP) in a secure manner, there are many cross-origin resources used in the web (e.g., scripts, stylesheets, images, iFrames) that can be loaded without CORS and without XMLHttpRequest. However, in HTML5 some elements (e.g., <**img**>) may have `crossorigin` attributes which invoke CORS and subsequently modify the SOP access controls.

[3] The preflight request can be skipped in simple cases

[4] This additionally denies the use credentials such as cookies in a CORS request.

3 Methodology

3.1 SOP-DOM Attributes

The *Same-Origin Policy for DOM Access (SOP-DOM)* controls the access of a *subject* – typically JavaScript code – to a *web object* (e.g., an HTML form). The subject may be located directly in the `HD` or in an `ED`. The element that loads the `ED` is called the `EE` (cf. Figure 1). Both `HD` and `ED` have a Web Origin. The Web Origin of `ED` is defined by `src` or similar attributes of `EE` (e.g, `dynsrc`, `lowsrc`, and `srcset`).

SOP-DOM is often described as a boolean switch which either allows interaction between `HD` and `ED` in the same-origin case or blocks access in case of different web origins (e.g., Karlof et al. [15]). In reality, SOP-DOM is more complex; some `EE`s like <**img**> block almost all access even in the same-origin case, some `EE`s like <**script**> allow full read and write access (in one direction) even in the case of different origins, and some `EE`s like <**iframe**> (in the cross-origin case) only grant partial access. Furthermore, access decisions may be influenced by additional attributes like CORS or `sandbox`.

In our investigations, we have used five values as our *test attributes*, two of which contribute to the definition of Web Origin. These attributes are summarized in Table 2.

Notation. In this paper and in our testbed, we use $\overline{\texttt{HD}}$ and $\overline{\texttt{ED}}$ to denote that `HD` and `ED` share the same Web Origin, and $\overline{\texttt{HD}}$ and $\underline{\texttt{ED}}$ if the origin differs. If cross-origin and same-origin behavior are identical we, use `HD` and `ED` to save space.

Coverage and Restrictions. The SOP-DOM is very complex, because with each newly considered attribute, the number of test cases may grow by a factor proportional to the number of possible attribute values. Thus, it should be clear that it is nearly impossible to test and describe the whole SOP-DOM in one research paper.

Since Web Origins are well understood and have been covered in numerous other publications, we have only covered two different origins with the same `protocol` (HTTP) and two different domains with different `domain` values. Our focus is on `ee`, where we considered HTML elements with URI attributes and

Attribute	Description	S/O/E	HD/ED
`protocol`	protocol of URL, value of `location.protocol`	S,O	HD+ED
`domain`	domain/hostname of URL, value of `location.hostname`	S,O	HD+ED
`ee`	type of `EE`	S,O	ED
`cors`	value of the CORS attribute of the `ee`, i.e., `ee.crossOrigin`	O	ED
`sandbox`	value of `sandbox`	S,O,E	ED

Table 2: SOP-DOM Attributes. *S* denotes subject attributes, *O* object attributes, and *E* denotes attributes which may also be set independent of the markup (e.g., through a HTTP security policy like Content Security Policy (CSP)).

properties. By systematically analyzing the provided list of the W3C [20] and the WHATWG [21], we picked the representative HTML elements <**script**>, <**img**>, <**canvas**>, <**link**>, <**iframe**>, <**object**>, <**embed**>, and <**link**>. We have also examined CORS (the value of the `crossorigin` attribute) and `sandbox`, as a proof-of-concept, to show that these attributes do have an influence on the SOP-DOM. More limitations of our approach are discussed in Section 5.

3.2 Access Control Test Cases

Web Object Structure. Web objects may have an internal DOM structure, as it is the case with iFrames or SVG images. In this case, we can use standard DOM selector methods to test for read and write access.

Other web objects do not have a DOM structure (e.g., JPEG and PNG images). In this case, we define the type of access for each such web object separately (e.g., single pixel access for JPEG) and use adapted code examples.

Distinguishing Full and Partial Access. In case that the object has an internal DOM structure, we define *full* access if we can access arbitrary parts of the DOM by standard selectors like `getElementbyID()`. We define *partial* access as only being able to read, or only being able to write some specific properties (e.g., `window.top.location`).

If the web object does not have an internal DOM, we always specify exactly what we can read or write. To name one example, single pixels in images or the source code of scripts.

Full Read and Full Write Access. Supposing that JavaScript code has DOM read access, it typically also has write access using some DOM methods (e.g., `innerHTML`). We have tested this by first writing into a particular DOM property, and then by reading the same property to verify whether it contains the newly written value. For full DOM access, we successfully verified that any DOM property which can be read, can also be written. In our proof-of-concept implementation, a script contained in the `ED` tries to read DOM properties from HD and vice versa. To test full DOM access, we inter alia use the code depicted in Listings 3 and 4.

```
1  <html>
2  <head>HD from HD.org</head>
3  <body>
4  <script>
5  ED=document.getElementById("EE").
       contentDocument;
6  HD2ED=ED.getElementById("ID2");
7  read_success = (HD2ED.textContent == "
       Text in ED");
8  </script>
9  <element id="ID1">Text in HD</element>
10 <EE id="EE" src="ED.org/ED.mime"></EE>
11 </body>
12 </html>
```

Listing 3: Host document (HD) verifying full read access.

```
1  <html>
2  <head>ED from ED.org</head>
3  <body>
4  <ED><element id="ID2">Text in ED</element
       ></ED>
5  <script>
6  var ED2HD;
7  ED2HD=parent.getElementById("ID1");
8  read_success = (ED2HD.textContent == "
       Text in HD");
9  </script>
10 </body>
11 </html>
```

Listing 4: Embedded Document (ED) for verifying full read access.

Partial Access. Many partial access rules have been added to browser implementations over the years in order to implement new features, or to defend against new attacks. The best-known examples are certainly the DOM properties of an iFrame's top frame that are used to build JavaScript framebusters to defend against UI Redressing [22].

Partial access cannot be tested systematically. Instead, we relied on our knowledge from pentesting, blog posts

of security researchers, and – in some cases – on intuition. Please note that our goal was not to give a full list of partial access rules, but only to document the variety of such rules.

Partial Read: Examples. An example for partial read (and write) access is the pixel-based manipulation of images with the help of CANVAS (e.g., via `context.getImageData`).

Lekies et al. [5] underlined that every script executed within the same web document is able to read global variables created by another script. However, local variables inside a function cannot be accessed unless their values are not explicitly returned by the function. This illustrates clearly that we have partial read access.

As an edge case example for partial read access, CSS in combination with browser features like plain HTML and inactive SVG files can be used to extract some values from the SOP-DOM [23].

Partial Write: Examples. Partially writable are properties like `parent.location.path` and `parent.location.hash`. In the past `location.hash` was used to share data cross-origin. Nowadays, this feature can be replaced by using PostMessage or CORS and write access to `parent.location` can be restricted in iFrames by using the `sandbox` attribute.

Execute. Current sandboxing concepts consider blocking JavaScript execution but not CSS execution. To be consistent with this view, we say that an `EE` grants execute rights to an `ED` when JavaScript code contained in the `ED` can be executed. For example, when EE=<**iframe** sandbox>, then the execution of JavaScript is blocked. We verified this by using script execution to send a PostMessageAPI message to HD.

4 Evaluation

We implemented a testbed as a web application which automatically evaluates the SOP implementation of the currently used browsers. Additionally, it displays the results of 10 tested browsers from six different vendors and highlights the differences between them. Our testbed is publicly available at *www.your-sop.com*.

4.1 Experiment Setup

We evaluated the following elements with `src` attributes and determined their Alexa 500 rank through an analysis of the Alexa Top–500 start pages. The results are (rank; domains; occurrences): <**script**> (3; 460; 12,625), <**link**> (8; 453; 5,197), <**img**> (11; 439; 24,015), and <**iframe**> (21; 261; 1,406). To name an example, the `script`-element was the third most common element listed on 453 out of 500 domains with a total of 12,625 findings. The elements <**object**> or <**embed**> are not listed under the TOP-30 elements.

Our testbed executes all tests on a single website so that tests can be easily repeated with different browsers. It uses one of the previously mentioned `EE`s and loads an external `ED` via its dedicated attributes. For example, the <**img**> elements uses the `src` attribute; however, the <**object**> elements uses the `data` attribute. If the element supports CORS, we created a test as follows; we used the three attribute cases, (1.) no `crossorigin` attribute is set, (2.) `crossorigin="use-credentials"`, and (3.) `crossorigin="anonymous"`. For each attribute, we created a test that receives an HTTP response header `Access-Control-Cross-Origin` (1.) set to a specific domain `your-sop.com` or `other-domain.org`, (2.) set to the wildcard $*$, (3.) or not set at all. In addition, the HTTP response header `Use-Credentials` is once set for each test to (1.) to `yes`, to (2.) `no`, (3.) and not set. The immense number of combinations lead to a significant number of test cases if CORS is supported.

Each test loads an external resource (`ED`), first from the same domain (`your-sop.com`), and then from a different one (`other-domain.org`). When retrieved through any browser, the SOP decisions of the currently used browser are presented in different overview tables. Since the exact method to access specific objects from `ED` to `HD` – and vice versa – differs with each test, its source code can be inspected by hovering on the result field in the table on the testbed website (cf. Figure 3).

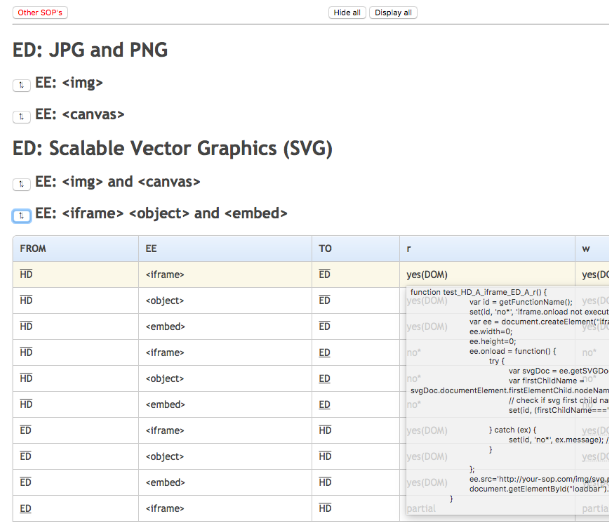

Figure 3: Screenshot of our `your-sop.com` testbed.

Using the testbed, we evaluated the SOP of ten differ-

ent browsers, including Google Chrome, Mozilla Firefox, Internet Explorer, Edge and Safari. We added a feature to export all test results in a JSON file. We then used this feature to add a comparison table of different browser behaviors. It displays all test cases and SOP decisions of all browsers at once or can only highlight the differences. Figure 4 shows a small part of the comparison of different SOP implementations.

4.2 Results

In the following, we describe the general outcome of our testbed. The results are structured by the type of the embedding element (EE).

Images. An `<img>` element acts like a sandboxed iFrame; read and write access is blocked in both directions, even in the same-origin case. Script execution is blocked in the `ED`; even if the `ED` is an SVG containing some JavaScript code, the script is not executed. This behavior holds for both the same-origin and cross-origin case.

If we use `<canvas>` as the embedding element `EE`[5], we can get read access to pixels in JPG, PNG and SVG images if loaded from the same origin. This allows reading out the color of each pixel and it may be critical in some security contexts like JPG- or PNG-based CAPTCHAs. Here, an attacker could use CANVAS to automatically read out the displayed token.[6]

SVG files are basically XML-based vector graphics. Please note, that unlike `<img>`, the `<svg>` element does not support a `src` attribute to load an external SVG file. If embedded into a website with `<img>` or `<canvas>`, they behave as if they were bitmaps; thus, we can only read pixels. It is also possible to include SVGs in `EE`s like `<iframe>`, `<object>`, and `<embed>`. Then the DOM of the SVG is mounted into the `HD` and we can access it fully, and additionally read all SVG vector instructions.

Scripts. Cross-origin loaded JavaScript code via `<script src="...">` is a well-known special case in the SOP; it is treated as if it had been loaded from the same origin. Technically, a script loaded by the `src` attribute is appended to the `document.scripts` array in the HD's DOM, independent of the domain on which the script is hosted. In the `<script>` case, no access restrictions are imposed by the SOP: we have full read-/write access from the `ED` to the `HD`, and execution rights from `HD` to `ED`.

[5]See the example on `https://developer.mozilla.org/en-US/docs/Web/API/Canvas_API/Tutorial/Pixel_manipulation_with_canvas`

[6]http://ejohn.org/blog/ocr-and-neural-nets-in-javascript/

For the read/write access from the `HD` (subject) to the `ED` (JavaScript, object), this is less well-known. It is clear that we cannot change the content of the external file (write), but we can overwrite functions defined in this external file, and thus change the functionality of the loaded code. We are able to read variable values and the source code of defined functions[7]. However, there are some exceptions: we cannot read `var cnt = 2+5;` but we can read the `cnt`'s value `7`. We can also read the complete line of code if it is contained in a function (cf. [5]). Thus, we have *partial* read/write access from the `HD` to the `ED`.

Style Sheets. External CSS code can be loaded via the embedding element `<link>`. In the case where the CSS code is loaded from the same origin, we can read the complete source code. If the CSS file is loaded cross-origin, we can only read the source code if proper CORS values are set. An exception is MS IE/Edge, which allows read access in every case (see Section 4.3 for details).

Write access for CSS code is defined by the ability of CSS to change the visual display of a web object. Since this is the desired behavior, write access from the `ED` to the HD is independent of the web origin.

Frames. For `<iframe>` (without `sandox` attribute) we have full read/write access in both directions in the same-origin case, and partial read/write access in the cross-origin case.

The cross-origin case from $\overline{\texttt{ED}}$ (subject) to $\underline{\texttt{HD}}$ (object) is of special interest; we have partial read/write access. Some properties that can be read are: `top.length` (number of frames/iFrames in `HD`), `top.closed` (boolean value if `HD` is closed), `top.opener` (reference to opener `HD` in the event of a popup). Although this is a very limited read access, we have a side-channel allowing us to read some cross-origin information. Especially the first property is noteworthy; it allows to get the number of frames/iFrames that are contained in the `HD`. We also have partial write access in this case; for example, to the `top.location` property (a property that we can only write, but are unable to read).

Similar results hold for the other direction (subject `HD` to object `ED`) in the cross origin case. In this case, the properties are accessed via the `window.frames[]` array (instead of `top`).

Sandboxed Frames. The origins of the SOP-DOM lie in the necessity of a clear separation of two HTML documents, shown by several attacks over the last ten years

[7]For example, by using `Object.getOwnPropertyNames(window)`, we can read all properties defined in the `window` object

Your SOP

Only display differences | Show all

You have detected 129 differences within 544 applicable test cases (23.71%).

Figure 4: Evaluation result by comparing 10 different browsers.

[24, 25, 26]. However, a complete separation between two HTML documents is often not possible; for example, to allow UI redressing countermeasures with JavaScript frame-busters [22].

To allow a better separation between the iFrame `ED` and the `HD`, *sandboxed iframes* were introduced [27]. We limited our evaluation to the attribute values that directly affect our read, write, and execute results: `allow-scripts`, `allow-same-origin`, `allow-top-navigation`.

The `sandbox` attribute is a special case that is discussed in Section 7.

Recommendations for Browser Vendors. From the perspective of a browser vendor, it is interesting to know how the results of our tool can be used to identify bugs and therefore potential vulnerabilities. In our analysis, we have automatically compared each SOP-DOM difference with the behavior of all other browsers. In case that at least one browser grants SOP-DOM access that the other browsers restrict, a browser vendor should have a closer look on this test case. We recommend to adjust the SOP-DOM behavior to the majority of other browser behaviors for reasons of clarity. For each test, our website recommends a result, which is based on the majority of all ten tested browsers (see Figure 4). Because our testbed includes browsers of different vendors (e.g., Apple, Google, Mozilla, Microsoft), we believe that this might be a representative SOP-DOM result.

4.3 Different Browser Behaviors

We implemented 544 test cases and 129 of these cases differ across ten tested browsers (23.71%).[8] We identified three subsets of different browser behaviors.

First, more than 35% of the identified differences could be attributed to <**canvas**> and PNG/SVG. In contrast to the other seven browser tests that allow partial read access with the help CORS from `HD` to `ED` cross-origin, FF, IE, and Edge do not allow read access in the following CORS cases of <**canvas**> with SVG and PNG: `Access-Control-Allow-Origin : your-sop.com` (`ED` sets the domain of `HD`) and `Use-Credentials: true`. Irrespective of CORS, <**canvas**> and SVG have 44 differences that are based on a denied access in IE 11.[9]

Second, over 12% of the test cases show differences between Safari 9 and the other browsers by looking on <**object**> and <**embed**> elements that load SVG files. Safari 9 does not show an SVG if it is loaded by code like `<object data="image.svg"></object>`. Therefore, JavaScript code contained in the SVG file cannot be executed. It needs an additional `type` attribute with the value `image/svg+xml` such that JavaScript execution is allowed. Since Safari 10.1 Apple has changed their implementation and both elements behave similar to the other browsers. The attribute `type="image/svg+xml"` is no more required.

Third, over 51% of the test cases show different behaviors because of <**link**>. Nearly all the cases have different CORS implementations. CORS thus shows that a relatively new and complex technology leads to different interpretations of "well-known" web concepts like SOP.

Similarly to Chromium's testbed that have been applied to other browsers to find bugs, our testbed could be used and extended by browser vendors and security researchers to identify browser differences leading to exploits.[10]

4.4 Cross-Origin Login Oracle Attack.

We have detected one browser difference due to IE/Edge, which does not need CORS. In this case, IE/Edge allows us to read CSS rules cross-origin while other browsers do not allow such access.

[8] `http://www.your-sop.com/stats.php`

[9] We have communicated these differences to Microsoft and it seems that they have fixed them in the newest browser versions.

[10] `https://github.com/thomaspatzke/BrowserCrasher`

By using the difference that was detected in case of <**link**>, we show that dynamically generated CSS files can be abused to attack the user's privacy. In case of CSS code from different origins, IE/Edge behaves differently from GC and FF; it does not set DOM properties like `cssRules` to `null`. Therefore, an attacker is always allowed to read the CSS code regardless of its origin. This allows us to build a novel login oracle:

- Suppose a webserver delivers different CSS files, depending on whether the user is logged in or not.
- The attacker's website consists of the `EE` <**link**> loading the victim's CSS code (`ED`).
- Though HD has another origin than `ED`, the attacker's JavaScript code in HD automatically reads all CSS rules. By comparing the CSS code with CSS code of a logged out user, the attacker can determine the logged in state.

We verified our login oracle with the startpage service `start.me` (`ED`); an attacker is clearly able to decide whether a user is logged in or not. This attack is similar to [5]. We have informed the website administrators about this vulnerability. Microsoft (Research Center, MSRC) acknowledged this bug (Case 32703) and the fix will be incorporated into a future version of IE/Edge.

5 Limitations

Even if we restrict our attention to SOP-DOM, the Same-Origin Policy has a very large scope. We have 15 HTML elements with `src` attributes, and several more with a similar functionality (e.g. `<canvas>`). There are six different sandbox attributes, and they (e.g., the CORS attribute) may be influenced by HTTP-based security policies like CSP. There are many different ways how to embed a document of a given MIME type into a webpage (e.g., SVG via `<img>` or `<iframe>`), and there are many different MIME types with and without a DOM structure to consider. There are pseudoprotocols like `data:` and `about:`, which have different Web Origin definitions. There is also a large number of DOM properties which could be tested for partial access.

Covering all interactions within this scope would result in an exponential number of test cases, which cannot be covered in one research paper. For example, Zalweski [28] lists four classes of common URL schemes (e.g., document-fetching and third-party) consisting of different subclasses (e.g., browser specific schemes like `vbscript`, `firefoxurl`, and `cf`). Moreover, it is possible to register self-defined handlers for particular schemes via `registerProtocolHandler`. In this section, we therefore discuss several technologies that we excluded from our research and give a rationale for these decisions.

Link. One technical limitation of our evaluation framework is that we used the <**link**> element only to load CSS. We did not consider, for example, HTML imports via `<link rel="import"href="data.html">`. An interesting novel technology that is highly under development are Service Workers [29]. They can, for example, be loaded using `<link rel="serviceworker"href="worker.js">`. However, it is currently "an experimental technology" according to Mozilla [30], although they are used by many websites (e.g., Google and Twitter). Our evaluation does not cover Web Workers [31]. This technology allows running a JavaScript in different context; for example, there is no `window` object reference. For this reason, we excluded it.

SVG. We only covered <**svg**> as an `ED` which directly embeds the JavaScript code for testing read/write access. It is also possible, to use <**svg**> as a `HD`; for example, an external JavaScript can be loaded by using `<svg><script xlink:href=".."></svg>`. Our testbed always uses an HTML document as `HD`.

JavaScript. We only cover a small, but hopefully representative, set of DOM properties. Our testbed only covers the `location` property, but sub-properties such as `location.hash` or `location.path` were not analyzed. The same holds for the `window.name` property, which is well-known to be writable across origins.

A design decision for our testbed was to be able to easily execute all test simultaneously. Therefore, only one *index.html* is capable to run all 544 tests with only one click by the user. For this reason, we excluded popups and the corresponding `window.opener` property.

Other Mime Types. Our testbed is limited to HTML, JavaScript, CSS, and SVG. For example, it would be interesting to investigate PDF, which can also include JavaScript code. There are many more *active* MIME types, such as Flash or ActiveX, which should be addressed in further research.

Pseudoprotocols. We excluded pseudo protocols (e.g., `about:`, `chrome:`) and Data and JavaScript-URIs from our tests, because in a (possibly outdated) overview, Zalewski [28] already pointed out that there are different Web Origin assignments in different browser implementations. However, extending the testbed to selected pseudoprotocols is future work.

6 Related Work

Different SOP Contexts. Jackson and Barth [32] discussed different SOP contexts, and showed vulnerabilities introduced by the interaction of these contexts. Zheng et al. [12] describe in detail the SOP for HTTP cookies. They also presented bypasses based on subdomains. Session integrity problems resulting from the cookie context SOP are discussed by Bortz et al. [13]. Karlof et al. [15] and Masone et al. [14] describe refined origins for the cookie SOP: they replaced the domain name with a server's X.509 certificate and public keys. Thus, they are able to use different cookies for different servers on the same domain. Singh et al. [7] analyzed in-coherencies in web browser access control policies by showing that there are different definitions of Web Origins; there are web-origins for DOM objects, localStorage, and XMLHttpRequest, as well as other definitions for cookies (domain, path) and the clipboard (user).

SOP Enhancements. Wang et al. [33] proposed their secure browser Gazelle with a multi-principal OS architecture and showed how to implement extended access control policies. Chen et al. [34] analyzed browser domain-isolation bugs and attacks. They proposed "script accenting" as a defense mechanism so that frames cannot communicate if they have different accents.

SOP Bypasses. Ways to bypass SOP restrictions are regularly published in the academic and non-academic areas. Jackson et al. [35] and Johns et al. [36] discuss DNS rebinding attacks (which manipulate Web Origins and thus disable the SOP) and proposed mitigation techniques. Oren and Keromytis [16] used Hybrid Broadcast-Broadband Televisio (HbbTV) to bypass the SOP. In contrast to websites, HbbTV data does not have a origin. This characteristic allows an attacker to inject malicious code of his choice into any website, which are loaded via the HbbTV data stream. Lekies et al. [5] are using dynamically generated JavaScript files to attack the privacy of a victim. Singh et al. [7] describe major access control flaws in browsers. Complicated side-channels have been abused to read DOM properties in [23].

Various non-academic publications describe ways to bypass the SOP. Jain [37] states that Safari v6.0.2 does not have SOP restrictions in case the `file` protocol is used. In 2010, Stone [38] showed that UI redressing can be used to bypass the SOP. Even if the SOP is restricting access on the script level, copy-and-paste as well as drag-and-drop actions are not restricted. In 2012, Heyes [39] showed that the location of a window can be accessed cross-origin in FF; however, this should not be allowed. Three years later, Bentkowski demonstrated with CVE-2015-7188 that FF's $\leq$42 SOP can be bypassed by adding whitespace characters to IP address strings.[11] In 2016, Ormandy [40] showed that Comodo's browser Chromodo disables, at least partially, the SOP and thus Chromodo "actually disables all web security". There are also SOP bypasses via Java applets [41], Adobe Reader [42], Adobe Flash [11], and inter alia Microsoft Silverlight [10].

Formal approaches to Web Security. Yang et al. [6] propose to describe the SOP in terms of Information Flow Control. Akhawe et al. [43] have a much broader scope and describes the backbone of a formal model for the Web itself.

Other Approaches. Crites et al. [44] proposed the abstraction and access control model OMash, as a replacement of SOP. Barth et al. [45] proposed a browser extension system for protecting browsers from extension vulnerabilities. They reused the SOP to isolate extensions from attacks, which needs inter alia access to browser internals and web page data. Chen et al. [46] described an opt-in app isolation mechanism that acts like the user is executing different browsers. Even if the attacker is able to act in the same origin, the users credentials might only be available in a logged-in state which is isolated. Stamm et al. [47] proposed CSP, which is implemented in all modern browsers. In CSP, code injection attacks are mitigated through restrictions imposed on code origins (whitelisting of allowed origins), and through abandoning inline code. Jackson and Wang [48] introduced Subspace as a cross-domain communication primitive allowing communication across domains.

7 Access Control Policies

Since SOP-DOM restricts access of subjects (mainly JavaScript code) to web objects, we think that an appropriate formal model could be found amongst the class of access control policies. Access control policies restrict the access of subjects from a set S (humans, machines or code) to objects from a set O. In the following, we discuss how well the three main classes fit our findings.

SOP-DOM is a global access control policy regulating access between websites throughout the Internet; however, decisions through the SOP-DOM can only be made on that which is locally available. This data includes the web origins of the different subjects and objects, the HTML markup (elements and attributes), and more recently, security policies communicated through HTTP headers like CORS, CSP, X-Frame-Options, and others.

[11] `https://www.mozilla.org/en-US/security/advisories/mfsa2015-122/`

In SOP-DOM, the set O of objects may contain any element or property of the local DOM of the web page. Typically, access rights granted to two objects o_1 and o_2 should only differ if the Web Origins of these two objects differ. The set S of subjects could be defined as $S = O$; however, this would only result in numerous "inactive" subjects which do not need any access rights since they never access any other objects (e.g., text nodes). We therefore restrict the set S to "active" objects, where the definition of "active" still awaits a mathematically precise definition. We include all script objects in S and all CSS code; however, since the discovery of scriptless attacks [23], there may be a need to extend this definition.

7.1 Discretionary Access Control (DAC)

DAC access control is well-known from operating systems (OSs); each user has a login name and the OS decides if this particular user has access to a certain resource (e.g., a data file or network printer). Each resource also has a unique name; therefore, S and O contain the names of users and resources. Another example is email encryption in which read access is granted on the basis of the RFC 822 email addresses of the recipients.

Definition 1 *In DAC, access rights are directly assigned to subjects: the policy set P is a subset of $S \times O$, and subject s has access to object o if $(s,o) \in P$.*

In the WWW, each subject from S and each object from O can be assigned a unique name, which is the URL at which it can be found. Thus, this part would fit in the DAC model. However, there is no global "web operating system" which keeps track of all possible pairs in $S \times O$. Instead SOP-DOM uses only a part of this name in its access decisions, namely the Web Origin.

Some sources trivialize RFC 6454 in the sense that they state that read and write access are only possible if the Web Origins of the subject and object are identical. If this was true, it would be a perfect fit for DAC and a very simple global DAC policy could be formulated as follows:

$$(s,o) \in P \iff origin(s) = origin(o).$$

This however is simply incorrect, since in many cases $(s,o) \in P$ even if $origin(s) \neq origin(o)$, for example, in case a script s was embedded via a `<script>` element, or if s is contained in a sandboxed iFrame with top-level frame access.

Unfortunately, the elegant DAC-based definition of SOP-DOM via web origins does not fit.

7.2 Role-Based Access Control (RBAC)

RBAC is often used in distributed environments as an abstraction to improve the manageability of access control rules. By means of example, the role *system administrator* may be assigned to different subjects over time or even periodically, and this role has many important access rights. Instead of assigning, revoking, and reassigning these access rights periodically to individual subjects, the access rights are assigned to the *role* "system administrator", and this single role is assigned, revoked and reassigned over time.

Definition 2 *In RBAC, subjects are assigned to* roles *from a set R, and access rights are assigned to roles: $P_1 \subseteq S \times R, P_2 \subseteq R \times O$, and s has access to o if there exists a role r such that $(s,r) \in P_1$ and $(r,o) \in P_2$.*

In typical RBAC installations, access rights to individual resources are assigned manually by the system administrator. This is problematic for SOP-DOM, since access policies must be created automatically. We discuss the following variant of RBAC where roles are assigned to both subjects and objects, and access decisions are based on both roles only.

Definition 3 *In enhanced RBAC (eRBAC), subjects are assigned* subject roles *from a set R_S, objects are assigned* object roles *from a set R_O, i.e. $P_S \subseteq S \times R_S, P_O \subseteq O \times R_O$. Access rights are assigned between roles: $P \subseteq R_S \times R_O$. So subject s has access to object o if there exists roles $rs \in R_S$ and $ro \in R_O$ such that $(s,rs) \in P_S, (o,ro) \in P_O$ and $(rs,ro) \in P$.*

Since we have identified the important influence of the embedding element `EE` on the access decisions in SOP-DOM, we may use `EE` to assign a "role" to subjects and objects. So in SOP-DOM, P_S and P_O would be computed locally from the HTML markup and additional security policies, and P would be the global SOP-DOM rules implemented in each browser.

For example, to specify that both external and inline scripts have full cross-origin read and write access rs^{co}_{rw} we may formulate:

$$(s, rs^{co}_{rw}) \in P_S \iff EE(s) = \texttt{<script>} \vee EE(s) = HD. \tag{1}$$

Access to objects is again mainly defined by the embedding element. An image embedded via `<img>` is, for example, inaccessible at all, whereas the same image embedded via `<canvas>` is partially readable. So we could define a role ro^{so}_r with the following equation:

$$(o, ro^{so}_r) \in P_O \iff EE(o) \notin \{ \texttt{<img>}, ... \} \tag{2}$$

Web origins could be taken into account in P by stating that for all values X, $(rs_X^{so}, ro_X^{so}) \in P$ (subject role has same-origin access to object role), $(rs_X^{co}, ro_X^{co}) \in P$ (subject role has cross-origin access to object role), and $(rs_X^{co}, ro_X^{so}) \in P$ (if subject role has cross-origin access to object role, then it also has same-origin access).

This shows that eRBAC seems to be a feasible model, however, the rules to assign roles to subjects and objects could become quite complicated because in addition to the `EE`, we have identified at least two attribute values (*cors* and *sandbox*) which may influence the assignment of such roles. This complexity will be increased if we extend the scope to HTTP security policies such as CSP and pseudo-URIs like `data:`, which are not covered by our current analysis.

7.3 Attribute-Based Access Control

Attribute-Based Access Control (ABAC) [49] is a flexible access control mechanism used in, for example, XACML [50]. It may also be used to implement RBAC: roles can be modeled as *role attributes* assigned to both subject and object. The policy decision in ABAC may depend on other subject, object and environment attributes as well.

Definition 4 *Let $A_i = \{NULL, value_i^1, ..., value_i^{k_i}\}$ be the set of different values of attribute i. Let $\mathscr{SA} = A_1 \times ... \times A_l$, $\mathscr{OA} = A_{l+1} \times ... \times A_m$ and $\mathscr{EA} = A_{m+1} \times ... \times A_n$ be the cartesian products of all subject, object and environment attribute values. Let $\mathscr{R}$ be the set of all access rights. Then an ABAC policy $\mathscr{P}$ is defined as $\mathscr{P} \subseteq \mathscr{SA} \times \mathscr{OA} \times \mathscr{EA} \times \mathscr{R}$.*

Now let $\vec{sa}$ be the array of subject attributes of subject s, $\vec{oa}$ the array of object attributes of object o, and $\vec{ea}$ the actual array of environment attributes. Then subject s has access $r \in \mathscr{R}$ to object o if the array $\vec{a}$, formed by concatenating $\vec{sa}$, $\vec{oa}$, $\vec{ea}$, and r, is contained in $\mathscr{P}$: $\vec{a} \in \mathscr{P}$.

ABAC could be suitable for SOP-DOM because we can model any parameter that influences the access decisions as an attribute. This allows to give a unified treatment to some well-known concepts.

Extended Web Origins. Both subject and object have attributes from which their Web Origin can be computed. In the classical definition of Web Origins in RFC6454 these are `protocol` (`location.protocol`), `domain` (`location.hostname`) and `port` (`location.port`).

- We can, for example, extend this definition to take the legacy `document.domain` declaration into account (see below). We define an additional variable `dd` and assign the value of `document.domain` to it. All these variables are both subject and object variables (cf. Section 7), and are present for both `HD` and `ED` (cf. Table 2).
- The assignment of random Web Origins to sandboxed iFrames can be specified by stating that $origin(o) = \$RAND$ if $sandbox(o) = TRUE$.

Embedding Element. The important role of the embedding element `EE` is modeled as a variable `ee`, applicable to both subject and object, but set only for the embedded document `ED`. The value of `ee` is set to the type of the embedding element. It modifies both same-origin and cross-origin access decisions significantly.

Additional Attributes. Similar to the `ee` attribute, the `cors` and `sandbox` attributes are only defined for the embedded document `ED`. For `cors`, our tests revealed that this attribute modifies access rights to a web object and therefore, it is only an object attribute.

Attributes not fixed by the HTML source code. The ABAC model also defines *environment attributes*, which may not depend on subject or object alone but rather on the execution environment. The only attribute we could qualify to be in $\mathscr{EA}$ during our tests is `sandbox`, since it may be set interactively by using a suitable directive of Content Security Policy.

Extended Web Origin. The ABAC model for SOP-DOM can be presented as the set $\mathscr{P}$ but this does not give any insights into the structure of SOP-DOM. However, four of the seven variables can be combined into a very elegant description of an extended Web Origin. This shows that the ABAC model can also be used to simplify the description of SOP-DOM.

```
1 Read(protocol,domain,port,dd);
2 if dd=NULL or (dd is not a
      superdomain)
3 then wo:=(protocol,domain,port)
4 else wo:=(protocol,dd,NULL)
```

Listing 5: Computation of extended Web Origin.

Listing 5 shows how an extended web origin is computed from the four given ABAC variables. Please note that the `else` branch of this algorithm has been verified by our testbed but different descriptions exist in the literature. In contrast to previous descriptions of the interaction of Web Origins and the `document.domain`

declaration, the novel ABAC based concept of *extended* Web Origin is both simpler ans less error-prone.

7.4 Summary

The requirements on an access control model for SOP-DOM can be formulated as follows: the general rules of SOP-DOM must be expressible without reference to the URL or the HTML context of a web subject or object, and to apply the SOP-DOM rules, URL and HTML context of each web object must be transformed into an abstracted description which then will serve as an input to the general SOP-DOM rules.

This rules out DAC as a model, since DAC rules would simply consist of a large global matrix, where each web object worldwide has a row, and each subject a column.

eRBAC and ABAC both seem promising candidates, since they fit the general requirements. A tentative formalization of the test results presented in this paper in both models could lead to new test cases which could help to decide which of the two approaches, if any, is better suited to formalize SOP-DOM.

8 Conclusions & Future Work

Our analysis highlights the importance to evaluate every single possibility of browser interactions in the SOP-DOM. Different browser data sets can be used to identify inconsistencies across implementations, which can lead to security vulnerabilities. Although edge cases (CORS, sandbox attribute) are mainly responsible for the detected browser behaviors in our evaluation, commonly known cases can also have differences and even vulnerabilities. Consequently, browser vendors have to compare their own implementation with those of other vendors.

Our discussion on access control policies as a model to describe the SOP-DOM helps for a better understanding. Browser implementations can use our insights to describe the SOP-DOM implementation more formally and thus preemptively prevent SOP bypasses. We strongly believe that a more formal SOP-DOM definition will help the scientific as well as the pentesting community to find more severe vulnerabilities. Our test results of the ten tested browsers are available on the testbed website.

Future Work. To extend the coverage, future work may address the following areas: (1.) local storage/session storage or even new data types like Flash or PDF; (2.) different protocols, including pseudo-protocols like `about:` and `data:`; (3.) other elements with URL attributes or properties; (4.) additional HTML attributes.

To generate novel insights into SOP-DOM, the path taken by integrating the `document.domain` declaration could be extended to other attributes like `ee`; for sandboxed iFrames, for example, a random Web Origin should be generated according to the specification. This is however only possible if other `EE`s imposing similar restrictions (e.g., the <**img**> element) also use random Web Origins. This remains to be tested.

Locally Differentially Private Protocols for Frequency Estimation

Tianhao Wang, Jeremiah Blocki, Ninghui Li

University of Wisconsin-Madison

Abstract

Protocols satisfying Local Differential Privacy (LDP) enable parties to collect aggregate information about a population while protecting each user's privacy, without relying on a trusted third party. LDP protocols (such as Google's RAPPOR) have been deployed in real-world scenarios. In these protocols, a user encodes his private information and perturbs the encoded value locally before sending it to an aggregator, who combines values that users contribute to infer statistics about the population. In this paper, we introduce a framework that generalizes several LDP protocols proposed in the literature. Our framework yields a simple and fast aggregation algorithm, whose accuracy can be precisely analyzed. Our in-depth analysis enables us to choose optimal parameters, resulting in two new protocols (i.e., Optimized Unary Encoding and Optimized Local Hashing) that provide better utility than protocols previously proposed. We present precise conditions for when each proposed protocol should be used, and perform experiments that demonstrate the advantage of our proposed protocols.

1 Introduction

Differential privacy [10, 11] has been increasingly accepted as the *de facto* standard for data privacy in the research community. While many differentially private algorithms have been developed for data publishing and analysis [12, 19], there have been few deployments of such techniques. Recently, techniques for satisfying differential privacy (DP) in the local setting, which we call LDP, have been deployed. Such techniques enable gathering of statistics while preserving privacy of every user, without relying on trust in a single data curator. For example, researchers from Google developed RAPPOR [13, 16], which is included as part of Chrome. It enables Google to collect users' answers to questions such as the default homepage of the browser, the default search engine, and so on, to understand the unwanted or malicious hijacking of user settings. Apple [1] also uses similar methods to help with predictions of spelling and other things, but the details of the algorithm are not public yet. Samsung proposed a similar system [21] which enables collection of not only categorical answers (e.g., screen resolution) but also numerical answers (e.g., time of usage, battery volume), although it is not clear whether this has been deployed by Samsung.

A basic goal in the LDP setting is frequency estimation. A protocol for doing this can be broken down into following steps: For each question, each user **encodes** his or her answer (called input) into a specific format, **randomizes** the encoded value to get an output, and then sends the output to the aggregator, who then **aggregates** and decodes the reported values to obtain, for each value of interest, an estimate of how many users have that value. With improvement on the basic task of frequency estimation, solutions to more complex problems that rely on it, such as heavy hitter identification, frequent itemset mining, can also be improved.

We introduce a framework for what we call "pure" LDP protocols, which has a nice symmetric property. We introduce a simple, generic aggregation and decoding technique that works for all pure LDP protocols, and prove that this technique results in an unbiased estimate. We also present a formula for the variance of the estimate. Most existing protocols fit our proposed framework. The framework also enables us to precisely analyze and compare the accuracy of different protocols, and generalize and optimize them. For example, we show that the Basic RAPPOR protocol [13], which essentially uses unary encoding of input, chooses sub-optimal parameters for the randomization step. Optimizing the parameters results in what we call the Optimized Unary Encoding (OUE) protocol, which has significantly better accuracy.

Protocols based on unary encoding require $\Theta(d)$ com-

munication cost, where d is the number of possible input values, and can be very large (or even unbounded) for some applications. The RAPPOR protocol uses a Bloom filter encoding to reduce the communication cost; however, this comes with a cost of decreasing accuracy as well as increasing computation cost for aggregation and decoding. The random matrix projection-based approach introduced in [6] has $\Theta(\log n)$ communication cost (where n is the number of users); however, its accuracy is unsatisfactory. We observe that in our framework this protocol can be interpreted as binary local hashing. Generalizing this and optimizing the parameters results in a new Optimized Local Hashing (OLH) protocol, which provides much better accuracy while still requiring $\Theta(\log n)$ communication cost. The variance of OLH is orders of magnitude smaller than the previous methods, for ε values used in RAPPOR's implementation. Interestingly, OLH has the same error variance as OUE; thus it reduces communication cost at no cost of utility.

With LDP, it is possible to collect data that was inaccessible because of privacy issues. Moreover, the increased amount of data will significantly improve the performance of some learning tasks. Understanding customer statistics help cloud server and software platform operators to better understand the needs of populations and offer more effective and reliable services. Such privacy-preserving crowd-sourced statistics are also useful for providing better security while maintaining a level of privacy. For example, in [13], it is demonstrated that such techniques can be applied to collecting windows process names and Chrome homepages to discover malware processes and unexpected default homepages (which could be malicious).

Our paper makes the following contributions:

- We introduce a framework for "pure" LDP protocols, and develop a simple, generic aggregation and decoding technique that works for all such protocols. This framework enables us to analyze, generalize, and optimize different LDP protocols.

- We introduce the Optimized Local Hashing (OLH) protocol, which has low communication cost and provides much better accuracy than existing protocols. For $\varepsilon \approx 4$, which was used in the RAPPOR implementation, the variance of OLH's estimation is $1/2$ that of RAPPOR, and close to $1/14$ that of Random Matrix Projection [6]. Systems using LDP as a primitive could benefit significantly by adopting improved LDP protocols like OLH.

Roadmap. In Section 2, we describe existing protocols from [13, 6]. We then present our framework for pure LDP protocols in Section 3, apply it to study LDP protocols in Section 4, and compare different LDP protocols in Section 5. We show experimental results in Section 6. We review related work in Section 7, discuss in Section 8, and conclude in Section 9.

2 Background and Existing Protocols

The notion of differential privacy was originally introduced for the setting where there is a **trusted data curator**, who gathers data from individual users, processes the data in a way that satisfies DP, and then publishes the results. Intuitively, the DP notion requires that any single element in a dataset has only a limited impact on the output.

Definition 1 (Differential Privacy) *An algorithm* $\mathbf{A}$ *satisfies* ε*-differential privacy (*ε*-DP), where* $\varepsilon \geq 0$*, if and only if for any datasets* D *and* D' *that* differ in one element*, we have*

$$\forall t \in Range(\mathbf{A}): \ \Pr[\mathbf{A}(D) = t] \leq e^{\varepsilon} \Pr\left[\mathbf{A}(D') = t\right],$$

where $Range(\mathbf{A})$ *denotes the set of all possible outputs of the algorithm* $\mathbf{A}$.

2.1 Local Differential Privacy Protocols

In the local setting, there is no trusted third party. An **aggregator** wants to gather information from **users**. Users are willing to help the aggregator, but do not fully trust the aggregator for privacy. For the sake of privacy, each user perturbs her own data before sending it to the aggregator (via a secure channel). For this paper, we consider that each user has a single value v, which can be viewed as the user's answer to a given question. The aggregator aims to find out the frequencies of values among the population. Such a data collection protocol consists of the following algorithms:

- Encode is executed by each user. The algorithm takes an input value v and outputs an encoded value x.

- Perturb, which takes an encoded value x and outputs y. Each user with value v reports $y = \text{Perturb}(\text{Encode}(v))$. For compactness, we use $\text{PE}(\cdot)$ to denote the composition of the encoding and perturbation algorithms, i.e., $\text{PE}(\cdot) = \text{Perturb}(\text{Encode}(\cdot))$. $\text{PE}(\cdot)$ should satisfy ε-local differential privacy, as defined below.

- Aggregate is executed by the aggregator; it takes all the reported values, and outputs aggregated information.

Definition 2 (Local Differential Privacy) *An algorithm* $\mathbf{A}$ *satisfies* ε*-local differential privacy (*ε*-LDP),*

where $\varepsilon \geq 0$, if and only if for any input v_1 and v_2, we have

$$\forall y \in Range(\mathbf{A}): \ \Pr[\mathbf{A}(v_1) = y] \leq e^{\varepsilon} \Pr[\mathbf{A}(v_2) = y],$$

where $Range(\mathbf{A})$ denotes the set of all possible outputs of the algorithm $\mathbf{A}$.

This notion is related to *randomized response* [24], which is a decades-old technique in social science to collect statistical information about embarrassing or illegal behavior. To report a single bit by random response, one reports the true value with probability p and the flip of the true value with probability $1-p$. This satisfies $\left(\ln \frac{p}{1-p}\right)$-LDP.

Comparing to the setting that requires a trusted data curator, the local setting offers a stronger level of protection, because the aggregator sees only perturbed data. Even if the aggregator is malicious and colludes with all other participants, one individual's private data is still protected according to the guarantee of LDP.

Problem Definition and Notations. There are n users. Each user j has one value v^j and reports once. We use d to denote the size of the domain of the values the users have, and $[d]$ to denote the set $\{1,2,\ldots,d\}$. Without loss of generality, we assume the input domain is $[d]$. The most basic goal of Aggregate is **frequency estimation**, i.e., estimate, for a given value $i \in [d]$, how many users have the value i. Other goals have also been considered in the literature. One goal is, when d is very large, identify values in $[d]$ that are frequent, without going through every value in $[d]$ [16, 6]. In this paper, we focus on frequency estimation. This is the most basic primitive and is a necessary building block for all other goals. Improving this will improve effectiveness of other protocols.

2.2 Basic RAPPOR

RAPPOR [13] is designed to enable longitudinal collections, where the collection happens multiple times. Indeed, Chrome's implementation of RAPPOR [3] collects answers to some questions once every 30 minutes. Two protocols, Basic RAPPOR and RAPPOR, are proposed in [13]. We first describe Basic RAPPOR.

Encoding. $\mathsf{Encode}(v) = B_0$, where B_0 is a length-d binary vector such that $B_0[v] = 1$ and $B_0[i] = 0$ for $i \neq v$. We call this **Unary Encoding**.

Perturbation. $\mathsf{Perturb}(B_0)$ consists of two steps:
Step 1: Permanent randomized response: Generate B_1 such that:

$$\Pr[B_1[i] = 1] = \begin{cases} 1 - \frac{1}{2}f, & \text{if } B_0[i] = 1, \\ \frac{1}{2}f, & \text{if } B_0[i] = 0. \end{cases}$$

RAPPOR's implementation uses $f = 1/2$ and $f = 1/4$. Note that this randomization is **symmetric** in the sense that $\Pr[B_1[i] = 1 | B_0[i] = 1] = \Pr[B_1[i] = 0 | B_0[i] = 0] = 1 - \frac{1}{2}f$; that is, the probability that a bit of 1 is preserved equals the probability that a bit of 0 is preserved. This step is carried out only once for each value v that the user has.
Step 2: Instantaneous randomized response: Report B_2 such that:

$$\Pr[B_2[i] = 1] = \begin{cases} p, & \text{if } B_1[i] = 1, \\ q, & \text{if } B_1[i] = 0. \end{cases}$$

This step is carried out each time a user reports the value. That is, B_1 will be perturbed to generate different B_2's for each reporting. RAPPOR's implementation [5] uses $p = 0.75$ and $q = 0.25$, and is hence also symmetric because $p + q = 1$.

We note that as both steps are symmetric, their combined effect can also be modeled by a symmetric randomization. Moreover, we study the problem where each user only reports once. Thus without loss of generality, we ignore the instantaneous randomized response step and consider only the permanent randomized response when trying to identify effective protocols.

Aggregation. Let B^j be the reported vector of the j-th user. Ignoring the Instantaneous randomized response step, to estimate the number of times i occurs, the aggregator computes:

$$\tilde{c}(i) = \frac{\sum_j \mathbb{1}_{\{i|B^j[i]=1\}}(i) - \frac{1}{2}fn}{1-f}$$

That is, the aggregator first counts how many time i is reported by computing $\sum_j \mathbb{1}_{\{i|B^j[i]=1\}}(i)$, which counts how many reported vectors have the i'th bit being 1, and then corrects for the effect of randomization. We use $\mathbb{1}_X(i)$ to denote the indicator function such that:

$$\mathbb{1}_X(i) = \begin{cases} 1, & \text{if } i \in X, \\ 0, & \text{if } i \notin X. \end{cases}$$

Cost. The communication and computing cost is $\Theta(d)$ for each user, and $\Theta(nd)$ for the aggregator.

Privacy. Against an adversary who may observe multiple transmissions, this achieves ε-LDP for $\varepsilon = \ln\left(\left(\frac{1-\frac{1}{2}f}{\frac{1}{2}f}\right)^2\right)$, which is $\ln 9$ for $f = 1/2$ and $\ln 49$ for $f = 1/4$.

2.3 RAPPOR

Basic RAPPOR uses unary encoding, and does not scale when d is large. To address this problem, RAPPOR uses Bloom filters [7]. While Bloom filters are typically used

to encode a set for membership testing, in RAPPOR it is used to encode a single element.

Encoding. Encoding uses a set of m hash functions $\mathbb{H} = \{H_1, H_2, \ldots, H_m\}$, each of which outputs an integer in $[k] = \{0, 1, \ldots, k-1\}$. $\mathsf{Encode}(v) = B_0$, which is k-bit binary vector such that

$$B_0[i] = \begin{cases} 1, & \text{if } \exists H \in \mathbb{H}, s.t., H(v) = i, \\ 0, & \text{otherwise.} \end{cases}$$

Perturbation. The perturbation process is identical to that of Basic RAPPOR.

Aggregation. The use of shared hashing creates challenges due to potential collisions. If two values happen to be hashed to the same set of indices, it becomes impossible to distinguish them. To deal with this problem, RAPPOR introduces the concept of cohorts. The users are divided into a number of cohorts. Each cohort uses a different set of hash functions, so that the effect of collisions is limited to within one cohort. However, partial collisions, i.e., two values are hashed to overlapping (though not identical) sets of indices, can still occur and interfere with estimation. These complexities make the aggregation algorithm more complicated. RAPPOR uses LASSO and linear regression to estimate frequencies of values.

Cost. The communication and computing cost is $\Theta(k)$ for each user. The aggregator's computation cost is higher than Basic RAPPOR due to the usage of LASSO and regression.

Privacy. RAPPOR achieves ε-LDP for $\varepsilon = \ln\left(\left(\frac{1-\frac{1}{2}f}{\frac{1}{2}f}\right)^{2m}\right)$. The RAPPOR implementation uses $m = 2$; thus this is $\ln 81 \approx 4.39$ for $f = 1/2$ and $\ln 7^4 \approx 7.78$ for $f = 1/4$.

2.4 Random Matrix Projection

Bassily and Smith [6] proposed a protocol that uses random matrix projection. This protocol has an additional Setup step.

Setup. The aggregator generates a public matrix $\Phi \in \{-\frac{1}{\sqrt{m}}, \frac{1}{\sqrt{m}}\}^{m \times d}$ uniformly at random. Here m is a parameter determined by the error bound, where the "error" is defined as the maximal distance between the estimation and true frequency of any domain.

Encoding. $\mathsf{Encode}(v) = \langle r, x \rangle$, where r is selected uniformly at random from $[m]$, and x is the v's element of the r's row of Φ, i.e., $x = \Phi[r, v]$.

Perturbation. $\mathsf{Perturb}(\langle r, x \rangle) = \langle r,\ b \cdot c \cdot m \cdot x \rangle$, where

$$b = \begin{cases} 1 & \text{with probability } p = \frac{e^\varepsilon}{e^\varepsilon + 1}, \\ -1 & \text{with probability } q = \frac{1}{e^\varepsilon + 1}, \end{cases}$$

$$c = (e^\varepsilon + 1)/(e^\varepsilon - 1).$$

Aggregation. Given reports $\langle r^j, y^j \rangle$'s, the estimate for $i \in [d]$ is given by

$$\tilde{c}(i) = \sum_j y^j \cdot \Phi[r^j, i].$$

The effect is that each user with input value i contributes c to $\tilde{c}(i)$ with probability p, and $-c$ with probability q; thus the expected contribution is

$$(p - q) \cdot c = \left(\frac{e^\varepsilon}{e^\varepsilon + 1} - \frac{1}{e^\varepsilon + 1}\right) \cdot \frac{e^\varepsilon + 1}{e^\varepsilon - 1} = 1.$$

Because of the randomness in Φ, each user with value $\neq i$ contributes to $\tilde{c}(i)$ either c or $-c$, each with probability $1/2$; thus the expected contribution from all such users is 0. Note that each row in the matrix is essentially a random hashing function mapping each value in $[d]$ to a single bit. Each user selects such a hash function, uses it to hash her value into one bit, and then perturbs this bit using random response.

Cost. A straightforward implementation of the protocol is expensive. However, the public random matrix Φ does not need to be explicitly computed. For example, using a common pseudo-random number generator, each user can randomly choose a seed to generate a row in the matrix and send the seed in her report. With this technique, the communication cost is $\Theta(\log m)$ for each user, and the computation cost is $O(d)$ for computing one row of the Φ. The aggregator needs $\Theta(dm)$ to generate Φ, and $\Theta(md)$ to compute the estimations.

3 A Framework for LDP Protocols

Multiple protocols have been proposed for estimating frequencies under LDP, and one can envision other protocols. A natural research question is how do they compare with each other? Under the same level of privacy, which protocol provides better accuracy in aggregation, with lower cost? Can we come up with even better ones? To answer these questions, we define a class of LDP protocols that we call "pure".

For a protocol to be pure, we require the specification of an additional function $\mathsf{Support}$, which maps each possible output y to a set of input values that y "supports". For example, in the basic RAPPOR protocol, an output binary vector B is interpreted as supporting each

input whose corresponding bit is 1, i.e., $\mathsf{Support}(B) = \{i \mid B[i] = 1\}$.

Definition 3 (Pure LDP Protocols) *A protocol given by* PE *and* Support *is pure if and only if there exist two probability values $p^* > q^*$ such that for all v_1,*

$$\Pr[\mathsf{PE}(v_1) \in \{y \mid v_1 \in \mathsf{Support}(y)\}] = p^*,$$
$$\forall_{v_2 \neq v_1} \Pr[\mathsf{PE}(v_2) \in \{y \mid v_1 \in \mathsf{Support}(y)\}] = q^*.$$

A pure protocol is in some sense "pure and simple". For each input v_1, the set $\{y \mid v_1 \in \mathsf{Support}(y)\}$ identifies all outputs y that "support" v_1, and can be called the support set of v_1. A pure protocol requires the probability that any value v_1 is mapped to its own support set be the same for all values. We use p^* to denote this probability. In order to satisfy LDP, it must be possible for a value $v_2 \neq v_1$ to be mapped to v_1's support set. It is required that this probability, which we use q^* to denote, must be the same for all pairs of v_1 and v_2. Intuitively, we want p^* to be as large as possible, and q^* to be as small as possible. However, satisfying ε-LDP requires that $\frac{p^*}{q^*} \leq e^{\varepsilon}$.

Basic RAPPOR is pure with $p^* = 1 - \frac{f}{2}$ and $q^* = \frac{f}{2}$. RAPPOR is not pure because there does not exist a suitable q^* due to collisions in mapping values to bit vectors. Assuming the use of two hash functions, if v_1 is mapped to $[1,1,0,0]$, v_2 is mapped to $[1,0,1,0]$, and v_3 is mapped to $[0,0,1,1]$, then because $[1,1,0,0]$ differs from $[1,0,1,0]$ by only two bits, and from $[0,0,1,1]$ by four bits, the probability that v_2 is mapped to v_1's support set is higher than that of v_3 being mapped to v_1's support set.

For a pure protocol, let y^j denote the submitted value by user j, a simple aggregation technique to estimate the number of times that i occurs is as follows:

$$\tilde{c}(i) = \frac{\sum_j \mathbb{1}_{\mathsf{Support}(y^j)}(i) - nq^*}{p^* - q^*} \tag{1}$$

The intuition is that each output that supports i gives an count of 1 for i. However, this needs to be normalized, because even if every input is i, we only expect to see $n \cdot p^*$ outputs that support i, and even if input i never occurs, we expect to see $n \cdot q^*$ supports for it. Thus the original range of 0 to n is "compressed" into an expected range of nq^* to np^*. The linear transformation in (1) corrects this effect.

Theorem 1 *For a pure LDP protocol* PE *and* Support*, (1) is unbiased, i.e., $\forall_i \mathrm{E}[\tilde{c}(i)] = nf_i$, where f_i is the fraction of times that the value i occurs.*

Proof 1

$$\begin{aligned}
\mathrm{E}[\tilde{c}(i)] =& \mathrm{E}\left[\frac{\left(\sum_j \mathbb{1}_{\mathsf{Support}(y^j)}(i)\right) - nq^*}{p^* - q^*}\right] \\
=& \frac{nf_i p^* + n(1-f_i)q^* - nq^*}{p^* - q^*} \\
=& n \cdot \frac{f_i p^* + q^* - f_i q^* - q^*}{p^* - q^*} \\
=& nf_i
\end{aligned}$$

The variance of the estimator in 1 is a valuable indicator of an LDP protocol's accuracy:

Theorem 2 *For a pure LDP protocol* PE *and* Support*, the variance of the estimation $\tilde{c}(i)$ in (1) is:*

$$\mathrm{Var}[\tilde{c}(i)] = \frac{nq^*(1-q^*)}{(p^*-q^*)^2} + \frac{nf_i(1-p^*-q^*)}{p^*-q^*} \tag{2}$$

Proof 2 *The random variable $\tilde{c}(i)$ is the (scaled) summation of n independent random variables drawn from the Bernoulli distribution. More specifically, nf_i (resp. $(1-f_i)n$) of these random variables are drawn from the Bernoulli distribution with parameter p^* (resp. q^*). Thus,*

$$\begin{aligned}
\mathrm{Var}[\tilde{c}(i)] &= \mathrm{Var}\left[\frac{\left(\sum_j \mathbb{1}_{\mathsf{Support}(y^j)}(i)\right) - nq^*}{p^* - q^*}\right] \\
&= \frac{\sum_j \mathrm{Var}[\mathbb{1}_{\mathsf{Support}(y^j)}(i)]}{(p^*-q^*)^2} \\
&= \frac{nf_i p^*(1-p^*) + n(1-f_i)q^*(1-q^*)}{(p^*-q^*)^2} \\
&= \frac{nq^*(1-q^*)}{(p^*-q^*)^2} + \frac{nf_i(1-p^*-q^*)}{p^*-q^*}
\end{aligned} \tag{3}$$

In many application domains, the vast majority of values appear very infrequently, and one wants to identify the more frequent ones. The key to avoid having lots of false positives is to have low estimation variances for the infrequent values. When f_i is small, the variance in (2) is dominated by the first term. We use Var^* to denote this approximation of the variance, that is:

$$\mathrm{Var}^*[\tilde{c}(i)] = \frac{nq^*(1-q^*)}{(p^*-q^*)^2} \tag{4}$$

We also note that some protocols have the property that $p^* + q^* = 1$, in which case $\mathrm{Var}^* = \mathrm{Var}$.

As the estimation $\tilde{c}(i)$ is the sum of many independent random variables, its distribution is very close to a normal distribution. Thus, the mean and variance of $\tilde{c}(i)$ fully characterizes the distribution of $\tilde{c}(i)$ for all practical purposes. When comparing different methods, we observe that fixing ε, the differences are reflected in the constants for the variance, which is where we focus our attention.

4 Optimizing LDP Protocols

We now cast many protocols that have been proposed into our framework of "pure" LDP protocols. Casting these protocols into the framework of pure protocols enables us to derive their variances and understand how each method's accuracy is affected by parameters such as domain size, ε, etc. This also enables us to generalize and optimize these protocols and propose two new protocols that improve upon existing ones. More specifically, we will consider the following protocols, which we organize by their encoding methods.

- **Direct Encoding (DE).** There is no encoding. It is a generalization of the Random Response technique.
- **Histogram Encoding (HE).** An input v is encoded as a histogram for the d possible values. The perturbation step adds noise from the Laplace distribution to each number in the histogram. We consider two aggregation techniques, SHE and THE.
  - **Summation with Histogram Encoding** (SHE) simply sums up the reported noisy histograms from all users.
  - **Thresholding with Histogram Encoding** (THE) is parameterized by a value θ; it interprets each noisy count above a threshold θ as a 1, and each count below θ as a 0.
- **Unary Encoding (UE).** An input v is encoded as a length-d bit vector, with only the bit corresponding to v set to 1. Here two key parameters in perturbation are p, the probability that 1 remains 1 after perturbation, and q, the probability that 0 is perturbed into 1. Depending on their choices, we have two protocols, SUE and OUE.
  - **Symmetric Unary Encoding** (SUE) uses $p+q=1$; this is the Basic RAPPOR protocol [13].
  - **Optimized Unary Encoding** (OUE) uses optimized choices of p and q; this is newly proposed in this paper.
- **Local Hashing (LH).** An input v is encoded by choosing at random H from a universal hash function family $\mathbb{H}$, and then outputting $(H, H(v))$. This is called Local Hashing because each user chooses independently the hash function to use. Here a key parameter is the range of these hash functions. Depending on this range, we have two protocols, BLH and OLH.
  - **Binary Local Hashing** (BLH) uses hash functions that outputs a single bit. This is equivalent to the random matrix projection technique in [6].
  - **Optimized Local Hashing** (OLH) uses optimized choices for the range of hash functions; this is newly proposed in this paper.

4.1 Direct Encoding (DE)

One natural method is to extend the binary response method to the case where the number of input values is more than 2. This is used in [23].

Encoding and Perturbing. $\mathsf{Encode}_{\mathrm{DE}}(v) = v$, and $\mathsf{Perturb}$ is defined as follows.

$$\mathsf{Pr}\left[\mathsf{Perturb}_{\mathrm{DE}}(x) = i\right] = \begin{cases} p = \frac{e^\varepsilon}{e^\varepsilon + d - 1}, & \text{if } i = x \\ q = \frac{1-p}{d-1} = \frac{1}{e^\varepsilon + d - 1}, & \text{if } i \neq x \end{cases}$$

Theorem 3 (Privacy of DE) *The Direct Encoding (DE) Protocol satisfies ε-LDP.*

Proof 3 *For any inputs v_1, v_2 and output y, we have:*

$$\frac{\mathsf{Pr}\left[\mathsf{PE}_{\mathrm{DE}}(v_1) = y\right]}{\mathsf{Pr}\left[\mathsf{PE}_{\mathrm{DE}}(v_2) = y\right]} \leq \frac{p}{q} = \frac{e^\varepsilon/(e^\varepsilon + d - 1)}{1/(e^\varepsilon + d - 1)} = e^\varepsilon$$

Aggregation. Let the $\mathsf{Support}$ function for DE be $\mathsf{Support}_{\mathrm{DE}}(i) = \{i\}$, i.e., each output value i supports the input i. Then this protocol is pure, with $p^* = p$ and $q^* = q$. Plugging these values into (4), we have

$$\mathrm{Var}^*[\tilde{c}_{\mathsf{DE}}(i)] = n \cdot \frac{d - 2 + e^\varepsilon}{(e^\varepsilon - 1)^2}$$

Note that the variance given above is linear in nd. As d increases, the accuracy of DE suffers. This is because, as d increases, $p = \frac{e^\varepsilon}{e^\varepsilon + d - 1}$, the probability that a value is transmitted correctly, becomes smaller. For example, when $e^\varepsilon = 49$ and $d = 2^{16}$, we have $p = \frac{49}{65584} \approx 0.00075$.

4.2 Histogram Encoding (HE)

In Histogram Encoding (HE), an input $x \in [d]$ is encoded using a length-d histogram.

Encoding. $\mathsf{Encode}_{\mathrm{HE}}(v) = [0.0, 0.0, \cdots, 1.0, \cdots, 0.0]$, where only the v-th component is 1.0. Two different input v values will result in two vectors that have L1 distance of 2.0.

Perturbing. $\mathsf{Perturb}_{\mathrm{HE}}(B)$ outputs B' such that $B'[i] = B[i] + \mathsf{Lap}\left(\frac{2}{\varepsilon}\right)$, where $\mathsf{Lap}\left(\beta\right)$ is the Laplace distribution where $\mathsf{Pr}\left[\mathsf{Lap}\left(\beta\right) = x\right] = \frac{1}{2\beta} e^{-|x|/\beta}$.

Theorem 4 (Privacy of HE) *The Histogram Encoding protocol satisfies ε-LDP.*

Proof 4 *For any inputs v_1, v_2, and output B, we have*

$$\begin{aligned} \frac{\mathsf{Pr}[B|v_1]}{\mathsf{Pr}[B|v_2]} &= \frac{\prod_{i\in[d]} \mathsf{Pr}[B[i]|v_1]}{\prod_{i\in[d]} \mathsf{Pr}[B[i]|v_2]} &&= \frac{\mathsf{Pr}[B[v_1]|v_1]\mathsf{Pr}[B[v_2]|v_1]}{\mathsf{Pr}[B[v_1]|v_2]\mathsf{Pr}[B[v_2]|v_2]} \\ &\leq e^{\varepsilon/2} \cdot e^{\varepsilon/2} &&= e^\varepsilon \end{aligned}$$

Aggregation: Summation with Histogram Encoding (SHE) works as follows: For each value, sum the noisy counts for that value reported by all users. That is, $\tilde{c}_{\text{SHE}}(i) = \sum_j B^j[i]$, where B^j is the noisy histogram received from user j. This aggregation method does not provide a $\mathsf{Support}$ function and is not pure. We prove its property as follows.

Theorem 5 *In* SHE*, the estimation* $\tilde{c}_{\text{SHE}}$ *is unbiased. Furthermore, the variance is*

$$\text{Var}\left[\tilde{c}_{\text{SHE}}(i)\right] = n\frac{8}{\varepsilon^2}$$

Proof 5 *Since the added noise is* 0*-mean; the expected value of the sum of all noisy counts is the true count.*

The $\mathsf{Lap}(\beta)$ *distribution has variance* $\frac{2}{\beta^2}$*, since* $\beta = \frac{\varepsilon}{2}$ *for each* $B^j[i]$*, then the variance of each such variable is* $\frac{8}{\varepsilon^2}$*, and the sum of n such independent variables have variance* $n\frac{8}{\varepsilon^2}$*.*

Aggregation: Thresholding with Histogram Encoding (THE) interprets a vector of noisy counts discretely by defining

$$\mathsf{Support}_{\text{THE}}(B) = \{v \mid B[v] > \theta\}$$

That is, each noise count that is $> \theta$ supports the corresponding value. This thresholding step can be performed either by the user or by the aggregator. It does not access the original value, and thus does not affect the privacy guarantee. Using thresholding to provide a $\mathsf{Support}$ function makes the protocol pure. The probability p^* and q^* are given by

$$p^* = 1 - F(\theta - 1);\;\; q^* = 1 - F(\theta),$$

$$\text{where } F(x) = \begin{cases} \frac{1}{2}e^{\frac{\varepsilon}{2}x}, & \text{if } x < 0 \\ 1 - \frac{1}{2}e^{-\frac{\varepsilon}{2}x}, & \text{if } x \geq 0 \end{cases}$$

Here, $F(\cdot)$ is the cumulative distribution function of Laplace distribution. If $0 \leq \theta \leq 1$, then we have

$$p^* = 1 - \frac{1}{2}e^{\frac{\varepsilon}{2}(\theta-1)};\;\; q^* = \frac{1}{2}e^{-\frac{\varepsilon}{2}\theta}.$$

Plugging these values into (4), we have

$$\text{Var}^*[\tilde{c}_{\text{HET}}(i)] = n \cdot \frac{2e^{\varepsilon\theta/2} - 1}{(1 + e^{\varepsilon(\theta-1/2)} - 2e^{\varepsilon\theta/2})^2}$$

Comparing SHE **and** THE**.** Fixing ε, one can choose a θ value to minimize the variance. Numerical analysis shows that the optimal θ is in $(\frac{1}{2}, 1)$, and depends on ε. When ε is large, $\theta \to 1$. Furthermore, $\text{Var}[\tilde{c}_{\mathsf{THE}}] < \text{Var}[\tilde{c}_{\mathsf{SHE}}]$ is always true. This means that by thresholding, one improves upon directly summing up noisy counts, likely because thresholding limits the impact of noises of large magnitude. In Section 5, we illustrate the differences between them using actual numbers.

4.3 Unary Encoding (UE)

Basic RAPPOR, which we described in Section 2.2, takes the approach of directly perturbing a bit vector. We now explore this method further.

Encoding. $\mathsf{Encode}(v) = [0, \cdots, 0, 1, 0, \cdots, 0]$, a length-$d$ binary vector where only the v-th position is 1.

Perturbing. $\mathsf{Perturb}(B)$ outputs B' as follows:

$$\mathsf{Pr}\left[B'[i] = 1\right] = \begin{cases} p, & \text{if } B[i] = 1 \\ q, & \text{if } B[i] = 0 \end{cases}$$

Theorem 6 (Privacy of UE) *The Unary Encoding protocol satisfies* ε*-LDP for*

$$\varepsilon = \ln\left(\frac{p(1-q)}{(1-p)q}\right) \tag{5}$$

Proof 6 *For any inputs* v_1, v_2*, and output B, we have*

$$\begin{aligned} \frac{\mathsf{Pr}[B|v_1]}{\mathsf{Pr}[B|v_2]} &= \frac{\prod_{i\in[d]}\mathsf{Pr}[B[i]|v_1]}{\prod_{i\in[d]}\mathsf{Pr}[B[i]|v_2]} & (6) \\ &\leq \frac{\mathsf{Pr}[B[v_1]=1|v_1]\,\mathsf{Pr}[B[v_2]=0|v_1]}{\mathsf{Pr}[B[v_1]=1|v_2]\,\mathsf{Pr}[B[v_2]=0|v_2]} & (7) \\ &= \frac{p}{q}\cdot\frac{1-q}{1-p} = e^{\varepsilon} \end{aligned}$$

(6) *is because each bit is flipped independently, and* (7) *is because* v_1 *and* v_2 *result in bit vectors that differ only in locations* v_1 *and* v_2*, and a vector with position* v_1 *being* 1 *and position* v_2 *being* 0 *maximizes the ratio.*

Aggregation. A reported bit vector is viewed as supporting an input i if $B[i] = 1$, i.e., $\mathsf{Support}_{\text{UE}}(B) = \{i \mid B[i] = 1\}$. This yields $p^* = p$ and $q^* = q$. Interestingly, (5) does not fully determine the values of p and q for a fixed ε. Plugging (5) into (4), we have

$$\begin{aligned} \text{Var}^*[\tilde{c}_{\text{UE}}(i)] &= \frac{nq(1-q)}{(p-q)^2} = \frac{nq(1-q)}{(\frac{e^{\varepsilon}q}{1-q+e^{\varepsilon}q} - q)^2} \\ &= n \cdot \frac{((e^{\varepsilon}-1)q+1)^2}{(e^{\varepsilon}-1)^2(1-q)q}. \end{aligned} \tag{8}$$

Symmetric UE (**SUE**)**.** RAPPOR's implementation chooses p and q such that $p + q = 1$; making the treatment of 1 and 0 symmetric. Combining this with (5), we have

$$p = \frac{e^{\varepsilon/2}}{e^{\varepsilon/2}+1},\;\; q = \frac{1}{e^{\varepsilon/2}+1}$$

Plugging these into (8), we have

$$\text{Var}^*[\tilde{c}_{\text{SUE}}(i)] = n \cdot \frac{e^{\varepsilon/2}}{(e^{\varepsilon/2}-1)^2}$$

Optimized UE (OUE)**.** Instead of making p and q symmetric, we can choose them to minimize (8). Take the partial derivative of (8) with respect to q, and solving q to make the result 0, we get:

$$\frac{\partial\left[\frac{((e^\varepsilon-1)q+1)^2}{(e^\varepsilon-1)^2(1-q)q}\right]}{\partial q} = \frac{\partial\left[\frac{1}{(e^\varepsilon-1)^2}\cdot\left(\frac{(e^\varepsilon-1)^2 q}{1-q}+\frac{2(e^\varepsilon-1)}{1-q}+\frac{1}{q(1-q)}\right)\right]}{\partial q}$$

$$= \frac{\partial\left[\frac{1}{(e^\varepsilon-1)^2}\cdot\left(-(e^\varepsilon-1)^2+\frac{e^{2\varepsilon}}{1-q}+\frac{1}{q}\right)\right]}{\partial q}$$

$$= \frac{1}{(e^\varepsilon-1)^2}\left(\frac{e^{2\varepsilon}}{(1-q)^2}-\frac{1}{q^2}\right)=0$$

$$\Longrightarrow \frac{1-q}{q}=e^\varepsilon, \text{i.e.}, q=\frac{1}{e^\varepsilon+1} \text{ and } p=\frac{1}{2}$$

Plugging $p=\frac{1}{2}$ and $q=\frac{1}{e^\varepsilon+1}$ into (8), we get

$$\mathrm{Var}^*[\tilde{c}_{\mathrm{OUE}}(i)] = n\frac{4e^\varepsilon}{(e^\varepsilon-1)^2} \tag{9}$$

The reason why setting $p=\frac{1}{2}$ and $q=\frac{1}{e^\varepsilon+1}$ is optimal when the true frequencies are small may be unclear at first glance; however, there is an intuition behind it. When the true frequencies are small, d is large. Recall that $e^\varepsilon=\frac{p}{1-p}\frac{1-q}{q}$. Setting p and q can be viewed as splitting ε into $\varepsilon_1+\varepsilon_2$ such that $\frac{p}{1-p}=e^{\varepsilon_1}$ and $\frac{1-q}{q}=e^{\varepsilon_2}$. That is, ε_1 is the privacy budget for transmitting the 1 bit, and ε_2 is the privacy budget for transmitting each 0 bit. Since there are many 0 bits and a single 1 bit, it is better to allocate as much privacy budget for transmitting the 0 bits as possible. In the extreme, setting $\varepsilon_1=0$ and $\varepsilon_2=\varepsilon$ means that setting $p=\frac{1}{2}$.

4.4 Binary Local Hashing (BLH)

Both HE and UE use unary encoding and have $\Theta(d)$ communication cost, which is too large for some applications. To reduce the communication cost, a natural idea is to first hash the input value into a domain of size $k<d$, and then apply the UE method to the hashed value. This is the basic idea underlying the RAPPOR method. However, a problem with this approach is that two values may be hashed to the same output, making them indistinguishable from each other during decoding. RAPPOR tries to address this in several ways. One is to use more than one hash functions; this reduces the chance of a collision. The other is to use cohorts, so that different cohorts use different sets of hash functions. These remedies, however, do not fully eliminate the potential effect of collisions. Using more than one hash functions also means that every individual bit needs to be perturbed more to satisfy ε-LDP for the same ε.

A better approach is to make each user belong to a cohort by herself. We call this the **local hashing** approach. The random matrix-base protocol in [6] (described in Section 2.4), in its very essence, uses a local hashing encoding that maps an input value to a single bit, which is then transmitted using randomized response. Below is the Binary Local Hashing (BLH) protocol, which is logically equivalent to the one in Section 2.4, but is simpler and, we hope, better illustrates the essence of the idea.

Let $\mathbb{H}$ be a universal hash function family, such that each hash function $H\in\mathbb{H}$ hashes an input in $[d]$ into one bit. The universal property requires that

$$\forall x,y\in[d], x\neq y: \Pr_{H\in\mathbb{H}}[H(x)=H(y)]\leq\frac{1}{2}.$$

Encoding. $\mathsf{Encode}_{\mathrm{BLH}}(v)=\langle H,b\rangle$, where $H\leftarrow_R\mathbb{H}$ is chosen uniformly at random from $\mathbb{H}$, and $b=H(v)$. Note that the hash function H can be encoded using an index for the family $\mathbb{H}$ and takes only $O(\log n)$ bits.

Perturbing. $\mathsf{Perturb}_{\mathrm{BLH}}(\langle H,b\rangle)=\langle H,b'\rangle$ such that

$$\Pr\left[b'=1\right]=\begin{cases} p=\frac{e^\varepsilon}{e^\varepsilon+1}, & \text{if } b=1\\ q=\frac{1}{e^\varepsilon+1}, & \text{if } b=0\end{cases}$$

Aggregation. $\mathsf{Support}_{\mathrm{BLH}}(\langle H,b\rangle)=\{v\mid H(v)=b\}$, that is, each reported $\langle H,b\rangle$ supports all values that are hashed by H to b, which are half of the input values. Using this Support function makes the protocol pure, with $p^*=p$ and $q^*=\frac{1}{2}p+\frac{1}{2}q=\frac{1}{2}$. Plugging the values of p^* and q^* into (4), we have

$$\mathrm{Var}^*[\tilde{c}_{\mathsf{BLH}}(i)]=n\cdot\frac{(e^\varepsilon+1)^2}{(e^\varepsilon-1)^2}.$$

4.5 Optimal Local Hashing (OLH)

Once the random matrix projection protocol is cast as binary local hashing, we can clearly see that the encoding step loses information because the output is just one bit. Even if that bit is transmitted correctly, we can get only one bit of information about the input, i.e., to which half of the input domain does the value belong. When ε is large, the amount of information loss in the encoding step dominates that of the random response step. Based on this insight, we generalize Binary Local Hashing so that each input value is hashed into a value in $[g]$, where $g\geq 2$. A larger g value means that more information is being preserved in the encoding step. This is done, however, at a cost of more information loss in the random response step. As in our analysis of the Direct Encoding method, a large domain results in more information loss.

Let $\mathbb{H}$ be a universal hash function family such that each $H\in\mathbb{H}$ outputs a value in $[g]$.

Encoding. $\mathsf{Encode}(v)=\langle H,x\rangle$, where $H\in\mathbb{H}$ is chosen

uniformly at random, and $x = H(v)$.

Perturbing. $\mathsf{Perturb}(\langle H, x\rangle) = (\langle H, y\rangle)$, where

$$\forall_{i\in[g]} \; \Pr[y = i] = \begin{cases} p = \frac{e^\varepsilon}{e^\varepsilon+g-1}, & \text{if } x = i \\ q = \frac{1}{e^\varepsilon+g-1}, & \text{if } x \neq i \end{cases}$$

Theorem 7 (Privacy of LH) *The Local Hashing (LH) Protocol satisfies ε-LDP*

Proof 7 *For any two possible input values v_1, v_2 and any output $\langle H, y\rangle$, we have,*

$$\frac{\Pr[\langle H,y\rangle | v_1]}{\Pr[\langle H,y\rangle | v_2]} = \frac{\Pr[\mathsf{Perturb}(H(v_1)) = y]}{\Pr[\mathsf{Perturb}(H(v_2)) = y]} \leq \frac{p}{q} = e^\varepsilon$$

Aggregation. Let $\mathsf{Support}_{\mathsf{LH}}(\langle H, y\rangle) = \{i \mid H(i) = y\}$, i.e., the set of values that are hashed into the reported value. This gives rise to a pure protocol with

$$p^* = p \text{ and } q^* = \frac{1}{g}p + \frac{g-1}{g}q = \frac{1}{g}.$$

Plugging these values into (4), we have the

$$\mathrm{Var}^*[\tilde{c}_{\mathsf{LP}}(i)] = n \cdot \frac{(e^\varepsilon - 1 + g)^2}{(e^\varepsilon - 1)^2(g-1)}. \quad (10)$$

Optimized LH (OLH) Now we find the optimal g value, by taking the partial derivative of (10) with respect to g.

$$\frac{\partial\left[\frac{(e^\varepsilon-1+g)^2}{(e^\varepsilon-1)^2(g-1)}\right]}{\partial g} = \frac{\partial\left[\frac{g-1}{(e^\varepsilon-1)^2} + \frac{1}{g-1}\cdot\frac{e^{2\varepsilon}}{(e^\varepsilon-1)^2} + \frac{2e^\varepsilon}{(e^\varepsilon-1)^2}\right]}{\partial g}$$

$$= \frac{1}{(e^\varepsilon-1)^2} - \frac{1}{(g-1)^2}\cdot\frac{e^{2\varepsilon}}{(e^\varepsilon-1)^2} = 0$$

$$\implies g = e^\varepsilon + 1$$

When $g = e^\varepsilon + 1$, we have $p^* = \frac{e^\varepsilon}{e^\varepsilon+g-1} = \frac{1}{2}$, $q^* = \frac{1}{g} = \frac{1}{e^\varepsilon+1}$ into (8), and

$$\mathrm{Var}^*[\tilde{c}_{\mathsf{OLH}}(i)] = n \cdot \frac{4e^\varepsilon}{(e^\varepsilon-1)^2}. \quad (11)$$

Comparing OLH with OUE. It is interesting to observe that the variance we derived for optimized local hashing (OLH), i.e., (11) is exactly that we have for optimized unary encoding (OUE), i.e., (9). Furthermore, the probability values p^* and q^* are also exactly the same. This illustrates that OLH and OUE are in fact deeply connected. OLH can be viewed as a compact way of implementing OUE. Compared with OUE, OLH has communication cost $O(\log n)$ instead of $O(d)$.

The fact that optimizing two apparently different encoding approaches, namely, unary encoding and local hashing, results in conceptually equivalent protocol, seems to suggest that this may be optimal (at least when d is large). However, whether this is the best possible protocol remains an interesting open question.

5 Which Protocol to Use

We have cast most of the LDP protocols proposed in the literature into our framework of pure LDP protocols. Doing so also enables us to generalize and optimize existing protocols. Now we are able to answer the question: Which LDP protocol should one use in a given setting?

Guideline. Table 1 lists the major parameters for the different protocols. Histogram encoding and unary encoding requires $\Theta(d)$ communication cost, and is expensive when d is large. Direct encoding and local hashing require $\Theta(\log d)$ or $\Theta(\log n)$ communication cost, which amounts to a constant in practice. All protocols other than DE have $O(n\cdot d)$ computation cost to estimate frequency of all values.

Numerical values of the approximate variances using (4) for all protocols are given in Table 2 and Figure 1 ($n = 10{,}000$). Our analysis gives the following guidelines for choosing protocols.

- When d is small, more precisely, when $d < 3e^\varepsilon + 2$, DE is the best among all approaches.
- When $d > 3e^\varepsilon + 2$, and the communication cost $\Theta(d)$ is acceptable, one should use OUE. (OUE has the same variance as OLH, but is easier to implement and faster because no hash functions is used.)
- When d is so large that the communication cost $\Theta(d)$ is too large, we should use OLH. It offers the same accuracy as OUE, but has communication cost $O(\log d)$ instead of $O(d)$.

Discussion. In addition to the guidelines, we make the following observations. Adding Laplacian noises to a histogram is typically used in a setting with a trusted data curator, who first computes the histogram from all users' data and then adds the noise. SHE applies it to each user's data. Intuitively, this should perform poorly relative to other protocols specifically designed for the local setting. However, SHE performs very similarly to BLH, which was specifically designed for the local setting. In fact, when $\varepsilon > 2.5$, SHE performs better than BLH.

While all protocols' variances depend on ε, the relationships are different. BLH is least sensitive to change in ε because binary hashing loses too much information. Indeed, while all other protocols have variance goes to 0 when ε goes to infinity, BLH has variance goes to n. SHE is slightly more sensitive to change in ε. DE is most sensitive to change in ε; however, when d is large, its variance is very high. OLH and OUE are able to better benefit from an increase in ε, without suffering the poor performance for small ε values.

Another interesting finding is that when $d = 2$, the variance of DE is $\frac{e^\varepsilon}{(e^\varepsilon-1)^2}$, which is exactly $\frac{1}{4}$ of that of

	DE	SHE	THE ($\theta = 1$)	SUE	OUE	BLH	OLH

Figure 1: Numerical values of $\mathrm{Var}[\tilde{c}(i)]$ for different methods.

OUE and OLH, whose variances do not depend on d. Intuitively, it is easier to transmit a piece of information when it is binary, i.e., $d = 2$. As d increases, one needs to "pay" for this increase in source entropy by having higher variance. However, it seems that there is a cap on the "price" one must pay no matter how large d is, i.e., OLH's variance does not depend on d and is always 4 times that of DE with $d = 2$. There may exist a deeper reason for this rooted in information theory. Exploring these questions is beyond the scope of this paper.

6 Experimental Evaluation

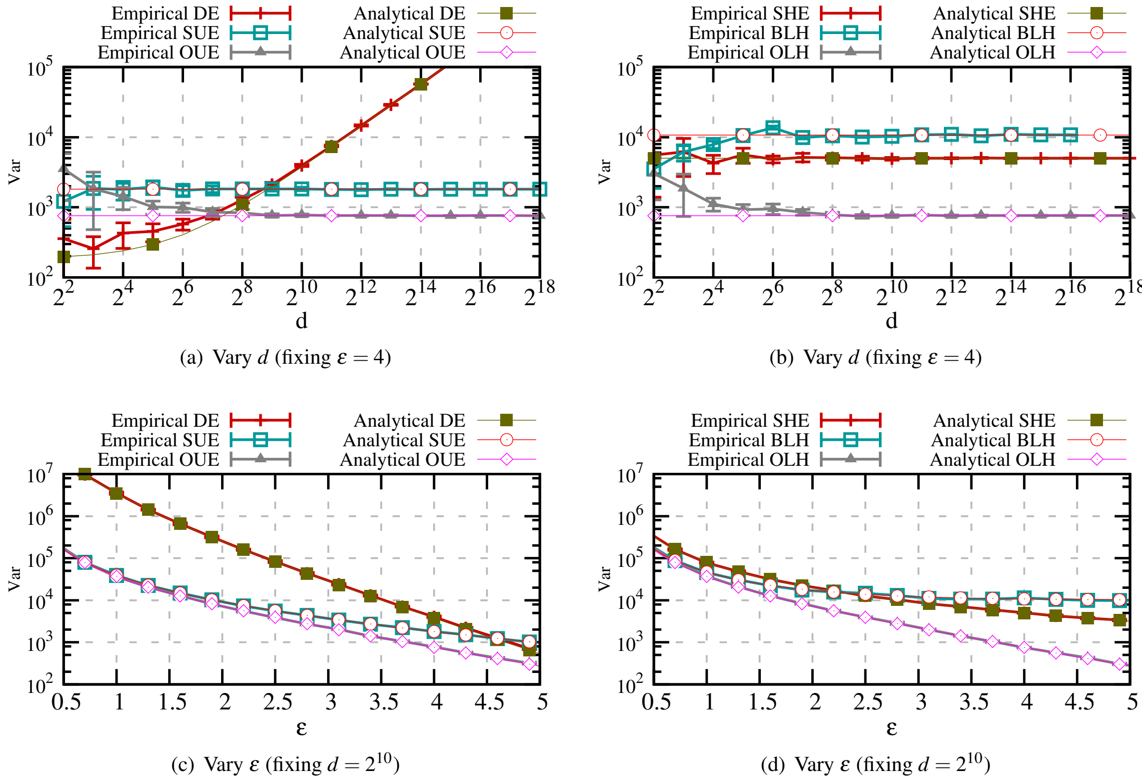
We empirically evaluate these protocols on both synthetic and real-world datasets. All experiments are performed ten times and we plot the mean and standard deviation.

6.1 Verifying Correctness of Analysis

The conclusions we drew above are based on analytical variances. We now show that our analytical results of variances match the empirically measured squared errors. For the empirical data, we issue queries using the protocols and measure the average of the squared errors, namely, $\frac{1}{d}\sum_{i\in[d]}\left[\tilde{c}(i) - nf_i\right]^2$, where f_i is the fraction of users taking value i. We run queries for all i values and repeat for ten times. We then plot the average and standard deviation of the squared error. We use synthetic data generated by following the Zipf's distribution (with distribution parameter $s = 1.1$ and $n = 10,000$ users), similar to experiments in [13].

Figure 2 gives the empirical and analytical results for all methods. In Figures 2(a) and 2(b), we fix $\varepsilon = 4$ and vary the domain size. For sufficiently large d (e.g., $d \geq 2^6$), the empirical results match very well with the analytical results. When $d < 2^6$, the analytical variance tends to underestimate the variance, because in (4) we ignore the f_i terms. Standard deviation of the measured squared error from different runs also decreases when the domain size increases. In Figures 2(c) and 2(d), we fix the domain size to $d = 2^{10}$ and vary the privacy budget. We can see that the analytical results match the empirical results for all ε values and all methods.

In practice, since the group size g of OLH can only be



(a) Vary d (fixing $\varepsilon = 4$)

(b) Vary d (fixing $\varepsilon = 4$)

(c) Vary ε (fixing $d = 2^{10}$)

(d) Vary ε (fixing $d = 2^{10}$)

Figure 2: Comparing empirical and analytical variance.

integers, we round $g = e^{\varepsilon} + 1$ to the nearest integer.

6.2 Towards Real-world Estimation

We run OLH, BLH, together with RAPPOR, on real datasets. The goal is to understand how does each protocol perform in real world scenarios and how to interpret the result. Note that RAPPOR does not fall into the pure framework of LDP protocols so we cannot use Theorem 2 to obtain the variance analytically. Instead, we run experiments to examine its performance empirically. Following the setting of Erlingsson et al. [13], we use a 128-bit Bloom filter, 2 hash functions and 8/16 cohorts in RAPPOR. In order to vary ε, we tweak the f value. The instantaneous randomization process is omitted. We implement RAPPOR in Python. The regression part, which RAPPOR introduces to handle the collisions in the Bloom filter, is implemented using Scikit-learn library [4].

Datasets. We use the **Kosarak** dataset [2], which contains the click stream of a Hungarian news website. There are around 8 million click events for $41,270$ different pages. The goal is to estimate the popularity of each page, assuming all events are reported.

6.2.1 Accuracy on Frequent Values

One goal of estimating a distribution is to find out the frequent values and accurately estimate them. We run different methods to estimate the distribution of the Kosarak dataset. After the estimation, we issue queries for the 30 most frequent values in the original dataset. We then calculate the average squared error of the 30 estimations produced by different methods. Figure 3 shows the result. We try RAPPOR with both 8 cohorts (RAP(8)) and 16 cohorts (RAP(16)). It can be seen that when $\varepsilon > 1$, OLH starts to show its advantage. Moreover, variance of OLH decreases fastest among the four. Due to the internal collision caused by Bloom filters, the accuracy of RAPPOR does not benefit from larger ε. We also perform this experiment on different datasets, and the results are similar.

6.2.2 Distinguish True Counts from Noise

Although there are noises, infrequent values are still unlikely to be estimated to be frequent. Statistically, the frequent estimates are more reliable, because the probability it is generated from an infrequent value is quite low. However, for the infrequent estimates, we don't know whether it comes from an originally infrequent value or

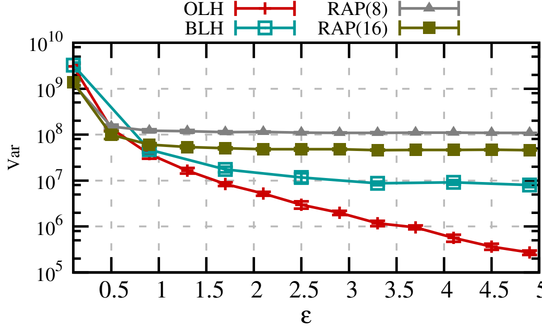


Figure 3: Average squared error, varying ε.

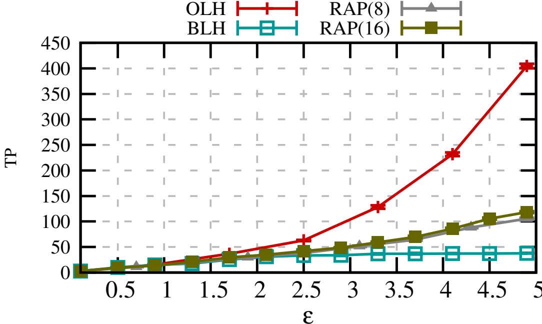

Figure 4: Number of true positives, varying ε, using significance threshold. The dashed line corresponds to the average number of items identified.

a zero-count value. Therefore, after getting the estimation, we need to choose which estimate to use, and which to discard.

Significance Threshold. In [13], the authors propose to use the significance threshold. After the estimation, all estimations above the threshold are kept, and those below the threshold T_s are discarded.

$$T_s = \Phi^{-1}\left(1 - \frac{\alpha}{d}\right)\sqrt{\text{Var}^*},$$

where d is the domain size, Φ^{-1} is the inverse of the cumulative density function of standard normal distribution, and the term inside the square root is the variance of the protocol. Roughly speaking, the parameter α controls the number of values that originally have low frequencies but estimated to have frequencies above the threshold (also known as false positives). We use $\alpha = 0.05$ in our experiment.

For the values whose estimations are discarded, we don't know for sure whether they have low or zero frequencies. Thus, a common approach is to assign the remaining probability to each of them uniformly.

Recall Var^* is the term we are trying to minimize. So a protocol with a smaller variance will have a lower threshold; thus more values can be detected reliably.

Number of Reliable Estimation. We run different protocols using the significance threshold T_s on the Kosarak dataset. Note that T_s will change as ε changes. We define a true (false) positive as a value that has frequency above (below) the threshold, and is estimated to have frequency above the threshold. In Figure 4, we show the number of true positives versus ε. As ε increases, the number of true positives increases. When $\varepsilon = 4$, RAPPOR can output 75 true positives, BLH can only output 36 true positives, but OLH can output nearly 200 true positives. We also notice that the output sizes are similar for RAPPOR and OLH, which indicates that OLH gives out very few false positives compared to RAPPOR. The cohort size does not affect much in this setting.

6.2.3 On Information Quality

Now we test both the number of true positives and false positives, varying the threshold. We run OLH, BLH and RAPPOR on the Kosarak dataset.

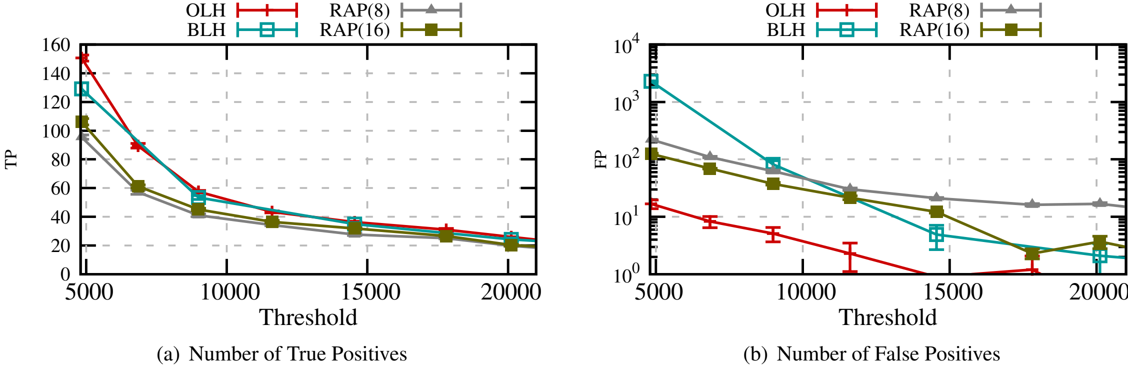
As we can see in Figure 5(a), fixing a threshold, OLH and BLH performs similarly in identifying true positives, which is as expected, because frequent values are rare, and variance does not change much the probability it is identified. RAPPOR performs slightly worse because of the Bloom filter collision.

As for the false positives, as shown in Figure 5(b), different protocols perform quite differently in eliminating false positives. When fixing T_s to be $5,000$, OLH produces tens of false positives, but BLH will produce thousands of false positives. The reason behind this is that, for the majority of infrequent values, their estimations are directly related to the variance of the protocol. A protocol with a high variance means that more infrequent values will become frequent during estimation. As a result, because of its smallest Var^*, OLH produces the least false positives while generating the most true positives.

7 Related Work

The notion of differential privacy and the technique of adding noises sampled from the Laplace distribution were introduced in [11]. Many algorithms for the centralized setting have been proposed. See [12] for a theoretical treatment of these techniques, and [19] for a treatment from a more practical perspective. It appears that only algorithms for the LDP settings have seen real world deployment. Google deployed RAPPOR [13] in Chrome, and Apple [1] also uses similar methods to help with predictions of spelling and other things.

State of the art protocols for frequency estimation under LDP are RAPPOR by Erlingsson et al. [13] and Random Matrix Projection (BLH) by Bassily and Smith [6],



(a) Number of True Positives

(b) Number of False Positives

Figure 5: Results on Kosarak dataset. The y axes are the number of identified hash values that is true/false positive. The x axes are the threshold. We assume $\varepsilon = 4$.

which we have presented in Section 2 and compared with in detail in the paper. These protocols use ideas from earlier work [20, 9]. Our proposed Optimized Unary Encoding (OUE) protocol builds upon the Basic RAPPOR protocol in [13]; and our proposed Optimized Local Hashing (OLH) protocol is inspired by BLH in [6]. Wang et al. [23] uses both generalized random response (Section 4.1) and Basic RAPPOR for learning weighted histogram. Some researchers use existing frequency estimation protocols as primitives to solve other problems in LDP setting. For example, Chen et al. [8] uses BLH [6] to learn location information about users. Qin et al. [22] use RAPPOR [13] and BLH [6] to estimate frequent items where each user has a set of items to report. These can benefit from the introduction of OUE and OLH in this paper.

There are other interesting problems in the LDP setting beyond frequency estimation. In this paper we do not study them. One problem is to identify frequent values when the domain of possible input values is very large or even unbounded, so that one cannot simply obtain estimations for all values to identify which ones are frequent. This problem is studied in [17, 6, 16]. Another problem is estimating frequencies of itemsets [14, 15]. Nguyên et al. [21] studied how to report numerical answers (e.g., time of usage, battery volume) under LDP. When these protocols use frequency estimation as a building block (such as in [16]), they can directly benefit from results in this paper. Applying insights gained in our paper to better solve these problems is interesting future work.

Kairouz et al. [18] study the problem of finding the optimal LDP protocol for two goals: (1) hypothesis testing, i.e., telling whether the users' inputs are drawn from distribution P_0 or P_1, and (2) maximize mutual information between input and output. We note that these goals are different from ours. Hypothesis testing does not reflect dependency on d. Mutual information considers only a single user's encoding, and not aggregation accuracy. For example, both global and local hashing have exactly the same mutual information characteristics, but they have very different accuracy for frequency estimation, because of collisions in global hashing. Nevertheless, it is found that for very large ε's, Direct Encoding is optimal, and for very small ε's, BLH is optimal. This is consistent with our findings. However, analysis in [18] did not lead to generalization and optimization of binary local hashing, nor does it provide concrete suggestion on which method to use for a given ε and d value.

8 Discussion

On answering multiple questions. In the setting of traditional DP, the privacy budget is split when answering multiple queries. In the local setting, previous work follow this tradition and let the users split privacy budget evenly and report on multiple questions. Instead, we suggest partitioning the users randomly into groups, and letting each group of users answer a separate question. Now we compare the utilities by these approaches.

Suppose there are $Q \geq 2$ questions. We calculate variances on one question. Since there are different number of users in the two cases (n versus n/Q), we normalize the estimations into the range from 0 to 1. In OLH, the variance is $\sigma^2 = \text{Var}^*[\tilde{c}_{\text{OLH}}(i)/n] = \frac{4e^\varepsilon}{(e^\varepsilon-1)^2 \cdot n}$.

When partitioning the users, n/Q users answer one question, rendering $\sigma_1^2 = \frac{4Qe^\varepsilon}{(e^\varepsilon-1)^2 \cdot n}$; when privacy budget is split, ε/Q is used for one question, we have $\sigma_2^2 = \frac{4e^{\varepsilon/Q}}{\left(e^{\varepsilon/Q}-1\right)^2 \cdot n}$. We want to show $\sigma_1^2 < \sigma_2^2$:

$$\sigma_2^2 - \sigma_1^2$$

$$
\begin{aligned}
=&\frac{4}{n}\left(\frac{e^{\varepsilon/Q}}{\left(e^{\varepsilon/Q}-1\right)^2}-\frac{Qe^{\varepsilon}}{(e^{\varepsilon}-1)^2}\right)\\
=&\frac{4e^{\varepsilon/Q}}{n\left(e^{\varepsilon/Q}-1\right)^2(e^{\varepsilon}-1)^2}\\
&\cdot\left[(e^{\varepsilon}-1)^2-Qe^{\varepsilon-\varepsilon/Q}\left(e^{\varepsilon/Q}-1\right)^2\right]
\end{aligned}
$$

The first term is always greater than zero since $\varepsilon > 0$. For the second term, we define $e^{\varepsilon/Q} = z$, and write it as:

$$
\begin{aligned}
&(z^Q-1)^2-Qz^{Q-1}(z-1)^2\\
=&(z-1)^2\cdot\left[(z^{Q-1}+z^{Q-2}+\ldots+1)^2-Qz^{Q-1}\right]>0
\end{aligned}
$$

Therefore, σ_1^2 is always smaller than σ_2^2. Thus utility of partitioning users is better than splitting privacy budget.

Limitations. The current work only considers the framework of pure LDP protocols. It is not known whether a protocol that is not pure will produce more accurate result or not. Moreover, current protocols can only handle the case where the domain is limited, or a dictionary is available. Other techniques are needed when the domain size is very big.

9 Conclusion

In this paper, we study frequency estimation in the Local Differential Privacy (LDP) setting. We have introduced a framework of pure LDP protocols together with a simple and generic aggregation and decoding technique. This framework enables us to analyze, compare, generalize, and optimize different protocols, significantly improving our understanding of LDP protocols. More concretely, we have introduced the Optimized Local Hashing (OLH) protocol, which has much better accuracy than previous frequency estimation protocols satisfying LDP. We provide a guideline as to which protocol to choose in different scenarios. Finally we demonstrate the advantage of the OLH in both synthetic and real-world datasets.

A Additional Evaluation

This section provides additional experimental evaluation results. We first try to measure average squared variance on other datasets. Although RAPPOR did not specify a particular optimal setting, we vary the number of cohorts and find differences. In the end, we evaluate different methods on the Rockyou dataset.

A.1 Effect of Cohort Size

In [13], the authors did not identify the best cohort size to use. Intuitively, if there are too few cohorts, many values will be hashed to be the same in the Bloom filter, making it difficult to distinguish these values. If there are more cohorts, each cohort cannot convey enough useful information. Here we try to test what cohort size we should use. We generate 10 million values following the Zipf's distribution (with parameter 1.5), but only use the first 128 most frequent values because of memory limitation caused by regression part of RAPPOR. We then run RAPPOR using 8, 16, 32, and 64, and 128 cohorts. We measure the average squared errors of queries about the top 10 values, and the results are shown in Figure 7. As we can see, more cohorts does not necessarily help lower the squared error because the reduced probability of collision within each cohort. But it also has the disadvantage that each cohort may have insufficient information. It can be seen OLH still performs best.

A.2 Performance on Synthetic Datasets

In Figure 6, we test performance of different methods on synthetic datasets. We generate 10 million points following a normal distribution (rounded to integers, with mean 500 and standard deviation 10) and a Zipf's distribution (with parameter 1.5). The values range from 0 to 1000. We then test the average squared errors on the most frequent 100 values. It can be seen that different methods perform similarly in different distributions. RAPPOR using 16 cohorts performs better than BLH. This is because when the number of cohort is enough, each user in a sense has his own hash functions. This can be viewed as a kind of local hashing function. When we only test the top 10 values instead of top 50, RAP(16) and BLH perform similarly. Note that OLH performs best among all distributions.

A.3 Performance on Rockyou Dataset

We run experiments on the **Rockyou** dataset, which contains 21 million users' password in plaintext. We first hash the plaintext into 20 bits, and use OLH, BLH, and Basic RAPPOR (also known as SUE in our framework) to test all hashed values. It can be seen that OLH performs best in all settings, and basic RAPPOR outperforms BLH consistently. When $\varepsilon = 4$, and threshold is 6000, OLH can recover around 50 true frequent hashes and 10 of false positives, which is 4 and 2 magnitudes smaller than BLH and basic RAPPOR, respectively. The advantage is not significant when ε is small, since the variance difference is small.

Abstract

We propose a *hybrid* model of differential privacy that considers a combination of regular and opt-in users who desire the differential privacy guarantees of the local privacy model and the trusted curator model, respectively. We demonstrate that within this model, it is possible to design a new type of *blended* algorithm for the task of privately computing the most popular records of a web search log. This blended approach provides significant improvements in the utility of obtained data compared to related work while providing users with their desired privacy guarantees. Specifically, on two large search click data sets comprising 4.8 million and 13.2 million unique queries respectively, our approach attains NDCG values exceeding 95% across a range of commonly used privacy budget values.

1 Introduction

Now more than ever we are confronted with the tension between collecting mass-scale user data and the ability to release or share this data in a way that preserves the privacy of individual users. Today, an organization that needs user data to improve the quality of service they provide often has no choice but to perform the data collection themselves. However, the users may not want to share their data with the organization, especially if they consider the data to be sensitive or private. Similarly, the organization assumes liability by collecting sensitive user data: private information may be directly leaked through security breaches or subpoenas, or indirectly leaked by the output of computations done on the data. Thus, both organizations and users would benefit not only from strong, rigorous privacy guarantees regarding the data collection process, but also from the organization collecting the minimum amount of data necessary to achieve their goal. Some of the philosophy behind our work stems from a desire to enable privacy-preserving *decentralized* data collection that aggregates data from multiple entities into high quality datasets.

1.1 Differential Privacy and Curator Models

In the last decade, we have witnessed scores of ad-hoc approaches that have turned out to be inadequate for protecting privacy [33, 23]. The problem stems from the impossibility of foreseeing all attacks of adversaries capable of utilizing outside knowledge. Differential privacy [10, 9, 11], which has become the gold standard privacy guarantee in the academic literature, and is gaining traction in industry and government [13, 17, 28], overcomes the prior issues by focusing on the *privatization* algorithm applied to the data, requiring that it preserves privacy in a mathematically rigorous sense under an assumption of an omnipotent adversary.

There are two primary models in the differential privacy framework that define how data is to be handled by the users and data collectors: the *trusted curator* model and the *local* model.

Trusted curator model: Most differentially private algorithms developed to date operate in the *trusted curator* model: all users' data is collected by the curator before privatization techniques are applied to it. In this model, although users are guaranteed that the released data set protects their privacy, they must be willing to share their private, unperturbed data with the curator and trust that the curator properly performs a privacy-preserving perturbation.

Local model: As was most recently argued by Apple [17], users may not trust the data collector with their data, and may prefer privatization to occur before their data reaches the collector. Since privatization occurs locally, this is known as the *local differential privacy* (LDP) model, or *local* model. Over

the last several years, we have seen some examples of the local model beginning to be used for data collection in practice, most notably in the context of the Chrome web browser [13] and Apple's data collection [17].

In the LDP model, a data collector such as Google or Apple obtains insights into the data without observing the exact values of user's private data. This is achieved by applying a privacy-preserving perturbation to each user's private data before it leaves the user's device. Since most people do not trust web companies with maintaining the privacy and security of their data [29], the minimal trust required of users towards the data collector is a very attractive property of the LDP model. This approach protects not only the individual users, but also the data collector from the possible privacy breaches. For these reasons, the local model directly embodies the "data minimization" principle described in the White House's 2012 consumer data privacy report [41].

Although it may seem counter-intuitive, it is possible to obtain useful insights even when the data collector does not have access to the original data and receives only data that has already been locally privatized. Suppose a data collector wants to determine the proportion of the population that is HIV-positive. The local privatization algorithm works as follows: each person contributing data secretly flips a coin. If the coin lands heads, they report their true HIV status; otherwise, they report a status at random. This algorithm, known as *randomized response* [40], guarantees each person plausible deniability and is differentially private. Since the randomness is incorporated into the algorithm in a precisely specified way, the data collector is able to recover an accurate estimate of the true proportion of HIV-positive people if enough people contribute their locally privatized data.

Differential privacy: Formally, an algorithm $\mathcal{A}$ is (ϵ, δ)-differentially private [11] if and only if for all neighboring databases D and D' differing in precisely one user's data, the following inequality is satisfied for all possible sets of outputs $Y \subseteq Range(\mathcal{A})$:

$$\Pr[\mathcal{A}(D) \in Y] \leq e^{\epsilon} \Pr[\mathcal{A}(D') \in Y] + \delta.$$

The definition of what it means for an algorithm to preserve differential privacy is the same for both the trusted curator model and the local model. The only distinction is in the timing of when the privacy perturbation needs to be applied – in the local model, the data needs to undergo a privacy-preserving perturbation before it is sent to the aggregator, whereas in the trusted curator model the aggregator may first collect all the data, and then apply a privacy-preserving perturbation. The timing distinction leads to differences in what is meant by "neighboring databases" in the definition and which algorithms are analyzed. In the local model, D represents data of a single user and D' represents data of the same user, with possibly changed values. In the trusted curator model, D represents data of all users and D' represents data of all users, except values of one of the user's data may be altered.

Current differential privacy literature considers the trusted curator model and the local model entirely independently. Our goal is to show that there is much to be gained by combining the two.

Hybrid model: Much of the contribution in this paper stems from our observation that the two models can co-exist. As others have observed [2, 1, 7], people's attitudes toward privacy vary widely. Specifically, some users may be comfortable with sharing their data with a trusted curator.

Many companies rely on a group of beta testers with whom they have higher levels of mutual trust. It is not uncommon for such beta testers to voluntarily opt-in to a less privacy-preserving model than that of an average end-user [32]. For example, Mozilla warns potential beta users of its Firefox browser that "Pre-release versions automatically send Telemetry data to Mozilla to help us improve Firefox[1]"; Google has a similar provision for the beta testers of the Canary build of the Chrome browser[2].

For the users who have higher trust in the company — we call them the *opt-in group*, the trusted curator privacy model is a natural match. For all other users — we call them *clients*, the local privacy model is appropriate. Our goal is to demonstrate that by separating the user pool into these two groups, according to their trust (or lack thereof) in the data aggregator, we can improve the utility of the collected data. We dub this new model the *hybrid differential privacy* model.

1.2 Applications

Heavy hitter discovery and estimation is a well-studied problem in the context of information retrieval, and is one of the canonical problems in privacy-preserving data analysis [6, 27]. Moreover, recent work in the LDP model is focused on precisely that problem [13, 34] or very closely related ones of histogram computations [5, 21]. However, current privacy-preserving approaches in the LDP model lead to utility losses that are quite significant, sometimes to the point where results are no

longer usable. Clearly, if the privacy-preserving perturbation makes the data deviate too far from the original, the approach will not be widely adopted. This is especially true in the context of search tasks, where users have been conditioned for years to expect high-quality results.

We consider two specific applications in the space of heavy hitter estimation: local search and search trend computation.

Local search: Much of the work in this paper is motivated by *local search*, an application of heavy hitter estimation. Local search revolves around the problem of how a browser maker can collect information about users' clicks as they interact with search engines in order to create the *head* of the search, i.e., the collection of the most popular queries and their corresponding URLs, and make it available to users *locally*, i.e., on their devices. Specifically, it involves computing on query-URL pairs, where the URLs are those clicked as a result of submitting the query and receiving a set of answers.

A browser maker may choose to combine the results obtained from user interactions that stem from several search engines depending on the context or surface results obtained from Baidu and not Bing depending on the user's current geographic location.

With proper privacy measures in place, this data set can be deployed in the end-user browser to serve the most common queries with a very low latency or in situations when the user is disconnected from the network. Local search can be thought of as a form of caching, where many queries are answered in a manner that does not require a round trip to the server. Such caching of the most frequently used queries locally has a disproportionately positive impact on the expected query latency [36, 3] as queries to a search engine follow a power-law distribution [4]. Furthermore, it would not be unusual or require a significantly novel infrastructure, as plenty of data is delivered to the browser today, such as SafeBrowsing malware databases in Chrome and Firefox, Microsoft SmartScreen data in Internet Explorer, blocking lists for extensions such as AdBlock Plus, etc.

Trend computation: Search trend computation is a typical example of heavy hitter estimation. This problem entails finding the most popular queries and sorting them in order of popularity; think about it as the top-10 computation based on local search observations. An example of this is the Google trends service[3], which has an always up-to-date list of trending topics and queries.

Although trend computation is interesting, local search is a great deal harder to do well on while preserving most of the utility. Luckily, in the domain of search quality, there are established metrics to numerically assess the quality of search results; one of such metrics is NDCG, and we rely on it heavily in assessing the performance of our proposed system.

1.3 Contributions

Our paper makes the following contributions:

- We introduce and utilize a more realistic, hybrid trust model, which removes the need for all users to trust a central curator.
- We propose Blender, an algorithm that operates with the hybrid differential privacy model for computing heavy hitters. Blender blends the data of opt-in and all other users in order to improve the resulting utility.
- We test Blender on two common applications: *search trend computation* and *local search* and find that it preserves high levels of utility while maintaining differential privacy for reasonable privacy parameter values.
- As part of Blender, we propose an approach for automatically balancing the data obtained from participation of opt-in users with that of other users to maximize the eventual utility.
- We perform a comprehensive utility evaluation of Blender on two large web search data sets, comprising 4.8 million and 13.2 million queries, demonstrating that Blender maintains very high level of utility (i.e., NDCG values in excess of 95% across a range of parameters).

2 System Overview

We now discuss the high-level overview of our proposed system, Blender, that coordinates the privatization, collection, and aggregation of data in the hybrid model, as well as some of the specific choices we make in this system. We use the task of enabling local search based on user histories while preserving differential privacy throughout, but, as will become clear from the discussion, our model and system can also be applied to other frequency-based estimation tasks. As discussed in Section 1, we consider two groups of users: the opt-in group, who are comfortable with privacy as ensured by the trusted curator model, and the clients, who desire the privacy guarantees of the local model.

2.1 Outline of Our Approach

The core of our innovation is to take advantage of the privatized information obtained from the opt-in group in order to create a more efficient (in terms of utility) algorithm for data collection from the

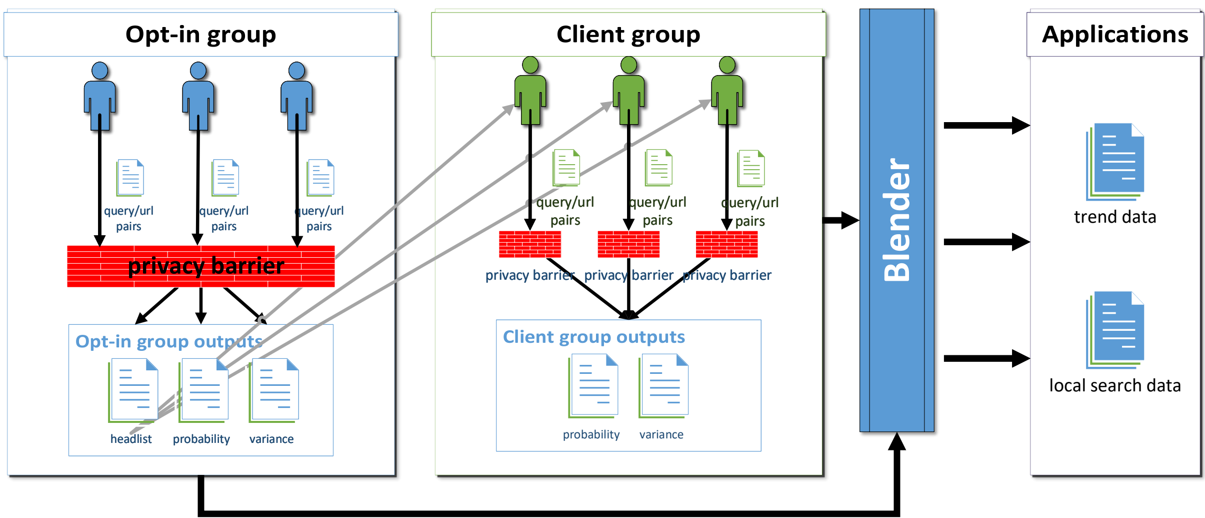

Figure 1: Architectural diagram of Blender's processing steps.

clients. Furthermore, the privatized results obtained from the opt-in group and from the clients are then "blended" in a way that takes into account the privatization algorithms used for each group, and thus, again, achieving an improved utility over a less-informed combination of data from the two groups.

The problem of enabling privacy-preserving local search using past search histories can be viewed as the task of identifying the most frequent search records among the population of users, and estimating their underlying probabilities (both in a differential privacy-preserving manner). In this context, we call the data collected from the users *search records*, where each search record is a pair of strings of the form $\langle query, URL \rangle$, representing a query that a user posed followed by the URL that the user subsequently clicked. We denote by $p_{\langle q,u \rangle}$ the true underlying probability of the search record $\langle q, u \rangle$ in the population. We assume that our system receives a sample of users from the population, each holding their own collection of private data drawn independently and identically from the distribution over all records p. Its goal is to output an estimate $\hat{p}$ of probabilities of the most frequent search records, while preserving differential privacy (in the trusted curator model) for the opt-in users and (in the local model) for the clients.

Informal Overview of Blender: Figure 1 presents an architectural diagram of Blender.

Blender serves as the trusted curator for the opt-in group of users, and begins by aggregating data from them. Using a portion of the data, it constructs a candidate *head list* of records in a differentially private manner that approximates the most common search records in the population. It additionally includes a single "wildcard" record, $\langle \star, \star \rangle$, which represents all records in the population that weren't previously included in the candidate head list. It then uses the remainder of the opt-in data to estimate the probability of each record in the candidate head list in a differentially private manner, and (optionally) trims the candidate head list down to create the final head list. The result of this component of Blender is the privatized trimmed head list of search records and their corresponding probability and variance estimates, which can be shared with each user in the client group, and with the world.

Each member of the client group receives the privatized head list obtained from the opt-in group. Each client then uses the head list to apply a differential privacy-preserving perturbation to their data, subsequently reporting their perturbed results to Blender. Blender then aggregates all the clients' reports and, using a statistical denoising procedure, estimates both the probability for each record in the head list as well as the variance of each of the estimated probabilities based on the clients' data.

For each record, Blender combines the record's probability estimates obtained from the two groups. It does so by taking a convex combination of the groups' probability estimates for each record, carefully weighted based on the record's variance estimate in each group. The combined result under this weighting scheme yields a better probability estimate than either group is able to achieve individually. Finally, Blender outputs the obtained records

and their combined probability estimates, which can be used to drive local search, determine trends, etc.

A Formal Overview of Blender: Figure 2 presents the precise algorithmic overview of each step, including key parameters. Lines 1-3 of BLENDER describe the treatment of data from opt-in users, line 4 – the treatment of clients, and line 5 – the process for combining the probability estimates obtained from the two groups. The only distinction between opt-in users and clients in terms of privacy guarantees provided is the curator model – trusted curator and local model, respectively. Other than that, both types of users are assumed to desire the same level of (ϵ, δ)-differential privacy.

We will detail our choices for the privatization sub-algorithms and discuss their privacy properties next. A key feature of BLENDER, however, is that its privacy properties do not depend on the specific choices of the sub-algorithms. That is, as long as CREATEHEADLIST, ESTIMATEOPTINPROBABILITIES, and ESTIMATECLIENTPROBABILITIES each satisfy (ϵ, δ)-differential privacy in its respective curator model, then so does BLENDER. This allows changing the sub-algorithms if better versions (utility-wise or implementation-wise) are discovered in the future. Among the parameters of BLENDER, the first four (the privacy parameters and the sets of opt-in and client users) can be viewed as given externally, whereas the following five (the number of records collected from each user and the distribution of the privacy budget among the sub-algorithms' sub-components) can be viewed as knobs the designer of BLENDER is at liberty to tweak in order to improve the overall utility of BLENDER's results.

BLENDER $(\epsilon, \delta, O, C, m_O, m_C, f_O, f_C, M)$

Parameters:

- ϵ, δ: the differential privacy parameters.
- O, C: the set of opt-in users and clients, respectively.
- m_O, m_C: the max number of records to collect from each opt-in / client user, respectively.
- f_O: the fraction of the opt-in users to use in head list creation (the remainder are used to estimate the record probabilities).
- f_C: the fraction of the clients' privacy budget to allocate to queries (as opposed to URLs).
- M: the maximum size of the finalized head list.

Variables:

- HL_S, HL: a map from each query to its corresponding set of URLs.
- $\hat{p}_O, \hat{\sigma}^2_O, \hat{p}_C, \hat{\sigma}^2_C$: vectors indexed by records in HL (and, overloaded to be indexed by queries in HL as well) containing the probability estimates and variance estimates for each record (and query).

Body

1: Arbitrarily partition O into S and $T = O \setminus S$, such that $|S| = f_O|O|$ and $|T| = (1 - f_O)|O|$.
2: **let** HL_S = CREATEHEADLIST$(\epsilon, \delta, S, m_O)$ be the initial head list of records computed based on opt-in users' data.
3: **let** $\langle HL, \hat{p}_O, \hat{\sigma}^2_O \rangle$ = ESTIMATEOPTINPROBABILITIES$(\epsilon, \delta, T, m_O, HL_S, M)$ be the refined head list of records, their estimated probabilities, and estimated variances based on opt-in users' data.
4: **let** $\langle \hat{p}_C, \hat{\sigma}^2_C \rangle$ = ESTIMATECLIENTPROBABILITIES$(\epsilon, \delta, C, m_C, f_C, HL)$ be the estimated record probabilities and estimated variances based on client reports.
5: **let** $\hat{p}$ = BLENDPROBABILITIES$(\hat{p}_O, \hat{\sigma}^2_O, \hat{p}_C, \hat{\sigma}^2_C, HL)$ be the combined estimate of record probabilities.
6: **return** $HL, \hat{p}$.

Figure 2: BLENDER, the server algorithm that coordinates the privatization, collection, and aggregation of data from all users.

2.2 Overview of Blender Sub-Algorithms

We now present the specific choices we made for the sub-algorithms in BLENDER. Detailed technical discussions of their properties follow in Section 3.

Algorithms for Head List Creation and Probability Estimation Based on Opt-in User Data (Figures 3, 4): The opt-in users are partitioned into two sets – S, whose data will be used for initial head list creation, and T, whose data will be used to estimate the probabilities and variances of records from the formed initial head list.

The initial head list creation algorithm, described in Figure 3, constructs the list in a differentially private manner using search record data from group S. The goal of the algorithm is to approximate the true set of most frequently searched and clicked search records as closely as possible, while ensuring differential privacy. The algorithm follows the strategy introduced in [26] by aggregating the records of the opt-in users from S, and including in the head list those records whose noisy count exceeds a threshold. The noise to add to the true counts and the threshold to use are calibrated to ensure differential privacy, using [24].

Our algorithm differs from previous work in two ways: 1) it replaces the collection and thresholding of queries with the collection and thresholding of records (i.e., query - URL pairs) and 2) its definition of neighboring databases is that of databases differing in *values* of one user's records, rather than

CreateHeadList$(\epsilon, \delta, S, m_O)$

Parameters:

- ϵ, δ: the differential privacy parameters.
- S: a set of opt-in users.
- m_O: the maximum number of records to collect from each opt-in user.

Body

1: **let** $N(r, D)$ = number of times an arbitrary record r appears in the given dataset D.
2: **for** each user $i \in S$ **do**
3: **let** $D_{S,i}$ be the database aggregating at most m_O arbitrary records from i.
4: **let** D_S be the concatenation of all $D_{S,i}$ databases.
5: **let** HL_S be an empty map.
6: $b_S = \frac{2m_O}{\epsilon}$.
7: $\tau = b_s \cdot \left(\ln(\exp(\frac{\epsilon}{2}) + m_O - 1) - \ln(\delta)\right)$.
8: Assert $\tau \geq 1$.
9: **for** each distinct $\langle q, u \rangle \in D_S$ **do**
10: **let** Y be an independent draw from $\text{Lap}(b_S)$, i.e., Laplace distribution with scale b_S centered at 0.
11: **if** $N(\langle q, u \rangle, D_S) + Y > \tau$ **then**
12: Add q to HL_S if $q \notin HL_S$.
13: Append u to $HL_S[q]$.
14: Add $\langle \star, \star \rangle$ to HL_S.
15: **return** HL_S.

Figure 3: Algorithm for creating the head list from a portion opt-in users in a privacy-preserving way.

in the *addition or removal* of records of one user. These necessitate the choice of $m_O = 1$, as well as higher values for noise and threshold than in [24].

We introduce a wildcard record $\langle \star, \star \rangle$ to represent records not included in the head list, for the subsequent task of estimating their aggregate probability.

For each record included in the initial head list, the algorithm described in Figure 4 uses the remaining opt-in users' data (from set T) to differentially privately estimate their probabilities, denoted by $\hat{p}_O$. This algorithm is the standard Laplace mechanism from the differential privacy literature [10], with scale of noise calibrated to output sensitivity due to our definition of neighboring datasets. Our implementation ensures $(\epsilon, 0)$-differential privacy, which is a more stringent privacy guarantee than for any non-zero δ. We need to set $m_O = 1$ for the privacy guarantees to hold, because we treat data at the search record rather than query level.

We form the final head list from the M most frequent records in $\hat{p}_O$. Finally, the head list is passed to the client group, and the head list and its probability and variance estimates are passed to the BlendProbabilities step of Blender.

The choice of how to split opt-in users into the sub-groups of S and T and the choice of M are unrelated to privacy constraints, and can be made by Blender's developer to optimize utility goals, as will be discussed in Section 4.2.1.

EstimateOptinProbabilities$(\epsilon, \delta, T, m_O, HL_S, M)$

Parameters:

- ϵ, δ: the differential privacy parameters. In fact, this algorithm achieves $(\epsilon, 0)$-differential privacy, which is a stricter privacy guarantee than (ϵ, δ)-differential privacy, for all $\delta > 0$.
- T: a set of opt-in users.
- m_O: the maximum number of records to collect from each opt-in user.
- HL_S: the initial head list of records whose probabilities are to be estimated.
- M: the maximum size of the finalized head list.

Body

1: **let** $N(r, D)$ = number of times an arbitrary record r appears in the given dataset D.
2: **for** each user $i \in T$ **do**
3: **let** $D_{T,i}$ be the database aggregating at most m_O arbitrary records from i.
4: **let** D_T be the concatenation of all $D_{T,i}$ databases.
5: Transform any record $\langle q, u \rangle \in D_T$ that doesn't appear in HL_S into $\langle \star, \star \rangle$.
6: **let** $\hat{p}_O$ be a vector indexed by records in HL_S containing the respective probability estimates.
7: **let** $\hat{\sigma}^2_O$ be a vector indexed by records in HL_S containing variance estimates of the respective probability estimate.
8: Denote $|D_T|$ as the total number of records in D_T.
9: **let** $b_T = \frac{2m_O}{\epsilon}$.
10: **for** each $\langle q, u \rangle \in HL_S$ **do**
11: **let** Y be an independent draw from $\text{Lap}(b_T)$.
12: $\hat{p}_{O,\langle q,u \rangle} = \frac{1}{|D_T|}(N(\langle q, u \rangle, D_T) + Y)$.
13: $\hat{\sigma}^2_{O,\langle q,u \rangle} = \frac{\hat{p}_{O,\langle q,u \rangle}(1-\hat{p}_{O,\langle q,u \rangle})}{|D_T|-1} + \frac{2b_T^2}{|D_T| \cdot (|D_T|-1)}$.
14: **let** HL map the M queries with the highest estimated marginal probabilities (according to $\hat{p}_O$) to their respective sets of URLs.
15: For the records not retained in HL, accumulate their estimated probabilities into $\hat{p}_{O,\langle \star,\star \rangle}$ and update $\hat{\sigma}^2_{O,\langle \star,\star \rangle}$ as in line 13.
16: **return** $HL, \hat{p}_O, \hat{\sigma}^2_O$.

Figure 4: Algorithm for privacy-preserving estimation of probabilities of records in the head list from a portion of opt-in users.

The technical discussions of the algorithms' privacy properties and variance estimate computations follow in Section 3.1 and Section 3.3.

Algorithms for client data collection (Figures 5, 6): For privatization of client data, the records are no longer treated as a single entity, but rather in a two-stage process: first privatizing the query, then privatizing the URL. This choice is intended to benefit utility as the number of queries is

ESTIMATECLIENTPROBABILITIES$(\epsilon, \delta, C, m_C, f_C, HL)$

Parameters:

- ϵ, δ: the differential privacy parameters.
- C: the set of clients.
- m_C: the number of records to collect from the client.
- f_C: the fraction of the privacy budget to allocate to reporting queries.
- HL: a map from each query to its corresponding set of URLs.

Body

1: Append query $q = \star$ to HL.
2: **for** each query $q \in HL$ **do**
3: Append URL $u = \star$ to $HL[q]$.
4: **for** each client $i \in C$ **do**
5: **let** $D_{C,i} =$ LOCALALG$(\epsilon, \delta, m_C, f_C, HL)$ be the reports from i's local execution of LOCALALG.
6: **let** D_C be the concatenation of all reported client datasets, $D_{C,i}$.
7: Denote $|D_C|$ as the total number of records in D_C.
8: **let** variables $\epsilon'_Q, \epsilon'_U, \delta'_Q, \delta'_U, k, t, k_q, t_q (\forall q \in HL)$ be defined as in lines 2–4 of LOCALALG.
9: **let** $\hat{r}_C, \hat{p}_C, \hat{\sigma}^2_C$ be vectors indexed by records in HL (and overloading its use, also indexed by queries).
10: **for** $q \in HL$ **do**
11: **let** $\hat{r}_{C,q}$ be the fraction of queries q in D_C.
12: $\hat{p}_{C,q} = \frac{\hat{r}_{C,q} - \frac{1-t}{k-1}}{t - \frac{1-t}{k-1}}$
13: $\hat{\sigma}^2_{C,q} = \frac{1}{\left(t - \frac{1-t}{k-1}\right)^2} \frac{\hat{r}_{C,q}(1-\hat{r}_{C,q})}{|D_C|-1}$
14: **for** $u \in HL[q]$ **do**
15: **let** $\hat{r}_{C,\langle q,u \rangle}$ be the fraction of records which are $\langle q,u \rangle$ in D_C.
16: $\hat{p}_{C,\langle q,u \rangle} = \frac{\hat{r}_{C,\langle q,u \rangle} - \frac{(1-t_q) t \hat{p}_{C,q}}{k_q - 1} - \frac{(1-t)(1-\hat{p}_{C,q})}{(k-1)k_q}}{t(t_q - \frac{1-t_q}{k_q-1})}$
17: $\hat{\sigma}^2_{C,\langle q,u \rangle} = \left(\frac{\hat{r}_{C,\langle q,u \rangle}(1-\hat{r}_{C,\langle q,u \rangle})}{|D_C|-1} + \frac{2|D_C|}{|D_C|-1} \left(\frac{1-t}{(k-1)k_q} - \frac{t-tt_q}{k_q-1} \right) \left(\frac{k-2+t}{kt-1} \right) \hat{r}_{C,\langle q,u \rangle} + \left(\frac{1-t}{(k-1)k_q} - \frac{t-tt_q}{k_q-1} \right)^2 \hat{\sigma}^2_{C,q} \right) \cdot \frac{1}{t^2 \left(t_q - \frac{1-t_q}{k_q-1} \right)^2}$
18: **return** $\hat{p}_C, \hat{\sigma}^2_C$.

Figure 5: Algorithm for estimating probabilities of records in the head list from the locally privatized reports of the client users.

LOCALALG$(\epsilon, \delta, m_C, f_C, HL)$

Parameters:

- ϵ, δ: the differential privacy parameters.
- m_C: the number of records to collect from the client.
- f_C: the fraction of the privacy budget to allocate to reporting queries.
- HL: the head list, represented as a map keyed by queries $\{q_1, \ldots, q_k, \star\}$. The value for each $q \in HL$ is defined as $HL[q] = \{u_1, \ldots, u_l, \star\}$, representing all URLs in the head list associated with q.

Body

1: **let** $D_{C,i}$ be the database aggregating at most m_C records from current client i.
2: $\epsilon' = \epsilon / m_C$, and $\delta' = \delta / m_C$.
3: $\epsilon'_Q = f_C \epsilon', \epsilon'_U = \epsilon' - \epsilon'_Q$ and $\delta'_Q = f_C \delta', \delta'_U = \delta' - \delta'_Q$.
4: $k = |HL|$, and $t = \frac{\exp(\epsilon'_Q) + (\delta'_Q/2)(k-1)}{\exp(\epsilon'_Q)+k-1}$.
5: **for** each $q \in HL$ **do**:
6: $k_q = |HL[q]|$, and $t_q = \frac{\exp(\epsilon'_U) + (\delta'_U/2)(k_q-1)}{\exp(\epsilon'_U)+k_q-1}$.
7: **for** each $\langle q,u \rangle \in D_{C,i}$ **do**
8: **if** $q \notin HL$ **then**
9: Set $q = \star$.
10: **if** $u \notin HL[q]$ **then**
11: Set $u = \star$.
12: With probability $(1-t)$,
13: **let** q' be a unif. random query from $HL \setminus q$.
14: **let** u' be a unif. random URL from $HL[q']$.
15: **report** $\langle q', u' \rangle$.
16: **continue**
17: With probability $(1-t_q)$,
18: **let** u' be a unif. random URL from $HL[q] \setminus u$.
19: **report** $\langle q, u' \rangle$.
20: **continue**
21: **report** $\langle q,u \rangle$.

Figure 6: Algorithm executed by each client for privately reporting their records.

significantly larger than the number of URLs associated with any query, and hence allocating a larger portion of the privacy budget to the query-reporting stage is a prudent choice.

The process of local privatization of each client's value (Figure 6) follows the strategy of the Exponential mechanism introduced by [30]. The privatization algorithm reports the true value with a certain bounded probability, and otherwise, randomizes the answer uniformly among all the other feasible values.

The fact that the head list (approximating the set of the most frequent records) is available to each client plays a crucial role in improving the utility of the data produced by this privatization algorithm compared to the previously known algorithms operating in the local privacy model. Knowledge of the head list allows dedicating the entire privacy budget to report the true value, rather than having to allocate some of it for estimating an analogue of the head list, as done in [15, 34]. Another distinction from the Exponential mechanism designed to improve utility is utilization of δ.

The choices of m_C and f_C are not related to privacy constraints, and can be made by BLENDER's developer to optimize utility goals, as will be dis-

cussed in Section 4.2.1.

The local nature of the privatization algorith, i.e., the use of a randomization procedure that can report any record with some probability, induces a predictable bias to the distribution of reported records. The removal of this bias, which we refer to as *denoising* (discussed further in Section 3.2), results in the proper probability estimates $\hat{p}_C$ (Figure 5). These probability estimates along with the variance estimates are then passed to the BlendProbabilities part of Blender.

The technical discussion of the algorithm's privacy properties, the denoising procedure and variance estimate computations follow in Sections 3.2 and 3.3.

Algorithm for Blending (Figure 7): The blending portion of Blender combines the estimates produced by the opt-in and client probability-estimation algorithms by taking into account the sizes of the groups and the amount of noise each sub-algorithm added. This produces a blended probability estimate $\hat{p}$ which, in expectation, is more accurate than either group produced individually. The procedure for blending is not subject to privacy constraints, as it operates on the data whose privacy has already been ensured by previous steps of Blender. The motivation and technical discussion of blending follows in Section 3.3.

BlendProbabilities($\hat{p}_O, \hat{\sigma}^2_O, \hat{p}_C, \hat{\sigma}^2_C, HL$)

Parameters:

- $\hat{p}_O, \hat{p}_C$: the probability estimates from the opt-in and client algorithms.
- $\hat{\sigma}_O, \hat{\sigma}_C$: the variance estimates from the opt-in and client algorithms.
- HL: the head list of records.

Body

1: **let** $\hat{p}$ be a vector indexed by records in HL.
2: **for** $\langle q, u\rangle \in HL$ **do**
3: $\quad w_{\langle q,u\rangle} = \frac{\hat{\sigma}^2_{C,\langle q,u\rangle}}{\hat{\sigma}^2_{O,\langle q,u\rangle} + \hat{\sigma}^2_{C,\langle q,u\rangle}}$.
4: $\quad \hat{p}_{\langle q,u\rangle} = w_{\langle q,u\rangle} \cdot \hat{p}_{O,\langle q,u\rangle} + (1 - w_{\langle q,u\rangle}) \cdot \hat{p}_{C,\langle q,u\rangle}$.
5: **Optional:** Project $\hat{p}$ onto probability simplex (e.g., see [39]).
6: **return** $\hat{p}$.

Figure 7: Algorithm for combining record probability estimates from opt-in and client estimates.

3 Technical Detail Summary

We now present further technical details related to the instantiations of the sub-algorithms for Blender, such as statements of privacy properties and the motivation for BlendProbabilities.

3.1 Opt-in Data Algorithms

Differential privacy of the algorithms handling opt-in client data follows directly from previous work.

Theorem 1. *([24])* CreateHeadList *guarantees (ϵ, δ)-differential privacy if $m_O = 1, \epsilon > \ln(2)$, and $\tau \geq 1$.*

Theorem 2. *([10])* EstimateOptinProbabilities *guarantees $(\epsilon, 0)$-differential privacy if $m_O = 1$.*

3.2 Client Data Algorithms

LocalAlg is responsible for the privacy-preserving perturbation of each client's data before it gets sent to the server, and EstimateClientProbabilities is responsible for aggregating the received privatized data into a meaningful statistic. We present the privacy statement and explain the logic behind the aggregation procedure next and prove them in Appendix A.

Theorem 3. LocalAlg *is (ϵ, δ)-differentially private.*

Denoising: The reports aggregated by the client mechanism form an empirical distribution over the records (and queries). Relative to the true underlying record distribution, this distribution is biased in an explicit and publicly-known way, as described by the reporting process. Thus, we seek to obtain an unbiased estimate of the true record distribution from this reported distribution. Concretely, we refer to this as *denoising* the reported empirical distribution $\hat{r}_C$ to obtain the final estimate from the client algorithm, $\hat{p}_C$. The denoising procedure relies only on the publicly-known reporting process as well as the already-privatized reports. Thus, this can be considered a *post-processing* step, which has no negative impact on the differential privacy guarantee [11] yet significantly improves utility.

Observation 1. *$\hat{p}_C$ gives the unbiased estimate of record and query probabilities under* EstimateClientProbabilities.

3.3 Blending

The opt-in algorithm and the client algorithm both output independent estimates $\hat{p}_O$ and $\hat{p}_C$ of the record distribution p. The question we address now is how to best combine these estimates using the information available.

A standard way to measure the quality of an estimate is by its variance. Although it may seem natural to choose the estimate with lower variance as the

final estimate $\hat{p}$, it is possible to achieve a better estimate by jointly utilizing the information provided by both algorithms. This is because the errors in these algorithms' estimates come from different, independent sources. The error in the estimates obtained from the opt-in algorithm is due to the addition of noise, whereas the error in the estimates obtained from the client algorithm is due to randomization of the reports over the set of records in the head list. Thus, if we determine the variances of the estimates obtained from the two algorithms, we can use these variances to *blend* the estimates in the best way.

More formally, for each record $\langle q,u\rangle$ let $\sigma^2_{O,\langle q,u\rangle}$ and $\sigma^2_{C,\langle q,u\rangle}$ be the variances of the opt-in and client algorithm's estimates of $\hat{p}_{O,\langle q,u\rangle}$ and $\hat{p}_{C,\langle q,u\rangle}$ respectively. Since these variances depend on the underlying distribution, which is unknown a priori, we will compute sample variances $\hat{\sigma}^2_{O,\langle q,u\rangle}$ and $\hat{\sigma}^2_{O,\langle q,u\rangle}$ instead. For each record $\langle q,u\rangle$, we will weigh the estimate from the opt-algorithm by $w_{\langle q,u\rangle}$ and the estimate from the client algorithm by $(1-w_{\langle q,u\rangle})$, where $w_{\langle q,u\rangle}$ is defined as in line 3 of BLENDPROBABILITIES. The optional step of projecting the blended estimates (e.g., as in [39]) ensures that the estimates sum to 1 and are non-negative.

Theorem 4 presents our computation of the sample variance of ESTIMATEOPTINPROBABILITIES, Theorem 5 presents our computation of the sample variance of ESTIMATECLIENTPROBABILITIES, and Theorem 6 motivates the weighting scheme used in BLENDPROBABILITIES. Their proofs are presented in Appendix B.

For the variance derivations, we make an explicit assumption that each piece of reported data is drawn independently and identically from the same underlying distribution. This is reasonable when comparing data across users. By setting $m_O = m_C = 1$, we remove the need to assume iid data *within* each user's own data, while simplifying our variance computations. We show in Section 4 that BLENDER achieves high utility even when $m_O = m_C = 1$.

Theorem 4. *When $m_O = 1$ the unbiased variance estimate for* ESTIMATEOPTINPROBABILITIES *can be computed as:* $\hat{\sigma}^2_{O,\langle q,u\rangle} = \frac{|D_T|}{|D_T|-1}\left(\frac{\hat{p}_{O,\langle q,u\rangle}(1-\hat{p}_{O,\langle q,u\rangle})}{|D_T|} + 2\left(\frac{b_T}{|D_T|}\right)^2\right)$.

Theorem 5. *When $m_C = 1$ the unbiased variance estimate for* ESTIMATECLIENTPROBABILITIES *can be computed as:* $\hat{\sigma}^2_{C,\langle q,u\rangle} = \frac{1}{t^2\left(t_q - \frac{1-t_q}{k_q-1}\right)^2} \cdot \Big(\frac{\hat{r}_{C,\langle q,u\rangle}(1-\hat{r}_{C,\langle q,u\rangle})}{|D_C|-1} + \big(\frac{1-t}{(k-1)k_q} - \frac{t-tt_q}{k_q-1}\big)^2\hat{\sigma}^2_{C,q} + \frac{2|D_C|}{|D_C|-1}\big(\frac{1-t}{(k-1)k_q} - \frac{t-tt_q}{k_q-1}\big)\big(\frac{k-2+t}{kt-1}\big)\hat{r}_{C,\langle q,u\rangle}\Big)$.

Theorem 6 (Sample Variance Optimal Weighting)**.** *If $\hat{\sigma}^2_{O,\langle q,u\rangle}$ and $\hat{\sigma}^2_{C,\langle q,u\rangle}$ are sample variances of $\hat{p}_{O,\langle q,u\rangle}$ and $\hat{p}_{C,\langle q,u\rangle}$ respectively, then $w_{\langle q,u\rangle} = \frac{\hat{\sigma}^2_{C,\langle q,u\rangle}}{\hat{\sigma}^2_{O,\langle q,u\rangle}+\hat{\sigma}^2_{C,\langle q,u\rangle}}$ is the sample variance optimal weighting.*

4 Experimental Evaluation

We designed BLENDER with an eye toward preserving the utility of the eventual results in the two applications we explore in this paper: trend computation and local search, as described in Section 1.2. We use two established domain-specific utility metrics to assess the utility, the L1 metric and NDCG.

L1: L1 is the Manhattan distance between the estimate and actual probability vectors, in other words, $L1 = \sum_i |\hat{p}_i - p_i|$. The smaller the L1, the better.

NDCG: NDCG is a standard measure of search quality [20, 38] that explicitly takes the ordering of the items in a results list into account. This measure uses a relevance score for each item: given a list of items and their true frequencies, we define the *relevance* or *gain* of the ith most frequent item as $rel_i = \frac{n_i}{\sum_j n_j}$, where n_j is the number of occurrences of the jth most frequent item. The *discounted cumulative gain* for the top k items in an estimated list (that is, a list that estimates the top k items and their frequencies) is typically computed as $DCG_k = \sum_{i=1}^{k} \frac{2^{rel_i}-1}{\log_2(i+1)}$. Here, the $\log_2(i+1)$ factor diminishes the contribution of items later in the list, hence the notion of *discounting*. In particular, getting the ordering correct for higher-relevance items early in the list yields a higher DCG_k value.

The magnitude of the DCG_k value doesn't mean much on its own. For better interpretability, it is usually normalized by the *Ideal DCG* ($IDCG_k$), which is the DCG_k value if the estimated list had the exact same ordering as the actual list. Thus, the *normalized discounted cumulative gain* ($NDCG_k$), which ranges between 0 and 1, is defined as $NDCG_k = DCG_k/IDCG_k$.

While NDCG is traditionally defined for lists, BLENDER outputs a list-of-lists: there is a URL list corresponding to each query, and the queries themselves form a list. Thus, we introduce a generalization of the traditional NDCG measure. Specifically, for each query q, we first compute the NDCG as described above of q's *URL list*, $NDCG^q_k$. We then define the DCG of the *query list* as $DCG^Q_k = \sum_{i=1}^{k} \frac{2^{rel_i}-1}{\log_2(i+1)} \cdot NDCG^i_k$. This is analogous to the typical DCG computation, except that each query's contribution is being further discounted by how well

	AOL	Yandex
Data set on disk	1.75 GB	16 GB
Unique queries	4,811,646	13,171,961
Unique clients	519,371	4,970,073
Unique URLs	1,620,064	12,702,350

Figure 8: Data set statistics.

its URL list was estimated. The DCG value for the query list as a whole is then normalized by the analogous *Ideal DCG* ($IDCG_k^Q$) – the DCG_k^Q if the estimated query list had the exact same ordering as the actual query list.

Compared to the traditional NDCG definition, the additional discounting within DCG_k^Q makes it even harder to attain high NDCG values than in the query-only case. Contrasted with the L1 measure, this formulation takes both the ranking and probabilities from the data set into account. Since changes to the probabilities may not result in ranking changes, L1 is an even less forgiving measure than NDCG.

Since the purpose of BLENDER is to estimate probabilities of the top records, we discard the artificially added $\star$ queries and URLs and rescale rel_i prior to L1 and NDCG computations. However, since we use the method of [39] in BLENDPROBABILITIES, the probability estimates involving $\star$ have a minor implicit effect on the L1 and NDCG scores.

4.1 Experimental Setup

Data sets: For our experiments, we use the AOL search logs, first released in 2006 and an order of magnitude bigger Yandex search data set[4], from 2013. Figure 8 compares their characteristics.

Data analysis: To familiarize the reader with the approach we used for assessing result quality, Figure 9 shows the top-10 most frequent queries in the AOL data set, with the estimates given by the different "ingredients" of BLENDER.

The table is sorted by column 2, which contains the non-private, empirical probabilities p_q for each query q from the AOL data set with 1 random record sampled from each user. We consider this as the baseline for the true, underlying probability of that query. Column 3 contains the final query probability estimates outputted by BLENDER, $\hat{p}_q$, after combining the estimates from the opt-in group and clients. The remaining columns show the estimates that are produced by the sub-components of BLENDER that are eventually combined to form the estimates in column 3. As the opt-in and client sub-components compute probability estimates over the *records* in the head list, we obtain *query* probability estimates by aggregating the probabilities associated with each

Query	AOL data prob. p_q	Blender estimate $\hat{p}_q$	Opt-in estimate $\sum_u \hat{p}_{O,\langle q,u\rangle}$	Client estimate $\hat{p}_{C,q}$	Client estimate $\sum_u \hat{p}_{C,\langle q,u\rangle}$
$\star$	0.9108	0.9103	0.9199	0.9100	0.1468

Figure 9: Top-10 most popular queries in the AOL dataset, their empirical probabilities p_q in the first numeric column, BLENDER's probability estimates $\hat{p}_q$ in the next column, and the various sub-components' estimates in the remaining columns. Parameter choices are shown in Figure 10.

URL for a given query (columns 4 and 6). The sample variance of these aggregated probabilities, used for blending, is naively computed as in Theorem 4. In addition to estimating the record probabilities, the client algorithm estimates query probabilities directly, which are shown in column 5. Regressions, i.e., estimates that appear *out of order* relative to column 2, are shown in red.

Takeaways: The biggest takeaway is that the numbers in columns 2 and 3 are similar to each other, with only one regression after BLENDER's usage. BLENDER compensates for the weaknesses of both the opt-in and the client estimates. Despite the sub-components having several regressions, their combination has only one.

The table also provides intuition for the usefulness of a two-stage reporting process in the client algorithm (first report a query and *then* the URL), thus allowing for separate estimates of query and record probabilities. Specifically, despite the high number of regressions for the client algorithm's aggregated record probability estimates (column 6), its query probability estimates (column 5) have only one.

4.2 Experimental Results

We formulate questions for our evaluation as follows: how to choose BLENDER's parameters (Section 4.2.1), how does BLENDER perform compared to alternatives (Section 4.2.2), and how robust are our findings (Section 4.2.3)?

4.2.1 Algorithmic and Parameter Choices

BLENDER has a handful of parameters, some of which can be viewed as given externally (by the laws of nature, so to speak), and others whose choice is purely up to the entity that's utilizing BLENDER. We now describe and, whenever possible, motivate, our choices for these.

Privacy parameters, ϵ and δ: Academic literature on differential privacy views the selection of the ϵ parameter as a "social question" [9] and thus

uses ϵ in the range of 0.01 to 10 for evaluating algorithm performance (see Table 1 in [18]). The two known industry deployments of differential privacy (by Google [13] and Apple [17]) do not explicitly reveal the parameters used. [25, 37] found via reverse-engineering of Apple's differential privacy implementation that Apple uses $\epsilon = 1$ or $\epsilon = 2$ per item submitted, but allows submission of several dozen items per day from one device. A typical user might experience an ϵ of $4 - 6$ per day, but $\epsilon = 20$ per day has also been observed [37]. The work most similar to ours, [34], performs evaluations using ϵ in the range $[1, 10]$. We use $\epsilon = 4$, unless otherwise stated. Similarly, a range of δs has been used for evaluations (e.g., $10^{-6}, 10^{-5}, 10^{-4}$ in [26] and 0.05 in [6]). We use $\delta = 10^{-5}$ for AOL and $\delta = 10^{-7}$ for Yandex data sets, with the smaller δ choice for the latter reflecting the larger number of users in the data set.

We use the same ϵ and δ values for the opt-in and client users. From a behavioral perspective, this reduces a user's opt-in decision down to one purely of trust towards the curator.

Opt-in and client group sizes, $|O|$ and $|C|$: The relative sizes of opt-in group and client group, $|O|$ and $|C|$, respectively, can be viewed as exogenous variables which are dictated by the trust that users place in the search engine. We choose 5% and 2.5% for the fraction of opt-in users as compared to total users as these seem reasonable for representing the fraction of "early adopters" who are willing to supply their data for the improvement of products and allow us to demonstrate the utility benefits of algorithms designed to operate in the hybrid privacy model.

The number of records to collect from each opt-in user, $m_O = 1$: This is mandated by the privacy constraints of CreateHeadList algorithm. If $m_O > 1$ is desired, one should modify the algorithm.

Remaining parameter choices (m_C, f_C, f_O, M) are driven purely by utility considerations.

The number of records to collect from each client, $m_C = 1$: Across a range of experimental values, collecting 1 record per user always yielded greatest utility, motivating this parameter choice. Apple makes an analogous choice in their implementation – they (temporarily) store all relevant items on a client's device, and then choose 1 item of each type to transmit at random each day [37].

How to split the privacy budget between query and url reporting for clients, $f_C = 0.85$: Figure 11 shows the effects of the budget split on both the L1 and NDCG metrics. Unsurprisingly, Figure 11a shows that the larger the fraction of client algorithm's budget dedicated to query estimation as opposed to URL estimation, the better the L1 score for the client and Blender results. The NDCG metric in Figure 11b shows a trade-off that emerges as we assign more budget to the queries, de-emphasizing the URLs; before and after 0.85, we start seeing a drop in NDCG values for the client algorithm. The orange opt-in line in Figure 11b is constant, as the opt-in group is not affected by the budget split. Somewhat surprisingly with this parameter setting, the NDCG for Blender result is also consistently high (nearly equal to and hidden by the opt-in line) and is unaffected by the budget split, unlike the L1 metric.

What fraction of opt-in data to use for creating the headlist, $f_O = 0.95$: Our goal is to build a large candidate head list, and unless we allocate most of the opt-in user data to building such a head list (algorithm CreateHeadList), our subsequent results may be accurate but apply only to a small number of records. Since our opt-in group's size is small relative to our client group size, and it is difficult to generate a head list in the local privacy model – it makes sense to utilize most of the opt-in group's data for the task that is most difficult in the local model. Through experiment we observe that increasing f_O past 95% gives diminishing returns for increasing the head list size; on the other hand, there is a significant utility gain (NDCG and L1) from the use of a small fraction of opt-in users for estimating probabilities of the head list. Thus, rather than using the entire opt-in group for head list generation (i.e., $f_O = 1$), we reserve 5% of the opt-in data for probability estimation.

What should be the final size of the set for which we provide probability estimates, M: The choice of M is influenced by competing considerations. The larger the head list for which we provide the probability estimates, the more effective the local search application (subject to those probability estimates being accurate). However, as desired head list size increases, the accuracy of our estimates drops (most notably due to client data privatization). We want to strike a balance that allows us to get a sensibly large record set with reasonably accurate probability estimates it. We choose $M = 50$ and $M = 500$ for the AOL and Yandex datasets, to reflect their differing sizes.

Subsequently, we use the parameters shown in Figure 10 unless explicitly stated.

4.2.2 Utility Comparison to Alternatives

The closest related work is a recent paper by Qin *et al.* [34] for heavy hitter estimation with local differential privacy, in which they provide a utility

Parameter	AOL	Yandex
ϵ	4	4
δ	10^{-5}	10^{-7}
$\frac{\lvert O\rvert}{\lvert O\rvert+\lvert C\rvert}$	5%	2.5%
m_O	1	1
m_C	1	1
f_O	0.95	0.95
f_C	0.85	0.85
M	50	500

Figure 10: Experimental parameters.

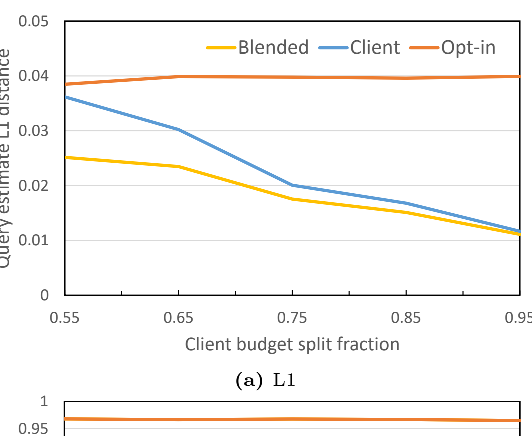
evaluation of their algorithm on the AOL data set for the head list size of 10. We perform a direct comparison of their NDCG results with BLENDER's across ϵ values in the range of 1–5, which we plot in Figure 12. Across the entire range of the privacy parameter, our NDCG values are above 95%, whereas the reported NDCG values for Qin *et al.* are in the 30% range, at best. We believe that given the intense focus on search optimization in the field of information retrieval, NDCG values as low as those of Qin *et al.* are generally unusable, especially for such a small head list size. Overall, BLENDER significantly outperforms what we believe to be the closest related research project.

A caveat to these findings is that Qin *et al.* [34] and this work use slightly different scoring functions. The former's relevance score is based on the rank of queries in the original AOL data set, which results in penalizing mis-ranked queries regardless of how similar their underlying probabilities may be. BLENDER's relevance score relies on the underlying probabilities, so mis-ranked items with similar underlying probabilities have only a small negative impact on the overall NDCG score; we believe this choice is justified. Although it yields increased NDCG scores, BLENDER operates on records (rather than queries, as Qin *et al.* does). Because of this, the generalized NDCG score used to evaluate BLENDER (Section 4) is a strictly less forgiving metric than the traditional NDCG score. Thus, although simultaneously compensating for both differences would yield the ideal comparison, the one in Figure 12 is reasonable.

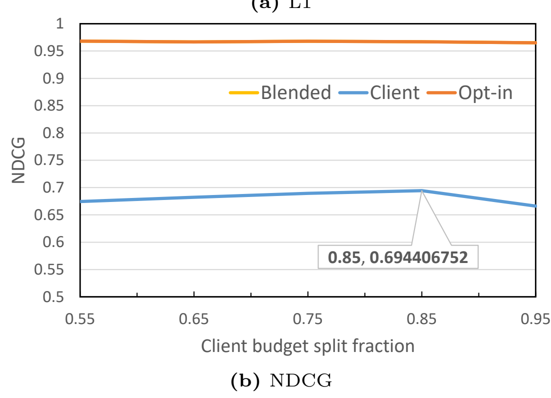
4.2.3 Robustness

We now discuss how the size of the opt-in group and the choice of ϵ affect BLENDER's utility.

Evaluation of trend computation: Figure 13 shows the L1 values as a function of the opt-in percentage ranging between 1% and 10%. We see slight differences in the two data sets and across the various head list sizes. Some of the differences might be due to the fact that given the relatively small size of the AOL data set, we need to consider higher opt-in percentages to get reasonably sized head lists



(a) L1



(b) NDCG

Figure 11: Comparing AOL data set results across a range of budget splits for client, opt-in, and blended results.

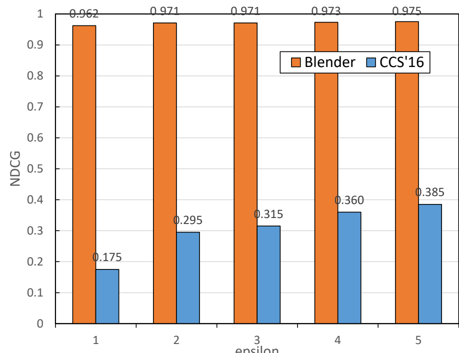


Figure 12: Comparing to the results in the CCS'16 paper by Qin *et al.* across a range of ϵ values; head list size=10.

and L1 values. In fact, when we increase the opt-in percentage to 10% for the AOL data set, we see a decline in L1 values similar to what is observed in Figure 13b for the Yandex data set. If our goal is to have head lists of 500+, we see that with the larger Yandex data set, an opt-in percentage as small as 2.5% is sufficient to achieve high utility. On the other hand, portions of lines do not appear on figures if the desired head list size was not reached; e.g., in Figure 13a, the line for a head list of size 50 does not begin until 4.5% because that size head list was not created with a smaller opt-in percentage.

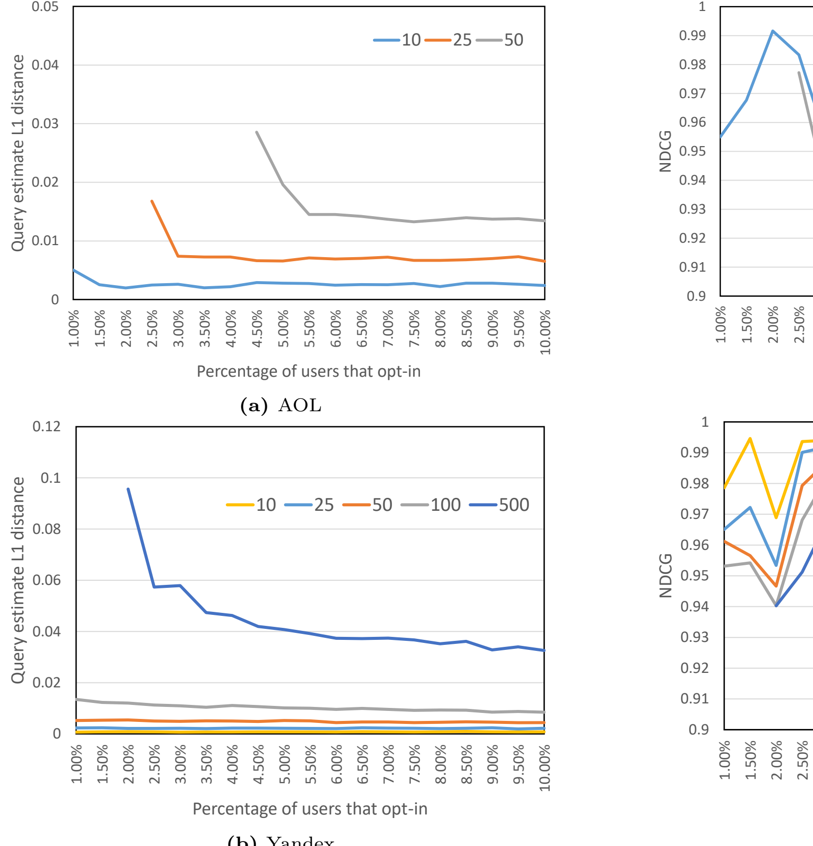

Figure 13: L1 statistics as a function of the opt-in percentage for select head list sizes.

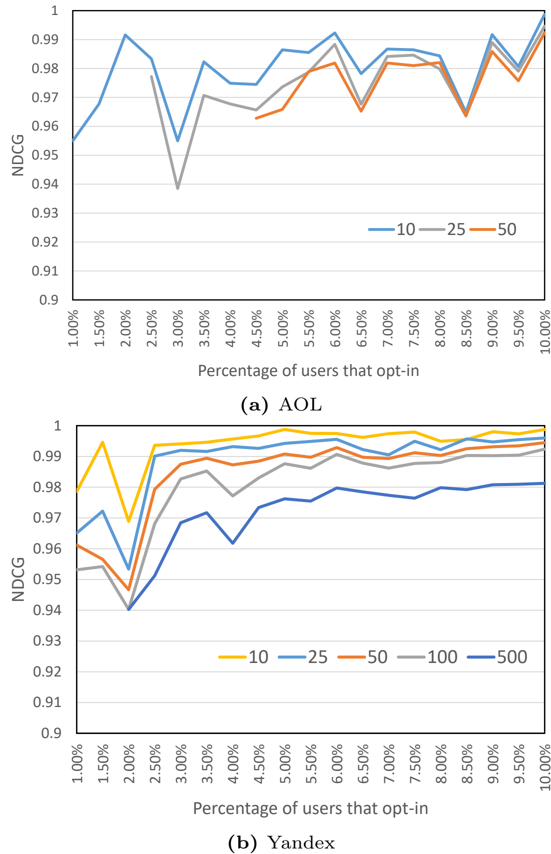

Figure 14: NDCG statistics as a function of the opt-in percentage for select head list sizes.

Figure 15 shows the L1 values as a function of ϵ, ranging from 1 to 5. For both data sets, we see a steady decline in the L1 metric, despite aggregating L1 values over longer estimate vectors. With more data in the Yandex data set, we are able to hit small values of L1 (under 0.1) with $\epsilon \geq 1$. Similar to the case with small opt-in percentages, having too small an ϵ makes it difficult to achieve head lists of their target size; e.g., in Figure 15a, the line for a head list of size 50 does not begin until $\epsilon = 3$ because that size head list was not created with a smaller ϵ value.

Evaluation of local search computation: Figure 14 shows the NDCG measurements as a function of the opt-in percentage ranging between 1% and 10%. The results are quite encouraging; for the smaller AOL data set, for instance, we need to have an opt-in level of ≈5% to achieve an NDCG level of 95%, which we regard as acceptable. However, for the larger Yandex data set, we hit that NDCG level even sooner: the NDCG value for 1.5% is above 95% for all but the largest head list size.

Figure 16 shows how the NDCG values vary across the two data sets for a range of head list sizes and ϵ values. We see a clear trend toward higher NDCG values for Yandex, which is not surprising given the sheer volume of data. For the Yandex data set, we can keep ϵ as low as 1 and still achieve NDCG values of 95% and above for all but the two largest head list sizes. For those, we must increase ϵ in order to generate larger head lists from the opt-in users.

5 Related Work

Algorithms for the trusted curator model: Researchers have developed numerous differentially private algorithms operating in the trusted curator model that result in useful data for a variety of applications. For example, [24, 26, 16, 31] address the problem of publishing a subset of the data contained in a search log with differential privacy guarantees; [27] and [6] propose approaches for frequent item identification; [14] propose an approach for monitoring aggregated web browsing activities; and so on.

Algorithms for the local model: Although the demand for privacy-preserving algorithms operating in the local model has increased in recent years, par-

ticularly among practitioners [17, 35], fewer such algorithms are known [40, 19, 8, 13, 5]. Furthermore, the utility of the resulting data obtained through these algorithms is significantly limited compared to what is possible in the trusted curator model, as shown experimentally [15, 21] and theoretically [22].

The recent work of [34] also takes a two-stage approach: first, spend some part of the privacy budget to learn a candidate head list and then use the remaining privacy budget to refine the probability estimates of the candidates. However, that's where the similarities with Blender end, as [34] focuses entirely on the local model (and thus has to use entirely different algorithms from ours for each stage) and addresses the problem of estimating probabilities of queries, rather than the more challenging problem of estimating probabilities of query-URL pairs.

Our contribution: Our work significantly improves upon the known results by developing application-specific local privatization algorithms that work in combination with the trusted curator model algorithms. Specifically, our insight of providing all users with differential privacy guarantees but achieving it differently depending on whether or not they trust the data curator, enables an efficient privacy-preserving head list construction. The subsequent usage of this head list in the algorithm operating in the local model helps overcome one of the main challenges to utility of privacy-preserving algorithms in the local model [15]. Moreover, the weighted aggregation of probability estimates obtained from algorithms operating in the two models (that explicitly factors in the amount of noise each contributed), enabled remarkable utility gains compared to usage of one algorithm's estimates. As discussed in Section 4.2.2, we significantly outperform the most recently introduced local algorithm of [34] on metrics of utility in the search context.

6 Discussion

Operating in the hybrid model is most beneficial utility-wise if the opt-in user records and client user records come from the same distribution – i.e., the two groups have fairly similar observed search behavior. If that is not the case, the differential privacy

guarantees still hold, but the accuracy of BLENDER's estimates may decrease.

Improvement in utility over what can be achieved in the local model comes from two sources: the hybrid privacy model lets us develop a better algorithm for client data collection and the analysis of algorithms' variances lets us smartly combine the results.

In practice, a system for local search or trend computation would be run at regular intervals in order to refresh the data as well as accommodate for users being added to, removed from, or moving between the opt-in and the client groups. We have focused on the problem of obtaining local search or trend computation results for a single execution of the system. While one could simply re-run BLENDER at regular intervals to obtain new results (with potentially different opt-in and client groups), this comes at a cost to privacy. We leave the task of improving the temporal aspect of BLENDER beyond what is achievable with standard composition techniques of differential privacy [11] to future work.

7 Conclusions

We proposed a hybrid privacy model and a blended approach that operates within it that combines the upsides of two common models of differential privacy: the local model and the trusted curator model. Using local search as a motivating application, we demonstrated that our proposed approach leads to a significant improvement in terms of utility, bridging the gap between theory and practicality.

Future work: We plan to continue this work in two directions: first, to address any systems and engineering challenges to BLENDER's adoption in practice, including those that arise due to data changing over time; and second, to develop algorithms for other settings where the hybrid privacy model is appropriate, thus facilitating adoption of differential privacy in practice by minimizing the utility impact of privacy-preserving data collection.

A Client Data Algorithm

A.1 Privacy

Theorem 3. LOCALALG *is (ϵ, δ)-differentially private.*

Proof. We show this by proving that each iteration of the `for` loop in line 7 of LOCALALG is (ϵ', δ')-differentially private, where $\epsilon' = \epsilon/m_C$ and $\delta' = \delta/m_C$. Since there are at most m_C iterations of this loop for each client, composition of differentially private mechanisms [12] guarantees that LOCALALG ensures (ϵ, δ)-differential privacy for each client.

Denote each iteration of the `for` loop in line 7 of LOCALALG by L; it takes as input a record $\langle q, u\rangle \in D$, and returns a record, which we denote $L(\langle q, u\rangle)$. If q is not in HL or u is not in $HL[q]$, then they immediately get transformed into a default value $(\star)$ that is in the head list. Since L outputs only values that exist in the head list, to confirm differential privacy we need to prove that for any arbitrary neighboring data sets $\langle q, u\rangle$ and $\langle q', u'\rangle$, $\Pr\big[L(\langle q, u\rangle) \in Y\big] \le e^{\epsilon'} \Pr\big[L(\langle q', u'\rangle) \in Y\big] + \delta'$ holds for all sets of head list records Y.

Whenever $k = 1$ or $k_q = 1$, the only query (or URL for a specific query) is $\star$, which will be output with probability 1. Thus, differential privacy trivially holds, since the reported values then do not rely on the client's data. Thus, we'll assume $k \ge 2$ and $k_q \ge 2$. Note that there is a single decision point where it is determined whether q will be reported truthfully or not. Thus, we can split the privacy analysis into two parts: 1) Usage of

the f_C fraction of the privacy budget to report a query, and 2) Usage of the remainder of the privacy budget to report a URL (given the reported query). This decomposes a simultaneous two-item (ϵ', δ') reporting problem into two single-item reporting problems with (ϵ'_Q, δ'_Q) and (ϵ'_U, δ'_U) respectively, where $\epsilon'_Q = f\epsilon'$, $\delta'_Q = f\delta'$, $\epsilon'_U = (1 - f_C)\epsilon'$, and $\delta'_U = (1 - f_C)\delta'$.

1. Privacy of Query Reporting:

Consider the query-reporting case first. Overloading our use of L, let $L(q)$ be the portion of L that makes use of q. We first ensure that

$$\Pr[L(q) = q_{HL}] \leq \exp(\epsilon'_Q) \Pr[L(q') = q_{HL}] + \frac{\delta'_Q}{2} \quad (1)$$

holds for all q, q', and $q_{HL} \in HL$. This trivially holds when $q_{HL} = q = q'$ or $q_{HL} \notin \{q, q'\}$. The remaining scenarios to consider are: 1) $q \neq q_{HL}, q' = q_{HL}$ and 2) $q = q_{HL}, q' \neq q_{HL}$. By the design of the algorithm, $\Pr[L(q_{HL}) = q_{HL}] = t$ and $\Pr[L(\bar{q}_{HL}) = q_{HL}] = (1-t)(\frac{1}{k-1})$, where $\bar{q}_{HL}$ represents any query not equal to q_{HL}. With $t = \frac{\exp(\epsilon'_Q)+(\delta'_Q/2)(k-1)}{\exp(\epsilon'_Q)+k-1}$, it is simple to verify that inequality (1) holds.

Consider an arbitrary set of head list queries Y.

$$\Pr[L(q) \in Y] = \sum_{q_{HL} \in Y} \Pr[L(q) = q_{HL}]$$
$$= \sum_{q_{HL} \in Y \setminus \{q,q'\}} \Pr[L(q) = q_{HL}] + \sum_{q_{HL} \in Y \cap \{q,q'\}} Pr[L(q) = q_{HL}]$$
$$= \sum_{q_{HL} \in Y \setminus \{q,q'\}} \Pr[L(q') = q_{HL}] + \sum_{q_{HL} \in Y \cap q,q'} \Pr[L(q) = q_{HL}] \quad (2)$$
$$\leq \sum_{q_{HL} \in Y \setminus \{q,q'\}} \Pr[L(q') = q_{HL}] + \sum_{q_{HL} \in Y \cap \{q,q'\}} (e^{\epsilon'_Q} \Pr[L(q') = q_{HL}] + \frac{\delta'_Q}{2}) \quad (3)$$
$$\leq e^{\epsilon'_Q} \sum_{q_{HL} \in Y} \Pr[L(q') = q_{HL}] + 2 \cdot \frac{\delta'_Q}{2}$$
$$= e^{\epsilon'_Q} \Pr[L(q') \in Y] + \delta'_Q,$$

Equality (2) stems from the fact that the probability of reporting a false query is independent of the user's true query. The inequality (3) is a direct application of inequality (1). Thus, L is (ϵ'_Q, δ'_Q)-differentially private for query-reporting.

2. Privacy of URL Reporting:

With t_q defined as $t_q = \frac{\exp(\epsilon'_U)+0.5\delta'_U(k_q-1)}{\exp(\epsilon'_U)+k_q-1}$, an analogous argument shows that the (ϵ'_U, δ'_U)-differential privacy constraints hold if the original q is kept. On the other hand, if it is replaced with a random query, then they trivially hold as the algorithm reports a random element in the URL list of the reported query, without taking into consideration the client's true URL u.

By composition [12], each of the at most m_C iterations of L is $(\epsilon'_Q + \epsilon'_U, \delta'_Q + \delta'_U) = (\epsilon', \delta')$-differentially private. □

A.2 Denoising

Observation 1. *$\hat{p}_C$ gives the unbiased estimate of record and query probabilities under* ESTIMATE-CLIENTPROBABILITIES.

Proof. Reporting records is a two-stage process (first, decide which query to report, then report a record); similarly, denoising is also done in two stages.

Denoising of query probability estimates: Let $r_{C,q}$ denote the probability that the algorithm has received query q as a report, and let p_q be the true probability of a user having query q. We want to learn p_q based on $r_{C,q}$. By the design of our algorithm, $r_{C,q} = t \cdot p_q + \sum_{q' \neq q} p_{q'}(1-t)\frac{1}{k-1} = t \cdot p_q + \frac{1-t}{k-1}\sum_{q' \neq q} p_{q'} = t \cdot p_q + \frac{1-t}{k-1}(1 - p_q)$.

Solving for p_q in terms of $r_{C,q}$ yields $p_q = \frac{r_{C,q} - \frac{1-t}{k-1}}{t - \frac{1-t}{k-1}}$. Using the obtained data for the query $\hat{r}_{C,q}$, we estimate $p_{C,q}$ as $\hat{p}_{C,q} = \frac{\hat{r}_{C,q} - \frac{1-t}{k-1}}{t - \frac{1-t}{k-1}}$.

Denoising of record probability estimates: Analogously, denote by $r_{C,\langle q,u\rangle}$ the probability that the algorithm has received a record $\langle q,u\rangle$ as a report, and recall $p_{\langle q,u\rangle}$ is the record's true probability in the data set. Then $r_{C,\langle q,u\rangle} = t \cdot t_q \cdot p_{\langle q,u\rangle} + \left(t\frac{1-t_q}{k_q-1}\right)(p_q - p_{\langle q,u\rangle}) + \left(\frac{1-t}{k-1}\frac{1}{k_q}\right)(1 - p_q)$, recalling from the algorithm that k_q is the number of URLs associated with query q and t_q is the probability of truthfully reporting u given that query q was reported. Solving for $p_{\langle q,u\rangle}$ yields $p_{\langle q,u\rangle} = \frac{r_{C,\langle q,u\rangle} - \left(t\frac{1-t_q}{k_q-1}p_q + \frac{(1-t)(1-p_q)}{(k-1)k_q}\right)}{t(t_q - \frac{1-t_q}{k_q-1})}$.

Using the obtained data for the empirical report estimate $\hat{r}_{C,\langle q,u\rangle}$ together with the query estimate $\hat{p}_{C,q}$, we estimate $p_{\langle q,u\rangle}$ as $\hat{p}_{C,\langle q,u\rangle} = \frac{\hat{r}_{C,\langle q,u\rangle} - \left(t\frac{1-t_q}{k_q-1}\hat{p}_{C,q} + \frac{(1-t)(1-\hat{p}_{C,q})}{(k-1)k_q}\right)}{t(t_q - \frac{1-t_q}{k_q-1})}$. □

B Blending

Theorem 4. *When $m_O = 1$ the unbiased variance estimate for* ESTIMATEOPT-INPROBABILITIES *can be computed as:* $\hat{\sigma}^2_{O,\langle q,u\rangle} = \frac{|D_T|}{|D_T|-1}\left(\frac{\hat{p}_{O,\langle q,u\rangle}(1-\hat{p}_{O,\langle q,u\rangle})}{|D_T|} + 2\left(\frac{b_T}{|D_T|}\right)^2\right)$.

Proof. Given the head list, the distribution of ESTIMATEOPTINPROBABILITIES' estimate for a record $\langle q,u\rangle$ is given by $r_{O,\langle q,u\rangle} = p_{\langle q,u\rangle} + \frac{Y}{|D_T|}$, where $Y \sim$ Laplace(b_T) where b_T is the scale parameter and $|D_T|$ is the total number of records from the opt-in users used to estimate probabilities. The empirical estimator for $r_{O,\langle q,u\rangle}$ is $\hat{r}_{O,\langle q,u\rangle} = \frac{1}{|D_T|}\sum_{j=1}^{|D_T|} X_j + Y$, where $X_j \sim$ Bernoulli$(p_{\langle q,u\rangle})$ is the random variable indicating whether report j was record $\langle q,u\rangle$.

The expectation of this estimator is given by $E[\hat{r}_{O,\langle q,u\rangle}] = p_{\langle q,u\rangle}$. Thus, $\hat{r}_{O,\langle q,u\rangle}$ is an unbiased estimator for $p_{\langle q,u\rangle}$. We denote $\hat{p}_{O,\langle q,u\rangle} = \hat{r}_{O,\langle q,u\rangle}$ to explicitly reference it as the estimator of $p_{\langle q,u\rangle}$. The variance for this estimator is

$$\begin{aligned}
\sigma^2_{O,\langle q,u\rangle} = V[\hat{p}_{O,\langle q,u\rangle}] &= V\Big[\frac{1}{|D_T|}\big(\sum_{j=1}^{|D_T|} X_j + Y\big)\Big] \\
&= \frac{1}{|D_T|^2}\Big(V\big[\sum_{j=1}^{|D_T|} X_j\big] + V[Y]\Big) \quad (4) \\
&= \frac{1}{|D_T|^2}\Big(\sum_{j=1}^{|D_T|} V[X_j] + V[Y]\Big) \quad (5) \\
&= \frac{1}{|D_T|^2}\big(|D_T| \cdot p_{\langle q,u\rangle}(1-p_{\langle q,u\rangle})\big) + 2\Big(\frac{b_T}{|D_T|}\Big)^2 \\
&= \frac{p_{\langle q,u\rangle}(1-p_{\langle q,u\rangle})}{|D_T|} + 2\Big(\frac{b_T}{|D_T|}\Big)^2.
\end{aligned}$$

Equality 4 comes from the independence between Y and all X_j. Equality 5 relies on an assumption of independence between X_j, X_k for all $j \neq k$ (i.e., the iid assumption discussed prior to the theorem statements in Section 3.3).

To actually compute this variance, we need to use the data in place of the unknown $p_{\langle q,u\rangle}$. Using $\hat{p}_{O,\langle q,u\rangle}$ directly in place of $p_{\langle q,u\rangle}$ requires a $\frac{|D_T|}{|D_T|-1}$ factor correction (known as "Bessel's correction[5]") to generate an unbiased estimate. Thus, the variance of each opt-in record probability estimate is: $\hat{\sigma}^2_{O,\langle q,u\rangle} = \frac{|D_T|}{|D_T|-1}\left(\frac{\hat{p}_{O,\langle q,u\rangle}(1-\hat{p}_{O,\langle q,u\rangle})}{|D_T|} + 2\left(\frac{b_T}{|D_T|}\right)^2\right)$. □

Note that in line 15 of EstimateOptinProbabilities, the use of this sample variance expression in re-computing $\hat{\sigma}^2_{O,\langle\star,\star\rangle}$ is not statistically valid, so our computation of $\hat{p}_{O,\langle\star,\star\rangle}$ and $\hat{p}_{\langle\star,\star\rangle}$ is sub-optimal. Despite that, our overall utility, which does not include $\star$, is good (see Section 4).

Theorem 5. *When $m_C = 1$ the unbiased variance estimate for* EstimateClientProbabilities *can be computed as:* $\hat{\sigma}^2_{C,\langle q,u\rangle} = \frac{1}{t^2\left(t_q - \frac{1-t_q}{k_q-1}\right)^2} \cdot \Big(\frac{\hat{r}_{C,\langle q,u\rangle}(1-\hat{r}_{C,\langle q,u\rangle})}{|D_C|-1} + \big(\frac{1-t}{(k-1)k_q} - \frac{t-tt_q}{k_q-1}\big)^2\hat{\sigma}^2_{C,q} + \frac{2|D_C|}{|D_C|-1}\big(\frac{1-t}{(k-1)k_q} - \frac{t-tt_q}{k_q-1}\big)\big(\frac{k-2+t}{kt-1}\big)\hat{r}_{C,\langle q,u\rangle}\Big)$.

Proof. From Section 3.2 on denoising, the distribution of the reported query q from the client mechanism is given by $r_{C,q} = t \cdot p_q + \frac{1-t}{k-1}(1-p_q)$, and so the true probability of query q is distributed as $p_q = \frac{r_{C,q} - \frac{1-t}{k-1}}{t - \frac{1-t}{k-1}}$. The empirical estimator for p_q is $\hat{p}_{C,q} = \frac{\hat{r}_{C,q} - \frac{1-t}{k-1}}{t - \frac{1-t}{k-1}}$, where $\hat{r}_{C,q}$ is the empirical estimator of $r_{C,q}$ defined explicitly as $\hat{r}_{C,q} = \frac{1}{|D_C|}\sum_{j=1}^{|D_C|} X_j$, where $X_j \sim \text{Bernoulli}(r_{C,q})$ is the random variable indicating whether report j was query q and $|D_C|$ is the total number of records from the client users.

The variance of $\hat{r}_{C,q}$ is

$$\begin{aligned}
V[\hat{r}_{C,q}] &= V\Big[\frac{1}{|D_C|}\sum_{j=1}^{|D_C|} X_j\Big] \\
&= \Big(\frac{1}{|D_C|}\Big)^2 \sum_{j=1}^{|D_C|} V[X_j] \quad (6) \\
&= \big(\frac{1}{|D_C|}\big)^2\big(|D_C| \cdot r_{C,q}(1-r_{C,q})\big) = \frac{r_{C,q}(1-r_{C,q})}{|D_C|},
\end{aligned}$$

where equality 6 relies on an assumption of independence between X_j, X_k for all $j \neq k$ (i.e., the iid assumption discussed prior to the theorem statements in Section 3.3).

Then, the variance of $\hat{p}_{C,q}$ is

$$\sigma^2_{C,q} = V[\hat{p}_{C,q}] = V\Big[\frac{\hat{r}_{C,q} - \frac{1-t}{k-1}}{t - \frac{1-t}{k-1}}\Big] = \frac{r_{C,q}(1-r_{C,q})}{|D_C|\big(t - \frac{1-t}{k-1}\big)^2}.$$

To actually compute this variance, we need to use the data in place of the unknown $r_{C,q}$. Using $\hat{r}_{C,q}$ directly in place of $r_{C,q}$ requires including Bessel's $\frac{|D_C|}{|D_C|-1}$ factor correction to yield an unbiased estimate. Thus, the variance of the query probability estimates by the client algorithm is: $\hat{\sigma}^2_{C,q} = \left(\frac{1}{t - \frac{1-t}{k-1}}\right)^2 \frac{\hat{r}_{C,q}(1-\hat{r}_{C,q})}{|D_C|-1}$.

Using a similar procedure for records we obtain the unbiased variance estimate as $\hat{\sigma}^2_{C,\langle q,u\rangle} = \frac{1}{t^2\left(t_q - \frac{1-t_q}{k_q-1}\right)^2} \cdot \Big(\frac{\hat{r}_{C,\langle q,u\rangle}(1-\hat{r}_{C,\langle q,u\rangle})}{|D_C|-1} + \big(\frac{1-t}{(k-1)k_q} - \frac{t-tt_q}{k_q-1}\big)^2\hat{\sigma}^2_{C,q} + \frac{2|D_C|}{|D_C|-1}\big(\frac{1-t}{(k-1)k_q} - \frac{t-tt_q}{k_q-1}\big)\big(\frac{k-2+t}{kt-1}\big)\hat{r}_{C,\langle q,u\rangle}\Big)$. □

Theorem 6. *If $\hat{\sigma}^2_{O,\langle q,u\rangle}$ and $\hat{\sigma}^2_{C,\langle q,u\rangle}$ are sample variances of $\hat{p}_{O,\langle q,u\rangle}$ and $\hat{p}_{C,\langle q,u\rangle}$ respectively, then $w_{\langle q,u\rangle} = \frac{\hat{\sigma}^2_{C,\langle q,u\rangle}}{\hat{\sigma}^2_{O,\langle q,u\rangle} + \hat{\sigma}^2_{C,\langle q,u\rangle}}$ is the sample variance optimal weighting.*

Proof. With the variance estimates for each algorithm fully computed, a blended estimate of $p_{\langle q,u\rangle}$ is given by $\hat{p}_{\langle q,u\rangle} = w_{\langle q,u\rangle} \cdot \hat{p}_{O,\langle q,u\rangle} + (1-w_{\langle q,u\rangle}) \cdot \hat{p}_{C,\langle q,u\rangle}$, which has sample variance $\hat{\sigma}^2_{\langle q,u\rangle} = w^2_{\langle q,u\rangle} \cdot \hat{\sigma}^2_{O,\langle q,u\rangle} + (1-w_{\langle q,u\rangle})^2 \cdot \hat{\sigma}^2_{C,\langle q,u\rangle}$. Minimizing $\hat{\sigma}^2_{\langle q,u\rangle}$ with respect to $w_{\langle q,u\rangle}$ yields the desired. □

Computer Security, Privacy, and DNA Sequencing: Compromising Computers with Synthesized DNA, Privacy Leaks, and More

Peter Ney, Karl Koscher, Lee Organick, Luis Ceze, Tadayoshi Kohno
University of Washington
{neyp,supersat,leeorg,luisceze,yoshi}@cs.washington.edu

Abstract

The rapid improvement in DNA sequencing has sparked a big data revolution in genomic sciences, which has in turn led to a proliferation of bioinformatics tools. To date, these tools have encountered little adversarial pressure. This paper evaluates the robustness of such tools *if* (or *when*) adversarial attacks manifest. We demonstrate, for the first time, the synthesis of DNA which — when sequenced and processed — gives an attacker arbitrary remote code execution. To study the feasibility of creating and synthesizing a DNA-based exploit, we performed our attack on a modified downstream sequencing utility with a deliberately introduced vulnerability. After sequencing, we observed information leakage in our data due to sample bleeding. While this phenomena is known to the sequencing community, we provide the first discussion of how this leakage channel could be used adversarially to inject data or reveal sensitive information. We then evaluate the general security hygiene of common DNA processing programs, and unfortunately, find concrete evidence of poor security practices used throughout the field. Informed by our experiments and results, we develop a broad framework and guidelines to safeguard security and privacy in DNA synthesis, sequencing, and processing.

1 Introduction

DNA sequencing costs have dropped exponentially, outstripping Moore's Law since 2008, primarily driven by advances in next-generation sequencing (NGS) technologies. For example, Illumina's cost to sequence the human genome dropped from around $100,000 in 2009 to just $1,000 in 2014 [39]. These advances have revolutionized genomic sciences, accelerating the pace of new discoveries in areas such as cancer biology and epidemiology.

Our research suggests that DNA sequencing and analysis have not to date received significant — if any — adversarial pressure. The key question that motivates our research then, is the following: How robust will the DNA sequencing and processing pipeline be *if* or *when* adversarial pressures manifest? This line of inquiry raises related questions, such as: Are DNA-based attacks possible? What potential consequences could occur if an adversary compromises a component of the DNA processing pipeline? How serious might those consequences be? Since DNA sequencing is rapidly progressing into new domains, such as forensics and DNA data storage [2, 9, 10, 15, 17], we believe it is prudent to understand current security challenges in the DNA sequencing pipeline before mass adoption.

The modern DNA sequencing and analysis pipeline is large, complicated, and computationally-intensive. DNA is pre-processed in a wet lab and analyzed with a high-throughput sequencer (itself a computer) that performs image analysis. It is then common to conduct a wide range of computational tasks with the raw output from the sequencer using many software utilities. We seek to assess the overall state of this pipeline in general, and to experimentally explore key aspects that are *not* represented in traditional computing systems: DNA samples.

Exploiting Computer Programs with DNA. The DNA processing pipeline begins with DNA strands in a test tube. Hence, we start our security explorations from this point. Namely, we first experimentally evaluate whether it is possible to compromise a computer program using physical DNA.

Our exploration of this question lead us to synthesize DNA strands that, after sequencing and post-processing, generated a file; when used as input into a vulnerable program, this file yielded an open socket for remote control. We elaborate on specifics in Section 3.

To the best of our knowledge, ours is the first example of compromising a computer system using biological or synthetic DNA samples. Our exploit did not target a program used by biologists in the field; rather it targeted one that we modified to contain a known vulnerability.

Our use of such a trojaned program was consistent with the primary focus of the first research phase to understand — and overcome — challenges posed by creating an exploit at a physical level. For example, our initial exploit contained too few C and G nucleotides (we review DNA background in Section 2) to synthesize the DNA strand; therefore, we modified our exploit to overcome this challenge. Our key finding is that it *is* possible to encode a computer exploit into synthesized DNA strands.

Side-Effect — Information Leakage. Although not a goal, our efforts to experimentally evaluate the ability to synthesize adversarial DNA resulted in our observing an information leakage channel. Standard practice multiplexes different samples on the same sequencing machine. The methods to multiplex (and later demultiplex) DNA samples can leak information between samples during sequencing. Our exploit sample was sequenced and multiplexed in this manner alongside samples from another research team. We noticed that our sequencing results contained DNA sequences derived from their samples.

Other biologists have observed these effects [16, 19, 25, 27, 33], but their concerns focused on experimental accuracy, not on security or information leakage. From our perspective we use these unanticipated results to guide a security discussion of information leakage inherent in the DNA sequencing pipeline.

Software Security Awareness Throughout the Pipeline. Having demonstrated the ability to exploit a computer program with synthesized DNA, we next evaluated the computer security properties of downstream DNA analysis tools. We analyzed the security of 13 commonly used, open source programs. We selected these programs methodically, choosing ones written in C/C++. We then evaluated the programs' software security practices and compared them to a baseline of programs known to receive adversarial pressure (e.g., web servers and remote shells).

We found that existing biological analysis programs have a much higher frequency of insecure C runtime library function calls (e.g., `strcpy`). This suggests that DNA processing software has not incorporated modern software security best practices. However, rather than rely solely on heuristics, we took the next step and determined whether we could target static buffers to cause program crashes. We readily found three buffer overflow vulnerabilities. Given the prevalence of poor software security practices and the well-known fact that program crashes can often be converted to exploits, we chose not to convert each program crash into a working exploit.

Threat Model and Guidelines. When exploring a technology domain new to computer security, any individual study lacks the breadth to address the entire domain. For example, early work on the attack surface of modern automobiles considered only one vehicle and a few example attacks [7, 20]. However, as the first work to explore a domain, an important contribution can involve drawing inferences from concrete results and domain knowledge to define broader lessons and extrapolate threat models for the entire domain, as others did for the modern automobile [7]. Leveraging our technical results and multidisciplinary backgrounds (computer security, synthetic biology, and the design and use of the DNA processing pipeline), we drew inferences to present a threat model and recommendations for the DNA sequencing and processing pipeline and the associated community.

Summary. To our knowledge, our research is the first to consider computer security implications of the modern DNA sequencing pipeline. Our four key contributions include:

- We demonstrate, for the first time, the ability to compromise a computer program with sequenced DNA. In so doing, we encountered challenges when synthesizing DNA strands containing exploits and developed methods to overcome those challenges.
- We observe a side channel resulting from fundamental properties of DNA sequencing technologies, and we pioneer the exploration of how one might exploit this side channel for adversarial purposes.
- We evaluate the software security in a wide set of DNA processing programs and find that they do not adhere to modern security best practices (e.g., they frequently use insecure function calls and contain buffer overflow vulnerabilities).
- We derive a threat model for the DNA sequencing pipeline and present recommendations to offset potential attacks.

2 Biology and DNA Sequencing: Background

Our work strives to apply computer security principles and perspectives to a new field: genomic sciences, and specifically, DNA synthesis, sequencing, and analysis. To do so, we offer a basic review of the biological, chemical, and computational processes in this field.

2.1 DNA

Deoxyribonucleic acid (DNA) is the carrier of genetic information for all known living organisms. It is composed of an alternating sugar-phosphate backbone to which a sequence of four possible *nucleotides* (also called *bases*) are linearly attached. These nucleotides — adenine, thymine, cytosine, and guanine — are commonly abbreviated as A, T, C, and G, respectively. Each nucleotide bonds with its complement — A with T, and C

with G. *Sequencing* is the process of reconstructing the original order of nucleotides in a DNA sample.

While DNA can form many structures, the most common is double-stranded DNA (dsDNA), where two strands with complementary base sequences bond to form the well-known double helix structure. DNA's sugar-phosphate backbone causes its strand ends to be asymmetric: The phosphate end, called the $5'$ end, and the sugar end, called the $3'$ end. By convention, nucleotide sequences are read from the $5'$ to the $3'$ end.

Many traditional lab protocols require DNA strands to be replicated (also called *amplification*). Amplification uses a technique called *polymerase chain reaction*, or PCR. dsDNA is first *melted* at high temperatures to separate its two strands. The temperature is then lowered, and *primers* (synthesized strands typically 20 nucleotides long) anneal (reattach) to the complimentary ends of the DNA strands. At slightly higher temperatures, DNA polymerase (an enzyme that synthesizes DNA), attaches to these end regions where the primer has annealed and produces a complimentary copy of the original strand. This process is repeated as needed to exponentially amplify DNA.

2.2 Next-Generation DNA Sequencing

Next-generation sequencing (NGS) systems differ from prior sequencing methods in that they read relatively short sequences, called *reads*, but in a massively parallel fashion. Longer DNA strands are sequenced by randomly cleaving DNA into shorter sequences, reading these sequences in parallel, and reconstructing the original, longer sequence. Several different types of NGS systems do this work; among the most popular are the various Illumina sequencers, which are based on a technique known as *sequencing by synthesis*.

Before sequencing a typical genomic DNA sample with an Illumina sequencer, the DNA sample must be manually processed in the lab. It is cleaved into short sequences of a few hundred bases and amplified using PCR. Special DNA *adapter* sequences are then attached to both ends of the amplified DNA. This double-stranded DNA sample is separated into single-stranded DNA and applied to a glass flow cell. The adapter sequences attached to the sample fragments bind to complementary fragments on the flow cell surface. The bound sequences locally replicate to produce clusters of identical DNA, called *clonal clusters*.

The DNA in each clonal cluster is sequenced in rounds (called *cycles*) by appending a complementary fluorescently labeled nucleotide to the single-stranded DNA in each clonal cluster. Each time a new fluorescent base is added to the strand, it emits a particular color specific to each base (e.g., A, C, G, and T). The cluster sequence is obtained by imaging the flow cell in each cycle and noting the fluorescent color each cluster emits. The number of cycles determines the length of resulting reads (often between 150-300 bases). These identified bases added in each cycle, called *base calls*, are written out to per-cycle base call files. A separate utility then takes these files and converts the reads into a standard text-based format called FASTQ.

FASTQ files are the de facto standard for exchanging next-generation sequencing results. Their structure is simple: each read has an ASCII header identifying the read source, followed by a line with the sequence written as an ASCII A, C, G, or T. Reads additionally contain a separator line, followed by a line with ASCII characters encoding the quality or confidence of each base call.

2.3 Downstream Processing

The raw FASTQ files that come directly from the sequencer are rarely useful by themselves, and extensive downstream processing and analysis is usually performed after sequencing. This processing is typically done in phases by dedicated programs; the output from a program in one stage is sent to a program in a later processing stage. This section describes some commonly used downstream processing steps, which we explore for security vulnerabilities in Section 6.

Before analyzing the sequence reads, an initial preprocessing phase occurs where by the reads (stored in a FASTQ files) are cleaned up to remove undesired ones. The last base calls in a read often have lower quality scores, so it is common to truncate the reads to a fixed length when the score drops below a defined threshold. DNA sequences from unintended sources — like the adapters used to bind sample DNA to the flow cell or control sequences used to verify sequencing accuracy — need to be removed from the sequence file. Other preprocessing steps merge paired-end reads if there is overlap, convert different quality score file formats, or compress FASTQ files for archival purposes.

Direct output from a sequencer contains only short chunks of reads derived from the full sequence, and in no particular order. These unordered reads can be merged by aligning them to a reference sequence (e.g., the human genome) if one exists, or they can be merged from scratch, using overlaps in the reads to stitch them together in a method called *de novo* assembly. When using a reference sequence, the alignment of each read in relation to the reference is stored in a text based format (SAM) or a compressed representation (BAM). Both methods, especially *de novo* assembly, are computationally and memory intensive and may be run on computer clusters if the size of the sample to reconstruct is sufficiently large (e.g., a mammalian genome).

After the sequence has been aligned or assembled more work may remain, and the following are but a

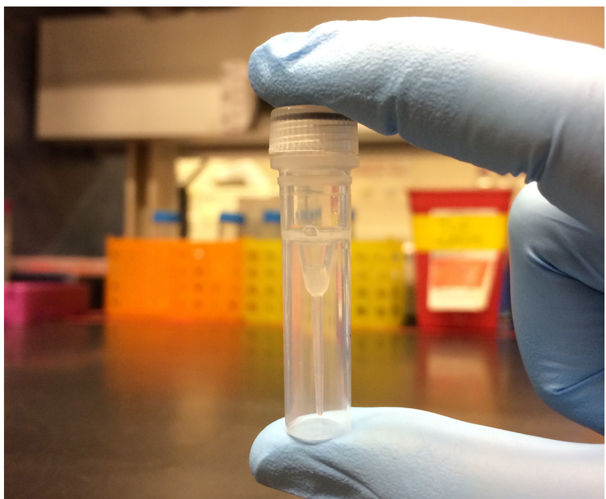

Figure 1: Our synthesized DNA exploit

few examples of the widely varied analysis methods commonly used. It is customary to look for variations between the sample and some reference for biologically meaningful differences (e.g., genetic variations that cause disease). Specific variations in the sequenced sample are usually stored in a plain text file (VCF) so redundant sequencing information can be discarded. NGS techniques are also used in more complicated biological assays to analyze RNA (RNA-seq) or protein-DNA interactions (ChIP-seq). In these cases, the samples' sequence are not only valuable, but the number and precise location of its reads in relation to a reference sequence are also meaningful.

2.4 DNA Synthesis

Synthetic DNA, commercially produced via phosphoramidite chemistry, is characterized by nucleotides attached to one another with specific reagents to form specified sequences. The resulting length, quality, and cost varies greatly depending on the method of reagent delivery, the substrate on which DNA is synthesized, and consumer specifications. For example, Integrated DNA Technologies (IDT) synthesis of a custom gene utilizes their "gBlock" service, which differs in capabilities and constraints from their "custom oligo" service designed for shorter strands (oligos or oligonucleotides are short DNA sequences commonly used in genetics). The cost for these two services varies significantly depending on the length of the strand ordered, the degree to which DNA must be washed, or whether there are DNA modifications (e.g., fluorescent tags).

3 Compromising a Computer with DNA

DNA, in its most basic form, stores data. Conceptually, if DNA were used as input to a computer system, an open issue is the possibility that it could be used to compromise that system. As one might predict, significant unknowns exist. Can DNA itself compromise a computer system, or does something in the DNA sequencing pipeline make such attacks impossible? Prior to our work, to the best of our knowledge, there has never been a demonstrated DNA-based exploit of a computer system. Indeed, without concrete, experimental evidence, it is impossible to know whether DNA-based computer compromises are purely hypothetical or a real possibility. We therefore seek to experimentally answer the previously unexplored question:

> **Can DNA be used to compromise a computer?**

To answer this question, we seek an end-to-end experimental evaluation of an exploit. Namely, we seek to mimic an adversary and (1) synthesize a real, biological DNA sequence with a malicious, embedded exploit. We then seek to experimentally evaluate the impact of that exploit DNA on a victim by having the victim (2) sequence that DNA using standard sequencing methods and (3) post-process the DNA sequence with a realistic program — a program that a scientist might use to analyze the resulting DNA sequence. If the exploit is successful, step (3) should result in arbitrary code execution on the victim computer.

This section explores the biological nature of this attack pipeline — how to encode an exploit into DNA such that, when sequenced, will hijack execution when processed by the victim program. We therefore intentionally chose to create our own vulnerable program for step (3), i.e., a program inspired by actual bioinformatics tools but with an obvious vulnerability. In Section 6, we consider the security of the sequencing pipeline in general. Our results suggest that while our exploited program in this section is vulnerable to a basic buffer overflow exploit, the security hygiene of the overall DNA sequencing pipeline is not much better.

Despite challenges, this section demonstrates that it *is* possible to create DNA that, when sequenced and processed, compromises a victim system. See Figure 1 for a photo of our DNA exploit. In conducting this work, we identified and overcame multiple challenges, which we describe — along with methods for overcoming them and the resulting lessons — below.

3.1 Target Program

The FASTQ compression utility, `fqzcomp`, is designed to compress DNA sequences. For experimental purposes, we inserted a vulnerability into this utility. To do so, we first copied `fqzcomp` from `https://sourceforge.net/projects/fqzcomp/` and inserted a vulnerability into version 4.6 of its source code; a function that processes and compresses DNA reads individually, using a fixed-size buffer to store the compressed data. This

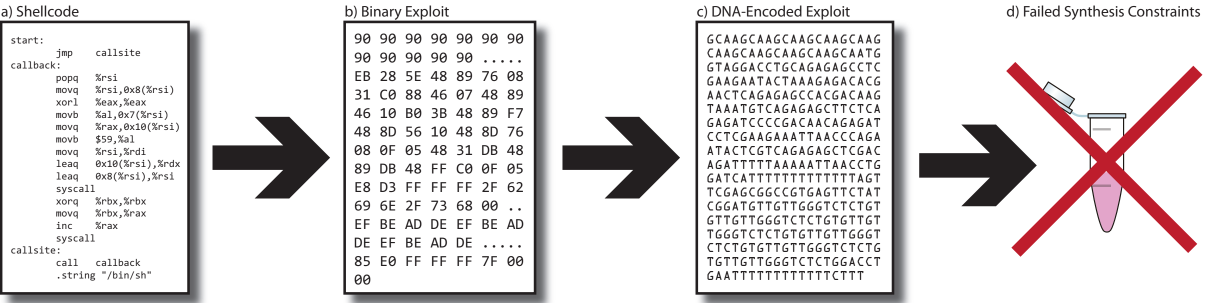

Figure 2: Our initial, unsuccessful exploit attempt

modification lets us perform a buffer overflow with a longer than expected DNA read in order to hijack control flow. While the use of such a fixed-size buffer is an obvious vulnerability, we note that `fqzcomp` already contains over two dozen static buffers. Our modifications added 54 lines of C++ code and deleted 127 lines from `fqzcomp`.

Our modified `fqzcomp` version used a simple 2-bit DNA encoding scheme. The four nucleotides were encoded as two bits — A as 00, C as 01, G as 10, and T as 11 — packing bits into bytes starting with the most significant bits.

We ran the target program in a simplified computing environment and disabled common security features. Specifically, we disabled stack canaries and ASLR, and we marked the stack as executable.

We stress that our target modified program has a known, and in some sense trivial, vulnerability. We also stress that its environment is in many ways the "best possible" environment for an adversary. For experimental purposes, however, we believe that these conditions are acceptable for the following reasons. First, our primary goal is to understand the issues unique to DNA-encoded exploits. Second, as we relate in Section 6, we find that the general security hygiene of bioinformatics programs is very low, with prevalent usage of fixed-size buffers, `strcpy`, and so on. Finally, we note that genome sequencing processes are rapidly improving: since early NGS machines read sequences on the order of 50-100 bases, a fixed-size buffer in that range may have been acceptable years ago. Today, any fixed-size buffer would likely be vulnerable, as new longer read sequencing technologies can produce reads that are upwards of 60,000 bases [30]. These newer sequencers lack the throughput of short-read counterparts and are not at present commonly used; Illumina short-read sequencers now have over 90% market share [18]. Future technological improvements will likely make long-read sequencers more viable in the future.

3.2 Creating and Synthesizing an Exploit

We now turn to our design of a DNA strand that, when sequenced, exploits the vulnerable target program. Our key goal was to identify potential challenges. Our efforts here were successful in two regards. First, we identified several challenges, including limitations on the exploit's size and type and problems inherent in the DNA synthesis process that constrained the sequences we could generate. Second, by overcoming these challenges, we found that it *was* possible to create a DNA sequence that could in fact compromise a program.

Our process was iterative. We created exploits that we thought would work, surfaced challenges, and then iterated on improved exploits.

We initially encoded one of the most straight-forward exploits, i.e., overwriting the return instruction pointer on the stack to point back into shellcode from Aleph One's "Smashing the Stack for Fun and Profit" [26]. We made minor modifications to port the shellcode to the 64-bit Linux syscall interface. To simplify exploit testing, we used a stripped-down version of the vulnerable program that simply compressed a single DNA read into a fixed-size buffer. Our shellcode was 55 bytes long, with another 39 bytes of padding needed for cache line alignment and saved registers. We filled this space with NOPs and bogus saved register values (`0xdeadbeef`). The resulting exploit, 94 bytes long, was encoded as 376 nucleotides. Figure 2 shows this process.

We submitted this sequence to the IDT gBlocks synthesis service, which creates synthetic gene fragments up to 3,000 bases long. Unfortunately, at this step we faced our first challenges. Our sequence contained many issues that prevented IDT from being able to synthesize our order:

- The NOP sled produced a repetitive sequence (`GCAA`) near the start of our sequence, which contributed to more than 69% of the sequence. Repetitive sequences can cause difficulties in sequencing and may cause the physical strand to fold in on itself or form other secondary structures because of DNA's complementary nature.

Figure 3: Our working exploit pipeline

- The negative offset JMP created a run of 13 consecutive Ts. Long runs of the same base, called *homopolymers*, can be difficult to accurately synthesize. The gBlocks service limits homopolymers to no more than nine As or Ts and five Gs or Cs.
- The repeated `0xdeadbeef` bytes produced a long (40+ base pair) repetitive sequence.
- The NOP sled resulted in low GC-content near the beginning of the sequence. Cs and Gs physically bind together more tightly than As and Ts and thus add stability to the DNA strand. Typically, each 20-base window must have 25 to 75 percent GC-content. The first and last 20 bases of a sequence are even more constrained since they must have 40 to 60 percent GC-content to be synthesized.
- A 20 base pair window containing the 13 base pair homopolymer did not meet the minimum GC-content threshold.

Another challenge we faced was the length of our exploit. Our Illumina NextSeq sequencer is rated for a maximum of 300 base pair reads, while the Illumina MiSeq is rated for a maximum of 600 base pair reads.

We addressed these challenges by making our target program and exploit designs more sophisticated. To minimize the number of homopolymers introduced by large pointers and offsets, we switched to targeting the 32-bit x86 instruction set architecture (ISA). We also reduced the buffer size in our target program to minimize the required size of our sequence. Since our ultimate goal was arbitrary remote code execution, we investigated swapping out Aleph One's simple shellcode, which simply spawns a local shell, with one that provided a reverse shell over TCP. We explored the `shell-storm.org` archive for a suitable example; however, even the most compact shellcode was too long to fit inside a sequence that could be reasonably sequenced by the NextSeq sequencer.

Our second exploit attempt uses an obscure feature of `bash`, which exposes virtual `/dev/tcp` devices that create TCP/IP connections. We use this feature to redirect `stdin` and `stdout` of `/bin/sh` to a TCP/IP socket, which connects back to our server. We combined this tactic with a return-to-libc attack that calls `system()`, resulting in a 43-byte exploit, shown in Figure 3. We used a short, fully qualified domain name we controlled as well as a single digit port number to keep exploit length as short as possible. While we considered obtaining a smaller FQDN (e.g., `r.sh`) to keep our exploit size as small as possible, we hypothesized that we could successfully sequence our 176-base[1] DNA strand with our Illumina NextSeq despite exceeding its recommended single-ended read size.

Since the bulk of this exploit consists of lowercase letters, whose two most significant bits were 01 in ASCII — or encoded as a nucleotide, C — we got an acceptable level of GC-content throughout the exploit. The one exception was near the original port number — 3 (encoded as `ATAT`) — which we changed to 9 (encoded as `ATGC`) to maintain a minimum level of GC-content. This sequence was accepted by the IDT gBlocks service with no errors or warnings. IDT's retail cost to synthesize of up to 500 base pairs was $89 USD.

As is standard for NGS runs, our sample was tagged and extended with a unique index (GCCAAT, in our case) and co-sequenced with other experiments. The sequencer was configured to perform 177 non-index read cycles; this is the typical configuration used by another research group that manages the sequencing machine and was sufficiently long to contain the 176 base pair exploit sequence within a single read.

The sample was sequenced on all four lanes (physically separate portions) of the flow cell. After demultiplexing by indices, there were four separate FASTQ files (one for each lane) together containing 811,118 reads.

We processed the four FASTQ files separately, which is done to account for lane-specific errors. We filtered out low-quality reads that did not identify one or more bases; these bases appear as Ns (representing an unknown base) in the FASTQ file. We provided the filtered FASTQ file from the first lane to our modified `fqzcomp` program, which immediately called back to our server, giving us

[1] A bug in our DNA encoding program repeated the final byte, which unnecessarily extended our exploit by four bases, but otherwise did not affect our results.

arbitrary remote code execution via a bash shell.

3.3 Exploit Reliability

The exploit was not robust to errors in sequencing; a single miscalled base would break the exploit. In this experiment, 76.2% of the reads were sequenced with no error. Another issue arose because DNA strands are randomly sequenced in the forward or reverse direction. Reverse sequenced reads will have the reverse complement sequence of the exploit, which is not functional code (see Section 4.2 for a possible solution to this problem). Of the remaining, error free reads, 49.1% were sequenced in the forward direction. Therefore, 37.4% of all reads contained working exploit code (i.e., in the forward direction with no sequencing errors).

The modified `fqzcomp` program contained a buffer too small for the 177 base pair read length, so it would overflow after processing the first read. Therefore, the first read in the file must be the exploit sequence for the exploit to work. With reads randomly appearing in a FASTQ file, we would expect the modified program to be exploited 37.4% of the time. Assuming all four lane files were processed, an attacker would be successful at least once 84.5% of the time. In our case, only the file from the first lane was a successful exploit.

4 Challenges in Encoding Malicious DNA

Informed by our evaluation of the feasibility of manufacturing synthetic DNA capable of exploiting computer systems, we next consider some challenges in crafting arbitrary exploits against other programs and identify directions for future research. In particular, while it is convenient to think of DNA as a simple storage mechanism, our results in Section 3 show that in practice there are several physical and computational constraints that limit the design space of DNA-based exploits.

4.1 Physical Constraints

Any DNA-based exploit must be physically instantiable in DNA. Therefore, any difficulties in the synthesis or amplification of DNA will constrain the sequences attacker can easily synthesize.

Primers. As previously mentioned, it is necessary to amplify the exploit sequence to increase its yield before sequencing. A simple way to do so is to use PCR, which requires a pair of primers to initiate replication. These primers, single stranded DNA sequences usually 18-22 bases long, are complementary to the ends of the target sequence being amplified. PCR primers used together must have similar melting point temperatures to maintain high amplification efficiency. They must also have a high enough annealing temperature to bind only to their complementary locations without mis-pairing to similar sequences. Other parameters also influence primer design such as the amplification region specificity desired, and the GC-content of the primer regions to be amplified.

Primer designing utilities, like Primer3, take these parameters into account to design optimal primer sequences [37]. Since the primers must be complementary to the ends of the exploit sequence, any restrictions in their design will necessarily constrain the ends of the exploit sequence.

Synthesis. DNA synthesis has its own physical constraints that vary across synthesis companies. In Section 3.2 we described constraints imposed by IDT's gBlock gene fragment service, a relatively low cost synthesis method. They required 25 to 75 percent GC-content per 20 base window, A/T and G/C runs no greater than 9 and 6 base pairs, respectively, and sequences that avoided secondary structures (created when different portions of the same strand are complementary to one another).

These synthesis constraints are common but not universal. Different synthesis methods and services can vary in their precise requirements — for example, IDT's custom gene service can tolerate longer homopolymers than gBlock, which may make it easier to synthesize 64-bit addresses. In cases where the exploit cannot be synthesized by any *de novo* synthesis service, it may be possible to synthesize sub-sequences and recombine them manually in a wet lab.

DNA synthesis services also follow strict guidelines to ensure that biologically malicious sequences are not synthesized and spliced into organisms that potentially create pathogens, toxins, or various other harmful products. The shipping, receiving, or purchase of all synthesized sequences must follow guidelines including, but not limited to, those described in the current U.S. Department of Health and Human Services (HHS) and U.S. Department of Agriculture (USDA) Select Agents and Toxins regulations [4–6].

4.2 Sequencing Randomness

Being a biochemical process, DNA sequencing is inherently noisy and random; long DNA strands are randomly cleaved into smaller ones and strands are sequenced in no particular order. This randomness makes DNA-based exploits probabilistic in nature, as discussed in Section 4.2. Robustness against random variations depends on factors like the vulnerability type and what stage in the pipeline is attacked. In general, analysis further along the sequencing pipeline works with more structured data, which will reduce the initial randomness from the sequencer. For example, variant calling programs return processed data in the same order as the reference sequence regardless of the initial read order.

Another source of randomness is that reads will be sequenced in both the forward and reverse direction, which

causes problems because most exploit sequences will be functional only if read in one direction. One solution is to synthesize strands that generate the same reads when sequenced from either end. These can be created by concatenating the forward exploit sequence to its reverse complement (e.g., ACCTG becomes ACCTGCAGGT). Since DNA is always read from 5′ to 3′, the same read will appear, regardless of whether the DNA was sequenced in the forward or reverse direction.

These palindrome like sequences are difficult to synthesize directly because the two halves will bind to each other and create secondary structures. Instead, the two halves could be synthesized separately and conjoined manually in a wet lab.

4.3 Encoding Exploits

Exploits typically contain up to three components: pointers, either to functions or data, instructions in the target instruction set architecture (ISA), and an encoded and/or obfuscated payload. DNA-based exploits introduce unique constraints on each of these components.

Pointers. Bioinformatics programs vary in how they encode DNA data. Some perform a straightforward mapping, encoding each base as two bits and packing these bits together, like our target program in Section 3. However, sequences often have non-standard bases, such as Ns to encode unknown nucelotides or Rs to indicate either an A or G. To support these non-standard bases, some tools use four-bit encodings, or even 8-bit ASCII. Since we can synthesize only standard bases, these alternative encodings will constrain the pointers that we can encode.

Another issue concerns sequencing accuracy and how that will affect the resulting sequence of pointers. Some pointers, such as those to libc or ROP gadgets, are intolerant of any errors. Others, such as pointers to attacker-controlled buffers, can be made somewhat tolerant to errors in the least-significant bits — for example, it could point to a large NOP sled.

Pointers often contain long runs of identical bits and therefore generate homopolymers. For example, without ASLR enabled, 64-bit Linux places user stacks at `0x00007fffffffffff`, which contains a run of 47 consecutive 1s. Using two-bit encoding, this results in a homopolymer of 23 bases. As previously described, a solution is to use a synthesis service more tolerant to homopolymers.

Code. Executable sequences of target ISA instructions can encode malicious operations more compactly than equivalent ROP chains and are easier to develop, which makes them desirable to attackers. However, encoding ISA instructions in DNA presents a number of challenges.

As with pointers, the target program's DNA encoding may restrict the bytes that can be represented. Depending on the encoding and ISA, this could also limit the set of instructions that are available.

The regular structure of most ISAs produces repeated base sequences when encoded into DNA, which again, are difficult to synthesize. Semantically-equivalent instructions and semantic NOPs can be used to break up repetitive sequences to make exploits easier to synthesize.

Another issue to consider is read length. All but the most trivial exploits exceed the read length of most high-throughput sequencers, and thus, the exploit will be randomly cleaved. Depending on which part of the pipeline is being exploited (i.e., whether the target program processes raw reads or fully aligned sequences), this could decode in the middle of a multi-byte instruction, or even in the middle of a byte. Therefore, for robustness, an exploit should encode instructions that are tolerant to such shifts. Prior work demonstrates techniques to generate these types of resynchronizing instruction sequences [22]. Long read sequencers may mitigate these challenges in the future but are currently less accurate than high-throughput sequencers.

Finally, we must consider the effects of sequencing errors. One way to address these errors is to encode redundant instructions that become semantic NOPs with random bit flips.

Payloads. To make payloads more robust to errors introduced by synthesis and sequencing, one may fortify payloads with error-correcting codes. Compression may be used to offset the increase in payload size and cause the sequence to be more equally distributed across the four nucleotides, avoiding issues of too much or too little GC-content.

5 Side Channel: Sample Bleeding

It is common to multiplex samples in NGS runs on modern Illumina sequencers to make better use of sequencing resources and increase throughput. This is accomplished by adding a 6-8 nucleotide index to each sample before sequencing, which is later used to demultiplex the samples. However, the demultiplexing process is not perfect. The sequence of each read is derived by sequencing a cluster of DNA on a flow cell. If clusters overlap, are seeded from multiple distinct strands, or if errors exist in sequencing the index, then the sequence of a cluster may be misassigned to an incorrect index [16]. A read assigned incorrectly will be associated with either an unused index and discarded or assigned to the index of a different sample. In the latter case, it is called *sample bleeding* or *index cross-talk*.

Illumina reports that sample bleeding occurs at a rate of 0.1%-0.2% with the type of flow cell used in this

study [24], though this continues to a topic of discussion in the sequencing community. The amount of sample bleeding depends on many factors, like index design, cluster density, sample diversity, and the underlying sequencing technology [25, 27, 33]. This situation is known to create a problem with the detection of rare genetic variants, like genetic markers for cancer [19].

The rise in outsourced sequencing at external facilities, which multiplex samples from different, untrusted sources creates opportunities for side channel attacks that are — to date — previously unconsidered by the genomic sciences. Since sample bleeding is bidirectional, an attacker could gather reads from other indices to reveal sensitive information or send data to other indices to corrupt or modify their results.

Evaluation of Data Leakage. We can leverage our sequencing results from Section 3 to better understand the security impact and amount of data leakage caused by sample bleeding. When the exploit was sequenced, it was multiplexed with seven other samples. One of these samples contained 1.5 million unique sequences, each 150 base pairs long; this sample is denoted as the target sample. With permission, we obtained the FASTQ file associated with the target sample's index after the sequences were demultiplexed. Using the two FASTQ files, one from the target sample and the other from the exploit, we sought a rough estimate of side channel effects. We note that all samples were sequenced using 6 nucleotide indices, so the sample bleeding rate may be higher than other configurations, like 8 nucleotide indices.

We assume that only the exploit sequence is attacker controlled and that attackers receive only demultiplexed results from the index of the exploit sample. To analyze their ability to pull information from other indices, we examined misassigned reads associated with the target sample in the exploit FASTQ file. There were 112 reads that aligned to sequences that came from the target sample. Two of them originated from the same sequence, so a total of 111 unique, 150 base pair sequences were leaked into the exploit FASTQ file. The quality of these reads was high; 68 of them were a perfect match (60.7%), and 103 had an edit distance of less than 2 (92.0%). Of the 235 million bases represented in the target sample, 16,521 were recoverable in the exploit FASTQ file — for context, the human genome contains around 3.2 billion bases — and, in total, 0.007% of the data was recoverable from the target sample.

If we now consider the sample bleeding side channel in the reverse direction, an attacker could modify the results that appear in other demultiplexed samples. The exploit sample contains many copies of the same short sequence. Thus, any sample bleeding from the exploit sample into the target sample resembles an attacker trying to inject a single sequence into the target FASTQ file. The exploit sequence was found 37 times in the target FASTQ file (30 times with no errors).

Hypothetical Attacks. Now that we have established sample bleeding as a source of information leakage, we propose attacks that leverage this side channel.

An attacker could use sample bleeding to inject specific DNA sequence reads into concurrently sequenced samples. These reads could contain malicious code or be used to confuse subsequent downstream analysis (e.g., variant calling).

Any reads which bleed from other samples into the attacker's sample could reveal sensitive information, like the identity of those samples. Even low levels of only a few reads could identify the species of a sample, which could be commercially sensitive in domains like drug discovery.

Another risk of multiplexing, similar to sample bleeding, is that an attacker may be able to sabotage an entire sequencing run. Most next-generation sequencers are calibrated to sequence biological DNA; they expect to see close to a 1:1:1:1 ratio of A:C:G:T. If one of the samples has low-diversity (a homogenous DNA sample), the read quality will suffer for all samples, and in extreme cases, the run could fail altogether. This could be induced with a high-concentration of the same sequence. Previous experiments by this group showed that if identical sequences compose more than roughly 25% of the total DNA, run quality deteriorated.

Summary. The read errors we encountered while developing the exploit in Section 3 caused us to reflect upon their origin, meaning, and implications. While the genome sciences community has measured rough estimates of sample bleeding, ours may be the first research to consider bleedover from an adversarial perspective and ask, for example, how *much* information is leaked and whether it is possible to push specific data into another party's sequencing files.

6 Software Security Analysis

Having evaluated the potential security threats for maliciously crafted synthetic DNA in Sections 3-4, as well as information leakage channels in Section 5, we now evaluate the software security practices of the larger bioinformatics pipeline. Specifically, we evaluate the security practices of common NGS programs to better understand the risks of DNA-based or other exploits in the real analysis pipeline. Although used broadly by biology researchers, many of these programs are written by small research groups and thus have likely not been subjected to serious adversarial pressure. We therefore hypothesize that the rate of serious vulnerabilities will be higher here than in more mature software (e.g., Internet services).

Category	Program	Version	Lines of Code	Normalized Count (Total Count)					
				strcat	strcpy	sprintf	vsprintf	gets	static buffers
NGS Analysis

Table 1: Insecure buffer overflow signatures for NGS analysis (top half) and control programs (bottom half). The counts reported are the number of lines containing the corresponding insecure function call or static buffer declaration. Each count is normalized by the number of appearances per 1000 lines of code. `scanf` is not included because it was not present in any program.

Program Selection. Many commonly used, open source analysis programs are written in unsafe languages, like C and C++, known to be vulnerable to buffer overflow attacks. To quantify the risk of buffer overflows in NGS analysis programs, we evaluated 13 programs that operate at different stages of the analysis pipeline (see Table 1). To generate the list of programs in a systematic manner, we choose 6 analysis categories: (1) preprocessing, (2) alignment, (3) *de novo* assembly, (4) alignment processing, (5) RNA-seq, and (6) ChiP-seq. We required at least one program from each category. We searched for programs that were open source and written in either C or C++. To ensure that all of these programs were actively used by biologists, we required that they be available as packages in the Galaxy bioinformatics workflow system (a popular web-based analysis platform) or be part of a major effort, like the ENCODE project or the assembly of the great panda genome [14, 21, 36]. Many of them, including `bwa`, `bowtie2`, and `samtools`, come installed on current Illumina sequencers. The one exception was the `fqzcomp` program, which we included because we used it earlier in Section 3. We shared our findings about these programs with their maintainers in the hope of raising their security mindfulness. Our discussions with them confirmed that many had not considered the security of their software.

Analysis Approach. We evaluated the risk of buffer overflow attacks in these programs by using the recommendations of the OWSAP buffer overflow review guide [29]. It suggests removing insecure C library function calls and checking static buffers and print format strings. To quantify this, we counted the number of lines containing commonly misused, insecure function calls (`strcat`, `strcpy`, `sprintf`, `vsprintf`, `gets`, and `scanf`) and static buffer declarations. We derived these counts using the clang-query tool, which searches the abstract syntax tree generated by the clang C and C++ compiler. We analyzed only those files compiled using the default build. Function calls and buffer declarations in headers were also counted if they were included in code files, but they were ignored if they were in standard library headers (like the C standard lib or Boost library). For comparison, we also computed these same metrics for 10 control programs. For these, we chose programs that were Internet connected and likely to have already received adversarial pressure. Again, we included programs from 7 different categories and only considered open source programs written in C or C++.

Analysis Results. The most common insecure functions in both the NGS and control programs were `strcat`, `strcpy`, and `sprintf`. The others were used infrequently, and `scanf` was not present in any program. The `gets` function appeared once in two NGS programs;

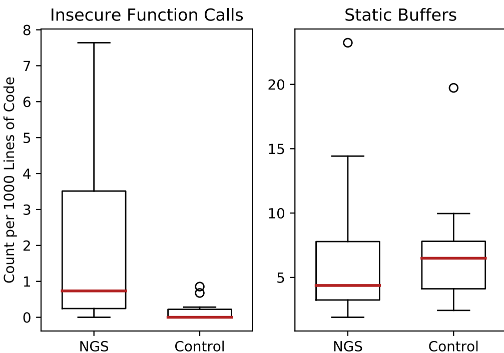

Figure 4: A box plot with the average number of insecure function calls (left) and number of static buffer declarations (right) in each program. Programs are separated into their corresponding type (NGS or control) and all counts are normalized (count / 1000 lines of code).

this is notable because `gets` is an especially insecure function that cannot do bounds checking, which is why it was removed from the 2011 C standard [1]. Overall, there was more insecure function usage in the NGS programs (Figure 4), with an average of 2.005 insecure function calls present per 1000 lines of code (sd=2.299) but only 0.185 in the control programs (sd=0.304) — an 11-fold difference. Using a two-tailed t-test, this difference was found to be statistically significant (p=0.027).

We hypothesized that there may be more static buffer declarations in the NGS programs due to poor coding practices, but there did not appear to be a difference. The NGS programs had an average of 6.729 buffer declarations per 1000 lines of code (sd=5.925), and the control programs had a similar average of 7.312 (sd=4.674). This difference was not statistically significant (p=0.809). These results are only heuristics for buggy code, but the high prevalence of insecure function calls in NGS programs provides evidence that the NGS analysis pipeline does not adhere to security best practices.

A Deeper Dive. To delve deeper into the security of the NGS pipeline, we next looked for vulnerabilities in the 13 programs. To identify them, we compiled each NGS program with the HP Fortify static code analyzer, which generates reports that include possible vulnerabilities [11]. We also manually inspected code for the insecure C library calls we noted previously. We quickly identified buffer overflow vulnerabilities in three of the NGS programs (`fastx-toolkit`, `samtools`, and `SOAPdenovo2`) and designed inputs that targeted these vulnerabilities to overflow buffers and crash programs (Figure 5). These vulnerabilities are described below:

- `fastx-toolkit`. This utility generates aggregate statistics on FASTQ files. It places aggregate results in a static array that is 2,000 bases long, and any reads longer than this will overflow the buffer. A check ensures that the read length does not exceed a limit; however, an incorrect limit of 25,000 was used by mistake. Fittingly, a comment next to the overflowable, static buffer says, "that's pretty arbitrary... should be enough for now."
- `samtools`. This program post-processes DNA read alignment files. In code that parses the header string of an alignment file (SAM file), it places the parsed header into the same buffer as the original unparsed header, which normally shrinks the result. However, if the header is malformed, then the parsed header grows larger than the original and will overflow the buffer.
- `SOAPdenovo2`. This large, *de novo* genome assembler parses reads in a FASTQ file and writes them into a static buffer that is 5,000 characters long. Any reads longer than 5,000 bases will overflow the buffer.

Given that the security risks of buffer overflow vulnerabilities are well known, we did not consider it within the scope of this paper to convert any of these vulnerabilities into working exploits. The aim here, to identify these three vulnerabilities and the construction of the crashing inputs, was straightforward. Thus, we suspect that these types of vulnerabilities are common.

These results have implications beyond direct DNA-based exploits, which we return to in Section 7. Foreshadowing that discussion, NGS data is commonly shared in large biological data repositories, making them a possible vector for spreading malicious files. There are also publicly available, remote servers, controlled and managed by 3rd parties, where users can upload and process data using these or similar programs.

Ethics and Disclosure. Numerous software developers and users are involved in the bioinformatics pipeline at large. Our findings are not specific to any single entity in this space, but rather apply broadly, across the industry as a whole. We have notified the authors of potential issues to the specific software packages that we analyzed, but we stress that many other software packages likely share similar types of vulnerabilities.

7 Discussion

Our results, and particularly our discovery that bioinformatics software packages do not seem to be written with adversaries in mind, suggest that the bioinformatics pipeline has to date not received significant adversarial pressure. We thus consider it critical — both as a research contribution and as a contribution to the broader community — to reflect upon a threat model for the next-gen sequencing pipeline. A concrete threat model can

```
#define MAX_SEQ_LINE_LENGTH (25000)
...
#define MAX_SEQUENCE_LENGTH (2000) //that's pretty arbitrary... should be enough for now
...
struct cycle_data cycles[MAX_SEQUENCE_LENGTH];
...
while ( fastx_read_next_record(&fastx) ) {
    if (strlen(fastx.nucleotides) >= MAX_SEQ_LINE_LENGTH)
        errx(1, "Internal error: sequence too long (on line %llu). Hard-coded max. length is %d",
            fastx.input_line_number, MAX_SEQ_LINE_LENGTH ) ;
    //for each base in the sequence...
    for (index=0; index<strlen(fastx.nucleotides); index++) {
        ....
        cycles[index].nucleotide[ALL].count += reads_count; // total counts
        cycles[index].nucleotide[nuc_index].count += reads_count ; //per-nucleotide counts
        ....
    }
```

```
// header->text is a string with the entire header
char * newtext = header->text;
...
// This is parsed incorrectly if the header
// included multiple LN:<num> in the same line
sprintf(len_buf, "LN:%d", header->target_len[tid]);
strcat(newtext, len_buf);
```

```
int gLineLen = 5000;
...
int lineLen = gLineLen;
char tmpStr[lineLen];
char * str; // = tempStr
...
memcpy ( str, &buf[p + 1], m - p - 1 );
```

Figure 5: Code fragments with buffer overflow vulnerabilities in three different NGS programs: `fastx-toolkit` (top), `samtools` (bottom left), and `SOAPdenovo2` (bottom right). Text in red highlights buggy code, and text in green denotes comments we included for clarification.

serve as a guideline for the community, encouraging the development of defenses and mitigation strategies as well as the investigation of future exploit vectors. We begin with a discussion on the future technological and market trends relevant for DNA sequencing, followed by a taxonomy of threats and directions for future defenses.

7.1 Future Trends

DNA Sequencing. The decreasing cost, the increasing throughput, and the broader deployments of DNA sequencing capabilities will expand the opportunities and motivations for attackers to target this pipeline, including important domains like forensics, medicine, and agriculture. Fundamental aspects of sequencing technology itself, such as the improving accuracy and ongoing development of long read sequencers, e.g., Oxford Nanopore Technologies [8], will radically change the structure of sequencing data.

DNA Synthesis. Another quickly improving technology is *de novo* DNA synthesis, which continues to get faster and cheaper. With novel uses of synthetically produced DNA, like DNA for data storage [2, 9, 15, 28], these improvements are expected to continue.

Wet Lab as a Service. There is increasing access to wet lab techniques and services by non-experts. New companies exist to provide customers with remote control of a wet lab through a computer (even offering wet lab "APIs") [35]. As these grow more prevalent, they will enable more actors, even those with scant laboratory experience, to attack the DNA sequencing pipeline.

Storage and Analysis. As DNA sequencing gets cheaper, the business focus will likely shift to keeping, analyzing and making use of genomic information in cloud services (e.g., Illumina's BaseSpace, Microsoft Genomics). Tools already exist to help scientists who have little programming or data science experience analyze DNA sequencing data. Notable examples include the Galaxy web analysis platform and the Broad Institute's cloud based variant calling workflow [3, 13].

7.2 Attack Surfaces

This section covers the attack surfaces that are present in the end-to-end DNA sequencing pipeline. Our exploration of this threat model focuses on exploits and is complementary to existing efforts that protect privacy in genetic computations [12, 32, 38].

Physical DNA Exploits. Sections 3-4 discussed how DNA strands themselves could be used as a vector for injecting code and data into the sequencing pipeline. To execute such an attack, an attacker could target any facility that accepts samples for sequencing and processing.

Outsourced sequencing facilities are common because next-gen sequencing machines are expensive and require expertise to operate. Many facilities even provide bioinformatics services, which means that it is not just the sequencing machine but downstream analysis utilities that

could be targeted by a DNA-based attack vector.

Another method of DNA injection is to contaminate a biological tissue sample (e.g., blood, hair, and saliva) with malicious DNA that the attacker knows will be sequenced. For example, they could send a contaminated saliva sample to a personalized genomics testing company, like Sure Genomics [34]. This method creates additional challenges because the malicious DNA sample would have to survive genomic DNA extraction and sample preparation, including DNA purification, quality controls, and library preparation.

DNA data storage services are an indirect means of DNA-based code injection; the attacker would provide digital data to be written that would be encoded and synthesized into DNA and later sequenced when read.

Multiplex Sequencing. To achieve high throughput, sequencers will continue to support high levels of sample multiplexing. However, as discussed in Section 5, sample bleeding gives a side channel to attackers that can be used to influence any concurrently sequenced samples. Therefore, it is important to consider the sources of all DNA samples when sequencing.

Analysis Services. Third party analysis service could be targeted if they process attacker controlled data with vulnerable software. Attackers could upload malicious files directly for processing (e.g., Galaxy) or send malicious data from biological instruments, like a DNA sequencer that is integrated with a cloud service (e.g., Illumina's Basespace Hub). Afterwards, the attacker would direct the analysis service to process the malicious files using a vulnerable workflow.

Shared Databases. Biological data generally, and NGS results specifically, are commonly shared and analyzed by different research teams. To facilitate this sharing, public repositories of NGS data are available for download. The NIH, the European Bioinformatics Institute, and the DNA Database of Japan maintain a large combined repository, called the Sequence Read Archive (SRA), which contains nearly 10 quadrillion bases of DNA [31]. Anyone who creates an account can submit sequencing files, which makes this an easy attack vector.

Direct sharing of biological data, including DNA sequences, could also occur directly between collaborators, e.g., via email. An adversary could also explore direct sharing as a potential attack vector.

7.3 Defenses

In this section we categorize possible defenses to help mitigate the attacks described above.

Follow Best Practices for Secure Software. Our analysis suggests that the bioinformatics software community has not received significant adversarial pressure. Hence, its software is in general not hardened against attack. Our first recommendation is therefore to encourage the widespread adoption of standard software security best practices like input sanitization, the use of memory safe languages or bounds checking at buffers, and regular security audits.

Patching is challenging because the analysis software is quite decentralized (packages are often located in individually managed repositories) and not regularly updated. One solution is to use a centralized repository to manage updates and deliver patches, similar to the APT package manager. Packages could also be signed to ensure their authenticity. In the case of file sharing, the sequencing files themselves could be signed by verified research groups before uploading them to centralized databases.

Secure Samples. In some domains, like forensics, attackers could be highly motivated to disrupt sequencing or cause mis-identification. In these cases, the biological sample should be tightly monitored from collection through sequencing. However, physical control of individual samples may not be sufficient to stop contamination because of sample bleeding, which we discuss below.

Minimize Sample Bleeding. Sample bleeding may make concurrently sequencing samples from untrusted sources risky. A simple solution is to enforce, by policy, that the sources of all samples are verified before they are sequenced together or else they are sequenced separately. A better solution is to reduce or detect sample bleeding with technical means.

The overall rate of bleeding can be reduced by preparing samples with two multiplex indices instead of one [19, 24] and by modifying the default cluster identification algorithm [25]. Another approach is to detect misassigned reads by cross-aligning samples against one another, and any found could be removed by the sequencer before returning the demultiplexed files. We encourage future research to minimize this side channel.

Detect Shellcode before Synthesis. Regulations already exist to prevent the synthesis of a known, dangerous DNA sequence. For example, DNA synthesizers are required to verify that it is not synthesizing biological viruses, like chicken pox [4–6]. While this approach works well when detecting known dangerous sequences, it could prove difficult to detect arbitrary DNA shellcode because general shellcode detection has proved difficult in other domains. For example, shellcode can be converted into syntactically correct English [23]. However, we still encourage researchers to find creative strategies that detect executable code in DNA.

8 Conclusions

Significant advances in DNA synthesis, DNA sequencing, and genomic sciences derive from tools and techniques not previously scrutinized for security robustness. We conducted a broad security analysis of the DNA processing pipeline, including a study of the feasibility of synthesizing DNA capable of compromising a computer program (Sections 3-4), a study of information leakage and information injection side-channels during the sequencing process (Section 5), and a study of the general software security practices in DNA processing software (Section 6). To our knowledge, ours is the first effort to broadly consider this pipeline, and the first to demonstrate a DNA-based exploit. Informed by our results, we presented lessons for this field, which has yet to receive adversarial pressure. We strongly encourage additional research before such adversarial pressure manifests.

Acknowledgements

This research was supported in part by the University of Washington Tech Policy Lab, the Short-Dooley Professorship, and the Torode Family Professorship. We thank Sandy Kaplan, R.B. Kohno, Paul Ney, Jay Shendure, Anna Kornfeld Simpson, Lok Yan, and the members of the Molecular Information Systems Lab and the Security and Privacy Research Lab for helpful discussions and comments on earlier drafts of this paper.

Abstract

Modern mobile bootloaders play an important role in both the function and the security of the device. They help ensure the Chain of Trust (CoT), where each stage of the boot process verifies the integrity and origin of the following stage before executing it. This process, in theory, should be immune even to attackers gaining full control over the operating system, and should prevent persistent compromise of a device's CoT. However, not only do these bootloaders necessarily need to take untrusted input from an attacker in control of the OS in the process of performing their function, but also many of their verification steps can be disabled ("unlocked") to allow for development and user customization. Applying traditional analyses on bootloaders is problematic, as hardware dependencies hinder dynamic analysis, and the size, complexity, and opacity of the code involved preclude the usage of many previous techniques.

In this paper, we explore vulnerabilities in both the design and implementation of mobile bootloaders. We examine bootloaders from four popular manufacturers, and discuss the standards and design principles that they strive to achieve. We then propose BOOTSTOMP, a multi-tag taint analysis resulting from a novel combination of static analyses and dynamic symbolic execution, designed to locate problematic areas where input from an attacker in control of the OS can compromise the bootloader's execution, or its security features. Using our tool, we find *six* previously-unknown vulnerabilities (of which five have been confirmed by the respective vendors), as well as rediscover one that had been previously-reported. Some of these vulnerabilities would allow an attacker to execute arbitrary code as part of the bootloader (thus compromising the entire chain of trust), or to perform permanent denial-of-service attacks. Our tool also identified two bootloader vulnerabilities that can be leveraged by an attacker with root privileges on the OS to unlock the device and break the CoT. We conclude by proposing simple mitigation steps that can be implemented by manufacturers to safeguard the bootloader and OS from all of the discovered attacks, using already-deployed hardware features.

1 Introduction

With the critical importance of the integrity of today's mobile and embedded devices, vendors have implemented a string of inter-dependent mechanisms aimed at removing the possibility of persistent compromise from the device. Known as "Trusted Boot" [6] or "Verified Boot," [8], these mechanisms rely on the idea of a Chain of Trust (CoT) to validate each component the system loads as it begins executing code. Ideally, this procedure can verify cryptographically that each stage, from a Hardware Root of Trust through the device's file system, is both unmodified and authorized by the hardware's manufacturer. Any unverified modification of the various bootloader components, system kernel, or file system image should result in the device being rendered unusable until a valid one can be restored.

Ideally, this is an uncircumventable, rigid process, removing any possibility of compromise, even when attackers can achieve arbitrary code execution on the high-level operating system (e.g., Android or iOS). However, hardware vendors are given a great amount of discretion when implementing these bootloaders, leading to variations in both the security properties they enforce and the size of the attack surface available to an adversary.

Unfortunately, analyzing the code of bootloaders to locate vulnerabilities represents a worst-case scenario for security analysts. Bootloaders are typically closed-source [21], proprietary programs, and tend to lack typical metadata (such as program headers or debugging symbols) found in normal programs. By their very nature, bootloaders are tightly coupled with hardware, making dynamic analysis outside of the often-uncooperative target platform impractical. Manual

reverse-engineering is also very complicated, as bootloaders typically do not use system calls or well-known libraries, leaving few semantic hints for an analyst to follow.

In this paper, we first explore the security properties, implementations, and weaknesses of today's mobile device bootloaders. We begin with a discussion of the proposed standards and guidelines a secure bootloader should possess, and what, instead, is left to the discretion of manufacturers. We then showcase four real-world Android bootloader implementations on the market today.

Then, we present a static analysis approach, implemented in a tool called BOOTSTOMP, which uses a novel combination of static analysis techniques and under-constrained symbolic execution to build a multi-tag taint analysis capable of identifying bootloader vulnerabilities. Our tool highlighted 36 potentially dangerous paths, and, for 38.3% of them, we found actual vulnerabilities. In particular, we were able to identify *six* previously-unknown vulnerabilities (five of them already confirmed by the vendors), as well as rediscover one that had been previously-reported (CVE-2014-9798). Some of these vulnerabilities would allow an adversary with root privileges on the Android OS to execute arbitrary code as part of the bootloader. This compromises the entire chain of trust, enabling malicious capabilities such as access to the code and storage normally restricted to TrustZone, and to perform *permanent* denial-of-service attacks (i.e., device bricking). Our tool also identified two bootloaders that can be unlocked by an attacker with root privileges on the OS.

We finally propose a modification to existing, vulnerable bootloaders, which can quickly and easily protect them from any similar vulnerabilities due to compromise of the high-level OS. These changes leverage hardware features already present in mobile devices today and, when combined with recommendations from Google [8] and ARM [6], enforce the least-privilege principle, dramatically constraining the attack surface of bootloaders and allowing for easier verification of the few remaining attackable components.

In summary, our contributions are as follows:

- We perform a study of popular bootloaders present on mobile devices, and compare the security properties they implement with those suggested by ARM and Google.
- We develop a novel combination of program analysis techniques, including static analysis as well as symbolic execution, to detect vulnerabilities in bootloader implementations that can be triggered from the high-level OS.
- We implement our technique in a tool, called BOOTSTOMP, to evaluate modern, real-world bootloaders, and find *six* previously-unknown critical vulnerabilities (which could lead to persistent compromise of the device) as well as two unlock-bypass vulnerabilities.
- We propose mitigations against such attacks, which are trivial to retrofit into existing implementations.

In the spirit of open science, we make our analysis tool publicly available to the community[1].

2 Bootloaders in Theory

Today's mobile devices incorporate a number of security features aimed at safeguarding the confidentiality, integrity, and availability of users' devices and data. In this section, we will discuss Trusted Execution Environments, which allow for isolated execution of privileged code, and Trusted Boot, aimed at ensuring the integrity and provenance of code, both inside and outside of TEEs.

2.1 TEEs and TrustZone

A Trusted Execution Environment (TEE) is the notion of separating the execution of security-critical ("trusted") code from that of the traditional operating system ("un-trusted") code. Ideally, this isolation is enforced using hardware, such that even in the event the un-trusted OS is completely compromised, the data and code in the TEE remain unaffected.

Modern ARM processors, found in almost all mobile phones sold today, implement TrustZone[1], which provides a TEE with hardware isolation enforced by the architecture. When booted, the primary CPU creates two "worlds"–known as the "secure" world and "non-secure" world, loads the un-trusted OS (such as Android) into the non-secure world, and a vendor-specific trusted OS into the secure world. The trusted OS provides various cryptographic services, guards access to privileged hardware, and, in recent implementations, can be used to verify the integrity of the un-trusted OS while it is running. The un-trusted kernel accesses these commands by issuing the Secure Monitor Call (SMC) instruction, which both triggers the world-switch operation, and submits a command the Trusted OS and its services should execute.

ARM Exception Levels (EL). In addition to being in either the secure or non-secure world, ARM processors support "Exception Levels," which define the amount of privilege to various registers and hardware features the executing code has. The 64-bit ARM architecture defines four such levels, EL0-EL3. EL0 and EL1 map directly to the traditional notion of "user-mode" and "kernel mode," and are used for running unprivileged user applications

[1] `https://github.com/ucsb-seclab/bootstomp`

and standard OS kernels respectively. EL2 is used for implementing hypervisors and virtualization, and EL3 implements the Secure Monitor, the most privileged code used to facilitate the world-switch between secure and non-secure. During the boot process described below, the initial stages, until the non-secure world bootloader is created, runs at EL3.

2.2 The Trusted Boot Process

In a traditional PC environment, the bootloader's job is to facilitate the location and loading of code, across various media and in various formats, by any means necessary. However, in modern devices, particularly mobile devices, this focus has shifted from merely loading code to a primary role in the security and integrity of the device. To help limit the impact of malicious code, its job is to verify both the integrity and provenance of the software that it directly executes.

As with the traditional PC boot process, where a BIOS loaded from a ROM chip would load a secondary bootloader from the hard disk, mobile bootloaders also contain a chain of such loaders. Each one must, in turn, verify the integrity of the next one, creating a Chain of Trust (CoT).

On ARM-based systems, this secured boot process is known as *Trusted Boot* and is detailed in the ARM Trusted Board Boot Requirements (TBBR) specification. While this document is only available to ARM's hardware partners, an open-source reference implementation that conforms to the standard is available [6].

While this standard, and even the reference implementation, does leave significant room for platform-specific operations, such as initialization of hardware peripherals, implementations tend to follow the same basic structure. One important aspect is the Root of Trust (RoT), which constitutes the assumptions about secure code and data that the device makes. In ARM, this is defined to be 1) the presence of a "burned-in," tamper-proof public-key from the hardware manufacturer that is used to verify subsequent stages, and 2) the very first bootloader stage being located in read-only storage.

While manufacturers are free to customize the Trusted Boot process when creating their implementations, ARM's reference implementation serves as an example of how the process should proceed. The boot process for the ARM Trusted Firmware occurs in the following steps, as illustrated in Figure 1.

1. The CPU powers on, and loads the first stage bootloader from read-only storage.
2. This first stage, known as BL1, Primary Boot Loader (PBL), or BootROM, performs any necessary initialization to locate the next stage from its storage, loads it into memory, verifies its integrity using the Root of Trust Public Key (ROTPK), and if this is successful, executes it. Since it is on space-restricted read-only media, its functionality is extremely limited.
3. BL2, also known as the Secondary Boot Loader (SBL) is responsible for creating the secure and non-secure worlds and defining the memory permissions that enforce this isolation. It then locates and loads into memory up to three third-stage bootloaders, depending on manufacturer's configuration. These run at each of the EL3, EL2, and EL1 levels, and are responsible for setting up the Secure Monitor, a hypervisor (if present), and the final-stage OS bootloader.
4. BL2 then executes BL31, the loader running at EL3, which is responsible for configuring various hardware services for the trusted and un-trusted OSes, and establishing the mechanism used to send commands between the two worlds. It then executes the BL32 loader, if present, which will eventually execute BL33.
5. BL33 is responsible for locating and verifying the non-secure OS kernel. Exactly how this is done is OS-dependent. This loader runs with the same privilege as the OS itself, at EL1.

Next, we will detail extensions to this process developed for the Android ecosystem.

2.3 Verified Boot on Android

ARM's Trusted Boot standard only specifies stages of the boot process up to the point at which the OS-specific boot loader is executed. For devices running Android, Google provides a set of guidelines for *Verified Boot* [8], which describes high-level functionality an Android bootloader should perform.

Unlike the previous stages, the Android bootloader provides more functionality than just ensuring integrity and loading code. It also allows for the user or OS to elect to boot into a special recovery partition, which deploys firmware updates and performs factory reset operations. Additionally, modern Android bootloaders also participate in enabling full-disk encryption and triggering the initialization of Android-specific TrustZone services.

Ideally, the verification of the final Android kernel to be booted would effectively extend the Chain of Trust all the way from the initial hardware-backed key to the kernel. However, users wishing to use their devices for development need to routinely run kernels not signed by the device manufacturer. Therefore, Google specifies two classes of bootloader implementations: Class A, which only run signed code, and Class B, which allow for the

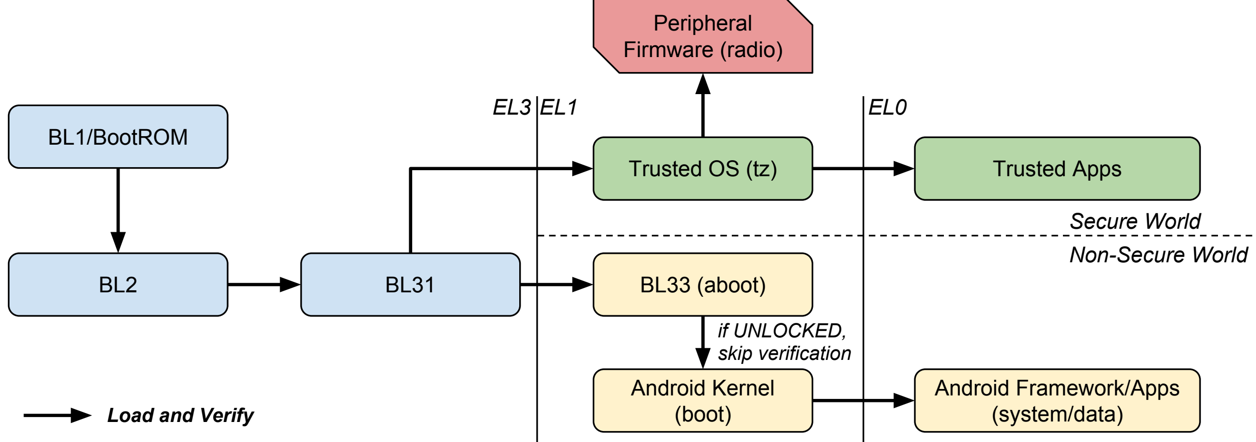

Figure 1: Overview of the Trusted/Verified Boot implementation according to the ARM and Google specifications. Between parentheses the name of the internal storage partition where the code is located in a typical implementation.

user to selectively break the Chain of Trust and run unsigned code, in a tamper-evident manner, referred to as *unlocking*. Devices will maintain a *security state* (either LOCKED or UNLOCKED) and properties of the transition between the two states must be enforced. With regard to Class B implementations, Google requires that:

- The bootloader itself must be verified with a hardware-backed key.
- If verification of the Android kernel with the OEM key (a key hard-coded by the device's manufacturer in the bootloader code) fails for any reason, a warning will be displayed to the user for at least five seconds. Then, if the bootloader is in the `LOCKED` state, the device will not boot, otherwise, if the bootloader is in the `UNLOCKED` state the Android kernel will be loaded.
- The device will only transition from the `LOCKED` state to the `UNLOCKED` state if the user first selects the "allow OEM Unlock" option from the Developer Options menu in Android's settings application, and then issues the Fastboot command `oem unlock`, or an equivalent action for devices without Fastboot.
- When the device's lock state changes for any reason, user-specific data will be rendered unreadable.

Beyond the guidelines, Android bootloaders (typically those that fall into Class B) also provide some means of rewriting partitions on internal storage over USB. Google suggests the use of the Fastboot protocol, also utilized for the locking and unlocking process, for this functionality.

3 Bootloaders in Practice

While the standards and guidelines on bootloader design in the previous section do cover many important security-related aspects, a significant amount of flexibility is given to OEMs to allow for functionality specific to their platforms. These involve both aspects of the hardware itself, but also logical issues with managing the security state of the device. Even though this flexibility makes it hard to reason about the actual security properties of bootloaders, it is difficult to envision a future for which these standards would be more precise. In fact, there are a number of technical reasons due to which the definition of these standards cannot be as comprehensive as we would hope.

One of these technical aspects is related to peripherals and additional custom hardware that is shipped with each device. While platform-specific code can be inserted at every stage in ARM's prototypical Trusted Boot implementation, no direction is given as to what code should be inserted at which points in the boot process. Additionally, initialization tasks cannot be too tightly coupled with the rest of the boot sequence, as peripheral hardware, such as modems, may incorporate code from different vendors and necessitate a modification of the initialization process. Furthermore, vendors of the final devices may not be able to alter earlier stages of the boot process to add necessary initialization code, as they may be locked to code supplied by the chip manufacturer. Finally, even aside from these issues, there are constraints on storage media. ROMs, such as those mandated for the first bootloader stage, tend to be small, and are inherently a write-once medium, precluding their use for any code that may need to be updated.

As an example, consider a mobile device with an onboard GSM or LTE modem. Depending on the hardware used, this modem could exist either as part of the System-on-a-chip (SoC) package or externally on another chip. Because the initialization of these two layouts has different requirements (e.g., initializing memory busses and

transferring code to an external modem vs. executing modem code on the same chip), this may need to happen at different phases in the boot process, where different levels of hardware access are available.

This also applies to various bootloader services, such as partition management and unlocking. Google's implementation provides the Fastboot protocol in the final-stage bootloader, but manufacturers are free to use alternative methods, as well as incorporate this functionality into other boot stages.

Where and how all of these features are implemented can have a significant security impact. If a stage in the bootloader is compromised, this could lead to the compromise of all following stages, along with any peripherals or secured storage that they manage. The impact of gaining control over a bootloader can be mitigated by using the lowest-possible Exception Level (discussed in the previous section), and performing tasks that involve taking potentially-untrusted input in later, less-privileged stages of the process. However, once again, other than the Trusted Firmware reference implementation, no guidance is given on how to manage exception levels with respect to bootloader features.

One aspect that increases the attack surface of modern bootloaders is that the code used to bootstrap additional hardware, such as modems, needs to be *updateable*, and thus needs to be stored on writable partitions. These writeable partitions, in turn, could be modified by an attacker with privileged code execution. Thus, it is critical that the content of these partitions is verified, such as by checking the validity of a cryptographic signature. This should ideally be accomplished by a previous bootloader stage, which thus needs to load, parse, and verify these partitions. This usage of data from writeable (and, as discussed previously, potentially attacker-controlled) partitions is what makes common memory corruption vulnerabilities in bootloaders very dangerous.

3.1 Bootloader Implementations

In the remainder of this section, we will explore four bootloaders from popular device manufacturers. These implementations all serve the same functions for their respective hardware platforms and aim to comply with both ARM and Google's standards, but do so in vastly different ways.

A comparison of the implementations can be found in Table 1. If an attacker can compromise the final stage bootloader, they will likely be able to also affect any functionality it contains, as well as any that it in turn loads, which in these cases, is the Android kernel and OS.

Vendor	EL	Fastboot	Modem Initialization	Peripherals Initialization
Qualcomm	EL1	✓	✗	✗
HiSilicon	EL3	✓	✓	✓
NVIDIA	EL1	✓	✗	✗
MediaTek	EL1	✓	✓	✗

Table 1: Final-stage Bootloader features, and which Exception Level they occur in

Qualcomm. The Qualcomm MSM chipset family is by far the most popular mobile chipset in devices today, representing over 60% of mobile devices [16]. While many manufacturers of MSM-based devices will customize the bootloader to fit their specific product's features, Qualcomm's "`aboot`" bootloader is still used with little modifications on many of them.

`aboot` is based on the Little Kernel (LK) open-source project, and provides the final stage non-secure OS loading functionality (equivalent to BL33 in ARM's reference implementation). In further similarity to BL33, it runs at EL1, giving it the same level of privilege as the kernel it aims to load. It conforms very closely to Google's Verified Boot guidelines, implementing the traditional set of Android-specific features, including Fastboot, recovery partition support, and unlocking. `aboot` can be used in either a Class A or Class B Verified Boot implementation, as Fastboot, and therefore unlocking can be disabled by the OEM or mobile carrier.

HiSilicon and Huawei. HiSilicon Kirin-based devices, such as those from Huawei, implement a very different bootloader architecture to the others we examined. Instead of merely being responsible for the initialization required to load Android, this loader also combines functionality usually found elsewhere in the boot process, such as initializing the radio hardware, secure OS, secure monitor, among others, giving it the equivalent roles of BL31, BL33, and BL2 in the ARM reference implementation. In fact, this bootloader is loaded directly by the ROM-based first-stage bootloader (BL1). To have the privilege necessary to perform all these tasks, HiSi's bootloader runs at EL3, and executes the Linux kernel in the boot partition at EL1 when it is finished. Along with its hardware initialization tasks, it also includes Fastboot support, by which it allows for unlocking.

MediaTek. Devices based on MediaTek chipsets, such as the Sony Xperia XA and other similar handsets, implement a bootloader similar to Qualcomm's but using a very different codebase. The Android-specific loader runs at EL1, and is also responsible for partition management and unlocking via Fastboot. Unlike Qualcomm's, this loader is also responsible for bootstrapping the modem's baseband firmware, meaning that any compromise in the bootloader could impact this critical component as well.

NVIDIA. NVIDIA's Tegra-based devices ship with a bootloader known as `hboot`. This bootloader is very similar to Qualcomm's, in that it runs at EL1, and implements only the fastboot functionality at this stage.

4 Unlocking Bootloaders

While security-focused bootloaders do significantly raise the bar for attackers wishing to persistently compromise the device, there are many cases in which "unlocking," as detailed in Section 2, has legitimate benefits. Only permitting the execution of signed code makes development of the Android OS itself problematic, as well as disallowing power-users from customizing and modifying the OS's code.

Of course, this is a very security-sensitive functionality; an attacker could unlock the bootloader and then modify the relevant partitions as a way of implementing a persistent rootkit. Google's Verified Boot standard covers the design of this important mechanism, discusses many high-level aspects of managing the device's security state (see Section 2), and even provides specifics about digital signatures to be used. However, as with the ARM specifications covering Trusted Boot, these specs must also allow for platform-specific variations in implementation, such as where or how these security mechanisms are integrated into the boot process.

Furthermore, there are many unspecified, implicit properties of Verified Boot that a valid implementation should enforce, to ensure that the device is protected from privileged code execution or unauthorized physical control. These properties include:

The device state should only transition from locked to unlocked with explicit user content. This is implicitly handled by requiring a command sent to Fastboot to unlock, as this usually requires physical access to activate, and causes a warning to be displayed to the user. Similarly, a malicious app — no matter how privileged it is — should not be able to silently unlock the bootloader.

Only the authorized owner of the device should be able to unlock the bootloader. This means that anyone in possession of a phone that is not theirs cannot simply access Fastboot or similar protocol (i.e., by rebooting the phone) and trigger an unlock. This is avoided on some devices through checking an additional flag called "OEM unlock," (or, more informally "allow unlock"). This flag is controlled by an option in the Android Settings menu, and it is only accessible if the device is booted and the user has authenticated (for instance, by inserting the correct "unlock pattern"). A proper implementation of Fastboot will honor the "OEM unlock" flag and it will refuse to unlock the bootloader if this flag is set to false.

Interestingly, there is no requirement on the storage of the device's security state. While the standard offers a suggestion about how to tie this state and its transitions to the security properties they wish to enforce, the exact storage of this information is left out, likely to account for hardware variations with respect to secured storage. Unfortunately, as we discuss in Section 5, specifics of such implementation details can negatively impact the security properties of the bootloader.

4.1 Unlocking vs Anti-Theft

Another interesting factor related to bootloaders and bootloader locking is the overall usability of a device by an attacker after it has been stolen. As mandated by laws [30] and industry standards [9], phones should implement mechanisms to prevent their usage when stolen. Google refers to this protection as Factory Reset Protection (FRP) [7], and it has been enabled in Android since version 5.0. In Google's own implementations, this means that the Android OS can restrict the usage of a phone, even after a factory-reset, unless the legitimate user authenticates.

This presents an interesting contradiction in relation to bootloader unlocking capabilities. First, since this mechanism is governed from within the OS, it could be leveraged by a malicious process with sufficient privilege. Of course, the original owner should be able to authenticate and restore the device's functionality, but this could still be used as a form of denial-of-service. Second, some manufacturers offer low-level firmware upload functionality, such as in the BL1 or BL2 stages, designed to restore the device to a working state in the event it is corrupted. This feature is in direct opposition to anti-theft functionality, as if a user can recover from any kind of corruption, this mechanism may be able to be bypassed. However, if this mechanism respects the anti-theft feature's restrictions on recovering partitions, this also means the device can be rendered useless by a sufficiently-privileged malicious process. In other words, there is an interesting tension between anti-theft and anti-bricking mechanisms: if the anti-theft is implemented correctly, an attacker could use this feature against the user to irremediably brick her device; vice versa, if an anti-bricking mechanism is available, a thief could use this mechanism to restore the device to a clean, usable state. In Section 8, we explore how this tension can be resolved.

5 Attacking Bootloaders

Regardless of implementation specifics bootloaders have many common functions that can be leveraged by an attacker. While they may appear to be very isolated from

possible exploitation, bootloaders still operate on input that can be injected by a sufficiently-privileged attacker. For example, the core task a bootloader must perform (that of booting the system) requires the bootloader to load data from non-volatile storage, figure out which system image on which partition to boot, and boot it. To enforce the Chain of Trust, this also involves parsing certificates and verifying the hash of the OS kernel, all of which involves further reading from the device's storage. In Class B implementations, the device's security state must also be consulted to determine how much verification to perform, which could be potentially stored in any number of ways, including on the device's storage as well. While bootloader authors may assume that this input is *trusted*, it can, in fact, be controlled by an attacker with sufficient access to the device in question.

In this work, we assume an attacker can control any content of the non-volatile storage of the device. This can occur in the cases that an attacker attains root privileges on the primary OS (assumed to be Android for our implementation). While hardware-enforced write protection mechanisms could limit the attacker's ability to do this, these mechanisms are not known to be in wide use today, and cannot be used on any partition the OS itself needs to routinely write to.

Given this attacker model, our goal is to automatically identify weaknesses, in deployed, real-world bootloader firmware, that can be leveraged by an attacker conforming to our attacker model to achieve a number of goals:

Code execution. Bootloaders process input, read from attacker-controlled non-volatile storage, to find, validate, and execute the next step in the boot process. What if the meta-data involved in this process is *maliciously crafted*, and the code processing it is not securely implemented? If an attacker is able to craft specified meta-data to trigger memory corruption in the bootloader code, they may achieve code execution *during the boot process*. Depending on when in the boot process this happens, it might grant the attacker control at exception levels considerably higher than what they may achieve with a root or even a kernel exploit on the device. In fact, if this is done early enough in the boot process, the attacker could gain control over Trusted Execution Environment initialization, granting them a myriad of security-critical capabilities that are unavailable otherwise.

Bricking. One aspect that is related to secure bootloaders is the possibility of "bricking" a device, i.e., the corruption of the device so that the user has no way to re-gain control of it. Bootloaders attempt to establish whether a piece of code is trusted or not: if such code is trusted, then the bootloader can proceed with their loading and execution. But what happens when the trust cannot be established? In the general case, the bootloader stops and issues a warning to the user. The user can, usually through the bootloader's recovery functionality (e.g., Fastboot) restore the device to a working state. However, if an attacker can write to the partition holding this recovery mechanism, the user has no chance to restore the device to an initial, *clean* state, and it may be rendered useless.

This aspect becomes quite important when considering that malware analysis systems are moving from using emulators to using real, physical devices. In this context, a malware sample has the capability of bricking a device, making it impossible to re-use it. This possibility constitutes a limitation for approaches that propose baremetal malware analysis, such as BareDroid [20].

One could think of having a mechanism that would offer the user the possibility of restoring a device to a clean state no matter how compromised the partitions are. However, if such mechanism were available, any anti-theft mechanism (as discussed in Section 4), could be easily circumvented.

Unsafe unlock. As discussed in Section 4, the trusted boot standard does not mandate the implementation details of storing the secure state. Devices could use an eMMC flash device with RPMB, an eFuse, or a special partition on the flash, depending on what is available. If the security state is stored on the device's flash, and a sufficiently-privileged process within Android can write to this region, the attacker might be able to unlock the bootloader, bypassing the requirement to notify the user. Moreover, depending on the implementation, the bootloader could thus be unlocked without the user's data being wiped.

In the next section, we will propose a design for an automated analysis approach to detect vulnerabilities in bootloader implementations. Unfortunately, our experiments in Section 7 show that currently deployed bootloaders are vulnerable to combinations of these issues. But hope is not lost – in Section 8, we discuss a mechanism that addresses this problematic aspect.

6 BootStomp

The goal of BootStomp is to automatically identify security vulnerabilities that are related to the (mis)use of attacker-controlled non-volatile memory, trusted by the bootloader's code. In particular, we envision using our system as an automatic system that, given a bootloader as input, outputs a number of alerts that could signal the presence of security vulnerabilities. Then, human analysts can analyze these alerts and quickly determine whether the highlighted functionality indeed constitute a security threat.

Bootloaders are quite different from regular programs, both regarding goals and execution environment, and

they are particularly challenging to analyze with existing tools. In particular, these challenges include:

- Dynamic analysis is infeasible. Because a primary responsibility of bootloaders is to initialize hardware, any concrete execution of bootloaders would require this hardware.
- Bootloaders often lack available source code, or even debugging symbols. Thus, essential tasks, including finding the entry point of the program, become much more difficult.
- Because bootloaders run before the OS, the use of syscalls and standard libraries that depend on this OS is avoided, resulting in all common functionality, including even functions such as `memcpy`, being reimplemented from scratch, thus making standard signature-based function identification schemes ineffective.

To take the first step at overcoming these issues, we developed a tool, called BOOTSTOMP, combining different static analyses as well as a dynamic symbolic execution (DSE) engine, to implement a taint analysis engine. To the best of our knowledge, we are the fist to propose a traceable offline (i.e., without requiring to run on real hardware) taint analysis completely based on dynamic symbolic execution. Other works as [24] [33] propose completely offline taint analyses on binaries. In contrast to our work, they implement static taint analyses, and are hence not based on dynamic symbolic execution.

The main problem with these types of approaches is that, though sound, they might present a high rate of false positives, which a human analyst has to filter out by manually checking them. Note that, in the context of taint analysis, a false positive result is a path which is mistakenly considered tainted. Furthermore, producing a trace (i.e., a list of basic blocks) representing a tainted path using a static taint analysis approach is not as simple as with symbolic execution.

On the other hand, our approach based on DSE, though not sound (i.e., some tainted paths might not be detected as explained in Section 7.4), presents the perk of returning a traceable output with a low false positives rate, meaning that the paths we detected as tainted are indeed tainted, as long as the initial taint is applied and propagated correctly. Note that there is a substantial difference between false positives when talking about taint analyses and when talking about vulnerability detection. Though our tool might return some false positives in terms of detected vulnerabilities, as seen in Section 7, false positives in tainted path detection are rare (we never found any in our experiments) as our tool is based on DSE. For a deeper discussion about the results obtained by BOOTSTOMP, please refer to Section 7.4.

With these considerations in mind, since the output of our analysis is supposed to be triaged by a human, we

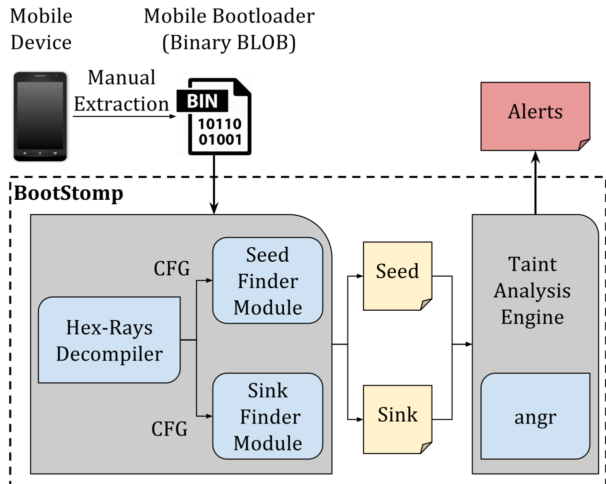

Figure 2: BOOTSTOMP's overview.

opted for a taint analysis based on DSE.

This section discusses the goal, the design features, and the implementation details of BOOTSTOMP.

6.1 Design

Our system aims to find two specific types of vulnerabilities: uses of attacker-controlled storage that result in a memory-corruption vulnerability, and uses of attacker-controlled storage that result in the unlocking of the bootloader. While these two kinds of bugs are conceptually different, we are able to find both using the same underlying analysis technique.

The core of our system is a taint analysis engine, which tracks the flow of data within a program. It searches for paths within the program in which a *seed of taint* (such as the attacker-controlled storage) is able to influence a *sink of taint* (such as a sensitive memory operation). The tool raises an alert for each of these potentially vulnerable paths. The human analyst can then process these alerts and determine whether these data flows can be exploitable.

Our system proceeds in the following steps, as shown in Figure 2:

Seed Identification. The first phase of our system involves collecting the seeds of taint. We developed an automated analysis step to find all the functions within the program that read data from any non-volatile storage, which are used as the seeds when locating memory corruption vulnerabilities. However, if the seeds have semantics that cannot be automatically identified, such as the unlocking mechanism of the bootloader, BOOTSTOMP allows for the manual specification of seeds by the analyst. This feature comes particularly in handy when source code is available, as the analyst can rely on

it to manually provide seeds of taint.

Sink Identification. We then perform an automated analysis to locate the sinks of taint, which represent code patterns that an attacker can take advantage of, such as bulk memory operations. Moreover, writes to the device's storage are also considered sinks for locating potentially attacker-controlled unlocking mechanisms.

Taint Analysis. Once the seeds of taint have been collected, we consider those functions containing the seed of taint and, starting from their entry point, perform a multi-tag taint analysis based on under-constrained symbolic execution [23] to find paths where seeds reach sinks. This creates alerts, for an analyst to review, including detailed context information, which may be helpful in determining the presence and the exploitability of the vulnerability.

In the remainder of this section, we will explore the details about each of these steps.

6.2 Seed Identification

```
1  #define SEC_X_LEN 255
2
3  void get_conf_x() {
4      //...
5      n = read_emmc("sec_x", a2, a3);
6      if (n < SEC_X_LEN) {
7          return;
8      }
9      //...
10 }
11
12 int get_user_data() {
13     // ...
14     if(!read_emmc(b1, b2, 0)) {
15         debug("EMMC_ERROR: no data read");
16         return -1;
17     }
18     // ...
19 }
```

Listing 1: By scanning every call site of `read_emmc`, BOOTSTOMP infers that the first parameter is a string, the third can assume the value zero, and the returned type is an integer.

For finding memory corruption vulnerabilities, our system supports the automatic identification of seeds of taint. We use approaches similar to those in prior work (e.g., [27]). We rely on error logging because there are many different mechanisms that may read from non-volatile memory, or different types of memory (plain flash memory vs. eMMC), and these error log strings give us semantic clues to help finding them. Our system looks for error logging functions using keywords as *mmc*, *oeminfo*, *read*, and *fail*, and avoiding keywords like *memory* and *write*.

This approach is useful for identifying functions that somehow retrieve the content from a device's storage. However, since the signature of these functions is not known, it is challenging to identify which argument of this function stores the receiving buffer. To determine the argument to be tainted, we use an approach based on type inference.

Ideally, the taint should only be applied to the seed's argument pointing to the memory location where the read data will be stored. As distinguishing pointers from integers is an undecidable problem [31], our analysis might dereference an integer in the process of applying the taint, resulting in a possible huge rate of false positive alarms. Nonetheless, during this study, we observed that, surprisingly, strings might not always be passed by reference to a function, but rather by value. During our analysis, we check every call site of the functions we retrieved using the above mentioned method and check the entity of every passed argument. If an argument is composed of only ASCII printable characters, we assume it is a string, and we consider the same argument to a be a string for every other call to the same function. When looking for the memory locations to apply the taint, we consider this information to filter out these arguments. We also do not taint arguments whose passed values are zeroes, as they might represent the NULL value.

As an example, consider Listing 1. First, BOOTSTOMP retrieves the function *read_emmc* as a possible seed function, by analyzing the error log at line 18. Then, it scans every call site of *read_emmc* and infers that the returned value is an integer (as it is compared against an integer variable), the first parameter is a string and the third parameter can assume the value zero. As *read_emmc* is a candidate seed function, it has to store the content read from a non-volatile storage in a valid buffer, pointed by a non-null pointer. Therefore, BOOTSTOMP applies the taint only to the second parameter of *read_emmc* (*a*2 and *b*2). Note that, as the receiving buffer could be returned by a seed function, if the type of the returned value cannot be inferred, the variable it is assigned to is tainted as well. Note that, when a tainted pointer is dereferenced, we taint the entire memory page it points to.

In the case of locating unlocking-related vulnerabilities, there is no bootloader-independent way of locating the unlocking function, since the implementation details significantly vary. Therefore, BOOTSTOMP also supports supplying the seeds manually: an analyst can thus perform reverse-engineering to locate which function implements the "unlock" functionality and manually indicate these to our analysis system. While this is not a straightforward process, there is a specific pattern a human analyst can rely on: Fastboot's main command handler often includes a basic command line parser that determines which functionality to execute, and the strings involved are often already enough to quickly pin-

point which function actually implements the "unlock" functionality.

6.3 Sink Identification

Our automatic sink identification strategy is designed to locate four different types of sinks:

memcpy-like functions. BootStomp locates memcpy-like functions (e.g., memcpy, strcpy) by looking for semantics that involve moving memory, unchanged, from a source to a destination. As mentioned above, there are no debugging symbols, and standard function signature-based approaches would not be effective. For this reason, we rely on a heuristic that considers the basic blocks contained within each function to locate the desired behavior. In particular, a function is considered memcpy-like if it contains a basic block that meets the following conditions: 1) Loads data from memory; 2) stores this same data into memory; 3) increments a value by one unit (one word, one byte, etc). Moreover, since it is common for bootloaders to rely on wrapper functions, we also flag functions that directly invoke one (and only one) function that contains a block satisfying the above conditions.

We note that there may be several other functions that, although satisfy these conditions as well, do not implement a memcpy-like behavior. Thus, we rely on an additional observation that memcpy and strcpy are among the most-referenced functions in a bootloader, since much of their functionality involves the manipulation of chunks of memory. We therefore sort the list of all functions in the program by their reference count, and consider the first 50 as possible candidates. We note that, empirically, we found that memcpy functions often fall within the top five most-referenced functions.

Attacker-controlled dereferences. BootStomp considers memory dereferences controlled by the attacker as sinks. In fact, if attacker-controlled data reaches a dereference, this is highly indicative of an attacker-controlled arbitrary memory operation.

Attacker-controlled loops. We consider as a sink any expression used in the guard of a loop. Naturally, any attacker able to control the number of iterations of a loop, could be able to mount a denial-of-service attack.

Writes to the device's storage. When considering unlocking vulnerabilities, we only use as sinks any write operation to the device's storage. This encodes the notion that an unlocking mechanism that stores its security state on the device's storage may be controllable by an attacker. To identify such sinks, we adopt the same keyword-based approach that we employed to identify the seeds of taint (i.e., by using relevant keywords in error logging messages).

Code

```
seed_func(ty);
x = ty[5];
```

Symbolic expressions

```
ty = TAINT_ty
x = deref(TAINT_ty_loc_5)
```

Memory

ty → x — Tainted Page

Figure 3: Taint propagation example.

6.4 Taint Tracking

While we cannot execute the bootloaders concretely, as we discussed above, we can execute them symbolically. Our interest is in the path the data takes in moving from a seed to a sink, and path-based symbolic execution lets us reason about this, while implicitly handling taint-propagation. Given a bootloader, along with the seeds and sinks identified in the previous stages, the analysis proceeds as follows:

- Locate a set of *entry points*, defined as any function that directly calls one of the identified seeds.
- Begin symbolic execution at the beginning of each entry point. Note that, before starting to symbolically execute an entry point, BootStomp tries to infer, looking for known header as ELF, where the global data is located. If it does find it, it unconstrains each and every byte in it, so to break any assumptions about the memory content before starting to analyze the entry point.
- When a path encounters a function, either step over it, or step into it, considering the code traversal rules below.
- When a path reaches a seed, the appropriate taint is applied, per the taint policy described below.
- Taint is propagated implicitly, due to the nature of symbolic execution. This includes the return values of functions handling tainted data.
- If a path reaches a sink affected by tainted data, an alert is raised.

Code traversal. To avoid state explosion, we constrain the functions that a path will traverse, using an *adaptive inter-function level*. Normally, the inter-function level specifies how many functions deep a path would traverse. However, the handling of tainted data in our analysis means that we implicitly care more about those functions which consume tainted data. Therefore, we only step into functions that consume tainted data, up to the inter-function level. For our experiments, we fixed the inter-function level at 1. More in detail, our analysis traverses the code according to the following rules:

- When no data is tainted, functions are not followed, such as at the beginning of an entry point, before the seed has been reached. Particularly, this path selection criteria allows us to have a fast yet accurate taint analysis, at the expense of possible false negative results, as some tainted paths might not be discovered due to some missed data aliases.
- Functions are not followed if their arguments are not tainted.
- Analysis terminates when all the possible paths between the entry point and its end are analyzed, or a timeout is triggered. Note that we set a timeout of ten minutes for each entry point. As we will show in Section 7.2 our results indicate that this is a very reasonable time limit.
- Unless any of the above conditions are met, we follow functions with an inter-function level of 1. In other words, the analysis will explore at least one function away from the entry point.
- We explore the body of a loop (unroll the loop) exactly once, and then assume the path exits the loop.

(Under-Constrained) Symbolic Execution. Our approach requires, by design, to start the analysis from arbitrary functions, and not necessarily from the bootloader's entrypoint, which we may not even be able to determine. This implies that the initial state may contain fewer constraints than it should have at that particular code point. For this reason, we use under-constrained symbolic execution, first proposed by Ramos et al. [23], which has been proven to reach good precision in this context.

Multi-tag taint analysis. To reach a greater precision, our system implements a multi-tag tainting approach [18]. This means that, instead of having one concept of taint, each taint seed generates tainted data that can be uniquely traced to where it was generated from. Furthermore, we create unique taint tags for each invocation of a seed in the program. This means, for example, that if a taint seed is repeatedly called, it will produce many different taint tags. This improves precision when reasoning about taint flow.

Taint propagation and taint removal. Taint is implicitly propagated using symbolic execution, as no constraint is ever dropped. This means that if a variable x depends on a tainted variable ty, the latter will appear in the symbolic expression of the former. As an example consider Figure 3. Suppose that a location of an array pointed by ty is dereferenced and assigned to x, such as $x = ty[5]$. Assuming now that ty is tainted because pointing to data read from an untrusted storage, the memory page it points to will be tainted, meaning that every memory location within that page will contain a symbolic variable in the form $TAINT_ty_loc_i$. After the instruction $x = ty[5]$, the symbolic variable x will be in the form $deref(TAINT_ty_loc_5)$.

On the other hand, taint is removed in two cases. Implicitly when a non-tainted variable or value is written in a tainted memory location, or when a tainted variable is constrained within non tainted values. As an example and by referring to the above tainted variable x, if a check such as $if(x < N)$, where N is non-tainted value, is present, x would get untainted.

Concretization strategy. When dealing with memory writes in symbolic locations, target address needs to be concretized. Unlike existing work [5], our analysis opts to concretize values with a bias toward smaller values in the possible range (instead of being biased toward higher values). This means that, when a symbolic variable could be concretized to more than one value, lower values are preferred. In previous work, higher values were chosen to help find cases where memory accesses off the end of an allocated memory region would result in vulnerabilities. However, these values may not satisfy conditional statements in the program that expect the value to be "reasonable," (such as in the case of values used to index items in a vector) and concretizing to lower values allows paths to proceed deeper into the program. In other words, we opt for this strategy to maximize the number of paths explored. Also, when BOOTSTOMP has to concretize some expressions, it tries to concretize different unconstrained variables to different (low) values. This strategy aims to keep the false positive rate as low as possible. For a deeper discussion about how false negatives and positive might arise, please refer to Section 7.4.

Finally, our analysis heavily relies on angr [28] (taint engine) and IDA Pro [11] (sink and seed finding).

7 Evaluation

This section discusses the evaluation of BOOTSTOMP on bootloaders from commercial mobile devices. In particular, for each of them, we run the analysis tool to locate the two classes of vulnerabilities discussed in Section 6. As a first experiment, we use the tool to automatically discover potential paths from attacker-controllable data (i.e., the flash memory) to points in the code that could cause memory corruption vulnerabilities. As a second experiment, we use the tool to discover potential vulnerabilities in how the lock/unlock mechanism is implemented. We ran all of our experiments on a 12-Core Intel machine with 126GB RAM and running Ubuntu Linux 16.04.

We first discuss the dataset of bootloaders we used, an analysis of the results, and an in-depth discussion of several use cases.

7.1 Dataset

For this work, we considered five different bootloaders. These devices represent three different chipset families: Huawei P8 ALE-L23 (Huawei / HiSilicon chipset), Sony Xperia XA (MediaTek chipset), and Nexus 9 (NVIDIA Tegra chipset). We also considered two versions of the LK-based bootloader, developed by Qualcomm. In particular, we considered an old version of the Qualcomm's LK bootloader (which is known to contain a security vulnerability, CVE-2014-9798 [19]) and its latest available version (according to the official git repository [22]).

7.2 Finding Memory Corruption

We used BOOTSTOMP to analyze the five bootloaders in our dataset to discover memory corruption vulnerabilities. These vulnerabilities could result in arbitrary code execution or denial-of-service attacks. Table 2 summarizes our findings. In particular, the table shows the number of seeds, sinks, and entry points identified in each bootloader. The table also shows the number of alerts raised for each bootloader. Out of a total of 36, for 12 of them, the tool identified a potential path from a source to memcpy-like sink, leading to the potential of a buffer overflow. The tool raised 5 alerts about the possibility of a tainted variable being dereferenced, which could in turn constitute a memory corruption bug. Finally, for 19, the tool identified that tainted data could reach the conditional for a loop, potentially leading to denial-of-service attacks. We then manually investigated all the alerts to determine whether the tool uncovered security vulnerabilities. Our manual investigation revealed a total of seven security vulnerabilities, *six* of which previously-unknown (five are already confirmed by the respective vendors), while the remaining one being the previously-known CVE-2014-9798 affecting an old version of Qualcomm's LK-based bootloader. Note that, as BOOTSTOMP provides the set of basic blocks composing the tainted trace together with the involved seed of taint and sink, manual inspection becomes easy and fast even for not-so-experienced analysts. We also note that, due to bugs in angr related to the analysis of ARM's THUMB-mode instructions, the MediaTek bootloader was unable to be processed correctly.

These results illustrate some interesting points about the scalability and feasibility of BOOTSTOMP. First, we note that each entry point's run elapsed on average less than five minutes (Duration per EP column), discovering a total of seven bugs. We ran the same set of experiments using a time limit of 40 minutes. Nonetheless, we noticed that no additional alerts were generated. These two results led us to believe that a timeout of ten minutes (i.e., twice as the average analysis run) was reasonable. Second, we noted a peak in the memory consumption while testing our tool against LK bootloaders. After investigating, we found out that LK was the only bootloader in the dataset having a well known header (ELF), which allowed us to unconstrain all the bytes belonging to the *.data* and *.bss* segments, as stated in Section 6. Third, we note that the overall number of alerts raised is very low, in the range that a human analyst, even operating without debugging symbols or other useful reverse-engineering information, could reasonably analyze them. Finally, as we show in the table, more than one alert triggered due to the same underlying vulnerability; the occurrence of multiple alerts for the same functionality was a strong indicator to the analyst of a problem. This can occur when more than one seed fall within the same path generating a unique bug, for instance, when more than one tainted argument is present in a memcpy-like function call.

With this in mind, and by looking at the table, one can see that around 38.3% of the tainted paths represent indeed real vulnerabilities. Note also that in the context of tainted paths, none of the reported alerts were false positives (i.e., not tainted paths), though false positives are theoretically possible, as explained in Section 7.4.

Our tool uncovered five new vulnerabilities in the Huawei Android bootloader. First, an arbitrary memory write or denial of service can occur when parsing Linux Kernel's device tree (DTB) stored in the boot partition. Second, a heap buffer overflow can occur when reading the root-writable `oem_info` partition, due to not checking the `num_records` field. Additionally, a user with root privileges can write to the `nve` and `oem_info` partitions, from which both configuration data and memory access permissions governing the phone's peripherals (e.g., modem) are read. The remaining two vulnerabilities will be described in detail below.

Unfortunately, due to the architecture of the Huawei bootloader, as detailed in Section 3.1, the impact of these vulnerabilities on the security of the entire device is quite severe. Because this bootloader runs at EL3, and is responsible for the initialization of virtually all device components, including the modem's baseband firmware and Trusted OS, this vulnerability would not only allow one to break the chain of trust, but it would also constitute a means to establish persistence within the device that is not easily detectable by the user, or available to any other kind of attack. Huawei confirmed these vulnerabilities.

BOOTSTOMP also discovered a vulnerability in NVIDIA's `hboot`. `hboot` operates at EL1, meaning that it has equivalent privilege on the hardware as the Linux kernel, although it exists earlier in the Chain of Trust, and therefore its compromise can lead to an attacker gaining persistence. We have reported the vulnerability to NVIDIA, and we are working with them on a fix.

Bootloader	Seeds	Sinks	Entry Points	Total Alerts			Bug-Related Alerts			Bugs	Timeout	Total Duration	Duration per EP	Memory
				loop	deref	memcpy	loops	deref	memcpy					
Qualcomm (Latest)	2	1	3	1	1	2	0	0	0	**0**	1	12:49	04:16	512
Qualcomm (Old)	3	1	5	3	0	5	0	0	4	**1**	0	10:14	02:03	478
NVIDIA	6	1	12	7	0	0	1	0	0	**1**	0	24:39	02:03	248
HiSilicon	20	4	27	8	4	5	8	4	3	**5**	1	21:28	00:48	275
MediaTek	2	2	2	-	-	-	-	-	-	**-**	-	00:08	00:04	272
Total	33	9	49	19	5	12	9	4	7	**7**	2	69:18	09:14	1785

Table 2: Alerts raised and bugs found by BOOTSTOMP's taint analysis. Time is reported in `MM:SS` format, memory in MB.

Finally, we rediscovered a previous vulnerability reported against Qualcomm's aboot, CVE-2014-9798. These vulnerabilities allowed an attacker to perform denial-of-service attack. However, this vulnerability has been patched, and our analysis of the current version of aboot did not yield any alerts.

Case study: Huawei memory corruption vulnerability. BOOTSTOMP raised multiple alerts concerning a function, whose original name we believe to be `read_oem()`. In particular, the tool highlighted how this function reads content from the flash and writes the content to a buffer. A manual investigation revealed how this function is vulnerable to memory corruption. In particular, the function reads a monolithic record-based datastructure stored in a partition on the device storage known as `oem_info`. This partition contains a number of *records*, each of which can span across multiple *blocks*. Each block is 0x4000 bytes, of which the first 512 bytes constitute a header. This header contains, among others, the four following fields: `record_id`, which indicates the type of record; `record_len`, which indicates the total length of the record; `record_num`, which indicates the number of blocks that constitute this record; `record_index`, which is a 1-based index.

The vulnerability lies in the following: the function will first scan the partition for blocks with a matching `record_id`. Now, consider a block whose record_num is 2 and whose record_index is 1. The fact that record_num is 2 indicates that this record spans across two different blocks. At this point, the `read_oem` function assumes that the length of the current block is the maximum, i.e., 0x4000, and it will thus copy all these bytes into the destination array, *completely ignoring the `len` value passed as argument*. Thus, since the `oem_info` partition can be controlled by an attacker, an attacker can create a specially crafted record so that a buffer overflow is triggered. Unfortunately, this bootloader uses this partition to store essential information that is accessed at the very beginning of every boot, such as the bootloader's logo. Thus, an attacker would be able to fully compromise the bootloader, fastboot, and the chain of trust. As a result, it would thus be possible for an attacker to install a persistent rootkit.

Case study: Huawei arbitrary memory write. The second case study we present is related to an arbitrary memory write vulnerability that our tool identified in Huawei's bootloader. In particular, the tool raised a warning related to the `read_from_partition` function. Specifically, the tool pinpointed the following function invocation `read_from_partition("boot", hdr->kernel_addr)`, and, more precisely, the tool highlighted that the structure `hdr` can be attacker-controllable. Manual investigation revealed that not only `hdr` (and its field, including `kernel_addr`) are fully controllable by an attacker, but that the function actually reads the content from a partition specified as input ("boot", in this case), and it copies its content to the address specified by `hdr->kernel_addr`. Since this destination address is attacker-controllable, an attacker could rely on this function to write arbitrary memory (by modifying the content of the "boot" partition) to an arbitrary address, which the attacker can point to the bootloader itself. We note that this vulnerability is only exploitable when the bootloader is unlocked, but, nonetheless, it is a vulnerability that allows an attacker to run arbitrary code as the bootloader itself (and not just as part of non-secure OS). Moreover, the next section provides evidence that, at least for this specific case, it is easy for an attacker to unlock the bootloader.

7.3 Analyzing (In)Secure State Storage

As a second use case for our tool, we use it to analyze the same five bootloaders we previously consider to determine how their security state (i.e., their lock/unlock state) is stored. In particular, as we discussed in Section 4, if the bootloader merely stores the security state on one of the flash partitions, then an attacker may be able to change the content of this partition, unlock the phone without the user's consent, and thus violate one of Google's core Verified Boot principles.

To run this experiment, we begin with the manually-identified unlocking functionality, as described in Section 6.2, and locate paths that reach automatically-identified writes to the device's storage. This means that each bootloader has one entry point. Table 3 shows the overall results of this experiment, including the number

Bootloader	Sinks	Potentially vulnerable?	Timeout	Duration	Remarks
Qualcomm (Latest)	6	✓	✗	01:00	Detected write on flash and mmc
Qualcomm (Old)	4	✓	✗	00:40	Detected write on flash and mmc
NVIDIA	9	✗	✗	02:21	Memory mapped IO
HiSilicon	17	✓	✓	10:00	Write `oeminfo`
MediaTek	1	✗	✓	10:00	Memory mapped IO

Table 3: Alerts raised by BOOTSTOMP on potentially vulnerable `write` operation inside unlock routines. Time is reported in `MM:SS` format.

of possible write operations to the device's storage that occurred within the unlocking functionality. Our system was easily able to locate paths in Qualcomm's bootloader (both the old and the newest version) and Huawei's bootloader where the security state was written to the device's non-volatile storage. Upon manual investigation, we discovered that Qualcomm's simply stores the bit '1' or '0' for whether the device is locked. Huawei's stores a static hash, but can still be recovered and replayed (see case study at the end of this section). In both cases, writing the needed value to the flash will unlock the bootloader, potentially bypassing the mandatory factory reset, if additional steps are not taken to enforce it, such as those mentioned in Section 8. Our tool did not identify any path to non-volatile storage for the NVIDIA's or MediaTek's bootloaders. Upon manual investigation, we discovered that these two bootloaders both make use of memory-mapped I/O to write the value, which could map to anything from the flash to special tamper-resistant hardware. Thus, we cannot exclude the presence of vulnerabilities.

Case Study: Huawei bootloader unlock. Our tool identified a path from a function, which we believe to be called `oem_unlock`, to a "write" sink. Upon manual investigation, we were able to determine the presence of a vulnerability in the implementation of this functionality, as shown in Figure 4. In a normal scenario, the user needs to provide to the bootloader a device-specific `unlock_code`. Such code can be obtained by a user through Huawei's website, by providing the hardware identifiers of the device. The problem lies in the fact that the "correct" MD5 of the `unlock_code`, `<target_value>`, is stored in a partition of the device's storage. Thus, even if it not possible to determine the correct `unlock_code` starting from its hash, an attacker could just *reuse* the *correct* MD5, compute the expected `unlock_state`, and store it to the `oem_info` partition, thus entirely bypassing the user's involvement.

7.4 Discussion

As stated in Section 6, and as demonstrated by the results in this section, our tool might present some false negatives as well as false positives. In this section we consider the results achieved by our taint analysis engine, and we discuss how false positive and false negatives might arise.

```
1 x = md5sum(unlock_code);
2 if (x == ``<target_value>'') {
3   unlock_state = custom_hash(x);
4   write(oem_info,unlock_state);
5 }
```

Figure 4: Implementation of the (vulnerable) unlock functionality in Huawei's bootloader.

As symbolic execution suffers from the path explosion problem, generally speaking, not all the possible paths between two program points can be explored in a finite amount of time. This might cause some tainted paths to be missed, causing some vulnerabilities to be missed. False negatives might be present also because BOOTSTOMP does not follow function calls when no taint is applied. This approach is very useful, since it makes our tool faster as less code has to be analyzed, but it might miss some correlation between pointers. In fact, if a future tainted variable is aliased, within a skipped function to a variable whose scope falls within the current function, and this variable later happens to reach a sink, it will not be reported.

Furthermore, since BOOTSTOMP relies on a maximum fixed inter-function level, it might not follow all the function calls it encounters, possibly resulting in some tainted variables not to be untainted as well as some pointer aliases not being tainted. This problem might create both false positives and false negatives.

Additionally, false positives could possibly arise from the fact that not all the reported tainted paths lead to actual vulnerabilities. In fact, when the initial taint is applied, our tool tries to understand which parameter represents the variable(s) that will point to the read data, as explained in Section 6. If the taint is not applied correctly, this will result in false positive results. Note however, that our tool would taint every parameter that our type inference heuristic does not exclude. Therefore, false negatives are not possible in this case.

Our concretization strategy could possibly introduce both false positives and false negatives. Given two unconstrained pointers, intuitively it is unlikely that they

will point to the same memory location. Therefore, the most natural choice is to concretize them (if necessary) to two different values. Assuming that these two pointers are indeed aliases, if one of them is tainted and the other reaches a sink, no alarm will be raised causing then a false negative. On the other hand if both of them are tainted, but the former becomes untainted and the latter reaches a sink, an alarm would be raised causing then a false positive. According to our observations these cases are very rare though, as we never encountered two unconstrained pointers that happened to be aliases.

Finally, it is worth noting that while we found some tainted paths that were not leading to actual vulnerabilities, our tool never detected a tainted path which was supposed to be untainted.

8 Mitigations

In this section, we will explore ways of mitigating the vulnerabilities discovered in the previous section. With the increasing complexity of today's devices, it may be difficult to completely ensure the correctness of bootloaders, but taking some simple steps can dramatically decrease the attack surface.

As we have discussed throughout the previous sections, the goal of Trusted Boot and Verified Boot is to prevent malicious software from persistently compromising the integrity of the operating system and firmware. The attacks we discovered all rely on the attacker's ability to write to a partition on the non-volatile memory, which the bootloader must also read. We can use hardware features present in most modern devices to remove this ability.

Binding the Security State. Google's implementations of Verified Boot bind the security state of the device (including the lock/unlock bit) to the generation of keys used to encrypt and decrypt user data, as described in Section 2.3. While not specifically requiring any particular storage of the security state, this does ensure that if the security state is changed, the user's data is not usable by the attacker, and the system will not boot without first performing a factory reset. This, along with the cryptographic verification mandated by Verified Boot, achieves the goals Google sets, but does not completely shield the bootloader from arbitrary attacker-controlled input while verifying partitions or checking the security state.

Protect all partitions the bootloader accesses. Most modern mobile devices utilize non-volatile storage meeting the eMMC specification. This specifies the set of commands the OS uses to read and write data, manage partitions, and also includes hardware-enforced security features. Since version 4.4, released in 2009 (a non-public standard, summarized in [17]), eMMC has supported *Power-on Write-Lock*, which allows individual partitions to be selectively write-protected, and can only be disabled when the device is rebooted. The standard goes as far as to specify that this must also be coupled with binding the reset pin for the eMMC device to the main CPU's reset pin, so that intrusive hardware attacks cannot be performed on the eMMC storage alone.

While we are not able to verify directly whether any handsets on the market today makes use of this feature, we note that none of the devices whose bootloaders we examined currently protect the partitions involved in our attacks in this manner. Furthermore, we note that many devices today make use of other features from the same standard, including Replay-protected Memory Blocks (RPMB) [17] to provide a secure storage accessible from Secure-World code.

eMMC Power-on Write-protect can be used to prevent any partition the bootloader must read from being in control of an attacker with root privileges. Before executing the kernel contained in the boot partition, the final stage bootloader should enable write protection for every partition which the bootloader must use to boot the device. In Android, the `system` and `boot` partitions contain entirely read-only data (excluding during OS updates), which the bootloader must read for verification, and therefore can be trivially protected in this way. To close any loopholes regarding unlocking the bootloader, the partition holding device's security state should also be write-protected. The `misc` partition used by Qualcomm devices, for example is also used to store data written by the OS, so the creation of an additional partition to hold the security state can alleviate this problem.

This does not impede any functionality of the device, or to our knowledge, cause any impact to the user whatsoever. Of course, this cannot be used to protect partitions the OS must write to. While the OS does need to write to `system` and `boot` to perform routine software updates, this too can be handled, with only small changes. If an update is available, the bootloader should simply not enable write-protection when booting, and perform the update. This increases only marginally the attack surface, adding only the update-handling code in the bootloader.

It should be noted that this method cannot protect the status of the "Allow OEM Unlock" option in the Android Settings menu, which by its very design must be writable by the OS. This means that a privileged process can change this setting, but unlocking the bootloader still requires physical control of the device as well.

Alternative: Security State in RPMB. eMMC Power-on Write Lock can be used to protect any partition which is not written to by the OS. If, for whatever reason, this is not possible, this could also be stored in the Replay-protected Memory Block (RPMB) portion of the eMMC

module.

We can enforce the property that the OS cannot tamper with the security state by having the Trusted OS, residing in the secure world, track whether the OS has booted, and only allow a change in the security state if the bootloader is running. Using RPMB allows us to enforce that only TrustZone can alter this state, as it holds the key needed to write the data successfully.

When the device boots to the final stage bootloader, it will signal to TrustZone, allowing modifications to the security state via an additional command. Once the bootloader is ready to boot the Android OS, it signals again to TrustZone, which disallows all writes to the device until it reboots.

While this requires minor modifications to the Trusted OS and final-stage bootloader, it does not require a change in the write-protection status or partition layout.

9 Related Work

Trusted Boot Implementations and Vulnerabilities Methods that utilize the bootloader to bootstrap a trusted environment have been studied extensively in the past. Recent Intel-based PC systems utilize UEFI Secure Boot, a similar mechanism for providing verification of operating system components at boot-time. This too has been prone to vulnerabilities.

Specifically, Wojtczuk et al., studied how unprivileged code can exploit vulnerabilities and design flaws to tamper with the SPI-flash content (containing the code that is first executed when the CPU starts), completely breaking the chain-of-trust [34] in Intel systems. Kallenberg et al., achieved a similar goal by exploiting the update mechanisms exposed by UEFI code [14]. Researchers have also shown how the chain-of-trust can be broken on the Mac platform, using maliciously crafted Thunderbolt devices [13, 12]. Other research focused on the way in which Windows bootloader, built on top of UEFI, works and how it can be exploited [4, 25]. Bazhaniuk et al., provided a comprehensive study of the different types of vulnerabilities found in UEFI firmware and propose some mitigations [2], whereas Rutkowska presented an overview of the technologies available in Intel processors, which can be used to enforce a trusted boot process [26].

All these works show how the complexity of these systems, in which different components developed by different entities have to collaborate, and the different, sometimes conflicting, goals they try to achieve has lead to both "classic" vulnerabilities (such as memory corruption), but also to hard-to-fix design issues. Our work shows how this is true also in the mobile world.

While all of the previously mentioned works rely entirely on manual analysis, Intel has recently explored auditing its own platform using symbolic execution [3]. This is similar in approach to our work, but it has a different goal. In particular they focus on detecting a very specific problem in the UEFI-compliant implementation of BIOS (out of bound memory accesses). Instead, we focus on vulnerabilities explicitly triggerable by an attacker inside the bootloader code of ARM mobile device, considering both memory corruption as well as additional logic flaws related to unlocking.

A recent work, BareDroid [20], proposes and implements modifications to the Android boot process to build a large-scale bare-metal analysis system on Android devices. Although with a different goal, in this work, authors introduce some aspects related to ours, such as difficulties in establishing a chain of trust in Android devices and how malware could permanently brick a device. We expand and integrate their findings, comparing different implementations and devices.

Automatic Vulnerability Discovery Our approach, as outlined in Section 6, attempts to automatically locate vulnerabilities statically. Other approaches include fully-dynamic analysis, such as coverage-based fuzzing [36], or hybrid systems, such as Driller [10] and Dowser [29], which switch between the static and dynamic analysis to overcome the limitations of both. Unfortunately, we could not use any approach leveraging concrete dynamic execution, as it is currently impossible to overcome the tight coupling of bootloaders and the hardware they run on. Previous work has looked into hardware-in-the-loop approaches [35, 15] to address this issue, by passing events directed at hardware peripherals to a real hardware device tethered to the analysis system. Unfortunately, none of this work can be adapted to our platform, as the hardware under analysis lacks the necessary prerequisites (e.g., a JTAG interface or a completely unlocked primary bootloader) that would be needed.

Many previous works have also proposed statically locating memory corruption vulnerabilities, including Mayhem [5] and IntScope [32], focusing on user-land programs. These approaches are not directly applicable to our goals, since in our work we are not focusing solely on memory corruption and our analysis requires an ad-hoc modeling and identification sources and sinks. FirmAlice [27] proposes a technique for locating authentication bypass vulnerabilities in firmware. The vulnerabilities we wish to locate stem from the presence and specific uses of "user input" (in this case, data from the non-volatile storage), whereas FirmAlice can detect its absence, en route to a pre-defined program state.

10 Conclusion

We presented an analysis of modern mobile device bootloaders, and showed that current standards and guidelines are insufficient to guide developers toward creating secure solutions. To study the impact of these design decisions, we implemented a static analysis approach able to find locations where bootloaders accept input from an adversary able to compromise the primary operating system, such as parsing data from partitions on the device's non-volatile storage. We evaluated our approach on bootloaders from four major device manufacturers, and discovered six previously-unknown memory corruption or denial of service vulnerabilities, as well as two unlock-bypass vulnerabilities. We also proposed mitigation strategies able to both limit the attack surface of the bootloader and enforce various desirable properties aimed at safeguarding the security and privacy of users.

Seeing Through The Same Lens: Introspecting Guest Address Space At Native Speed

Abstract

Software-based MMU emulation lies at the heart of out-of-VM live memory introspection, an important technique in the cloud setting that applications such as live forensics and intrusion detection depend on. Due to the emulation, the software-based approach is much slower compared to native memory access by the guest VM. The slowness not only results in undetected transient malicious behavior, but also inconsistent memory view with the guest; both undermine the effectiveness of introspection. We propose the *immersive execution environment* (ImEE) with which the guest memory is accessed at native speed without any emulation. Meanwhile, the address mappings used within the ImEE are ensured to be consistent with the guest throughout the introspection session. We have implemented a prototype of the ImEE on Linux KVM. The experiment results show that ImEE-based introspection enjoys a remarkable speed up, performing several hundred times faster than the legacy method. Hence, this design is especially useful for real-time monitoring, incident response and high-intensity introspection.

1 Introduction

The thriving cloud computing has kept driving the research on virtual machine introspection (VMI) [14, 18, 19, 21, 23, 29, 33, 34, 35, 36] in the recent years to address the growing security concerns on virtual machines. The center of the VMI research is to bridge the semantic gap [24], namely, to reconstruct the high level kernel semantics by accessing the guest kernel's virtual address space. For instance, the VMI tool in the monitor VM extracts all running processes' identifiers in an untrusted guest VM by traversing the guest kernel's `task_struct` list.

When the tool is deployed inside the target VM, it is trivial to access the guest virtual address space. Nonetheless, such an in-VM introspection [14, 34] induces guest OS modification and is subject to attacks if the guest kernel is subverted. Placing the introspection agent outside of the guest is a more appealing approach. Such an out-of-VM introspection then faces the problem of replicating the guest's virtual address (VA) to host physical address (HPA) translation.

Existing out-of-VM introspection systems [18, 19, 33, 35] tackle the problem using a software-based address translation whereby the MMU's function is replaced by software. As a result, the software-based access is much slower than the native speed access in the guest. The speed inferiority clearly impacts introspection performance, e.g., longer turnaround time to scan the kernel's code section. Moreover, it has several negative security implications. It costs more precious time for live forensics and incident response. It is also incapable of continuously monitoring a critical memory location as the introspection loses the race against the attack running at native speed. Most importantly, it is difficult for the software-based method to maintain consistent VA-to-HPA mappings with the guest kernel, because it is not amenable to tracking and following `CR3` updates in the guest. Inconsistent mappings consequently impair the security of introspection. We stress that the cache mechanism does improve performance, however, at the cost of potential mapping and data inconsistency since the cached mappings and data could be stale.

In fact, mapping consistency can not be assumed for an in-VM introspection scheme without trusting the guest kernel, even though the memory is introspected at native speed. For instance, SIM [34] isolates its monitoring code in an isolated address space whereas it does not prevent the malicious kernel thread from using a different address mapping. The consistency issue persists in the broader scope of system monitoring. As shown by Jang et. al [25], hardware-assisted monitor systems such

*Work was mainly done when visiting SMU as a research assistant.

as Copilot [30] and KI-mon [26] are circumvented by using address translation redirection attacks which deceive the monitor into using a faked mapping.

In this paper, we propose a novel mechanism to allow the introspection code in the monitor VM to access a target guest kernel's virtual address space at native speed and with mapping consistency, despite the kernel-level attacks from the target. The code runs in a carefully designed execution environment named as the *Immersive Execution Environment* (ImEE). During a guest access, the ImEE's MMU walks the present paging structures same as the guest's, pointed to by the `CR3` registers both in the ImEE and in the guest.

We have implemented a prototype of the ImEE on Linux KVM. The experiments demonstrate a remarkable performance boost. As compared to the existing software-based guest access method, the ImEE is several hundred times faster to traverse kernel objects. The ImEE is so lightweight and nimble that it only needs 23μs to activate and 7μs to switch the introspection target, around 200 times faster than the software method. Hence, the ImEE is more attractive to applications desiring strong security, faster response and high speed, for instance, critical data monitoring, virtual machine scanning, and live forensics.

CAVEAT. Our contribution in this paper is complementary to existing out-of-VM introspection systems [19, 18, 29, 33]. Those innovations focus upon more software issues, like efficient kernel-level semantic reconstruction [19] and race conditions [29]. In contrast, it is out of our scope to deal with the high-level issues like which virtual addresses or kernel objects to read and how to reuse the existing kernel code [19]. We expect that, with modest retrofitting, those VMI applications can harness the ImEE as a powerful guest access engine to achieve better performance and stronger security.

ORGANIZATION. The next section briefly reviews the legacy method to access the target VM and analyze its weakness. We present a synopsis of the work in Section 3. The design details of the ImEE and the code running inside are presented in Section 4. The implementation and performance evaluation are described in Section 5 and 6, respectively. We then discuss several related issues in Section 7, and briefly review the literature in Section 8. Lastly, Section 9 concludes the paper.

2 Inadequacy of Software-based Guest Access

It is a common practice in the VMI literature to use the software-based method to translate virtual addresses before accessing a target guest VM. The guest's own paging structures cannot be directly replicated in the monitor VM, because it is incompatible with all software therein. In addition, there is also a security concern that the guest's code or data could be used to attack the monitor VM.

In this software-based approach, the target memory is mapped to the monitor VM as a set of read-only pages. Given a virtual address X, the introspection code walks through all levels of the paging structures, including the Extended Page Tables (EPTs[1]) in the memory to find out the corresponding HPA. It then maps the HPA to its own virtual address space, and finally issues an instruction to read it. Obviously, such a procedure incurs a much longer latency than the native access to X in the guest.

To assess how slow the software-based guest access is in relative to the native speed access, we run a "cat-and-mouse" experiment. The introspection program using LibVMI keeps reading a guest process's `task->cred` pointer, while a guest kernel thread periodically modifies the pointer and the new value stays for 20,000 CPU cycles before being restored. The page-level data cache of LibVMI is disabled to ensure the freshness of every read whereas the translation caches are on since no address mapping is modified. We conduct the experiment for eight times, each lasting 10 seconds. In average, the modification is only spotted after being repeated 60 rounds. In one of the eight rounds, no modification is caught. The experiment result demonstrates that introspection at low speed cannot catch up with the fast-running attacker. It is ill-suited for scenarios demanding quick responses such as live forensics and real-time I/O monitoring.

The slow speed also affects the mapping consistency as the guest malware in the kernel may make transient changes to the page tables, rather than the data. Since walking the paging structures appears instant to the malware using the MMU, but not to the introspection software, the malware's attack on the page tables causes the VMI tool to use inconsistent information obtained from the paging structures.

Caching techniques have been used in order to reduce the latency of guest accesses. For instance, LibVMI [31] introduces three types of caches: the page-level data cache, the VA-to-HPA translation cache and the `pid` to `CR3` cache. While promoting the performance, using the caches is detrimental to effective introspection. Since the guest continuously runs during the introspection, any cached mapping or data is not guaranteed to be consistent with the one in the memory. Moreover, it is difficult for the software-based method with caches to catch up with the pace of `CR3` updates in the guest. Since the guest kernel is untrusted, the introspection cannot presume that all

[1]Throughout this paper, we following Intel's terminology to describe the scheme. It can also be implemented on AMD processors supporting MMU virtualization.

guest threads share the same kernel address space. CR3 synchronization with the guest may lead to cache thrashing which backfires on the introspection performance.

Besides the security related limitations described above, the software method has performance-related drawbacks. It usually has a bulky code base since it has to fully emulate the MMU's behavior, such as supporting 32-bit and 64-bit paging structures as well as different modes and page sizes. Its operation leaves a large memory footprint because of the intensive reliance on data and translation caches. It also suffers from slow-start due to the complex setup. For instance, the LibVMI initialization costs 100 milliseconds according to our measurement. To change the introspection target from one VM to another requires a new setup. With these performance pitfalls, the software-based method is not the best choice for introspection in data centers where the VMI tools may need to scan a large crowd of virtual machines.

3 Synopsis

3.1 Models and Scope

System Model. We consider a multicore platform supporting both CPU and MMU virtualization. Under the management of a bare metal hypervisor, the platform runs a trusted monitor VM and a set of untrusted guest VMs which are the targets of introspection. The platform administrator runs VMI applications inside the monitor VM to introspect the *live* kernel states in the targets without modifying or suspending them.

To avoid ambiguity, we use the "target" to refer to the virtual machine under introspection, and use "guest" with its hardware virtualization notion as in a "guest physical address" (GPA) which refers to the physical address a kernel uses inside a hardware-assisted virtual machine.

Trust Model. We assume all hardware and firmware in the platform behave as expected. We trust the hypervisor and the software in the monitor VM and assume that the adversary cannot compromise the hypervisor or the monitor VM's kernel at launching time and runtime. We do not trust any software running in the target, including the kernel.

Scope of Study. The adversary we cope with resides in the target kernel. Its goal is to stage a *fake* kernel address space view to the VMI application. Namely, its attack causes the VMI application to read those memory bytes that are "thought" to be used by kernel threads but are actually not. Attacks that aim to beat the VMI logic, e.g., manipulating a function pointer not known to the introspection logic, are beyond and orthogonal to our scope of study. Side-channel attacks or denial-of-service attacks are not considered either.

3.2 Basic Idea

Our idea is to create a special computing environment called *Immersive Execution Environment* (ImEE) with a twisted address mapping setting (as in Figure 1). The ImEE's CR3 is synchronized with the target VM's active CR3 so that its MMU directly uses the target's VA-to-GPA mappings. Its GPA-to-HPA mappings are split into two. The GPAs for the intended introspection are translated with the same mappings as in the target VM; the GPAs for the local usage (indicated by the dotted box in Figure 1) are mapped to the local physical pages via separated GPA-to-HPA mappings. With this setting, memory accesses are automatically directed by the MMU into the target and the local memory regions according to the paging structures.

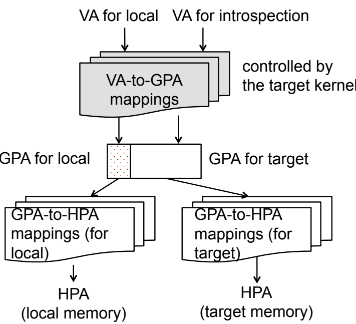

Figure 1: Illustration of the idea of direct usage of the target VM's VA-to-GPA mappings and splitting in GPA-to-HPA mappings. Note that the shadow box is fully controlled by the target (i.e., the adversary).

The paging structure setup in the ImEE ensures mapping consistency with the target VM. Firstly, the ImEE's VA-to-GPA mappings remain the same as the target's, because its CR3 and the target CR3 always point to the same location. Any mapping modification in the target also takes effect in the ImEE simultaneously. Secondly, the hypervisor ensures that the ImEE GPAs intended for introspection are mapped in the same way as within the target. Hence, any VA for introspection is translated with mapping consistency with the target. Note that the VA is accessed at native speed because the MMU performs the address translation.

3.3 Challenges

Suppose that the ImEE has been set up following the idea above with an introspection agent running inside and accessing the target memory. The following design chal-

lenges need to be addressed in order to achieve a successful introspection.

Functionality Challenge. The ImEE agent's virtual address space comprises of the executable code, data buffers to read and write, and the target kernel's address space. Since the agent code and data are logically different from the target kernel, we need a way to properly *split* the GPA domain so that VAs for the local uses are not mapped to the target and VAs for introspection are not mapped to the agent memory.

This challenge to divide the GPA domain is further complicated by two issues. Firstly, the virtual address space layout of the target is not priorly known, because it is entirely dependent on the current thread in the target. Therefore, it is a challenge to device a universal mechanism to load the ImEE agent regardless the target's address space layout. Secondly, read/write operations on the local memory and on the target memory are not distinguishable to the hardware. Therefore, it is difficult to separate access to local pages and target pages. For example, it is difficult to detect whether a VA for introspection is wrongly mapped to the local data (which could be induced by the target kernel inadvertently or willfully) because it does not violate the access permissions on the page table.

Security Challenge. The ImEE is not fully isolated from the adversary. The target VM's kernel has the full control of the VA-to-GPA mappings which affect the resulting HPA. Hence, the adversary can manipulate the ImEE agent's control flow and data flow by modifying the mappings at runtime. Although access permissions can be enforced via the GPA-to-HPA translation, the adversary can still redirect the memory reference at one page to another with the same permissions.

A more subtle, yet important issue, is that the introspection *blind spot*, namely the set of virtual addresses in the target which are not reachable by the ImEE agent. As shown in Figure 2, a VA for introspection is in the blind spot if and only if it is mapped to the GPA for local use. This is because the full address translation ends up with a local page, instead of the target VM's page. The malicious target can turn its pages into the blind spot by manipulating its guest page table. The blind spot issue has two implications. First, detecting its existence efficiently is challenging. Note that it is time-consuming to find out all VAs in the blind spot, because the guest page tables have to be traversed to obtain the GPA corresponding to a suspicious VA. Second, the attacker can manipulate VA to GPA mappings in an attempt to disrupt the execution of the ImEE agent. By manipulate the mappings, the attacker tries to cause invalid code to be executed inside the environment, or cause the introspection to read arbitrary data.

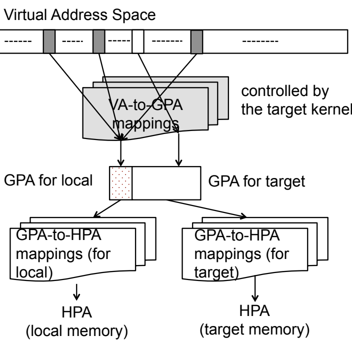

Figure 2: Illustration of the blind spot comprising three virtual pages (in the dark color). Target kernel objects in those pages cannot be introspected since they are mapped to the local memory.

Performance Challenge. Although the ImEE agent accesses the target memory at native speed, we aim to minimize the time for setting it up in order to maximize its capability of quickly responding to real-time events and/or adapting to a new introspection target (e.g., another thread in the target VM or even another target VM). The challenge is how to load the agent into the virtual address space currently defined by the target thread and to prepare the corresponding GPA-to-HPA mappings. Searching in the virtual address space is not an option since it is time-consuming to walk the target VM's paging structures. In addition, it is also desirable to minimize the hypervisor's runtime involvement, because the incurred VM exit and VM entry events cost non-negligible CPU time.

Besides the above three major challenges, there are other minor issues related to the runtime event handling, such as page faults and the target VM's EPT updates. The requirement of Out-of-VM introspection is to minimize intrusive effects on the target. For example, the hypervisor is refrained from modifying the target VM's guest page tables because it leads to execution exceptions in the target. Therefore, the minor issues also need careful treatment.

3.4 System Overview

The ImEE is in essence a special virtual machine which is created and terminated by the hypervisor based on the VMI application's request. Like a normal VM, the ImEE hardware consists of a vCPU core and a segment of physical memory, both (de)allocated by the hypervisor when needed. No I/O device is attached to the ImEE. The ImEE does not have an OS and the only software running in it is the ImEE agent which reads the target memory. Figure 3 depicts an overview of the whole system.

The VMI application can launch the ImEE, put it into

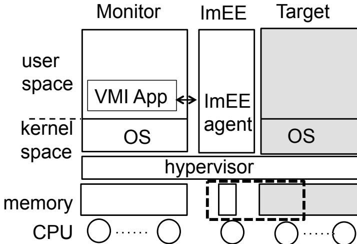

Figure 3: Overview of ImEE-based introspection. The box with dashed lines illustrates the mixture of physical memory. The shadowed regions belong to the target and are not trusted.

sleep, and terminate it. Like a regular VM, the ImEE can also migrate from one logic core to another. While the ImEE is active, it runs in *sessions* which is defined as the tenure of its CR3 content. To kick off a session, the hypervisor either induces a VM exit or intercepting CR3 changes in the target.

4 The Design Details

In this section, we first explain the internals of the ImEE with the focus on the paging structures, and then explain the ImEE agent. We show our design choices for performance where appropriate. Lastly, we describe the life-cycle of ImEE, focusing on the runtime issues such as transitions between sessions.

The approach is to carefully concert system design, e.g., setting the ImEE's EPTs and software design (i.e. crafting the agent) so that the ImEE agent execution straddles between two virtual address spaces: one for the local usage and the other for accessing the target VM.

4.1 ImEE Internals

The ImEE requires a vCPU core which can be migrated from one core to another. It also comprises one executable code frame and one read/writable data frame. The former stores the agent code while the latter stores the agent's input and output data. To differentiate them from the target VM's physical memory, we name them as the *ImEE frames*.

According to the CR3 content, the agent runs either in the *local address space* or the *target address space*, as depicted in Figure 4. When in the local address space, the agent interacts with the VMI application while it runs in the target address space to read the target memory. The code frame is mapped into both spaces while the data frame is mapped in the local address space only.

Local Address Space. The paging structures used in the local address space comprise GPT_L and EPT_L, which

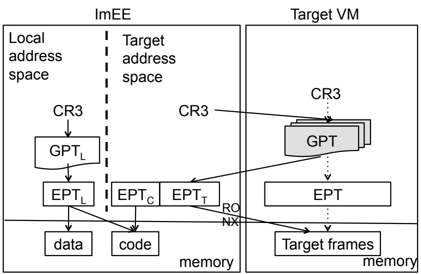

Figure 4: The solid arrows describe the translation for a VA within the ImEE, while the dotted arrows describe the translation inside the target. All target frames accessible to the ImEE agent are set as read-only and non-executable in EPT_T.

map the entire space to the ImEE frames. GPT_L only consists of two pages as shown in Figure 5. The global flag on the GPT_L is set so that the local address space mappings in the TLB are not flushed out during CR3 update. Specifically, only one virtual page is mapped to the data frame while all others are mapped to the code frame. With this setup, the agent code can execute from all but one page. Moreover, the GPAs of the ImEE frames are *not* within the GPA range the target VM uses, which avoids conflict mappings used in the target address space.

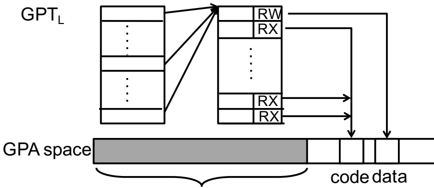

Figure 5: The Illustration of GPT_L. All entries in the page table directory point to the same page table page which has one PTE points to the data frame and all other to the code frame.

Target Address Space. The target address space implements our idea in Figure 1. To run the agent in this space, the ImEE CR3 register is synchronized with the target CR3, so that they use the same guest page tables. The GPA-to-HPA mapping used in this space are governed by EPT_T and EPT_C.

All GPAs are mapped to the target frames by EPT_T, except one page is redirected by EPT_C to the ImEE code frame. Specifically, EPT_T is populated with the GPA-to-HPA mappings from the target VM's EPT, except that all target frames are guarded by read-only and non-executable permissions. This stops the agent from modifying the target memory for the sake of non-intrusiveness. It also prevents the adversary from injecting code, because the adversary can place arbitrary bi-

naries to those frames. The permission of the mapping defined by EPT_C is set as *executable-only*. Namely, it cannot be read or written from the target address space.

Note that the ImEE data frame is not mapped in the target address space for two reasons. Firstly, it minimizes the number of GPA pages redirected from the target to the ImEE, and therefore reduces the potential blind spot. Secondly, *all* memory read accesses performed in the target address space are bounded to the target. Therefore, it feasible to configure the hardware to regulate memory accesses so that any manipulation on the target GPT that attempts to redirect the introspection access to the ImEE memory is caught by a page fault exception.

CAVEAT. Address switches inside the ImEE do not cause any changes on the EPT level. The GPA-to-HPA mappings used in one address space are cached in the ImEE TLBs and are not automatically invalidated during switches. Note that EPT_L, EPT_C and EPT_T do not have conflict mappings because they map different GPA ranges. The two address spaces are assigned with different Process-Context Identifier (PCID) avoid undesired TLB invalidation on address space switch.

4.2 ImEE Agent

The ImEE agent is the only piece of code running inside the ImEE, without the OS or other programs. It is granted with Ring 0 privilege so that it has the privilege to read the target kernel memory and to manage its own system settings, such as updating the CR3 register. It is self-contained without external dependency and does not incur address space layout changes at runtime in the sense that all the needed memory resources are priorly defined and allocated.

Our description below involves many addresses. We use Table 1 to define the notations.

	VA	GPA
ImEE data	P_d	GP_d
ImEE code (local addr. space)	P_c	GP_c
ImEE code (target addr. space)	P_c	GP_c'
Target page	P_t	GP_t

Table 1: Address notations. For instance, GP_c is the guest physical address of the ImEE code page in the local address space.

Overview. The main logic of the agent is as follows. Initially, the agent runs in the local address space and reads an introspection request from the data frame. Then it switches to the target address space and reads the targeted memory data from the target memory into the registers. Finally, it switches back to the local address space, dumps the fetched data to the data page and fetches the next request.

The Agent. Figure 6 presents the pseudo code of the agent. The agent has only one code page and one data page. Since the data frame is out of the target address space, all needed introspection parameters (e.g., the destination VA and the number of bytes to read) are loaded into the general-purpose registers (Line 6). For the same reason, the agent loads the target memory data into the ImEE floating-point registers as a cache (Line 12), before switching to the local address space to write to the data frame (Line 17).

```
1:  while TRUE do
2:      /* local address space: Read the request */
3:      repeat
4:          poll the interface lock;
5:      until the lock is off
6:      Read the request from the data frame to
        general-purpose registers;
7:
8:      /* switch to target address space */
9:      Load the target CR3 provided by the hypervisor;
10:
11:     /* target access */
12:     Move n bytes from the target address x to
        floating-point registers;
13:
14:     /*switch to local address space */
15:     Load CR3 with GPT_L;
16:     /* output to data frame */
17:     Move data from the floating-point registers to
        the ImEE data page;
18:     if requested service not completed then
19:         goto Line 9;
20:     end if
21:     Set interface lock;
22: end while
```

Figure 6: The sketch of the ImEE agent's pseudo code

The agent is loaded at P_c in the local address space by the hypervisor. P_c is chosen by the hypervisor such that it is an executable page according to the target's guest page table. Because GPT_L maps the entire VA range (except one page) to the code frame. Therefore, there is an overwhelming probability that P_c is also an executable page in the local address space[2]. Therefore, the agent can execute in the two address spaces back and forth which explain Line 12 and 17 can run successfully without re-

[2]In case P_c is not executable under GPT_L, the hypervisor only needs to adjust the corresponding PTE.

location.

Impact of TLB. No matter whether there is an attack or not, TLB retention has no adverse effect on the introspection. Suppose that the mappings in the local address space are cached in the TLB. When the agent runs in the target address space, the only VAs involved are for the instructions (P_c) and the target addresses (P_t). For VAs in P_c, the cached mapping remains valid because the address mappings are not changed. There are two exclusive cases for P_t. If $P_t \neq P_d$, the translation does not hit any TLB entry because it is never used in the local address space. Otherwise, the TLB entry for P_d is still considered as a miss because of different PCIDs. The same reasoning also applies to the cached mappings in the target address space.

Note that the adversary gains no advantage from a TLB hit on a cached local address space translation. Since EPT_L is available in the target address space, the adversary can manipulate its own page tables to achieve the same outcome as a TLB hit. It can use arbitrary GPA in its page tables.

4.3 Defeating Attacks via the Blind Spot

The introspection security demands the agent execution to have both control flow integrity and data flow integrity. Data confidentiality is also required since the leakage of the introspection targets can help the adversary evade introspection. The EPT settings of the ImEE and of the target ensure that the adversary can only launch side-channel attacks, which is beyond the scope of our study.

The only attack vectors exposed by the ImEE to the adversary are the shared GPT and the target physical memory which are fully controlled by the adversary. The adversary can manipulate the VA-to-GPA mappings for P_c and P_t. Depending on the specific manipulation, either we can detect such attempts by the EPT violation triggered, or the attack does not adversely affect the introspection.

Detecting Blind Spot. The attacks on P_c is defeated by the fact that the code frame is the only executable frame inside the ImEE. Hence, the attack on P_c's mapping, i.e. mapping P_c to a page in GP_t, is doomed to trigger an EPT violation exception. Similarly, mapping P_t to GP'_c also triggers EPT violations because the read is on a execute-only page.

Defeating Mapping Attacks. The attack attempts that manipulate the mappings of P_t do not adversely affect the introspection. Specifically, there are three cases for the GP_t which virtual page P_t which is mapped to by the adversary.

- $GP_t = GP'_c$. Nonetheless, our EPT_C maps the agent code frame non-readable. Therefore, an EPT violation exception is thrown. The hypervisor can find out the faulting VA and reports to the VMI tool. The hypervisor can also reload the agent into a new executable page to introspect the faulting page. This is the same case as in detecting blind spot described above.

- $GP_t \neq GP'_c$, and GP_t is within the pre-assigned GPA range for the target VM. In this case, the ImEE's MMU walks the target VM's GPT and fetches the data in the same way as in the target VM. In other words, the mapping consistency between the ImEE and the target VM is still guaranteed. Although the agent may read invalid data, its execution is not affected by such mappings. The attack has no harm to the execution as it is equivalent to feeding poisonous contents to the VMI application, in the hope to exploit a programming vulnerability. We remark that this is the inevitable risk faced by any memory introspection and can be coped with software security countermeasures.

- GP_t is mapped out of the pre-assigned GPA range for the target. If $GP_t = GP_d$ or $GP_t = GP_c$, the attack causes the agent to read from the ImEE frames; otherwise it causes an EPT page fault as the needed mapping is absent. We do not consider this case as a blind-spot problem, because the target VM's EPT does not have the mapping for GP_t. Hence, the target VM's kernel, including the adversary, is not able to access this page. This attack does not give the adversary any advantage over mapping P_t to an in-range GPA whose physical frame stores the same contents prepared by the adversary. (Note that we do not assume or rely on the secrecy of the introspection code.)

4.4 Operations of ImEE

Initialization. To start the introspection, the hypervisor loads the needed agent code and data into the memory. It initializes EPT_T as a copy of the entire EPT used for the target, and allocates a vCPU core for the ImEE. The ImEE `CR3` is initially loaded with the address of GPT_L.

In case the target's EPT occupies too many pages, the hypervisor copies them in an on-demand fashion. In other words, when the agent's target memory access encounters a missing GPA-to-HPA mapping, the hypervisor then copies the EPT page from the target's EPT. Note that it does not weaken security or effectiveness, because the EPTs are managed by the hypervisor only.

Activation. Based on the VMI application's request, the hypervisor launches the ImEE wherein the agent runs in

the local address space with an arbitrarily chosen virtual address. The start of an session is marked by the target VM's CR3 capture. If it is the first session, the hypervisor may send out an Inter-Processor Interrupt (IPI) to the target VM, or induce an EPT violation to the target, or passively wait for a natural VM-exit (which is more stealthy). After the trapping the core, the hypervisor configures the target's Virtual Machine Control Structure (VMCS) to intercept CR3 updates on it. Namely, the execution of CR3 loading instruction(s) on the captured vCPU triggers a VM exit. Note that the target's other vCPUs (if any) are not affected.

Agent Reloading. Once the target CR3 value is switched, the hypervisor sends an IPI to the ImEE CPU to cause it to trap to the hypervisor. The hypervisor then reloads the agent. If the agent is currently running in the target address space, its CR3 in the VMCS is immediately replaced. The hypervisor then extracts the page frame number from the target's Instruction Pointer (IP). It replaces the page frame number in the ImEE IP with the one in the target IP without changing the offset. Since the agent code lies within one page, preserving the offset allows it to smoothly continue the interrupted execution.

If the agent is in the local address space, the CR3 for the new target address space is saved in a register. The crux of the session transition is to *minimize the hypervisor execution time* as it hinders the ImEE's performance by holding the core.

We use a *lazy-allocation* method to find GP_c' for the purpose of setting up EPT_C. When the agent resumes execution, an EPT violation is triggered because the corresponding physical page is mapped as read-only in EPT_T. From the exception, the hypervisor reads the faulting GPA, changes the corresponding EPT permissions, and restores the previous one to read-only. The newly modified EPT_T entry becomes the new EPT_C. Since the lazy method uses the MMU to find GP_c', it saves the CPU time for walking the page table.

Page Fault Handling. Although it is rare for kernel introspection, it is possible to encounter a page fault due to absent pages in the target VM. One possible reason is that the malware inside the target attempts to evade introspection by swapping out page content to disk. In this case, since the mapping inside ImEE is consistent with the one in the target VM, introspection on the swapped-out page results in a page fault inside ImEE. We remark that this behavior is the expected consequence of maintaining mapping consistency between ImEE and the target. The effectiveness of ImEE's introspection is not undermined because once the swapped-out page is swapped in, it is visible to ImEE immediately.

For the sake of resilience, we install a page fault handler inside the ImEE. Since the agent resides in Ring 0, the exceptions do not cause any context switch. Out of the consideration of transparency and stealthiness, the ImEE's page fault handler does not attempt to resolve the cause. Instead, it simply runs dozens of NOP instructions and retries the read. If the rounds of failure exceed the predefined threshold, it aborts the execution.

5 Implementation

In this section, we report the details of our ImEE prototype implementation. We describe our prototype based on KVM and the introspection tools we implemented on top of our prototype.

5.1 ImEE on KVM

We have implemented a prototype of the ImEE and its agent on Ubuntu 12.04 with Linux kernel 3.2.79. Our implementation adds around 1400 SLOC to the Linux KVM module. The main changes on the KVM module include two new `ioctl` call handlers as the interface for the VMI application to request the ImEE setup and execution. The new handlers leverage existing KVM utility in the kernel to setup the ImEE as a special VM.

We customize the KVM's handling of VM-exit events in order to achieve better performance. Those events intended for the ImEE introspection are redirected to the new handler dedicated for the ImEE. Therefore, the long execution path of the KVM's event handling routines is bypassed.

5.2 Specialized Agent

According to the commonly seen memory reading patterns, we have implemented three types of ImEE agents as listed in Table 2. The Type-1 agent performs a block read, i.e., to read a contiguous memory block at the base address. The Type-2 agent performs a traversal read, i.e., to read the specified member(s) of a list of structured objects chained together through a pointer defined in the structure. The Type-3 agent reads the memory in the same way as the Type-2, except that the extracted member is a pointer and a dereference is performed to read another structure. Note that the Type-2 and 3 agents are particularly useful for traversing the kernel objects.

Type	Mode of read	# of Instructions
1	Block-read	38
2	Traversal-read	22
3	Traversal-read-dereference	40

Table 2: Three ImEE agents. The Type-3 agent uses 2 pointer deferences while the Type-2 agent uses one.

The interface between the VMI application and the ImEE agent are two fixed-size buffers residing on the agent's data frame and being mapped into the VMI application's space. One buffer is for the request to the agent and the other stores the reply from the agent. Both buffers are guarded by one spin-lock to resolve the read-write conflict from both sides. When the ImEE session starts, the agent polls the buffer and serves the request. The VMI application ensures that the reply buffer is not overflowed. We remark that the polling based approach is faster than using interrupts as it does not induce any VM-exit/entry.

5.3 Usability

The simple interface of ImEE allows easy development of introspection tools. For common introspection tasks that focus on kernel data structures, the development requires a selection of the agent type, and a set of memory reading parameters including the starting virtual address, the number of bytes to read, and the offset(s) used for traversal. Based on this method, we have developed four user space VMI programs that collect different critical kernel objects and have distinct memory reading behaviors. The objectives and logics of the four programs are explained below.

- syscalldmp It dumps totally 351 entries of the guest's system call table pointed to by `sys_call_table`. A continuous block of 1404 bytes from the guest is returned to the program.
- pidlist It lists all process identifiers in the guest. It traverses the `task_struct` list pointed to by the kernel symbol `init_task`, and records the `PID` value of every visited structure in the list. In total, 4 bytes are returned while 8 bytes are read from the guest for each task.
- pslist It lists all tasks' identifiers and task names stored in `task_struct`. A task's name is stored in the member `comm` with a fixed size of 16 bytes. Hence, 24 bytes are returned for each task node.
- credlist It lists all tasks' credential structures referenced by the `task_struct`'s `cred` pointer. In total, 116 bytes including the credential structure to the application for each task node. Hence it takes more time than pidlist and pslist.

Because of their different memory access patterns, they run with different types of agents. The syscalldmp tool runs with Type-1 agent to perform block-reads. The pidlist and pslist programs work with Type-2 agent and the credlist program works with Type-3 agent. These tools are linked with a small wrapper code to interact with the ImEE-enabled KVM module via the customized `ioctl` handler.

6 Evaluation

We evaluate our prototype from four aspects with LibVMI as the baseline. LibVMI [31] is a cross-platform introspection library which a variety of tools depend on. To the best of our knowledge, LibVMI is the only open-source tool that provides a comprehensive set of API for reading the memory of a VM. In particular, it provides the capability to handle translation from VA to GPA. Therefore, LibVMI plays the role of a building block for live memory access in tools such as Drakvuf[27] and Volatility[37]. Our evaluation consists of four parts. Firstly, we consider the overhead of ImEE, in terms of component costs and the impact on the target VM due to `CR3`-update interception. Secondly, we measure the ImEE's throughput in reading the target memory. Thirdly, we compare the introspection performance of the tools with two functionally equivalent ones implemented with the LibVMI and in the kernel. Lastly, we compare ImEE with LibVMI in a setting with multiple guest VMs.

The hardware platform used to evaluate our implementation is a Dell OptiPlex 990 desktop computer with an Intel Core i7-2600 3.4GHz processor (supporting VT-x) and 4GB DRAM. The target VM in our experiments is a normal KVM instance with 1GB of RAM and 1 vCPU.

6.1 ImEE Overhead

Table 3 summarizes the overheads of the ImEE. It takes a one-time cost of 97 μs to prepare the ImEE environment where the main tasks are to make a copy of the target guest EPT as $\texttt{EPT}_T$, to set up $\texttt{GPT}_L$ and $\texttt{EPT}_L$, and to allocate and setup the ImEE vCPU context. The ImEE activation requires about 3.2 μs, and the agent loading/reloading time is around 6.5 μs. The difference is mainly due to handling of the incoming IPI by host kernel on the ImEE core in the agent reloading case. In comparison, it takes about 100 milliseconds to initialize the LibVMI setting, which is around 1,000 times slower than the ImEE setup.

Overhead	ImEE	LibVMI
Launch time	97 μs	100 ms
Activation time	3.2 μs	-
Agent reloading time	6.5 μs	-

Table 3: Overhead comparison between ImEE and LibVMI.

Guest CR3 Update Interception. To maintain `CR3`

consistency with the target during a session, the hypervisor intercepts the CR3 updates. To evaluate its performance impact on the target, we measure the entailed time cost and run several benchmarks to assess the VM's performance.

The cost due to interception mainly consists of VM-exit, sending an IPI, recording VMCS data, and VM-entry. In total, it takes about 2000 CPU cycles which amounts 0.58 μs in our experiment platform. We run three performance benchmarks: LMbench [3] for system performance, Bonnie++ [1] for disk performance and SPECint 2006 [7] for CPU performance while context switches during their executions are intercepted by the hypervisor. Figure 7 reports the LMbench score for context switch time where the performance drops about 50%.

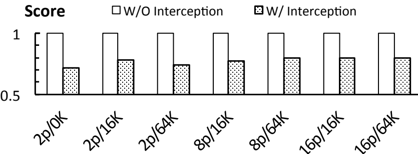

Figure 7: LMBench: normalized result on context switch time. The higher score means better performance.

Nonetheless, the interception does not seem to incur noticeable impact to other benchmark results such as disk I/O and network I/O, as shown in Figure 8, 9 and 10. We attribute this effect to the relatively fewer number of context switches involved during the macro-benchmark runs, because the benchmark processes fully occupy the CPU time slot. It is typical for a Linux process to have between 1ms to 10 ms time-slot before being scheduled off from the CPU.

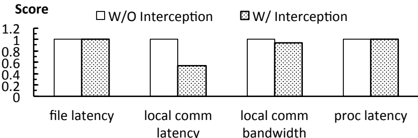

Figure 8: LMBench: normalized result on others system aspects. The higher score means better performance..

Figure 9: Bonnie++: normalized results on disk performance. The higher score means better performance.

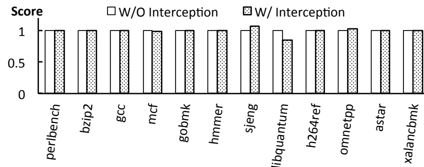

Figure 10: SPEC INT: normalized results on CPU performance. The higher score means better performance.

To understand the impact of CR3 interception in real-life scenarios, we test it with three different workloads on the target VM: idle, online video streaming and file downloading. Neither test shows noticeable performance drop. When the target is under interception, the video is rendered smoothly without noticeable jitters and the file downloading still saturates the network bandwidth.

In our experiments, we find that the introspection encounters few context switches in the target VM. To understand this phenomena, we run experiments to measure the intervals between context switches. Figure 11 shows the distribution of their lengths under different workloads. The analysis shows that the context switch is expected to occur after around 40 μs, which could be used as a guideline for the VMI application to determine the duration of a session. Note that an encounter with the context switch costs about 6.5 μs for the introspection and 0.58 μs for the target VM.

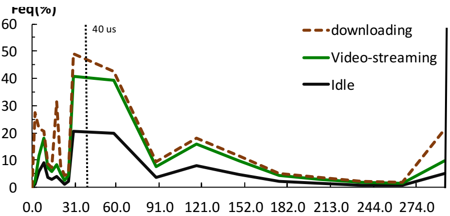

Figure 11: The frequency distribution of interval lengths between context switches in three workloads: idle, video streaming and file downloading. The x-axis is not displayed to the scale.

Lastly, the ImEE has a small memory footprint of a few hundred KB on the host OS. LibVMI has a large memory footprint as it uses up to 14MB to perform a system call table dump.

6.2 Guest Access Speed

The turnaround time for accessing the VM refers to the interval between sending a request and the arrival of the reply. It consists of the time spent for checking the shared buffers and the agent's execution time. To assess the efficiency of the ImEE's interface with the VMI application,

we measure the turnaround time with the ImEE agent performing no task but returning immediately. The result is approximately 265 CPU cycles (or 77 ns) in our setting.

To evaluate the memory-reading performance of the ImEE, we run experiments to evaluate the turnaround time with normal read requests. Table 4 below reports the turnaround time in comparison with LibVMI for the same workload. To make a fair comparison, LibVMI's translation cache is turned on whereas the page-level data cache is turned off.

# of Bytes	**ImEE** (μs)	**LibVMI** (μs)
4	0.353	18.4
64	0.358	18.5
128	0.389	18.4
512	1.643	18.9
1024	1.715	38.1

Table 4: Memory read performance comparison.

We have also tested ImEE with the experiment described in Section 2. The experiment shows that the modification on the `cred` address is caught immediately when the malware makes the first attack. Note that with the ImEE support, it takes less than 1200 CPU cycles for the VMI application to get a DWORD from the guest, in contrast to more than 60,000 cycles using LibVMI. The maximum introspection frequency of ImEE based introspection is 2.83 MHz while an introspection using LibVMI in our setting can only achieve 54 KHz in maximum.

6.3 Introspection Performance Comparison

We run introspection tools (syscalldump, pidlist, pslit and credlist) in three settings: within the kernel, with ImEE, and with LibVMI. Since this set of tests concerns with real-life scenarios, we tested LibVMI on both KVM and Xen for completeness. For each of the scenario, we measure the turnaround time of introspection. The time for the processing the semantics and the time for setting up the ImEE/LibVMI are not included in the measurement. Table 5 summarizes the results.

The experiments show that the ImEE-based introspection has a comparable performance to running inside the kernel. It has a superior performance advantage over LibVMI for traversing the kernel object lists. On KVM, The LibVMI based introspection is around 50 times slower than the ImEE with all caches and 300 times slower without cache. On Xen, LibVMI is around 15 times and 70 times slower, respectively. Since the traversal only returns a few bytes from different pages, LibVMI's optimization in bulk data transferring does not result in performance gain.

6.4 Handling Multiple VMs

In a data center setting, a large number of VMs are hosted on the same physical server. Therefore, for a VMI solution to be effective in such a setting, the capability to handle multiple VM is important. Besides raw introspection speed, two additional capabilities are important for a VMI solution. Firstly, the VMI solution should respond quickly to requests to introspect VMs encountered for the first time. Secondly, it should also maintain swift response for introspection requests on VMs already launched.

We compared the time taken for LibVMI and ImEE to perform a syscall table dump by our tool in two scenarios. We launch four VMs on our experiment platform. Firstly we measure the time for each solution to introspect four VMs once for each in a sequence. It takes 561 ms for LibVMI and 377 μs for ImEE, respectively. In this case, LibVMI is about 1,400 times slower than ImEE. The performance of LibVMI mainly due to the initialization needed for each newly encountered VM.

Secondly, we measure the time taken for each solution for switching the introspection target among the four VMs that are already scanned. The switching requires to reset certain data between consecutive scans. For this purpose, we slightly modified LibVMI to allow us to update the `CR3` value in the introspection context of a VM with a new one. The experiment shows that it takes 19 ms for LibVMI to perform such work while 4.4 μs for ImEE. ImEE shows around 4,300 times speed up. The reason is that LibVMI's software-based approach needs to reset a number of memory states. In contrast, ImEE only needs to fetch the current `CR3` on the target VM's vCPU and replace the ImEE `CR3`, `IP` and the EPT root pointer of the ImEE vCPU.

7 Discussions

7.1 CPU State

In-memory paging structure is only one of the factors that determines the final outcome of the translation of a virtual address. In fact, the final outcome is determined by both in-memory state and in-CPU states. The affecting in-CPU states include control registers and buffers such as the TLB. For example, the TLB can be intentionally made out-of-sync with paging structures in memory, therefore causes the introspection code to use a different mapping from the one currently used by the target. An ideal introspection solution should take into considera-

Tools	Kernel module	ImEE		LibVMI(KVM / Xen)		
		time	mode	without any cache	without page cache	with all cache
syscalldmp	0.2	2.9	block	28.2 / 43	18.7 / 47	2 / 54
pidlist	10	31.6	traversal	5,887 / 2,180	2,864 / 2,041	1,568 / 490
pslist	10.4	38.6	traversal	8,319 / 1477	2,695 / 1,442	1,672 / 542
credlist	25.3	25.6	hybrid	8,234 / 2,274	7,150 / 2,153	2,215 / 757

Table 5: Kernel object introspection performance (time in μs).

tion both sets of states because they collectively represent the current address translation.

However, for out-of-VM live introspection, it is required that it runs on a core that is independent of the target VM. This limits the introspection's capability to utilize such in-CPU states because there is no mechanism to fetch in-CPU states from another CPU. One possible solution is to preempt the vCPU of the target on a physical core by a more privileged entity such as the hypervisor, trying to preserve as many in-CPU states as possible, including buffers and caches. However, the behavior of the buffers an caches when across VM transition is not fixed. Therefore, without hardware assistance, attempts to implement an ideal solution is likely met with hardware-specific tweaks and hacks, making it very difficult. We leave this issue as future work and present a primitive solution in the Appendix.

7.2 Integration with Existing VMI Tools

The ImEE serves as the guest access engine for the VMI applications without involving kernel semantics. It is not challenging to retrofit exiting VMI tools that focus on high-level semantics to benefit from the ImEE's performance and security. We use VMST [19] as an examples to briefly discuss how to combine a VMI application with the ImEE. When an introspection instruction is executed in VMST, the XED library [10] decides whether a data access should be redirected to the guest VM or not. If so, the code fetches the data from the guest memory by traversing the guest VM's page table in the same way as LibVMI. It is easy to integrate VMST with the ImEE. When a read redirection is generated by the XED library, the code simply issues a memory read request to the ImEE and waits for the reply. With the support from the ImEE, shadow TLB and shadow `CR3` proposed in VMST are no longer needed.

7.3 ImEE vs. In-VM Introspection

Strictly speaking, the ImEE and in-VM introspection systems are not comparable, as they are geared for different purposes. The ImEE is for effective target VM access while in-VM systems are designed for reusing the OS's capability [23, 14] or for monitoring events in the guest [34]. Since Process-Implant [23] and SYRINGE [14] rely on a trusted guest kernel, we compare the ImEE with SIM [34] from the perspective of accessing the target VM memory.

Security. Address space isolation in SIM prevents the target VM kernel from tampering with SIM data and code. In a multicore VM, it does not prevent the target VM kernel from interrupting SIM code execution by using non-maskable interrupts. By knocking down the SIM thread from its CPU core, the rootkit can safely erase the attack traces without being caught. In comparison, the entire ImEE environment is separated from the target VM. It is much more challenging (if not feasible) for the target VM kernel to disrupt the ImEE agent's execution. Note that the manipulation on the page tables backfires on the adversary since they are shared between the adversary and the target.

Effectiveness. SIM does not enforce consistent address mappings. The SIM code and the target VM threads are in separated address spaces, namely using separated page tables. The SIM hypervisor does not update the SIM page tables according to the updates in the kernel. In comparison, any update on the target VM page table takes immediate effect on the ImEE and `CR3` consistency is ensured by the hypervisor.

Performance and Usability. Both SIM and ImEE make native speed accesses to the memory without emulating the MMU. ImEE uses EPT and does not require any modification on the target VM, while SIM relies on the shadow page tables and makes non-negligible changes on the target VM.

7.4 Paging Modes Compatibility

The design of ImEE is by nature compatible with various paging modes such as Physical Address Extension mode (PAE mode) and 64-bit paging. It only requires setting of two additional bits in the control registers, namely `PAE` bit in `CR4` register and `LME` bit in `EFER` register so that the ImEE core runs in the needed paging mode. To prevent the adversary from changing the paging mode, the hypervisor trap access to the above registers. To intro-

spect a 64-bit VM, the agent needs to be compiled into 64-bit code as well. In fact, the ImEE performs better on a 64-bit platform, because there are more general purpose registers available, reducing the number of address space switches, and the PCID can be used to prevent the needed TLB entries from being flushed.

7.5 Architecture Compatibility

The ImEE's design is also compatible to other multi-core architectures such as ARM, on the condition that the hardware supports MMU virtualization. Like the x86 platform, ARM multicore processors also feature a per-core MMU, thus each core's translation can be performed independently. As a result, a core can be set up to use the translation used by the other, by setting it to use the same root of paging structures. Moreover, by using $TTBR0$ and $TTBR1$, the hypervisor can easily separate the virtual address ranges used for the target accessing and for the local usage. It simplifies the design as both can use separated page tables. The ARM processor also grants the software more control over the TLB entries. Thus, the needed TLB entries can be locked by the agent. Therefore, we expect better performance than the current design.

8 Related Work

The fundamental problem of VMI is to acquire the kernel's semantic by reconstructing the kernel objects. Significant efforts have been spent in directly recovering the kernel's data structures from the raw bytes. It can be based on expert knowledge (e.g., Memparser [12], GREPEXEC [13], Draugr [17], and others [2, 4, 5, 6, 8, 9, 22, 32]) and automatic tools (e.g, SigGraph [28], KOP [15], and MAS [16]). These studies usually involve a large amount of engineering work and are useful for memory forensic analysis. Since they do not emphasize on live memory introspection, the security and effectiveness of accessing the guest's live state are not their main concerns. In general, they are orthogonal to our study in this paper.

A more sophisticated approach is to reuse the existing kernel to interpret and construct the desired kernel objects from a live guest memory image. Based on whether the introspection uses the guest VM's kernel or not, schemes using this approach can be further divided into in-VM introspection and out-of-VM introspection.

In-VM Introspection. In general, in-VM introspection schemes aim to save the engineering efforts by relying on the guest kernel's capabilities. Process Implanting [23] loads a VMI program such as *strace* and *ltrace* into the guest VM and executes it with the camouflage of an existing process. SYRINGE [14] runs the VMI application in the monitor VM and allows the introspection code to call the guest kernel functions under a guest thread's context. When the guest kernel is not trusted, the security and effectiveness are totally broken, because it is straightforward for a rootkit to evade or tamper with the introspection. Hence, these in-VM introspection schemes are only useful to monitor the user space behavior in the guest VM. SIM [34] is an in-VM monitoring scheme against rootkits. To run the monitoring code inside the untrusted guest, it creates a SIM virtual address space isolated from the guest kernel. Hooks are placed in the guest to intercept events. The address switches between the kernel and the SIM code is guarded by dedicated gates.

Out-of-VM Introspection. The out-of-VM introspection code stays outside of the target guest. Therefore, it is capable of introspecting the guest VM to detect kernel-level malicious activities without directly facing the attack. Virtuoso [18] generates the introspection code by training the monitor application in a trusted VM and reliably extracting the introspection related instructions from the application. The execution trace is replayed in a trusted VM when performing introspection, whose data accesses are redirected to the guest VM's memory. VMST [19] is another out-of-VM introspection technique. It manages to reuse the kernel code by running the introspection application in a monitor VM emulated by QEMU[11]. A taint analysis runs in the monitor VM and relevant data accesses are redirected to the guest's live memory. Hybrid-bridge [33] is a hybrid approach which combines the strengths of both VMST and Virtuoso. Similarly, the VMI application is running in the trusted monitor VM and the OS code is reused. The kernel data accesses which are related to the monitoring functionality are identified and redirected to the guest kernel memory when needed. EXTERIOR [20] is another space traveling approach inspired by VMST, which supports not only guest VM introspection but also reconfiguration and recovery of the guest VM.

Process Out-Grafting [35] relocates the monitored process from the guest VM to the monitor VM. The monitor VM always forwards system calls to the guest. The guest kernel handles it and return back the results to the monitored process. This approach requires the implicit assumption that the guest kernel is trusted.

TxIntro [29] is an out-of-VM and non-blocking approach designed for timely introspection. It mainly focuses on retrofitting the hardware transactional memory to avoid reading inconsistent kernel states. In its design, the VMI code runs on an implanted core and can also access the guest memory at a native speed. Nevertheless, it lacks sufficient security concerns and also fails to help

the introspection code have a consistent memory view with the guest's. In order to make the VMI code see the same mapping with the guest VM's kernel, the L4 entries of kernel addresses in its page table directly point to the L3 page entries existing in the guest VM's memory. However, there is no guarantee that the guest kernel uses these L3 page entries to translate kernel address indeed during its execution. The L4 page table entries can be changed on-the-fly during an introspection run and the guest kernel can have completely different page tables to translate addresses by using another `CR3` value. In fact, unless the introspection code always keeps using the same CR3 value with the guest's directly when reading the guest like ImEE, any change is able to happen on the address mapping used in the guest and it is infeasible for the VMI tool note that. Therefore by following its design, a consistent address translation cannot be achieved and the effectiveness of the introspection is lost.

9 Conclusion

To summarize, we have shown that the software-based address translation widely used in existing out-of-VM introspection systems is not effective to bridge the address gap. We then present the ImEE which provides the architectural support for effective target accesses. The ImEE agent reads the target VM memory at the native speed as its kernel, and the address translation is performed by the hardware in the same way as in the guest. ImEE's native access speed allows consistent memory view with that of the target VM.

Appendices

A TLB-inclusive Introspection

Since the hardware does not automatically maintain the consistency between the TLB entries and the PTEs in the memory, the target VM's adversary can leverage this hardware behavior to defeat introspection. After accessing a page at VA, the adversary then modifies the PTE to map VA to anther GPA without updating the TLB. An introspection based on the page tables then results in a different memory view from the adversary.

The ImEE scheme can be extended to access the target memory through the TLB used by the running target thread. The hypervisor traps the target's core in the same way as describe before. Note that with the new VPID technique from Intel, the TLB entries used by the target are not evicted due to VM-exit. Our basic idea is to load the agent to the trapped vCPU and to set up the identical context used for TLB lookup.

The strongest method is that the hypervisor injects the introspection agent to the thread's address space, by either directly modifying the target memory or using EPT redirection as in the ImEE scheme. The execution of the agent on the target's core uses the TLB for translation since it is in the same address space. Note that it differs from the in-VM introspection, because the agent execution is independent of the target OS. Obviously, this method is intrusive as it changes the target states and may affect the execution of other target's threads involving the modified memory or mappings.

A non-intrusive way is to run the agent in an external address space. As shown in Figure 12, the hypervisor creates a new page table directory with all its entries being copied from the target's except that one entry is mapped to a separated page storing the mappings for the agent. It loads the target's `CR3` with the new page table base. Note that the PCID in the original `CR3` is not changed. When the agent runs, the TLB entries that match the targeted VAs are used by the MMU (if the entry has the same PCID). In case of TLB misses, the agent still introspects the memory in the same way as in the ImEE. The consistency is maintained because the target's thread is not active during introspection. We have experimented with this method. The result shows that the agent does use the mappings in the TLB to read the global page of the target, instead of following the mapping in the page table.

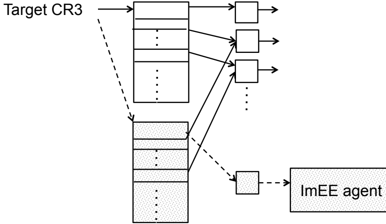

Figure 12: Basic idea of TLB-inclusive introspection. The dashed arrows are used for introspection. The shadowed pages are allocated out of the target's GPA range so that the target's core does not have TLBs for the page table pages.

CAVEAT. The two methods above are only applicable to check the intercepted thread. The adversary can still use a secret PCID to hide its TLBs. It remains as a challenging problem to detect those entries. TLB-inclusive introspection is not equivalent to checking the mappings inside the TLB. Without using special hardware techniques, it is infeasible to for software to inspect every TLB entries.

Oscar: A Practical Page-Permissions-Based Scheme for Thwarting Dangling Pointers

Abstract

Using memory after it has been freed opens programs up to both data and control-flow exploits. Recent work on temporal memory safety has focused on using explicit lock-and-key mechanisms (objects are assigned a new lock upon allocation, and pointers must have the correct key to be dereferenced) or corrupting the pointer values upon `free()`. Placing objects on separate pages and using page permissions to enforce safety is an older, well-known technique that has been maligned as too slow, without comprehensive analysis. We show that both old and new techniques are conceptually instances of lock-and-key, and argue that, in principle, page permissions should be the most desirable approach. We then validate this insight experimentally by designing, implementing, and evaluating Oscar, a new protection scheme based on page permissions. Unlike prior attempts, Oscar does not require source code, is compatible with standard and custom memory allocators, and works correctly with programs that `fork`. Also, Oscar performs favorably – often by more than an order of magnitude – compared to recent proposals: overall, it has similar or lower runtime overhead, and lower memory overhead than competing systems.

1 Introduction

A temporal memory error occurs when code uses memory that was allocated, but since freed (and therefore possibly in use for another object), i.e., when an object is accessed outside of the time during which it was allocated.

Suppose we have a function pointer stored on the heap that points to function `Elmo()` (see Figure 1) at address `0x05CADA`. The pointer is used for a bit and then de-allocated. However, because of a bug, the program accesses that pointer again after its deallocation.

This bug creates a control-flow vulnerability. For example, between the de-allocation (line 7) and faulty re-

```
1  void(**someFuncPtr)() = malloc(sizeof(void*));
2  *someFuncPtr = &Elmo;      // At 0x05CADA
3  (*someFuncPtr)();          // Correct use.
4  void(**callback)();
5  callback = someFuncPtr;
6  ...
7  free(someFuncPtr);         // Free space.
8  userName = malloc(...);    // Reallocate space.
9  ... // Overwrite with &Grouch at 0x05DEAD.
10 (*callback)();             // Use after free!
```

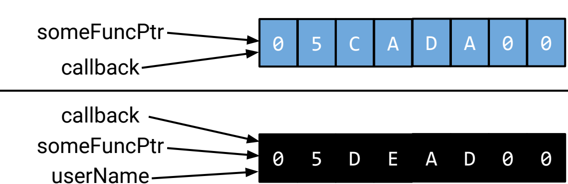

Figure 1: Top: `someFuncPtr` and `callback` refer to the function pointer, stored on the heap. Bottom: `userName` reuses the freed memory, formerly of `someFuncPtr`/`callback`.

use of the pointer (line 10), some other code could allocate the same memory and fill it from an untrusted source – say a network socket. When the de-allocated pointer is faultily invoked, the program will jump to whatever address is stored there, say the address of the ROP gadget `Grouch()` at address `0x05DEAD`, hijacking control flow.

Heap temporal memory safety errors are becoming increasingly important [27, 42]. Stack-allocated variables are easier to protect, e.g., via escape analysis, which statically checks that pointers to a stack variable do not outlive the enclosing stack frame, or can be reduced to the heap problem, by converting stack allocations to heap allocations [33]. Stack use-after-free is considered rare [42] or difficult to exploit [27]; a 2012 study did not find any such vulnerabilities in the CVE database [15]. We therefore focus on temporal memory safety for heap-

allocated objects in the rest of this paper.

Various defenses have been tried. A decade ago, Dhurjati and Adve [23] proposed using page permissions and aliased virtual pages for protection. In their scheme, the allocator places each allocated object on a distinct virtual page, even though different objects may share the same physical page; when an object is deallocated, the corresponding virtual page is rendered inaccessible, causing pointer accesses after deallocation to fail. Although a combination of the technique with static analysis led to reasonable memory economy and performance, critics found faults with evaluation and generality, and – without quantitative comparison – summarily dismissed the general approach as impractical [31, 42], or without even mentioning it [41]. Since then, researchers have proposed more elaborate techniques (CETS [31], DangSan [41], Dangling Pointer Nullification [27] ("DangNull") and FreeSentry [42]), relying on combinations of deeper static analysis and comprehensive instrumentation of heap operations such as object allocation, access, and pointer arithmetic. However, these schemes have yielded mixed results, including poor performance, partial protection, and incompatibility.

In this work, we first study past solutions, which we cast as realizations of a *lock-and-key* protection scheme (Section 2). We argue that using page permissions to protect from dangling pointers, an implicit lock-and-key scheme with lock changes, is less brittle and complex, and has the potential for superior performance. We then develop *Oscar*, a new protection mechanism using page permissions, inspired by Dhurjati and Adve's seminal work [23]. We make the following contributions:

- We study in detail the overhead contributed by the distinct factors of the scheme – shared memory mappings, memory-protection system calls invoked during allocation and deallocation, and more page table entries and virtual memory areas – using the standard SPEC CPU 2006 benchmarks (Section 3).
- We reduce the impact of system calls by careful amortization of virtual-memory operations, and management of the virtul address space (Section 4).
- We extend Oscar to handle server workloads, by supporting programs that `fork` children and the common case of custom memory allocators other than those in the standard C library (Section 5).
- We evaluate Oscar experimentally using both SPEC CPU 2006 and the popular memcached service, showing that Oscar achieves superior performance, while providing more comprehensive protection than prior approaches.

Our work shows, in principle and experimentally, that protection based on page permissions – previously thought to be an impractical solution – may be the most promising for temporal memory safety. The simplicity of the scheme leads to excellent compatibility, deployability, and the lowest overhead: for example, on SPEC CPU, CETS and FreeSentry have 48% and 30% runtime overhead on `hmmer` respectively, vs. our 0.7% overhead; on `povray`, DangNull has 280% overhead while ours is $< 5\%$. While DangSan has runtime overhead similar to Oscar, DangSan's memory overhead (140%) is higher than Oscar's (61.5%). Also, our study of `memcached` shows that both standard and custom allocators can be addressed effectively and with reasonable performance.

2 Lock-and-Key Schemes

Use of memory after it has been freed can be seen as an authorization problem: pointers grant access to an allocated memory area and once that area is no longer allocated, the pointers should no longer grant access to it. Some have therefore used a lock-and-key metaphor to describe the problem of temporal memory safety [31]. In this section, we show how different published schemes map to this metaphor, explicitly and sometimes implicitly, and we argue that page-permission-based protection may be the most promising approach for many workloads (see Table 1 for a summary).

2.1 Explicit Lock-and-Key: Change the Lock

In this scheme, each memory allocation is assigned a lock, and each valid pointer to that allocation is assigned the matching key. In Figure 1, the code is modified so in line 1, the allocated object gets a new lock (say 42), and the matching key is linked to the pointer (see Figure 2). Similarly, in line 5, the key linked to `someFuncPtr` is copied to `callback`. The code is instrumented so that pointer dereferencing (lines 3 and 10) is preceded by a check that the pointer's key matches the object's lock.

When the space is deallocated and reallocated to a new object, the new object is given a new lock (say, 43), and `userName` receives the appropriate key in line 8. The keys for `someFuncPtr` and `callback` no longer match the lock past line 7, avoiding use after free (Figure 3).

Since this scheme creates explicit keys (one per pointer), the memory overhead is proportional to the number of pointers. The scheme also creates one lock per object, but the number of objects is dominated by the number of pointers.

Example Systems: Compiler-Enforced Temporal Safety for C (CETS) [31] is an example of this scheme. Although in our figure we have placed the key next to the pointer (similar to bounds-checking schemes that store

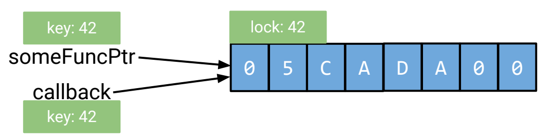

Figure 2: Each pointer has a key, each object has a lock.

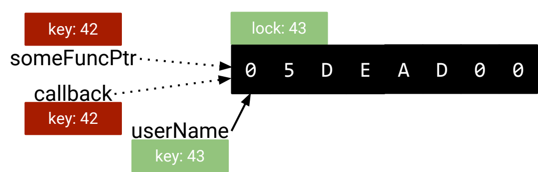

Figure 3: Lock change (see Figure 2 for the 'Before').

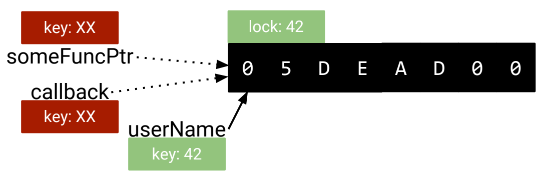

Figure 4: Key revocation (see Figure 2 for the 'Before').

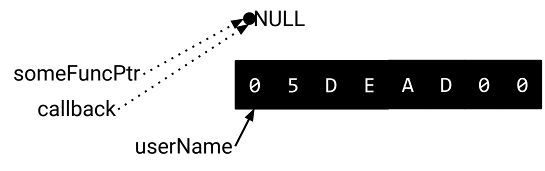

Figure 5: After pointer nullification (see Figure 1 for the 'Before'), object space can be reused safely.

both the pointer plus the size [25], called *plus-size pointers*) and lock next to the object, this need not be the case in implementations. Indeed, one of the key advances of CETS over prior lock-and-key schemes is that it uses a disjoint metadata space, with a separate entry for each pointer that stores the key and the lock location; this avoids changing the memory layout of the program.

2.2 Explicit Lock-and-Key: Revoke the Keys

Instead of changing the lock, one could revoke all keys upon reallocation. This requires tracking of keys throughout memory; for example, freeing either `someFuncPtr` *or* `callback` should revoke the keys for both pointers (Figure 4).

To enable this, upon allocation (line 1) instrumentation must maintain global metadata tracking all pointers to a given object, and this index must be updated at every relevant assignment (line 5). Deallocation (line 7) must be followed by looking up all pointers to that object, revoking (nullifying or otherwise invalidating) their keys. Revoking keys is harder than changing the lock, since it requires tracking of key propagation.

Example Systems: To our knowledge, this has not been used for any published explicit lock-and-key scheme; but, it segues to the next idea that has been used in prior work: revoking the keys with *implicit* lock-and-key.

2.3 Implicit Lock-and-Key: Revoke the Keys

We can view a pointer as the key, and the object as the lock. Thus, instead of revoking a key from a separate *explicit* namespace, we can change the pointer's value [27]. The relevant code instrumentation is similar to the explicit case. Upon allocation or pointer assignment, we update a global index tracking all pointers to each object. Upon deallocation, we find and corrupt the value of all pointers to the deallocated object (Figure 5), say by setting them to `NULL`. Pointer dereferences need not be instrumented, since the memory management unit (MMU) performs the null check in hardware.

Although this scheme does not need to allocate memory for explicit lock or key fields, it does need to track the location of each pointer, which means the physical memory overhead is at least proportional to the number of pointers.[1]

Example Systems: DangNull's dangling pointer nullification [27] is an example of this scheme. FreeSentry [42] is similar, but instead of nullifying the address, it flips the top bits, for compatibility reasons (see Section 6.3). DangSan [41] is the latest embodiment of this technique; its main innovation is the use of append-only per-thread logs for pointer tracking, to improve runtime performance for multi-threaded applications.

2.4 Implicit Lock-and-Key: Change the Lock

Implicit lock-and-key requires less instrumentation than explicit lock-and-key, and changing locks is simpler than tracking and revoking keys. The ideal scheme would therefore be implicit lock-and-key in which locks are changed.

One option is to view the object as a lock, but this lacks a mechanism to "change the lock". Instead, it is more helpful to view the *virtual address* as the lock.

[1] DangSan can use substantially more memory in some cases due to its log-based design.

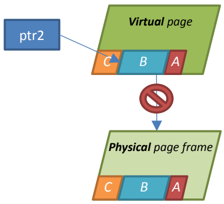

Figure 6: The virtual page has been made inaccessible: accesses to objects A, B or C would cause a fault.

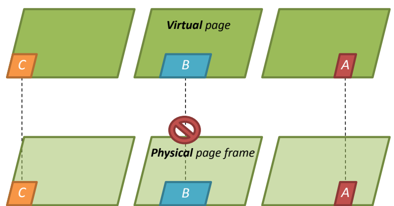

Figure 7: With one object per page, we can selectively disable object B.

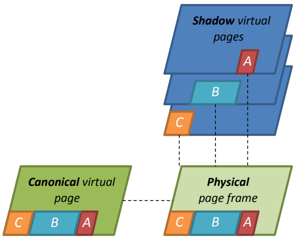

Figure 8: Each object has its own shadow virtual page, which all map to the same physical frame.

Recall that objects (and physical memory) are accessed via virtual addresses, which are translated (by the MMU) into physical addresses. By removing the mapping or changing the page permissions, we can make a virtual page inaccessible; the underlying physical memory can then be mapped to a different virtual address (changed lock) for reuse. A drawback is that making a virtual page inaccessible renders *all* objects on that page – often a non-trivial number, since pages are 4KB or larger – inaccessible (Figure 6). Placing one object per page (Figure 7) is wasteful of memory resources: it uses more memory and strains the cache and the TLB.

It is not strictly necessary to use page permissions to enforce page inaccessibility after deallocation. In principle, we could maintain a hashtable of live pointers, and instrument all the pointer dereferences to check that the pointer is still live, trading off instrumentation for system calls. This would still have less overhead than an explicit lock-and-key scheme, because we would not need to instrument pointer arithmetic.

Example Systems: Electric Fence [9] implements this scheme, by placing one object per physical frame. Its high physical memory usage renders it impractical for anything other than debugging.

Dhurjati and Adve [23] overcame this shortcoming through virtual aliasing. Normally, `malloc` might place multiple objects on one virtual page, which Dhurjati and Adve refer to as the *canonical* virtual page. For each object on the canonical virtual page, they create a *shadow* virtual page that is aliased onto the same underlying physical page frame. This allows each object to be disabled independently (by changing the permissions for the corresponding shadow page), while using physical memory/cache more efficiently than Electric Fence (Figure 8). However, this still requires many syscalls and increases TLB pressure. Furthermore, creating shadows introduces compatibility issues with `fork` (Section 5.1).

The physical memory overhead – one page table entry, one kernel virtual memory area struct, plus some user-space allocator metadata, per object – is proportional to the number of live objects. We expect this to be more efficient than the other classes of lock-and-key schemes, which have overhead proportional to the number of pointers (albeit with a smaller constant factor). Some engineering is required to avoid stateholding of `munmap`'ed page table entries (Section 8).

2.5 Summary of Lock and Key Schemes

Table 1 compares the plausible lock-and-key schemes. Implicit lock-and-key schemes that change the lock (i.e., one object per virtual page) are advantageous by having no overhead for any pointer arithmetic, and no direct cost (barring TLB and memory pressure) for pointer dereferences. Furthermore, the core technique does not require application source code: for programs using the standard allocator, we need only change the `glibc` `malloc` and `free` functions. However, Dhurjati and Adve's full scheme requires application source code to apply their static analysis optimization, which allows them to reuse virtual addresses when a pool is destroyed.

3 Baseline Oscar Design

We will develop the shadow virtual pages idea in a direction that does not require source-code analysis, with less stateholding of kernel metadata for freed objects, and with better compatibility with `fork`. We focus on `glibc` and Linux.

While we have argued that page-permissions-based protections should require less instrumentation than newer schemes, there has been no good data on the overhead of shadows (without reliance on static analysis), let alone quantitative comparisons with recent schemes. In the first part of this paper, we quantify and predict the overhead when using only shadows. These measurements informed our approach for reducing the overhead, which are described in the second part of this paper.

To help us improve the performance of shadow-page-based schemes, we first measure their costs and break

Instrumentation	Explicit lock-and-key: changing the lock e.g., CETS	Implicit lock-and-key: revoking the keys e.g., DangNull/FreeSentry	Implicit lock-and-key: changing the lock e.g., Electric Fence
`malloc ()`	Allocate lock address; Issue key; Set lock	Register pointer	Syscall to create virtual page
Simple ptr arithmetic: `p+=2`	✓ No cost		
General ptr arithmetic: `p=q+1`	Propagate lock address and key	Update ptr registration	✓ No cost
Pointer dereference: `*p`	Check key vs. lock value (at lock address)	✓ No cost	<TLB and memory pressure>
`free ()`	Deallocate lock address	Invalidate pointers	Syscall to disable virtual page
No application source needed	Needs source + recompilation		✓ Yes; Req'd by Dhurjati&Adve
Physical memory overhead	O(# pointers)	O(# pointers)	✓ O(# objects)

Table 1: Comparison of lock-and-key schemes. Green and a tick indicates an advantageous distinction.

down the source of overhead. Shadow-page schemes consist of four elements: modifying the memory allocation method to allow aliased virtual pages, inline metadata to record the association between shadow and canonical pages, syscalls to create and disable shadow pages, and TLB pressure. We measure how much each contributes to the overhead, so we can separate out the cost of each.

It is natural to hypothesize that syscall overhead should be proportional to the number of `malloc`/`free` operations, as page-permissions-based schemes add one or two syscalls per `malloc` and `free`. However, the other costs (TLB pressure, etc.) are less predictable, so measurements are needed.

Our baseline design [23] uses inline metadata to let us map from an object's shadow address to its canonical address. When the program invokes `malloc(numBytes)`, we allocate instead with `internal_malloc(numBytes + sizeof(void*))` to allocate an object within a physical page frame and then immediately perform a syscall to create a shadow page for the object. The object's canonical address is stored as inline metadata within the additional `sizeof(void*)` bytes. This use of inline metadata is transparent to the application, unlike with plus-size pointers. Conceivably, the canonical addresses could instead be placed in a disjoint metadata store (similar to CETS), improving compactness of allocated objects and possibly cache utilization, but we have not explored this direction.

3.1 Measurement Methodology

We quantified the overhead by building and measuring incrementally more complex schemes that bridge the design gap from `glibc`'s `malloc` to one with shadow virtual pages, one overhead factor at a time.

Our first scheme simply changes the memory allocation method. As background, `malloc` normally obtains large blocks of memory with the `sbrk` syscall (via the macro `MORECORE`), and subdivides it into individual objects. If `sbrk` fails, `malloc` obtains large blocks using `mmap(MAP_PRIVATE)`. (This fallback use of `mmap` should not be confused with `malloc`'s special case of placing very large objects on their own pages.) We cannot create shadows aliased to memory that was allocated with either `sbrk` or `mmap(MAP_PRIVATE)`; the Linux kernel does not support this. Thus, our first change was MAP_SHARED arenas: we modified `malloc` to always obtain memory via `mmap(MAP_SHARED)` (which can be used for shadows) instead of `sbrk`. This change unfortunately affects the semantics of the program if it `fork()`s: the parent and child will share the physical page frames underlying the objects, hence writes to the object by either process will be visible to the other. We address this issue – which was not discussed in prior work – in Section 5.1.

MAP_SHARED with padding further changes `malloc` to enlarge each allocation by `sizeof(void*)` bytes for the canonical address. We do not read or write from the padding space, as the goal is simply to measure the reduced locality of reference.

Create/disable shadows creates and disables shadow pages in the `malloc` and `free` functions using `mremap` and `mprotect(PROT_NONE)` respectively, but does not access memory via the shadow addresses; the canonical address is still returned to the caller. To enable the `free` function to disable the shadow page, we stored the shadow address inside the inline metadata field (recall that in the complete scheme, this stores the canonical).

Use shadows returned shadow addresses to the user. The *canonical* address is stored inside the inline metadata field. This version is a basic reimplementation of a shadow-page scheme.

All timings were run on Ubuntu 14.04 (64-bit), using an Intel Xeon X5680 with 12GB of RAM. We disabled hyper-threading and TurboBoost, for more consistent timings. Our "vanilla" `malloc`/`free` was from `glibc 2.21`. We compiled the non-Fortran SPEC CPU2006 benchmarks using `gcc/g++` v4.8.4 with `-O3`. We configured `libstdc++` with `--enable-libstdcxx-allocator=malloc`, and configured the kernel at run-time to allow more virtual memory mappings.

We counted `malloc` and `free` operations using

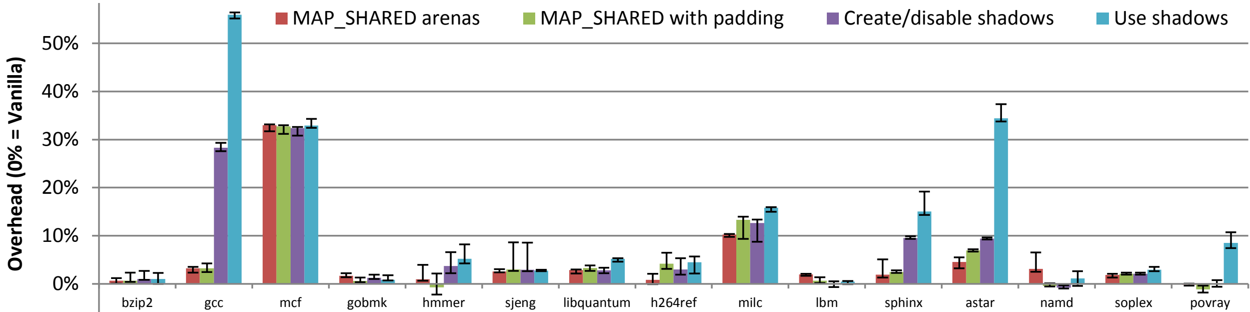

Figure 9: SPEC CPU2006 C/C++ benchmarks, showing the overhead as we reach the full design.

`mtrace`. We placed `mtrace` at the start of `main`, which does miss a small number of allocations (e.g., static initializers and constructors for global C++ objects), but these are insignificant.

3.2 Results

The overhead measurements of the four incrementally more complete schemes are shown in Figure 9 for 15 of the 19 SPEC CPU2006 C/C++ benchmarks. The remaining four benchmarks (`perlbench`, `dealII`, `omnetpp`, `xalancbmk`) exhaust the physical memory on the machine when creating/disabling shadows, due to the accumulation of `vm_area_structs` corresponding to `mprotect`'ed pages of "freed" objects. We therefore defer discussion of them until the following section, which introduces our improvements to the baseline design.

Even for the complete but unoptimized scheme (Use shadows), most benchmarks have low overhead. `gcc` and `sphinx` have high overhead due to creating/destroying shadows, as well as using shadows. `astar` and `povray` have a noticeable cost mainly due to using shadows, a cost which is not present when merely creating/disabling shadows; we infer that the difference is due to TLB pressure. Notably, `mcf`'s overhead is entirely due to MAP_SHARED arenas, as is most of `milc`'s. Inline padding is a negligible cost for all benchmarks.

In Figure 10, we plot the run-time of creating/disabling shadows, against the number of shadow-page-related syscalls[2]. We calculated the y-values by measuring the runtime of Create/disable shadows (we used the high watermark optimization from Section 4 to ensure all benchmarks complete) *minus* MAP_SHARED with padding: this discounts runtime that is not associated with syscalls for shadows. The high correlation matches our mental model that each syscall has an approximately fixed cost, though it is clear from `omnetpp` and `perlbench` that it is not perfectly fixed. Also, we can

[2] A `realloc` operation involves both creating a shadow and destroying a shadow, hence the number of `malloc/free` operations is augmented with `(2 * realloc)`.

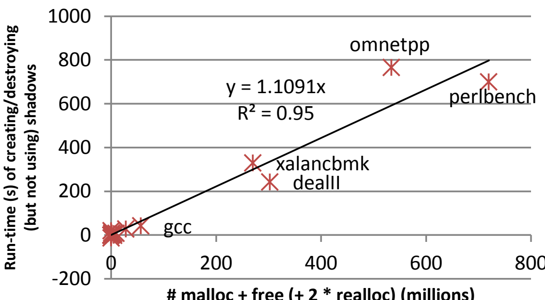

Figure 10: Predicting syscall overhead.

see that `perlbench`, `dealII`, `omnetpp` and `xalancbmk` each create over 100 million objects, which is why they could not run to completion using the unoptimized implementation.

4 Lowering Overhead Of Shadows

The previous section shows that the overhead is due to `MAP_SHARED`, creating/destroying shadows, and using shadows. The cost of using shadows – via TLB pressure – can be reduced with hardware improvements, such as larger TLBs (see Section 6.2). In this section, we propose, implement, and measure three optimizations for reducing the first two costs.

High water mark. The naïve approach creates shadows using `mremap` without a specified address and disables shadows using `mprotect(PROT_NONE)`. Since disabled shadows still occupy virtual address space, new shadows will not reuse the addresses of old shadows, thus preventing use-after-free of old shadows. However, the Linux kernel maintains internal data structures for these shadows, called `vm_area_structs`, consuming 192 bytes of kernel memory per shadow. The accumulation of `vm_area_structs` for old shadows prevented a few benchmarks (and likely many real-world applications) from running to completion.

We introduce a simple solution. Contrary to conven-

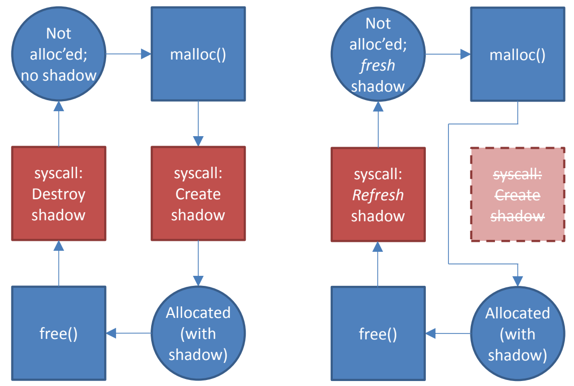

Figure 11: Left: Simplified lifecycle of a chunk of memory. Right: The `destroyShadow` syscall has been modified to simultaneously destroy the old shadow and create a new one.

tional wisdom [23], with a small design modification, Oscar can both unmap and prevent reuse of a virtual page. We use a "high water mark" for shadow addresses: when Oscar creates a shadow, we specify the high water mark as the requested shadow address, and then increment the high water mark by the size of the allocation. This is similar to the `sbrk` limit of `malloc`. Oscar can now safely use `munmap` to disable shadows, without risk of reusing old shadows. As we show in Section 6.1, virtual address space exhaustion is an unlikely, tractable problem.

Our scheme, including the high water mark, is compatible with address space layout randomization (ASLR). At startup, we initialize the high-water mark at a fixed offset to the (randomized) heap base address. To reduce variability in run-times, all benchmarks, including the baseline, were measured without ASLR, as is typical in similar research [40].

Refreshing shadows. Figure 11 (left) depicts the simplified circle of life of a heap-allocated chunk of physical memory. Over the lifetime of a program, that chunk may be allocated, freed, allocated, freed, etc., resulting in syscalls to create a shadow, destroy a shadow, create a shadow, destroy a shadow, etc. Except for the very first time a chunk has been created by `malloc`, every shadow creation is preceded by destroying a shadow.

Oscar therefore speculatively creates a new shadow each time it destroys a shadow, in Figure 11 (right). This saves the cost of creating a new shadow, the next time an object is allocated on that canonical page. The optimistically renewed shadow is stored in a hash table, keyed by the size of shadow (in number of pages) and the address of the canonical *page* (not the canonical object). This means the shadow address can be used for the next similarly-sized object allocated on the canonical page(s), even if the new object does not coincide precisely with the old object's size or offset within the page. It also improves the likelihood that the shadow can be used when objects are coalesced or split by the allocator.

Up to now, we have used `mremap` to create shadows. `mremap` actually can be used to both destroy an old mapping and create a new virtual address mapping (at a specified address) in a single system call. We use this ability to both destroy the old shadow mapping and create a new one (i.e., refresh a shadow) with one system call, thereby collapsing 2 system calls to 1 system call. This optimization depends on the high water mark optimization: if we called `mremap` with `old_size = new_size` without specifying a `new_address`, `mremap` would conclude that there is no need to change the mappings at all, and would return the old shadow virtual address.

Using MAP_PRIVATE when possible. As mentioned earlier, `MAP_SHARED` is required for creating shadows, but sometimes has non-trivial costs. However, for large objects that `malloc` places on their own physical page frames, Oscar does not need more than one shadow per page frame. For these large allocations, Oscar uses `MAP_PRIVATE` mappings.

Implementing `realloc` correctly requires care. Our ordinary `realloc_wrapper` is, in pseudo-code:

```
munmap(old_shadow);
new_canonical = internal_realloc(old_canonical);
new_shadow = create_shadow(new_canonical);
```

This works when all memory is `MAP_SHARED`. However, if the reallocated object (`new_canonical`) is large enough to be stored on its own `MAP_PRIVATE` pages, `create_shadow` will allocate a different set of physical page frames instead of creating an alias. This requires copying the contents of the object to the new page frames. Copying is mildly inefficient, but few programs use `realloc` extensively.

The overhead saving is upper-bounded by the original cost of MAP_SHARED arenas.

Abandoned approach: Batching system calls. We tried batching the creation or destruction of shadows, but did not end up using this approach in Oscar.

We implemented a custom syscall (loadable kernel module ioctl) to create or destroy a batch of shadows. When we have no more shadows for a canonical page, we call our `batchCreateShadow` ioctl once to create 100 shadows, reducing the amortized context switch cost per malloc by 100x. However, this does not reduce the overall syscall cost by 100x, since `mremap`'s internals are costly. In a microbenchmark, creating and destroying 100 million shadows took roughly 90 seconds with individual `mremap/munmap` calls (i.e., 200 million syscalls) vs. ≈80 seconds with our batched syscall. The savings of 10 seconds was consistent with the time to call a no-op ioctl 200 million times.

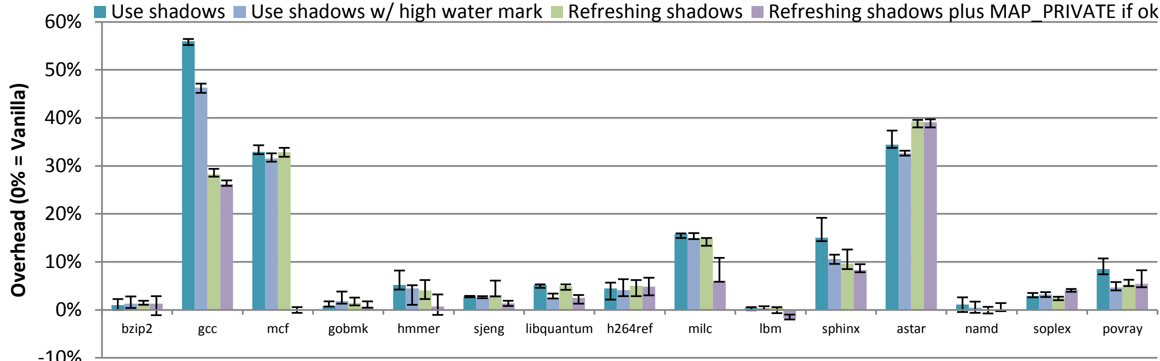

Figure 12: SPEC CPU2006 C/C++ benchmarks, showing the benefits of our optimizations.

In our pilot study, batching did not have a significant benefit. It even slowed down some benchmarks, due to mispredicting which shadows will be needed in the future. For example, we may create 100 shadows for a page that contains solely of a single object which is never freed, wasting 99 shadows.

We also tried batch-disabling shadows: any objects that are `free()`'d are stored in a "quarantine" of 100 objects, and when the quarantine becomes full, we disable all 100 shadows with a single batched syscall, then actually free those 100 objects. This approach maintains temporal memory safety, unlike the standard use of quarantine (see Section 7). Unlike batch-creating shadows, with batch-deletion we need not predict the future.

In our pilot study, batch deletion had mixed effects on runtime overhead. We hypothesize this is due to disrupting favorable memory reuse patterns: `malloc` prefers to reuse recently freed objects, which are likely to be hot in cache; quarantine prevents this.

4.1 Performance Evaluation

The effect of these improvements on the previous subset of 15 benchmarks is shown in Figure 12.

Our first two optimizations (high water mark, refreshing shadows) greatly reduce the overhead for `gcc` and `sphinx`; this is not a surprise, as we saw from Figure 9 that much of `gcc` and `sphinx`'s overhead is due to creating/destroying shadows. These two optimizations do not benefit `mcf`, as its overhead was entirely due to MAP_SHARED arenas; instead, fortuitously, the overhead is eliminated by the `MAP_PRIVATE` optimization. The `MAP_PRIVATE` optimization also reduces the overhead on `milc` by roughly ten percentage points, almost eliminating the overhead attributed to `MAP_SHARED`.

The four allocation-intensive benchmarks are shown in Figure 13. Recall that for these benchmarks, the baseline scheme could not run to completion, owing to the excessive number of leftover `vm_area_structs`

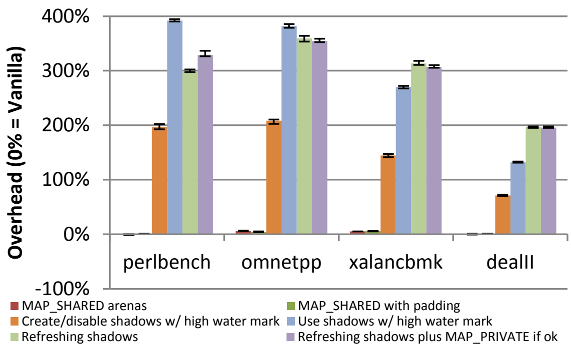

Figure 13: The 4 allocation-intensive benchmarks.

for `mprotect`'ed shadows corresponding to "freed" objects. The high water mark optimization, which permanently `munmaps` the shadows, allows Linux to reclaim the `vm_area_structs`, reducing the memory utilization significantly and enabling them to complete successfully. To separate out the cost of syscalls from TLB pressure, we backported the high water mark change to Create/disable shadows.

For all four benchmarks, `MAP_SHARED` and inline metadata costs (the first two columns) are insignificant compared to creating/disabling and using shadows. Refreshing shadows reduces overhead somewhat for `perlbench` and `omnetpp` but increases overhead for `xalancbmk` and `dealII`.

The `MAP_PRIVATE` optimization had a negligible effect, except for `perlbench`, which became 30 p.p. slower. This was initially surprising, since in all other cases, `MAP_PRIVATE` is faster than `MAP_SHARED`. However, recall that Oscar also had to change the `realloc` implementation. `perlbench` uses `realloc` heavily: 11 million calls, totaling 700GB of objects; this is 19x the `realloc`s of all other 18 benchmarks *combined* (by calls or GBs of objects). We confirmed that `realloc` caused the slowdown, by modifying Refreshing shadows to use the inefficient `realloc` but with `MAP_SHARED` always;

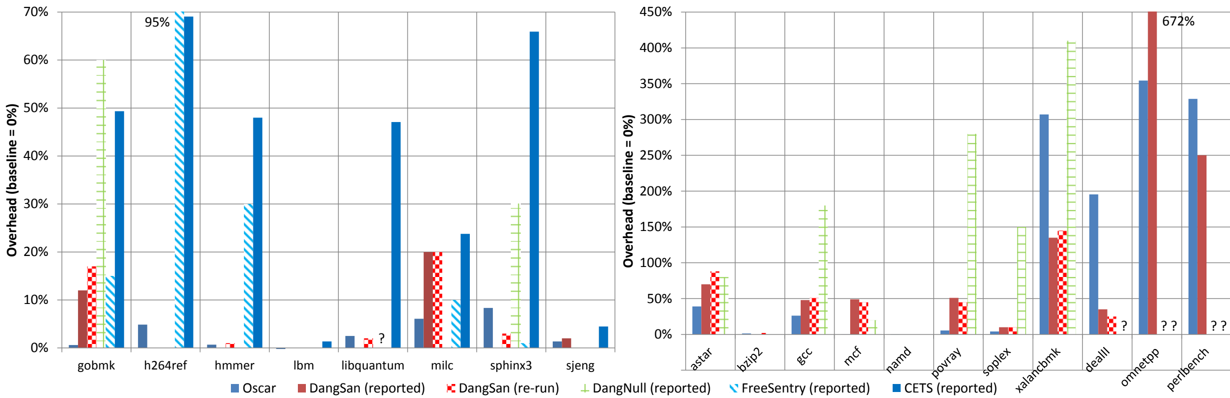

Figure 14: Runtime overhead of SPEC benchmarks. The graphs have different y-axes. Some overheads are based on results reported in the papers, not re-runs (see legend). '?' indicates that FreeSentry did not report results for `libquantum`, DangNull did not report results for `dealII`, `omnetpp`, or `perlbench`, and we could not re-run DangSan on `omnetpp` or `perlbench`. FreeSentry and CETS did not report results for any of the benchmarks in the right graph.

this was marginally slower than refreshing shadows and using `MAP_PRIVATE` where possible.

4.2 Runtime Overhead Comparison

Figure 14 (left) compares the runtime overhead of Oscar against DangSan, DangNull, FreeSentry, and CETS. Figure 14 (right) shows the remaining SPEC benchmarks, for which results were reported by DangSan and DangNull, but not FreeSentry or CETS.

A caveat is that CETS' reported overheads are based on providing temporal protection for both the stack and heap, which is more comprehensive than Oscar's heap-only protection. However, since CETS must, to a first approximation, fully instrument pointer arithmetic and dereferencing instructions even if only heap protection is desired, we expect that the overhead of heap-only CETS would still be substantially higher than Oscar.

All other comparisons (DangSan, DangNull, FreeSentry) are based on the appropriate reported overheads for heap-only temporal protection.

Comparison to DangSan. We re-ran the latest publicly available version of DangSan[3] on the same hardware as Oscar. DangSan re-run overheads were normalized to a re-run with their "baseline LTO" script. We were unable to re-run `perlbench` due to a segmentation fault, or `omnetpp` due to excessive memory consumption[4]. As seen in the graphs, our re-run results are very similar to DangSan's reported results; thus, unless otherwise stated, we will compare Oscar against the latter.

Across the complete set of C/C++ SPEC CPU2006 benchmarks, Oscar and DangSan have the same overall overhead, within rounding error (geometric means of 40% and 41%). However, for all four of the allocation-intensive benchmarks, as well as `astar` and `gcc`, the overheads of both Oscar and DangSan are well above the 10% overhead threshold [39], making it unlikely that either technique would be considered acceptable. If we exclude those six benchmarks, then Oscar has average overhead of 2.5% compared to 9.9% for DangSan. Alternatively, we can see that, for five benchmarks (`mcf`, `povray`, `soplex`, `gobmk`, `milc`), Oscar's overhead is 6% or less, whereas DangSan's is 10% or more. There are no benchmarks where DangSan has under 10% overhead but Oscar is 10% or more.[5]

Comparison to DangNull/FreeSentry. We emailed the first authors of DangNull and FreeSentry to ask for the source code used in their papers, but did not receive a response. Our comparisons are therefore based on the numbers reported in the papers rather than by re-running their code on our system. Nonetheless, the differences are generally large enough to show trends. In many cases, Oscar has almost zero overhead, implying there are few `malloc`s/`free`s (the source of Oscar's overhead); we expect the negligible overhead generalizes to any system. Oscar does not instrument the application's pointer arithmetic/dereferencing, which makes its overhead fairly insensitive to compiler optimizations. We also note that DangSan – which we were able to re-run and compare against Oscar – *theoretically* should have better performance than DangNull[6].

[3] March 19, 2017, `https://github.com/vusec/dangsan/commit/78006af30db70e42df25b7d44352ec717f6b0802`

[4] We estimate that it would require over 20GB of memory, taking into account the baseline memory usage on our machine and DangSan's reported overhead for `omnetpp`.

[5] Of course, there is a wide continuum of "under 10%", and those smaller differences may matter.

[6] However, DangSan's empirical comparisons to DangNull and FreeSentry were also based on reported numbers rather than re-runs.

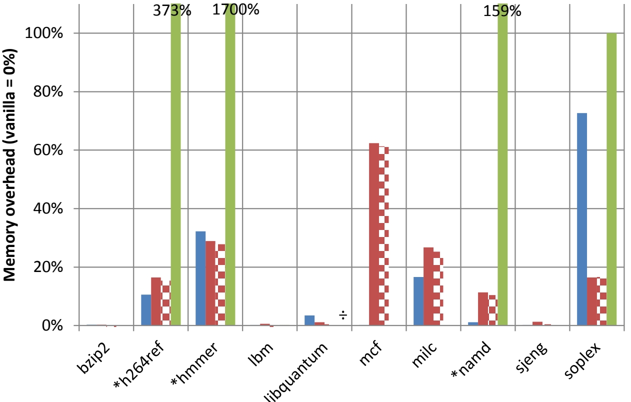

Figure 15: Memory overhead on CPU2006. DangNull reported a baseline of 0MB for libquantum, so an overhead ratio is not calculable.

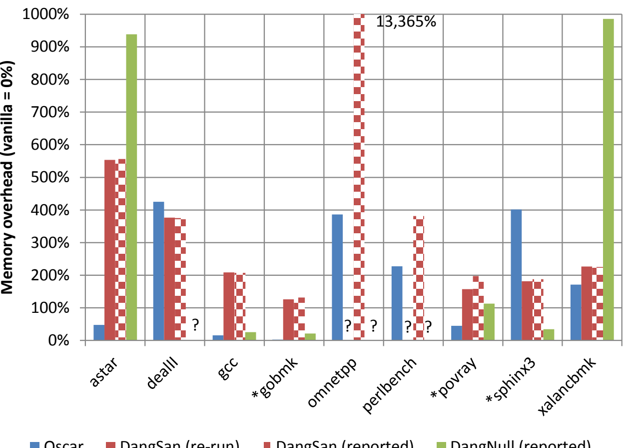

Figure 16: Memory overhead on CPU2006 (continued). '?' indicates that DangNull did not report memory usage for `dealII`, `omnetpp`, or `perlbench`, and we could not re-run DangSan on the latter two.

Oscar's performance is excellent compared to FreeSentry and DangNull, even though DangNull provides less comprehensive protection: DangNull only protects pointers to heap objects *if* the pointer is itself stored on the heap. Figure 14 (left) compares all SPEC CPU2006 benchmarks for which DangNull and FreeSentry both provide data. FreeSentry has higher overhead for several benchmarks (`milc`, `gobmk`, `hmmer`, `h264ref`) – especially higher for the latter three. FreeSentry is faster on the remaining three benchmarks, but in all those cases except for `sphinx3`, our overhead is negligible anyway. DangNull has much higher overhead than Oscar for `gobmk` and `sphinx3`. For other benchmarks, DangNull often gets zero overhead, though it is not much lower than Oscar's, and comes with the caveat of their weaker protection.

Our comparisons are based on our overall "best" scheme with all three optimizations. For some benchmarks, using just the high water mark optimization and not the other two optimizations would have performed better. Even the basic shadow pages scheme without optimizations would often beat DangNull/FreeSentry.

Figure 14 (right) shows additional SPEC CPU2006 benchmarks for which DangNull reported their overhead but FreeSentry did not. For the two benchmarks where DangNull has zero overhead (`bzip2`, `namd`), Oscar's are also close to zero. For the other six benchmarks, Oscar's overhead is markedly lower. Two highlights are `soplex` and `povray`, where DangNull's overhead is 150%/280%, while Oscar's is under 6%.

When considering only the subset of CPU2006 benchmarks that DangNull reports results for (i.e., excluding `dealII`, `omnetpp` and `perlbench`), Oscar has a geometric mean runtime overhead of 15.4% compared to 49% for DangNull. For FreeSentry's subset of reported benchmarks, Oscar has just 2.8% overhead compared to 18% for FreeSentry.

Comparison to CETS. We compare Oscar to the temporal-only mode of SoftBoundCETS [32] (which we will also call "CETS" for brevity), since that has lower overhead and a more comprehensive dataset than the original CETS paper.

The latest publicly available version of SoftBoundCETS for LLVM 3.4[7] implements both temporal and spatial memory safety. We received some brief advice from the author of SoftBoundCETS on how to modify it to run in temporal-only mode, but we were unable to get it to work beyond simple test programs. Thus, our comparisons rely on their reported numbers rather than a re-run.

We have omitted the `bzip2` and `mcf` benchmarks, as CETS' bzip2 is from the CPU2000 suite [29] and we suspect their mcf is as well.[8] SPEC specifically cautions that, due to differences in the benchmark workload and/or source, the results on CPU2000 vs. CPU2006 might not be comparable [5].

Figure 14 (left) shows the overhead of CETS vs. our overall best scheme. We are faster than CETS for all benchmarks, often by a significant margin. For example, CETS has >48% overhead on `gobmk` and `hmmer`, compared to less than 1% for Oscar. The geometric mean across CETS' subset of CPU2006 benchmarks is 2.8% for Oscar compared to 36% for CETS.

[7] September 19, 2014, `https://github.com/santoshn/softboundcets-34/commit/9a9c09f04e16f2d1ef3a906fd138a7b89df44996`

[8] In any case, since CETS has 23% and 114% overhead on `bzip2` and `mcf` respectively – compared to less than 1.5% on each for Oscar – including them in the comparison would not be favorable to CETS.

4.3 Memory Overhead Comparison

Figures 15 and 16 show the memory overhead of Oscar, DangSan (re-run and reported), and DangNull (reported only). We did not find any reported data for FreeSentry, CETS or SoftBoundCETS temporal-only. The graphs have different y-axes to highlight differences in overheads in the lower-overhead benchmarks of Figure 15.

We calculated the memory overhead based on the combined maximum resident set size (RSS)[9], size of the page tables[10], and approximate size of the `vm_area_structs`[11]. Our polling approach introduces some minor inaccuracies with regard to obtaining the maxima and baseline values. For DangSan, which does not greatly increase the number of page table entries or `vm_area_structs`, this is very similar to their maximum resident set size metric. It is unclear what memory consumption metric DangNull used, so some care should be taken when interpreting their overheads.

The RSS values reported in `/proc/pid/status` are misleading for Oscar because it double-counts every shadow page, even though many of them are aliased to the same canonical. We know, however, that the physical memory usage of Oscar – and therefore the resident set size when avoiding double-counting – is essentially the same as the MAP_SHARED with padding scheme (from Section 3.1). We therefore calculated the maximum RSS for that scheme, but measured the size of the page tables and `vm_area_structs` for the full version of Oscar.

For the complete suite of CPU2006 benchmarks, Oscar has 61.5% memory overhead, far lower than DangSan's 140%. Even if we omit DangSan's pathological case of `omnetpp` (reported overhead of over 13,000%), Oscar is still far more memory-efficient with 52% overhead vs. 90% for DangSan. The only benchmarks on which Oscar performs substantially worse than DangSan are `sphinx3` and `soplex`. `sphinx3` with Oscar has a maximum RSS of ≈50MB (compared to a baseline of ≈45MB), maximum page tables size of ≈130MB, and maximum `vm_area_structs` of ≈45MB. In Section 8, we propose methods to reduce the memory overhead by garbage collecting old page table entries (which would benefit `sphinx3`), and sharing inline metadata (which benefits would `soplex` with its many small allocations).

DangNull has roughly 127% memory overhead, but, as also noted by the DangSan authors, DangNull did not report data for many of the memory-intensive benchmarks. If we use the same subset of SPEC benchmarks that DangNull reported, then Oscar has only 36% memory overhead (vs. ≈75% for DangSan).

[9] `VmHWM` (peak RSS) in `/proc/pid/status`

[10] `VmPTE` and `VmPMD` in `/proc/pid/status`

[11] We counted the number of mappings in `/proc/pid/maps` and multiplied by `sizeof(vm_area_struct)`.

5 Extending Oscar for Server Applications

When applying Oscar to server applications – which are generally more complex than the SPEC CPU benchmarks – we encountered two major issues that resulted in incompatibility and incomplete protection: forking and custom memory allocators. Additionally, we modified Oscar to be thread-safe when allocating shadows.

5.1 Supporting shadows + fork()

Using `MAP_SHARED` for all allocations is problematic for programs that `fork`, as it changes the semantics of memory: the parent and child's memory will be shared, so any post-`fork` writes to pre-`fork` heap objects will unexpectedly be visible to both the parent and child. In fact, we discovered that most programs that `fork` and use `glibc`'s `malloc` will crash when using `MAP_SHARED`. Surprisingly, they may crash even if neither the parent nor child read or write to the objects post-`fork`.[12]

Oscar solves this problem by wrapping `fork` and emulating the memory semantics the program is expecting. After `fork`, in the child, we make a copy of all heap objects, unmap their virtual addresses from the shared physical page frames, remap the same virtual addresses to new (private) physical page frames, and repopulate the new physical page frames with our copy of the heap objects. The net effect is that the shadow and canonical virtual addresses have not changed – which means old pointers (in the application, and in the allocator's free lists) still work – but the underlying physical page frames in the child are now separated from the parent.

Method. Oscar instruments `malloc` and `free` to keep a record of all live objects in the heap and their shadow addresses. Note that with a loadable kernel module, Oscar could avoid recording the shadow addresses of live objects and instead find them from the page table entries or `vm_area_structs`.

Then, Oscar wraps `fork` to do the following:

1. call the vanilla `fork()`. After this, the child address space is correct, except that the `malloc`'d memory regions are aliased with the parent's physical page frames.

2. in the child process:

   (a) for each `canonical_page` in the heap:

[12] `glibc`'s `malloc` stores the main heap state in a static variable (not shared between parent and child), but also partly through inline metadata of heap objects (shared); thus, when the parent or child allocates memory post-`fork`, the heap state can become inconsistent or corrupted. A program that simply `malloc()`s 64 bytes of memory, `fork()`s, and then allocates another 64 bytes of memory in the child, is sufficient to cause an assertion failure.

   i. allocate a new page at any unused address `t` using `mmap(MAP_SHARED | MAP_ANONYMOUS)`
   ii. copy `canonical_page` to `t`
   iii. call `mremap(old_address=t, new_address=canonical_page)`. Note that `mremap` automatically removes the previous mapping at `canonical_page`.

(b) for each live object: use `mremap` to recreate a shadow at the same virtual address as before (using the child's new physical page frames).

Compared to the naïve algorithm, the use of `mremap` halves the number of memory copy operations.

We can further reduce the number of system calls by observing that the temporary pages `t` can be placed at virtual addresses of our choice. In particular, we can place all the temporary pages in one contiguous block, which lets us allocate them all using just one `mmap` command.

The parent process must sleep until the child has copied the canonical pages, but it does not need to wait while the child patches up the child's shadows. Oscar blocks signals for the duration of the `fork()` wrapper.

This algorithm suffices for programs that have only one thread running when the program forks. This covers most reasonable use cases; it is considered poor practice to have multiple threads running at the time of `fork` [6]. For example, `apache`'s event multi-processing module forks multiple children, which each then create multiple threads. To cover the remaining, less common case of programs that arbitrarily mix threads and `fork`, Oscar could "stop the world" as in garbage collection, or LeakSanitizer (a memory leak detector) [1].

Our algorithm could readily be modified to be "copy-on-write" for efficiency. Additionally, batching the remappings of each page might improve performance; since the intended mappings are known in advance, we could avoid the misprediction issue that plagued regular batch mapping. With kernel support we could solve this problem more efficiently, but our focus is on solutions that can be deployed on existing platforms.

Results. We implemented the basic algorithm in Oscar. In cursory testing, `apache`, `nginx`, and `openssh` run with Oscar's `fork` fix, but fail without. These applications allocate only a small number of objects pre-`fork`, so Oscar's `fork` wrapper does not add much overhead (tens or hundreds of milliseconds).

5.2 Custom Memory Allocators

The overheads reported for SPEC CPU are based on instrumenting the standard `malloc/free` only, providing a level of protection similar to prior work. However, a few of the SPEC benchmarks [19] implement their own custom memory allocator (CMAs). Since standard schemes for temporal memory safety require instrumenting memory allocation and deallocation functions, without special provisions none of them – including Oscar – will protect objects allocated via arbitrary CMAs.

We found that CMAs seem to be even more common in server programs, such as `apache`, `nginx`, and `proftpd`. Prior work typically ignores the issue of CMAs. We solve this by manually identifying CMAs and wrapping them with Oscar as well. CMA identification could also be done automatically [18].

If we do not wrap a CMA with Oscar, any objects allocated with the CMA would obviously not be resistant to use-after-free. However, there are no other ill effects; it would not result in any false positives for any objects, nor would it result in false negatives for the non-CMA objects.

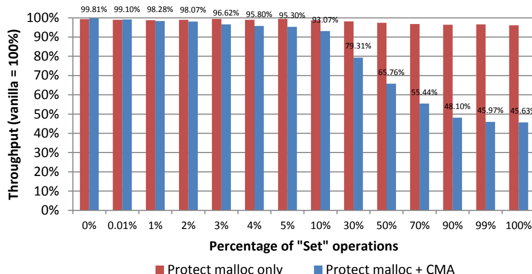

Figure 17: Throughput of Oscar on memcached.

5.3 Case Study: malloc-like custom memory allocator in memcached

`memcached` is a memory object caching system that exports a get/set interface to a key-value store. We compiled `memcached 1.4.25` (and its prerequisite, `libevent`) and benchmarked performance using `memaslap`.

When we wrapped only `glibc`'s `malloc`, the overhead was negligible: throughput was reduced by 0–3%, depending on the percentage of set operations (Figure 17). However, this is misleadingly low, as it fails to provide temporal memory safety for objects allocated by the CMA. Therefore, we applied Oscar to wrap the CMA, in the same way we wrapped glibc's `malloc/free`.

Method. To support wrapping the CMA, we had to ensure that Oscar `malloc` always used `MAP_SHARED` even for large objects. This is because the allocation may be used by the CMA to "host" a number of shadows. Additionally, we partitioned the address space to use separate high-water marks for the `malloc` wrapper and CMA wrapper.

We identified that allocations and deallocations via

memcached's slab allocator are all made through the do_item_alloc and item_free functions. Thus, it is sufficient to add shadow creation/deletion to those functions.

For ease of engineering, we made minor changes directly to the slab allocator, similar to those we applied to glibc's malloc: inserting a canonical address field in the memcached item struct, and modifying the allocation/deallocation functions. In principle, we only need to override the CMA allocate/deallocate symbols, without needing to recompile the main application.

In this paper, the per-object metadata (e.g., the canonical address) is stored inline. If Oscar switched to a disjoint metadata store (e.g., a hashtable), it would be easy to extend Oscar to protect any custom memory allocators (not just CMAs with malloc-like interfaces) that are identified: as with glibc's malloc, the allocator function simply needs to be wrapped to return a new shadow, and the deallocator function wrapped to destroy the shadow. This would be a better long-term approach than individually dealing with each CMA that is encountered.

Results. When set operations are 3% of the total operations (a typical workload [12]), the performance overhead is roughly 4%. The overhead is higher for set operations because these require allocations (via the CMA), which involves creating shadows. Get operations have almost no overhead because they do not perform memory allocation or deallocation and consequently do not require any system calls.[13] Unlike SPEC CPU, which is single-threaded, we ran memcached with 12 threads. This shows that Oscar's overhead is low even for multi-threaded applications, despite our naïve use of a mutex to synchronize part of Oscar's internal state (namely, the high-water mark; see Section 8).

5.4 Special case: Region-based allocators

We have found several server programs that use region-based custom memory allocators [14]. Region-based allocators are particularly favorable for page-permissions-based schemes such as Oscar.

Typically, region-based allocators obtain a large block of memory from malloc, which they carve off into objects for their allocations. The distinguishing feature is that only the entire region can be freed, but not individual objects.

Region-based allocators by themselves are not resistant to use-after-free, since the blocks from malloc may be reused, but they provide temporal memory safety when the underlying malloc/free is protected by a lock-and-key scheme. Thus, there is no need to explicitly identify region-based CMAs; merely wrapping glibc's malloc/free with Oscar suffices to provide temporal memory safety for such programs i.e., Oscar would provide full use-after-free protection for a region-based allocator, without the need for any custom modifications.

Oscar's performance is especially good for programs that use region-based allocators: since there are few malloc()s or free()s to instrument, and correspondingly low memory or TLB pressure, Oscar imposes negligible overhead. Other classes of lock-and-key schemes also provide full protection to programs with region-based allocators, but they often have high overhead, since they must instrument all pointer arithmetic operations (and possibly pointer dereferences).

[13] Technicality: memcached lazily expires entries, checking the timestamp only during the get operation. Thus, the overhead of destroying shadows may be attributed to get operations.

6 Discussion

Our results show that shadow-page-based schemes with our optimizations have low overhead on many benchmarks. From Table 1, we argue that changing the lock is theoretically easier than revoking all the keys, and implicit lock-and-key is better than explicit. Our experimental results confirm that prediction: Oscar's runtime overhead is lower than CETS, DangNull, and FreeSentry overall and on most benchmarks, and comparable to DangSan (but with lower memory overhead for Oscar), even though they all need source code while Oscar does not.

6.1 Virtual Address Space Considered Hard to Fill

A concern might be that Oscar would exhaust the $2^{47}B$ =128TB user-space virtual address space, necessitating reuse of addresses belonging to freed pages. This is unlikely in common scenarios. Based on extrapolating the CPU2006 benchmarks, it would take several *days* of continuous execution even for allocation-intensive programs. For example, with perlbench, which allocates 361 million objects (≈1.4TB of shadow virtual pages; >99% of objects fit in one page) over 25 minutes, it would take 1.6 days (albeit less on newer, faster hardware) to allocate 128TB. dealII, omnetpp and xalancbmk would take over 2.5 days each, gcc would take 5 days, and all other CPU2006 benchmarks would take at least 2 *weeks*. We expect that most programs would have significantly shorter lifetimes, and therefore would never exhaust the virtual address space. It is more likely that they would first encounter problems with the unreclaimed page-table memory (see Section 8). Nonetheless, it is possible to ensure safe reuse of virtual address space, by applying a conservative garbage collector to old shadow addresses (note that this does not

affect physical memory, which is already reused with new shadow addresses); this was proposed (but not implemented) by Dhurjati and Adve.

Recently, Intel has proposed 5-level paging, allowing a 57-bit virtual address space [20]; implementation of Linux support is already underway [37]. This 512-fold increase would make virtual address space exhaustion take *years* for every CPU2006 benchmark.

6.2 Hardware Extensions

Due to the high overhead of software-based temporal memory safety for C, some have proposed hardware extensions (e.g., Watchdog [30]). Oscar is fast because it *already* utilizes hardware – hardware which is present in many generations of x86 CPUs: the memory management unit, which checks page table entries. We believe that, with incremental improvements, shadow-page-based schemes will be fast enough for widespread use, without the need for special hardware extensions. For example, Intel's Broadwell CPUs have a larger TLB and also a second TLB page miss handler [7], which are designed to improve performance for general workloads, but would be particularly useful in relieving Oscar's TLB pressure. Intel has also proposed finer grained memory protection [35]; if future CPUs support read+write protection on subpage regions, Oscar could be adapted to one-object-per-*subpage*, which would reduce the number of shadows (and thereby TLB pressure).

6.3 Compatibility

Barring virtual address space exhaustion (discussed in Section 6.1), Oscar will crash a program if and only if the program *dereferences* a pointer after its object has been freed. It does not interfere with other uses of pointers. Unlike other lock-and-key schemes, page-permissions-based schemes do not need to instrument pointer arithmetic or dereferencing (Table 1).

Accordingly, Oscar correctly handles many corner cases that other schemes cannot handle. For example, DangNull/FreeSentry do not work correctly with encrypted pointers (e.g., PointGuard [21]) or with typecasting from non-pointer types. CETS has false positives when casting from a non-pointer to pointer, as it will initialize the key and lock address to invalid values.

Additionally, DangNull does not allow pointer arithmetic on freed pointers. For example, suppose we allocate a string `p` on the heap, search for a character, then free the string:

```
char* p = strdup("Oscar"); // Memory from malloc
char* q = strchr(p, 'a');  // Find the first 'a'
free(p);
```

Computing the index of "a" (`q - p == 3`) fails with DangNull, since `p` and `q` were nullified. It does work with DangSan and FreeSentry (since they only change the top bits) and with Oscar.

DangSan, DangNull and FreeSentry only track the location of pointers when they are stored in memory, but not registers. This can lead to false negatives: DangSan notes that this may happen with pointers spilled from registers onto the stack during function prologues, as well as race conditions where a pointer may be stored into a register by one thread while another thread frees that object. DangSan considers both issues to be infeasible to solve (for performance reasons, and also the possibility of false positives when inspecting the stack).

7 Related Work

7.1 Dhurjati and Adve (2006)

Our work is inspired by the original page-permission with shadows scheme by Dhurjati and Adve [23]. Unlike Dhurjati and Adve's automatic pool allocation, Oscar can unmap shadows as soon as an object is freed, and does not require source code. Oscar also addresses compatibility with `fork`, which appears to be a previously unknown limitation of Dhurjati and Adve's scheme[14]. They considered programs that `fork` to be advantageous, since virtual address space wastage in one child will not affect the address space of other children. Unfortunately, writes to old (pre-`fork`) heap objects will be propagated between parent and children (see Section 5.1), resulting in memory corruption.

While Dhurjati and Adve did measure the runtime of their particular scheme, their measurements do not let us break down how much each aspect of their scheme contributes to runtime overhead. First, their scheme relies upon static analysis (*Automatic Pool Allocation*: "PA"), and they did not measure the cost of shadow pages without PA. We cannot simply obtain "cost of syscalls" via "(PA + dummy syscalls) − PA", since pool allocation affects the cost of syscalls and cache pressure. Second, they did not measure the cost of each of the four factors we identified. For instance, they did not measure the individual cost of inline metadata or changing the memory allocation method; instead, they are lumped in with the cost of dummy syscalls. This makes it hard to predict the overhead of other variant schemes, e.g., using one object per physical page frame. Finally, they used a custom benchmark and Olden [34], which make it harder to compare their results to other schemes that are benchmarked with SPEC CPU; and many of their benchmark

[14] We inspected their source `http://safecode.cs.illinois.edu/downloads.html` and found that they used `MAP_SHARED` without a mechanism to deal with `fork`.

	One object per physical page frame	One object per shadow virtual page (core technique of Dhurjati & Adve [D&A])		
Physical memory overhead	**e.g., Electric Fence**	**Vanilla**	**Automatic pool allocation [D&A]**	**Our work**
User-space memory	0 – 4KB per object (page align)	✓ Low overhead (O(sizeof(void*)) per object)		
Page table entry for live objects	1 page table entry per object			
Page table entry for freed objs	<Depends on implementation>	1 PTE per object	1 PTE per object in live pools	0 PTEs*
VMA struct for live objects	1 VMA struct per object			
VMA struct for freed objects	<Depends on implementation>	1 VMA struct per object		✓ None
No application source needed	✓ Yes	✓ Yes	No; needs source + recompilation	✓ Yes
Compatible with fork()	✓ Yes	No; changes program semantics		✓ Mostly

Table 2: Comparison with Dhurjati and Adve. Green and a tick indicates an advantageous distinction. $*$ Oscar unmaps the shadows for freed objects, but Linux does not reclaim the PTE memory (see Section 8).

run-times are under five seconds, which means random error has a large impact. For these reasons, in this work we undertook a more systematic study of the sources of overhead in shadow-page-based temporal memory safety schemes.

To reduce their system's impact on page table utilization, Dhurjati and Adve employed static source-code analysis (Automatic Pool Allocation) – to separate objects into memory pools of different lifetimes, beyond which the pointers are guaranteed not to be dereferenced. Once the pool can be destroyed, they can remove (or reuse) page table entries (and associated `vm_area_structs`) of freed objects. Unfortunately, there may be a significant lag between when the object is freed, and when its containing pool is destroyed; in the worst case (e.g., objects reachable from a global pointer), a pool may last for the lifetime of the program. Besides being imprecise, inferring object lifetimes via static analysis also introduces a requirement to have application source code, making it difficult and error-prone to deploy. Oscar's optimizations do not require application source code or compiler changes.

We cannot directly compare Oscar's overhead to Dhurjati and Adve's full scheme with automatic pool allocation, since they did not report numbers for SPEC CPU.

Oscar usually keeps less state for freed objects: they retain a page table entry (and associated `vm_area_struct`) for each freed object in live pools – some of which may be long-lived – whereas Oscar `munmaps` the shadow as soon as the object is freed (Table 2). Dhurjati and Adve expressly target their scheme towards server programs – since those do few allocations or deallocations – yet they do not account for `fork` or custom memory allocators.

If we are not concerned about the disadvantages of automatic pool allocation, it too would benefit from our optimizations. For example, we have seen that using `MAP_PRIVATE` greatly reduces the overhead for `mcf` and `milc`, and we expect this benefit to carry over when combined with automatic pool allocation.

7.2 Other Deterministic Protection Schemes

The simplest protection is to never `free()` any memory regions. This is perfectly secure, does not require application source code (change the `free` function to be no-op), has excellent compatibility, and low run-time overhead. However, it also requires infinite memory, which is impractical.

With DangNull [27], when an object is freed, all pointers to the object are set to NULL. The converse policy – when all references to a region are NULL (or invalid), automatically `free` the region – is "garbage collection". In C/C++, there is ambiguity about what is a pointer, hence it is only possible to perform conservative garbage collection, where anything that might plausibly be a pointer is treated as a pointer, thus preventing `free()`'ing of the referent. This has the disadvantages of false positives and lower responsiveness.

The Rust compiler enforces that each object can only have one owner [4]; with our lock-and-key metaphor, this is equivalent to ensuring that each lock has only one key, which may be "borrowed" (ala Rust terminology) but not copied. This means that when a key is surrendered (pointer becomes out of scope), the corresponding lock-/object can be safely reused. It would be impractical to rewrite all legacy C/C++ software in Rust, let alone provide Rust's guarantees to binaries that are compiled from C/C++.

MemSafe [38] combines spatial and temporal memory checks: when an object is deallocated, the bounds are set to zero (a special check is required for sub-object temporal memory safety). MemSafe modifies the LLVM IR, and does not allow inline assembly or self-modifying code. Of the five SPEC 2006 benchmarks they used, their run-times appear to be from the 'test' dataset rather than the 'reference' dataset. For example, for `astar`, their base run-time is 0.00 seconds, whereas Oscar's is 408.9 seconds. Their non-zero run-time benchmarks have significant overhead – 183% for `bzip2`, 127% for `gobmk`, 124% for `hmmer`, and 120% for `sjeng` – though this in-

cludes spatial and stack temporal protection.

Dynamic instrumentation (e.g., Valgrind's memcheck [3]) is generally too slow other than for debugging.

Undangle [15] uses taint tracking to track pointer propagation. They do not provide SPEC results, but we expect it to be even slower than DangNull/FreeSentry, because Undangle determines how pointers are propagated by, in effect, interpreting each x86 instruction.

Safe dialects of C, such as CCured [33], generally require some source code changes, such as removing unsafe casts to pointers. CCured also changes the memory layout of pointers (plus-size pointers), making it difficult to interface with libraries that have not been recompiled with CCured.

7.3 Hardening

The premise of heap temporal memory safety schemes, such as Oscar, is that the attacker could otherwise repeatedly attempt to exploit a memory safety vulnerability, and has disabled or overcome any mitigations such ASLR (nonetheless, as noted earlier, Oscar is compatible with ASLR). Thus, Oscar provides deterministic protection against heap use-after-free (barring address space exhaustion/reuse, as discussed in Section 6.1).

However, due to the high overhead of prior temporal memory safety schemes, some papers trade off protection for speed.

Many papers, starting with DieHard [13], approximate the infinite heap (use a heap that is M times larger than normally needed) and randomize where objects are placed on the heap. This means even if an object is used after it is freed, there is a "low" probability that the memory region has been reallocated. Archipelago [28] extends DieHard but uses less physical memory, by compacting cold objects. Both can be attacked by making many large allocations to exhaust the M-approximate heap, forcing earlier reuse of freed objects.

AddressSanitizer [36] also uses a quarantine pool, though with a FIFO reuse order, among other techniques. PageHeap [2] places freed pages in a quarantine, with the read/write page permissions removed. Attempted reuse will be detected only if the page has not yet been reallocated, so it may miss some attacks. These defenses can also be defeated by exhausting the heap.

Microsoft's MemoryProtection consists of Delayed Free (similar to a quarantine) and Isolated Heap (which separates normal objects from "critical" objects) [8]. Both of these defenses can be bypassed [22].

Cling [11] only reuses memory among heap objects of the same type, so it ensures type-safe heap memory reuse but not full heap temporal memory safety.

7.4 Limiting the Damage from Exploits

Rather than attempting to enforce memory safety entirely, which may be considered too expensive, some approaches have focused on containing the exploit.

Often the goal of exploiting a user-after-free vulnerability is to hijack the control flow, such as by modifying function pointers per our introductory example. One defense is control-flow integrity (CFI) [10], but recent work on "control-flow bending" [16] has shown that even the ideal CFI policy may admit attacks for some programs. Code pointer integrity (CPI) is essentially memory safety (spatial and temporal) applied only to code pointers [26]. Code pointer separation (CPS) is a weaker defense than CPI, but stronger than CFI. Both CPI and CPS require compiler support.

CFI, CPS and CPI do not help against non-control data attacks, such as reading a session key or changing an 'isAdmin' variable [17]; recently, "data-oriented programming" has been shown to be Turing-complete [24].

8 Limitations and Future Work

Oscar is only a proof-of-concept for measuring the overhead on benchmarks, and is not ready for production, primarily due to the following two limitations.

Reclaiming page-table memory takes some engineering, such as using `pte_free()`. Alternatively, the Linux source mentions they "Should really implement gc for free page table pages. This could be done with a reference count in struct page."[15] Not all page-tables can be reclaimed, as some page-tables may contain entries for a few long-lived objects, but the fact that most objects are short-lived (the "generational hypothesis" behind garbage collection) suggests that reclamation may be possible for many page-tables. Note that the memory overhead comparison in Section 4.3 already counts the size of paging structures against Oscar, yet Oscar still has lower overall overhead despite not cleaning up the paging structures at all.

We did not encounter any issues with users' `mmap` requests overlapping Oscar's region of shadow addresses (or vice-versa), but it would be safer to deterministically enforce this by intercepting the users' `mmap` calls.

Currently, all threads share the same high-water mark for placing new shadows, and this high-water mark is protected with a global mutex. A better approach would be to dynamically partition the address space between threads/arenas; for example, when a new allocator arena is created, it could split half the address space from the arena that has the current largest share of the address space. Each arena could therefore have its own

[15] http://lxr.free-electrons.com/source/arch/x86/include/asm/pgalloc.h

high-water mark, and allocations could be made independently of other arenas. This could lower the overhead of the `memcached` benchmarks, but not the SPEC CPU benchmarks (which are all single-threaded).

Our techniques could be applied to other popular memory allocators (e.g., `tcmalloc`), or more generally, any custom memory allocator. The overheads reported for SPEC CPU are based on instrumenting the standard `malloc/free` only, providing a level of protection similar to prior work. Wrapping CMA's provides more comprehensive protection, though the overheads would be higher for a few benchmarks, as discussed in Section 5.2.

If we are willing to modify `internal_malloc`, Oscar can be selective in how to refresh (or batch-create) shadows. For example, objects that are small enough (among other conditions) to fit in `internal_malloc`'s "small bins" are reused in a first-in-first-out order, which means that a speculatively created shadow is likely to be used eventually. Other bins are last-in-first-out or even best-fit, which makes their future use less predictable. This optimization may particularly benefit `xalancbmk` and `dealII`, for which the ordinary refresh shadow approach was a net loss.

We could take advantage of the short-lived nature of most objects to experiment with placing multiple objects per shadow; fewer shadows means lower runtime and memory overhead. To further reduce memory overhead, we could change `internal_malloc` to place the canonical address field at the start of each page, rather than the start of each object. All objects on the page would then share the canonical address field, which could drastically reduce the memory overhead for programs with many small allocations (e.g., `soplex`).

9 Conclusion

Efficient, backwards compatible, temporal memory safety for C programs is a challenging, unsolved problem. By viewing many of the existing schemes as lock-and-key, we showed that page-permissions-based protection schemes were the most elegant and theoretically promising. We built upon Dhurjati and Adve's core idea of one shadow per object. That idea is unworkable by itself due to accumulation of `vm_area_structs` for freed objects and incompatibility with programs that `fork()`. Dhurjati and Adve's combination of static analysis partially solves the first issue but not the second, and comes with the cost of requiring source-code analysis. Our system Oscar addresses both issues and introduces new optimizations, all without needing source code, providing low overheads for many benchmarks and simpler deployment. Oscar thereby brings page-permissions-based protection schemes to the forefront of practical solutions for temporal memory safety.

Abstract

We present a new class of content masking attacks against the Adobe PDF standard, causing documents to appear to humans dissimilar to the underlying content extracted by information-based services. We show three attack variants with notable impact on real-world systems. Our first attack allows academic paper writers and reviewers to collude via subverting the automatic reviewer assignment systems in current use by academic conferences including INFOCOM, which we reproduced. Our second attack renders ineffective plagiarism detection software, particularly Turnitin, targeting specific small plagiarism similarity scores to appear natural and evade detection. In our final attack, we place masked content into the indexes for Bing, Yahoo!, and DuckDuckGo which renders as information entirely different from the keywords used to locate it, enabling spam, profane, or possibly illegal content to go unnoticed by these search engines but still returned in unrelated search results. Lastly, as these systems eschew optical character recognition (OCR) for its overhead, we offer a comprehensive and lightweight alternative mitigation method.

1 Introduction

Designed as a solution for displaying formatted information consistently on computers with myriad hardware and software configurations, Adobe's Portable Document Format (PDF) has become the standard for electronic documents. Academic and collegiate papers, business write-ups and fact sheets, advertisements for print, and anything else meant to be viewed as a final product make use of the PDF standard. Indeed, there is an element of constancy implied in the creation of a PDF document. End users cannot easily change the text of a PDF document, so most come to expect a degree of integrity present in all PDF documents encountered.

Attacks are studied and corresponding defenses developed dealing with arbitrary code execution through some allowances made by Adobe to execute JavaScript within the rendering process of a PDF file [1] [2] or from other rendering vulnerabilities [3] [4]. These typically allow data exfiltration, botnet creation, or other objectives unrelated to the PDF file itself aside from using it as a delivery mechanism [5] [6] [7] [8]. We present a class of attacks against the *content* integrity of PDF documents themselves, and following this, describe and test a comprehensive defense method against these attacks. Without changing the appearance of a PDF, we are able to alter how several information-based services see it, with the following implications:

1. We demonstrate how academic paper writers can collude with multiple conference reviewers, by altering a paper invisibly to humans, to be assigned to those reviewers by automatic reviewer assignment systems, such as that used by the IEEE International Conference on Computer Communications (INFOCOM) [9] that openly publishes its automated algorithm. We simulate this reviewer assignment system using 100 sample academic papers and a corpus of 2094 papers from 114 reviewers of a past security conference, finding that we can cause any of said sample papers to match with any reviewer.

2. We show how an unethical student can invisibly alter a document to avoid plagiarism detection, namely the dominant market share Turnitin [10], and generalize methods to target specific small plagiarism similarity scores to simulate the few false positives such systems typically detect. We illustrate this attack by inducing plagiarism scores, as measured by Turnitin, from 0-100% in 10 academic papers without changing their appearance.

3. Lastly, we show real-world examples of making leading search engines display arbitrary (potentially spam, offensive material, etc.) results for innocuous keywords. We have successfully caused Bing, Yahoo!, and DuckDuckGo to index five documents under keywords not displayed in those documents.

These systems have in common the need to scrape

PDFs for their content for further processing or searching within. Online conference paper or other document repositories and companies that index the Internet require text from PDFs so they may be located via search. Natural language processing tools scrape PDFs to discover the topics within, and this information is used in several large conferences to assign unpublished work to conference reviewers as well as in document repositories to categorize large volumes of works without manual effort. Finally, plagiarism checkers require text from new articles for comparison against currently published work to detect impermissible similarity.

Scraping of PDF documents can be done in an automated setting by text extraction tools such as the PDFMiner package [11]. However, fonts of any name may be embedded in the PDF document, and these tools cannot check the fonts' authenticity. A font is actually akin to an encoding mechanism, which maps keys pressed on a keyboard to glyphs representing those keys. Without some way to check the validity of fonts in a PDF, which glyphs a font maps keys to is arbitrary. Moreover, humans reading a PDF read the rendered version of what a tool such as PDFMiner reads, meaning that machines and humans are on opposite ends of this encoding mechanism and may be caused to read different information.

Consequently, the various PDF document scraping environments may be misused through the remapping of keys to arbitrary rendered glyphs. Using one or more custom fonts, an attacker may cause a word to be rendered as another word by switching the glyph mapping within the font file, or rather change the underlying text while keeping a constant rendered output. That is to say, in a document containing the word "kind" an attacker may force that to be rendered as "mean" with a custom font mapping *k* to *m*, *i* to *e*, *n* to *a*, and *d* to *n*, so the human now sees "mean" while the machine still sees "kind"; or to avoid human detection an attacker can change the underlying text to "mean" and use a font with the reverse mapping to render it as "kind" for the human to see. The latter tactic subverts aforementioned end applications, while still rendering PDFs in all appearances normal to humans. We refer to this as a *content masking* attack, as humans are caused to view a masked version of the content these computer systems read.

To assign papers to reviewers for a conference, several large conferences employ automated systems to compare the subject paper with a corpus of papers written by each reviewer to find the best match. This matching is executed upon the most important topics, or keywords, found in the paper via natural language processing methods. If an author replaces the keywords of a paper with those of a reviewer's paper, a high match is guaranteed, and the two may thereby collude. By creating custom glyph mappings for characters, the masked paper can make perfect sense to the human eye, while the underlying text read by the machine has many substituted words which would not make sense to a human reader. This exploit has the technical challenges of replacing words of differing lengths (larger and smaller replacements require different methods) and also constructing multiple fonts required for different mappings of the same letter (for example, to map the word "green" to "brown" requires two different font mappings for *e*). A naive defense could check the number of fonts embedded, so in Section 4 we design algorithms to minimize the number of auxiliary fonts used, in order to avoid detection. To evaluate, we construct our own automatic reviewer assignment system reproducing the current INFOCOM system [9], and show that for 100 test papers, targeting a specific reviewer is possible by masking 4-9 unique words in most papers and no more than 12 for all tested.

This content masking attack also undermines plagiarism detection. In this case, we need only switch out isolated characters to change plagiarized text to text never written before, while again masking these changes as the original text to the human reader. In fact, as most papers have a small (false positive) percentage of similarity present due to common phrases within the English language, this method simulates that by varying the number of characters changed, to simulate the usual small but nonzero plagiarism percentage. Only one font is required to make this mapping, as the resultant text does not need to make sense to the plagiarism detector. Thus, say, all rendered *e*'s may be represented by some other letter in a font that maps that key to the glyph *e*, and other letters may be changed similarly, building a one-to-one mapping covering at most all letters. The challenge is to target a small plagiarism percentage, but accomplishing that as we do in Section 5, a single embedded font bearing the name of a popular font will cause no suspicion.

Finally, search engines and document repositories may be subverted to display unexpected content also. Here, we may replace the entire text of a PDF without changing the rendered view, with a variety of implications. One may hide advertisements in academic papers or business fact sheets, for example, to spam users searching for information. In this exploit, the attacker should replace an entire document with the fewest number of fonts necessary, to avoid seeming particularly unusual. This must be done in a different way than for the topic matching exploit, due to changing the entire document rather than a few words, so we outline another method in Section 6. We then test it on popular search engines, finding that Yahoo!, Bing, and DuckDuckGo are susceptible.

Having enumerated these vulnerabilities, as these systems eschew optical character recognition (OCR) for its overhead, we offer a comprehensive and lightweight alternative mitigation method in Section 7. While a naive

method would perform OCR over the full document, we instead render the unique characters used within the document and perform OCR on these. This font verification method has several technical challenges in its implementation, due to the number and variety of glyphs within font files, and all these issues are overcome in the algorithm we provide. We find it performs at a roughly constant speed regardless of document length (a tenth of that for full document OCR at 10 pages), with glyph distinction accuracy just under 100%, and with 100% content masking attack detection rate.

2 Background Information

PDF Text Extraction: The Adobe PDF standard contains eight basic types of objects, including strings. Strings house the text in a document, including plain text, octal or hexadecimal representations of plain text, or text with some type of encoding [12]. PDF rendering software treats each string as a series of character identifiers (CIDs), each mapping to its corresponding glyph within the font associated with that string via the Character Map (CMap) [13]. A series of glyphs is thus displayed.

Text information extracted from PDF files by using tools like the Python package PDFMiner. These tools extract text by copying the plaintext from all string objects in a PDF file. Though these tools can extract the font name for each string as well, a whitelist will not defend against this attack, as fonts may be given any name.

Topic Matching: The exponential growth of human knowledge/record keeping and the ease of its access demands an efficient means of providing context-relevant search results, stemming the research field of natural language processing. This field extracts the specific subject of a document without the need for human classification. The ultimate goal of useful search results prompts the companion research field of matching keywords to topics which has been tackled by the leading search engines.

Latent Semantic Indexing (LSI) is a popular natural language processing algorithm for extracting topics from documents. The LSI approach infers synonymous words/phrases to be those with similar surrounding contexts, rather than constructing a thesaurus. These detected patterns can allow singular value decomposition to reduce the number of important words in a document such that it may be represented by a small subset. This small subset, of cardinality k, then contains frequency data for each element, such that the document may be represented by a dot in k-space. Similarity between documents is easily calculated via their Euclidean distances apart in this geometric representation [14].

Latent Dirichlet Allocation is a newer popular topic extraction algorithm, which is generally speaking a probabilistic extension of LSI [9]. Topics are generated as collections of related words, using supervised learning. The probability of a document corresponding to each of the predefined topics is calculated based on how well the words within the document correspond to the words within each topic [15, 16].

Topic matching is used within the automation of the review assignment process for several large conferences, such as the ACM Conference on Computer and Communications Security (CCS) or the IEEE International Conference on Computer Communications (INFOCOM). These conferences receive many submissions and have many reviewers, and the manual task of finding the most suitable reviewers for each paper is onerous, so they automate by comparing topics extracted from subject papers and papers published by reviewers. The authors of [9] execute a performance comparison between LSI and LDA for use in the present (as of 2016) INFOCOM reviewer assignment system, which uses PDFMiner for text extraction, finding LSI to work well with the academic papers submitted to that conference. We accordingly perform our experiments using LSI to determine the important keywords of each paper, and note that the attack functions equivalently using LDA.

Plagiarism Detection: Turnitin, LLC has the dominant market share for plagiarism detection software. Its software is proprietary, but current documentation states "Turnitin will not accept PDF image files, forms, or portfolios, files that do not contain highlightable text..." [10], indicating that PDFMiner or some similar internally developed tool is used to scrape the text from PDF documents. We may assume from the lack of support for image files that optical character recognition (OCR) is not used, meaning that our proposed attack should succeed, which is proved in Section 5.2.

Additionally, the Turnitin documentation states that "All document data must be encoded using UTF-8 character set" [17]. As mentioned in Section 2, text may have custom encodings, but here we find they are not permitted by Turnitin. This disallows any attack where text, gibberish in appearance, is translated via decoding into legible text. However, no restriction on fonts is in place, due to the necessary ability for Turnitin's client institutions to specify their own format requirements.

Document Indexing: Extracting topics from a document is somewhat of a subproblem to the larger issue of document indexing. As information highly relevant to a search may appear in a small portion of a document, simply relying on the overall topic of every document to infer relevancy to a search may miss some useful results. A search engine should do more than simply topic modeling to show results for a query. In fact, Google uses more than 200 metrics to determine search relevancy [18], including its famous PageRank system of inferring quality of a site based on the number of sites linking to it [19].

Though documentation is sparse on other search engines such as Bing or Yahoo, Google does host some discussion of its treatment of PDF files. It states that they can index "textual content ... from PDF files that use various kinds of character encodings" [20] but that aren't encrypted. "If the text is embedded as images, we may process the images with OCR algorithms to extract the text" [20], but for our content masking attack, text is not embedded as images, so logically the system would not perform OCR. Our experiment finds out for sure for Google, Bing, Yahoo, and DuckDuckGo in Section 6.2.

3 Masking Font Creation

The content masking attack is facilitated by the ability to embed custom fonts within PDF documents. In fact, having all fonts embedded is a formatting requirement for the submission of academic papers to conferences. However, no integrity check is performed on those fonts as to the proper correlation between text strings within the PDF file and the respective glyphs rendered in the PDF viewer. An attacker may map characters to arbitrary glyphs and alter the text extracted from a PDF document while it appears unchanged to humans in a PDF viewer. This requires two steps, firstly to create the requisite font files and secondly to encode the text via these font files.

The first step may employ one of the multiple open source multi-platform font editing tools such as FontForge [21]. With this tool, one can open a font and directly edit the character glyphs with the typical vector graphics toolbox, or copy the glyph for a character and paste it into the entry for another character. One can then edit the PDF file directly with open source tools such as QPDF [22], or in the case of manipulating academic papers, quicken the process by adding custom fonts in LaTeX, and aliasing each to a simple command [23]. We employ the latter method for its greater ease. It employs the program ttf2tfm, included with LaTeX, to convert TrueType fonts to "TeX font metric" fonts which are usable by LaTeX. Two LaTeXcode files are supplied by [23]: T1-WGL4.enc for encoding, and t1custom.fd for easy importing of the font into a LaTeXdocument.

The second step of choosing how to mask this content and what in a document to encode with custom fonts depends on the system targeted, and the technique and evaluation for each of the three scenarios introduced in Section 1 appears in the following three sections.

4 Content Masking Attack Against Conference Reviewer Assignment Systems

As learned in Section 2, topic matching works from groups of words constituting the main topic of the document. Assignment of conference paper submissions to reviewers is accomplished by finding the highest similarity between detected topics within submissions and those within a corpus of reviewers' papers. Meanwhile, a lazy paper writer may wish to collude with specific reviewers, know of some more generous to papers, or just think reviewers may be less critical of papers not within their specializations. This lazy writer needs to change the paper topic to target a specific reviewer, replacing words corresponding to the topic of the paper with words comprising the topic of a paper from the reviewer's corpus, while being masked as the original words to still make visual sense. We now discuss the challenges for this attack and methods to target one or more reviewers, and subsequently evaluate the attack efficacy.

4.1 Construct Word and Character Maps

We primarily require a list of original words within the subject document to change, and a list of words from the target document to which to change these original words. The new words will then be masked to display as the original words using the masking fonts described in Section 3. First, any stopwords within the document should be eliminated from consideration. These are common words within the paper's language, such as "the," "of," "her," or "from." Stopwords may be removed by using existing tools like the Natural Language Toolkit (NLTK) Python package [24]. From here an attacker can replace the most frequently used words in the subject paper with the most frequently used words in the target reviewers paper. This will result in the most frequently used words in the target paper also appearing in the subject paper, for a high similarity score as measured by the LSI method within the automatic reviewer assignment system.

Consider word lists A and B having constituent words $\{a_1, a_2, ..., a_n\}$ and $\{b_1, b_2, ..., b_n\}$ which are in descending order of appearance within the subject and target papers, respectively. An attacker wishes to replace words A with topic B and must therefore replace each word a_i within the text of the subject paper with a word b_i, encoded using some font(s) to render b_i the same graphically as a_i (a *word mapping*). No other words should/need be changed. Consequently, the objective is to construct a mapping between the letters of each b_i and a_i (a *character mapping*). If a_i and b_i are character arrays $\{a_i[1], a_i[2], ..., a_i[p_i]\}$ and $\{b_i[1], b_i[2], ..., b_i[q_i]\}$, then the attacker should construct a *masking font* such that the character $b_i[1]$ maps to the glyph $a_i[1]$, $b_i[2]$ to $a_i[2]$, etc. We may consider this analogous to a map data structure, where $b_i[1]$ is a key and $a_i[1]$ its value, and so on. Two challenges naturally arise in constructing the required character mappings:

One-to-Many Character Mapping: From the brief

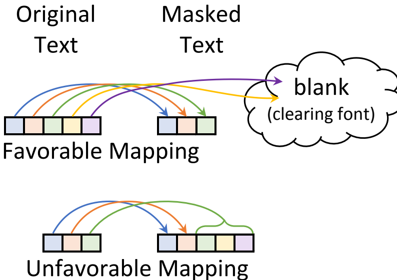

Figure 1: Handling the word length disparity challenge. Each box represents a character.

Algorithm 1 Build Character Map

Input: subject paper s, target paper t
Output: character mapping $C : B \rightarrow A$, encoding fonts $F = \{f_1, f_2, ..., f_x\}$

1: $A \leftarrow$ top k topic words of LSI(s)
2: $B \leftarrow$ top k topic words of LSI(t)
3: $C \leftarrow$ empty character map
4: **for** $i \leftarrow 1$ to k **do**
5: $\quad p_i \leftarrow length(a_i)$
6: $\quad q_i \leftarrow length(b_i)$
7: $\quad$ **if** $p_i < q_i$ **then** ▷ favorable mapping
8: $\quad\quad$ **for** $j \leftarrow 1$ to p_i **do**
9: $\quad\quad\quad C \leftarrow C \cup \{(b_i[j], a_i[j])\}$
10: $\quad\quad$ **for** $j \leftarrow p_i + 1$ to q_i **do**
11: $\quad\quad\quad C \leftarrow C \cup \{(b_i[j], \emptyset)\}$
12: $\quad$ **else if** $p_i > q_i$ **then** ▷ unfavorable mapping
13: $\quad\quad$ **for** $j \leftarrow 1$ to $q_i - 1$ **do**
14: $\quad\quad\quad C \leftarrow C \cup \{(b_i[j], a_i[j])\}$
15: $\quad\quad rest \leftarrow$ combine $\{a_i[q_i], ..., a_i[p_i]\}$
16: $\quad\quad C \leftarrow C \cup \{(b_i[q_i], rest)\}$
17: $\quad$ **else** ▷ equal word length
18: $\quad\quad$ **for** $j \leftarrow 1$ to q_i **do**
19: $\quad\quad\quad C \leftarrow C \cup \{(b_i[j], a_i[j])\}$
20: $x \leftarrow$ largest number of key collisions in C
21: $temp \leftarrow C$
22: **for** $i \leftarrow 1$ to x **do** ▷ build fonts
23: $\quad f_i \leftarrow$ empty font
24: $\quad$ **for each** $c \in C$ **do**
25: $\quad\quad$ **if** value in c is $\emptyset$ **then**
26: $\quad\quad\quad C \leftarrow C \setminus \{c\}$
27: $\quad\quad\quad$ use clearing font for key in c
28: $\quad\quad$ **else if** no key collision between c, f_i **then**
29: $\quad\quad\quad C \leftarrow C \setminus \{c\}$
30: $\quad\quad\quad f_i \leftarrow f_i \cup \{c\}$
31: $\quad F \leftarrow F \cup f_i$
32: $C \leftarrow temp$
33: **return** C, F

example in Section 1 of changing the word *green* to *brown*, we know that in terms of a map data structure there is a collision for the key e and the values o and w, such that an attacker will require two masking font "maps" to render *green* as *brown*. The first challenge is to minimize the number of fonts required in the document, so as to avoid suspicion, while fully switching topic A for B. This problem is not delimited by word: some character mappings may be reused in the same or other words, and many may not. Additionally, changing all of the words in A to those in B may be unnecessary, which also impacts the number of one-to-many mappings and resultant number of required font files. If fewer words must be changed while ensuring the required similarity between papers, fewer fonts may be required, and a naive font count threshold defense will be less effective.

Word Length Disparity: Further, the lengths p_i and q_i of words a_i and b_i may differ, causing a_i to be longer than b_i or vice versa. If $p_i > q_i$, to render b_i as a_i, a font file entry is necessary for the letter $b_i[q_i]$ mapping to the last $p_i - q_i + 1$ letters of a_i. Several additional fonts may be necessary if some $b_i \in B$ have the same last character. Thus, we define a *favorable keyword mapping* as a word mapping $b_i \rightarrow a_i$ such that $p_i < q_i$. In this case, only a single *clearing font* is needed, wherein all characters map to a blank glyph of no width. Figure 1 illustrates handling favorable and unfavorable mappings. In practice, a blank glyph of no width is in fact a single dot, of width (and height) equal to the smallest unit of measure within a font drawing program. In contrast, an i is 569 units wide (and a w is 1500 units wide), so this dot will not be rendered at all. And because this clearing font has all letters map to no-width blanks, it will be the only additional font required if $\forall i, p_i < q_i$, hence its favorability.

4.2 Matching One or More Papers to One Reviewer

Mapping of words from B to A is by their original descending order of frequency within the target and subject papers, respectively. Algorithm 1 shows the overall encoding process and begins by running the LSI model on the subject and target papers, then constructing a map between characters in k of the topic words returned. Then, the mapping is added to C for each character, for each word of B, to the corresponding character(s) in the corresponding word of A. Here, comments (Lines 7, 12, 17) indicate the steps taken for favorable and unfavorable mappings and the case when both words are of the same length. Finally at Line 22, the mappings in C are broken up into collections to be made into custom masking fonts, with the exception of those characters from favorable mappings which map to null, for which the previously introduced single clearing font is used. Resulting

from this algorithm are fonts to be used for each character of the words in B to mask them as the words in A. If the attacker has multiple papers under submission, this process may be repeated independently for each paper.

4.3 Matching One Paper to Multiple Reviewers

For a better chance at cheating the peer review process and to collude with multiple reviewers, the content masking attack can be adapted to split up the masked words among two (or more) different lists of frequently used words. Instead of mapping between word lists A and B, the attacker will map between A and B and A and C, such that a_1 will be replaced with b_1 part of the time and c_1 the rest of the time, and so on. The method is otherwise the same as shown in Algorithm 1, but has its own challenge.

Intuition would suggest replacing a_1 half of the time with b_1 and half of the time with c_1. However, the requirement for the attacker's paper to be the most similar of a large number of papers to a reviewer's paper and also the most similar of all others to another reviewer's paper is quite stringent. The intuitive method fails as the similarity score for one target reviewer will be high enough but the other too low. So we use an iterative refinement method which tunes the replacement percentages according to the calculated similarity scores until they are both the highest among their peers. This is generalizable to more than two reviewers, by refining the percentages proportionally according to the successive differences in similarity scores between the subject paper and each of the target papers. We match one paper to three reviewers in Section 4.4, the typical number of reviewers to which papers are assigned (barring contention in reviews, which would not happen during collusion).

4.4 Experiment

We have built a conference simulation system reproducing the INFOCOM automatic assignment process described in [9]. We imported into this system 114 TPC members from a well-known recent security conference as reviewers, and downloaded a collection of each of these reviewers' papers published in recent years. In total, this comprised 2094 papers used as training data for the automatic reviewer assignment system. For testing data, we also downloaded 100 papers published in the greater Computer Science field. Our experiment, then, is to test the topic matching of the test papers with the training papers, via our content masking attack. Following are evaluations of the content masking attack matching one paper to one reviewer, multiple papers to one reviewer, and one paper to multiple reviewers.

Matching one paper to one reviewer: The automatic reviewer assignment process compares a subject paper with every paper from the collection of reviewers' papers to gather a list of similarity scores. The reviewer with the highest similarity score is assigned the paper to judge (if available). We therefore aim to change a testing paper topic to a training paper topic, and to examine how well this works with all papers. For each such pair of papers, then, we replace the frequently appearing words A in the testing paper with those frequently appearing words B in the training paper via Algorithm 1. We test the topic matching of each of the 100 testing papers against our training data to see what is required to induce a match.

For each pair of training and testing papers, we replace important words in the testing paper one by one, to see how many replacements are needed to make that pair the most similar. Figure 2 illustrates this iterative process for one example training/testing paper pair, showing resultant similarity scores. The box plots show where the greatest concentration of the 2094 similarity scores dwell, while red pluses show outliers. The blue stars which emerge to the top correspond to the similarity scores between the testing paper and the target training paper. Figure 2 shows a clear separation of that similarity score from the rest after replacing 9 words, meaning that for this pair, content masking all appearances of those 9 unique words in the testing paper will result in its assignment to the reviewer who wrote that training paper.

Performing this process for all 100 testing papers, we compile the results into Figure 3, which displays the cumulative distribution function (CDF) for the number of words requiring replacement. Evidently, all 100 papers may be matched with the target with 12 words or fewer masked. The sharp jump appearing from 4-9 words indicates that most papers can be successfully targeted to a specific reviewer masking between 4 and 9 words. The font requirements for replacing these words is then represented in Figure 4. A majority of papers require 3 or fewer masking fonts, while almost all of them need only as many as 5. This is a comparatively small number and should go unnoticed among the collection of fonts natural to academic papers. For example, this paper has some 19 embedded fonts, between bold/italic variants, fonts used in figures, and one picture font used in Table 1.

Matching multiple papers to a single reviewer: Should an author wish to have multiple submitted papers all assigned to a target reviewer, the author may simply repeat the content masking process on each paper. While in the previous case we find that an average of 3 or 4 fonts is necessary to make a single test paper sufficiently similar to the target training paper, that needs not directly translate to 3 or 4 fonts per paper with multiple papers. Some fonts may be reused among papers, resulting in

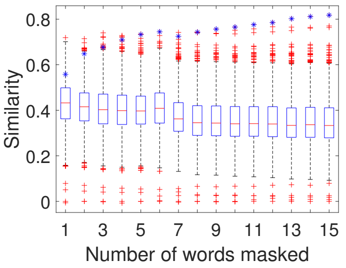

Figure 2: Similarity scores relative to amount of words masked. Blue stars show the desired matching.

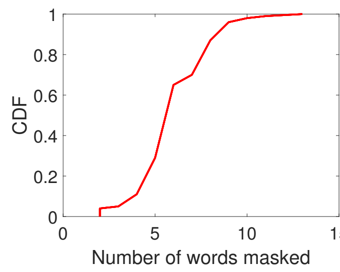

Figure 3: Word masking requirements for all 100 testing papers.

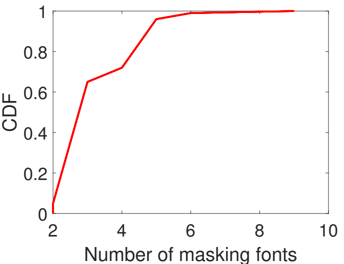

Figure 4: Masking font requirements for all 100 testing papers.

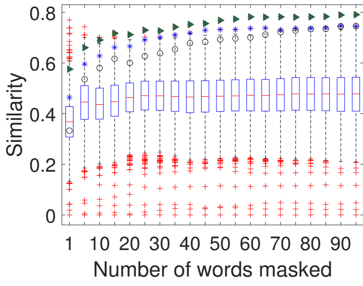

Figure 6: Similarity scores relative to amount of words masked, between a paper and three reviewers. Blue stars, black circles, and green triangles show the desired matchings.

fewer overall fonts used. Figure 5 confirms this, showing a trend more logarithmic than linear.

Matching a paper to multiple reviewers: Finally, we evaluate the iterative refinement method to split masked words among three reviewers' papers as discussed in Section 4.3. Figure 6 shows that the similarity scores for the three target reviewers (blue star, black circle, and green triangle) consistently increase; after some 70 words masked, the subject paper is more similar to the three target papers than any others.

5 Content Masking Attack Against Plagiarism Detection

While a method similar to the topic matching subversion technique just outlined may be used to hide plagiarism, fewer requirements constrain the plagiarist than the lazy author targeting a specific reviewer in a conference. Specifically, an attacker needs only make the underlying text *different* than the rendered, plagiarized text. The underlying text does not need to be actual words, and so only one font is needed, ensuring the naive defense of limiting fonts is defeated. This *scrambling font* is just a random scrambling of the characters. Each original letter is replaced with the letter which displays as the original. Resulting is a human-legible PDF document which appears as gibberish to Turnitin and necessarily has a similarity score of 0%. Details and options for this method are below, followed by an evaluation of each option.

5.1 Targeting a Specific Plagiarism Score

Because Turnitin is a similarity checker, not a plagiarism detector, it relies on the human factor to actually detect plagiarism. Turnitin informs the individual with grading duties of any pieces of similar prose, which naturally arise due to the plethora of written work in existence and the human tendency toward common patterns and figures of speech. It is unlikely then, and would stand out to the grader, that a submission would have 0% similarity with anything ever written. We offer and evaluate two methods an attacker can use to target a specific (low but non-zero) similarity score and more likely go unnoticed.

By Letter: Here, the attacker begins with a scrambling font and removes characters from being scrambled successively until a target percentage of the text is not being replaced. Intuitively, this small target percentage would then appear plagiarized, yielding a credible similarity score. This may be done in a calculated fashion using the known frequency of usage of letters in the English (or other) language. The letters may be listed by their

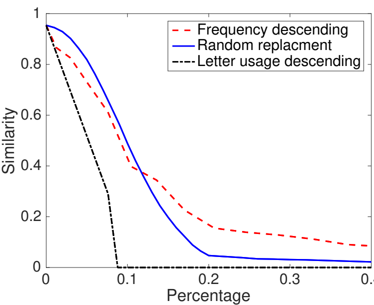

Figure 7: Effects of the percentage of text changed upon plagiarism similarity scores for 10 sample documents.

frequency in ascending or descending order (we evaluate both) and then excluded from scrambling in that order until the target percentage of unaltered text is reached.

By Word: This method is similar to the previous, but instead of leaving some characters unscrambled in the custom font, the attacker leaves some words unaltered by not applying the custom scrambling font to them. Here, words within the document may be listed in frequency of appearance, ascending or descending, and excluded from the scrambling font in that order (we again evaluate both). We also consider changing words at random with a probability targeting some similarity score. This method may be more effective for an attacker in the long run, if Turnitin implements a requirement that some percentage of words be found in a dictionary, English or otherwise. In that case, this attack may be augmented by the previously described method of replacing real words for other real words rendered as the originals.

5.2 Experiment

We use 10 already published papers retrieved from the Internet and mask the content in varying degrees to see the effects on Turnitin's returned similarity scores. We vary the amount a scrambling font is applied to the text according to the previously described methods and upload the resultant papers to Turnitin. Again, we target a specific range of similarity scores, between 5% and 15%, such that a human grader is unlikely to suspect foul play.

Figure 7 plots the three methods. "Frequency descending" refers to the method of masking words in the order of their frequency of appearance in the document, while "Letter usage descending" refers to masking letters by their frequency of usage. Ascending order proved unwieldy in both cases and not worth displaying. Finally, "Random replacement" refers to the method of iterating over all words and masking them with a probability of 1-100% in increments of 1%. These are all plotted in terms of the percentage of text changed. Masking letters by their frequency of usage results in a similarity curve that is too steep to be manageable for selecting a small range of similarity scores. In contrast, the other two methods are very suitable for comfortably picking a specific range. Any probability between 17% and 20% will net a similarity score in our desired 5-15% range in the case of randomly chosen masking. When words are replaced in order of their frequency of appearance, the 5-15% range may be achieved by replacing anywhere between 20 and 40% of the words, offering a very wide range of safety for the plagiarist.

6 Document Indexing Subversion

The final direction of this attack is against search engines, whether for the entire web or for small document repositories or websites. Websites can implement a simple search returning pages housing the query text, or they can use custom search engines offered by Google [25] or Yahoo! [26]. Microsoft Bing also offers its API [27]. As small sites are unlikely to have a more sophisticated search mechanism than the leading search engines, we target and demonstrate our attack against these.

6.1 Method

We here consider modifying the entire content of a PDF to render as something else. Both the underlying text extracted by PDFMiner (or otherwise) and the rendered text should make sense in this case, so that an individual searching for certain terms will be caused to find a PDF holding those words but displaying something entirely different. This results in a more extreme version of the one-to-many character mapping challenge from the attack against topic matching. Instead of masking a small finite number of words, we now examine masking the entire content. However, this is facilitated by the realization that these masks are not necessarily delineated by spaces as before; the attacker can treat the entire document as a single word to be masked. It consequently encounters the word length disparity challenge, to treat the variation in length between real and rendered text, but only once.

Nevertheless, the strategy of adding new fonts, ad hoc, to cover each new mapping quickly balloons out of control, in terms of the attacker needing to keep track of what mappings appear in what font. The number of fonts will increase with the number of characters to be masked, to an upper limit of every character needing a map to every other. Considering (for English) upper and lower case letters, numbers, and common punctuation (22 symbols, dependent upon count), all $26+26+10+22 = 84$ characters must each map to the other 83 different characters, as well as themselves for those cases which a character and its mask are the same. This requires 84 fonts and represents $84^2 = 7056$ mappings. Code can certainly be

Search Engine	Indexed Papers	Attack Successful	Evades Spam Detection	Not Later Removed
Google	✓	✗	✗	✗
Bing	✓	✓	✓	✓
Yahoo!	✓	✓	Flagged / Cleared	✓
DuckDuckGo	✓	✓	✓	✓

Table 1: Results of content masking attack on search engines.

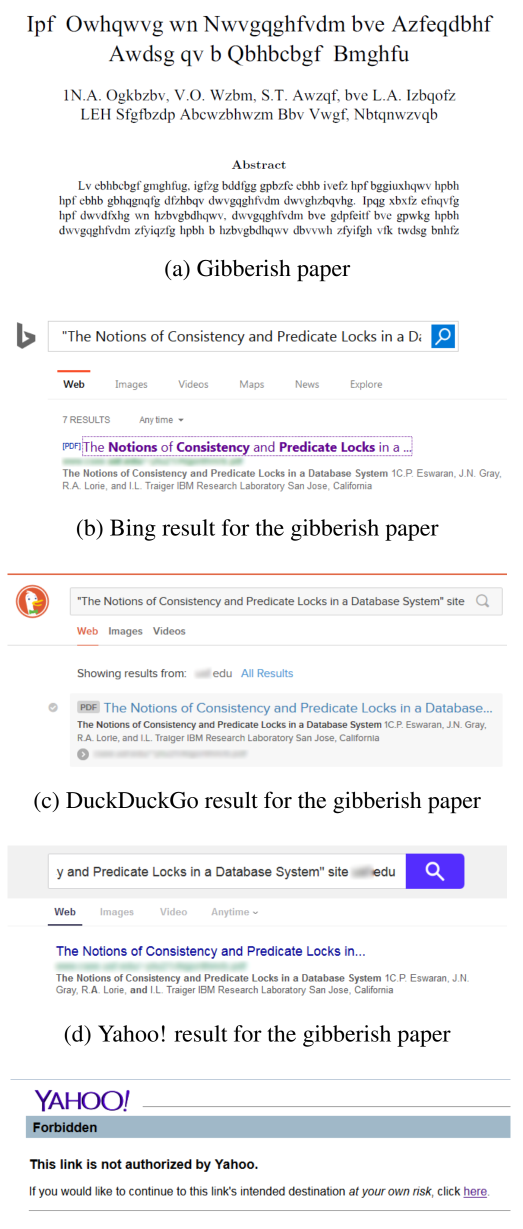
written to automatically construct all these mappings, but to make this more efficient, we offer an alternative - 84 fonts, in each of which all characters map to one masking character. For example, in font "MaskAsA" character *a* maps to *a*, *b* to *a*, *4* to *a*, *!* to *a*, etc. To mask a document as another, the attacker may simply apply fonts, character by character, that correspond to the desired mask. At the end of the documents, the three end behavior options presented as part of Algorithm 1 and illustrated in Figure 1 function here as well, to handle the length variation.

6.2 Experiment

To demonstrate the efficacy of this attack, we obtained a handful of well-known academic papers, masked their content, and then placed them on one author's university website to be indexed by several leading search engines. For this simple proof of attack, we only used one masking font which scrambled the letters for rendering. The resulting papers have legible text that renders to gibberish, meaning that if they can be located by searching for that legible text, the search engine is fooled.

We submitted the site housing these papers to Google, Bing, and Yahoo! and searched for them some days later. Search engine DuckDuckGo does not accept website submissions but we searched there as well. Table 1 lists the results of our content masking attack on these search engines. "Indexed Papers" indicates the search engine listed the papers in its index. "Attack Successful" means they are indexed using the underlying text, not the rendered gibberish. After a successful attack, the papers may later be put behind a spam warning or removed from the index, as shown in the last two columns. We found similar results for each of the 5 papers tested: that Bing, Yahoo!, and DuckDuckGo all indexed the papers according to the masked legible text, and none removed them later (at time of writing). Yahoo! did mark them as spam after two days but confusingly some days after that removed the spam warning.

Figure 8 illustrates this for one of tested paper. The masked paper is shown in Figure 8a and contains no rendered English words beyond what is shown. Figures 8b, 8c, and 8d show the search results for the legible underlying text, and Figure 8e shows the spam warning appearing days later but later disappearing. Each query was



(a) Gibberish paper

(b) Bing result for the gibberish paper

(c) DuckDuckGo result for the gibberish paper

(d) Yahoo! result for the gibberish paper

(e) Temporary Yahoo! spam warning

Figure 8: Results of the content masking attack against popular search engines. The attack was not successful against Google.

appended with "site:XXX.edu" to isolate the university website where they are hosted for this proof of concept.

Interestingly, Google indexed the papers, but according to the rendered gibberish, not the underlying text. This indicates, of these four engines, only it performs OCR on PDF files it indexes rather than extracting the text through PDFMiner or the like. After two days, the papers were removed from Google's index, before the authors obtained screenshots. We conclude that Google has a robust defense against the content masking attack, while the other three engines remain susceptible.

7 Defense Against Content Masking

As intoned through this paper, Optical Character Recognition (OCR) is able to move the text extraction process from targeting the underlying text to the rendered version, preventing this masking attack. OCR is required for print documents scanned to PDF, but for documents with rendered text, system designers have been loath to use OCR in lieu of PDFMiner or its ilk. OCR is far more complex and requires more processing time than simply running the PDF file through a lightweight parser to collect its strings. We propose here a lightweight font verification method that enables the use of OCR in a highly efficient way to prevent the content masking attack. The intuition is simple; we render each character in the fonts embedded in the subject PDF file and then perform OCR on those characters rather than the rendered PDF file itself. Where an academic paper may be some 50,-75,000 characters, the fonts embedded therein usually contain at most just a couple hundred characters.
